Paliperidone palmitate (Invega Sustenna) can be injected into either the deltoid or the gluteal muscle, and treatment is initiated with 234 mg on day 1 and 156 mg a week later. No overlap with oral drug is necessary. Monthly IM doses are then titrated according to response within a range of 39 to 234 mg.[41] A 3 month formulation of paliperidone palmitate (Invega Trinza) is approved for the management of schizophrenia and significantly delays time to relapse compared with placebo. This 3 month formulation provides the longest dosing interval currently available but requires patients to be treated for at least 4 months with Invega Sustenna prior to its initiation. The first Invega Trinza dose is based on the previous 1 month injection dose as shown in **Table 67-5**.[45] Olanzapine pamoate monohydrate is recommended for deep gluteal injection, and the initial injectable dose varies from 210 to 405 mg depending on the oral olanzapine daily maintenance dose and the frequency of injectable administration. The official product information should be consulted regarding preparation and administration information.[41,42]

Aripiprazole monohydrate LAI is administered as a single intramuscular injection in the gluteal or deltoid muscle once a month at a starting and maintenance dose of 400 mg. If the patient does not tolerate the 400 mg dose, the next injection can be reduced to 300 mg. After the first injection of aripiprazole monohydrate LAI, a 14 day overlap with oral aripiprazole (10-20 mg/day) or any other antipsychotic is recommended.[41] Aripiprazole lauroxil LAI is administered as a single intramuscular injection in the deltoid (441 mg dose only) or gluteal (441 mg, 662 mg, or 882 mg, once a month). The 882 mg dose can be administered every 6 weeks however. As mentioned earlier, oral overlap is needed for 3 weeks with this LAI formulation.[46]

For fluphenazine decanoate, the simplest dosing conversion method recommends 1.2 times the oral fluphenazine daily dose for stabilized patients, rounding up to the nearest 12.5-mg interval, administered in weekly doses for the first 4 to 6 weeks; or 1.6 times the oral daily dose for more acutely ill patients.[47] Subsequently, fluphenazine decanoate can be administered once every 2 to 3 weeks. Oral fluphenazine can be overlapped for 1 week. Fluphenazine decanoate can be administered subcutaneously, though it is usually administered by intramuscular injection in the deltoid or gluteal muscle.[41] For haloperidol decanoate, the first dose should be 10 to 20 times the oral haloperidol daily dose, and the maintenance dose is typically 10 to 15 times the oral dose once monthly. The initial injection is limited to 100 mg followed by the remaining balance of the first monthly dose given 3 to 7 days later.[41] An oral haloperidol overlap is recommended for the first month. Table 67-4 provides a summary of LAIs discussed in this chapter.

Methods to Enhance Patient Adherence

It is often challenging for individuals with chronic illnesses to maintain appropriate medication adherence, and partial adherence is a reality in the treatment of all chronic illnesses.[29] Individuals with serious mental disorders have somewhat higher nonadherence rates than those with general medical disorders, with the following explanations provided: denial of illness, lack of insight, grandiosity or paranoia, no perceived need for medication, perceived lack of input into choice of medication or dosage, side effects, misperceived "allergies," too many medications prescribed, or too many doses prescribed daily. It is estimated that half of patients with schizophrenia or schizoaffective disorder take their medication less than 70% of the time.[29] Clinicians should expect partial medication adherence to be the norm. This should be approached in a positive, nonjudgmental manner, with the clinician actively engaging the patient in care and using motivational interviewing techniques as mechanisms to enhance therapeutic alliance and patient adherence.

Numerous different methods have been used in an attempt to improve treatment adherence of patients with schizophrenia. Interventions that provide continuous focus on adherence and that are of long duration have shown benefit. These should incorporate problem solving techniques and be accompanied by technical learning aids. It has been suggested that programs need to include a focus on patient-driven outcomes, and not just medication adherence. For example, interventions should include efforts to allow patients to achieve life goals and

function. This requires that programs be tailored to the needs of individual patients.[48] Psychoeducation strategies should include motivational interviewing techniques in individual counseling as well as group activities.

Some studies suggest that compliance therapy, targeted cognitive behavioral therapy focusing on medication adherence, can improve patient adherence, but the success seen in early studies has not been consistently replicated.[48]

Groups facilitated by trained individuals who have the illness are alleged to be more effective in enhancing awareness and acceptance of schizophrenia and necessary treatment than groups led only by professionals. Active involvement of family members further increases the likelihood of patient adherence with treatment. In addition to programs provided by community mental health centers, support groups operated by consumer groups such as the National Alliance on Mental Illness (NAMI) are available in most urban areas. In the hospital, self-medication administration can reinforce the patient's perception of his or her active role in treatment. When patients miss outpatient appointments, active outreach interventions must be implemented to enhance patient engagement in treatment.[48]

Management of Treatment-Resistant Schizophrenia

In general, "treatment resistant" describes a patient who has had inadequate symptom response from multiple antipsychotic trials.[26,27,28,29] Traditionally, treatment resistance has been defined as lack of improvement in positive symptoms, but it can be defined by poor improvement in negative symptoms, or even by medication intolerance. Between 10% and 30% of patients receive minimal symptomatic improvement after multiple FGA monotherapy trials.[26,27,28,29] An additional 30% to 60% of patients have partial but inadequate improvement in symptoms or unacceptable side effects associated with antipsychotic use.[26,27,28,29] In those patients failing two or more pharmacotherapy trials, a treatment-refractory evaluation should be performed to reexamine diagnosis, substance abuse, medication adherence, and psychosocial stressors. Targeted cognitive behavioral therapy or other psychosocial augmentation strategies should be considered.[29]

Clozapine

Only clozapine has shown superiority over other antipsychotics in randomized clinical trials for the management of treatment-resistant schizophrenia. Most other SGAs have either not been studied in treatment-refractory patients or have been evaluated in small open trials. In a seminal study, clozapine was effective in approximately 30% of patients with treatment-resistant schizophrenia, compared with only 4% treated with a combination of chlorpromazine and benztropine.[49] The definition of treatment resistance requires two treatment failures with either FGAs or SGAs. Other treatment candidates for clozapine include those patients with severe suicidality, aggressive behavior, or those who cannot tolerate neurologic side effects of even conservative doses of other antipsychotics.

Clinical Controversy…

Although clozapine is the only treatment that has evidence of proven benefit in patients with treatment-resistant schizophrenia, and its use in treatment-resistant schizophrenia is recommended in all treatment guidelines, it is underutilized by clinicians in practice. Although the reasons for its underutilization are not totally understood, factors may include clinician fear of clozapine's potential adverse effects, the Absolute Neutrophil Count (ANC) monitoring required by the FDA, and mental health treatment systems that do not support use of the drug and the required ANC monitoring.

Symptomatic improvement with clozapine in the treatment-resistant patient often occurs slowly, and as many as 60% of patients may improve if clozapine is used for up to 6 months. This, in combination with clozapine's adverse effect profile, provides sufficient information to conclude that clozapine is not a panacea for schizophrenia. Polydipsia and hyponatremia (psychogenic water drinking) is a frequent problem among treatment-resistant patients, and clozapine reportedly decreases water drinking and increases serum sodium in such patients.[27,29]

Because of the risk of orthostatic hypotension, clozapine is usually titrated more slowly than other antipsychotics, particularly on an outpatient basis. If a 12.5-mg test dose does not produce hypotension, then clozapine 25 mg at bedtime is recommended, increased to 25 mg twice a day after 3 days, and then increased in 25 to 50 mg/day increments every 3 days until a dose of at least 300 mg/day is reached. Because high doses are associated with significantly increased side effects, including seizures, a clozapine serum concentration is recommended before exceeding 600 mg/day. If the clozapine serum concentration is less than 350 ng/mL (mcg/L; 1.07 µmol/L), then the dose should be increased as side effects allow, to achieve this serum concentration.[29]

Augmentation and Combination Strategies

Little empirical evidence exists to guide treatment decisions for patients who do not respond to clozapine.[26,29] Augmentation therapy involves the addition of a nonantipsychotic drug to an antipsychotic drug in a poorly or partially responsive patient, whereas combination treatment involves using two antipsychotics simultaneously.

In a small, single blind, randomized trial, 50% of patients demonstrated clinically significant improvement in symptoms with ECT augmentation of clozapine, compared with no responders in the clozapine monotherapy group. When the patients in the clozapine monotherapy group received ECT, 47% demonstrated clinically significant improvement.[37]

Mood stabilizers are frequently used as an augmentation strategy. Lithium does not enhance antipsychotic effect but may improve labile affect and agitated behavior in selected patients.[27,28] Valproic acid and carbamazepine have also been used. A large placebo-controlled trial supports faster symptom improvement, but no difference in maintenance treatment, when divalproex was used in combination with either olanzapine or risperidone.[50] Enzyme induction with carbamazepine can cause a decrease in antipsychotic serum concentrations and potentially worsen psychotic symptoms in some patients.[29] The 2009 PORT recommendations do not endorse the use of mood stabilizer augmentation in treatment-resistant patients.[26]

Only limited data are available to support antidepressant augmentation of antipsychotics.[29] Consistently positive results have been reported when using selective serotonin reuptake inhibitors (SSRIs) to treat obsessive-compulsive symptoms that worsen or arise during clozapine treatment.

Combining an FGA with an SGA and combining different SGAs have been suggested as intervention strategies for treatment-resistant patients. Pharmacodynamically, there is limited rationale to explain how combinations of antipsychotics would produce enhanced efficacy, but increased side effects, particularly increased EPS, metabolic effects, and hyperprolactinemia, are possible results.[51] Clinically, scant evidence exists to prove that antipsychotic combinations are superior to monotherapy, and the 2009 PORT recommendations do not support their use.[26] However, a recent placebo controlled trial indicated that ziprasidone added to clozapine improved negative symptoms and general psychopathology.[36] This topic remains highly contentious, and clinicians' practice is not aligned with available evidence. In general, a series of antipsychotic monotherapies, including clozapine, are preferred over antipsychotic combinations,[26] and it is observed that clozapine is itself associated with lower rates of polypharmacy over time.[52] However, when clozapine fails to produce desired outcomes, a time-limited combination trial is sometimes considered.[27,29] Such antipsychotic combination treatment trials should be time-limited (eg, maximum 12 weeks) and the patient carefully evaluated with rating scales for changes in symptomatology. If no apparent improvement is observed, then one of the medications should be tapered and discontinued. However, if the patient has a partial response (greater than or equal to 20% improvement in positive symptoms) after 12 weeks with combination treatment, medications should be titrated to doses at the upper end of the therapeutic range, and treatment should continue for an additional 12 weeks before a change in treatment is considered.

Clinical Controversy…

Insufficient evidence exists to support the routine use of antipsychotic combination treatment, and guidelines such as PORT do not recommend this practice, even in patients with treatment-resistant schizophrenia. However, a recent small placebo controlled trial showed improvement in negative and general psychopathology when ziprasidone was added to clozapine. A small recent, single blinded study found improvement when ECT was added to clozapine. Although we have insufficient evidence regarding the treatment of patients who are clozapine nonresponders, a few positive studies are beginning to emerge. Clinical guidelines may lag behind the current research, and busy clinicians are often unable to keep up with the current biomedical literature. In difficult to treat patients, clinicians must weigh the evidence from available guidelines versus the need to treat seriously ill patients with treatment resistant illnesses.

Violence in Schizophrenia

Most patients with schizophrenia do not exhibit violent behavior—perhaps this is even surprising given the severity and stress of hearing voices, being paranoid, etc. That said, patients with schizophrenia are more likely to be violent than the general population. Risk factors for violence include those associated with violence in the general population (eg, childhood trauma and exposure to violence, alcohol and substance abuse, psychopathy, and access to firearms) and (to some lesser extent) psychotic symptoms.[53] Results from a meta-analysis indicate that most of the risk of violence is associated with co-occurring substance abuse.[54] Patients are at risk to become violent when they relapse and so keeping patients with schizophrenia clinically stable is a major consideration. Some states even have outpatient commitment laws where patients at risk of violence are "forced" to get ongoing care, and if they default, they are sent back to the hospital. Patients who are really dangerous are invariably contained either in the legal system itself or legally as "forensic" patients where they are held by court order in a psychiatric facility.

Antipsychotic Mechanism of Action

The exact mechanism of action of antipsychotics is unknown. It has been suggested that antipsychotics be classified into three different categories: (a) typical or traditional (high D_2 antagonism and low serotonin-2 receptor [5-HT_{2A}] antagonism); (b) atypical (moderate to high D_2 antagonism and high 5-HT_{2A} antagonism); and (c) atypical clozapine-like (low D_2 antagonism and high 5-HT_{2A} antagonism).[55] With the exception of aripiprazole and brexipiprazole, all current SGAs have a greater affinity for 5-HT_{2A} receptors than D_2 receptors, and brexipiprazole shows stronger antagonism of the 5-HT_{2A} receptor than aripiprazole.[55,56] Brexipiprazole also demonstrates higher affinity

for the serotonin-1A (5-HT_{1A}) receptor compared to aripiprazole but with less intrinsic D_2 activity than aripiprazole.[56]

Prospective studies of antipsychotic receptor binding in humans have used PET scans to examine neurotransmitter receptor binding at steady state, 12 hours postdose in small numbers of individuals. It has been proposed that at least 60% to 65% D_2 receptor occupation is necessary to decrease positive psychotic symptoms, whereas blockade of approximately 77% or more of D_2 receptors is associated with EPS.[55] FGAs are DA receptor antagonists with high affinity for D_2 receptors. During chronic treatment with these agents, between 70% and 90% of D_2 receptors in the striatum are usually occupied. In contrast, during clozapine treatment only 38% to 47% of D_2 receptors are occupied, even with high doses. Newer SGAs have variable D_2 binding. With low-dose risperidone (2-5 mg/day), D_2 binding ranges from 60% to 79%, but with doses greater than 6 mg daily, binding commonly exceeds the 77% threshold associated with the development of EPS. Risperidone 2 mg/day produces 5-HT_{2A} binding greater than 70%, and with 4 mg/day it is nearly 100%.[55,57] Olanzapine 10 to 20 mg/day produces D_2 binding ranging from 71% to 80%, whereas at 30 to 40 mg/day, it ranges from 83% to 88%. At 5 mg/day, 5-HT_{2A} receptors are near saturation of binding.[55,57] Ziprasidone has the highest 5-HT_{2A}-to-D_2 affinity ratio of any of the currently available antipsychotics. It is also a potent serotonin-1A (5-HT_{1A}) agonist.[55]

Quetiapine has the lowest D_2 binding. At doses of 300 to 600 mg/day, 12-hour post dose D_2 binding ranges from 0% to 27%. Even at quetiapine 800 mg/day, only 30% of D_2 receptors are occupied. At these same daily doses, 45% to 90% of 5-HT_{2A} receptors are occupied. However, when quetiapine D_2 binding is examined 2 to 3 hours postdose, 58% and 64% of receptors were occupied with 400 and 450 mg, respectively. Transient blockade of DA receptors may be adequate to produce antipsychotic effect, but long-term D_2 blockade is required for production of EPS and sustained hyperprolactinemia. Low D_2 binding, and thus atypicality, can be directly associated with how rapidly the antipsychotic disassociates from the D_2 receptor.[55,57] Aripiprazole and brexpiprazole, partial agonists at D_2 receptors, represent a further elaboration of the DA hypothesis of antipsychotic action.[55,56]

Iloperidone has high affinity for D_2, dopamine-3 (D_3), and 5-HT_{2A} receptors, and moderate affinity for dopamine-4 (D_4), serotonin-6 (5-HT_6), serotonin-7 (5-HT_7), and α_1-receptors.[58] Asenapine has high affinity for 5-HT_{2A} and D_2 receptors as well as for α_1- and histamine-1 receptors. D_2 occupancy of approximately 80% is predicted to occur with a sublingual dose of 5 to 10 mg twice daily.[59] Cariprazine has high affinity for D_2 and D_3 receptors as a partial agonist, with the D_3 potency being significantly greater than D_2. It is also a partial agonist at 5-HT_{1A} receptors and an antagonist at serotonin-1B (5-HT_{1B}) receptors.[60] It is clear that the SGAs differ in their mechanisms of action and most likely in the manner in which they produce an atypical clinical profile.

The primary therapeutic effects of antipsychotics are thought to occur in the limbic system, including the ventral striatum, whereas EPS are thought to be related to DA blockade in the dorsal striatum. 5-HT_{2A} antagonism in combination with modest D_2 blockade leads to release of DA in the prefrontal cortex, and this is one explanation for the decrease in negative symptoms and improvement in cognition reported with atypical antipsychotics.[55]

Antipsychotics vary in their effects on other neurotransmitter receptor systems.[55] Although the significance of these different mechanisms on efficacy is unclear, they do potentially explain differences in side effect profiles. These differences in pharmacodynamic profiles point out that the SGAs are not all alike, and patients obtaining an inadequate clinical response (either efficacy or side effects) with one antipsychotic may have a superior response on an alternate drug. Thus, serial SGA monotherapy trials should be tried in patients receiving a suboptimal clinical response (see Fig. 67-1).

Pharmacokinetics

As a class, antipsychotics are highly lipophilic and highly bound to membranes and plasma proteins. They distribute readily into most tissues with a high blood supply and can accumulate in tissues; therefore, they have large volumes of distribution.[61] Most antipsychotics are largely metabolized, primarily through the cytochrome P450 (CYP) pathways in the liver, except for ziprasidone, which is largely metabolized by aldehyde oxidase. Fluphenazine, perphenazine, and risperidone are metabolized through CYP2D6, and thus are susceptible to polymorphic metabolism.[62] This is also one of the major pathways for the metabolism of aripiprazole, brexpiprazole and iloperidone.[58,63] Thirty to 35% of Africans and Asians are slow to intermediate metabolizers. Approximately 0% to 5% of African Americans, 1% of Asians, and 5% to 10% of whites are poor metabolizers.[62,64] In addition, some people of Swedish descent and up to 30% of those from Northern Africa may be ultrarapid metabolizers.[64] Polymorphisms in CYP1A2 can potentially result in a decrease in the metabolic rate of clozapine, and increased clozapine metabolic rate in smokers has been linked to a specific genotype.[62] The possibility of genetic polymorphism should be considered when dosing and monitoring the clinical effects of antipsychotics.[62,65] **Table 67-5** outlines the prominent metabolic pathways of selected antipsychotics.

TABLE 67-5 Pharmacokinetic Parameters of Selected Antipsychotics

Drug	Bioavailability (%)	Half-Life	Major Metabolic Pathways	Active Metabolites

Drug	Bioavailability (%)	Half-Life	Major Metabolic Pathways	Active Metabolites
Selected First-Generation Antipsychotics (FGAs)				
Chlorpromazine	10-30	8-35 hours	FMO3, CYP3A4	7-Hydroxy, others
Fluphenazine	20-50	14-24 hours	CYP2D6	?
Fluphenazine decanoate		14.2 ± 2.2a days	CYP2D6	
Haloperidol	40-70	12-36 hours	CYP1A2, CYP2D6, CYP3A4	Reduced haloperidol
Haloperidol decanoate		21 days	CYP1A2, CYP2D6, CYP3A4	Reduced haloperidol
Perphenazine	20-25	8.1-12.3 hours	CYP2D6	7-OH-perphenazine
Second-Generation Antipsychotics (SGAs)				
Aripiprazole	87	48-68 hours	CYP2D6, CYP3A4	Dehydroaripiprazole
Aripiprazole Lauroxil		29.2-34.9 days	CYP2D6. CYP3A4	Dehydroaripiprazole
Aripiprazole Monohydrate		29.9-46.5 days	CYP2D6, CYP3A4	Dehydro-aripiprazole
Asenapine	<2 orally 35 SL Nonlinear	13-39 hours	UGT1A4, CYP1A2	None known
Brexpiprazole	95	91 hours	CYP2D6, CYP3A4	DM-3411
Cariprazine		2-4 days, DDCAR 1-3 weeks	CYP2D6, CYP3A4	Desmethyl cariprazine [DCAR], Didesmethyl cariprazine [DDCAR]
Clozapine	12-81	11-105 hours	CYP1A2, CYP3A4, CYP2C19	Desmethylclozapine
Iloperidone	96	18-33 hours	CYP2D6, CYP3A4	P88
Lurasidone	10-20	18 hours	CYP3A4	ID-14233 and ID-14326
Olanzapine	80	20-70 hours	CYP1A2, CYP3A4, FMO3	*N*-Glucuronide; 2-OH-methyl; 4-*N*-oxide
Olanzapine LAI		30 days	CYP1A2, CYP3A4, FMO3	*N*-Glucuronide; 2-OH-methyl; 4-*N*-oxide
Paliperidone ER	28	23 hours	Renal unchanged (59%) CYP3A4 and multiple pathways	None known
Paliperidone palmitate		25-49 days	Renal unchanged (59%) CYP3A4 and multiple pathways	None known
Paliperidone Palmitate ER		84-89 days (deltoid) 118-139 days (gluteal)	Renal unchanged (59%) CYP3A4 and multiple pathways	None known
Quetiapine	9 ± 4	6.88 hours	CYP3A4	N-desalkylquetiapine
Quetiapine XR		7 hours	CYP3A4	N-desalkylquetiapine
Risperidone	68	3-24 hours	CYP2D6	9-OH-risperidone
Risperidone Consta		3-6 days	CYP2D6	9-OH-risperidone
Ziprasidone	59	4-10 hours	Aldehyde oxidase, CYP3A4	None

UGT, UDP glucuronosyltransferases genes; FMO3, flavin containing monooxygenase 3 gene; SL, sublingual.

[a]Based on multiple-dose data. Single-dose data indicate a β-half-life of 6-10 days.

Data from references [40,41,42, 45,46,47, 58,59,60,61, 63,64, 69, 116, 130].

Asenapine is unique in that it has less than 2% bioavailability after oral administration, but has a bioavailability of approximately 35% sublingually—the FDA-approved route of administration. Eating and drinking within 10 minutes after sublingual administration will reduce bioavailability, and bioavailability decreases with single doses above 10 mg.[59,64]

Most antipsychotics have fairly long elimination half-lives, generally 24 hours or more, with the exception of quetiapine and ziprasidone, which have short half-lives.[61,64] Among the SGAs, only clozapine has an established therapeutic serum concentration, with efficacy being associated with a clozapine plasma concentration greater than 350 ng/mL (mcg/L; 1.07 µmol/L).[61] Whether a potential maximum therapeutic clozapine serum concentration exists is unknown. Clozapine serum concentration should be obtained before exceeding 600 mg daily, in patients who develop unusual or severe adverse side effects, in patients who are taking concomitant medications that can cause drug interactions, in patients who have age or pathophysiologic changes suggesting a change in pharmacokinetics, or for assessment of patient adherence.[61,64]

Adverse Effects

Table 67-6 presents the relative incidence of common categories of antipsychotic side effects. Side effects are discussed below with respect to organ system affected. A general approach to monitoring and assessing side effects requires prospective monitoring by clinicians, preferably using a thorough review of systems approach. Patient-oriented self-rated side effect scales can be helpful, as many patients with schizophrenia do not readily complain of side effects.

TABLE 67-6 Relative Side Effect Incidence of Commonly Used Antipsychotics[a,b]

	Sedation	EPS	Anticholinergic	Orthostasis	Weight Gain	Prolactin
Aripiprazole	+	+	+	+	+	+
Asenapine	+	++	±	++	+	+
Brexpiprazole	+	+	+	+	+	+
Chlorpromazine	++++	+++	+++	++++	++	+++
Clozapine	++++	+	++++	++++	++++	+
Fluphenazine	+	++++	+	+	+	++++
Haloperidol	+	++++	+	+	+	++++
Iloperidone	+	±	++	+++	++	+
Lurasidone	+	+	+	+	±	±
Olanzapine	++	++	++	++	++++	+
Paliperidone	+	++	+	++	++	++++
Perphenazine	++	++++	++	+	+	++++
Quetiapine	++	+	+	++	++	+
Risperidone	+	++	+	++	++	++++
Thioridazine	++++	+++	++++	++++	+	+++
Thiothixene	+	++++	+	+	+	++++
Ziprasidone	++	++	+	+	+	+

EPS, extrapyramidal side effects. Relative side effect risk: ±, negligible; +, low; ++, moderate; +++, moderately high; ++++, high.

[a]Side effects shown are relative risk based on doses within the recommended therapeutic range.

[b]Individual patient risk varies depending on patient-specific factors.

With the variety of antipsychotics available, using an alternative antipsychotic should be considered in patients who complain of poorly tolerated side effects. Because medication side effects are one of the primary predictors of patient nonadherence, the clinician should take advantage of the treatment options currently available in an attempt to improve patient outcomes. As we learn more about relative side effect risks (eg, weight gain, glucose intolerance, QTc prolongation, acute EPS, and tardive dyskinesia), it will be necessary to regularly reconsider which antipsychotics should be considered first-line treatment alternatives.

Endocrine System

DA blockade in the tuberoinfundibular tract results in increased prolactin levels as DA is the major prolactin-inhibiting factor. Hyperprolactinemia may occur in up to 71% of patients diagnosed with schizophrenia and treated with FGAs or SGA. US based studies show no gender difference in incidence of antipsychotic induced hyperprolactinemia, however UK based studies suggest women are twice as likely to experience antipsychotic induced hyperprolactinemia than men (52% vs 26% respectively).[66,67] The major side effects associated with hyperprolactinemia are gynecomastia, galactorrhea, menstrual irregularities, decreased libido, and sexual dysfunction. Although the clinical significance is unclear, chronic hyperprolactinemia has been associated with decreased bone mineral density.[68] Tolerance does not appear to develop to antipsychotic-induced hyperprolactinemia. Newer antipsychotics including asenapine, iloperidone, and lurasidone have not been shown to induce clinically meaningful changes in prolactin levels.[58,59,69] Switching to an SGA

that has minimal sustained effect on prolactin is a reasonable treatment option. A recent meta-analysis suggests that augmentation with aripiprazole 5 to 30 mg daily may help reduce risperidone induced hyperprolactinemia.[70]

Weight gain is frequently reported in both adults and children receiving antipsychotics.[71] Although the exact mechanism is uncertain, weight gain has been associated with antihistaminic effects, antimuscarinic effects, and blockade of 5-HT_{2C} receptors including 5-HT_{2C} receptor polymorphism. However, dietary factors and activity levels can play a significant role in this population, as well as re-nourishment after a period of poor self-care. In particular, significant weight gain, defined by the FDA as greater than or equal to 7% of the baseline body weight, after 1 year of treatment has been seen in as many as 80% of patients treated with olanzapine, 58% treated with risperidone, 50% treated with quetiapine, and 21% treated with iloperidone.[58,72] The risk of weight gain may be greater in patients with their first psychotic episode. A recent meta-analysis evaluating antipsychotic induced weight changes in first episode psychosis showed an overall clinically significant increase in weight and body mass index (BMI) in short and long term use of antipsychotics compared with placebo. In the same meta-analysis, olanzapine, and clozapine were associated with the greatest weight changes over time, while ziprasidone showed no clinically significant weight changes. Ziprasidone and aripiprazole, as well as newer agents asenapine and lurasidone, are associated with minimal weight gain.[59,69]

The risk of cardiovascular-related mortality is higher in individuals with schizophrenia,[72,74] and this is further aggravated by drug-related weight gain and the high prevalence of smoking. Additionally, obesity is a risk factor for diabetes mellitus.[71] Weight gain during treatment is concerning for patients and a major reason for poor medication adherence.[75]

Several different genetic variations have been correlated with predisposition for antipsychotic-associated weight gain. A meta-analysis of all genetic studies looking at the –759 C/T promoter region polymorphism of the *5-HT_{2C}* receptor gene confirmed an association of 5-HT_{2C} in antipsychotic-induced weight gain.[76] Polymorphisms in leptin and leptin receptor genes have also been linked with clozapine- and olanzapine-associated weight gain.[77] Alpha-2a-adrenergic receptor gene, G protein β_3 subunit gene, melanocortin-4-receptor (*MC4R*), methylenetetrahydrofolate reductase (*MTHFR*) and brain-derived neurotrophic factor (*BDNF*) gene have been genetic targets; however, results are inconsistent as to whether a relationship exists with these polymorphisms and antipsychotic-associated weight gain.[77,78]

Several approaches have been recommended to address weight gain. Stroup et al. have shown that switching the antipsychotic to another agent with less weight gain liability is one choice.[79] Metformin has been shown to be effective in treating antipsychotic induced weight gain with a meta-analysis indicating an average of a 3.17 kg weight loss compared with placebo.[80] Dietary restriction, exercise, and behavior modification programs are reported to be successful. Both the Reducing Weight and Diabetes Risk in an Underserved Population (STRIDE) and the Randomized Trial of Achieving Healthy Lifestyles in Psychiatric Rehabilitation (ACHIEVE) clinical trials showed behavioral weight loss interventions resulted in significant weight loss in patients with mental illness receiving antipsychotics. The STRIDE study also showed reductions in fasting glucose over 6 and 12 month periods using such interventions.[78,81,82] An American Diabetes Association consensus task force recommends consideration of a change in antipsychotic if a patient gains more than 5% of baseline body weight after starting the drug.[83]

Clinical Controversy…

Although weight gain with antipsychotics is a major challenge in psychiatry, no clear consensus currently exists regarding how to address weight gain in these patients. Medications such as metformin have been shown to decrease weight in patients taking SGAs, and studies have shown that multipronged behavioral interventions result in weight loss in such patients. Although it is tempting to use medication in attempt to achieve weight loss, multipronged behavioral interventions including diet and exercise offer health benefits beyond just losing weight.

Patients with schizophrenia have a higher prevalence of type 2 diabetes compared to patients without schizophrenia. Beyond this, antipsychotics may adversely affect glucose levels in diabetic patients. The extent to which these effects are related to drug-induced weight gain is unclear.[71] Data collected from the FDA MedWatch Drug Surveillance System for clozapine, olanzapine, quetiapine, and risperidone indicate that nearly 60% of new-onset diabetes occurred within the first 6 months of treatment initiation.[72] Clozapine and olanzapine have the highest risk of new-onset diabetes followed by risperidone and then quetiapine. Although less likely than with the other SGAs, inadequate data are available to accurately estimate the risk with ziprasidone and aripiprazole.[72] In a study comparing first episode patients compared with healthy controls, the greatest increases in glucose impairment occurred during the first 14 weeks of treatment, with olanzapine being the greatest contributor.[81] The 2009 PORT guidelines do not recommend olanzapine as a first-line antipsychotic option due to its side effect profile.[26] The FDA approved product labeling for all SGAs reflects the increased risk of diabetes mellitus in patients taking these medications. Designing care models and standards for managing diabetes in patients with schizophrenia is important in addressing this major health problem.

Cardiovascular System

Orthostatic Hypotension

Orthostatic hypotension is thought to be caused by α-adrenergic blockade, and may occur in up to 75% of treated patients.[84] Clozapine and quetiapine had the highest incidence of orthostatic hypotension in the CATIE study, and iloperidone appears to have the highest risk among newer SGAs.[84] Orthostatic hypotension can occur in any patient, but diabetic patients with preexisting cardiovascular disease and the elderly seem particularly predisposed. Other risk factors may include older age, dehydration and presence of alcoholic neuropathy.[84,85] Antipsychotic combination treatment has been reported to result in a greater risk of orthostasis.[84,85] Patients should be advised to avoid sudden positional changes to allow for adaptation. Tolerance to this effect may occur within 2 to 3 months. If not, lower doses or a change to an antipsychotic with less α-blockade can be attempted. Fluid resuscitation or increasing salt intake may also help minimize orthostatic blood pressure changes.[84]

Electrocardiographic Changes

Among the antipsychotics, thioridazine is most likely to cause electrocardiographic (ECG) changes. ECG changes include increased heart rate (through sinus tachycardia from anticholinergic effects, or reflex tachycardia from α-adrenergic blockade), flattened T waves, ST segment depression, and prolongation of QT and PR intervals. The most clinically important of these potential changes is prolongation of the QTc interval, which has been associated with ventricular arrhythmias, including torsade de pointes syndrome. This is thought to occur as a result of blockade of the cardiac delayed potassium rectifier channel as well as impairment in autonomic function.[85,86] Thioridazine has been shown to prolong the QTc on average approximately 20 milliseconds longer than haloperidol, risperidone, olanzapine, or quetiapine.[86] Thioridazine's effect on QTc prolongation is dose related, and has led to a boxed warning in the FDA-approved product labeling. In the same study, ziprasidone prolonged the QTc by approximately 10 milliseconds or about one half of the effect of thioridazine.[87] A recent comprehensive review was not able to stratify the degree of QTc prolongation of nine different SGAs.[88] Iloperidone however, is subject to polymorphic metabolism and there may be an increased risk of QTc prolongation in CYP2D6 slow metabolizers.[58] High IV doses of haloperidol elevate the risk for QTc prolongation, and it has a boxed warning in the FDA approved labeling.[89] Although the precise point at which QTc prolongation becomes clinically dangerous is unclear, the risk for arrhythmia escalates when the QTc interval exceeds 500 milliseconds, or is 60 milliseconds above the baseline QTc.[85,90] Accordingly, it has been recommended to discontinue a medication associated with QTc prolongation if the interval consistently exceeds 500 milliseconds. A recent comprehensive review suggests that QTc intervals greater than or equal to 450 milliseconds and/or a 30 milliseconds increase in QTc interval from baseline are predictors of a drug's risk to cause torsades.[88]

While QTc prolongation may predict torsade de pointes, it rarely happens in the absence of other risks factors, including patients greater than 60 years, female gender, those with preexisting cardiac or cerebrovascular disease (including bradycardia, second- or third-degree AV block, and congenital long QTc syndrome), hepatic impairment, hypokalemia, hypomagnesemia, concomitant medications that prolong the QTc interval, metabolic inhibition by another medication, and preexisting QTc prolongation.[87,88,89] For patients over the age of 50 years of age, a pretreatment ECG is recommended, as are baseline serum potassium and magnesium levels.

Sudden Cardiac Death

A large retrospective analysis found that the risk of sudden cardiac death (SCD) with use of FGAs and SGAs was twice that of nonusers, with risk increasing with escalated dose.[87,91] It has been estimated that 15 cases of SCD occur per 10,000 years of antipsychotic exposure.[86] Meta-analysis has conferred a lack of evidence for differential effects on cardiovascular mortality favoring one class of antipsychotics over the other.[87,91] A recent case cross over study involving over 17,000 patients showed that use of antipsychotics was associated with a 1.53 fold increase in ventricular arrhythmia or SCD. The magnitude of effect was greatest among patients who received antipsychotics for a short term (less than 28 days).[92] Nonetheless, prospectively designed studies are needed to confirm a dose-dependent increase in cardiovascular sudden death with antipsychotic use, and to determine whether certain antipsychotics are associated with a greater risk than others.

Lipid Changes

Treatment with at least some SGAs and phenothiazines appears to be associated with elevations in serum triglycerides and cholesterol. Oxidation of apolipoprotein B lipoproteins and elevations in sterol regulatory element binding protein-controlled gene expression are among the purported mechanisms by which these lipid changes occur during antipsychotic treatment.[93] Among the SGAs, less risk for change in serum lipid or cholesterol levels has been associated with risperidone, ziprasidone, aripiprazole, asenapine, iloperidone, and lurasidone.[59,69,72,74] In the CATIE trial, olanzapine was associated with greater and significant adverse effects on metabolic parameters, including lipids, blood glucose, and body weight versus the other study treatments, but these differences in tolerability did not affect discontinuation rates.[30]

The occurrence of weight gain, diabetes, and lipid abnormalities during antipsychotic therapy is consistent with the development of metabolic syndrome (ie, syndrome X). Cohorts of patients with schizophrenia have shown elevated prevalence of metabolic syndrome as compared with general population cohorts. Prevalence rates of metabolic syndrome in US populations treated with antipsychotics range from 28% to 60%, with 40.9% reported in the prospectively designed CATIE trial.[94]

Metabolic syndrome consists of raised triglycerides (greater than or equal to 150 mg/dL [1.70 mmol/L]), low HDL cholesterol (less than or equal to 40 mg/dL [1.03 mmol/L] for males, less than or equal to 50 mg/dL [1.29 mmol/L] for females), elevated fasting glucose (greater than or equal to 100 mg/dL [5.6 mmol/L]), blood pressure elevation (greater than or equal to 130/85 mm Hg), and weight gain (abdominal circumference greater than 102 cm [40 in] for males, greater than 89 cm [35 in] in females).[72,74] These abnormalities dictate an important role for general health screening and monitoring in patients with schizophrenia, and prompt intervention when such abnormalities occur. The propensity of individual antipsychotics to produce metabolic disturbances should be considered in the context of individual patient risk factors at the time of drug selection.

Anticholinergic Effects

Patients receiving antipsychotics or antipsychotics in combination with anticholinergics can experience anticholinergic side effects (eg, dry mouth, constipation, tachycardia, blurred vision, inhibition or impairment of ejaculation, urinary retention, or impaired memory). These side effects are particularly seen when low-potency FGAs are used, and in elderly patients who are especially sensitive to these effects. Of the SGAs, clozapine, and olanzapine have moderately high rates of causing anticholinergic effects. Constipation, caused by slowed peristaltic movement and decreased intestinal fluid content, should be closely monitored and treated, especially in the elderly. Paralytic ileus and necrotizing enterocolitis can also occur.

CNS

Extrapyramidal System

Extrapyramidal symptoms is an umbrella term used to describe antipsychotic induced movement side effects due to excess dopamine blockade in the nigrostriatal pathway. These symptoms include: dystonia, akathisia, pseudoparkinsonism, and tardive dyskinesia, which are explained in detail below.

- ***Dystonia—***a state of abnormal tonicity, sometimes described simplistically as a severe, "muscle spasm.[95] More accurately, dystonias are prolonged tonic contractions, with a rapid onset, usually within 24 to 96 hours of initiating or increasing the dose of an antipsychotic. They can be life-threatening, as in the case of pharyngeal–laryngeal dystonias, and can contribute to patient nonadherence with their medications. Types of dystonic reactions include trismus, glossospasm, tongue protrusion, pharyngeal–laryngeal dystonia, blepharospasm, oculogyric crisis, torticollis, and retrocollis. Dystonic reactions occur primarily with FGAs. Risk factors include younger patients (especially males), the use of high-potency agents, and high dosage. The overall incidence from the 1960s to the mid-1970s ranged from 2.3% to 10%, but as higher-potency traditional antipsychotics became more widely used, the rate increased to as high as 64%.

  Intramuscular or IV anticholinergics (**Table 67-7**) or benzodiazepines are the treatments of choice for dystonia. Benztropine 2 mg or diphenhydramine 50 mg can be given intramuscularly or IV. Diazepam 5 to 10 mg by slow IV push or lorazepam 1 to 2 mg intramuscularly is a treatment alternative. Relief is typically seen within 15 to 20 minutes of an intramuscular injection and within 5 minutes of IV administration. The antipsychotic can be continued, with concomitant short-term use of oral anticholinergic agents. In general, prophylactic anticholinergic medications are not recommended routinely with all FGAs. However, prophylaxis is reasonable when using high-potency FGAs (eg, haloperidol or fluphenazine) in young men, and in patients with a history of dystonia.[95] Dystonias can also be minimized by the use of lower initial FGA doses. Anticholinergics are good choices for prophylaxis, whereas amantadine has not been proven effective for this purpose. The risk of dystonia is greatly reduced with SGAs.

- ***Akathisia—***defined as the inability to sit still and having functional motor restlessness. The most accurate diagnosis is made by combining subjective complaints with objective symptoms (pacing, shifting, shuffling, or tapping feet). Subjectively, patients may describe a feeling of inner restlessness or disquiet or a compulsion to move or remain in constant motion. Akathisia occurs in 20% to 40% of patients treated with high-potency FGAs.[95,96] It is frequently accompanied by dysphoria. In severe cases, akathisia may be mistaken for aggression and if left untreated, akathisia has been linked to causing insomnia, increased suicidality and development of tardive dyskinesia.[97]

  Akathisia responds poorly to anticholinergics.[96] Traditionally, reduction in antipsychotic dosage has been considered the best intervention; however, this might not be a realistic goal in an acutely psychotic patient. A logical alternative is to switch to an antipsychotic with a lower risk of akathisia, or an antipsychotic previously used in the patient without adverse effect. Akathisia can occasionally occur with SGAs, particularly aripiprazole and risperidone. Quetiapine and clozapine appear to have the lowest risk of producing akathisia.[96,97]

  Benzodiazepines have been used for treatment of akathisia, but the high prevalence of co-occurring substance abuse in schizophrenia discourages their prescribing.[96] The β-blockers (eg, propranolol in doses up to 160 mg daily, nadolol in doses up to 80 mg daily, and metoprolol in β_2-selective doses of 100 mg daily or less) are reported as effective.[95,96] Emerging literature suggests that agents with antagonist activity at the 5-HT_2 receptor may be protective against akathisia and may be used for its management.

Examples of such agents include cyproheptadine, mirtazapine, and trazodone.[95,97]

- ***Pseudoparkinsonism***—is produced by D_2 blockade in the nigrostriatum, resembling idiopathic Parkinson's disease. A patient with pseudoparkinsonism can present with any of four cardinal symptoms: (a) akinesia, bradykinesia, or decreased motor activity including difficulty initiating movement, as well as extreme slowness, mask-like facial expression, micrographia, slowed speech, and decreased arm swing; (b) tremor, known as pill-rolling type, that is predominant at rest and decreases with movement, usually involving the fingers and hands, although tremors can also be seen in the arms, legs, neck, head, and chin; (c) cogwheel rigidity, seen as the patient's limbs yielding in jerky, ratchet-like fashion when passively moved by the examiner; and (d) postural abnormalities and instability manifested as stooped posture, difficulty in maintaining stability when changing body position, and a gait that ranges from slow and shuffling to festinating. Fatigue and weakness can be noted, as well as oral abnormalities including dysphagia, dysarthria, and abnormal palmomental and glabellar reflexes. The overall incidence of pseudoparkinsonism from FGAs ranges from 15.4% to 36%, depending on the drug and dose. Akinesia alone can be seen in 59% of patients on high-potency FGAs. Other risk factors include increasing age and possibly female gender. The onset of symptoms is typically 1 to 2 weeks after initiation of antipsychotic therapy or a dose increase.[95,96]

  The efficacy of anticholinergic medications in treating symptoms of pseudoparkinsonism is well established.[95,96] Recent meta-analyses and trial data, such as a secondary analysis of data from the Cost Utility of the Latest Antipsychotic drugs in Schizophrenia Study (CUtLASS-1) and CATIE studies, did not report marked differences in rates of EPS between FGAs and SGAs when FGA treatments were accompanied by appropriate use of anticholinergic medications.[98]

  Anticholinergic dosing for pseudoparkinsonism is outlined in Table 67-7. Diphenhydramine produces more sedation than the other agents. Symptoms typically begin to resolve within 3 to 4 days after initiation of treatment, but a minimum of at least 2 weeks of treatment is normally required for full response. All of the anticholinergics have been abused for their euphoriant effects.[99] Amantadine may be as efficacious for pseudoparkinsonism as anticholinergics, but with significantly less effect on memory function.[96] Rotigotine, a dopamine agonist, is effective at doses ranging from 2 to 8 mg per day, and without worsening positive or negative symptoms of schizophrenia.[100] Prophylactic use of these agents against pseudoparkinsonism is less convincing compared with dystonias, and is unnecessary when using SGAs.[96] The long-term treatment of pseudoparkinsonism with antiparkinsonism medication is somewhat controversial. An attempt should be made to taper and discontinue these agents 6 weeks to 3 months after symptom resolution. If symptoms reappear, then switching to a SGA should be considered. The risk of pseudoparkinsonism with SGAs is low. When risperidone is used in doses greater than 6 mg/day, the risk of pseudoparkinsonism symptoms approaches that with FGAs. Quetiapine, aripiprazole, and clozapine are reasonable alternatives in a patient experiencing EPS with other SGAs.[96,98]

- ***Tardive Dyskinesia (TD)***—is a syndrome characterized by abnormal involuntary movements occurring late in onset in relation to initiation of antipsychotic therapy. It is sometimes irreversible and continues to be a controversial issue.

  The classic description of tardive dyskinesia is the buccal–lingual–masticatory (BLM) syndrome, or orofacial movements. The onset of BLM movements is usually insidious. Typically, they are the first detectable signs of tardive dyskinesia which begin with mild forward, backward, or lateral movements of the tongue. If the disorder progresses, more obvious or frank BLM movements appear, including tongue thrusting, rolling, or fly-catching movements, and chewing or lateral jaw movements. Tardive dyskinesia symptoms can interfere with the patient's ability to chew, speak, or swallow. Further complications include oral ulcerations, inability to wear dentures, and inflammation and loosening of mandibular joints. Eating difficulties and malnutrition can be severe complications. Weight loss can be seen in patients with esophageal or respiratory manifestations. Facial movements include frequent blinking, brow arching, grimacing, upward deviation of the eyes, and lip smacking. Involvement of the extremities sometimes occurs, with the appearance of restless choreiform and distal athetosis of limbs including twisting, spreading, flexion and extension of fingers, toe tapping, and toe dorsiflexion. Unusual posture, hyperextension, pelvic thrusting, axial hyperkinesia ballismus, exaggerated lordosis, rocking, and swaying are occasionally observed. Among the differential diagnoses are withdrawal dyskinesias occurring after short-term use of antipsychotics, spontaneous orofacial dyskinesias in the elderly, orofacial dyskinesias in the edentulous, Huntington's disease, congenital torsion dystonia, and stereotypic movements associated with schizophrenia. Orofacial movements are more common in older patients, whereas the truncal axial movements are classically reported in young adults. Movements can worsen with stress, decrease with sedation, and disappear during sleep. Concentration on motor tasks or attempts to suppress the movements can actually increase them.[101]

  Early signs of tardive dyskinesia can be reversible but if allowed to persist, they can become irreversible, even with drug discontinuation. When the antipsychotic dose is decreased or tapered and discontinued, worsening of abnormal movements may occur, followed by possible slow improvement after months or years if the patient remains on lower doses or discontinues treatment. No standardized diagnostic criteria for tardive dyskinesia are available. Abnormal involuntary movements can be detected early through physical assessment and the use of rating scales. Available rating scales include the Abnormal Involuntary Movement Scale (AIMS) and the Dyskinesia Identification System: Condensed User Scale (DISCUS).[102] Neither scale is diagnostic in itself.

  Risk factors include increasing age, the occurrence of acute EPS, poor antipsychotic drug response, diagnosis of organic mental

disorder, diabetes mellitus, mood disorders, and possibly female gender.[101] Duration of antipsychotic therapy, daily dosage, and possibly total cumulative dosage are probably the most significant risk factors. Polymorphisms of the D2, D3, 5-HT2C receptor, and the superoxide dismutase-2 genes have all been implicated in varying the risk of TD with antipsychotic use.[101] Overall morbidity and mortality are greater in tardive dyskinesia patients.

With FGAs, the reported prevalence of TD ranges from 20% to 50%.[101] In first episode schizophrenia, the incidence is estimated at about 5% per year, with the overall prevalence ranging from 20% to 25% with long-term treatment. Among the elderly, the overall risk of TD is higher.[96] Tardive dyskinesia is not always permanent, with remission of symptoms observed in 25% of patients after 5 years of continued treatment.[29,96]

With SGAs, a systematic review of 12 studies lasting 1 year or more found the overall risk of tardive dyskinesia to be approximately 2.98% per year in nonelderly adults as compared with 7.7% for FGAs.[103] Although lower than the FGAs, the PORT guidelines report no difference in the risk of TD among SGAs.[26,29]

Prevention of tardive dyskinesia is important, as treatment of the movements once they occur is difficult. One of the more compelling arguments for the first-line use of SGAs is their lower risk of TD.[27,28,29] Regular neurologic examinations (AIMS or other scales) should be performed at baseline and at least quarterly to assess for possible early signs of tardive dyskinesia. At the first signs of tardive dyskinesia, the need for continuing antipsychotic treatment should be assessed. In such situations, if the patient is taking an FGA and continuing treatment is indicated, the medication should be switched to a SGA.

Numerous drugs have been used in an attempt to treat tardive dyskinesia. In two controlled trials lasting 22 to 52 weeks, clozapine decreased abnormal involuntary movements.[26,29] Although some treatment guidelines recommend switching antipsychotic therapy to clozapine as a favored first-line pharmacotherapeutic strategy in patients with moderate to severe dyskinesias, others do not support this.[31,96,104] A guideline developed by the American Academy of Neurology recommends short-term treatment of TD with either clonazepam or ginkgo biloba based upon randomized clinical trial data. However, long-term treatment data are lacking.[104]

TABLE 67-7 Agents Used to Treat Extrapyramidal Side Effects

Generic Name	Equivalent Dose (mg)	Daily Dosage Range (mg)
Antimuscarinics		
Benztropine[a]	1	1-8[b]
Biperiden[a]	2	2-8
Trihexyphenidyl	2	2-15
Antihistaminic		
Diphenhydramine[a]	50	50-400
Dopamine Agonist		
Amantadine	NA	100-400
Benzodiazepines		
Lorazepam[a]	NA	1-8
Diazepam	NA	2-20
Clonazepam	NA	2-8
***β*-Blockers**		
Propranolol	NA	20-160

NA, Not applicable.

[a]Injectable dosage form can be given intramuscularly for relief of acute dystonia.

[b]In treatment-refractory cases, dosage can be titrated to 12 mg/day with careful monitoring; nonlinear pharmacokinetics have been reported.

Sedation and Cognition

Chlorpromazine, thioridazine, clozapine, olanzapine, and quetiapine are the most sedating antipsychotics. Administration of most or all of the daily dosage at bedtime can decrease daytime sedation and in some patients eliminate the need for hypnotic agents. Sedation occurs early in treatment and can decrease over time. Over-sedation can play a large role in cognitive, perceptual, and motor dysfunction. However, positive effects of medication on cognition are seen with chronic administration, evidenced by improvements in tasks involving visual motor skills, attention to task, and working memory. Compared with FGAs, several studies have shown cognitive benefits of SGAs.

However, results from the CATIE trial showed no differences in cognitive improvement between SGAs and the FGA perphenazine.[105] Comparative effects of different SGAs on cognition are as yet unclear, but available studies suggest that different SGAs can have effects on varying cognitive domains.[27,29,]

As discussed in Long-Acting Injectable Antipsychotics section, olanzapine pamoate monohydrate injectable is associated with a postinjection sedation/delirium syndrome.[42,43,44]

Seizures

An increased risk of drug-induced seizures occurs in patients receiving antipsychotics as these agents decrease the seizure threshold. However, this risk is greater if the following predisposing factors are present: preexisting seizure disorder, history of drug-induced seizure, abnormal electroencephalogram (EEG), and preexisting CNS pathology or head trauma. Seizures are more closely associated with higher doses of antipsychotics, rapid dosage titrations, and when treatment is initiated. When an isolated seizure occurs, a dosage reduction in the antipsychotic is first recommended; routine prophylactic use of anticonvulsant therapy is not recommended. Although spontaneously occurring seizures have been reported with most antipsychotics, the highest potential risk for an antipsychotic-related seizure is with clozapine or chlorpromazine. If a change in antipsychotic therapy is required because of a drug-induced seizure, risperidone, thioridazine, haloperidol, pimozide, trifluoperazine, and fluphenazine are associated with the lowest potential.[96]

Thermoregulation

Poikilothermia, the body temperature adjusting to the ambient temperature, can be a serious side effect of antipsychotic therapy in temperature extremes.[106] Hyperpyrexia can be a danger in hot weather or during exercise. Inhibition of sweating, a result of anticholinergic properties impairing the peripheral mechanisms of heat dissipation, can contribute to this problem, which in its severest form can lead to heat stroke. Hypothermia is a risk in cold temperatures, particularly in the elderly. All patients receiving antipsychotics should be educated about these potential problems. Thermoregulatory problems are reportedly more common with the use of low-potency FGAs and can occur with the more anticholinergic SGAs.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) occurs in 0.5% to 1% of patients receiving FGAs. NMS can occur more frequently in patients receiving high-potency FGAs, injectable or depot FGAs, and in patients who are dehydrated, with physical exhaustion, or organic mental disorders. Additionally, young to middle aged men as well as postpartum women are at elevated risk for NMS.[107] Although less common, NMS has been reported with SGAs, including clozapine. The onset of symptoms varies from early in treatment to months later. It develops rapidly, over the course of 24 to 72 hours. NMS can occur after antipsychotic discontinuation, especially when depot agents are used. Possible mechanisms of NMS include disruption of the central thermoregulatory process or excess production of heat secondary to skeletal muscle contractions. The differential diagnosis includes heat stroke, lethal catatonia, anesthetic-associated malignant hyperthermia, anticholinergic toxicity, and monoamine oxidase inhibitor drug interactions. Cardinal signs and symptoms of NMS are body temperature exceeding 38°C (100.4°F), altered level of consciousness, autonomic dysfunction (tachycardia, labile blood pressure, diaphoresis, tachypnea, or urinary or fecal incontinence), and rigidity. Laboratory evaluation, although nonspecific, frequently shows leukocytosis with or without a left shift, increases in creatine kinase (CK), aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and myoglobinuria.[96,106]

Treatment should begin with antipsychotic discontinuation and supportive care. In many cases that alone is effective. The role of adjunctive agents is unclear, yet they are often used. The DA agonist bromocriptine reduces rigidity, fever, or CK in up to 94% of patients, whereas the use of amantadine has been successful in up to 63% of patients. Dantrolene has been used as a skeletal muscle relaxant, with positive effects on temperature, heart rate, respiratory rate, and CK in up to 81% of patients.[96,106] Wide recognition and rapid antipsychotic discontinuation has drastically reduced mortality from 20% 25 years ago to 4% in the mid-1990s.

Many patients with schizophrenia, despite having had NMS, will require future antipsychotic pharmacotherapy. A review of antipsychotic rechallenges suggests that the risk of rechallenge is acceptable in most patients, provided that the patient is observed for an extended period of time (2 weeks or more is suggested) without antipsychotics, that there is careful monitoring and slow dose titration, and that the patient is maintained on the lowest possible dose.[96] A different antipsychotic, a SGA or a low-potency FGA, should be used for rechallenge following an episode of NMS.

Psychiatric Side Effects

Antipsychotic-induced akathisia, akinesia, and dysphoria can have unfortunate sequelae, resulting in what has been termed *behavioral toxicity*.[38] Akinesia, characterized by "diminished spontaneity," results in symptoms of apathy and withdrawal, often mistaken for the negative symptoms of schizophrenia; these patients can actually appear depressed. Delirium and psychosis are reported with larger doses of FGAs or combinations of anticholinergics with FGAs. Chronic confusion and disorientation can occur in the elderly as a result of antipsychotic treatment.[108] Unfortunately, the link is not always made with antipsychotic therapy, and the patient is misdiagnosed with

delirium from a different etiology. This clinical presentation, called a *pseudodementia*, may be reversible upon discontinuation of the antipsychotic.

Ophthalmologic Effects

Anticholinergic effects of antipsychotics or concomitant antiparkinson medications can exacerbate narrow-angle (angle-closure) glaucoma. Antipsychotics with low anticholinergic effects should be used in such individuals, and they should be appropriately monitored.[109]

Opaque deposits in the cornea and lens occur with chronic phenothiazine treatment, most frequently with chlorpromazine. Although visual acuity is not usually affected, periodic ophthalmologic examinations are frequently recommended in patients receiving long-term treatment with phenothiazines, as fully formed cataracts are possible.[109]

Because of cataract development and lenticular changes in animals, baseline and periodic eye examinations are recommended in the product labeling for quetiapine. However, quetiapine's effects on lens opacity was found to be no different than risperidone in a 2 year comparative trial.[110] Retinitis pigmentosa can result from use of thioridazine doses greater than 800 mg daily. It is caused by melanin deposits and can result in permanent visual impairment or blindness.

Genitourinary System

Urinary hesitancy and retention, secondary to anticholinergic effects, are reported with low-potency FGAs and with clozapine. Men with benign prostatic hypertrophy are especially prone to this effect.[111] Reducing the antipsychotic dose or switching to an antipsychotic with less anticholinergic activity may help manage this side effects. Alternatively, bethanecol can be used to treat antipsychotic induced urinary hesitancy and retention.

Urinary incontinence is thought to be caused by α-blockade, and among the SGAs, it appears to be particularly problematic with clozapine. The incidence has been reported to be as high as 44%, and it can be persistent in 25% of patients. Female gender, and previous urinary incontinence can be risk factors for developing this side effect.[112]

Although inadequately studied, multiple mechanisms are likely responsible for sexual dysfunction, including dopaminergic blockade, hyperprolactinemia, histaminergic blockade anticholinergic effects, and α-adrenergic blockade. Unmedicated individuals with schizophrenia report decreased libido. Most but not all studies show a relationship between hyperprolactinemia and sexual dysfunction, including decreased libido, erectile dysfunction, difficulty achieving orgasm, and ejaculatory abnormalities. Risperidone produces at least as much sexual dysfunction as FGAs; while other SGAs, with weak effects on prolactin, produce less sexual dysfunction. Patients experiencing sexual dysfunction with FGAs or risperidone should be switched to an SGA with less effect on prolactin.[113]

Priapism, a sustained and painful erection which is unprovoked and persists for longer than an hour, is increasingly reported with antipsychotic medication use. This is believed to occur as a result of α_1-adrenergic receptor blockade, leading to intracavernosal blood stasis.[114] This can evolve into a urologic emergency, due to the ischemic nature of the priapism. If left untreated, priapism may lead to permanent impotence.

Hematologic System

Transient leukopenia can occur during initial treatment with antipsychotics; however, it typically does not progress to be clinically significant.[115] Agranulocytosis reportedly occurs in 0.01% of patients receiving FGAs, and more frequently with chlorpromazine and thioridazine. The three antipsychotics with the highest relative risk for neutropenia in rank order are clozapine, chlorpromazine, and olanzapine.[115] The onset is usually within the first 8 weeks of therapy. If the absolute neutrophil count (ANC) is less than 500/μL (0.5×10^9/L) the antipsychotic should be discontinued and the ANC monitored closely until it returns to normal. Agranulocytosis can initially manifest as a local infection, with sore throat, leukoplakia, erythema, and ulcerations of the pharynx. These symptoms in any patient receiving antipsychotics should signal the immediate need for an ANC. If the ANC is less than 500/μL (0.5×10^9/L) the drug should be discontinued immediately and the patient monitored closely for the development of secondary infections. Isolated rare cases of thrombocytopenia and eosinophilia have also been reported.

Agranulocytosis with clozapine significantly limits the usefulness of this agent, and it is only available through the Clozapine REMS Program.[116] The risk of developing neutropenia or agranulocytosis with clozapine is approximately 3% and 0.8%, respectively.[115] Increasing age and female gender are associated with greater risk. The baseline ANC must be at least 1,500/μL (1.5×10^9/L) in order to start clozapine. Weekly ANC monitoring for the first 6 months of therapy is mandated in the FDA-approved product labeling. After this time, if the patient's ANC remains greater than 1,500/μL (1.5×10^9/L) the labeling allows ANC monitoring to be decreased to every 2 weeks for the next 6 months. After this, monitoring can be decreased to monthly if all ANCs remains greater than 1,500/μL (1.5×10^9/L). If at any time the ANC drops to less than 500/μL (0.5×10^9/L) clozapine must be discontinued and the ANC monitored daily until it is greater

than 1,500/μL (1.5×10^9/L). The FDA approved product labeling should be consulted for more detailed information regarding ANC monitoring, including monitoring for mild and moderate leukopenia and recommendations for patients with benign ethnic neutropenia.[116]

Dermatologic System

Allergic reactions are rare and usually occur within 8 weeks of initiating therapy, manifesting as maculopapular, erythematous, pruritic rashes that are evident on the face, neck, trunk, or extremities. Contact dermatitis, including the oral mucosa, has been reported in patients and medical personnel exposed to FGA liquid formulations. The risk of oral mucosal reactions can be decreased by mixing the FGA concentrate in a sufficient quantity of a nonacidic liquid and swallowing it quickly. Care should be taken in the handling and preparation of liquid FGAs. Recently, the FDA added a warning for ziprasidone to its labelling regarding the risk for a rare but fatal skin reaction called *Drug Reaction with Eosinophilia and Systemic Symptoms* (DRESS).[117]

Phenothiazines can absorb ultraviolet light, resulting in the formation of free radicals, which can have damaging effects on the skin. All antipsychotics can cause photosensitivity resulting in erythema and sunburn. Exposure to sunlight should be limited, and patients should be educated about the use of a maximally blocking sunscreen, hats, protective clothing, and sunglasses.[115]

Blue-gray or purplish skin coloration in areas exposed to sunlight occurs in patients receiving higher doses of low-potency phenothiazines during long-term administration, especially with chlorpromazine. It commonly occurs with concurrent corneal or lens pigmentation.

Miscellaneous Adverse Effects

A sometimes troubling side effect with clozapine is sialorrhea (drooling), which is typically prominent at night.[118] This side effect can affect up to 54% of patients receiving clozapine. The mechanism of clozapine-induced drooling is unclear, however two theories exist. The first involves muscarinic receptor activity and clozapine's imbalanced binding affinity to this receptor. The other involves clozapine's alpha antagonist activity at the salivary glands leaving unopposed beta-receptor stimulation and hence hyper-salivation.[118] Anticholinergics such as benztropine and atropine, and α-agonists such as clonidine have been used to treat clozapine-related sialorrhea.[118]

Toxicity with Overdose

Acute overdose with antipsychotics rarely results in serious symptomatology. Mild intoxication manifests as sedation, hypotension, and miosis, whereas with severe intoxication, agitation and delirium can typically progress to motor retardation, seizures, cardiac arrhythmias, respiratory arrest, and coma. Dystonias and pseudoparkinsonism symptoms also occur. Supportive measures, gastric lavage, and activated charcoal are recommended. Induction of emesis can be difficult because of effects on the chemoreceptor trigger zone. Dialysis is ineffective due to antipsychotics' high degree of drug–protein binding. Phenytoin or sodium bicarbonate is useful in the treatment of quinidine-like cardiac conduction effects on the QRS or QTc interval. Physostigmine is not generally recommended to reverse anticholinergic toxicity because of deleterious effects on arrhythmias and seizure threshold.[119]

Use in Pregnancy and Lactation

Minimal data exist regarding the effects of pregnancy on schizophrenia and its treatment. However, disorganized thought processes, impaired cognition, and negative symptoms can have a detrimental effect on the functioning and self-care of the mother, and therefore adversely affect the fetus.[120] Currently available data assessing the risk of teratogenesis with antipsychotic agents are insufficient. Epidemiologic studies show a slightly increased risk of birth defects with low-potency FGAs. Haloperidol is the best studied of all antipsychotics, and no relationship between its use and teratogenicity has been found. One study indicates a greater than twofold elevated risk of preterm birth in women with schizophrenia taking FGAs as compared with unaffected mothers not taking antipsychotics.[120]

Although increasing information regarding the safety of SGAs in pregnancy is becoming available, very few large studies and very few prospective studies have been performed to evaluate possible teratogenicity of SGAs. One large registry data study performed in Sweden found a significantly increased risk of cardiovascular defects with antipsychotic exposure; however, when stratifying by antipsychotic class, it was found that all defects were found in those exposed to FGAs, while no cardiovascular defects were reported with SGAs.[121] A meta-analysis of 12 studies found a greater risk of first trimester birth defects with SGAs, but no specific abnormality. An increased risk of preterm birth was also present in the SGA treated group. However, healthy women composed the control group in these studies, and the underlying disease state being treated with a SGA is an important confounder.[122] Thus, large, well-controlled studies are needed to determine the safety of SGAs during pregnancy.

Other potential interest in studying early and late exposure to antipsychotics include postnatal and gestational complications. Weight gain associated with olanzapine and clozapine and the potential risk of gestational diabetes should be considered in drug selection.[123] A recent retrospective cohort study reported nearly twofold odds of gestational diabetes in women who used antipsychotics during pregnancy, and this was confirmed by a population cohort study.[123,124] In addition, an increased risk of hypertension in women taking antipsychotics

during pregnancy as well as venous thromboembolism have been reported.

Risk of neonatal EPS is increased with in utero exposure to FGAs, with effects in the infant lasting for 3 to 12 months after birth.[125] In February 2011, the FDA issued a safety announcement informing healthcare professionals that the pregnancy section of drug labels had been updated for the entire antipsychotic class, highlighting the potential risk for EPS and withdrawal symptoms in newborns whose mothers were treated with antipsychotics during their third trimester.[125] Symptoms of neonatal withdrawal reported to the FDA included agitation, hypertonia, hypotonia, tremor, somnolence, respiratory distress, and feeding disorder.

The risk of antipsychotic use must be weighed against the benefits of pharmacotherapy in pregnant women experiencing disorganized thoughts, delusions about change in body image or pregnancy, or who are unable to provide adequate prenatal care.[120,125] A national pregnancy exposure registry monitors pregnancy outcomes in women exposed to atypical antipsychotics during pregnancy. This registry can be accessed at http://womensmentalhealth.org/clinical-and-research-programs/pregnancyregistry/atypicalantipsychotic.

Antipsychotics appear in breast milk with milk-to-plasma ratios of 0.5:1. However, 1 week after delivery, clozapine milk concentrations were found to be as much as 279% of serum concentrations. Its use during breast-feeding is not recommended due to the risk of bone marrow suppression.[126] Aripiprazole and quetiapine have the most data regarding their use in breastfeeding and are generally considered safe.[126] Information regarding olanzapine use in breastfeeding is inconclusive. First generation antipsychotics are detected in breast milk, however haloperidol, perphenazine, and trifluoperazine have not been reported to cause clinically evident adverse effects. Infants exposed to chlorpromazine through breast milk have been reported to be drowsy and lethargic. The co-administration of chlorpromazine and haloperidol is reported to result in developmental delays at 12 to 18 months of age.[127] Although not contraindicated, the lowest dosage for antipsychotics should be used in the mother, and the infant carefully monitored for antipsychotic adverse events such as EPS, sedation, seizures and developmental delays.[126]

Drug Interactions

Most drug interactions occur because of pharmacodynamic or pharmacokinetic interactions. Common examples of pharmacodynamic interactions resulting in enhanced effect include the excess sedation that can occur when antipsychotics are used concomitantly with other medications that have sedative side effects. Additive antimuscarinic effects can be seen when antipsychotics are used with other medications possessing antimuscarinic effects, potentially resulting in urinary retention, constipation, blurred vision, or other anticholinergic side effects.[38,128] Both combined sedative and anticholinergic effects from multiple medications can result in impaired cognition, particularly in the elderly and other patients predisposed to such problems.[128] Patients are more likely to experience symptomatic orthostatic hypotension when an antipsychotic is used with other medications that cause orthostasis. Metoclopramide is prescribed for treating esophageal reflux; it is a DA antagonist, and patients are more likely to experience akathisia and other EPS if it is used concomitantly with antipsychotics.[129] Although some SSRIs can interact with antipsychotics through enzyme inhibition, they can also interact through pharmacodynamic mechanisms. 5-HT_2 receptors are present on the presynaptic dopaminergic neuron, and their activation leads to decreased DA release from the presynaptic terminal. Increased availability of 5-HT through SSRI effect can activate these receptors, decrease DA release, and add to the dopaminolytic effects of antipsychotics.[130] In the absence of enzyme inhibition, SSRIs can still precipitate akathisia or EPS when added to a patient stabilized on an antipsychotic. A potentially more dangerous interaction can occur when medications that slow myocardial conduction, and thus prolong the QTc interval, are used in combination with antipsychotics having the same effect.[130] Careful monitoring should occur with medications that prolong the QTc interval, as well as when antipsychotics with this effect are combined with diuretics.[130]

Asenapine inhibits CYP2D6, and is the only SGA that has been shown to significantly affect the pharmacokinetics of other medications.[59] Table 67-6 lists the known major pathways involved in the metabolism of SGAs. Risperidone is metabolized primarily by CYP2D6 to its active metabolite, 9-OH-risperidone (paliperidone), which is thought to have a similar pharmacodynamic profile.[130] Although paliperidone is primarily eliminated renally unchanged, potent inducers of CYP3A4 can cause a potential need for dosage adjustment.[64,130] CYP1A2 is the primary isoenzyme for metabolism of asenapine with CYP3A4 also being a significant pathway.[64,130]

Based on current information, inhibitors of CYP1A2 have the greatest potential for causing interactions with clozapine and olanzapine, and some concern with asenapine.[130] Examples include cimetidine, fluvoxamine, and fluoroquinolone antibiotics (ie, ciprofloxacin) to varying degrees. To date, however, no serious inhibition interactions have been reported with olanzapine, which may be a result of olanzapine's wide therapeutic index. Carbamazepine has been reported to increase olanzapine elimination by as much as 50%.[130] Cigarette smoking is a potent inducer of CYP1A2, and one would expect lower mean olanzapine serum concentrations in smokers compared with those in nonsmokers.

Because of the risk of seizures with higher clozapine tissue concentrations, interactions that inhibit clozapine's metabolism are potentially significant. In particular, fluvoxamine increases clozapine serum concentrations by an average of two to threefold and up to fivefold.[130] Ciprofloxacin, other fluroquinolones, fluoxetine and erythromycin can also increase clozapine serum concentrations.[130] Smoking has been associated with a 33% to 55% increase in clozapine clearance.[130] If a patient taking clozapine stops smoking, the resulting increase in

clozapine serum concentration could be associated with seizures.[64] Carbamazepine can also induce clozapine metabolism and lead to lower serum concentrations.[130]

A study with the potent CYP3A4 inhibitor ketoconazole showed minimal effects on ziprasidone single-dose pharmacokinetics, with only a 33% mean increase in the ziprasidone area under the time-versus-concentration curve.[130] These results are consistent with data suggesting that aldehyde oxidase is the major metabolic pathway for ziprasidone, with only 30% to 35% being metabolized by CYP3A4.[130]

Modest elevations of aripiprazole serum concentration occur in the presence of ketoconazole or quinidine, which inhibit CYP3A4 and 2D6, respectively. Ketoconazole has a profound effect on decreasing lurasidone metabolism, and it is recommended that they not be used concomitantly.[69,130] Carbamazepine has been reported to decrease aripiprazole serum concentrations.[130]

Since iloperidone is metabolized through CYP2D6 and 3A4, its clearance can be impaired by inhibitors of these pathways. Since iloperidone prolongs the QTc interval, these types of interactions have the potential to be clinically significant. For example, it is recommended that the iloperidone dose be decreased by 50% when used with CYP2D6 inhibitors such as fluoxetine or paroxetine.[58,130]

Table 67-8 summarizes potential antipsychotic drug interactions.

TABLE 67-8 Common Potential Drug Interactions with Antipsychotic Medications

Mechanism of Interaction	Examples of Interacting Drugs or Other Substances	Clinical Effect
Pharmacodynamic Drug Interactions with Antipsychotics		
Muscarinic receptor blockade	*Anticholinergics* Benztropine Diphenhydramine Trihexyphenidyl	↑ Anticholinergic SE [Blurred vision, Constipation, Impaired Cognition, and Urinary retention]
Additive or synergistic sedation	*Sedatives* Benzodiazepines Concomitant AP Diphenhydramine Melatonin and melatonin agonists Mirtazapine Trazodone TCAs Hypnotics Opiates	↑ sedation Lethargy Impaired cognition Impaired psychomotor activity ↑ Risk of accidents
DA antagonist use for different indication	*Anticholinergics* Benztropine Diphenhydramine Trihexyphenidyl Mirtazapine Metoclopramide	↑ EPS
Cardiovascular interactions		

Mechanism of Interaction	Examples of Interacting Drugs or Other Substances			Clinical Effect
QTc prolongation	Amitriptyline Clomipramine Imipramine Citalopram Fluorquinolone antibiotics	Procainamide Quinidine		↑ Risk of ECG changes and dysrhythmias
Electrolyte changes	Diuretics			↑ Risk of ECG changes and dysrhythmias
Stimulation of presynaptic 5-HT receptors on DA neuron	SSRIs			↑ EPS
Sympatholytics: α-blockade-↓ NE release	Clonidine Methyldopa Prazosin, Nitric oxide containing products			↑ Hypotension
↑ DA receptor binding	Antipsychotics			↑ SEs, particularly EPS

Pharmacokinetic Drug Interactions with Antipsychotics

Substrate Antipsychotic and Mechanism of Action	***Inhibitor or Inducer***			***Clinical Effect***
Aripiprazole, brexipiprazole, Cariprazine, and iloperidone				
Inhibition of AP metabolism (CYP2D6, CYP3A4)	*Antidepressants* Bupropion Clomipramine Doxepin Duloxetine Fluoxetine Fluvoxamine Paroxetine Sertraline *HIV protease inhibitors* Indinavir Nelfinavir Ritonavir	*Anti-infectives* Ciprofloxacin Clarithromycin Erythromycin Fluconazole Ketoconazole Itraconazole *Antipsychotics* Asenapine Chlorpromazine Haloperidol Perphenazine Thioridazine	*Miscellaneous* Ciprofloxacin Chlorpheniramine Cimetidine Cocaine Diltiazem Diphenhydramine Cimetidine Grapefruit juice Haloperidol Hydroxyzine Methadone Quinidine Ticlopidine Verapamil	↑ AP effect ↑ SE

	Ritonavir	Itraconazole	Verapamil	
	Antiepileptics	*Anti-infectives*		
	Carbamazepine	Nafcillin	*Herbals*	
Induction of AP metabolism	Oxcarbazepine	Rifampin	St. John's wort	↓ AP effect
	Phenobarbital	Miscellaneous	Smoking tobacco	

Mechanism of Interaction	Examples of Interacting Drugs or Other Substances			Clinical Effect
		Broccoli		
		Brussels sprouts		
	Phenytoin	Chargrilled meat		
	HIV protease inhibitors	Glucocorticoids		
	Efavirenz	Insulin		
	Nevirapine	Modafinil		
		Omeprazole		

Paliperidone

The bioavailability of paliperidone is significantly increased when it is taken with food. Although this could increase paliperidone effect, including adverse effects, the clinical significance is undetermined. Only potent CYP3A4 (eg, carbamazepine, rifampin, St. John's wort) inducers appear to increase paliperidone metabolism and affect dose requirements

Pharmacokinetic Drug Interactions with Antipsychotics

Substrate Antipsychotic and Mechanism of Action	***Inhibitor or Inducer***			***Clinical Effect***
Lurasidone and quetiapine	*Antidepressants*	*Anti-infectives*	*Miscellaneous*	↑ AP effect
	Fluoxetine (norfluoxetine)			
	Fluvoxamine			
	Nefazodone			
Inhibition of AP metabolism (CYP3A4)		Ciprofloxacin	Amiodarone	↑ SE
		Clarithromycin	Cimetidine	
		Erythromycin	Diltiazem

	HIV protease inhibitors	Glucocorticoids		
	Efavirenz	Modafinil		
	Nevirapine			

Lurasidone AUC and C_{max} increase by two and threefolds when given with at least 350 calories, (1460 J) of food regardless of fat content.

Perphenazine and risperidone

Mechanism of Interaction	Examples of Interacting Drugs or Other Substances		Clinical Effect
Note: Because risperidone's metabolite formed through CYP2D6 metabolism is active (paliperidone), the clinical significance of metabolic drug interactions with risperidone is unclear			
Inhibition of AP metabolism (CYP2D6)	*Antidepressants* Bupropion Clomipramine Doxepin Duloxetine Fluoxetine Paroxetine Sertraline *Antipsychotics* Chlorpromazine Haloperidol (reduced haloperidol) Perphenazine	*Miscellaneous* Amiodarone Cimetidine Chlorpheniramine Cocaine Diphenhydramine Cimetidine Haloperidol Hydroxyzine Methadone Quinidine	↑ AP effect ↑ SE
Induction of AP metabolism (via CYP3A34, a minor pathway for risperidone)	Dexamethasone Rifampin		↓ AP effect
Ziprasidone			
The bioavailability of ziprasidone is increased twofold when it is taken with food. Consistent administration with food is recommended			

AP, antipsychotic; DA, dopamine; EPS, extrapyramidal symptoms; 5-HT, serotonin; SE, side effect; SSRI, serotonin selective reuptake inhibitor; TCAs, tricyclic antidepressants, AUC, Area Under the Curve; C_{max}, maximum plasma concentration; NE, norepinephrine.

Data from references 29, 41, 42, 45,46,47, 58,59,60, 63,64, 69, 115, 128,129,130.

Personalized Pharmacotherapy

Pharmacotherapy must be individualized for each person with schizophrenia. With the possible exception of iloperidone, no laboratory tests are generally available that will predict a patient's response to treatment. Past response to treatment, potential adverse effects, patient personal preference, and medication price are the primary variables that should be used in selecting an antipsychotic that is included in stages 1A, 1B, or 2 of the treatment algorithm. In the CATIE study, the number one reason for drug discontinuation was the patient not wanting to take that medication any more, and the second most common reason was adverse effects.[30] These two factors should be carefully considered in antipsychotic selection. Medication dosage must also be individualized within the usual dose ranges. Careful consideration must also be given to concomitant medications that may interact with the antipsychotic and necessitate a change in dosage.

Preliminary data suggest a relationship between different genetic markers and clinical improvement as well as QTc prolongation in patients treated with iloperidone. [131] Substantial interest exists regarding the potential utility of pharmacogenetic monitoring in the pharmacotherapy of schizophrenia. Increasing relationships are being identified between specific genetic polymorphisms and both the pharmacodynamics and pharmacokinetics of different antipsychotics. However, no convincing data have demonstrated that clinical outcomes are superior when using routine pharmacogenetic monitoring in the pharmacotherapy of schizophrenia, nor have cost-effectiveness studies of its use been performed.[132] Although promising for the future, routine pharmacogenetics monitoring in schizophrenia is not currently recommended. It will be important to learn to what extent schizophrenia treatment will realize the aspirations of personalized medicine as other areas of medicine are moving toward.[133]

Given that no antipsychotic has proven superiority with regard to efficacy in the treatment of schizophrenia (with the exception of

clozapine in treatment resistance), cost should be a factor in antipsychotic selection. Aripiprazole, clozapine, olanzapine, quetiapine, risperidone, ziprasidone, and all FGAs have generic equivalents available, and this should be a factor in selecting an antipsychotic.

Clinical Controversy…

Approximately 32% of people presenting with prodromal symptoms will go on to have a florid psychosis within 3 years.[136] Early identification of people who exhibit the prodrome of schizophrenia, raises the possibility that intervening early might either avert psychosis altogether or at best, alter its course. This is a major international focus of research, and while intuitive, it is currently not clear that prodrome identification is easily done, offers effective treatment options that are ethically justified, or alters the course of schizophrenia.

Evaluation of Therapeutic Outcomes

Assessment of response has traditionally been done subjectively or empirically (a relative sense of how the clinician feels the patient is doing). A formal MSE is used to structure the patient interview and focus on items related to appearance, mood, sensorium, intellectual functioning, and thought processes. However, the MSE is neither specific nor quantitative for the measurement of drug response. Clinicians should be trained to use simple, standardized psychiatric rating scales to assist in objectively rating patient drug responses.[134] The Brief Psychiatric Rating Scale (BPRS) and the Positive and Negative Symptom Scale (PANSS) were developed for use in clinical trials as research tools to quantify symptom improvement seen with antipsychotic treatment. Objectively, the use of a numeric indicator (eg, 20%, 30%, or 40% reduction in BPRS score) has been used to quantify overall symptom reduction and classify patients according to different degrees of response. However, these types of rating scales are too long and unwieldy to be routinely used within the time constraints of most clinical practices. Symptom scales used in clinical practice must be sufficiently brief to be used during an ordinary clinic visit (eg, 15-30 minutes) while measuring both positive and negative symptoms, and being sufficiently representative of overall symptomatology. The four-item Positive Symptom Rating Scale (PSRS) and the Brief Negative Symptom Assessment are brief scales that meet such criteria (**Table 67-9**).[134] A brief rating scale of positive symptoms, such as the PSRS, should be used at baseline before starting pharmacotherapy, and at each time response to pharmacotherapy is assessed.

TABLE 67-9 Brief Clinical Assessments for Monitoring Antipsychotic Response in Schizophrenia

4-Item Positive Symptom Rating Scale (PSRS)				
Use each item's anchor points to rate the patient				
1. Suspiciousness	NA[a]	1 2 3 4	5 6	7
2. Unusual thought content	NA	1 2 3 4	5 6	7
3. Hallucinations	NA	1 2 3 4	5 6	7
4. Conceptual disorganization	NA	1 2 3 4	5 6	7
Each item is scored from 1 (not present) to 7 (extremely severe)			SCORE:	
Brief Negative Symptom Assessment (BNSA)				
Use each item's anchor points to rate the patient				
1. Prolonged time to respond	1	2 3 4 5	6	
2. Emotion: Unchanging facial expression, blank, expressionless face	1	2 3 4 5	6	
3. Reduced social drive	1	2 3 4 5	6	
4. Poor grooming and hygiene	1	2 3 4 5	6	
Each item is scored from 1 (normal) to 6 (severe)			SCORE:	

[a]NA, not able to be assessed.

Data from reference 134.

Clinical Controversy…

Psychiatry is one of the few specialties in medicine in which measurement is not a routine component of patient care. Although biologic measures do not currently exist in psychiatry, symptoms associated with a patient's illness can be measured and quantified. Although increasing evidence attests to the benefits of quantifying symptom severity, the use of symptom rating scales remains uncommon in clinical practice.

Similarly, the pharmacotherapeutic plan should include specific monitoring parameters for side effects (**Table 67-10**). The plan should include how the potential side effect will be evaluated, and the frequency of assessment. Given the risk of weight gain, diabetes, and lipid abnormalities associated with many of the SGAs, a consensus task force led by the American Diabetes Association recommends the following baseline parameters before beginning antipsychotics: family history, weight, height, BMI, waist circumference, blood pressure, fasting plasma glucose, and fasting lipid profile.[83] They also recommend follow-up monitoring of these parameters after beginning or

changing SGAs. Weight should be monitored monthly for the first 3 months, and quarterly thereafter. The other parameters should be assessed at the end of 3 months and then annually. Self-assessments can be a useful adjunct in treating the patient. Although the patient with schizophrenia may not always be accurate in evaluating symptom severity, the use of patient self-assessments increases patient engagement in care, enhances therapeutic alliance, and gives the clinician an opportunity to identify misconceptions the patient may have regarding symptoms associated with the illness, medication side effects, and the like.[135] Traditionally, clinicians have often accepted partial symptom response in schizophrenia as success, and have not been aggressive in attempting to achieve greater symptomatic remission. The advent of multiple different SGAs with varying side effect profiles should encourage clinicians to be more assertive in attempting to achieve symptom remission. This is consistent with an increasing focus on remission as a goal of treatment and evolving recovery movements with an emphasis on consumerism in the care of the severely mentally ill.[22]

TABLE 67-10 Antipsychotic Adverse Effects and Monitoring Parameters

Adverse Reaction	Monitoring Parameter	Frequency	Comments
Adverse Effect Monitoring Parameters for all Antipsychotic Medications			
Akathisia	Ask about restless or anxiety. Observe patient for restlessness. Barnes Akathisia Scale can also be used	Every visit	
Anticholinergic side effects	Ask patient about constipation, blurry vision, urinary retention, or unusual dry mouth	Every visit	
Glucose intolerance	FBS or HbA1c	At baseline, after 3 months, and if normal, then annually	
Hyperlipidemia	Lipid profile	At baseline, after 3 months, and if normal, then annually	
Orthostatic hypotension	Ask patient about dizziness on standing. If present, check BP and HR in sitting and standing positions	Every visit	The degree of orthostatic change in BP to produce symptoms varies. In general, a BP change of 20 mm Hg or more is significant
Hyperprolactinemia	In women, ask about expression of milk from the breast and menstrual irregularities. In men, ask about breast enlargement or expression of milk from nipples. If symptoms present, check serum prolactin level	Every visit	In the absence of symptoms, there is no need to monitor serum prolactin
Sedation	Ask patient about unusual sedation or sleepiness	Every visit	
Sexual dysfunction	Ask patient about decreased sexual desire, difficulty being aroused, or problems with orgasm	Every visit	Patients with schizophrenia have more sexual dysfunction than the normal population. Compare symptoms with medication-free state
Tardive dyskinesia	Standardized rating scale such as the AIMS or the DISCUS	At baseline, and then every 3 months for FGAs and every 6 months for SGAs	
Weight gain	Measure body weight, BMI, and waist circumference	At baseline, monthly for the first 3 months, and then quarterly	Waist circumference is the single best predictor of cardiac morbidity
Adverse Effect Monitoring Parameters for Specific Antipsychotics			
Agranulocytosis	White blood cell (WBC) and absolute neutrophil counts (ANC)	At baseline, weekly for 6 months, then every 2 weeks for 6 months, and then monthly	Clozapine only
Sialorrhea or excess drooling	Ask patient about problems with excess drooling, waking in the morning with a wet ring on his or her pillow. Visual observation of the patient for drooling	Every visit	Clozapine only
Bronchospasm, respiratory distress, respiratory depression, respiratory arrest	Before administration, patients must be screened for a history of asthma, chronic obstructive pulmonary disease, or other lung disease associated with bronchospasm. Monitor patient every 15 minutes for a minimum of 1	Every dose administration	Inhaled loxapine only. Can only be administered in approved healthcare facilities registered in REMS program

Adverse Reaction	Monitoring Parameter	Frequency	Comments
	hour after drug administration for signs and symptoms of bronchospasm (ie, vital signs and chest auscultation). Only one 10 mg dose can be given every 24 hours		
Postinjection sedation/delirium syndrome	Observation of the patient for at least 3 hours after drug administration. Monitor for possible sedation, altered level of consciousness, coma, delirium, confusion, disorientation, agitation, anxiety, or other cognitive impairment	Every dose administration	Long-acting olanzapine pamoate monohydrate only. Can only be administered in approved healthcare facilities registered in REMS program

APA	American Psychiatric Association
AUC	area under the curve
β_2	beta-2 adrenergic receptor
BDNF	brain-derived neurotrophic factor
BLM	buccal–lingual–masticatory
BMI	body mass index
BP	blood pressure
BPRS	Brief Psychiatric Rating Scale
C4	complement component 4 genes
CACN1A2	voltage-dependent Ca channel 1A2
CATIE	Clinical Antipsychotic Trials of Intervention Effectiveness
CK	creatine kinase
CNS	central nervous system
CNV	copy number variant
COMT	catecholamine-*O*-methyl transferase
C_{max}	maximum plasma concentration
CUtLASS-1	Cost Utility of the Latest Antipsychotic drugs in Schizophrenia Study
CYP	cytochrome P450
D_1	dopamine-1 receptor
D_2	dopamine-2 receptor
D_3	dopamine-3 receptor
D_4	dopamine-4 receptor
DA	dopamine
DISCUS	Dyskinesia Identification System: Condensed User Scale
DRESS	Drug Reaction with Eosinophilia and Systemic Symptoms
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*
ECG	electrocardiogram or electrocardiographic
ECT	electroconvulsive therapy
EEG	electroencephalogram
EPS	extrapyramidal side effect
FBS	fasting blood sugar
FDA	Food and Drug Administration

FGA	first-generation antipsychotic
FMO3	flavin containing monooxygenase 3 gene
GABA	*γ*-aminobutyric acid
GWAS	genome-wide association studies
5-HT	serotonin or 5-hydroxytryptamine
5-HT_{1A}	serotonin-1A $_{\text{receptor}}$
5-HT_{2}	serotonin-2 $_{\text{receptor}}$
5-HT_{2A}	serotonin-2A receptor
5-HT_{2C}	serotonin-2C receptor
5-HT_{6}	Serotonin-6 receptor
5-HT_{7}	Serotonin-7 receptor
HR	heart rate
IM	intramuscular
LAI	Long acting injectable
LBW	low birth weight
MC4R	Melanocortin-4-Receptor
MTHFR	methylenetetrahydrofolate reductase
MSE	mental status examination
NAMI	National Alliance on Mental Illness
NE	norepinephrine
NIMH	National Institute of Mental Health
NMDA	*N*-methyl-D-aspartate
NMS	neuroleptic malignant syndrome
NRGN	neurogranin
PANSS	Positive and Negative Symptom Scale
PDSS	Post-injection delirium/sedation syndrome
PET	positron emission tomography
PORT	Patient Outcomes Research Team
PBRM1	polybromo 1
PSRS	Positive Symptom Rating Scale
RAISE	Recovery After Initial Schizophrenia Episode
REMS	Risk Evaluation and Mitigation Strategy
RNA	ribonucleic acid
SCD	sudden cardiac death
SEs	side effects
SGA	second-generation antipsychotic
SNP	single nucleotide polymorphism
SSRI	selective serotonin reuptake inhibitor
STRIDE	Reducing Weight and Diabetes Risk in an Underserved Population
TCA	tricyclic antidepressant
UGT	UDP glucuronosyltransferases genes
158*Val/Met*	158 valine/methionine
WBC	white blood cell
ZNF804A	zinc finger protein 804A

Chapter 68: Major Depressive Disorder

Christian J. Teter; Judith C. Kando; Barbara G. Wells

INTRODUCTION

KEY CONCEPTS

- 1 Extensive treatment guidelines are available to assist in the treatment of major depressive disorder, including medication management. Clinicians treating individuals with major depressive disorder should be familiar with these guidelines.
- 2 When evaluating a patient for the presence of depression, it is essential to rule out medical causes of depression and drug-induced depression.
- 3 The goals of treatment for depression are the resolution of current symptoms (ie, remission) and the prevention of further episodes of depression (ie, relapse or recurrence).
- 4 When counseling patients with depression who are receiving antidepressant medications, the patient should be informed that adverse effects might occur immediately, while resolution of symptoms may take 2 to 4 weeks or longer. Adherence to the treatment plan is essential for a successful outcome, and tools to help increase medication adherence should be discussed with each patient.
- 5 Antidepressants are generally considered equally efficacious in groups of patients with major depressive disorder. Therefore, other factors, such as age, side effect profile, and past history of response, are used to guide the selection of antidepressants.
- 6 When determining if a patient has been nonresponsive to a particular pharmacotherapeutic intervention, it must be determined whether the patient has received an adequate dose for an adequate duration and whether the patient has been medication adherent.
- 7 Pharmacogenetic tests (eg, the FDA-approved AmpliChip to evaluate CYP2D6 and CYP2C19 polymorphisms) are now commercially available. However, there are no standard or well-accepted recommendations for the use of pharmacogenetic testing as it relates to antidepressant treatment of major depressive disorder.

- 8 When evaluating response to an antidepressant, in addition to target signs and symptoms, the clinician must consider quality-of-life issues, such as role, social, and occupational functioning. In addition, the tolerability of the agent should be assessed because the occurrence of side effects may lead to medication nonadherence, especially given the chronicity of the disease and need for long-term medication management.

A diagnosis of major depressive disorder (MDD) is given when an individual experiences one or more major depressive episodes without a history of a manic or hypomanic episode. A major depressive episode is defined by the criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*).[1] Depression is associated with significant functional disability, morbidity, and mortality. Newer generations of antidepressants, such as the selective serotonin reuptake inhibitors (SSRIs), are effective and better tolerated than older agents, such as the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs). In addition, substantial efforts have been undertaken to improve the ability of clinicians to recognize and appropriately treat the signs and symptoms of depression. This chapter focuses exclusively on the diagnosis and treatment of MDD.

1 In the absence of well-accepted evidence-based medicine for the medication management of MDD, the reader is referred to the *Practice Guideline for the Treatment of Patients with Major Depressive Disorder*, which is available at *www.psych.org*. This extensive document (now available in its third iteration) is a practical guide to the management of depression based on the best available data as well as clinical consensus.[2] Alternatively, the reader should refer to the British Association of Psychopharmacology (BAP) guidelines, which provide a complementary data-driven viewpoint on antidepressant treatment for MDD.[3]

EPIDEMIOLOGY

The true prevalence of depressive disorders in the United States is unknown. The National Comorbidity Survey Replication found that 16.2% of the population studied had a history of MDD in their lifetime, and more than 6.6% had an episode within the past 12 months.[4] Women have a higher risk of depression than men from early adolescence until their mid-50s, with a lifetime rate that is 1.7 to 2.7 times greater.[5] Although depression can occur at any age, adults 18 to 29 years of age experience the highest rates of major depression during any given year.[4] The estimated lifetime prevalence of major depression in individuals aged 65 to 80 recently was reported to be 20.4% in women and 9.6% in men.[6] Depressive disorders are common during adolescence, with comorbid substance abuse, suicide attempts, and deaths occurring frequently in these young patients.[7,8] Depressive disorders and suicide tend to occur within families. For example, approximately 8% to 18% of patients with major depression have at least one first-degree relative (father, mother, brother, or sister) with a history of depression, compared with 5.6% of those without depression.[9] Furthermore, first-degree relatives of patients with depression are 1.5 to 3 times more likely to develop depression than normal controls.[1,9] A recent meta-analysis found that the heritability of liability for major depression was 37%, whereas the remaining 63% of the variance in liability was due to individual-specific environment.[10] Therefore, MDD is relatively common, occurs more frequently in

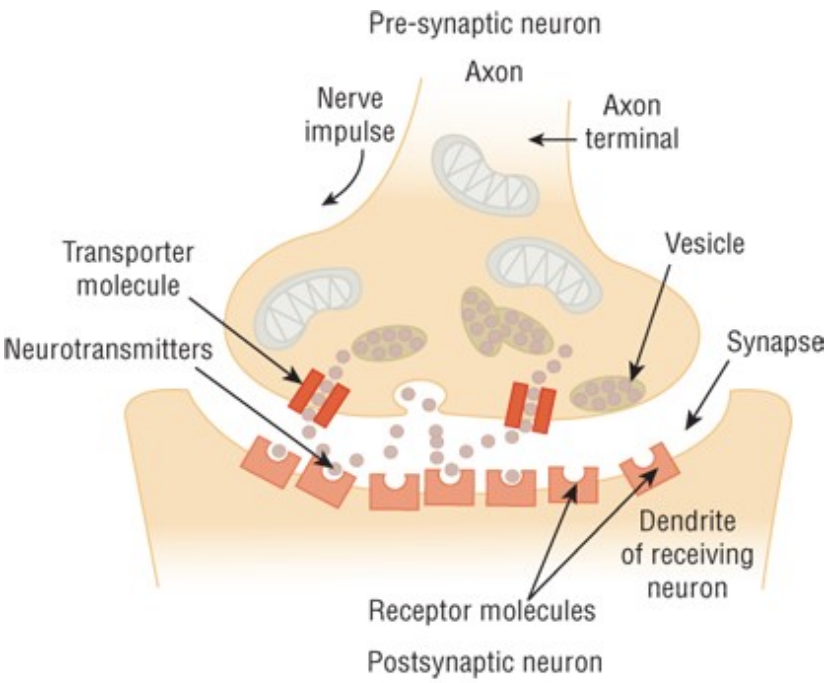
women than in men, and prevalence is influenced by both genetic and environmental factors.

ETIOLOGY

The etiology of depressive disorders is too complex to be totally explained by a single social, developmental, or biologic theory. Several factors appear to work together to cause or precipitate depressive disorders. The symptoms reported by patients with MDD consistently reflect changes in brain monoamine neurotransmitters (NTs), specifically norepinephrine (NE), serotonin (5-HT), and dopamine (DA).[11,12] See **Figure 68-1** for a visual explanation of how these monoamine NTs are regulated at the level of the neuron and within the synapse.

FIGURE 68-1

Monoamine neurotransmitter (NT) regulation at the neuronal level. NTs carry messages between cells. Each NT generally binds to a specific receptor, and this coupling initiates a cascade of events. NTs are reabsorbed back into nerve cells by reuptake pumps (ie, transporter molecules) at which point they may be recycled for later use or broken down by enzymes. For their primary mechanism of action, most antidepressants are thought to inhibit the transporter molecules and allow more NT to remain in the synapse. *(Reproduced from Mind Over Matter. NIH Publication No. 09-7423. The National Institute on Drug Abuse, National Institutes of Health, U.S. Department of Health and Human Services. Printed 2009.)*



PATHOPHYSIOLOGY

Several years before the introduction of antidepressants, the cause of depression was linked to decreased brain levels of the NTs NE, 5-HT, and DA, although the actual cause remains unknown. This biogenic amine hypothesis evolved as a result of several observations made in the early 1950s. It was noted that the antihypertensive drug reserpine depleted neuronal storage granules of NE, 5-HT, and DA and produced clinically significant depression in 15% or more of patients.[13]

Although the reuptake blockade of monoamines (eg, NE, DA, and 5-HT) occurs immediately on administration of an antidepressant, the clinical antidepressant effects (ie, measurable improvement) are generally delayed by weeks.[11,14] This delay may be the result of a cascade of events from receptor occupancy to gene transcription.[15] This delay in onset of action has caused researchers to focus on the adaptive changes induced by antidepressants. Accordingly, theories that focus on adaptive (or chronic) changes in amine receptor systems have emerged. In the mid-1970s, it was recognized that chronic, but not acute, administration of antidepressants to animals caused desensitization of NE-stimulated cyclic adenosine monophosphate synthesis. In fact, for most antidepressants, downregulation of β-adrenergic receptors accompanies this desensitization.[16] Studies of many antidepressants have demonstrated that either desensitization or downregulation of NE receptors corresponds to a clinically relevant time course for antidepressant effects.[11] Other studies have revealed desensitization of presynaptic 5-HT_{1A} autoreceptors following chronic administration of antidepressants.[17] Thus, a theory based on changes in receptor sensitivity provides a cogent explanation of the delayed onset of therapeutic response of antidepressant drugs. The dysregulation hypothesis incorporates the diversity of antidepressant activity with the adaptive changes occurring in receptor sensitization over several weeks. In this theory, emphasis is placed on a failure of homeostatic regulation of NT systems rather than on absolute increases or decreases in their activities. According to this hypothesis, effective antidepressant agents restore efficient regulation to the dysregulated NT system.[18]

The 5-HT/NE link hypothesis maintains that both the serotonergic and noradrenergic systems are involved in an antidepressant response.[16] This hypothesis is consistent with the rationale of the postsynaptic alteration theory of depression, which emphasizes the importance of β-adrenergic receptor downregulation for achieving an antidepressant effect.[16] Furthermore, both serotonergic and noradrenergic medications downregulate β-adrenergic receptors, and there is a link between 5-HT and NE.[16] This implies that medications that are effective in the treatment of depression act at both of these NT systems.

Traditional explanations of the biologic basis of depressive disorders have focused largely on NE and 5-HT; however, most of the evidence that coalesced into the biogenic amine hypothesis of depression does not clearly distinguish between NE and DA. There is an abundance of evidence suggesting that DA transmission is decreased in depression and that agents that increase dopaminergic transmission have been found to be effective antidepressants.[19] Specifically, studies suggest that increased DA transmission in the mesolimbic pathway accounts for at least part of the mechanism of action of antidepressant medications.[19] The mechanisms by which antidepressant drugs alter DA transmission remain unclear, but may be mediated either directly by dopaminergic changes or indirectly by primary actions at NE or 5-HT terminals. The complexity of the interaction

between 5-HT, NE, and DA is gaining greater appreciation, but a more in-depth understanding of the precise mechanism is needed. Furthermore, the availability of dopaminergic-based first-line and augmentation antidepressant strategies has been slowly growing (eg, bupropion, high-dose venlafaxine, aripiprazole, and most recently brexpiprazole).

More recent insight into the many possible mechanisms underlying depressive disorders comes from studies on brain-derived neurotrophic factor (BDNF). BDNF is a growth factor protein that regulates the differentiation and survival of neurons. A growing body of evidence suggests this process might be disrupted in depressive disorders. More specifically, chronic stress and an associated increase in glucocorticoids such as cortisol may cause a disruption of BDNF expression in the hippocampus. This process may be prevented, or possibly even reversed, by antidepressant medications.[20] This relatively recent theory has not been firmly established; however, if validated, it will demonstrate that antidepressants may help prevent deleterious effects of chronic stress and depressive symptoms. It also highlights the fact that antidepressants may work by a mechanism that is not yet evident at this time, as we continue to learn more about the complexities of major depression and its treatment.

Biologic Markers

Investigators continue to search for biologic or pharmacodynamic (PD) markers to assist in the diagnosis and treatment of depressed patients. Although no biologic marker has been discovered, several biologic abnormalities are present in many depressed patients. Approximately 45% to 60% of patients with major depression have a neuroendocrine abnormality, including hypersecretion of cortisol or a lack of cortisol suppression after dexamethasone administration (ie, a positive dexamethasone suppression test). In fact, it has been suggested that the inability of the brain to suppress the hypothalamic–pituitary–adrenal (HPA) axis and the associated stress response could lead to the pathophysiology and symptoms of depression.[21] According to this theory, there is a disruption somewhere in the normal negative feedback system that controls cortisol levels (see Fig. 76-3 for a representation of this negative feedback system). There are many potential negative consequences of excess circulating cortisol, including disruption in BDNF expression as discussed above.

Unfortunately, the high rate of false-positive and false-negative results associated with neuroendocrine abnormalities in depressed patients limits the usefulness of testing for these markers, and has led to their relative lack of use in clinical practice. However, they still provide a clue to the potential pathophysiology of depressive disorders, which may lead us to more effective treatment options.

CLINICAL PRESENTATION

2 When a patient presents with depressive symptoms, it is necessary to investigate the possibility of a contributing medical or drug-induced etiology. All depressed patients should have a complete physical examination, mental status examination, and basic laboratory workup, including a complete blood count with differential, thyroid function tests, and electrolyte determinations, to identify any potential medical problems. A listing of all possible medical conditions associated with depression is

beyond the scope of this chapter. The *DSM-5* describes a diagnostic category for both "Depressive Disorder Due to Another Medical Condition" and "Substance/Medication-Induced Depressive Disorder,"[1] which are common causative factors for depressive symptoms. For example, multiple medical conditions (eg, stroke, Parkinson disease, traumatic brain injury, and hypothyroidism) have strong associations with the development of depressive symptoms.[1] Furthermore, individuals experiencing withdrawal from substances of abuse (eg, cocaine) commonly present with depressive symptoms.[1]

Table 68-1 lists medications commonly associated with causing or exacerbating depressive symptoms.[2,22,23] A complete medication review should be performed because several medications (in addition to those listed in Table 68-1) may contribute to depressive symptoms. Once a medical condition or concomitant medication has been ruled out as the cause of the depressive symptoms, the patient should be evaluated for MDD. According to the *DSM-5*, a single major depressive episode is characterized by five (or more) of the symptoms described in **Table 68-2**. At least one of the symptoms is depressed mood (often an irritable mood in children or adolescents) or loss of interest or pleasure in nearly all activities.[1] These symptoms must have been present nearly every day for at least 2 weeks and must represent a change from the patient's previous level of functioning. The DSM-5 *omits* the bereavement exclusion that appeared in earlier DSM editions. Some feel that this omission opens the door to misdiagnosis of normal grief as MDD. The diagnostic code for MDD is determined by whether this is a single or recurrent depressive episode, current severity, presence of psychotic features, and remission status. The diagnosis can be followed by specifiers that apply to the current episode. The possible specifiers include anxious distress, mixed features (ie, presence of some manic/hypomanic features), melancholic features, atypical features, mood-congruent or incongruent psychotic features, catatonia, peripartum onset, and seasonal pattern. The clinician must consider presenting symptoms, their duration, and the patient's current level of social, occupational, or other important areas of functioning. Significant stressors or life events may trigger depression in some individuals but not others, and there may be an important precipitant at the beginning of the disorder.[1]

TABLE 68-1 Selected Medications Associated with Drug-Induced Depressive Symptoms

Acne treatment

Isotretinoin

Anticonvulsants

Levetiracetam

Topiramate

Vigabatrin

Antimigraine agents

Triptans

Cardiovascular medications

β-Blocker

Clonidine

Methyldopa

Reserpine

Hormonal therapy

Gonadotropin-releasing hormone

Oral contraceptives

Steroids (eg, prednisone)

Tamoxifen

Immunologic agents

Interferons

Smoking cessation medications

Varenicline

Data from references 2, 22, 23.

TABLE 68-2 DSM-5 Diagnostic Criteria for Major Depressive Disorder

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

   Note: Do not include symptoms that are clearly attributable to another medical condition.

   1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (eg, feels sad, empty, and hopeless) or observation made by others (eg, appears tearful). (**Note:** In children and adolescents, can be irritable mood.)

   2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day. (as indicated by either subjective account or observation.)

   3. Significant weight loss when not dieting or weight gain (eg, a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. (**Note:** In children, consider failure to make expected weight gain.)

   4. Insomnia or hypersomnia nearly every day.

   5. Psychomotor agitation or retardation nearly every day. (observable by others, not merely subjective feelings of restlessness or being slowed down.)

   6. Fatigue or loss of energy nearly every day.

   7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day. (not merely self-reproach or guilt about being sick.)

   8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others.)

9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The episode is not attributable to the physiological effects of a substance or to another medical condition.

Note: Criteria A–C represent a major depressive episode.

Note: Responses to a significant loss (eg, bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.

In distinguishing grief from a major depressive episode (MDE), it is useful to consider that in grief the predominant affect is feelings of emptiness and loss, while in MDE it is persistent depressed mood and the inability to anticipate happiness or pleasure. The dysphoria in grief is likely to decrease in intensity over days to weeks and occurs in waves, the so-called pangs of grief. These waves tend to be associated with thoughts or reminders of the deceased. The depressed mood of MDE is more persistent and not tied to specific thoughts or preoccupations. The pain of grief may be accompanied by positive emotions and humor that are uncharacteristic of the pervasive unhappiness and misery characteristic of MDE. The thought content associated with grief generally features a preoccupation with thoughts and memories of the deceased, rather than the self-critical or pessimistic ruminations seen in MDE. In grief, self-esteem is generally preserved, whereas in MDE feelings of worthlessness and self-loathing are common. If self-derogatory ideation is present in grief, it typically involves perceived failings vis-à-vis the deceased (eg, not visiting frequently enough, not telling the deceased how much he or she was loved). If a bereaved individual thinks about death and dying, such thoughts are generally focused on the deceased and possibly about "joining" the deceased, whereas in MDE such thoughts are focused on ending one's own life because of feeling worthless, undeserving of life, or unable to cope with the pain of depression.

D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.

E. There has never been a manic episode or a hypomanic episode.

Note: This exclusion does not apply if all of the manic-like or hypomanic-like episodes are substance-induced or are attributable to the physiological effects of another medical

condition.

Depression Rating Scales

Instruments to assess the severity of depressive symptoms can be used for both clinical and research purposes. For example, the Montgomery-Åsberg Depression Rating Scale (MADRS) is a clinician-administered scale that is commonly used in drug trials given its sensitivity to change.[24] Some depression rating scales are self-administered. For example, the Beck Depression Inventory (BDI) takes only 5 to 10 minutes to complete by the respondent.[25] For a more detailed explanation for both of these instruments, as well as other rating scales and evaluation approaches, refer to Chapter e62.

Emotional Symptoms

A major depressive episode is characterized by a persistent, diminished ability to experience pleasure. A loss of interest and pleasure in usual activities, hobbies, or work is common. Patients appear sad or depressed, and they are often pessimistic and believe that nothing will help them feel better. Anxiety symptoms are present in almost 90% of depressed outpatients. The presence of feelings of worthlessness or inappropriate guilt may identify patients at risk for suicide.[26] Patients often have guilt feelings that are unrealistic, and these may reach delusional proportions. Patients may feel that they deserve punishment and may view their present illness as a punishment. A patient suffering from major depression with psychotic features may hear voices (auditory hallucinations) saying that he or she is a bad person and that he or she should commit suicide. Depression with psychotic features may require hospitalization, especially if the patient becomes a danger to self or others.

Physical Symptoms

Physical symptoms often motivate patients, especially the elderly, to seek medical attention. Chronic fatigue is a common complaint, with a decreased ability to perform normal daily tasks. Fatigue often appears worse in the morning and does not improve with rest. Complaints of pain, especially headache, often accompany fatigue.

Sleep disturbances generally present as frequent early morning awakening with difficulty returning to sleep. This may coexist with difficulty falling asleep and frequent nighttime awakening. Less frequently, depressed patients complain of increased sleep (hypersomnia), although they experience daytime exhaustion or fatigue. Recognition and management of sleep disturbances among depressed patients is crucial, as it has been estimated that approximately 60% to 90% of patients experiencing MDD report sleep disturbances.[27]

Appetite disturbances, including complaints of decreased appetite, often result in substantial weight

loss, especially in the elderly.[28] Some patients lose 2 lb (0.9 kg) or more per week without dieting. Other patients, especially in the ambulatory setting, may overeat and gain weight, although they actually may not enjoy eating.

Patients may present with a variety of other symptoms such as GI issues, cardiovascular complaints (eg, palpitations), or muscle fatigue. Patients frequently present with a loss of sexual interest or libido.[29]

Intellectual or Cognitive Symptoms

Intellectual or cognitive symptoms include a decreased ability to concentrate, slowed thinking, and a poor memory for recent events. Patients may appear confused and indecisive. Depression should be considered when cognitive symptoms are present in the elderly.[28]

Psychomotor Disturbances

Patients may appear noticeably slowed or retarded in physical movements, thought processes, and speech (psychomotor retardation). Conversely, depression may be accompanied by psychomotor agitation, manifesting as purposeless, restless motion (eg, pacing, wringing of hands, or outbursts of shouting).

SUICIDE RISK EVALUATION AND MANAGEMENT

As of 2013, the Centers for Disease Control and Prevention listed suicide as the 10th leading cause of death among Americans and the 2nd leading cause of death among 25- to 34-year-olds.[30] All patients diagnosed with MDD should be assessed for suicidal thoughts. Factors associated with an increased risk for suicide include psychiatric and substance use disorders, adolescence and younger age adults, physical illness, recent stressful life event, childhood trauma, hopelessness, and male gender.[31] Those with a higher level of risk have high degrees of suicidal intent and describe more specific plans, in particular, plans that are violent and irreversible.[31] It is important to remember that the risk of suicide in those recovering from major depression may increase as they develop the energy and capacity to act on a plan made earlier in a course of illness. Additionally, despite factors to help identify those at greatest risk, it remains very difficult to predict suicidality in any given individual. Therefore, when suicidal intent is suspected, it is important to ask, “Are you thinking about harming or killing yourself?” If the risk is significant, the patient must be referred immediately to an appropriate healthcare professional. Additionally, certain depression rating scales, such as the MADRS discussed above, include questions that target suicidality, which may help identify those patients at risk.

In September 2004, the FDA required manufacturers of antidepressants to add a boxed warning stating that antidepressants increase the risk of suicidal thinking and behavior in short-term studies in children and adolescents with depressive disorders. These risks have become a new source of concern among those treating their patients with antidepressants. In order to help deal with the

confusion these risks have caused, experts have recommended the following:[32]

1. It is especially important to closely monitor patients for suicidal ideation and behavior at the beginning of treatment and among younger patients.
2. Discuss the possibility that adverse events may occur, including behavioral agitation or anger, and encourage patients to seek help should this occur.
3. Deal with the subject of suicide directly.

It is important to note that there is little evidence to suggest that withholding antidepressant treatment decreases the risk of eventual suicide and may actually increase the risk. Furthermore, it may be that longer-term medication is needed for any protective effects against suicidality.[32]

In May 2007, the FDA released additional requests to the makers of antidepressants that the black box warning regarding suicidality be expanded to include warnings about the increased risk of suicidality (thinking and behavior) in young adults 18 to 24 years of age, during the initial stages of treatment.

In contrast to some of the concerns discussed above, recent evidence suggests that fluoxetine and venlafaxine may be associated with a "protective" effect from suicidality among adults and older patients; however, among youth, the medications lacked this apparent protective effect. It should be noted that this recent research did not find that fluoxetine and venlafaxine increased the risk of suicidality among youth.[33] The complex relationships between antidepressant use and suicidality will continue to be explored with the hopes of more unequivocal recommendations.

TREATMENT

Desired Outcomes

3 The goals of treatment for depression are the resolution of current symptoms (ie, remission) and the prevention of further episodes of depression (ie, relapse or recurrence). Whether or not to hospitalize the patient is often the first decision that is made in consideration of the patient's risk of suicide, physical state of health, social support system, and presence of a psychotic depression.

General Approach to Treatment

There are three phases of treatment for patients with MDD: (a) the *acute* phase lasting approximately 6 to 12 weeks in which the goal is remission (ie, absence of symptoms); (b) the *continuation* phase lasting 4 to 9 months after remission is achieved, in which the goal is to eliminate residual symptoms or prevent relapse (ie, return of symptoms within 6 months of remission); and (c) the *maintenance* phase lasting at least 12 to 36 months in which the goal is to prevent recurrence (ie, a separate episode of depression).[2,34] The duration of antidepressant therapy depends on the risk of recurrence. The risk of recurrence increases as the number of past episodes increases. Some investigators recommend lifelong maintenance therapy for persons at greatest risk for recurrence (persons

younger than 40 years of age with two or more prior episodes and persons of any age with three or more prior episodes).[2] An alternative approach is to treat for at least 2 years in patients considered to be at high risk for relapse.[3] The decision as to "when" and "how" to taper/discontinue an antidepressant regimen is always going to depend on patient- and medication-specific variables, and is briefly discussed below.

Clinical Controversy…

There are no universally agreed upon approaches (eg, dose over time-course) for tapering antidepressants to discontinuation. However, research suggests there may be no advantage to shorter versus longer duration tapers. For example, a small study (*n*= 28) demonstrated that 3-day and 14-day antidepressant tapers resulted in similar rates of discontinuation symptoms according to the Discontinuation Emergent Signs and Symptoms checklist.[113] The precise rate of the antidepressant taper is typically influenced by many variables (eg, medication half-life, patient sensitivity to withdrawal symptoms). Therefore, the clinician (and patient) must carefully monitor for discontinuation signs and symptoms and for a return of depressive symptoms. Regardless of the taper approach employed in a given situation, monitoring the patient's status is essential throughout (and for days to weeks following) the taper period.

4 Educating the patient and their support system (eg, family and friends) regarding the delay in antidepressant effects and the importance of adherence should occur before and during the entire course of treatment. The treatment of MDD generally includes nonpharmacologic and pharmacologic strategies, which are discussed in further detail below.

Nonpharmacologic Therapy

In addition to pharmacologic interventions, psychotherapy should be employed whenever the patient is able and willing to participate. Psychotherapy alone is not recommended for the acute treatment of patients with severe and/or psychotic MDD. However, if the depressive episode is mild to moderate in severity, psychotherapy may be the first-line therapy.[35] The effects of psychotherapy and antidepressant medications are considered to be additive. Combined treatment may be advantageous for patients with partial responses to either treatment alone and for those with a chronic course of illness. However, for uncomplicated, nonchronic MDD, combined treatment may provide no unique advantage.[35] Cognitive therapy, behavioral therapy, and interpersonal psychotherapy appear equally effective.[35] Maintenance psychotherapy as the sole treatment to prevent recurrence generally is not recommended. Often, medication alone may prevent a depressive recurrence during the maintenance phase.[35]

Electroconvulsive therapy (ECT) is a safe and effective treatment for certain severe mental illnesses, including MDD. Patients with depression are candidates for ECT when a rapid response is needed, risks of other treatments outweigh potential benefits, there is a history of poor response to antidepressants and a history of good response to ECT, and the patient expresses a preference for ECT. Guidelines developed by the American Psychiatric Association (APA) include indications and contraindications for the appropriate use of ECT, procedures for obtaining informed consent, and

issues in administering ECT. A more recent nonpharmacologic approach is repetitive transcranial magnetic stimulation (rTMS), which has demonstrated efficacy in treating MDD and does not require anesthesia as does ECT.[36]

Physical activity has long been recommended for individuals with many ailments, and recent data suggest benefits in depressed patients. For example, positive preliminary findings led to the Treatment with Exercise Augmentation for Depression (TREAD) study, which is a study designed to confirm the promising initial findings. Recently published findings from this study showed that 16 kcal (67 kJ) per kilogram per week (KKW) exercise was associated with greater remission rates compared with 4 KKW, when both were used as augmentation to an SSRI.[86] The task force concluded that integrating exercise into the MDD treatment plan is medically appropriate and confers many well-accepted health benefits.

Pharmacologic Therapy

Antidepressants are considered first-line treatment for a moderate to severe depressive episode,[3] and they can be classified in several ways, including by chemical structure and the presumed mechanism of antidepressant activity. Although the link between the presumed mechanism of drug action and antidepressant response is tenuous, this classification has the advantage of being based on established pharmacology and clearly explains some of the common, but expected, adverse effects. The knowledgeable clinician can use these facts to tailor treatment to individual patient needs and thereby optimize treatment outcome. Currently available antidepressants, including dosing guidance, are provided in **Table 68-3**.[2,14,34,37,38,39,40]

TABLE 68-3 Adult Dosing Guidance for Currently Available Antidepressant Medications

Drug (Brand Name)	Initial Dose (mg/day)	Usual Dosage Range (mg/day)	Comments (eg, Maximum Daily Dosage, Suggested Therapeutic Plasma Concentration)[a]
Selective Serotonin Reuptake Inhibitors (SSRIs)			
Citalopram (Celexa)	20	20-40	Doses >40 mg/day not recommended due to QT prolongation risk; maximum 20 mg/day for CYP2C19 poor metabolizers or coadministration with CYP2C19 inhibitors; 20 mg/day recommended for patients older than 60 years of age
Escitalopram (Lexapro)	10	10-20	Maximum 20 mg/day; dose may be increased to maximum daily dose after at least 1 week if needed; 5 mg tablet available for unique circumstances
Fluoxetine (Prozac)	20	20-60	Maximum 80 mg/day; dose may be increased in 20 mg increments; doses of 5 or 10 mg/day have been used as initial therapy; doses >20 mg/day may be given in a single daily dose or divided twice daily

Drug (Brand Name)	Initial Dose (mg/day)	Usual Dosage Range (mg/day)	Comments (eg, Maximum Daily Dosage, Suggested Therapeutic Plasma Concentration)[a]
Fluvoxamine (Luvox)	50	50-300	Maximum 300 mg/day; daily doses >100 mg total dose should be divided twice daily, with the larger dose given at night
Paroxetine (Paxil)	20	20-50	Maximum 300 mg/day (ER formulation) Maximum 50 mg/day (IR formulation); titrate 10 mg/day increments weekly Maximum 62.5 mg/day (CR formulation); titrate 12.5 mg/day increments weekly
Sertraline (Zoloft)	50	50-200	Maximum 200 mg/day; titrate 25 mg/day increments weekly
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)			
Newer-generation SNRIs			
Desvenlafaxine (Pristiq)	50	50	Doses up to 400 mg/day have been studied; however, AEs are increased and no additional benefit has been shown at doses exceeding 50 mg/day. Dose reductions or discontinuation may be required if sustained hypertension occurs
Duloxetine (Cymbalta)	30	30-90	Maximum 120 mg/day (given once or twice daily); doses exceeding 60 mg/day not shown to provide increased efficacy for the treatment of MDD
Venlafaxine (Effexor)	37.5-75	75-225	Maximum 375 mg/day (IR); maximum 225 mg/day (ER); may increase in increments up to 75 mg/day at a minimum of every 4 days. Dose reductions or discontinuation may be required if sustained hypertension occurs
Levomilnacipran (Fetzima)	20	40-120	Initial dose (20 mg) for 2 days before dose increases are recommended at intervals of two or more days. Dose adjustment or discontinuation may be required if sustained elevated heart rate or hypertension occurs
Tricyclic antidepressants (TCAs)			
Amitriptyline (Elavil)	25	100-200	Maximum 300 mg/day for MDD; depending on the total dose, it may be given as a single daily dose at bedtime or in divided doses throughout the day; Therapeutic serum level 100-250 ng/mL (mcg/L; 370-925 nmol/L); parent drug plus metabolite (ie, nortriptyline)

Drug (Brand Name)	Initial Dose (mg/day)	Usual Dosage Range (mg/day)	Comments (eg, Maximum Daily Dosage, Suggested Therapeutic Plasma Concentration)[a]
Desipramine (Norpramin)	25	100-200	Maximum 300 mg/day; Suggested therapeutic concentration range for combined imipramine + desipramine: 150-300 ng/mL (mcg/L; 550-1,100 nmol/L)
Doxepin (Sinequan)	25	100-200	Maximum 300 mg/day; may be given in a single daily dose at bedtime (if tolerated) or in divided doses throughout the day; a single dose should not exceed 150 mg
Imipramine (Tofranil)	25	100-200	Maximum 300 mg/day; may be given in a single daily dose at bedtime (if tolerated) or in divided doses throughout the day; Suggested therapeutic concentration range for combined imipramine + desipramine: 150-300 ng/mL (mcg/L; 550-1,100 nmol/L)
Nortriptyline (Pamelor)	25	50-150	Maximum 150 mg/day; total daily may be given as a single daily dose (if tolerated) or 25 mg doses given three to four times daily; Therapeutic serum level 50-150 ng/mL (mcg/L; 190-570 nmol/L)
Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)			
Bupropion (Wellbutrin)	150 (75 mg given twice daily)	150-300	Please see text for proper dosing, which can help decrease seizure risk; Maximum 450 mg/day (IR, ER), 400 mg/day (SR); ER dosed once daily; SR dosed once or twice daily; IR may be dosed up to three times daily
Mixed Serotonergic Effects (Mixed 5-HT)			
Nefazodone (Serzone)	100	200-400	Maximum 600 mg/day; daily doses should be divided twice daily
Trazodone (Desyrel; Oleptro)	50	150-300	Maximum 600 mg/day; IR daily dose should be divided three times daily and may increase by 50 mg/day increments every 3-7 days; ER dose titration initiated at 150 mg at bedtime and can be increased 75 mg/day every 3 days
Vilazodone (Viibryd)	10	20-40	Target dose 20-40 mg/day unless coadministered with CYP3A4 inhibitor (dose not to exceed 20 mg/day). Dose titration: 10 mg/day for 7 days, 20 mg/day for 7 days, and then may increase to 40 mg/day. Dose must be taken with food to ensure adequate drug absorption and bioavailability.

Drug (Brand Name)	Initial Dose (mg/day)	Usual Dosage Range (mg/day)	Comments (eg, Maximum Daily Dosage, Suggested Therapeutic Plasma Concentration)[a]
Vortioxetine (Brintellix)	10	20	Maximum 20 mg/day; US studies demonstrated better treatment effects at the higher dose
Serotonin and α_2-Adrenergic Antagonist			
Mirtazapine (Remeron)	15	15-45	Maximum 45 mg/day; may increase dose no more frequently than every 1-2 weeks; dose adjustment may be required for renal impairment
Monoamine Oxidase Inhibitors (MAOIs)			
Phenelzine (Nardil)	15	30-90	Early phase recommended dosing: 15 mg three times daily; dosing may be increased to 90 mg/day based on tolerance and response; Maintenance phase: dose should be reduced over several weeks to a daily dose as low as 15 mg/day or 15 mg every other day
Selegiline (transdermal) (Emsam)	6	6-12	Not to exceed 12 mg/24 hours; dose may be increased by 3 mg/day increments every 2 weeks; transdermal delivery system designed to deliver dose continuously over a 24-hour period
Tranylcypromine (Parnate)	10	20-40	Maximum 60 mg/day; divided dosing; if no response after 2 weeks, increase by 10 mg increments at 1- to 3-week intervals; Medication cross-taper: allow at least 1 medication-free week, an then initiate tranylcypromine at 50% of usual starting dose for at least 1 week

AE, adverse effects; CR, continuous release; ER, extended release; IR, immediate release; MDD, major depressive disorder; SR, sustained release.

[a]SI conversion for cases where reference ranges are for a mixture of parent drug and active metabolite is calculated based on a 1:1 ratio.

Data from references 2, 14, 34, 37,38,39,40, 46, 57, 65.

5 Studies have found that antidepressants are of *equivalent efficacy* in groups of patients when administered in comparable doses. Because one cannot predict which antidepressant will be the most effective in an individual patient, the initial choice is made empirically. Factors that often influence the choice of an antidepressant include the patient's history of response, history of familial antidepressant response, patient's concurrent medical illnesses and medications, presenting symptoms (eg, fatigue as compared with insomnia), potential for drug–drug interactions, adverse events profile, patient preference, and drug cost. Although the pathophysiology of major depression remains elusive, the clinician can now select from multiple approved drug therapies with presumed

different mechanisms of action as highlighted in **Table 68-4**.[2,14,34,39,40,41,42] Failure to respond to one antidepressant class or one antidepressant drug within a class does not predict a failed response to another drug class or another drug within the same class. Approximately 50% to 60% of patients with varying types of depression improve with acute drug therapy, compared with about 30% to 40% who improve with placebo.[3,43]

TABLE 68-4 Relative Potencies of Norepinephrine and Serotonin Reuptake Blockade and Selected Side Effect Profile of Antidepressants

	Reuptake Antagonism		ACh Effects	Sedation	OH	Seizures[a]	Conduction Changes[a]
	NE	5-HT					
Selective Serotonin Reuptake Inhibitors (SSRIs)							
Citalopram	0	++++	0	+	0	++	++
Escitalopram	0	++++	0	0	0	0	0
Fluoxetine	+	++++	0	0	0	++	0
Fluvoxamine	0	++++	0	+	0	++	0
Paroxetine	++	++++	+	+	0	++	0
Sertraline	0	++++	0	0	0	++	0
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)							
Duloxetine[b]	+++	++++	+	0	+	0	0
Levomilnacipran[c]	++++	+++	+	0	0	0	0
Venlafaxine[d] and desvenlafaxine	+++	++++	+	+	0	++	+
Tricyclic Antidepressants (TCAs)							
Amitriptyline	++	++++	++++	++++	+++	+++	+++
Desipramine	++++	++	++	++	++	++	++++
Doxepin	++	++	+++	++++	++	+++	++
Imipramine	++	++++	+++	+++	++++	+++	+++
Nortriptyline	++++	++	++	++	+	++	++
Mixed Serotonergic (Mixed 5-HT)							
Nefazodone	0	++	0	+++	+++	++	+
Trazodone	0	++	0	++++	+++	++	+
Vilazodone	0	++++	0	+	0	++	0
Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)							
Bupropion[e]	+	0	+	0	0	++++	+
Serotonin and α_2-Receptor Antagonist							
Mirtazapine	0	0	+	++	++	0	+

++++, high; +++, moderate; ++, low; +, very low; 0, absent or not adequately studied.

Ach, anticholinergic; OH, orthostatic hypotension.

[a]These are uncommon side effects of antidepressant drugs, particularly when used at normal therapeutic doses; they may be dose-dependent, resulting in corresponding dose restrictions. (eg, citalopram 40 mg/day maximum due to QTc prolongation concerns.)

[b]Duloxetine: balanced 5-HT and NE reuptake inhibition.

[c]Levomilnacipran: greater potency at NE reuptake inhibition compared to 5-HT.

[d]Venlafaxine: primarily 5-HT at lower doses, NE at higher doses, and DA at very high doses.

[e]Bupropion: also blocks dopamine reuptake.

Data from references 2, 14, 34, 37,38,39,40, 46, 65

Selective Serotonin Reuptake Inhibitors

The efficacy of SSRIs is superior to placebo and comparable to other classes of antidepressants in treating patients with major depression.[2,34] SSRIs are generally chosen as *first-line antidepressants* due to their safety in overdose and improved tolerability. Furthermore, the decision as to which SSRI to use *within* the class is typically based on the nuances of each medication, such as differences in drug interaction profile and pharmacokinetic (PK) parameters (eg, half-life), or due to cost considerations. These concepts will be discussed in greater detail later in this chapter. Evidence suggests that two of the SSRIs, escitalopram and sertraline, demonstrate the 'best' efficacy/side effect profile compared to other newer-generation antidepressants.[44]

Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)

Tricyclic Antidepressants

Although TCAs are effective in treating all depressive subtypes, their use has diminished greatly due to the availability of equally effective therapies that are much safer in overdose and better tolerated. All TCAs potentiate the activity of NE and 5-HT by blocking their reuptake. However, the potency and selectivity of TCAs for the inhibition of reuptake of NE and 5-HT vary greatly among these agents (see Table 68-4). Because TCAs affect other receptor systems (eg, cholinergic, histaminergic, and α-adrenergic systems, adverse events are reported frequently during TCA therapy.[14]

Newer-Generation SNRIs

Venlafaxine inhibits 5-HT reuptake at low doses, and NE reuptake at higher doses; thus, it is referred to as an SNRI. Desvenlafaxine, the primary active metabolite of venlafaxine, is also an SNRI approved to treat depressive disorders. Duloxetine is an SNRI with both 5-HT and NE reuptake inhibition across all doses. Some studies suggest that the SNRIs may be associated with higher rates of response and remission than other antidepressants; however, most of these studies involved venlafaxine, and not

all studies support this conclusion.[41] A report from the Agency for Healthcare Research and Quality (AHRQ) found that discontinuation rates secondary to lack of efficacy are 34% lower (odds ratio = 0.66, 95% CI = 0.47-0.93) for venlafaxine compared with those for SSRIs.[45] This is consistent with the BAP guidelines, which discuss the possibility of a slight (ie, large numbers needed to treat; NNT) efficacy advantage for venlafaxine (in addition to escitalopram/sertraline as discussed above) compared to other antidepressants.[3]

The most recent SNRI to be FDA-approved is levomilnacipran. It is too soon to determine its place in the pharmacotherapy for MDD; however, a pharmacological mechanism that makes it relatively unique among the SNRIs is greater potency at inhibiting NE reuptake as compared to 5-HT reuptake.[46]

Mixed Serotonergic Medications (Mixed 5-HT)

Trazodone and nefazodone have dual actions on serotonergic neurons, acting as both 5-HT_2 antagonists and 5-HT reuptake inhibitors. They may also enhance 5-HT_{1A}-mediated neurotransmission.[14] Trazodone blocks α_1-adrenergic and histaminergic receptors leading to increased side effects (eg, dizziness and sedation) that limit its use as an antidepressant. Recently, a longer-acting extended-release preparation of trazodone was approved by the FDA. This extended-release trazodone preparation has the potential to demonstrate a more tolerable side effect profile compared to its immediate-release predecessor. Nefazodone's use as an antidepressant has declined after reports of hepatic toxicity began to emerge. The FDA-approved nefazodone labeling includes a black box warning describing rare cases of liver failure. Trazodone and nefazodone are effective agents in treating major depression; however, both of them carry risks that limit their usefulness. Generic, immediate-release trazodone is often used adjunctively (in low doses) to induce sleep among depressed patients who are taking other antidepressant medications.

Recently, vilazodone became the first combination SSRI and 5-HT_{1A} receptor partial agonist to be approved for the treatment of MDD based on two 8-week, placebo-controlled MDD trials.[47] More recently, the *multi-modal* serotonergic medication, vortioxetine, was FDA approved for the treatment of MDD. The place for these two serotonin-based medications in the management of depression has yet to be determined. However, based upon their *multi-modal* mechanisms of action and the possibility of other neurotransmitter involvement (especially with vortioxetine), it has been proposed that vilazodone may be particularly efficacious for depressed patients experiencing anxiety while vortioxetine may help patients suffering from depression accompanied by cognitive difficulties.[48,49]

Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)

Bupropion has no appreciable effect on the reuptake of 5-HT, but it inhibits both the NE and DA reuptake pumps.[17,42] These pharmacologic properties make bupropion unique among all currently available antidepressants.

Serotonin and α_2-Adrenergic Receptor Antagonists

Mirtazapine enhances central noradrenergic and serotonergic activity through the antagonism of central presynaptic α_2-adrenergic autoreceptors and heteroreceptors.[50] Furthermore, it antagonizes 5-HT_2 and 5-HT_3 receptors as well as histamine receptors. The antagonism of 5-HT_2 and 5-HT_3 receptors has been linked to lower anxiety and GI side effects, respectively. Blockade of histamine receptors is associated with the sedative properties of mirtazapine.[17]

Monoamine Oxidase Inhibitors

MAOIs increase the concentrations of NE, 5-HT, and DA within the neuronal synapse through inhibition of the MAO enzyme. Similar to TCAs, chronic therapy causes changes in receptor sensitivity (ie, downregulation of β-adrenergic, α-adrenergic, and serotonergic receptors).[51] The MAOIs phenelzine and tranylcypromine are nonselective inhibitors of MAO-A and MAO-B. A selegiline transdermal patch was approved by the FDA for treatment of MDD that allows inhibition of MAO-A and MAO-B in the brain, yet has reduced effects on MAO-A in the gut[37] (see tyramine interactions with MAOIs below).

Adverse Effects

Selective Serotonin Reuptake Inhibitors

The SSRIs have a low affinity for histaminic, α_1-adrenergic, and muscarinic receptors, and therefore they produce fewer anticholinergic and cardiovascular adverse effects than the TCAs, and are not usually associated with significant weight gain.[52,53,54] The most common adverse effects, which generally are mild and short-lived, are gastrointestinal (GI) symptoms (eg, nausea, vomiting, and diarrhea), sexual dysfunction in both males and females, headache, and insomnia.[53] It should be noted that medications which augment serotonergic function, such as the SSRIs, may cause clinically relevant impairment in all three stages of the human sexual response.[55] A discontinuation or withdrawal syndrome may occur if SSRIs are abruptly discontinued. However, the longer the half-life of the drug and its active metabolite, the less likely a withdrawal syndrome will occur.[54,56] Although SSRIs are known to improve the anxiety symptoms associated with depression, a few patients experience an increase in anxiety symptoms or agitation early in treatment. Lastly, despite their excellent safety profile, there have been growing concerns with the SSRIs. For example, citalopram has been linked to a dose-dependent increase in QT interval that requires careful attention to maximum dosages.[57] This dose-dependent increase in QT interval may also be associated with escitalopram.[58]

Serotonin–Norepinephrine Reuptake Inhibitors

The TCAs affect several NTs and produce a wide range of pharmacologic actions, including several unwanted, but expected, adverse effects. The most commonly occurring side effects are dose-related and are associated with blockade of cholinergic receptors (anticholinergic effects) and include dry mouth, constipation, blurred vision, urinary retention, dizziness, tachycardia, memory impairment, and, at higher doses, delirium.[59] Although some tolerance does develop to these adverse effects,

they have the potential to impact patient adherence, particularly in the elderly and those receiving long-term maintenance therapy. Additional adverse effects that may lead to TCA nonadherence include weight gain and sexual dysfunction.[60]

Orthostatic hypotension is a common, dose-related, and potentially problematic adverse effect that has been attributed to the affinity of the TCAs for adrenergic receptors.[61] TCAs also cause cardiac conduction delays and may induce heart block in patients with a preexisting conduction disorder. TCA overdose can produce severe arrhythmias.[61] Furthermore, the FDA released a warning in December 2009 that the desipramine prescribing information will be changed to reflect an increased risk of death in patients receiving desipramine who have a *family history* of sudden cardiac death, cardiac dysrhythmias, and cardiac conduction disturbances. More on this reaction can be found at the FDA's MedWatch website. Therefore, caution should be exercised when prescribing these agents, especially in higher doses, to patients with clinically significant cardiac disease, and to patients with a family history of a cardiac event.

The most commonly reported adverse effects with venlafaxine are similar to those of SSRIs and may be dose-related; they include nausea, sexual dysfunction, and activation.[2] However, recent evidence strongly suggests that venlafaxine is associated with a higher incidence of nausea and vomiting compared with the SSRIs.[45] Venlafaxine may also cause a dose-related increase in diastolic blood pressure, and baseline blood pressure is not a useful predictor of the occurrence of this phenomenon. Blood pressure should be monitored regularly during venlafaxine therapy, and dosage reduction or discontinuation may be necessary if sustained hypertension occurs.[62] This is also true of levomilnacipran, given the increases in blood pressure (and heart rate) that have been documented in levomilnacipran clinical trials.[46]

Duloxetine was relatively well tolerated in short-term clinical trials; however, experience in long-term studies and in a larger population of patients will more clearly define its risks and benefits. The most commonly reported adverse events were nausea, dry mouth, constipation, decreased appetite, insomnia, and increased sweating.[41] According to the AHRQ report cited above, there were higher discontinuation rates secondary to side effects associated with both duloxetine and venlafaxine compared with the SSRI class of antidepressants.[45]

Mixed Serotonergic Medications

Trazodone and nefazodone have minimal anticholinergic effects and comparatively less 5-HT agonist side effects (eg, sexual dysfunction), but they can cause orthostatic hypotension. Sedation, cognitive slowing, and dizziness are the most frequent dose-limiting side effects associated with trazodone.[51] Common adverse effects associated with nefazodone include light-headedness, dizziness, orthostatic hypotension, and somnolence. Due to the previously discussed potential for hepatic injury associated with nefazodone use, treatment should not be initiated in individuals with active liver disease or with elevated baseline serum transaminases. A rare but potentially serious adverse effect of trazodone is priapism, which is reported to occur in approximately 1 in 6,000 male patients. Some cases have required surgical intervention (1 in 23,000), and permanent impotence may result.[63] There have been

no reports of priapism associated with nefazodone use in men, but there is a published case report of nefazodone-induced clitoral priapism.[63] Vilazodone is associated with GI side effects (eg, diarrhea and nausea), dizziness, insomnia, and decreased libido (particularly among men).[64] The most pronounced side effects associated with vortioxetine are GI related (eg, nausea and constipation). There also appeared to be a greater incidence of "treatment emergent sexual dysfunction" among men at the highest vortioxetine dose (20 mg/day) compared to placebo.[65]

Norepinephrine and Dopamine Reuptake Inhibitor

Adverse effects associated with bupropion include nausea, vomiting, tremor, insomnia, dry mouth, and skin reactions. The occurrence of seizures in patients taking bupropion appears to be strongly dose-related, and may be increased by predisposing factors such as history of prior seizure activity, severe alcohol withdrawal, head trauma, and CNS tumor. Additionally, bupropion use is contraindicated in patients with eating disorders such as bulimia and anorexia, as these patients are prone to electrolyte abnormalities and are therefore at higher risk for seizure activity. At daily doses of 450 mg (the FDA-approved maximum dose) or less, the incidence of seizures is 0.4%.[66] Due to its pharmacologic profile (ie, proadrenergic), bupropion may cause activation or agitation in some patients.[17] Bupropion is associated with less sexual dysfunction compared with the SSRIs.[45]

Serotonin and α_2-Adrenergic Receptor Antagonists

The most common adverse effects of mirtazapine are somnolence, weight gain, dry mouth, and constipation. Certain side effects associated with mirtazapine (eg, somnolence and weight gain in particular) are likely due to mirtazapine's relatively strong antihistaminergic properties.[27] Furthermore, side effects such as weight gain may be less with larger mirtazapine doses due to different mechanisms of action at different doses,[54] such as increased noradrenergic transmission as the dose is increased. Weight gain associated with mirtazapine after 6 to 8 weeks is in the range of 0.8 to 3 kg.[45] Mirtazapine should be considered as an option for those patients who experience sexual dysfunction following antidepressant treatment, which may be due to mirtazapine's ability to antagonize postsynaptic serotonergic receptors and/or its pro-noradrenergic effects.

Monoamine Oxidase Inhibitors

The most common adverse effect of MAOIs is postural hypotension; this is more likely to occur with phenelzine than with tranylcypromine and may be minimized through divided dosage scheduling. Other common adverse effects include weight gain and sexual side effects (eg, decreased libido and anorgasmia).[2] Phenelzine has mild to moderate sedating effects, while tranylcypromine may exert a stimulating effect, and therefore insomnia can occur. In addition, fever, myoclonic jerking, and brisk deep tendon reflexes may occur.[67]

Hypertensive crisis, a potentially serious and life-threatening but rare adverse reaction, may occur when MAOIs are taken concurrently with certain foods, especially those high in tyramine, or some medications. Examples of potentially high tyramine foods and medications that should be avoided or

used with caution are provided in **Table 68-5**.[39,40] Ten milligrams of tyramine can cause a marked pressor effect, and 25 mg can result in a serious hypertensive crisis. These incidents may culminate in cerebrovascular accident and death. Symptoms of hypertensive crisis include occipital headache, stiff neck, nausea, vomiting, sweating, and sharply elevated blood pressure. Hypertensive crises can be treated with antihypertensive agents such as captopril.[68] Education of patients taking MAOIs regarding dietary and medication restrictions is extremely important.

TABLE 68-5 Dietary and Medication Restrictions for Patients Taking Monoamine Oxidase Inhibitors[a]

Foods	
Aged cheese[b]	
Sour cream[c]	Liver (chicken or beef, more than 2 days old)
Yogurt[c]	Raisins
Cottage cheese[c]	Pods of broad beans (fava beans)
American cheese[c]	Yeast extract and other yeast products
Mild Swiss cheese[c]	Soy sauce
Wine[d] (especially Chianti and sherry)	Chocolate[e]
Beer	Coffee[e]
Sardines	Ripe avocado
Canned, aged, or processed meats	Sauerkraut
Monosodium glutamate	Licorice
Medications	
Amphetamines	Levodopa
Appetite suppressants	Local anesthetics containing sympathomimetic vasoconstrictors
Asthma inhalants	Meperidine
Buspirone	Methyldopa
Carbamazepine	Methylphenidate
Cocaine	Other antidepressants[f]
Cyclobenzaprine	Other MAOIs
Decongestants (topical and systemic)	Reserpine
Dextromethorphan	Rizatriptan
Dopamine	Stimulants

Foods	
Ephedrine	Sumatriptan
Epinephrine	Sympathomimetics
Guanethidine	Tryptophan

[a]According to the FDA-approved prescribing information for the transdermal selegiline patch, patients receiving the 6-mg/24-hour dose are not required to modify their diet. However, patients receiving the 9- or 12-mg/24-hour dose are still required to follow the dietary restrictions similar to the other MAOIs.

[b]Clearly warrants absolute prohibition (eg, English Stilton, blue, Camembert, and cheddar).

[c]Up to 2 oz (~60 g) daily is acceptable.

[d]Three ounce white wine or a single cocktail is acceptable.

[e]Up to 2 oz (~ 60 mL) daily is acceptable: larger amounts of decaffeinated coffee are acceptable.

[f]Tricyclic antidepressants may be used with caution by experienced clinicians in treatment-resistant populations.

Data from references 39,40.

Serotonin Syndrome (SS)

Any antidepressant that increases serotonergic neurotransmission can be associated with SS. The typical triad of symptoms seen in SS includes mental status changes, autonomic instability, and neuromuscular abnormalities. However, SS has been identified in cases without all three of these symptoms being present. Therefore, alternative approaches to the well-accepted SS triad have been suggested. For example, it has been proposed that the presence of any of the following symptom clusters is highly diagnostic of SS: (a) tremor + hyperreflexia, (b) spontaneous clonus, (c) muscle rigidity + temperature greater than 38°C (100.4°F) + ocular clonus or inducible clonus, (d) ocular clonus + agitation or diaphoresis, and (e) inducible clonus + agitation or diaphoresis.[69,67]

Pharmacokinetics and Pharmacodynamics

The PK of the antidepressants is summarized in **Table 68-6**.[39,40,41,70,71,72] The diversity of SSRIs is evident not only in their chemical structures but also in their PK profiles.[70,73] The unique PK attributes of each SSRI can be used to guide treatment. For example, the long half-life of fluoxetine and its active metabolite norfluoxetine may be beneficial in instances of partial nonadherence (eg, missed doses). Conversely, caution must be taken to monitor for drug–drug interactions prior to combining another medication with fluoxetine. SSRIs are extensively distributed to the tissues, and all, with the possible exception of citalopram and sertraline, may have a nonlinear pattern of drug accumulation with long-term administration.[52,73] Therefore, the relationship between the dose and observed effect

(eg, side effect) may change over time for the nonlinear SSRIs, and this needs to be considered during treatment.

TABLE 68-6 Pharmacokinetic Properties of Antidepressants

Generic Name	Elimination Half-Life[a]	Time of Peak Plasma Concentration (Hours)	Plasma Protein Binding (%)	Percentage Bioavailable	Clinically Important Metabolites
Selective Serotonin Reuptake Inhibitors (SSRIs)					
Citalopram	33 hours	2-4	80	≥80	None
Escitalopram	27-32 hours	5	56	80	None
Fluoxetine	4-6 days[b]	4-8	94	95	Norfluoxetine[e]
Fluvoxamine	15-26 hours	2-8	77	53	None
Paroxetine	24-31 hours	5-7	95		None
Sertraline	27 hours	6-8	99	36[c]	None
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)					
Desvenlafaxine	11 hours	7.5	30	80	None
Duloxetine	12 hours	6	90	50	None
Levomilnacipran	12 hours	6-8	22	92	None
Venlafaxine	5 hours	2	27-30	45	*O*-Desmethyl-venlafaxine
TCAs					
Amitriptyline	9-46 hours	1-5	90-97	30-60	Nortriptyline
Desipramine	11-46 hours	3-6	73-92	33-51	2-Hydroxy-desipramine
Doxepin	8-36 hours	1-4	68-82	13-45	Desmethyl-doxepin
Imipramine	6-34 hours	1.5-3	63-96	22-77	Desipramine
Nortriptyline	16-88 hours	3-12	87-95	46-70	10-Hydroxy-nortriptyline
Mixed Serotonergic (Mixed 5-HT)					
Nefazodone	2-4 hours	1	99	20	*meta*-Chlorophenyl-piperazine
Trazodone	6-11 hours	1-2	92	*d*	*meta*-Chlorophenyl-piperazine
Vilazodone	25 hours	4-5	>95	72[e]	
Vortioxetine	66 hours	7-11	98	75	
Norepinephrine/Dopamine Reuptake Inhibitor (NDRI)					
Bupropion	10-21 hours	3	82-88	*d*	Hydroxy-bupropion

Generic Name	Elimination Half-Life[a]	Time of Peak Plasma Concentration (Hours)	Plasma Protein Binding (%)	Percentage Bioavailable	Clinically Important Metabolites
					Threohydro-bupropion Erythrohydro-bupropion
Serotonin and α_2-Adrenergic Antagonists					
Mirtazapine	20-40 hours	2	85	50	None

[a]Biologic half-life in slowest phase of elimination.

[b]Four to 6 days with chronic dosing; norfluoxetine, 4-16 days.

[c]Increases 30%-40% when taken with food.

[d]No data available.

[e]Take with food to increase area under the curve concentrations by greater than 60%.

Data from references 39,40,41, 46, 65, 70,71,72.

Bioavailability is low (30%-70%) for most TCAs as a result of the first-pass hepatic effect, which shows great interindividual variation.[74] The TCAs have a large volume of distribution and concentrate in brain and cardiac tissue in laboratory animals. They are bound extensively and strongly to plasma albumin, erythrocytes, α_1-acid glycoprotein, and lipoprotein.[74] The major metabolic pathways are demethylation, aromatic and aliphatic hydroxylation, and glucuronide conjugation. Enterohepatic cycling has been described.[74,75] Metabolism of TCAs is linear within the usual dosage range. The elimination half-lives of the TCAs can vary greatly among individual patients.[74]

Venlafaxine is metabolized to an active metabolite, *O*-desmethylvenlafaxine, which contributes to the overall pharmacologic effect,[76] and has received FDA approval as an antidepressant. As might be expected, different formulations of venlafaxine with different PK profiles have led to different adverse effect profiles. For example, venlafaxine extended-release formulation, with its sustained plasma concentrations, has been associated with higher rates of sexual dysfunction among men (37%) compared with the immediate-release formulation (6%).[76]

Bupropion is metabolized to multiple active metabolites (see Table 68-6). There are currently three formulations of bupropion (immediate release, sustained release, and extended release), which are considered bioequivalent.[77] The bupropion peak plasma concentrations are lower for the sustained-release formulation of bupropion, and it is believed this may contribute to a lower seizure risk with that formulation.[78]

Mirtazapine undergoes extensive biotransformation to several metabolites[79] and is primarily eliminated in the urine (renal elimination). However, these metabolites are present at such low plasma concentrations as to minimally contribute to the overall pharmacologic profile of mirtazapine. Levomilnacipran is another newer-generation antidepressant with renal excretion playing a major role in its elimination.

Altered Pharmacokinetics

In patients with cirrhosis, the half-lives of fluoxetine and norfluoxetine increased to 7.6 and 12 days, respectively.[73] Patients with hepatic impairment had a twofold increase in plasma concentrations of paroxetine.[80] Similarly, in patients with mild stable cirrhosis, the half-life of sertraline was 2.5 times greater than in patients without liver disease.[81] Patients with renal impairment had a twofold to fourfold increase in paroxetine plasma concentrations compared with normal volunteers.[80] Plasma concentrations of SSRIs in the elderly are reported to be greater than in younger patients.[73]

Factors that influence TCA plasma concentrations include disease states, genetics, age, cigarette smoking, and concurrent drug administration. Hepatic disease may result in increased TCA plasma concentrations.[38] Renal failure does not alter nortriptyline metabolism, but the 10-hydroxy metabolite may accumulate, and protein binding may be diminished, with resulting enhanced sensitivity to the drug.[74] Clinicians should be alert to the possibility of higher-than-expected plasma concentrations of some TCAs in the elderly.

The clearance of venlafaxine, mirtazapine, and their metabolites may be reduced among patients with hepatic or renal disease,[71] and doses should be adjusted accordingly. Elderly patients may require a dose reduction with mirtazapine.[71]

Plasma Concentration and Clinical Response

For the newer antidepressants, a strong correlation has not been established between plasma concentration and clinical response or adverse effects. Studies in acutely depressed patients have demonstrated a correlation between antidepressant effect and plasma concentrations for some TCAs. There are four TCAs (amitriptyline, nortriptyline, desipramine, and imipramine) with evidence to support an association between plasma concentrations and clinical response. However, the best established therapeutic range is for nortriptyline (50-150 ng/mL [190-570 nmol/L]),[38] which appears to demonstrate a curvilinear plasma concentration–response relationship. See Table 68-3 for a listing of suggested therapeutic plasma concentration ranges.

It must be noted that the patient's clinical response, not plasma concentration, dictates dosage adjustments. Some patients with plasma concentrations outside the suggested therapeutic plasma concentration range respond, whereas others are nonresponsive regardless of their plasma concentration.

Plasma Concentration Monitoring

Because of interindividual variations in plasma concentrations achieved by a given dose, interpretation of plasma concentrations can be very difficult for the TCAs.[38] Although plasma level monitoring is not performed routinely, some indications include inadequate response, relapse, serious or persistent adverse effects, use of higher-than-standard doses, suspected toxicity, elderly patients, pregnant patients, cardiac disease, suspected nonadherence, suspected PK drug interactions, and change in the manufacturer of the product. If plasma concentration monitoring is used to detect nonadherence, a cutoff as low as 30 ng/mL (mcg/L; ~110 nmol/L) for the TCAs has been suggested to avoid confusion with low bioavailability or unusually rapid metabolism. Blood samples for plasma concentration determinations should be obtained at steady state, usually after a minimum of 1 week at constant dosage. Sampling should be performed during the drug elimination phase, usually in the morning, 12 hours after the last dose. Samples collected in this manner are comparable for patients on once-, twice-, or thrice-daily regimens.[74]

Drug Interactions

Drug–drug interactions fall into two broad categories: PK or PD drug interactions. In contrast to the SSRIs, which have potential for both PK and PD interactions, other newer-generation antidepressants such as venlafaxine, duloxetine, mirtazapine, and bupropion have drug interactions that are primarily PD. This may be partly explained by the relative lack of cytochrome P450 inhibition among these newer agents compared with that among SSRIs (see **Table 68-7**).[39,40,52,70,71,72]

TABLE 68-7 Second- and Third-Generation Antidepressants and Cytochrome (CYP) P450 Enzyme Inhibitory Potential

Drug	CYP Enzyme			
	1A2	2C	2D6	3A4
Bupropion	0	0	+	0
Citalopram	0	0	+	NA
Duloxetine	0	0	+++	0
Escitalopram	0	0	+	0
Fluoxetine	0	++	++++	++
Fluvoxamine	++++	++	0	+++
Mirtazapine	0	0	0	0
Nefazodone	0	0	0	++++
Paroxetine	0	0	++++	0
Sertraline	0	++	+	+
(des)-Venlafaxine	0	0	0/+	0

++++, high; +++, moderate; ++, low; +, very low; 0, absent.

Data from references 39, 40, 52, 70,71,72.

Pharmacokinetic Drug Interactions

Drug–drug interactions may occur when an SSRI is coadministered with another drug metabolized through the cytochrome P450 system. Two of the isoenzymes of the cytochrome P450 system, 2D6 and 3A4, are responsible for the metabolism of more than 80% of currently marketed drugs.[72] The ability of an SSRI, or any antidepressant, to inhibit or induce the activity of these enzymes will be a significant contributory factor in determining its capability to cause a PK drug interaction when administered concomitantly. Table 68-7 shows the cytochrome P450 enzyme inhibitory potential of the second- and third-generation antidepressant agents. In patients receiving a stable dose of any medication known to interact with SSRIs, if an SSRI is to be initiated, the starting dose should be low and titrated carefully to evaluate the potential importance of the interaction.

Because the TCAs are metabolized in the liver through the cytochrome P450 system, they may interact with other drugs that modify hepatic enzyme activity or hepatic blood flow. TCAs are also extensively protein bound, which can cause drug interactions through displacement from protein-binding sites. Many commonly used medications can interact when given concurrently with TCAs. Due to their frequent coadministration, a common drug interaction occurs between the TCAs and certain SSRIs, such as paroxetine and fluoxetine. These drugs are known to inhibit cytochrome P450 (eg, CYP2D6) with the resultant increase in TCA plasma concentrations.

As nefazodone use has been severely limited due to its potential to induce liver toxicity, and trazodone is primarily used as a non-FDA-approved hypnotic at low doses, neither of these agents are likely to be involved in clinically significant drug interactions. However, it should be noted that nefazodone is a potent inhibitor of cytochrome P450 3A4.[72]

Pharmacodynamic Drug Interactions

Certain PD drug interactions that may occur with SSRIs are concerning and require close monitoring. For example, the combination of an SSRI with another drug that augments serotonergic function (eg, linezolid) can lead to SS, which is characterized by symptoms such as clonus, hyperthermia, and mental status changes,[69] although these symptoms are not unanimously agreed upon; therefore, a washout period of 2 to 5 weeks (depending on the half-life of the SSRI) may be necessary before the initiation of another serotonergic medication. Lastly, the TCAs, SNRIs, and SSRIs can also potentially be involved in SS as described within Adverse Effects above and in **Table 68-8**.[39,40]

There are two types of pharmacodynamic drug interactions that may occur between antidepressant medications and NSAIDs. First, increased risk for abnormal bleeding (eg, upper GI and intracranial hemorrhage) associated with the combined use of antidepressants and NSAIDs is a potentially very serious pharmacodynamic interaction that has been reported in the literature.[82,83] This first PD interaction is likely mediated by serotonergic mechanisms that occur at the platelet level. Second, recent research, in both mice and humans, suggests the possibility that NSAIDs may lessen the efficacy of SSRIs. A recent editorial in the *American Journal of Psychiatry* provided a thoughtful discussion on the topic.[84] At this time evidence is insufficient to draw firm conclusions. However, given the volume of prescriptions for both NSAIDs and SSRIs, this is an area of pharmacotherapy that certainly deserves further research and thoughtful prescribing practices.

TABLE 68-8 Selected Drug Interactions of Newer-Generation Antidepressants

Antidepressant	Interacting Drug/Drug Class	Effect
Selective Serotonin Reuptake Inhibitors		
Citalopram and escitalopram	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Linezolid (*MAOI effects*)	Serotonin syndrome
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Fluoxetine	Alprazolam	Increased plasma concentrations and half-life of alprazolam; increased psychomotor impairment
	Antipsychotics (eg, haloperidol and risperidone)	Increased antipsychotic concentrations; increased extrapyramidal side effects
	β-Adrenergic blockers	Increased metoprolol serum concentrations; increased bradycardia; possible heart block
	Carbamazepine	Increased plasma concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Linezolid (*MAOI effects*)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Phenytoin	Increased plasma concentrations of phenytoin; symptoms of phenytoin toxicity
	TCAs	Markedly increased TCA plasma concentrations; symptoms of TCA toxicity
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
Fluvoxamine	Alosetron	Increased alosetron AUC (sixfold) and half-life (threefold)
	Alprazolam	Increased AUC of alprazolam by 96%, increased alprazolam half-life by 71%; increased psychomotor impairment
	β-Adrenergic blockers	Fivefold increase in propranolol serum concentration; bradycardia and hypotension
	Carbamazepine	Increased plasma concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Clozapine	Increased clozapine serum concentrations; increased risk for seizures and orthostatic hypotension

Antidepressant	Interacting Drug/Drug Class	Effect
	Diltiazem	Bradycardia
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Methadone	Increased methadone plasma concentrations; symptoms of methadone toxicity
	Ramelteon	Increased AUC (190-fold) and C_{max} (70-fold)
	Sibutramine	Serotonin syndrome
	TCAs	Increased TCA plasma concentration; symptoms of TCA toxicity
	Theophylline and caffeine	Increased serum concentrations of theophylline or caffeine; symptoms of theophylline or caffeine toxicity
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
	Warfarin	Increased hypoprothrombinemic response to warfarin
Paroxetine	Antipsychotics (eg, haloperidol, risperidone)	Increased antipsychotic concentrations; increased CNS and extrapyramidal side effects
	β-Adrenergic blockers	Increased metoprolol serum concentrations; increased bradycardia; possible heart block
	Linezolid (*MAOI effects*)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	TCAs	Markedly increased TCA plasma concentrations; symptoms of TCA toxicity
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
Sertraline	Linezolid (*MAOI effects*)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Serotonin–Norepinephrine Reuptake Inhibitors		
Venlafaxine and desvenlafaxine	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome

Antidepressant	Interacting Drug/Drug Class	Effect
Duloxetine	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
	Triptans	Serotonin syndrome
Levomilnacipran	CYP3A4 inhibitors	Clinically relevant increases in levomilnacipran plasma concentrations may occur
	MAOIs	Potential for hypertensive crisis, serotonin syndrome
Mixed Serotonergic (mixed 5-HT)		
Vilazodone	CYP3A4 inhibitors	Maximum vilazodone dose 20 mg with coadministration of potent CYP3A4 inhibitor
Vortioxetine	CYP2D6 inhibitors	May need to reduce vortioxetine dose by half with coadministration of potent CYP2D6 inhibitor
Serotonin and α-2-Adrenergic Antagonist		
Mirtazapine	Carbamazepine	Mirtazapine concentration decreased (60%)
	MAOIs	Theoretically, central serotonin syndrome could occur
Norepinephrine and Dopamine Reuptake Inhibitor		
Bupropion	MAOIs	Potential for hypertensive crisis
	Medications that lower seizure threshold	Increased incidence of seizures

NOTE: any medication that augments serotonergic function may impact bleeding risk and should be used with caution in patients receiving NSAIDs or other medications with hematologic effects.

AUC, area under the time concentration curve; C_{max}, maximum concentration; MAOI, monoamine oxidase inhibitor.

Data from references 2, 39, 40, 46, 65.

Lastly, refer to Monoamine Oxidase Inhibitors under Adverse Effects above and Table 68-5 to read more about the hypertensive crisis that may result following the coadministration of MAOIs and other medications that increase vasopressor response (eg, amphetamines). Notably, MAOIs and TCAs may be coadministered safely in refractory patients with apparent increased efficacy compared with monotherapy; however, severe reactions (eg, hypertensive crisis) and fatalities have occurred.[2,74] Therefore, this combination should be used sparingly by experienced clinicians and monitored extremely carefully.

Alternative Pharmacotherapy

The APA Task Force on Complementary and Alternative Medicine (CAM) recently provided consensus-based recommendations on the use of CAM for the treatment of MDD.[85] While these recommendations are not the focus of this chapter, clinicians treating patients with MDD should be cognizant of them.

Omega-3 Fatty Acids

It appears from the literature reviewed by the task force that eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) omega-3 fatty acids can be used as augmentation in the treatment of MDD. Furthermore, EPA alone or the combination of EPA/DHA is likely more effective than DHA alone.

St. John Wort

There is a lack of consensus regarding St. John's wort for the treatment of MDD. Furthermore, St. John's wort induces hepatic metabolic enzymes and is associated with significant drug interactions. Therefore, the APA Task Force conservatively states that St. John's wort may be reasonable for some individuals with mild to moderate MDD. It should be noted, that the BAP guidelines state a "standardized" preparation of St. John's wort "could be considered" in patients with mild to moderate MDD, if other first-line medications are not an option.[3]

S-Adenosyl-l-Methionine (SAMe)

The use of SAMe received a favorable review by the APA Task Force. However, the final consensus was that more rigorous studies need to confirm the efficacy of SAMe for treating MDD. In agreement, the BAP guidelines state that evidence is developing for use of SAMe as an augmentation strategy in the treatment of MDD.[3]

Folate

The three compounds in this category are (a) folic acid, (b) folinic acid, and (c) 5-methyltetrahydrofolate (5-MTHF). These folate compounds are involved in the synthesis of key NTs, such as 5-HT. The task force states that augmentation with these compounds is reasonable, but more work is needed to clarify which subgroup of patients may achieve the greatest response. For example, in one study, only women responded to folic acid augmentation of fluoxetine treatment.

Special Populations

Elderly Patients

Depression in the elderly is a major public health problem. Many elderly depressed patients are inadequately treated, or depression is missed or mistaken for another disorder, such as dementia. In the elderly, depressed mood, the typical signature symptom of depression, may be less prominent than other depressive symptoms such as loss of appetite, cognitive impairment, sleeplessness,

anergia, and loss of interest in and enjoyment of the normal pursuits of life. Older adults may not recognize common symptoms associated with depression such as anhedonia (inability to experience pleasure), fatigue, and concentration difficulties. Somatic (physical) complaints are quite frequently the presenting symptoms in elderly depressed patients. Appropriate recognition and treatment of depression in the elderly is extremely important. In fact, individuals 65 years of age and older have a very high rate of suicidality. Increased suicide attempts in the depressed elderly may be due to access to firearms, diminished cognitive functioning, sleep disruptions, poor social interactions, and inattention among primary caregivers.[87]

Before initiating antidepressant treatment, a complete physical examination should be performed. In prescribing antidepressants, elderly patients may be either overtreated or undertreated. Overtreatment occurs when age-related PK and PD factors are overlooked. Undertreatment results from an overly conservative approach as a result of the patient's advanced age or concurrent medical problems. SSRIs are usually selected as first-choice antidepressants in the elderly, and this may enable the clinician to avoid some of the problematic adverse effects commonly associated with TCAs (eg, sedative, anticholinergic, and cardiovascular side effects). Furthermore, there is evidence to suggest that the long-term use of antidepressants such as SSRIs in the elderly, administered with either psychotherapy or clinical management, may prevent a depressive relapse.[88] Bupropion and venlafaxine are often selected because of milder anticholinergic and less frequent cardiovascular side effects.[89] Mirtazapine has been shown to be an effective antidepressant in the elderly (at least 65 years of age) and better tolerated than the SSRI paroxetine; furthermore, secondary measures of anxiety and sleep were improved following mirtazapine administration.[90] Regardless of the specific antidepressant chosen, the effect sizes for antidepressants as a pharmacological class (as compared to placebo) may be smaller in older patients than in younger adult populations.[3]

Pediatric Patients

Accumulating evidence indicates that childhood depression occurs quite commonly. Symptoms of depression in the young may vary from accepted diagnostic criteria and include several nonspecific symptoms such as boredom, anxiety, failing adjustment, and sleep disturbance.[91]

Data collected under controlled conditions that support the efficacy of antidepressants in children and adolescents are sparse, and no antidepressant, except fluoxetine and escitalopram, is FDA-approved for the treatment of depression in patients younger than 18 years of age, although other antidepressants (eg, sertraline) have been studied in this population.[92]

The use of antidepressants in children and adolescents was complicated when, in March 2004, the FDA issued a black box warning in the product labeling for antidepressant medications warning clinicians and patients of the increased risk for suicidal ideation and behavior when antidepressants are used in this population. However, several retrospective longitudinal reviews of the use of antidepressants in children found no significant increase in the risk of suicide attempts or deaths.[93,94,95] Furthermore, adolescents suffering from depression who remain untreated may successfully commit suicide.[96,97] Further study is needed to resolve this important clinical dilemma.

Several cases of sudden death have been reported in children and adolescents taking antidepressants, such as desipramine. A baseline electrocardiogram (ECG) is recommended before initiating treatment with a TCA in children and adolescents, and many clinicians recommend an additional ECG when steady-state plasma concentrations are achieved.[98]

The treatment of depression in children remains challenging, as depression can be difficult to diagnose and treat once identified. Furthermore, differences in efficacy between medication and placebo may be small and nonsignificant in children below the age of 13 years.[3] However, antidepressants (in particular, the SSRIs) remain viable treatment options when prescribed and monitored appropriately.

Pregnant and Lactating Patients

The crucial decision as to whether to use antidepressants during pregnancy continues to be debated and must always include a risk-benefit analysis based upon the available evidence at the time of treatment.[99] There are findings that both support and refute the decision to use antidepressants during pregnancy.[100,101,102] For example, approximately 14% of pregnant women develop a serious depression during pregnancy.[100] Furthermore, it has been documented that women who discontinued antidepressant therapy were five times more likely to have a relapse during their pregnancy than were women who continued treatment.[102] In contrast, another study found that prenatal exposure to SSRIs was associated with an increased risk of low birth weight and respiratory distress, and that this relationship remained after accounting for maternal illness severity.[100] A study by Chambers et al. reported a sixfold greater likelihood of the occurrence of persistent pulmonary hypertension of newborn infants exposed to an SSRI after the 20th week of gestation.[101] These are selected examples of studies on either the pro or con "side" of the argument and a full exploration of the conflicting literature on this topic is beyond the scope of this chapter.

A recent editorial on the use of antidepressants in pregnancy lists four therapeutic principles to guide the clinician in treating women during pregnancy: (a) Pregnancy does not protect against the occurrence of depression, and the likelihood of relapse is very high in untreated women with recurrent illness. (b) Maternal depression adversely affects child development, and prenatal depression may adversely affect the offspring. (c) When attempting to balance benefit and risk, transient postnatal behavioral abnormalities in the offspring of treated mothers must not be assumed to portend long-term compromise. (d) SSRIs, the most commonly used and best-tolerated treatment for depression, carry a small but significant risk for a serious medical consequence.[103]

In September 2009, the APA and the American College of Obstetricians and Gynecologists released a report discussing the treatment of depression during pregnancy. One of the prominent conclusions of this report was that *both* antidepressant treatment and untreated depression have been associated with potential problems during pregnancy. However, studies to date have not been able to adequately control for all the necessary variables involved in birth outcomes (eg, maternal depressive disorder) and more work needs to be done.[104]

In summary, the risks and benefits of drug therapy during pregnancy must always be weighed, and

concerns about the risks of untreated depression during pregnancy should be considered. These include the possibility of low birth weight secondary to poor maternal weight gain, suicidality, potential for hospitalization, potential for marital discord, inability to engage in appropriate obstetric care, and difficulty caring for other children.[105] Several different approaches exist for dealing with pregnancy and antidepressant use. First, discontinuation of an antidepressant before conception is an option for women who are stable and appear likely to remain well while not taking antidepressant medication. Second, continuation of the antidepressant until conception may be reasonable. For those who have a history of depressive relapse after medication discontinuation, the antidepressant should be continued throughout pregnancy.

Further evaluations of the newer antidepressants are needed to fully understand the risks associated with their use at various stages of the gestational period. There is some recent evidence to suggest there may be less risk associated with particular antidepressants (eg, sertraline) compared to others (eg, paroxetine and fluoxetine) during early pregnancy.[106]

There is a great deal of uncertainty regarding long-term antidepressant exposure during breastfeeding due to the lack of data. However, both sertraline and paroxetine appear in relatively low concentrations in breast milk and in samples taken from infants.[107] Again, the risks of not treating depression in a pregnant or breastfeeding woman should not be underestimated or minimized.

Relative Resistance and Treatment-Resistant Depression

The majority of "treatment-resistant" depressed patients are likely the result of inadequate therapy (relative resistance). This theory is supported by data from the National Institute of Mental Health (NIMH) Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, which is generally considered to be one of the premier antidepressant trials among patients with depressive disorders.[108] This study showed that one in three depressed patients who previously did not achieve remission using an antidepressant became symptom free with the help of an additional medication (eg, bupropion SR) and one in four achieved remission after switching to a different antidepressant (eg, venlafaxine XR). Furthermore, patients can be switched to another medication within the same class. For example, patients in the STAR*D study not responding to an initial SSRI were shown to be as likely to respond to another SSRI as they were to a medication from a different class.[109] Consistent with the STAR*D findings, the BAP guidelines place a higher level of confidence in both augmentation and switching strategies, compared to dose increase approaches.[3]

Although several different definitions for treatment-resistant depression have been proposed, the most widely accepted is depression that has not achieved remission even after two optimal antidepressant trails.[110] More than 40% of patients with MDD being treated with antidepressants meet these criteria.[110] Three pharmacologic approaches that have been used with success for treatment-resistant depression include the following:

1. The current antidepressant may be stopped and a trial with another agent initiated (ie, switching). For example, the STAR*D trial compared switching to mirtazapine (up to 60 mg/day)

versus nortriptyline (up to 200 mg/day) after two consecutive failed medication treatments.[111] In the mirtazapine group, 12.3% of patients met the remission criterion of a score of 7 or less on the Hamilton Rating Scale for Depression (HAM-D), while 19.8% of nortriptyline patients met this criterion at the end of 14 weeks.

2. The current antidepressant can be augmented by the addition of another agent such as lithium, or another antidepressant can be added (ie, combination antidepressant treatment). For example, the STAR*D trial evaluated the addition of lithium or triiodothyronine (T_3) to current antidepressant treatment. After approximately 10 weeks, T_3 augmentation resulted in higher remission rates (24.7%) compared with lithium (15.9%). However, the differences between these two augmentation strategies were modest and not statistically significant.[110] Although T3 and lithium demonstrated similar remission rates in this seminal trial, the BAP guidelines provide a stronger recommendation rating for lithium (ie, "A") compared to T3-based approaches (ie, "B").[3]

3. The use of atypical antipsychotic agents to augment the antidepressant response. Aripiprazole was the first atypical antipsychotic to receive FDA approval for adjunctive use in adults with MDD. Aripiprazole and quetiapine have been recommended as first-line agents to augment an antidepressant medication.[3] More recently, brexpiprazole was FDA-approved for this indication.

The APA practice guideline for the treatment of patients with MDD offers guidance for managing patients who fail to respond. These guidelines advise that if patients fail to respond to medication after 6 to 8 weeks, a reappraisal of the treatment regimen should be considered.[2] Partial responders should consider changing the dose, augmenting the antidepressant, or adding psychotherapy or ECT. For those with no response, options include changing to a second antidepressant or the addition of psychotherapy or ECT. Again, the BAP guidelines suggest that stronger evidence exists for switching or augmentation strategies compared to dose increases in patients with inadequate antidepressant response.[3] Comorbid medical or psychiatric conditions should be identified and treated because they may complicate treatment.

6 Before changing a patient's treatment, the clinician is advised to evaluate the adequacy of the medication dosage and adherence with the prescribed regimen. Issues to be addressed in assessing the patient who has not responded to treatment include the following:

1. Is the diagnosis correct?
2. Does the patient have a psychotic depression?
3. Has the patient received an adequate dose and adequate duration of treatment?
4. Do adverse effects preclude adequate dosing?
5. Has the patient adhered to the prescribed regimen?
6. Was a stepwise approach to treatment used?

7. Was treatment outcome adequately measured?

8. Is there a coexisting or preexisting medical or psychiatric disorder?

9. Are there other factors that interfere with treatment?

Clinical Controversy…

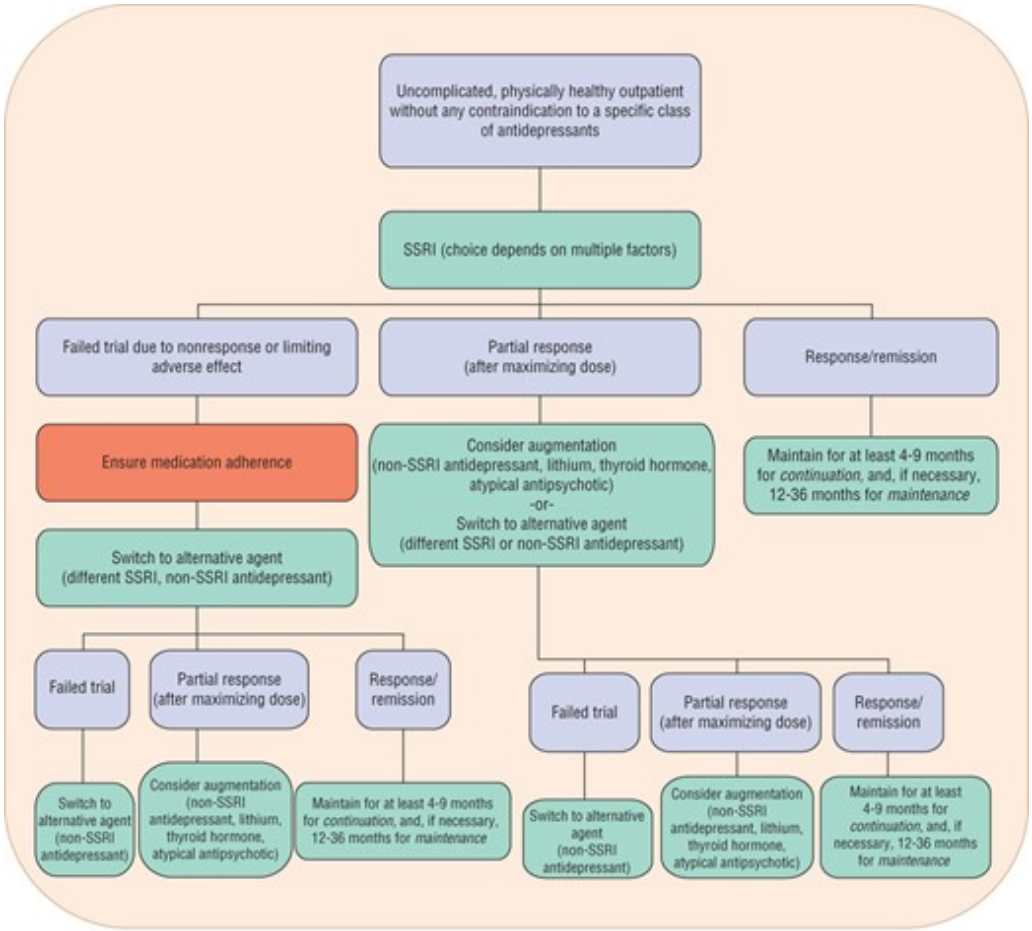
Low dose buprenorphine has been assessed for treatment resistant depression (TRD) among adults age 50 years and older.[114] The average buprenorphine dose used in this study was very low (0.4 mg/day) compared to buprenorphine for other conditions, such as opioid dependence. This low dose was provided by the authors as one explanation for the lack of "clinically significant physiologic or psychological withdrawal" when buprenorphine was tapered. Obviously, pharmacological approaches such as buprenorphine for TRD would need to be carefully monitored for misuse or diversion behaviors. However, it is possible that such approaches could provide relief for patients suffering from TRD. Clearly, more study is needed.

Clinical Application

A suggested algorithm for the management of uncomplicated MDD is shown in **Figure 68-2**. Recommended initial doses and dosage ranges are shown in Table 68-3. Antidepressant doses are generally titrated upwards depending on symptom response and adverse effects. Table 68-3 provides some medication-specific guidelines for dose titration. It is important to remember that 3 to 4 weeks is usually required before a mood-elevating response is seen. A 6-week trial at a maximum dosage is considered an adequate trial.[2] It is crucial to counsel the patient about the expected lag time before the onset of clinical response. Patients uneducated in this regard often fail to adhere to their prescribed regimens.

FIGURE 68-2

Suggested algorithm for treatment of uncomplicated MDD. (SSRI, selective serotonin reuptake inhibitor.) Note: both the BAP guidelines and the STAR*D trial suggest that switching and augmentation strategies are supported by stronger evidence compared to dose increases (among poor antidepressant responders).



Some of the newer-generation antidepressant dosing regimens are particularly important from a safety standpoint. For example, bupropion must be carefully dosed in order to reduce seizure risk. Bupropion IR formulation is usually initiated at 75 mg twice daily, and this dose may be increased to 100 mg three times daily after a few days. Most patients will respond at 300 mg/day; however, an increase to 450 mg/day, given as 150 mg three times daily, may be considered in patients with no or partial response after several weeks of treatment at 300 mg/day. Additionally, both a 12-hour and a 24-hour sustained-release formulation are available, allowing for less frequent dosing. More recently, a maximum citalopram dose of 40 mg has been recommended, given increased QT prolongation at higher doses. Again, it should be noted that caution must be used with any dose regimen of TCAs or MAOIs. According to the FDA-approved prescribing information for the transdermal selegiline patch, patients receiving the 6-mg/24-hour dose are not required to modify their diet. However, patients receiving the 9- or 12-mg/24-hour dose are required to follow the dietary restrictions similar to the other MAOIs.

Caution is urged when dosing antidepressants in special populations. For example, in elderly patients, as a general rule, dosing is started at one half the initial dose that would be administered to younger adults, and the dose is increased at a slower rate.

Personalized Pharmacotherapy

7 Pharmacogenetic applications in psychiatry have been explored for some time. Pharmacogenetic

tests (eg, the FDA-approved AmpliChip to evaluate CYP2D6 and CYP2C19 polymorphisms) are now available. However, there are no standard or well-accepted guidelines for the use of pharmacogenetic testing as it relates to antidepressant treatment. In contrast, PK parameters have long been one of the primary considerations when choosing among the antidepressants, particularly within a medication class.[2] For example, PK parameters help the clinician choose a particular SSRI (eg, longer fluoxetine half-life for partial nonadherence).

A clinician can use other aspects of a medication's pharmacological profile to tailor the treatment to a particular patient. For example, antidepressants can generally be classified as either activating or sedating based upon their mechanism of action, and this is often a major consideration in antidepressant choice. Medications that promote noradrenergic activity (eg, venlafaxine) or serotonin (eg, SSRIs) may be activating upon initiation and therefore poor choices for a patient suffering from significant insomnia. In contrast, medications with antihistaminergic properties (eg, mirtazapine) may be highly sedating and therefore appropriate for the depressed patient suffering from insomnia. Furthermore, trazodone has moderate antihistaminergic properties (ie, sedating), but also has antagonist properties at post-synaptic 5-HT receptors (ie, it may block activating effects of other serotonergic antidepressants). In fact, some antidepressants are so effective at helping patients to sleep, they have been studied (typically in lower doses compared to depressive disorders) as pharmacotherapy for primary insomnia.

EVALUATION OF THERAPEUTIC OUTCOMES

8 Several monitoring parameters, in addition to plasma concentrations, are useful in managing patients (**Table 68-9**).[2,39,40] Patients must be monitored for adverse effects, such as sedation and anticholinergic effects, and for remission of previously documented target symptoms. The presence of side effects does not necessarily indicate adequate dosage. In addition, changes in social and occupational functioning should be assessed. Patients receiving SNRIs should have their blood pressure monitored at regular intervals. Patients older than 40 years of age should receive a pretreatment ECG before starting TCA therapy, and followup ECGs should be performed periodically. Patients should be monitored for the emergence of suicidal ideation after initiation of any antidepressant, especially if other risk factors for suicidality (eg, sleep disturbances) are present. If significant activation or insomnia occurs upon antidepressant initiation, a short-term anxiolytic or hypnotic may be appropriate.[27] Weight gain and sexual dysfunction, common events associated with most antidepressants, are associated with nonadherence and should be monitored and discussed with the patient.

TABLE 68-9 Adverse Drug Reactions and Monitoring Parameters Associated with Select New-Generation Antidepressants

Drug	ADR(s)	Monitoring	Comments
Antidepressants from Each Pharmacologic Class			
Common to all antidepressants			

Drug	ADR(s)	Monitoring	Comments
	Suicidality	Behavioral changes Mental status	(US boxed warning) for all antidepressants; caregivers should be alerted to monitor for acute changes in behavior (especially early in treatment)
Selective Serotonin Reuptake Inhibitors (SSRIs)			
Common to all SSRIs			
	Anxiety or nervousness	Assess severity and impact on patient functioning and quality of life	Most prominent on initial treatment; generally subsides over time as antidepressant causes neurochemical adaptations
	Insomnia	Sleep patterns	Among SSRI class: fluoxetine may be more activating; fluvoxamine and paroxetine may be more sedating
	Nausea	Frequency and severity	
	Serotonin syndrome	Autonomic function (eg, pulse, temperature); neuromuscular function	Criteria include mental status change, clonus, hyperthermia, diaphoresis, and tachycardia
	Sexual dysfunction	Assess severity and impact on patient functioning and quality of life	Spontaneous self-reporting may be low; clinician should assess symptoms; reversible on drug discontinuation
SSRI-Specific			
Citalopram (possibly escitalopram)	QT interval prolongation	Electrocardiogram; electrolytes (eg, potassium, magnesium)	Caution use in "at-risk" patients (eg, electrolyte disturbance); discontinue if QTc persistently >500 milliseconds
Fluoxetine	Anorexia	Weight (over time)	SSRIs are generally considered weight neutral
Fluvoxamine	Somnolence	Mental status	May be less tolerable than other SSRIs
Paroxetine	Anticholinergic effects	Symptoms: dry mouth, constipation, urinary retention, mental status	Paroxetine possesses relatively more anticholinergic effects than other SSRIs
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)			
Common to all SNRIs			

Drug	ADR(s)	Monitoring	Comments
	Cardiovascular changes	Increases in blood pressure; heart rate	Possibly less likely with duloxetine; may need to lower/discontinue dose
	Insomnia	Sleep patterns	Possibly less likely with duloxetine
	Nausea	Frequency and severity	
	Serotonin syndrome	Autonomic function (eg, pulse temperature); neuromuscular function	Criteria include mental status changes, clonus, hyperthermia, diaphoresis, and tachycardia
	Sexual dysfunction	Assess severity and impact on patient functioning and quality of life	Spontaneous self-reporting may be low; clinicians should assess symptoms; reversible on drug discontinuation
SNRI-Specific			
Desvenlafaxine	Dose-related hyperlipidemia	Lipid profile	Elevations in total cholesterol, low-density lipoproteins, and triglycerides
Duloxetine	Orthostatic hypotension	Blood pressure, pulse	Initial treatment or on dose increase
Venlafaxine	Dose-related hypertension	Blood pressure, pulse	May need to lower dose or discontinue
Mixed Serotonergic Effects (Mixed 5-HT)			
Nefazodone	Liver toxicity	Liver function tests	Nefazodone use is extremely limited in the United States due to concerns about liver toxicity
Trazodone	Orthostatic hypotension	Blood pressure, pulse	May be more severe as compared with other antidepressants; rate-limiting side effect
	Priapism	Patient report of sexual side effects, especially painful erection	Patient should seek medical attention for prolonged erection (ie, >4 hours)
Vilazodone	Serotonin syndrome	Autonomic function (eg, pulse temperature); neuromuscular function	Criteria include mental status changes, clonus, hyperthermia, diaphoresis, and tachycardia
Serotonin and α_2-Adrenergic Antagonist			
Mirtazapine	Weight gain	Body weight	Frequently occurring and significant (>7%) weight gain among adults
Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)			

Drug	ADR(s)	Monitoring	Comments
Bupropion	Seizure activity	Electroencephalogram	See text for proper dosing, which can help decrease seizure risk; caution use in patients with eating disorders or alcohol use disorders

Data from references 2, 39, 40, 46, 65.

In addition to the clinical interview, psychometric rating instruments (such as those highlighted earlier in this chapter and in Chapter e62) allow for rapid and reliable measurement of the nature and severity of depressive and associated symptoms. It is helpful to administer the rating scales prior to treatment, 6 to 8 weeks after initiation of therapy, and periodically thereafter. Interviewing a family member or friend (with the patient's permission) regarding symptoms and daily functioning also can assist in assessment of progress. Patients should be monitored at more frequent intervals early in treatment, particularly for suicidality. Monitoring is then continued at regular intervals throughout the continuation and maintenance phases of treatment. Regular monitoring for reemergence of target symptoms should be continued for several months after antidepressant therapy is discontinued.

Finally, one useful set of criteria that can be used with a variety of psychometric scales was suggested by Mann.[34] Following these criteria, the following definitions are used: (a) *nonresponse* is less than 25% decrease in baseline symptoms, (b) *partial response* is a 26% to 49% decrease in baseline symptoms, and (c) *partial remission or response* is greater than a 50% decrease in baseline symptoms. Consistent with other recommendations, *remission* is a return to baseline functioning with no symptoms present.[2]

COLLABORATIVE PRACTICE

Significant evidence exists to show that depression is common and chronic and causes significant morbidity and mortality. Pharmacists, in conjunction with other healthcare providers, can play a crucial role in the screening, recognition, and treatment of this disorder. In fact, the US Preventive Services Task Force recommends screening adults for depression in clinical practices that have systems in place to ensure accurate diagnosis, effective treatment, and followup.[112] In addition, pharmacists and other healthcare clinicians play a crucial role in ensuring adherence to medication regimens through assessment of a patient's willingness and ability to take a medication, including an assessment of financial viability, and through patient education regarding dosing, side effects and drug interactions, and guidance regarding followup appointments with prescribing clinicians.

ACKNOWLEDGMENT

The authors would like to thank Brian Wells, PharmD Candidate, for his thoughtful review and comments on this book chapter.

Chapter 69: Bipolar Disorder

Shannon J. Drayton; Christopher S. Fields

INTRODUCTION

KEY CONCEPTS

- 1 Bipolar disorder is a cyclic mental illness with recurrent mood episodes that occur over a person's lifetime. The symptoms, course, severity, and response to treatment differ among individuals.
- 2 Bipolar disorder is likely caused by genetic factors, environmental triggers, and the dysregulation of neurotransmitters, neurohormones, and second messenger systems in the brain.
- 3 Clinicians should obtain a detailed history, including potential substance use and medical illness, to avoid a delay in the diagnosis and treatment of bipolar disorder.
- 4 The goal of therapy for bipolar disorder should be to improve patient functioning by reducing mood episodes. This is accomplished by maximizing adherence to therapy and limiting adverse effects.
- 5 Patients and family members should be educated about bipolar disorder and treatments. Long-term monitoring and adherence to treatment are major factors in achieving stabilization of the disorder.
- 6 Lithium and valproate are the mainstays of treatment for both acute mania and prophylaxis for recurrent manic and depressive episodes. Anticonvulsants (eg, lamotrigine, carbamazepine) and second-generation antipsychotics (eg, aripiprazole, quetiapine) are alternative or adjunctive treatments for bipolar disorder depending on the phase of illness (ie, mania, depression, maintenance). Anticonvulsants may be more effective than lithium in several mood subtypes (eg, mixed states and rapid cycling). The use of lithium, valproate, or quetiapine for acute bipolar depression should be considered a first-line treatment option.
- 7 Baseline and follow-up laboratory tests are required for most medications for bipolar disorder to monitor for adverse effects.
- 8 Some patients can be stabilized on one mood stabilizer, but others may require combination therapies or adjunctive agents during an acute mood episode. If possible, adjunctive agents should be tapered and discontinued when the acute mood episode remits and the patient is stabilized. Adjunctive agents may include benzodiazepines, additional mood stabilizers, antipsychotics, and/or antidepressants.

1 Bipolar disorder is a common, chronic, and often severe cyclic mood disorder characterized by recurrent fluctuations in mood, energy, and behavior.[1,2,3] It differs from recurrent major depression (or unipolar depression) in that a manic or hypomanic episode occurs during the course of the illness.[1] Bipolar disorder is a lifelong illness with a variable course and requires both nonpharmacologic and pharmacologic treatments for mood stabilization.[1,2]

EPIDEMIOLOGY

The overall prevalence of bipolar disorder was 4.5% in a U.S. comorbidity study: 1% meeting criteria for bipolar I, 1.1% for bipolar II, and 2.4% of patients with subthreshold bipolar disorder (ie, cyclothymia, unspecified bipolar disorder).[4] Symptom onset for depression, mania, or hypomania in bipolar disorder typically occurs in late adolescence or early adulthood, with greater than two-thirds of those affected developing symptoms before age 18 years.[5] Bipolar I disorder occurs equally in men and women, whereas bipolar II disorder is more common in women.[1,2] Depression and mixed presentations may occur more frequently in women.[6,7,8]

ETIOLOGY AND PATHOPHYSIOLOGY

2 The exact etiology of bipolar disorder is unknown. Bipolar disorder is thought to be a complex disease that is influenced by developmental, genetic, neurobiologic, and psychological factors.[9] Many theories have been proposed regarding the pathophysiology of mood disorders. Family, twin, and adoption studies report an increased lifetime prevalence risk of having mood disorders among first-degree relatives of patients with bipolar disorder.[10,11] Genetic linkage studies suggest multiple gene loci can be involved in the heredity of mood disorders.[12,13,14] Neuroimaging studies indicate that several anatomic regions (primarily the anterior paralimbic and adjacent prefrontal regions) may contribute to functional abnormalities in bipolar patients.[15] Many researchers suspect that altered synaptic and circuit functioning accounts for mood and cognitive changes seen in bipolar disorder, rather than dysfunction of individual neurotransmitters.[16] Environmental or psychosocial stressors, immunologic factors, and sleep dysregulation all have been associated with bipolar disorder and can negatively influence the course of illness.[17,18,19,20,21]

CLINICAL PRESENTATION AND DIAGNOSIS

1 The essential feature of bipolar spectrum disorders is a history of mania or hypomania that is not caused by any other medical condition, substance, or psychiatric disorder.[1,2] The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) of the American Psychiatric Association (APA) details the present understanding of mood disorders.[1] Bipolar disorder is divided into five subtypes based on the identification of specific mood episodes: bipolar I, bipolar II, cyclothymic disorder, other specified bipolar and related disorder, and unspecified bipolar and related disorder.[1] **Table 69-1** for a definition of mood disorders by type of episode. Specifiers can be added to bipolar I and II to reflect the most recent mood state (ie, hypomanic or major depressive episode). **Table 69-2** for the evaluation and diagnostic criteria of mood episodes. Bipolar disorder is a cyclic mood disorder, and patients may sequentially experience different types of episodes with or without a period of normal mood (euthymia) between episodes. Individuals with bipolar disorder can have mood fluctuations that continue for months, or after one episode they can sometimes go years without recurrence of any type of mood episode. Comorbid conditions associated with bipolar disorder include, but are not limited to, substance abuse, personality disorders, anxiety disorders, eating disorders, and a higher incidence of several medical conditions.[1,2,3,22,23,24,25,26]

TABLE 69-1 Mood Disorders Defined by Episodes

Disorder Subtype	Episode(s)[a]
Major depressive disorder, single episode	Major depressive episode
Major depressive disorder, recurrent	Two or more major depressive episodes
Bipolar I disorder[b]	Manic episode ± major depressive or hypomanic episode
Bipolar II disorder[c]	Major depressive episode + hypomanic episode
Persistent depressive disorder (Dysthymia)	Depressed mood most days for at least 2 years (1 year in children and adolescents)
Cyclothymic disorder[d]	Chronic fluctuations between subsyndromal depressive and hypomanic episodes (2 years for adults and 1 year for children and adolescents)
Unspecified bipolar and related disorder	Mood states do not meet full criteria for any specific disorder in the bipolar and related disorders class

[a]The length and severity of a mood episode and the interval between episodes vary from patient to patient. Manic episodes are usually shorter and end more abruptly than major depressive episodes. The average length of untreated manic episodes ranges from 4 to 13 months. Episodes can occur regularly (at the same time or season of the year) and often cluster at 12-month intervals. Women have more depressive episodes than manic episodes, whereas men have a more even distribution of episodes.

[b]For bipolar I disorder, 90% of individuals who experience a manic episode later have multiple recurrent major depressive, manic, or hypomanic episodes alternating with a normal mood state.

[c]Approximately 5% to 15% of patients with bipolar II disorder will develop a manic episode over a 5-year period. If a manic episode develops in a patient with bipolar II disorder, the diagnosis is changed to bipolar I disorder.

[d]Patients with cyclothymic disorder have a 15% to 50% risk of later developing a bipolar I or II disorder.

Data from references 1,2,3.

TABLE 69-2 Evaluation and Diagnosis of Mood Episodes

Diagnosis Episode	Impairment of Functioning or Need for Hospitalization[a]	*DSM-5* Criteria[b]
Major depressive	Yes	At least 2 week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms: • Depressed, sad mood (adults); can be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased or increased appetite, weight loss or weight gain • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feelings of excessive guilt or worthlessness • Impaired concentration or indecisiveness • Recurrent thoughts of death, suicidal thoughts or attempts
Manic	Yes	At least 1 week period of abnormally and persistently elevated mood (expansive or irritable) and energy, associated with at least three of the following symptoms (four if the mood is only irritable):

Diagnosis Episode	Impairment of Functioning or Need for Hospitalization[a]	*DSM-5* Criteria[b]
		• Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractibility (poor attention) • Increased goal-directed activity (socially, at work, or sexually) or psychomotor agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Hypomanic	No	At least 4 days of abnormally and persistently elevated mood (expansive or irritable) and energy, associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractibility (poor attention) • Increased goal-directed activity (socially, at work, or sexually) or psychomotor agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)

[a]Impairment in social or occupational functioning; may include need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

[b]The disorder is not caused by a medical condition (eg, hypothyroidism) or substance-induced disorder (eg, antidepressant treatment, medications, drugs of abuse). Numerous specifiers are available to further characterize episodes (eg, with mixed features, with anxious distress, with rapid cycling, with melancholic features).

Data from reference 1.

DIAGNOSTIC DIFFICULTY

Episodes of mania or depression may be induced or caused by medical illness, medications, or substance intoxication or withdrawal (refer to **Table 69-3**[27,28,29,30,31,32,33,34,35,36] for causes of mania and Chapter 68 for causes of depression).[1,2] A complete medical, psychiatric, and medication history; physical examination; and laboratory testing are important tools to rule out any organic causes of mania or depression.[2] An accurate diagnosis is critical because some psychiatric and neurologic disorders present with manic-like or depressive-like symptoms.[2,3] Bipolar disorder commonly co-occurs with substance use disorders and may be difficult to diagnose in the presence of cocaine use or other illicit substances (psychostimulants, bath salts, synthetic marijuana).[37] When making the diagnosis of new-onset bipolar disorder in a geriatric population, clinicians should be particularly aware of secondary causes of mania and depression that may impact treatment.[38]

TABLE 69-3 Secondary Causes of Mania

Medical conditions that induce mania

- CNS disorders (brain tumor, strokes, head injuries, subdural hematoma, multiple sclerosis, systemic lupus erythematosus, temporal lobe seizures, Huntington disease)
- Infections (encephalitis, neurosyphilis, sepsis, human immunodeficiency virus)
- Electrolyte or metabolic abnormalities (calcium or sodium fluctuations, hyperglycemia or hypoglycemia)
- Endocrine or hormonal dysregulation (Addison disease, Cushing disease, hyperthyroidism or hypothyroidism, menstrual-related or pregnancy-related or perimenopausal mood disorders)

Medications or drugs that induce mania

- Alcohol intoxication

- Drug withdrawal states (alcohol, α_2-adrenergic agonists, antidepressants, barbiturates, benzodiazepines, opiates)
- Antidepressants (MAOIs, TCAs, 5-HT and/or NE and/or DA reuptake inhibitors, 5-HT antagonists)
- DA-augmenting agents (CNS stimulants: amphetamines, cocaine, sympathomimetics; DA agonists, releasers, and reuptake inhibitors)
- Hallucinogens (LSD, PCP)
- Marijuana intoxication precipitates psychosis, paranoid thoughts, anxiety, and restlessness
- NE-augmenting agents (α_2-adrenergic antagonists, β-agonists, NE reuptake inhibitors)
- Steroids (anabolic, adrenocorticotropic hormone, corticosteroids)
- Thyroid preparations
- Xanthines (caffeine, theophylline)
- Nonprescription weight loss agents and decongestants (ephedra, pseudoephedrine)
- Herbal products (St. John wort)

Somatic therapies that induce mania

- Bright light therapy
- Deep brain stimulation
- Sleep deprivation

CNS, central nervous system; DA, dopamine; 5-HT, serotonin; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; PCP, phencyclidine; TCA, tricyclic antidepressant.

Data from references 1, 27,28,29,30,31,32,33,34,35,36.

Another disease state that has a similar presentation to bipolar disorder is schizoaffective disorder. This disease is essentially a mix between schizophrenia and bipolar disorder or unipolar depression. Patients with schizoaffective disorder have mood episodes, but the distinguishing factor from bipolar disorder is that these patients experience psychosis between mood episodes during periods of euthymic mood. Clinicians must rely on the longitudinal history provided by collateral historians who know the patient well to determine if the patient is psychotic between mood episodes. It can be difficult for clinicians to obtain a full psychiatric history on patients presenting with manic or psychotic symptoms, thus making schizoaffective disorder difficult to differentiate from bipolar disorder. Schizoaffective disorder is best treated with mood stabilizers and antipsychotics as maintenance therapy.

COURSE OF ILLNESS

3 Bipolar disorder is frequently not recognized or treated for many years because of its fluctuating course and episodic mood states.[2,3] Patients may experience delays ranging from 8 to 13 years after the onset of the index mood episode until initiation of appropriate medications.[39] This delay confers a risk of poor social functioning, increased hospitalizations, and a greater likelihood of lifetime suicide attempts.[40] Onset of illness in early childhood tends to be associated with increased mood episodes, rapid cycling, and comorbid psychiatric conditions as well as a stronger family history of mood disorders.[41] Gender differences may influence a patient's course of illness, tolerability of medication, and response to treatment. Women are more likely to have increased depressive symptoms, older age of onset, better compliance, complex management in pregnancy, and higher association with physical illness such as thyroid abnormalities than men are. In men there may be increased incidence of mania and substance use.[42]

The kindling theory is used to explain why bipolar disorder progresses over one's life and why preventive treatment is imperative. Episodes can become more frequent, severe, and refractory to treatment with aging.[2,43] Usually there is a period of normal functioning between episodes, but approximately 20% to 30% of patients with bipolar I disorder and 15% with bipolar II disorder have no interepisode period of euthymia because of mood lability, residual mood symptoms, or a direct switch to the opposite polarity.[1]

Rapid cycling (more than four mood episodes per year) is more common in women and occurs in approximately 10% to 20% of bipolar I and II disorder patients.[2,3,44] Frequent and severe episodes of depression appear to be the most common hallmark of rapid cycling. Use of alcohol, stimulants, and antidepressants, as well as, sleep deprivation hypothyroidism, and seasonal changes can play a role in rapid cycling.[3,44,45] Seasonal patterns of mania in the summer and depression during the winter have been observed. Rapid-cycling patients have a poorer long-term prognosis and often require combination therapies.[3]

Fluctuations in hormones and neurotransmitters during the luteal phase of the menstrual cycle, postpartum period, and perimenopause (starting ~10 years before menopause) can precipitate mood changes and increase cycling.[1,46] Women with bipolar I disorder are at greater risk for relapse into mania or depression during the postpartum period.[2] If a severe mood episode occurs postpartum, there is an increased risk for recurrences during subsequent postpartum periods.[2]

Alcohol and substance abuse is common among patients with bipolar disorder and can have a significant impact on the age of onset, course of the illness, and response to treatment.[3,22,23] Alcohol and drug abuse or dependence has been reported in 46% and 41% of bipolar patients, respectively.[2,22] Patients

with substance use disorders are more likely to have an earlier onset of their illness, mixed states, higher rates of relapse, a poorer response to treatment, comorbid personality disorders, increased suicide risk, and more psychiatric hospitalizations.[3] Bipolar patients often self-medicate with substances such as alcohol, marijuana, or cocaine during episodes, resulting in further impairment of judgment, poor impulse control, treatment nonadherence, and a worsening of the clinical course.[2,3,47]

More than one half (55%-65%) of bipolar I patients have some degree of functional disability after the onset of their illness, and approximately 10% to 20% of bipolar patients have severe impairment in their psychosocial and occupational functioning.[2,3,48] In a 1-year longitudinal study in 258 bipolar patients, two-thirds had four or more mood episodes a year despite comprehensive pharmacologic treatment, and approximately 33.2% of the year was spent being depressed compared with 10.8% of the time in a manic phase.[48]

Compared with the general population, individuals with bipolar disorder have a 2.3 times higher mortality rate. Suicide attempts occur in up to 50% of patients with bipolar disorder, and approximately 10% to 19% of individuals with bipolar I disorder commit suicide.[1,2,3,49] Studies suggest patients with bipolar II disorder have more suicide attempts than bipolar I patients.[49]

The best predictor for level of functioning during a person's lifetime is adherence with medication treatment. Medication discontinuation occurs in up to 50% of patients secondary to intolerance of drug-induced side effects.[50] Failure to recognize the disorder, reluctance to acknowledge it, or poor adherence with treatment are reasons an estimated two-thirds of patients with bipolar disorder do not receive appropriate treatment. Nonadherence with pharmacologic treatment and substance abuse are major factors in relapse and hospitalizations.[2,3]

TREATMENT

Desired Outcomes

4 The desired outcome in treating bipolar disorder is to effectively resolve acute manic, hypomanic, and depressive episodes, prevent further episodes, maintain good functioning, promote treatment adherence, and minimize side effects.[2,3] The general principles and goals for the management of bipolar disorder are found in **Table 69-4**.

TABLE 69-4 General Principles for the Management of Bipolar Disorder

Goals of treatment

- Eliminate mood episode with complete remission of symptoms (ie, acute treatment)
- Prevent recurrences or relapses of mood episodes (ie, continuation phase treatment)
- Return to baseline psychosocial functioning
- Maximize adherence with therapy
- Minimize adverse effects
- Use medications with the best tolerability and fewest drug interactions
- Treat comorbid substance use and abuse
- Eliminate alcohol, marijuana, cocaine, amphetamines, and hallucinogens
- Minimize nicotine use and stop caffeine intake at least 8 hours prior to bedtime
- Avoidance of stressors or substances that precipitate an acute episode

Monitor for

- Mood episodes: Document symptoms on a daily mood chart (document life stressors, type of episode, length of episode, and treatment outcome); monthly and yearly life charts are valuable for documenting patterns of mood cycles
- Medication adherence (missing doses of medications is a primary reason for nonresponse and recurrence of episodes)
- Adverse effects, especially sedation and weight gain (manage rapidly and vigorously to avoid noncompliance)
- Suicidal ideation or attempts (suicide completion rates with bipolar I disorder are 10%-15%; suicide attempts are primarily associated with depressive episodes, mixed episodes with severe depression, or presence of psychosis)

Data from references 2, 22, and 51.

General Approach to Treatment

5 Treatment of bipolar disorder must be individualized because the clinical presentation, severity, and frequency of episodes vary widely among patients. Treatment approaches should include both nonpharmacologic and pharmacologic strategies.[3] Patients and family members should be educated about bipolar disorder (eg, symptoms, causes, and course) and treatment options. Long-term adherence to treatment is the most important factor in achieving stabilization of the disorder.

The treatment of bipolar disorder can vary depending on what type of episode the patient is experiencing. Once diagnosed with bipolar disorder, patients should remain on a mood stabilizer (eg, lithium, valproate) for their lifetime. During acute episodes, medications can be added and then tapered once the patient is stabilized and euthymic. For example, when treating a patient for mania with psychotic features, the patient should be on a mood stabilizer and an antipsychotic. If the antipsychotic is the patient's maintenance therapy, the dose should be increased or perhaps the medication should be changed altogether if the patient goes into a manic episode. If treating a patient for a severe depressive episode, a clinician may need to maximize the dose of the mood stabilizer or add another medication (eg, quetiapine).

Nonpharmacologic Therapy

The basics of nonpharmacologic approaches should address issues of adequate nutrition, sleep, exercise, and stress reduction.[3] Sleep deprivation, high stress, and deficiencies in dietary essential amino acids, fatty acids, vitamins, and minerals can exacerbate mood episodes and result in poorer outcomes.[3] Mood charting is an effective strategy in detecting early signs and symptoms of mania and depression. Another effective treatment is to combine medications with adjunctive psychoeducational programs, supportive counseling, insight-oriented psychotherapy (individual or group), couples or family therapy, cognitive behavioral therapy, and communication enhancement training.[2,3,22,51]

Pharmacologic Therapy

Pharmacotherapy is crucial for the acute and maintenance treatment of bipolar disorder and includes lithium, valproate, carbamazepine, lamotrigine, first-generation antipsychotics (FGAs) a second-generation antipsychotics (SGAs), and adjunctive agents such as antidepressants and benzodiazepines. General treatment guidelines for the acute treatment of mood episodes in patients with bipolar I disorder are found in **Table 69-5**.[52-53]

TABLE 69-5 Algorithm and Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder

Acute Manic or Mixed Episode		Acute Depressive Episode	
General Guidelines		**General Guidelines**	
Assess for secondary causes of mania or mixed states (eg, alcohol or drug use)		Assess for secondary causes of depression (eg, alcohol or drug use)	
Discontinue antidepressants		Taper off antipsychotics, benzodiazepines, or sedative–hypnotic agents if possible	
Taper off stimulants and caffeine if possible		Treat substance abuse	
Treat substance abuse		Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy	
Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy			
Hypomania	**Mania**	**Mild to Moderate Depressive Episode**	**Severe Depressive Episode**
First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium,[a] valproate,[a] carbamazepine,[a] or SGAs	**First**, two- or three-drug combinations (lithium,[a] valproate,[a] or SGA) **plus** a benzodiazepine (lorazepam or clonazepam) and/or antipsychotic for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia	**First**, initiate and/or optimize mood-stabilizing medication: lithium,[a] quetiapine, lurasidone	**First**, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium[a] or quetiapine or lurasidone
Consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed	Do not combine antipsychotics	Alternative anticonvulsants: lamotrigine,[b] valproate[a]; antipsychotics: fluoxetine/olanzapine combination	Alternative fluoxetine/olanzapine combination
Alternative medication treatment options: oxcarbazepine	Alternative medication treatment options: carbamazepine[a]; if patient does not respond or tolerate, consider oxcarbazepine		If psychosis is present, initiate an antipsychotic in combination with above
Second, if response is inadequate, consider a two-drug combination:	**Second**, if response is inadequate, consider a three-drug combination:		Do not combine antipsychotics
Lithium[a] **plus** an anticonvulsant or an SGA	Lithium[a] **plus** an anticonvulsant **plus** an antipsychotic		Alternative anticonvulsants: lamotrigine,[b] valproate[a]
Anticonvulsant **plus** an anticonvulsant or SGA	Anticonvulsant **plus** an anticonvulsant **plus** an antipsychotic		**Second**, if response is inadequate, consider carbamazepine[a] or adding antidepressant
	Third, if response is inadequate, consider ECT for mania with psychosis or catatonia,[d] or add clozapine for treatment-refractory illness		**Third**, if response is inadequate, consider a three-drug combination:
			Lithium **plus** lamotrigine[b] **plus** an antidepressant
			Lithium **plus** quetiapine **plus** antidepressant[c]
			Fourth, if response is inadequate, consider ECT for treatment-refractory illness and depression

Acute Manic or Mixed Episode

General Guidelines

Acute Depressive Episode

General Guidelines

with psychosis or catatonia[d]

ECT, electroconvulsive therapy; SGA, second-generation antipsychotic.

[a]Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

[b]Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy of bipolar I disorder. Lamotrigine may be initiated during acute treatment with plans to transition to this medication for long-term maintenance. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (ie, lamotrigine doses must be halved from standard dosing titration).

[c]Controversy exists concerning the use of antidepressants, and they are often considered third line in treating acute bipolar depression, except in patients with no recent history of severe acute mania or potentially in bipolar II patients.

[d]ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

Data from references 2, 52, and 53.

Product information, dosing, and administration of agents used in the treatment of bipolar disorder are found in **Table 69-6**.

TABLE 69-6 Products, Dosage and Administration, and Clinical Use of Agents Used in the Treatment of Bipolar Disorder

Drug "Brand name"	Initial Dosing	Usual Dosing; Special Population Dosing	Comments
Lithium salts: FDA-approved for bipolar disorder			
Lithium carbonate[a,b] "Eskalith" "Eskalith CR" "Lithobid" Lithium citrate[a,b] "Cibalith-S"	300 mg twice daily	900-2,400 mg/day in two to four divided doses, preferably with meals Renal impairment: lower doses required with frequent serum monitoring There is wide variation in the dosage needed to achieve therapeutic response and trough serum lithium concentration (ie, 0.6-1.2 mEq/L [mmol/L] for maintenance therapy and 0.8-1.2 mEq/L [mmol/L] for acute mood episodes taken 12 hours after the last dose)	Use alone or in combination with other medications (eg, valproate, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment
Anticonvulsants: FDA-approved for bipolar disorder			
Divalproex sodium[a] "Depakote" "Depakote ER" Valproic acid[a] "Stavzor"	250-500 mg twice daily A loading dose of divalproex (20-30 mg/kg/day) can be given	750-3,000 mg/day (20-60 mg/kg/day) given once daily or in divided doses Titrate to clinical response Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment Use caution when combining with lamotrigine because of potential drug interaction
Lamotrigine[b] "Lamictal"	25 mg daily	50-400 mg/day in divided doses. Dosage should be slowly increased (eg, 25 mg/day for 2 weeks, then 50 mg/day for weeks 3 and 4, and then 50-mg/day increments at weekly intervals up to 200 mg/day) Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, carbamazepine) for long-term maintenance treatment for bipolar I disorder
Carbamazepine "Equetro[a]"	200 mg twice daily	200-1,800 mg/day in two to four divided doses Titrate to clinical response Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, valproate, antipsychotics) for the acute and long-term maintenance treatment of mania or mixed episodes for bipolar I disorder. APA guidelines recommend reserving it for patients unable to tolerate or who have inadequate response to lithium or valproate Extended-release tablets should be swallowed whole and not be broken or chewed

Drug	Initial Dosing	Usual Dosing; Special Population Dosing	Comments
Anticonvulsants: not FDA-approved for bipolar disorder			
Carbamazepine			
"Tegretol"		200-1,800 mg/day in two to four divided doses	
"Epitol"	200 mg twice daily	Titrate to clinical response	"Carbatrol" capsules can be opened and contents sprinkled over food
"Tegretol-XR"		Dose adjustment needed with hepatic impairment	
"Carbatrol"			
Valproic acid	250-500 mg twice daily	750-3,000 mg/day (20-60 mg/kg/day) given once daily or in divided doses	
"Depakene"	A loading dose of divalproex (20-30 mg/kg/day) can be given	Titrate to clinical response	Use caution when combining with lamotrigine because of potential drug interaction
Valproate sodium		Dose adjustment needed with hepatic impairment	
"Depacon"			
Oxcarbazepine	300 mg twice daily	300-1,200 mg/day in two divided doses	Use after patients have failed treatment with carbamazepine or have intolerable side effects
"Trileptal"		Titrate based on clinical response	
		Dose adjustment required with severe renal impairment	May have fewer adverse effects and be better tolerated than carbamazepine
Atypical antipsychotics: FDA-approved for bipolar disorder			
Aripiprazole[a,b]			
"Abilify"			
Asenapine[a]			
"Saphris"			
Cariprazine[a]			
"Vraylar"			
Lurasidone[c]	10-15 mg daily	10-30 mg/day once daily	
"Latuda"	5-10 mg twice daily sublingually	5-10 mg twice daily sublingually	
Olanzapine[a,b]	1.5 mg daily	3-6 mg daily	
"Zyprexa"	20 mg daily	20-120 mg daily with food	
"Zyprexa Zydis"	2.5-5 mg twice daily	5-20 mg/day once daily or in divided doses	
Olanzapine and fluoxetine[c]	6 mg olanzapine and 25 mg fluoxetine daily	6-12 mg olanzapine and 25-50 mg fluoxetine daily	
"Symbyax"	50 mg twice daily	50-800 mg/day in divided doses or once daily when stabilized	
Quetiapine[a,c]	0.5-1 mg twice daily	0.5-6 mg/day once daily or in divided doses	
"Seroquel"	40-60 mg twice daily	40-160 mg/day in divided doses	
Risperidone[a]			
"Risperdal"			
"Risperdal M-Tab"			
Ziprasidone[a]			
"Geodon"			
Benzodiazepines	Dosage should be slowly adjusted up and down according to response and adverse effects		Use in combination with other medications (eg, antipsychotics, lithium, valproate) for the acute treatment of mania or mixed episodes Use as a short-term adjunctive sedative–hypnotic agent

FDA-approved agents may be used as monotherapy in various phases of the illness as noted in table footnotes.[a,b,c]

[a]FDA-approved for acute mania.

[b]FDA-approved for maintenance.

[c]FDA-approved for acute bipolar depression.

Data from references 2, 3, 22, and 53.

6 The term *mood stabilizer* is often used to describe the class of medications used in the treatment of bipolar disorder, but this may not be accurate, as some medications are more effective for acute mania, some for the depressive episode, and others for the maintenance phase.[54] Lithium, valproate (or divalproex sodium), extended-release carbamazepine, aripiprazole, asenapine, cariprazine, olanzapine, quetiapine, risperidone, and ziprasidone are currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of acute mania in bipolar disorder; only lithium, aripiprazole, olanzapine, and lamotrigine are approved for the maintenance treatment of bipolar disorder. Quetiapine and lurasidone are the only FDA-approved monotherapy antipsychotics for bipolar depression.

Combination therapies (eg, lithium plus valproate or carbamazepine; lithium or valproate plus an SGA) can provide better acute response and long-term prevention of relapse and recurrence than monotherapy in some bipolar patients.[55] The majority of patients hospitalized for an acute episode will be on combination therapy.

Several guidelines and algorithms have been published regarding the treatment of bipolar disorder, and these are generally based on the best available data and clinical consensus of experts. The Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders (ISBD) published updated treatment guidelines in 2013.[53] In addition, an international task force of the World Federation of Societies of Biological Psychiatry (WFSBP) has published guidelines for the treatment of bipolar disorder. The WFSBP mania, depression, and maintenance guidelines were updated in 2009, 2010, and 2013, respectively.[56,57,58]

Based on the CANMAT and ISBD guidelines and available research, an example treatment algorithm and guidelines for acute mood episodes in adult patients with bipolar I disorder are listed in Table 69-5. Selection of treatments for acute mood episodes (eg, mania, depression) and for maintenance treatment should be individualized. Treatment plans should be based on patient-specific characteristics, comorbid psychiatric and medical conditions, consideration of drug interactions, and avoidance of adverse effects.[2]

Specific Pharmacologic Therapies

Lithium

Lithium was first used in 1949 as a treatment for mania and was approved in 1972 in the United States for the treatment of acute mania and for maintenance therapy. Despite numerous investigations into the biologic and clinical properties of lithium, there is no unified theory for its mechanism of action.[22,59] Chronic lithium administration may modulate gene expression and have neuroprotective effects. Lithium has unique pharmacokinetics because it is a monovalent cation. It is rapidly absorbed, is widely distributed with no protein binding, is not metabolized, and is excreted unchanged in the urine and in other body fluids.[60]

Efficacy

Lithium is considered a first-line agent for acute mania, acute bipolar depression, and maintenance treatment of bipolar I and II disorders.[53] Early placebo-controlled studies with lithium reported up to a 78% response rate in aborting an acute manic or hypomanic episode, but more recent studies suggest a slower onset of action and a more moderate effectiveness when compared with other agents.[61] In placebo-controlled studies in bipolar depression, lithium has been found to have efficacy, but there can be a 6- to 8-week delay for its antidepressant effects.[61] Lithium's role in the maintenance phase of bipolar disorder in preventing mania and depressive episodes is supported by numerous studies.[61] Lithium also produces a prophylactic response of reducing suicide in patients with bipolar disorder.[62] Relapse can be reduced with the combination of lithium and other medications such as divalproex sodium, carbamazepine, lamotrigine, and antipsychotics.[61] Abrupt discontinuation or noncompliance with lithium therapy can increase the risk of relapse.[61]

Adverse Effects

Adverse effects related to lithium use can be divided into those that occur early in therapy but are generally innocuous and transient, those that are not dose-related occurring with long-term treatment, and toxic effects that occur with high serum concentrations.[60]

Initial gastrointestinal (GI) and central nervous system (CNS) side effects are often dose-related and are worse at peak serum concentrations (1-2 hours postdose). Standard approaches for minimizing adverse effects include lowering the dose, taking doses with food, using extended-release products, and trying once-daily dosing at bedtime. Diarrhea can sometimes be managed by switching from tablet or capsule formulation to liquid formulation. Diarrhea produced by lithium is commonly an osmotic diarrhea, and therefore switching to a formulation that clears the gut quickly can ameliorate symptoms. Muscle weakness and lethargy develop in about 40% to 50% of patients,[60] but these symptoms are usually transient. A benign fine hand tremor can be evident in up to 45% to 50% of patients and will usually resolve with continued treatment.[60] Strategies to reduce the tremor include standard approaches (eg, switch to long-acting preparation, lower dose if possible) or adding a β-adrenergic antagonist (eg, propranolol 20-120 mg/day).[60]

Polydipsia with polyuria associated with or without nephrogenic diabetes insipidus (DI) can occur in patients treated with lithium. About 30% to 50% of patients will develop nephrogenic DI soon after initiation of lithium treatment.[60] Nephrogenic DI will persist in about 10% to 25% of patients on continued treatment and typically is reversible with discontinuation of lithium.[60] Other nonspecific renal effects may be seen with lithium treatment, but no causality has been established for many of these findings.[60]

Hypothyroidism can occur in 1% to 4% of patients treated with lithium and does not require discontinuation of lithium.[60] Supplemental exogenous thyroid hormone (ie, levothyroxine) can be added to the patients' regimen. If lithium is discontinued, the need for the exogenous thyroid hormone should be reassessed, because hypothyroidism can be reversible.

Lithium can cause a variety of benign and reversible cardiac effects, particularly T-wave flattening or inversion (in up to 30% of patients), atrioventricular block, and bradycardia.[60] If a patient has significant preexisting cardiac disease, consultation with a cardiologist and an electrocardiogram (ECG) is recommended at baseline and during lithium therapy.

Other adverse effects associated with the use of lithium include: acne and folliculitis (1%), reversible leukocytosis, and weight gain.[60] Weight gain is common (~20% of patients gain greater than 10 kg [22 lb]) and can be related to fluid retention, the consumption of high-calorie beverages as a result of polydipsia, or a decreased metabolic rate because of hypothyroidism.[22,63]

Lithium is an extremely toxic medication if accidentally or intentionally taken in overdose. Lithium toxicity usually occurs with blood levels greater than 1.5 mEq/L (mmol/L), but elderly patients may experience toxicity at lower levels.[2] Severe lithium intoxication occurs when concentrations are higher than 2 mEq/L (mmol/L), and there is a worsening in several key symptoms: *GI* (eg, vomiting, diarrhea, or incontinence), *coordination* (eg, severe fine to coarse hand tremor, unstable gait, slurred speech, and muscle twitching), and *cognition* (eg, poor concentration, drowsiness, disorientation, apathy, and coma).[2] There have been several reports of seizures, cardiac dysrhythmias, permanent neurologic impairments with ataxia and memory deficits, and kidney damage with reduced glomerular filtration rate after lithium intoxication.[2]

Situations that predispose patients to lithium toxicity include sodium restriction, dehydration, vomiting, diarrhea, age greater than 50, heart failure, cirrhosis, and drug interactions that decrease lithium clearance. Heavy exercise, sauna baths, hot weather, and fever can promote sodium loss. Patients should be cautioned to maintain adequate sodium and fluid intake (2.5-3 qt [~2.5-3 L] per day of fluids) and to avoid the excessive use of coffee, tea, cola, and other caffeine-containing beverages and alcohol.

If lithium toxicity is suspected, the person should go to an emergency room to be monitored, and lithium should be discontinued.[2] Gastric lavage and IV fluids may be needed, and the patient should be monitored for fluid balance, renal and electrolyte status, and neurologic changes. Under the following circumstances clinicians should consider hemodialysis and continue until the lithium concentration is below 1 mEq/L (mmol/L) when taken 8 hours after the last dialysis: in lithium-naïve patients when lithium concentrations equal or exceed 4 mEq/L (mmol/L) regardless of clinical status, in patients previously taking lithium when lithium concentrations are 2.5 mEq/L (mmol/L) or greater and moderate-to-severe neurologic toxicity, or as clinically indicated.[60]

Drug–Drug Interactions

Thiazide diuretics, nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, angiotensin-converting enzyme inhibitors, and salt-restricted diets can elevate lithium levels.[60] Neurotoxicity can occur when lithium is combined with antipsychotics, metronidazole, methyldopa, phenytoin, and verapamil.[2,60] Combining lithium with calcium channel blockers is not recommended because of reports of decreased lithium levels and neurotoxicity.[60] Analgesics such as acetaminophen or aspirin and loop diuretics are less likely to interfere with lithium clearance. Caffeine and theophylline can enhance the renal elimination of lithium. Because lithium has no effect on hepatic metabolizing enzymes, it has fewer drug–drug interactions compared with carbamazepine, oxcarbazepine, and valproate.

Dosing and Administration

Lithium dosing depends on the patient's age and weight, tolerance to adverse effects, and the acuity of the illness. Lithium therapy is usually initiated with low to moderate doses (600 mg/day) for prophylaxis and higher doses (900-1,200 mg/day) for acute mania, using a two- to three-times daily dosing regimen.[2,60] The dose should be adjusted based on the steady-state serum concentration and clinical picture of the patient. Immediate-release lithium preparations should be given in two or three divided daily doses, whereas extended-release products can be given once or twice daily. In clinical practice many clinicians dose the immediate-release and extended-release preparations once daily. It can be best to initially begin a patient on divided dosing, but once stabilized many patients are able to switch to once-daily dosing without decompensating.

Lithium levels should be monitored for efficacy and to guide dosing. In general, lithium serum concentrations should be maintained between 0.6 and 1.0 mEq/L (mmol/L).[61] Lithium levels are considered to be at steady state at approximately day 5, and serum samples should be drawn 12 hours postdose. Once a desired serum concentration has been achieved, levels should be drawn in 2 weeks and then if stable every 3 to 6 months or as clinically indicated. Maintenance lithium serum concentrations are usually measured every 3 months, but can be adjusted to every 6 months for stabilized patients, and every 1 to 2 months for patients with frequent mood episodes.[2] Lithium clearance rates increase by 50% to 100% during pregnancy and return to normal postpartum; thus, lithium levels should be determined monthly during pregnancy and weekly the month before delivery. At delivery, rapid fluid changes can significantly increase lithium levels; thus, a reduction to prepregnancy lithium doses and adequate hydration are recommended.[2]

The recommended guidelines for baseline and routine laboratory testing for lithium are listed in **Table 69-7**.[65,66,67,68] A therapeutic trial for outpatients should last a minimum of 4 to 6 weeks with lithium serum concentrations of 0.6 to 1.2 mEq/L (mmol/L). Acutely manic patients can require serum concentrations of 1 to 1.2 mEq/L (mmol/L), and some need up to 1.5 mEq/L (mmol/L) to achieve a therapeutic response. Although serum concentrations less than 0.6 mEq/L (mmol/L) may be associated with higher rates of relapse, some patients can do well at 0.4 to 0.7 mEq/L (mmol/L).[61] For bipolar prophylaxis in elderly patients, serum concentrations of 0.4 to 0.6 mEq/L (mmol/L) are recommended because of increased sensitivity to adverse effects.[60]

TABLE 69-7 Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Patients with Bipolar Disorder Taking Mood Stabilizers

Baseline: Physical Examination and General Chemistry[a]	Hematologic Tests[b]	Metabolic Tests[c]	Liver Function Tests[d]	Renal Function Tests[e]	Thyroid Function Tests[f]	Serum Electrolytes[g]	Dermatologic[h]

	Baseline	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months
SGAs[i]	X			X	X										
Carbamazepine[j]	X	X	X			X	X	X				X	X	X	X
Lamotrigine[k]	X													X	X
Lithium[l]	X	X	X	X	X			X	X	X	X	X	X	X	X
Oxcarbazepine[m]	X											X	X		
Valproate[n]	X	X	X	X	X	X	X							X	X

SGAs, second-generation antipsychotics.

[a]Screen for drug abuse and serum pregnancy.

[b]Complete blood cell count (CBC) with differential and platelets.

[c]Fasting glucose, serum lipids, and weight.

[d]Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, and alkaline phosphatase.

[e]Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, and specific gravity.

[f]Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.

[g]Serum sodium.

[h]Rashes, hair thinning, and alopecia.

[i]Second-generation antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.

[j]Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (eg, CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, and then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are <100,000/mm^3 (<100 × 10^9/L), if white blood cell (WBC) count is <3,000/mm^3 (<3 × 10^9/L), or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.

[k]Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2 to 8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.

[l]Lithium: Obtain baseline electrocardiogram for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2 to 3 months during the first 6 months, and then every 6 to 12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume >3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, and then every 6 to 12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1 to 2 months until thyroid function indices are within normal range, and then monitor every 3 to 6 months.

[m]Oxcarbazepine: Hyponatremia (serum sodium concentrations <125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (eg, diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (eg, confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25% to 30% of patients with a history of carbamazepine hypersensitivity and require immediate discontinuation.

[n]Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3 to 6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are <100,000/mm^3/L (<100 × 10^9/L) or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

Anticonvulsants

Divalproex sodium (also known as sodium valproate) was marketed in 1995, for the acute treatment of mania in adults and is now the most prescribed mood stabilizer in the United States. It is FDA-approved only for the treatment of acute manic or mixed episodes; however, it is commonly used in clinical practice as maintenance monotherapy for bipolar disorder. Limited data support its use in acute bipolar depression. Carbamazepine is commonly used for both acute and maintenance therapy. The only formulation approved in the United States for bipolar disorder is extended-release carbamazepine, although other

formulations can be used. Some data support the use of oxcarbazepine, a 10-keto analogue of carbamazepine, in the treatment of bipolar disorder; however, it is not approved for the treatment of bipolar disorder in the United States. Valproate, carbamazepine, and oxcarbazepine all have a wide range of neurologic, GI, electrolyte, and hematologic adverse effects that require regular assessment and routine blood work. Lamotrigine is FDA-approved for the maintenance treatment of bipolar I disorder. This medication appears to be most effective in the prevention of relapse of depression and does not appear to have efficacy for treatment of acute depression or mania.[69]

Valproate Sodium and Valproic Acid

Valproate has antimigraine, mood-stabilizing, and antiaggressive effects.[64] In 1995, the enteric-coated formulation divalproex sodium (sodium valproate) was approved for the acute treatment of mania. Several controlled studies have shown valproate to be as effective as lithium and olanzapine in patients with pure mania, and it can be more effective than lithium in certain subtypes of bipolar disorder (eg, rapid cycling, mixed features, comorbid substance abuse).[2,3,22,44,70] Placebo- and lithium-controlled and open studies report that valproate reduces or prevents recurrent manic, depressive, and mixed episodes.[2,3,22]

Giving lithium, carbamazepine, antipsychotics, or benzodiazepines with valproate can augment its antimanic effects. The addition of valproate to lithium can have synergistic effects in patients who are treatment-refractory and have specifiers of rapid cycling or mixed features, and the combination has demonstrated efficacy in maintenance therapy for bipolar I disorder. Combinations of valproate and carbamazepine can have synergistic effects, but the potential drug interactions make blood level monitoring of both agents essential.[22] Adding adjunctive SGAs to valproate can be effective for breakthrough mania or if there is incomplete or partial response to monotherapy. Clozapine, olanzapine, and quetiapine can increase the risk of sedation and weight gain when combined with valproate. The combination of valproate and lamotrigine can be effective, but there is an increased risk of rashes, ataxia, tremor, sedation, and fatigue.[64]

Adverse Effects

The most frequent dose-related adverse effects with valproate are GI complaints (anorexia, nausea, indigestion, vomiting, mild diarrhea, and flatulence), fine hand tremors, and sedation.[2,22,64] The GI complaints are usually transient, but giving the medication with food, using lower initial doses with gradual increases in doses, or switching to divalproex sodium extended-release tablets can minimize them.[2,22] Reduction of the dose or the addition of a β-blocker can alleviate tremors, and giving the total daily dose at bedtime can minimize daytime sedation.[2,22]

Other adverse effects of valproate include ataxia, lethargy, alopecia, changes in the texture or color of hair, pruritus, prolonged bleeding because of inhibition of platelet aggregation, transient increases in liver enzymes, and hyperammonemia.[22,64] Increased appetite and weight gain occurs in approximately 50% of patients on long-term valproate therapy. Thrombocytopenia can occur at higher doses, and patients should be monitored for bleeding and bruising. Lowering the valproate dose can restore platelet counts to normal levels.[2] Fatal necrotizing hepatitis is a rare idiosyncratic, non–dose-related adverse effect that has occurred in children with epilepsy receiving multiple anticonvulsants.[22,64] A life-threatening hemorrhagic pancreatitis has been reported in both children and adults.[2,22,64] An in-depth discussion of adverse effects can be found in Chapter 56.

Drug–Drug Interactions

A summary of drug–drug interactions for valproate can be found in Chapter 56.

Dosing and Administration

For healthy inpatient adults with acute mania, the initial starting dosage of valproate is typically 20 mg/kg/day in divided doses over 12 hours. The daily dose is adjusted by 250 to 500 mg every 1 to 3 days based on clinical response and tolerability. Maximum recommended dosing is 60 mg/kg/day (see Table 69-6).[2,22,64] For outpatients who are hypomanic or euthymic, or for elderly patients, the initial starting dose is generally lower (5-10 mg/kg/day in divided doses) and gradually titrated to avoid adverse effects. Once an optimal dose has been achieved, the total daily dose can be divided into two doses or given at bedtime if tolerated.[2,22,64] Extended-release divalproex can be administered once daily, but bioavailability can be 15% lower than that of immediate-release products, thus requiring slightly higher doses.[2] In clinical practice, patients with bipolar disorder who are stable can be switched between formulations without having to change the dose. This is not the case for patients with seizure disorder.

Recommended baseline and routine laboratory tests for patients taking valproate are listed in Table 69-7. Although therapeutic serum concentrations of valproic acid have not been established in bipolar disorder, most clinicians use the anticonvulsant therapeutic serum range of 50 to 125 µg/mL (347-866 µmol/L) taken 12 hours after the last dose.[2,22] In one study patients with valproate levels greater than 94.1 µg/mL (652 µmol/L) had greater efficacy for bipolar mania.[71] Patients with cyclothymia or mild bipolar II disorder can have a therapeutic response to lower doses and blood levels, whereas some patients with a more severe form of bipolar disorder can require up to 150 µg/mL (1,040 µmol/L). Serum valproic acid levels are most useful when assessing for compliance and toxicity.

Carbamazepine

Carbamazepine, a iminostilbene derivative, is structurally related to tricyclic antidepressants (TCAs).[65] Carbamazepine is not a first-line agent for bipolar disorder, and is generally reserved for use after treatment failure with lithium or divalproex sodium. Carbamazepine is effective for the treatment of mania, but its use is generally reserved due to drug interactions.[56] Data supporting the use of carbamazepine for bipolar depression are lacking and are not strong for the use of carbamazepine in maintanence treatment.[57,58] The combination of carbamazepine with lithium, valproate, and antipsychotics is often used for treatment-resistant patients experiencing a manic episode.[22]

Adverse Effects

A summary of adverse effects for carbamazepine can be found in Chapter 56. Acute overdoses of carbamazepine are potentially lethal, and serum levels

above 15 µg/mL (63 µmol/L) are associated with ataxia, choreiform movements, diplopia, nystagmus, cardiac conduction changes, seizures, and coma.[2] Gastric lavage, emesis, ECG, and symptomatic treatment are recommended for the management of carbamazepine toxicity.[65]

Drug–Drug Interactions

There are numerous drug-drug interactions that clinicians must consider when prescribing carbamazepine. Carbamazepine significantly induces the hepatic cytochrome P450 isoenzyme 3A4 and to a lesser degree 1A2, 2C9/10, and 2D6, which increases the metabolism of many medications (eg, quetiapine, aripiprazole).[2,3,65] Women taking oral contraceptives who receive carbamazepine should be counseled to use a nonhormonal method of birth control.[65]

Carbamazepine is metabolized to an active 10,11-epoxide metabolite; thus, medications that inhibit 3A4 isoenzymes can result in carbamazepine toxicity (eg, diltiazem, fluconazole, ketoconazole, nefazodone, verapamil).[2,3,22,65] When carbamazepine is combined with valproate, the carbamazepine dose should be reduced because valproate displaces carbamazepine from protein-binding sites, thus increasing free levels.[3,22] Combining clozapine and carbamazepine is not recommended because of decreased clozapine concentrations and the possibility of bone marrow suppression with both agents.[65]

Dosing and Administration

During an acute manic episode in most hospitalized patients, carbamazepine can be started at 400 to 600 mg/day in divided doses with meals and increased by 200 mg/day every 2 to 4 days up to 10 to 15 mg/kg/day. In outpatients the initial dose of carbamazepine should be lower and titrated gradually in order to avoid adverse effects. In clinical practice many patients are able to tolerate once-daily dosing of carbamazepine once their mood episode has stabilized. The dose of carbamazepine should be gradually increased until response is achieved or there is evidence of toxicity. During the first month of therapy, serum concentrations of carbamazepine may be affected due to autoinduction of cytochrome P450 3A4 enzymes.[65]

Carbamazepine serum levels are usually obtained every 1 to 2 weeks during the first 2 months, and then every 3 to 6 months during maintenance therapy. Serum levels should be drawn 10 to 12 hours after the dose (trough levels) and at least 4 to 7 days after a dosage change. Although there is no correlation between carbamazepine serum concentration and degree of antimanic or antidepressant response, most clinicians attempt to maintain levels between 6 and 10 µg/mL (25 and 42 µmol/L) (although some treatment-resistant patients can require serum concentrations of 12-14 µg/mL [51-59 µmol/L]). Recommended baseline and routine laboratory tests for carbamazepine are listed in Table 69-7.

Oxcarbazepine

There are currently less data supporting the use of oxcarbazepine than carbamazepine in the treatment of bipolar disorder. Guidelines typically recommend oxcarbazepine as a third-line treatment option for bipolar mania, as a third- or fourth-line treatment option for maintenance treatment, and it is not recommended for the treatment of bipolar depression.[53]

Adverse Effects

Severe dermatologic reactions (eg, Stevens-Johnson syndrome) have been reported at 3 to 10 times the rate of the general population, therefore oxcarbazepine should be discontinued at the first sign of a skin reaction.[66] Other adverse effects may include impaired cognitive or psychomotor performance, somnolence or fatigue, and coordination difficulties.[66] In one study, hyponatremia was reported to occur in patients taking oxcarbazepine and carbamazepine at rates of 29.9% and 13.5%, respectively.[72] Severe hyponatremia (sodium ≤128 mEq/L [mmol/L]) was reported by Dong et al. as 12.4% and 2.8% of patients for oxcarbazepine and carbamazepine, respectively.[72] An in-depth discussion of adverse effects can be found in Chapter 56.

Drug–Drug Interactions

Oxcarbazepine, a cytochrome P450 2C19 enzyme inhibitor and a 3A3/4 enzyme inducer, has the potential for causing drug interactions.[66] It induces the metabolism of oral contraceptives; thus, alternative contraceptive measures are required.[3,73]

Dosing and Administration

Initial dosing is usually 150 to 300 mg twice daily, and daily doses can be increased by 300 to 600 mg every 3 to 6 days up to 1,200 mg/day in divided doses (with or without food).[66]

Lamotrigine

The effectiveness of lamotrigine for the maintenance treatment of bipolar I disorder in adult patients was established in two multicenter, double-blind, placebo-controlled studies.[2] Doses of 200 mg/day were more effective than lower doses, and there were no advantages to using 400 mg/day. Lamotrigine has mood-stabilizing effects; it may have augmenting properties when combined with lithium or valproate, and has low rates of switching patients to mania.[74] Although lamotrigine is not effective for acute mania compared with standard mood stabilizers, it may be beneficial as maintenance therapy of treatment-resistant bipolar I and II disorders.[2,3,58] Lamotrigine seems to be most effective for the prevention of bipolar depression; therefore, clinically it is often used in the treatment of patients with bipolar II. There are case reports of possible lamotrigine-induced mania when added to lithium, carbamazepine, and valproate.[75] In each of the cases reported, the patients had depressive mood symptoms or rapid mood changes requiring additional therapy.[75]

Adverse Effects

Common adverse effects include headache, nausea, dizziness, ataxia, diplopia, drowsiness, tremor, rash, and pruritus.[67] Approximately 10% of patients in premarketing clinical trials developed a maculopapular rash and required discontinuation of therapy.[67] Although most rashes are self-limiting and resolve with continued treatment, some cases progressed to life-threatening conditions such as Stevens-Johnson syndrome. The incidence of rash appears to be greatest with coadministration of valproate, with higher than recommended initial doses, and with rapid dose escalation.[67] Patients should be warned about the rash, and the need for discontinuing lamotrigine if the rash is diffuse, involves mucosal membranes, and is accompanied by a fever or sore throat. For an

in-depth discussion of the adverse effects of lamotrigine, see Chapter 56.

Drug–Drug Interactions

Valproate decreases the clearance of lamotrigine (ie, more than doubles the half-life), and lamotrigine must be administered at a reduced dosage (approximately half the standard dose).[67] For an in-depth discussion of drug–drug interactions with lamotrigine, see Chapter 56.

Dosing and Administration

For the maintenance treatment of bipolar disorder, the usual dosage range of lamotrigine is 50 to 300 mg/day. The target dose is generally 200 mg/day (100 mg/day in combination with valproate and 400 mg/day in combination with carbamazepine).[67] For patients not taking medications that affect lamotrigine's clearance, the dose is 25 mg/day for the first 2 weeks of therapy, 50 mg/day for weeks 3 and 4, 100 mg/day for week 5, and 200 mg/day for week 6 and beyond.[2,67] Patients who stop lamotrigine therapy for more than a few days should be restarted on a low dose and titrated every 2 weeks back to their maintanence dose.

Antipsychotics

FGAs and SGAs such as aripiprazole, asenapine, haloperidol, olanzapine, quetiapine, risperidone, and ziprasidone are effective as monotherapy or adjunctive therapy in the treatment of acute mania.[76] Controlled studies in acute mania with lithium or valproate plus an antipsychotic suggest greater efficacy with combination therapies compared to any of these agents alone.[2,76] FGAs (eg, chlorpromazine and haloperidol) are effective in up to 70% of patients with acute mania, particularly those with psychosis and psychomotor agitation. SGAs have demonstrated similar efficacy for the treatment of acute mania associated with agitation, aggression, and psychosis.[2,76]

Treating acute bipolar depression is very challenging, and some antipsychotics may play a useful role. Multiple large randomized controlled trials support use of quetiapine and lurasidone as a monotherapy and adjunctive treatment options for bipolar depression.[77] Data also support use of combined fluoxetine/olanzapine in treating bipolar depression.[77]

Long-term safety of antipsychotics as monotherapy or as adjunctive therapy for bipolar maintenance treatment should be evaluated.[2,53,76] Risks versus benefits must be weighed due to the long-term adverse effects (eg, weight gain, type 2 diabetes, hyperlipidemia, hyperprolactinemia, and tardive dyskinesia) antipsychotics may cause.[76,78] Aripiprazole, olanzapine, quetiapine, and risperidone long-acting injection are effective monotherapy options for maintenance treatment in bipolar disorder.[53] First-generation depot antipsychotics (eg, haloperidol decanoate, fluphenazine decanoate) can have a place in maintenance treatment of bipolar disorder in patients who are noncompliant or treatment-resistant.[2]

Clozapine monotherapy has acute and long-term mood-stabilizing effects in refractory bipolar disorder, but requires regular white blood cell monitoring for agranulocytosis.[22,76]

Clinical Controversy…

What is the role of SGAs in bipolar disorder?

The desire to shorten hospital stays may contribute to increased use of SGAs added to a traditional mood stabilizer to return patients quickly to a baseline level of functioning. When and even whether to taper and discontinue the SGA once an acute manic episode has subsided is a complex decision. The risk of metabolic side effects including weight gain, hyperglycemia, and hyperlipidemia must be weighed against the potential benefits offered by the SGA. Often the longitudinal course of each patient's bipolar illness and each patient's response and relapse pattern with previous medications will inform decision making.

Adverse Effects

A summary of adverse effects for antipsychotics can be found in Chapter 67.

Drug–Drug Interactions

A summary of drug interactions with antipsychotics can be found in Chapter 67.

Dosing and Administration

For acute mania, higher initial doses of antipsychotics can be required (eg, olanzapine 20 mg/day in hospitalized patients). Once acute mania is controlled (usually within 7-28 days), the antipsychotic can be gradually tapered and discontinued, and the patient maintained on the mood stabilizer monotherapy.

Monitoring

7 Recommendations for baseline and routine laboratory testing for patients receiving carbamazepine, lamotrigine, lithium, oxcarbazepine, SGAs, and valproate are found in Table 69-7.

Alternative Medication Treatments

Benzodiazepines

Weighing the risk-to-benefit ratio, high-potency benzodiazepines such as clonazepam and lorazepam are commonly used as an alternative to or in

combination with antipsychotics when patients are experiencing acute mania, agitation, anxiety, panic, and insomnia, or cannot take mood stabilizers (eg, during the first trimester of pregnancy).[2,3,79,80] Lorazepam is available for intramuscular injection and is useful in the acute management of agitation. Benzodiazepines cause minimal adverse effects compared with antipsychotics, and at higher doses, rapidly sedate agitated patients.[3] They can cause CNS depression, sedation, cognitive and motor impairment, dependence, and withdrawal reactions. When no longer required, benzodiazepines should be gradually tapered and discontinued to avoid withdrawal symptoms.

Antidepressants

For many years antidepressants were recommended as adjunctive therapy for acute bipolar depression. Data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) suggest that adjunctive antidepressants may be no better than placebo for acute bipolar depression when combined with mood stabilizers.[81] Controversy exists concerning the use of antidepressants, and many clinicians consider them third line in treating acute bipolar depression, except in patients with no history of severe and/or recent mania or potentially in bipolar II patients.[82] The concern of mood switching (ie, rapidly switching from depression to mania or hypomania) with the use of antidepressants is valid, although not common. Data show that the rate of mood switch with selective serotonin reuptake inhibitors (SSRIs) is around 3.8%, similar to placebo, when combined with mood stabilizers. The rate of mood switch with dual-acting agents (eg, TCAs or venlafaxine) is higher, and thus these agents should be used with caution.[82,83] Before initiating therapy with an antidepressant it is very important to ensure that the patient is on a therapeutic dosage or blood level of a primary mood stabilizer.[2] Patients who have a history of mania after a depressive episode or who have frequent cycling should be treated cautiously with antidepressants.[2,3] In general, the antidepressant should be gradually withdrawn 2 to 6 months after remission, and the patient maintained on a mood-stabilizing agent.[84,85] For more information, see Chapter 68 for comparisons among antidepressants.

Calcium Channel Antagonists

Verapamil, a nondihydropyridine, has demonstrated mood-stabilizing properties in some studies, but negative results were found in other trials.[3,22,86] Nimodipine, a dihydropyridine, can be more effective than verapamil for rapid-cycling bipolar disorder because of its anticonvulsant properties, high lipid solubility, and good penetration into the brain.[3,22,45,86] Calcium channel blockers are generally well tolerated, and the most common adverse effects are bradycardia and hypotension. These are seldom used in everyday clinical practice.

Newer Anticonvulsants

Third-generation anticonvulsants have been investigated for treating bipolar disorder with the hope that a different mechanism of action would be beneficial for mood stabilization. Gabapentin, levetiracetam, tiagabine, topiramate, and zonisamide have negative or limited positive data supporting their use in bipolar disorder. Topiramate has been used as an add-on weight-reduction medication, but there are no randomized, controlled trials supporting its use in bipolar disorder.[87]

Special Populations

The approach for treating bipolar disorder in special populations (eg, comorbid medical or psychiatric disorders, pregnancy) can vary among clinicians. Patients with comorbid medical conditions or concomitant substance abuse, those older than 65 or younger than 18 years, and pregnant patients can require different treatment approaches.

Clinical Controversy…

What are the roles of traditional mood stabilizers, antipsychotics, and benzodiazepines in the pregnant female patient with acute mania?

Ebstein's anomaly, a congenital heart defect associated with first trimester exposure to lithium was once thought to be much more common than recent data suggest, leading some clinicians to consider treating pregnant patients with severe debilitating acute manic episodes with lithium, though this remains controversial. Valproic acid and carbamazepine remain contraindicated during the first trimester of pregnancy due to concerns about neural tube defects. Given the length of time haloperidol has been available, there is considerable safety data on this first-generation antipsychotic in treating the acutely manic patient. Safety data on SGAs are still limited. Short-acting benzodiazepines such as lorazepam are often considered during the first trimester of pregnancy for severe manic episodes in an effort to minimize exposure to traditional mood stabilizers. A risk benefit analysis of all psychotropic interventions during pregnancy is critical to maternal and fetal well-being.

Comprehensive management during pregnancy is important to decrease the risk of birth defects, perinatal complications and mortality, preterm birth, low birth weight, and low Apgar scores.[88] Pharmacotherapy during pregnancy is complicated, and the risk-to-benefit ratio must be weighed. Clinicians should always use the lowest effective dose of any medication during pregnancy. Monotherapy should also be considered in order to decrease risk to the mother and child.

When lithium is given during the first trimester the prevalence of Ebstein's anomaly is estimated between 1 and 10.78:1000 and the risk of neural tube defects is 13.4:1000.[88] Lithium freely crosses the placenta and is found in equal concentrations in maternal and fetal blood.[60] When lithium is used during pregnancy, it should be tapered down to the lowest effective dose necessary to decrease the risk of relapse. Lithium can cause perinatal complications such as hypotonia, jaundice, cyanosis, and lethargy.[88] Milk concentrations of lithium range from 30% to 50% of the mother's serum concentration, and serum concentrations in the nursing infant are 10% to 50% of the mother's; thus, breastfeeding is usually discouraged.[2,89] If using lithium during pregnancy, dose adjustments and close monitoring of serum levels will be needed due to changes in glomerular filtration rates and renal perfusion rates during pregnancy and immediately after delivery.[88]

Neural tube defects cause the most concern for clinicians treating pregnant patients during their first trimester. Data from the North American Antiepileptic Drug Pregnancy Registry show the risk of neural tube defects is about 0.12% for nonexposed babies.[90] Carbamazepine's risk of neural tube defects is

estimated to be 3%.[90] Carbamazepine is excreted in breast milk (the milk-to-maternal plasma ratio of carbamazepine is ~0.4).[3] Craniofacial abnormalities, developmental delays, microcephaly, and other abnormalities are also of concern when using anticonvulsants. For pregnant patients treated with lamotrigine, the risk of neural tube defects is estimated to be 2%, but data for lamotrigine are limited compared with those for some older anticonvulsants.[90] Valproate is usually not recommended during the first trimester of pregnancy because the risk of neural tube defects is estimated to be 4%.[90] Australian registry data in patients with epilepsy show dose-related teratogenicity with doses greater than 1,100 mg/day of valproate.[91] Administration of folate can reduce the risk of neural tube defects; therefore, the risks versus benefits of using valproate during pregnancy must be discussed with the patient.[22] Women of childbearing age on valproic acid and pregnant women should receive folic acid supplementation. Valproic acid is excreted into human breast milk in low concentrations (less than 1%-10% of the mother's serum level), so is considered to be compatible with breastfeeding.[3] One case report of thrombocytopenia and anemia from valproate exposure has been reported in a nursing infant. If the mother receives valproate during breastfeeding, mother and infant should have identical laboratory monitoring.

Caution should be used when prescribing antipsychotics during pregnancy. FGAs have been prescribed for many years in pregnancy and data show little teratogenic risk, but the data are not without question.[92] Data on the SGAs are limited, and clinicians should consider the potential risk of gestational diabetes.[92] Extrapyramidal symptoms, neonatal withdrawal, and sedation should also be considered when prescribing both FGAs and SGAs. There is still a paucity of human data with antipsychotics, and therefore risk-to-benefit ratio must be weighed.

There are few controlled studies in children and adolescents with bipolar disorder; thus, little is known about the long-term efficacy and safety of specific agents or combination therapies in this population.[10,93] Lithium, valproic acid, and carbamazepine are all used in pediatric bipolar disorder though data are limited supporting their use. Lithium is the only medication approved as a mood stabilizer for children older than 12 years.[94] Aripiprazole and risperidone are FDA-approved for bipolar mania in patients aged 13 to 17 years.[95] Quetiapine is approved as monotherapy or adjunct to lithium or divalproex in patients aged 10 to 17 years during a manic episode.[95] It did not show efficacy in a small pilot study of adolescent bipolar depression.[96] Olanzapine is approved for use in patients with manic or mixed episodes aged 13 to 17 years.[95] Ziprasidone has supporting data for it's use in pediatric acute mania, but does not have FDA approval.[97] Long-term data are still needed for all of these agents. Recommendations on the treatment of pediatric bipolar depression and maintenance treatment are lacking due to insufficient data.[97] Published guidelines for treatment of bipolar disorder in children and adolescents include the *Practice Parameters for the Assessment and Treatment of Children and Adolescents with Bipolar Disorder* by the American Academy of Child and Adolescent Psychiatry.[10]

Patients with bipolar illness are more likely to have medical comorbidities than the general population (64.3% vs 48.3%).[98] As people age, medical comorbidities tend to increase, which complicates the management of bipolar disorder in elderly patients. Renal clearance decreases, and elimination half-life nearly doubles for lithium in elderly patients.[99] Half-life of valproate has been reported to increase with aging.[100] Patients with dementia can have increased sensitivity to the side effects of mood stabilizers and antipsychotics. No prospective, randomized, placebo-controlled trials have been published examining efficacy of lithium or valproate in elderly patients.[101]

Personalized Pharmacotherapy

New information is quickly evolving in the area of pharmacogenetics and pharmacogenomics that may help clinicians individualize treatment for patients with bipolar disorder. Genetic testing is available to determine if patients are poor or rapid metabolizers of cytochrome P450 2D6 and 2C19, thus helping predict potential response as well as adverse effects. It is recommended to obtain genetic testing for the human leukocyte antigen (HLA) allele, HLA-B 1502, in patients of Asian ancestry to help detect a higher risk of Stevens-Johnson syndrome and toxic epidermal necrolysis.[65]

EVALUATION OF THERAPEUTIC OUTCOMES

The establishment and maintenance of a therapeutic alliance between the patient and clinician is essential in monitoring a patient's psychiatric status and safety; enhancing treatment adherence; promoting good nutrition, sleep, and exercise; identifying stressors; recognizing new mood episodes; and minimizing adverse reactions and drug interactions.[2] Patients who have a partial response or nonresponse to established bipolar therapies should be reassessed for an accurate diagnosis, concomitant medical or psychiatric conditions, compliance with treatment (including blood levels if appropriate), and medications or substances that exacerbate mood symptoms. Nonadherence to medication treatment, delusional symptoms, alcohol or substance abuse, rapid cycling, or mixed states are often associated with poorer treatment outcomes.

Chapter 70: Anxiety Disorders: Generalized Anxiety, Panic, and Social Anxiety Disorders

Sarah T. Melton; Cynthia K. Kirkwood

INTRODUCTION

KEY CONCEPTS

- 1 Anxiety disorders are among the most common of mental disorders and are underdiagnosed and undertreated.
- 2 The long-term goal in treatment of generalized anxiety disorder (GAD) is remission with minimal or no anxiety symptoms and no functional impairment.
- 3 Antidepressants are the agents of choice for the management of GAD.
- 4 Antidepressants have a lag time of 2 to 4 weeks or longer before antianxiety effects occur in GAD.
- 5 When monitoring the effectiveness of antidepressants in panic disorder, it is important to allow an adequate amount of time (8-12 weeks) to achieve full therapeutic response.
- 6 The optimal duration of panic therapy is unknown; 12 to 24 months of pharmacotherapy is recommended before gradual drug discontinuation over 4 to 6 months is attempted.
- 7 Social anxiety disorder (SAD) is a chronic long-term illness requiring extended therapy. After improvement, at least a 6- to 12-month medication maintenance period is recommended.
- 8 The selective serotonin reuptake inhibitors or venlafaxine are considered first-line pharmacotherapy for social anxiety disorder.
- 9 An adequate trial of antidepressants in generalized SAD lasts at least 8 weeks, and maximal benefit may not be seen until 12 weeks.

- 10 The three principal domains in which improvement should be observed in generalized SAD are symptoms, functionality, and well-being.

Anxiety is an emotional state commonly caused by the perception of real or perceived danger that threatens the security of an individual. It allows a person to prepare for or react to environmental changes. Everyone experiences a certain amount of nervousness and apprehension when faced with a stressful situation. This is an adaptive response and is transient in nature.

Anxiety can produce uncomfortable and potentially debilitating psychological (eg, worry or feeling of threat) and physiologic arousal (eg, tachycardia or shortness of breath) if it becomes excessive. Some individuals experience persistent, severe anxiety symptoms and possess irrational fears that significantly impair normal daily functioning. These persons often suffer from an anxiety disorder.[1]

1 Anxiety disorders are among the most frequent mental disorders encountered in clinical practice and are often underdiagnosed and undertreated.[2] Healthcare professionals often mistake anxiety disorders for physical illnesses, and only one quarter of patients receive appropriate treatment.[3] Failure to diagnose and manage anxiety disorders results in negative outcomes including overuse of healthcare resources, increased risk for suicide and substance abuse.[4] Individuals with anxiety disorders develop cardiovascular, cerebrovascular, gastrointestinal (GI), and respiratory disorders at a significantly higher rate than the general population.[4]

To treat anxiety appropriately, the clinician must make a reliable diagnosis. It is essential that the distinction between short-term symptoms of anxiety and anxiety disorders be understood. Common or situational anxiety is a normal response to a stressful circumstance. Although symptoms can be severe, they are temporary and usually last no more than 2 or 3 weeks. Although short-term, "as-needed" treatment with an anxiolytic agent such as a benzodiazepine is common and can provide some symptomatic relief, prolonged drug therapy is not recommended for situational anxiety.[5]

EPIDEMIOLOGY

Anxiety disorders, as a group, are the most commonly occurring psychiatric disorders. According to large population-based surveys, up to 33.7% of the population are affected by an anxiety disorder during their lifetime.[6] According to the National Comorbidity Survey Replication of the prevalence, severity, and comorbidity estimates of mental disorders in the United States, the most recent 1-year prevalence rate for anxiety disorders was 21.3% in persons aged 18 years and older. Specific phobias were the most common anxiety disorder, with a 12-month prevalence of 10.1%. The 1-year prevalence of generalized anxiety disorder (GAD) was 2.9%, that of panic disorder was 3.1%, and that of social anxiety disorder (SAD) was 8.0%.[6]

In general, anxiety disorders are a group of heterogeneous illnesses that develop before age 30 years and are more common in women, individuals with social issues, and those with a family history of anxiety and depression. Patients often develop another anxiety disorder, major depression, or substance abuse.[1,2,3] The clinical picture of mixed anxiety and depression is much more common

than an isolated anxiety disorder.[7,8]

ETIOLOGY

The differential diagnosis of anxiety disorders includes medical and psychiatric illnesses and certain drugs.[7,8] Hypotheses on the etiology of anxiety disorders are based on interactions between a combination of factors including vulnerability (eg, genetic predisposition and early childhood adversity) and stress (eg, occupational and traumatic experience). The vulnerability may be associated with genetic factors and neurobiologic adaptations of the central nervous system (CNS).[9]

Medical Diseases Associated with Anxiety

Anxiety symptoms are an inherent part of the initial clinical presentation of several diseases, thus complicating the distinction between anxiety disorders and medical disorders.[5,8] Anxiety disorders are associated with chronic medical illness, low levels of physical health-related quality of life (QOL), and physical disability.[2] If anxiety symptoms are secondary to a medical illness, they usually will subside as the medical situation stabilizes. However, the knowledge that one has a physical illness can trigger anxious feelings and further complicate therapy. Persistent anxiety subsequent to a physical illness requires further assessment for an anxiety disorder. Common somatic symptoms of anxiety that frequently present in medical disorders include abdominal pain, palpitations, tachycardia, sweating, flushing, tremor, chest pain or tightness, and shortness of breath. Although less specific, symptoms of muscle tension, headache, and fatigue are also common manifestations of anxiety. Medical disorders most closely associated with anxiety are listed in **Table 70-1**

TABLE 70-1 Common Medical Illnesses Associated with Anxiety Symptoms

Cardiovascular

Angina, arrhythmias, cardiomyopathy, congestive heart failure, hypertension, ischemic heart disease, mitral valve prolapse, myocardial infarction

Endocrine and metabolic

Cushing disease, diabetes, hyperparathyroidism, hyperthyroidism, hypothyroidism, hypoglycemia, hyponatremia, hyperkalemia, pheochromocytoma, vitamin B_{12} or folate deficiencies

Gastrointestinal

Crohn disease, irritable bowel syndrome, ulcerative colitis, peptic ulcer disease

Neurologic

Migraine, seizures, stroke, neoplasms, poor pain control

Respiratory system

Asthma, chronic obstructive pulmonary disease, pulmonary embolism, pneumonia

Others

Anemias, cancer, systemic lupus erythematosus, vestibular dysfunction

Data from references 4, 7, and 8.

Psychiatric Diseases Associated with Anxiety

Anxiety can be a presenting feature of several major psychiatric illnesses. Anxiety symptoms are extremely common in patients with mood disorders, schizophrenia, dementia, and substance-use disorders. Most psychiatric patients will have two or more concurrent psychiatric disorders (comorbidity) within their lifetime.[6] It is important to diagnose and treat all comorbid psychiatric conditions in patients with anxiety disorders.

Drug-Induced Anxiety

Drugs are a common cause of anxiety symptoms (**Table 70-2**). Anxiety occurs during the use of CNS-stimulating drugs in a dose-dependent manner, but ingestion of minimal amounts can result in marked anxiety, including panic attacks, in some individuals. The onset of drug-induced anxiety is usually rapid after the initiation of therapy. A thorough medication history evaluating for a recent drug or dosage change is important to rule out a drug-induced etiology for the anxiety.

TABLE 70-2 Drugs Associated with Anxiety Symptoms

Anticonvulsants: Carbamazepine, phenytoin

Antidepressants: Bupropion, selective serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors

Antihypertensives: Clonidine, felodipine

Antibiotics: Quinolones, isoniazid

Bronchodilators: Albuterol, theophylline

Corticosteroids: Prednisone

Dopamine agonists: Amantadine, levodopa

Herbals: Ma huang, ginseng, ephedra

Illicit substances: Ecstasy, marijuana

Nonsteroidal antiinflammatory drugs: Ibuprofen, indomethacin

Stimulants: Amphetamines, caffeine, cocaine, methylphenidate, nicotine

Sympathomimetics: Pseudoephedrine, phenylephrine

Thyroid hormones: Levothyroxine

Toxicity: Anticholinergics, antihistamines, digoxin

Data from references 1 and 5.

Anxiety occurs occasionally during the use of CNS depressants, especially in children and the elderly; however, anxiety complaints are more common as complications of drug withdrawal after the abrupt discontinuation of these agents.[7]

PATHOPHYSIOLOGY

Data from biochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain and abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ-aminobutyric acid (GABA), serotonin (5-HT), corticotropin-releasing factor (CRF), and cholecystokinin.[10] Current neuroanatomic models of fear (ie, the response to danger) and anxiety (ie, the feeling of fear that is disproportionate to the actual threat) include some key brain areas. The amygdala, a temporal lobe structure, plays a critical role in the assessment of fear stimuli and learned response to fear.[10,11] The locus ceruleus (LC), located in the brain stem, is the primary NE-containing site, with widespread projections to areas responsible for implementing fear responses (eg, vagus, lateral and paraventricular hypothalamus). The hippocampus is integral in the consolidation of traumatic memory and contextual fear conditioning. The hypothalamus is the principal area for integrating neuroendocrine and autonomic responses to a threat.[10,11]

Neurochemical Theories

Noradrenergic Model

The basic premise of the noradrenergic theory is that the autonomic nervous system of anxious patients is hypersensitive and overreacts to various stimuli. Many anxious patients clearly display symptoms of peripheral autonomic hyperactivity. In response to threat or fearful situations, the LC serves as an alarm center, activating NE release and stimulating the sympathetic and parasympathetic nervous systems. Chronic central noradrenergic overactivity downregulates α_2-adrenoreceptors in patients with GAD. This receptor is hypersensitive in some patients with panic disorder.[10] By administering drugs that have a relatively specific effect on the LC, researchers have further explored the NE theory of anxiety and panic disorder. Drugs with anxiogenic effects (eg, yohimbine [an α_2-adrenergic receptor antagonist]) stimulate LC firing and increase noradrenergic activity. NE in turn increases glutamate release (an excitatory neurotransmitter).[10] This produces subjective feelings of anxiety and can precipitate a panic attack in those with panic disorder, but not in normal volunteers.[10] Drugs with anxiolytic or antipanic effects (eg, benzodiazepines and antidepressants) inhibit LC firing, decrease noradrenergic activity, and block the effects of anxiogenic drugs.[10]

GABA-Receptor Model

There are two superfamilies of GABA-protein receptors: $GABA_A$ and $GABA_B$. Drugs that reduce anxiety and produce sedation target the $GABA_A$ receptor. The $GABA_B$ receptor is a G-protein–coupled receptor postulated to be involved in the presynaptic inhibition of GABA release.[10,11,12] $GABA_A$ receptors are ligand-gated ion channels composed of five protein subunits. Several classes of subunits (ie, α_{1-6}, β_{1-3}, γ_{1-3}, δ, ε, θ, π, ρ_{1-3}) surround a central pore, and the receptor is connected to the cytoskeleton.[12,13] Benzodiazepine ligands enhance the inhibitory effects of GABA.[12] GABA, the major inhibitory neurotransmitter in the CNS, has a strong regulatory or inhibitory effect on the 5-HT, NE, and dopamine (DA) systems. When GABA binds to the $GABA_A$ receptor, neuronal excitability is reduced.

The specific role of the GABA receptors in anxiety disorders has not been established. The number of $GABA_A$ receptors can change with alterations in the environment (eg, chronic stress), and the subunit expression can be altered by hormonal changes.[12,13]

Serotonin Model

Although there are data suggesting that the 5-HT system is dysregulated in patients with anxiety disorders, definitive evidence that shows a clear abnormality in 5-HT function is lacking. 5-HT is primarily an inhibitory neurotransmitter that is used by neurons originating in the raphe nuclei of the brain stem and projecting diffusely throughout the brain (eg, cortex, amygdala, hippocampus, and limbic system). Abnormalities in serotonergic functioning through release and uptake at the presynaptic autoreceptors ($5\text{-}HT_{1A/1D}$), the serotonin-reuptake transporter (SERT) site, or effect of 5-HT at the postsynaptic receptors (eg, $5\text{-}HT_{1A}$, $5\text{-}HT_{2A}$, and $5\text{-}HT_{2C}$) may play a role in anxiety disorders.[10] Preclinical models suggest that greater 5-HT function facilitates avoidance behavior; however, primate studies show that reducing 5-HT increases aggression.[10] It is postulated that greater 5-HT activity reduces NE activity in the LC, inhibits defense/escape response via the periaqueductal gray (PAG) region, and reduces hypothalamic release of CRF. The selective serotonin reuptake inhibitors (SSRIs) acutely increase 5-HT levels by blocking the SERT to increase the amount of 5-HT available postsynaptically, and are efficacious in blocking the manifestations of panic and anxiety.[10]

Low 5-HT activity may lead to a dysregulation of other neurotransmitters. NE and 5-HT systems are closely linked, and interactions between the two are reciprocal and vary. NE may act at presynaptic 5-HT terminals to decrease 5-HT release, and its activity at postsynaptic receptors can cause increased 5-HT release.

Buspirone is a selective $5\text{-}HT_{1A}$ partial agonist that is effective for GAD but not for panic disorder. Because the selective $5\text{-}HT_{1A}$ partial agonists reduce serotonergic activity, GAD symptoms may reflect excessive 5-HT transmission or overactivity of the stimulatory 5-HT pathways.[14] There is circumstantial evidence for the involvement of serotonergic and dopaminergic systems in the pathophysiology of generalized SAD.[15]

Neuroimaging Studies

Functional neuroimaging studies support the crucial role of the amygdala, anterior cingulate cortex (ACC), and insula in the pathophysiology of anxiety.[11] In GAD there is an abnormal increase in the brain's fear circuitry, as well as increased activity in the prefrontal cortex, which appears to have a compensatory role in reducing GAD symptoms.[16] Patients with panic have abnormalities of midbrain structures, including the PAG. Neuroimaging studies have shown activation of insula and upper brain stem (including the PAG), as well as deactivation of the ACC during experimental panic attacks.[10] Patients with SAD have greater activity than matched comparison subjects in the amygdala and insula, structures linked to negative emotional responses.[17] Both pharmacotherapy and psychotherapy decreased cerebral blood flow in the amygdala, hippocampus, and surrounding cortical areas in patients with SAD.[17]

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* classifies anxiety disorders into categories including GAD, panic disorder, agoraphobia, SAD, specific phobia, and separation anxiety disorder.[1] The characteristic features of these illnesses are anxiety and avoidance behavior. Anxiety symptoms must cause significant distress and impairment in social, occupational, or other areas of functioning, and should not be secondary to a drug or illicit substance or a general medical disorder, or occur solely as part of another psychiatric disorder.[1] The anxiety-related syndromes posttraumatic stress disorder and obsessive-compulsive disorder are discussed in Chapter 71.

Generalized Anxiety Disorder

The diagnostic criteria for GAD require persistent symptoms for most days for at least 6 months.[1] The essential feature of GAD is unrealistic or excessive anxiety and worry about a number of events or activities.[1] The anxiety or apprehensive expectation is accompanied by at least three psychological or physiologic symptoms. Anxiety and worry are not confined to features of another psychiatric illness (eg, having a panic attack, being embarrassed in public).[1]

The onset, course of illness, and comorbid conditions of GAD are important considerations. GAD has a gradual onset with an average age of 21 years; however, there is a bimodal distribution. Onset occurs earlier when GAD is the primary presentation and later when GAD is secondary. GAD can be exacerbated or precipitated in later life by severe psychological stressors. Most patients present between the ages of 35 and 45 years, with women twice as likely to have GAD as men. The course of the illness is chronic (ie, episodes can last for a decade or longer); there is a high percentage of relapse and low rates of recovery.[1] Patients report substantial interference with their lives and have a high probability of seeking treatment. Lifetime comorbidity with another psychiatric disorder occurs in 90% of patients with GAD, with depression being found in over 60%.[18]

Panic Disorder

Panic disorder begins as a series of unexpected (spontaneous) panic attacks involving an abrupt surge of intense fear or intense discomfort. The unexpected panic attacks are followed by at least 1 month of persistent concern about having another panic attack, worry about the possible consequences of the panic attack, or a significant maladaptive change in behavior related to the attacks.[1] During an attack, patients describe at least four physiologic and physical symptoms. Panic attacks usually last no more than 20 to 30 minutes, with the peak intensity of symptoms within the first 10 minutes. Often patients seek help at a physician's office or emergency department, only to have their symptoms resolve before or on arrival. Because panic symptoms mimic those present in several medical conditions, patients often are misdiagnosed, and multiple referrals are common.[1]

CLINICAL PRESENTATION Generalized Anxiety Disorder Psychological and Cognitive Symptoms

- Excessive anxiety
- Worries that are difficult to control
- Feeling keyed up or on edge
- Trouble concentrating or mind going blank

Physical Symptoms

- Restlessness
- Fatigue
- Muscle tension
- Sleep disturbance
- Irritability

Data from references 1, 2, and 4.

CLINICAL PRESENTATION Panic Attack Psychological Symptoms

- Depersonalization (being detached from oneself)
- Derealization (feelings of being detached from one's environment)
- Fear of losing control, going crazy, or dying

Physical Symptoms

- Abdominal distress
- Chest pain or discomfort
- Chill

- Dizziness or light-headedness
- Feeling of choking
- Heat sensations
- Nausea
- Palpitations
- Paresthesias
- Sensations of shortness of breath or smothering
- Sweating
- Tachycardia
- Trembling or shaking

Data from references 1, 2, and 4.

Secondary to the panic attacks, up to 50% of patients develop agoraphobia.[1] Agoraphobia is marked fear or anxiety about being in at least two situations in which escape might be difficult or where help might not be available in the event of developing panic-like symptoms.[1] As a result, patients often avoid specific situations (eg, using public transportation, being in open or enclosed places, being in a crowd or being outside of the home alone) in which they fear a panic attack might occur.[1]

Complications of panic disorder include depression (10%-65% have major depressive disorder), alcohol abuse, and high use of health services and emergency rooms.[1] Patients with panic disorder have a high lifetime risk for suicide attempts compared with the general population.[1] The usual course is chronic but waxing and waning.

Social Anxiety Disorder

SAD is characterized by marked fear about one or more social situations in which the individual is exposed to possible scrutiny by others. Exposure to the feared circumstance usually provokes an immediate situation-related panic attack. Blushing is the principal physical indicator and distinguishes SAD from other anxiety disorders. The fear and anxiety is out of proportion to the actual threat posed by the social situation and is persistent, typically lasting for 6 months or longer.[1] If the fear is restricted to speaking or performing in public, the SAD is specified as performance only.

The mean age of onset of SAD is during the mid-teens. Rates of SAD are slightly higher among women than men and more frequent in younger cohorts. It is a chronic disorder with a mean duration of 20 years.[1] People with SAD can be reluctant to seek professional help despite the existence of beneficial treatments because consultation with a clinician is perceived as a feared social

interaction.[19]

Differentiating SAD from other anxiety disorders can be difficult. Panic attacks occur in both SAD and panic disorder, but the distinction between the two is the rationale behind fear; fear of anxiety symptoms is characteristic of panic disorder, whereas fear of embarrassment from social interaction typifies SAD.[1] A majority of SAD patients eventually develop a concurrent mood, anxiety, or substance abuse disorder.[19]

Specific Phobia

Specific phobia is marked and persistent fear of a circumscribed object or situation (eg, insects or heights). Apart from contact with the feared object or situation, the patient is usually free of symptoms. Most persons simply avoid the feared object and adjust to certain restrictions on their activities.[1]

CLINICAL PRESENTATION Social Anxiety Disorder Fears of Being

- Scrutinized by others
- Negatively evaluated (ie, humiliated, embarrassed, or rejected)

Some Feared Situations

- Eating or writing in front of others
- Interacting with authority figures
- Speaking in public
- Talking with strangers
- Use of public toilets

Symptoms of Anxiety

- Blushing
- “Butterflies in the stomach”
- Diarrhea
- Stumbling over words
- Sweating
- Tachycardia
- Trembling

Specifier

- Performance; Applies only if the fear is restricted to speaking or performing in public.

Data from references 1 and 19.

TREATMENT

Generalized Anxiety Disorder

Desired Outcomes

2 The goals of therapy in the acute management of GAD are to reduce the severity and duration of the anxiety symptoms and to improve overall functioning. The long-term goal in GAD is remission with minimal or no anxiety symptoms, no functional impairment, and increased QOL.[18] Prevention of recurrence is another long-term consideration.

General Approach

Once GAD is diagnosed, a patient-specific treatment plan, which usually consists of both psychotherapy and drug therapy, is developed. The plan depends on the severity and chronicity of symptoms, age, medication history, and comorbid medical and psychiatric conditions.[18] Factors such as anticipated adverse effects, history of prior response in the patient or family member, patient preference, and cost should be considered when treatment is initiated. Psychotherapy is the least invasive and safest treatment modality. Antianxiety medication is indicated for patients experiencing symptoms severe enough to produce functional disability. **Table 70-3** lists drug choices for GAD, panic disorder, and SAD.

TABLE 70-3 Drug Choices for Anxiety Disorders

Anxiety Disorder	First-Line Drugs	Second-Line Drugs	Alternatives
Generalized anxiety disorder	Duloxetine Escitalopram Paroxetine Sertraline Venlafaxine XR	Benzodiazepines Buspirone Imipramine Pregabalin Alprazolam Citalopram Clomipramine Clonazepam	Hydroxyzine Quetiapine
Panic disorder	SSRIs Venlafaxine XR		Phenelzine

Anxiety Disorder	First-Line Drugs	Second-Line Drugs	Alternatives
Social anxiety disorder	Escitalopram Fluvoxamine CR Paroxetine Sertraline Venlafaxine XR	Imipramine Clonazepam Citalopram	Gabapentin Phenelzine Pregabalin

CR, controlled-release; SSRI, selective serotonin reuptake inhibitor; XR, extended-release.

Data from references 2, 18, 20 to 23.

Nonpharmacologic Therapy

Nonpharmacologic treatment modalities in GAD include psychoeducation, short-term counseling, stress management, psychotherapy, meditation, or exercise. Psychoeducation includes information on the etiology and management of GAD. Anxious patients should be instructed to avoid caffeine, nicotine, nonprescription stimulants, diet pills, and excessive use of alcohol. Most patients with GAD require psychological therapy, alone or in combination with antianxiety drugs, to overcome fears and to learn to manage their anxiety and worry.[19] Cognitive behavioral therapy (CBT) is the most effective psychological therapy in GAD patients. CBT for GAD includes self-monitoring of worry, cognitive restructuring, relaxation training, and rehearsal of coping skills.[19] Psychotherapy or medication alone has comparable efficacy in acute treatment.[22] The relapse rate with CBT is less than with other types of psychological modalities.[22] Controlled trials comparing the efficacy of combining drug and psychotherapy over long-term treatment are lacking.[22] Advantages of CBT over pharmacotherapy include patient preference and lack of troubling adverse effects. However, CBT is not widely available, requires specialized training, and entails weekly sessions for an extended time period (ie, 12-20 weeks).[23]

Pharmacologic Therapy

The benzodiazepines are the most effective and commonly prescribed drugs for the rapid relief of acute anxiety symptoms (**Table 70-4**). All benzodiazepines are equally effective anxiolytics, and consideration of pharmacokinetic properties and the patient's clinical situation will assist in the selection of the most appropriate agent.[23,24]

TABLE 70-4 Benzodiazepine Antianxiety Agents

Drug	Brand Name	Approved Dosage Range	Maximum Dosage for Geriatric	Approximate Equivalent Dose (mg)	Comments

		(mg/day)	Patients (mg/day)		
Alprazolam[a]	Niravam,[b] Xanax Xanax XR	0.75-4 1-10[c]	2	0.5	Associated with interdose rebound anxiety
Chlordiazepoxide[a]	Librium	25-400	40	10	
Clonazepam[a]	Klonopin Klonopin Wafer[b]	1-4[c]	3	0.25-0.5	
Clorazepate[a]	Tranxene	7.5-60	30	7.5	
Diazepam[a]	Valium	2-40	20	5	
Lorazepam[a]	Ativan	0.5-10	3	1	Preferred in elderly
Oxazepam[a]	Serax	30-120	60	30	Preferred in elderly

XR, extended-release.

[a]Available generically.

[b]Orally disintegrating formulation.

[c]Panic disorder dose.

Dosing and equivalence data from references 25,26,27.

Because of the lack of dependency and tolerable adverse effect profile, antidepressants have emerged as the treatment of choice for the management of chronic anxiety, especially in the presence of comorbid depressive symptoms. Buspirone is an additional anxiolytic option (**Table 70-5**) in patients without comorbid depression or other anxiety disorders. Because of the high risk of adverse effects and toxicity, barbiturates, antipsychotics, antipsychotic–antidepressant combinations, and antihistamines generally are not indicated in the treatment of GAD.[4] The benzodiazepines are more effective in treating the somatic and autonomic symptoms of GAD as opposed to the psychic symptoms (eg, apprehension and worry), which are reduced by antidepressants.[4]

TABLE 70-5 Nonbenzodiazepine Antianxiety Agents for Generalized Anxiety Disorder

Drug	Brand Name	Initial Dose	Usual Range (mg/day)[a]	Comments
Antidepressants				
Duloxetine	Cymbalta	30 or 60	60-120	FDA-approved

Drug	Brand Name	Initial Dose	Usual Range (mg/day)[a]	Comments
Escitalopram	Lexapro	10 mg/day	10-20	FDA-approved, available generically
Imipramine	Tofranil	50 mg/day	75-200	Available generically
Paroxetine	Paxil Pexeva	20 mg/day	20-50	FDA-approved, available generically, avoid in pregnancy
Sertraline	Zoloft	50 mg/day	50-200	Available generically
Venlafaxine XR	Effexor XR	37.5 or 75 mg/day	75-225[b]	FDA-approved, available generically
Vilazodone	Viibryd	10 mg/day	20-40[b]	During concomitant use of a strong CYP3A4 inhibitor (eg, itraconazole, clarithromycin, voriconazole), dose should not exceed 20 mg once daily
Vortioxetine	Brintellix	5 mg/day	5-20	
Azapirone				
Buspirone	BuSpar	7.5 mg twice daily	15-60[b]	FDA-approved, available generically
Diphenylmethane				
Hydroxyzine	Vistaril	25 or 50 mg four times daily	200-400	FDA-approved, available generically, approved in children for anxiety and tension in divided daily doses of 50-100 mg
Anticonvulsant				
Pregabalin	Lyrica	50 mg three times daily	150-600	Dosage adjustment required in renal impairment
Atypical antipsychotic				
Quetiapine XR	Seroquel XR	50 mg at bedtime	150-300	

XR, extended-release.

[a]Elderly patients are usually treated with approximately one half of the dose listed.

[b]No dosage adjustment is required in elderly patients.

Data from references 4, 24, 28, 29, 30, 31, 32, 33, 34, 35.

The most recent treatment guidelines from the World Federation of Societies of Biological Psychiatry, the National Institute for Health and Clinical Evidence, and British Association for Psychopharmacology are evidence-based.[4,21,22] A descriptive flowchart with recommendations based on levels of evidence from the International Psychopharmacology Algorithm Project for the management of GAD is shown in **Fig. 70-1**.[36]

FIGURE 70-1

International Psychopharmacology Algorithm Project (IPAP) generalized anxiety disorder (GAD) algorithm flowchart. Yellow, first-line treatment (nodes 2, 3, 5, 6); green, second-line treatment (nodes 8-12); blue, third-line treatment, no comorbidity (nodes 13,17,18,19); orange, third-line treatment, with comorbidity (nodes 14-16); light green, assessment and evaluation. Levels of evidence used in development of the flowchart were: 1, more than one placebo-controlled trial with sample sizes over 30; 2, one placebo-controlled trial (or active vs active drug comparison) with sample size of 30 or greater; 3, one or small (n < 30) placebo-controlled trial; 4, case reports or open-label trials; and 5, expert consensus without published evidence. *(Used by permission of The International Psychopharmacology Algorithm Project. IPAP–Generalized Anxiety Disorder Algorithm. http://www.ipap.org/gad/index.php, accessed December 22, 2015.*

Alternative Drug Treatments

Hydroxyzine, pregabalin, and atypical antipsychotics are alternatives.[18,22,28] The effectiveness of hydroxyzine as an antianxiety agent for long-term use (ie, more than 4 months) has not been assessed by systematic clinical studies.[35] Hydroxyzine is commonly used in the primary care setting, but it is considered be to be a second-line agent because of adverse effects and lack of efficacy for comorbid disorders.[4] Pregabalin, which binds to the $\alpha_2\delta$ subunit of voltage-gated calcium channels to reduce nerve terminal calcium influx, acts on "hyperexcited" neurons. Pregabalin produced anxiolytic effects similar to lorazepam, alprazolam, and venlafaxine in acute efficacy trials.[24] Quetiapine extended-release 150 mg/day monotherapy was superior to placebo in three studies, and as effective as paroxetine 20 mg/day and escitalopram 10 mg/day but with an earlier onset of action.[28] In a 52-week treatment of GAD, quetiapine extended-release was superior to placebo in the prevention of anxiety relapse.[28] Quetiapine is not FDA-approved for GAD, and the long-term risks and benefits of atypical antipsychotics in the treatment of GAD are unclear.[28] Despite some evidence of efficacy, support for the use of kava kava for GAD has been blunted by ongoing safety concerns following numerous reports of liver toxicity.[37] Although valerian, St. John's wort, and passionflower have been used to manage GAD, there is insufficient evidence of their effectiveness and safety.[37,38]

Clinical Controversy…

Atypical antipsychotics have been used as monotherapy and as add-on treatment for nonresponse to first-line pharmacotherapy of GAD in numerous trials. Adverse effects include sedation, orthostatic hypotension, metabolic syndrome, extrapyramidal effects, and others. Although effective in GAD, they are not approved for this indication and should probably be reserved for use by specialists.

Antidepressant Therapy

3 Antidepressants are considered first-line agents in the management of GAD. Venlafaxine extended-release, duloxetine, paroxetine, and escitalopram are FDA-approved antidepressants for GAD (see Table 70-5). Imipramine is considered a second-line agent, despite its efficacy, because of higher toxicity and adverse effect rates.[4] 4 The antianxiety response of antidepressants is delayed by 2 to 4 weeks or longer.[4] The pharmacology, pharmacokinetics, and drug interactions of the antidepressants are reviewed in Chapter 68.

Efficacy

Antidepressants are efficacious in the acute and long-term management of GAD. Data support the use of the SSRIs (eg, escitalopram, paroxetine, sertraline), and the serotonin–norepinephrine reuptake inhibitors (SNRIs) (eg, venlafaxine extended-release and duloxetine), for acute therapy (8- to 12-week trials) with response rates between 60% and 68%, and remission rates of 30%.[4,22] A recent meta-analysis indicated that fluoxetine was most likely to achieve remission of GAD symptoms, and sertraline was the best tolerated. In a subanalysis comparing duloxetine, escitalopram, paroxetine, [illegible]e was most likely to produce a beneficial response,

escitalopram most likely to establish a remission, and pregabalin was best tolerated.[39]

Mechanism of Action

The mechanism of action of antidepressants in anxiety disorders is not fully understood. Research indicates that antidepressants modulate receptor activation of neuronal signal transduction pathways connected to the neurotransmitters 5-HT, DA, and NE. In an animal model of anxiety, a number of candidate genes were identified that were normalized by fluoxetine treatment selectively in the hypothalamus.[40] It is theorized that by activating stress-adapting pathways, SSRIs and SNRIs reduce the somatic anxiety symptoms and the general distress experienced by patients.

Adverse Effects

The adverse effects of medications used to treat generalized anxiety are provided in **Table 70-6**. SSRIs and SNRIs are generally well tolerated, with GI adverse effects and sleep disturbances being the most commonly reported. Headaches and diaphoresis occur early in treatment and are often transient, whereas weight gain and sexual dysfunction may continue in long-term treatment. The use of tricyclic antidepressants (TCAs) is limited by troublesome adverse effects (eg, sedation, anticholinergic effects, and weight gain) in some patients and the risk of toxicity in overdose.

TABLE 70-6 Monitoring of Adverse Effects Associated with Medications Used for Anxiety Disorders

Medication Class/Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
SSRIs			
	Jitteriness syndrome	Patient interview	
	Suicidality	Patient interview	Monitor weekly in first few weeks in patients with comorbid depression and patients under age 25
	Nausea, diarrhea	Patient interview	Typically transient
	Headache	Patient interview	Typically transient
	Weight gain	Body weight, BMI, waist circumference	Paroxetine may be more likely to cause weight gain
	Sexual dysfunction	Patient interview	Significant reason for nonadherence
	Hyponatremia	Basic metabolic panel	Monitor at baseline and periodically thereafter. More frequent monitoring required in high-risk groups, especially the elderly (>65 years)
	Thrombocytopenia	Complete blood count	
	Teratogenicity	Pregnancy test at baseline	
	QT prolongation	ECG	Reported with citalopram
	Discontinuation		

Medication Class/Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
			Avoid paroxetine in pregnancy; Pregnancy Category D
		Patient interview	Before starting citalopram, consider ECG and measurement of QT interval in patients with cardiac disease
			Avoid abrupt discontinuation in all but fluoxetine
SNRIs			
	Jitteriness syndrome	Patient interview	Monitor weekly in first few weeks in patients with comorbid depression and patients under age 25
	Suicidality	Patient interview	
	Nausea, diarrhea	Patient interview	Typically transient
	Headache	Patient interview	Typically transient
	Elevated blood pressure	Blood pressure	Monitor blood pressure on initiation and regularly during treatment
	Sexual dysfunction	Patient interview	Significant reason for nonadherence
	Discontinuation syndrome	Patient interview	
			Avoid abrupt discontinuation
TCAs			
	Jitteriness syndrome	Patient interview	
	Suicidality	Patient interview	Monitor weekly in first few weeks in patients with comorbid depression and patients under age 25
	Anticholinergic effects	Patient interview	
	Weight gain	Body weight, BMI, waist circumference	Contraindicated with narrow-angle glaucoma, prostatic hypertrophy, and urinary retention
	Sexual dysfunction	Patient interview	Significant reason for nonadherence
	Sedation	Patient interview	Administer dosage at bedtime when feasible
	Arrhythmia	ECG	
	Orthostatic hypotension	Blood pressure with	

Medication Class/Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
		position changes	At baseline and periodically in children and patients >40 years of age
	Cholinergic rebound	Patient interview	Avoid abrupt discontinuation; taper doses
Benzodiazepines			
	Drowsiness, fatigue	Patient interview	Avoid operating large machinery; tolerance to sedation develops after repeated dosing
	Anterograde amnesia and memory impairment	Patient interview	Risk of anterograde amnesia is worsened with concomitant intake of alcohol
	Dependence	Patient interview; Prescription Monitoring Program	Monitor for early refills or escalation of dosage
	Withdrawal symptoms	Physical examination; patient interview	Taper doses on discontinuation
	Respiratory depression	Respiratory rate	Avoid administering with other CNS depressants (ie, opioids, alcohol)
	Psychomotor impairment	Physical examination	Increased risk of falls
	Paradoxical disinhibition	Physical examination; family report	Increase in anxiety, irritability, or agitation may be seen in the elderly or children
Other Drugs			
	Nausea, abdominal pain	Patient interview	Typically transient
	Drowsiness, dizziness	Patient interview	Typically transient
Buspirone	Jitteriness syndrome	Patient interview	
Phenelzine	Suicidality	Patient interview	Monitor weekly in first few weeks in patients with comorbid depression and patients under age 25
Pregabalin	Hypertensive crisis	Blood pressure	
Quetiapine	Orthostatic hypotension	Blood pressure with position changes	Tyramine-free diet and avoidance of drug interactions required
	Dizziness, somnolence	Patient interview	Fasting labs at baseline and then periodically

Medication Class/Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
		Physical examination	
	Peripheral edema	Complete blood count	
	Thrombocytopenia	Body weight	
	Weight gain	Patient interview	
	Sedation	Body weight, BMI, waist circumference, fasting lipids and glucose	Fasting labs at baseline and then periodically
	Metabolic syndrome		
	Akathisia	Patient interview	
	Tardive dyskinesia	Abnormal Involuntary Movement Scale	
	Orthostatic hypotension	Blood pressure with position changes	

BMI, body mass index; ECG, electrocardiogram; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Dosing and Administration

The antidepressants can be dosed once a day (see Table 70-5). Some patients require small initial daily doses for the first week of therapy to limit the development of transient increased anxiety, also known as jitteriness syndrome.

Benzodiazepine Therapy

Although all benzodiazepines possess anxiolytic properties, only 7 of the 14 currently marketed agents have FDA approval for the treatment of GAD (see Table 70-4). Estazolam, flurazepam, temazepam, quazepam, and triazolam are marketed as sedative–hypnotic agents. Clonazepam is marketed as an antipanic agent and anticonvulsant,[41] and midazolam is labeled for preoperative sedation. Alprazolam is indicated for the treatment of panic disorder with or without agoraphobia, as well as GAD.[42] Clobazam in indicated for adjunctive treatment of seizures in Lennox-Gastaut syndrome.[27]

Pharmacology and Mechanism of Action

The GABA-receptor model of anxiety theorizes that benzodiazepines ameliorate anxiety through

potentiation of the inhibitory activity of GABA.[43] Benzodiazepines bind on the $GABA_A$ receptor at the α_1, α_2, α_3, and α_5 subunits in combination with a β subunit and the γ_2 subunit.[43] The anxiolytic effects of benzodiazepines are mediated at the α_2 site, while sedative effects result from binding at the α_1 subunit. The binding sites of GABA and benzodiazepines are at the receptor interfaces of α/β and α/γ_2, respectively. The GABA receptor controls tonic inhibition to reduce neuronal excitability.[43] Other neurotransmitters (eg, 5-HT, NE, and DA) may also be involved in benzodiazepine activity.

Pharmacokinetics

A wide difference in milligram potency exists between the benzodiazepine compounds; however, when appropriately dosed, all agents have similar anxiolytic and sedative–hypnotic activity. The variations in lipid solubility between compounds influence the pharmacokinetic properties of benzodiazepines. Knowledge of the different pharmacokinetic and pharmacodynamic properties can assist in choosing an appropriate anxiolytic (**Table 70-7**). After a single dose, the onset, intensity, and duration of pharmacologic effects are important factors to consider when using benzodiazepines for the short-term, intermittent, or as-needed treatment of anxiety.

TABLE 70-7 Pharmacokinetics of Benzodiazepine Antianxiety Agents

Drug	Time to Peak Plasma Level (Hours)	Elimination Half-Life, Parent (Hours)	Metabolic Pathway	Clinically Significant Metabolites	Protein Binding (%)
Alprazolam	1-2	12-15	Oxidation	—	80
Chlordiazepoxide	1-4	5-30	*N*-Dealkylation	Desmethyl chlordiazepoxide	96
			Oxidation	Demoxepam	
				DMDZ[a]	
Clonazepam	1-4	30-40	Nitroreduction	—	85
Clorazepate	1-2	Prodrug	Oxidation	DMDZ	97
Diazepam	0.5-2	20-80	Oxidation	DMDZ	98
				Oxazepam	
Lorazepam	2-4	10-20	Conjugation	—	85
Oxazepam	2-4	5-20	Conjugation	—	97

*a*Desmethyldiazepam (DMDZ) half-life 50-100 hours.

Data from references 27 and 44.

The primary determinant of a drug's onset of effect after a single oral dose is the rate of drug absorption. Because of high lipophilicity, diazepam and clorazepate are absorbed rapidly and distributed quickly into the CNS. Therefore, the onset of anxiolytic effect occurs within 30 to 60

minutes, which results in a rapid and intense relief of anxiety. High lipophilicity also increases the extent of drug redistribution into the periphery, particularly adipose tissue, resulting in a shorter duration of effect after a single dose than is suggested by single-dose elimination half-life studies.[44] Clinically, patients perceive a rapid onset of action, but some experience an unpleasant feeling of drowsiness or loss of control. This "rush" can be euphoric and contribute to abuse.

Compared with diazepam, lorazepam and oxazepam are relatively less lipophilic and have a slower absorption and onset of effect. These benzodiazepines have smaller volumes of distribution and a resulting longer duration of action.[44]

Parenteral administration via the intramuscular route should be avoided with diazepam secondary to variability in the rate and extent of drug absorption. Intramuscular lorazepam provides rapid, reliable, and complete absorption.

After multiple dosing, the rate and extent of drug accumulation are functions of the drug's elimination half-life in relation to dosing intervals, clearance, and formation of active metabolites. Differences in clinical effects that occur during and after repeated dosages with the benzodiazepines are related in part to variability in metabolism and metabolite accumulation.[44]

The benzodiazepines undergo two primary metabolic processes, hepatic oxidation (catalyzed by cytochrome P450 3A4) and glucuronide conjugation. With the exception of lorazepam and oxazepam (which are conjugated only) and clonazepam (which undergoes nitroreduction), all benzodiazepines are oxidized first and then conjugated and excreted renally.[44] Diazepam's metabolism is also catalyzed by cytochrome P450 2C19. Oxidation can be impaired in patients with liver disease, in the elderly, and in those who simultaneously use drugs that inhibit oxidation resulting in higher levels of the parent drug and/or an active metabolite.

Many benzodiazepines are converted to desmethyldiazepam (DMDZ), an active metabolite with a long elimination half-life (see Table 70-7). DMDZ is further oxidized to oxazepam and then conjugated and excreted. After multiple dosing, accumulation of DMDZ is slow and extensive, providing a long-lasting antianxiety effect. If oxidation of DMDZ is impaired, the half-life is prolonged, and extensive drug accumulation can result with repeated dosing.

Clorazepate is a prodrug and possesses no anxiolytic effects until metabolized to DMDZ. Before absorption, clorazepate is metabolized rapidly in the stomach through a pH-dependent process under acidic conditions.

Benzodiazepines with shorter half-lives (eg, alprazolam, lorazepam, and oxazepam) reach steady-state plasma concentrations rapidly, and drug accumulation after repeated dosing is minimal. Oxazepam and lorazepam have no active metabolites.

Benzodiazepine protein binding is extensive, especially for the drugs with a long elimination half-life. After a single dose of a benzodiazepine with a long elimination half-life, the expected duration of clinical activity may not parallel the drug's pharmacokinetic half-life because of drug redistribution.[44] After multiple dosing, drugs with long elimination half-lives and active metabolites require 1 to 2

weeks to reach steady state.

Efficacy

Clinical trials of benzodiazepines show that 65% to 75% of patients with GAD have a marked to moderate response, with most of the improvement occurring in the first 2 weeks of therapy.[21,22] Benzodiazepines are more effective on the somatic symptoms of anxiety and fail to obviate the cognitive or psychic symptoms (eg, worry).

Adverse Effects

The most common adverse events associated with benzodiazepine therapy involve CNS depression (see Table 70-6). This is manifested clinically as drowsiness, sedation, psychomotor impairment, and ataxia.[45,46] A transient mild drowsiness is experienced commonly by patients during the first few days of treatment; however, tolerance often develops. Disorientation, depression, confusion, irritability, aggression, and excitement are reported.[45,46]

Impairment of memory and recall also can occur during benzodiazepine treatment. The memory loss induced by the benzodiazepines typically is limited to events occurring after drug ingestion (anterograde amnesia).[45,46] Anterograde amnesia is secondary to disordered consolidation processes that store information and is not impairment in the perception or retrieval of information.[3] Benzodiazepines with high affinity for binding to the benzodiazepine receptor (eg, alprazolam) appear to possess a higher potential for amnesia.[45,46]

Abuse, Dependence, Withdrawal, and Tolerance

Two serious complications of benzodiazepine therapy are the potential for abuse and development of physical dependence. Benzodiazepine abuse is rare in the general population of users; however, individuals with a history of multiple drug abuse (eg, alcohol or sedatives) are at the greatest risk for becoming benzodiazepine abusers.[46]

Because of the chronicity of illness, persons with GAD and panic disorder are at high risk of developing benzodiazepine dependence. Benzodiazepine dependence is a physiologic phenomenon demonstrated by the appearance of a predictable abstinence syndrome (withdrawal symptoms) on abrupt discontinuation of therapy.[46,47] Withdrawal symptoms can result because of the sudden dissociation of a benzodiazepine from its receptor site. After abrupt discontinuation, an acute decrease in GABA neurotransmission results, producing a less inhibited CNS.

Benzodiazepine Discontinuation

After benzodiazepine therapy is discontinued suddenly, several events can occur. Rebound anxiety represents an immediate but transient return of original symptoms having an increased intensity compared with baseline. Recurrence or relapse is the return of original symptoms with similar

Withdrawal symptoms are the emergence of new symptoms and a worsening of preexisting symptoms after benzodiazepine discontinuation. Symptoms can persist for days to weeks and resolve gradually over months.

Common symptoms of benzodiazepine withdrawal include anxiety, insomnia, restlessness, muscle tension, and irritability. Less frequently occurring symptoms are nausea, malaise, coryza, blurred vision, diaphoresis, nightmares, depression, hyperreflexia, and ataxia. Tinnitus, confusion, paranoid delusions, hallucinations, and seizures occur rarely. Withdrawal seizures can occur with both therapeutic and high doses of benzodiazepines with a short elimination half-life, usually within 3 days of drug discontinuation. They can occur approximately 1 week after discontinuation of agents with a long elimination half-life. High benzodiazepine doses, a long duration of therapy, and concurrent ingestion of drugs that lower the seizure threshold are risk factors for withdrawal seizures.

The onset of withdrawal symptoms in patients ingesting benzodiazepines with short elimination half-lives occurs much earlier (within 24-48 hours) than in those taking benzodiazepines with long elimination half-lives (within 3-8 days). Other factors associated with an increased incidence and severity of benzodiazepine withdrawal include high doses and long-term benzodiazepine therapy.[46,47]

A strategy to minimize the severity of benzodiazepine withdrawal is a 25% per week reduction in dosage until 50% of the dose is reached, and then dosage reduction by one-eighth every 4 to 7 days.[47] If therapy exceeds 8 weeks, a slow dosage taper over 2 to 3 weeks is recommended; however, if the duration of treatment is 6 months, a taper over 4 to 8 weeks should ensue.[47] Long-term use of benzodiazepines (ie, 1 year or longer) requires a 2- to 4-month slow taper.[47] Tapering will not eliminate the emergence of withdrawal symptoms entirely but will prevent severe withdrawal. Slow drug taper is extremely important for the drugs with a short elimination half-life, because some individuals have greater difficulty with discontinuation. Withdrawal symptoms with short half-life benzodiazepines were no more severe than with longer half-life agents; therefore, switching from a short- to long-acting benzodiazepine before gradual taper is not supported.[47] Adjunctive use of pregabalin can help reduce withdrawal severity during the benzodiazepine taper.[48] A combination of psychotherapy interventions (including CBT) with tapering protocols resulted in superior discontinuation outcomes.[49] Patients should avoid the intake of alcohol and stimulants during the withdrawal process. Although tolerance develops to the sedative, muscle relaxant, and anticonvulsant activities, the benzodiazepines do not appear to lose anxiolytic or antipanic efficacy. However, the anxiolytic efficacy of benzodiazepines in long-term clinical trials (greater than 6-8 months of chronic use) has not been documented.[4,21,22,]

Drug Interactions

Drug interactions with the benzodiazepines generally fall into two categories: pharmacodynamic and pharmacokinetic. Simultaneous use of alcohol and a benzodiazepine results in additive CNS depressant effects. In addition, concurrent use of a benzodiazepine and other drugs with CNS depressant properties (eg, opioids, antipsychotics, and antihistamines) can potentiate the adverse

e in an overdose attempt, benzodiazepines are rarely

life-threatening; however, the combination of benzodiazepines with alcohol or other CNS depressant agents is potentially fatal.

Concurrent use of medications that inhibit cytochrome P450 3A4 (eg, ketoconazole, nefazodone, and ritonavir) can increase the blood levels of alprazolam and diazepam. Drugs that induce cytochrome P450 3A4 (eg, carbamazepine, St. John's wort) can reduce benzodiazepine levels. Consult a drug interaction Web site (http://www.factsandcomparisons.com/facts-comparisons-online.aspx) for further information.

Dosing and Administration

Benzodiazepine dosage requirements vary widely among patients and must be individualized. Therapy should be initiated using low doses (eg, alprazolam 0.25 mg three times a day or equivalent doses of other benzodiazepines) and titrated upward to relieve anxiety symptoms and avoid adverse events. After an initial treatment response is achieved, agents with long elimination half-lives can be dosed at bedtime. Dosage adjustments should be made weekly. Three to 4 weeks of a daily dose at the maximum dose constitutes an adequate clinical trial (see Table 70-4).[2,21,22]

The duration of benzodiazepine therapy for the acute management of anxiety should be limited to 2 to 4 weeks. In general, benzodiazepines should be used with a regular dosing regimen and not on an as-needed basis.[4,18] Only in the treatment of short-term distress (eg, air travel, dental phobia) as-needed use may be justified.[4] Individuals with persistent symptoms should be managed with antidepressants because of the risk of dependence with continued benzodiazepine therapy.

Patient education should include the anticipated length of drug therapy, potential side effects, and consequences of the ingestion of alcohol and other CNS depressants. Patients should understand that benzodiazepines provide symptomatic relief but do not solve underlying psychological problems. Patients should be instructed not to decrease or discontinue benzodiazepine usage without contacting their prescriber.

Buspirone Therapy

Buspirone is a nonbenzodiazepine anxiolytic that lacks anticonvulsant, muscle relaxant, hypnotic, motor impairment, and dependence properties. It is considered to be a second-line agent for GAD because of inconsistent reports of efficacy (particularly long-term), delayed onset of effect (ie, 2 weeks or longer), and lack of efficacy for other potential concurrent depressive and anxiety disorders.[2] Unlike benzodiazepines, buspirone is effective for the psychic symptoms of anxiety.[2]

Pharmacology and Mechanism of Action

Buspirone's anxiolytic mechanism of action is unknown. It is thought to exert its anxiolytic effect through partial agonist activity at the 5-HT_{1A} presynaptic receptors, thus reducing the firing of 5-HT neurons.[44]

Pharmacokinetics

After an oral dose, buspirone is absorbed rapidly and completely and undergoes extensive first-pass metabolism. The mean elimination half-life is 2.5 hours, and it must be dosed two to three times daily, which adversely affects adherence to the drug regimen.[44]

Adverse Effects

Adverse events include dizziness, nausea, and headaches[44] (see Table 70-6).

Drug Interactions

Drugs that inhibit cytochrome P450 3A4 (eg, verapamil, itraconazole, fluvoxamine) can increase buspirone levels. Rifampin caused a 10-fold reduction in buspirone levels. Buspirone reportedly elevates blood pressure in patients taking a monoamine oxidase inhibitor (MAOI).

Dosing and Administration

The dose of buspirone can be titrated in increments of 5 mg/day every 2 to 3 days as needed.[44] The onset of improvement in psychic symptoms precedes the relief of somatic symptoms; maximum therapeutic benefit might not be evident for 4 to 6 weeks.

Buspirone is a treatment option for patients with GAD, particularly for patients with uncomplicated GAD, in patients who fail other anxiolytic therapies, or in patients with substance abuse. It is not useful in clinical situations requiring immediate anxiolysis or for situations requiring as-needed anxiolytic therapy.[44] Evidence suggests that buspirone may have less efficacy in patients who have previously used benzodiazepines.[2]

Special Populations

The management of anxiety in patients with substance abuse, pregnant women, children, elderly patients, and those patients with adherence problems requires special consideration in the choice of anxiolytic. Patients with GAD may misuse alcohol, cannabis, or other substances to manage anxiety. The symptoms of GAD are similar to those of withdrawal, and it is difficult to confirm the diagnosis of GAD until after abstinence is obtained. Benzodiazepine therapy should be avoided in this population.

There is evidence that maternal anxiety during pregnancy and the postpartum period potentially pose significant risk to the child. Clinical practice guidelines for anxiety disorders recommend use of fluoxetine, sertraline, or citalopram; however, jitteriness, myoclonus, and irritability in the neonate and premature infant have been reported.[50] Paroxetine (Pregnancy Category D) should be avoided in pregnant women because of risk of cardiovascular malformations.[31]

Cleft lip, cleft palate, and other teratogenic effects are associated with benzodiazepine use, but a causal relationship is inconclusive. Clinicians should avoid benzodiazepine use during the first

trimester, use the lowest dosage for the shortest period of time, divide the total daily dosage into two or three doses to prevent high peak plasma levels, and use the agent as monotherapy.[18,50] Benzodiazepine risks during the third trimester include sedation, withdrawal symptoms, and "floppy baby syndrome" (eg, hypotonia, low Apgar scores, hypothermia). Alprazolam should be avoided during pregnancy because of neonatal withdrawal. Should benzodiazepines be required during pregnancy, the preferred agents are diazepam and chlordiazepoxide.[51] The antidepressants are favored for GAD during pregnancy based on safety considerations. Diazepam and clonazepam should not be used in nursing mothers because infants can experience sedation, lethargy, and weight loss.[18,50]

There are few controlled clinical trials of drugs in children and adolescents with GAD. CBT alone or in conjunction with antidepressants can have long-term benefits.[52] Randomized controlled trials of fluvoxamine, fluoxetine, sertraline, duloxetine, and venlafaxine extended-release indicate short-term efficacy[52]; however, irritability and oppotional behavior was reported with clonazepam.[52] No antidepressant is FDA-indicated for GAD in children or adolescents. Increased monitoring for behavioral changes with benzodiazepines and suicide-related adverse effects with antidepressants is necessary if these agents are prescribed.

Patients with hepatic disease are at risk for drug accumulation and subsequent complications. Duloxetine use should be avoided in patients with hepatic insufficiency.[29] Drug accumulation of benzodiazepines can result in the elderly secondary to a decreased capacity for oxidation and alterations in the volume of distribution. Therefore, intermediate- or short-acting benzodiazepines without active metabolites are preferred for chronic use. Elderly patients are also sensitive to the CNS adverse effects of benzodiazepines (regardless of half-life), and their use is associated with a high frequency of falls and hip fractures. Recent studies of buspirone, duloxetine, escitalopram, sertraline, venlafaxine, and pregabalin showed efficacy in elderly patients with GAD.[2,53,54,55]

Personalized Pharmacotherapy

The need for treatment is determined by patient-specific factors including severity and duration of symptoms, degree of disability, and the presence of coexisting disorders (ie, mood or other anxiety disorders). The patient should be assessed for response to or intolerance of previous treatment approaches. The selection of a specific treatment modality should be based on concurrent medical conditions, contraindications, patient's preference of treatment, and the availability of potential treatment options. The clinician should consider FDA warnings (eg, QTc prolongation for citalopram, teratogenicity with paroxetine) and potential for adverse events with medical disease (eg, anticholinergic effects and weight gain with paroxetine in patients with diabetes, obesity, or benign prostatic hyperplasia) when selecting an agent. Increased risk of suicidality should be considered in patients taking antidepressants who are younger than 25 years. All patients should receive education that includes information about GAD, treatment choices, and resources for support in the community. The patient should be an integral part of decision making and should be informed about effectiveness, common adverse effects, duration of treatment, cost associated with treatment, and what to expect when treatment is discontinued.[2]

Evaluation of Therapeutic Outcomes

Initially, anxious patients should be monitored once every 2 weeks for a reduction in the frequency, duration, and severity of anxiety symptoms and improvement in functioning.[2] The clinician should assess the patient for response to treatment by asking about specific target symptoms of anxiety and emergence of adverse events. Ideally, the patient should have no or minimal anxiety or depressive symptoms and no functional impairment. Use of an objective measurement of remission of GAD (eg, Hamilton Rating Scale for Anxiety score less than or equal to 7 and a Sheehan Disability Scale score less than or equal to 1 on each item) can assist in the evaluation of drug response.[2,18] The definition of treatment resistance is defined as a poor, partial, or lack of response with at least two antidepressants from different classes. Treatment strategies for patients who do not achieve an appropriate response with a first-line agent include increasing the dose of the SSRI/SNRI, changing to a different agent in the same class, changing to a different agent of a different class, or augmentation of therapy. At any point of nonresponse or loss of previous response, the clinician should assess for (a) symptoms (eg, psychotic symptoms) that may suggest a need for additional medications or (b) reasons for treatment nonadherence (eg, adverse effects, cost of medications, limited understanding of the illness or treatments).[18] Patients should also be assessed for concurrent substance abuse, concurrent illnesses, and suicidal thoughts. Once a patient has responded to pharmacotherapy, the regimen should be continued for at least 1 year.[18] Early discontinuation is associated with a greater risk of relapse.[18]

TREATMENT

Panic Disorder

Desired Outcomes

The goal of therapy in panic disorder is remission. Patients should be free of panic attacks, have no or minimal anticipatory anxiety and agoraphobic avoidance, and have no functional impairment.[20]

General Approach

Therapeutic options include single or combined pharmacologic agents, concurrent psychotherapy, or psychotherapy followed by pharmacotherapy. Most patients without agoraphobic avoidance will improve with pharmacotherapy alone; however, if avoidance is present, CBT typically is initiated concurrently. With all effective drug therapies, resolution of agoraphobic avoidance tends to occur slowly. A meta-analysis comparing the use of SSRIs and venlafaxine in panic disorder showed response to be similar among treatments.[56] Adding psychosocial treatment to pharmacotherapy may improve long-term outcomes by reducing the likelihood of relapse when pharmacotherapy is stopped.[20]

Nonpharmacologic Therapy

 substances that can precipitate panic attacks, including

caffeine, nicotine, alcohol, drugs of abuse, and nonprescription stimulants.[1,20] Epidemiologic data suggest that daily smoking increases risk for panic attacks and may be a causal or exacerbating factor in some individuals with panic disorder.[20] Preliminary evidence suggests that aerobic exercise (eg, walking for 60 minutes or running for 20-30 minutes 4 day/wk) may benefit patients with panic disorder.[21] CBT is associated with short-term improvement in 80% to 90% of patients and 6-month improvement in 75% of patients. A course of CBT for panic disorder is 16 to 20 hours in length conducted over a period of 4 months.[21] Bibliotherapy (the use of self-help books), exercise, and Internet-based CBT are other options.[20]

Pharmacologic Therapy

Panic disorder is treated effectively with several drugs including SSRIs, the SNRI venlafaxine, the TCA imipramine, and the benzodiazepines alprazolam and clonazepam[20,21] (**Table 70-8**). Alprazolam, clonazepam, fluoxetine, paroxetine, sertraline, and venlafaxine are approved for this indication. SSRIs are the first-line agents because of their tolerability and efficacy in acute and long-term studies[2,20]; however, the benzodiazepines are the most commonly used drugs for panic disorder.[20] In a meta-analysis of the pharmacotherapy of panic disorder, the following antidepressants were significantly superior to placebo with the following increasing order of effectiveness: citalopram, sertraline, paroxetine, fluoxetine, and venlafaxine for panic symptoms and paroxetine, fluoxetine, fluvoxamine, citalopram, venlafaxine, and mirtazapine for overall anxiety symptoms.[56] Imipramine is effective for panic disorder; however, it is considered to be a second-line agent because of the significant cardiovascular and anticholinergic effects associated with it. Five practice guidelines are published.[2,4,20,21,22] An algorithm for the pharmacologic therapy of panic disorder appears in **Fig. 70-2**.

TABLE 70-8 Drugs Used in the Treatment of Panic Disorder

Class/Generic Name	Brand Name	Starting Dose	Antipanic Dosage Range (mg)	Comments
SSRIs				
Citalopram	Celexa	10 mg/day	20-40	Dosage used in clinical trials; maximum dose limited by QT prolongation; available generically
Escitalopram	Lexapro	5 mg/day	10-20	Dosage used in clinical trials; available generically
Fluoxetine	Prozac	5 mg/day	10-30	Available generically
Fluvoxamine	Luvox	25 mg/day	100-300	Available generically
Paroxetine	Paxil	10 mg/day	20-60	FDA-approved; available generically
	Pexeva			
	Paxil CR	12.5 mg/day	25-75	
Sertraline	Zoloft	25 mg/day	50-200	FDA-approved; available generically

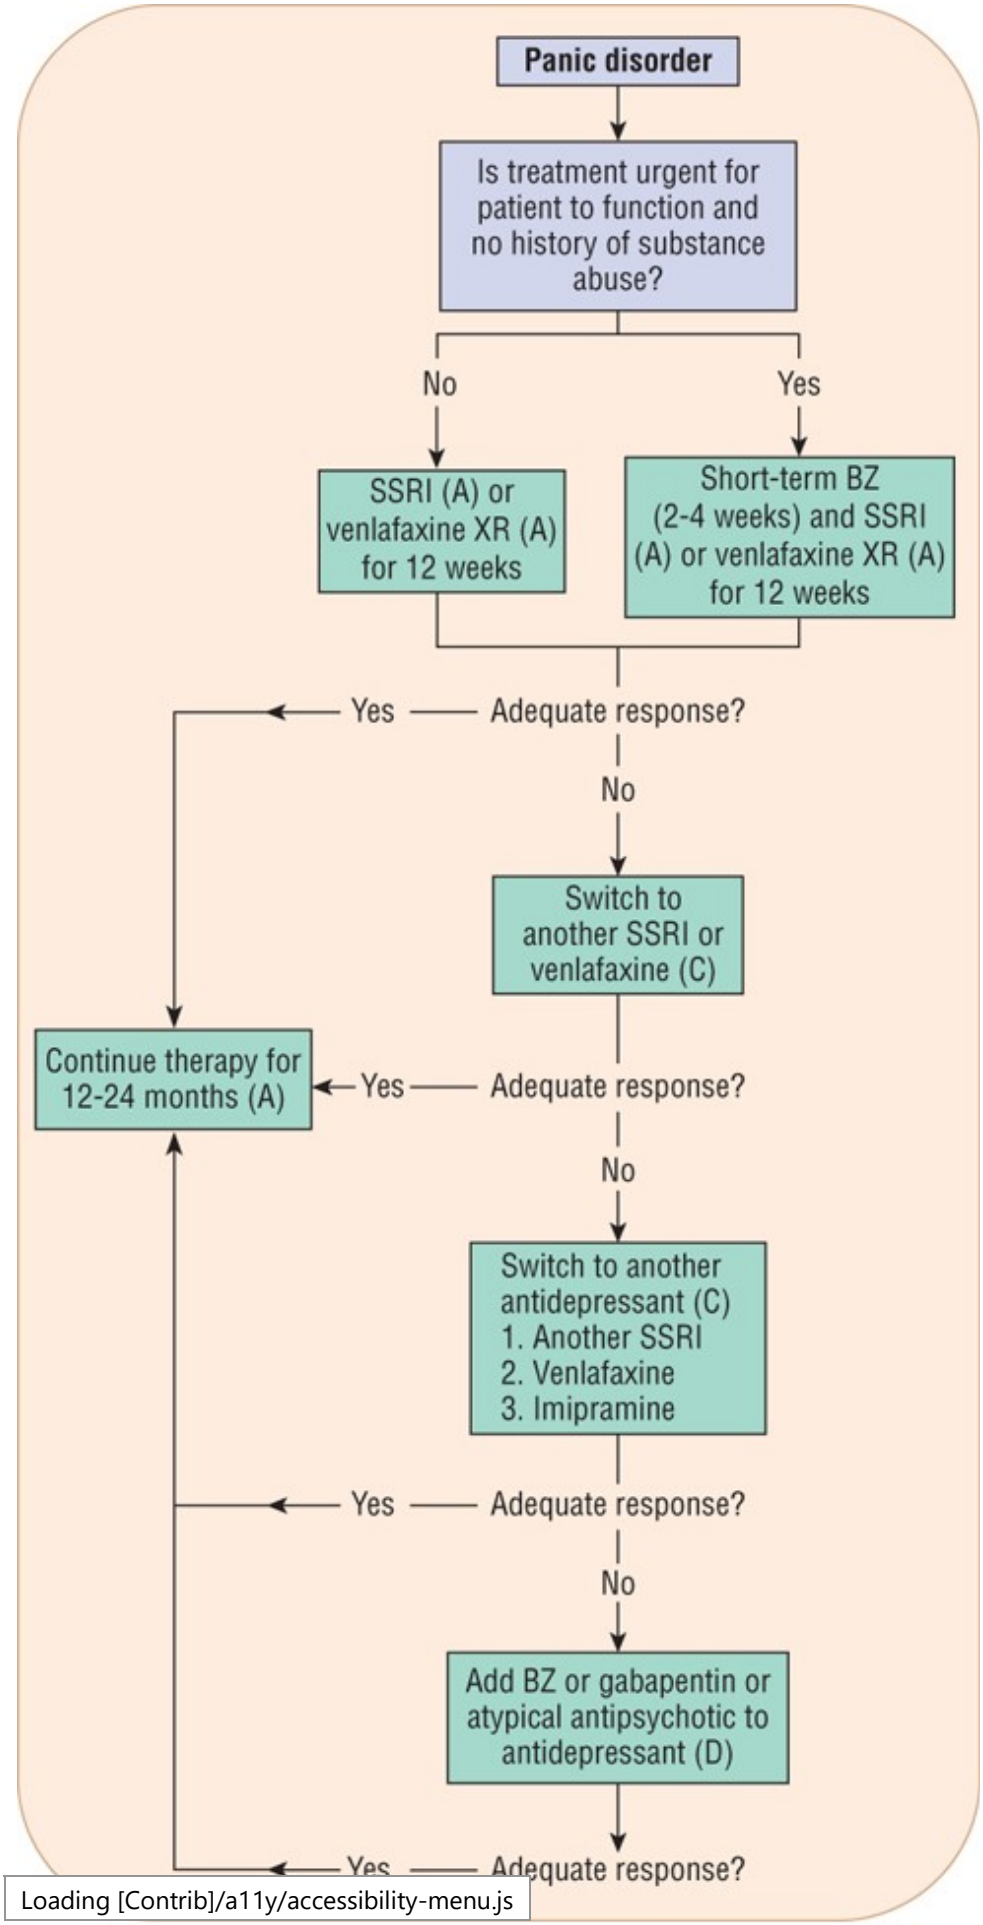
Class/Generic Name	Brand Name	Starting Dose	Antipanic Dosage Range (mg)	Comments
SNRI				
Venlafaxine XR	Effexor XR	37.5 mg/day	75-225	FDA-approved; available generically
Benzodiazepines				
Alprazolam	Xanax	0.25 mg three times a day	4-10	FDA-approved; available generically
	Xanax XR	0.5-1 mg/day	1-10	
Clonazepam	Klonopin	0.25 mg once or twice per day	1-4	FDA-approved; available generically
Diazepam	Valium	2-5 mg three times a day	5-20	Dosage used in clinical trials; available generically
Lorazepam	Ativan	0.5-1 mg three times a day	2-8	Dosage used in clinical trials; available generically
TCA				
Imipramine	Tofranil	10 mg/day	75-250	Dosage used in clinical trials; available generically
MOI				
Phenelzine	Nardil	15 mg/day	45-90	Dosage used in clinical trials

CR, controlled release; MOI, monoamine oxidase inhibitor; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRIs, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressant; XR, extended release.

Data from references 4, 20, and 57.

FIGURE 70-2

Algorithm for the pharmacotherapy of panic disorder. Strength of recommendations: A, directly based on category I evidence (ie, meta-analysis of randomized controlled trials [RCT] or at least one RCT); B, directly based on category II evidence (ie, at least one controlled study without randomization or one other type of quasi-experimental study); C, directly based on category III evidence (ie, nonexperimental descriptive studies); D, directly based on category IV evidence (ie, expert committee reports or opinions and/or clinical experience of respected authorities). (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor.) *(Adapted from references 20 and 21.)*



Benzodiazepines are considered second-line agents. Because of the risk of dependency, benzodiazepines should be used only after several trials of antidepressants have failed.[2,20] Because of potential emergence of depressive symptoms during treatment, benzodiazepines should not be used as monotherapy in a patient who is clinically depressed or has a history of depression. In patients whose illness is complicated by a history of alcohol or drug abuse, benzodiazepine use should be avoided.[20] Controlled trials have established that the short-term (4-6 weeks) addition of alprazolam or clonazepam to antidepressants produces a more rapid therapeutic response, with discontinuation of the benzodiazepine by week 7 of therapy.[2]

Alternative Drug Treatments

Buspirone, trazodone, bupropion, antipsychotics, antihistamines, and β-blockers are ineffective in panic disorder.[2,4,20,21,22] The majority of studies assessing the efficacy of MAOIs in treating panic disorder were open-labeled, and lacked adequate sample sizes. MAOIs are reserved for the most refractory or difficult patients.[20]

Antidepressant Therapy

Tricyclic Antidepressants

Efficacy

Imipramine is the most studied TCA, alleviating panic attacks in 75% of patients with panic disorder. Imipramine effectively blocks panic attacks within at least 4 weeks; however, maximal improvement (including antiphobic response) does not occur until 8 to 12 weeks.[20]

Adverse Effects

The adverse effects of medications used to treat panic disorder are found in Table 70-6. Up to 40% of patients experience stimulant-like effects, including anxiety, insomnia, and jitteriness.[20] These adverse effects often affect patient adherence, prevent medication dosage increases, and interfere with the overall treatment outcome.

Other problems with TCA use in panic disorder are well documented and include anticholinergic effects, orthostatic hypotension, delayed onset of antipanic effects, and toxicity in overdose.[20] Approximately 25% of patients reportedly discontinue treatment because of side effects, especially weight gain.[20]

Dosing and Administration

When using imipramine, treatment should be slowly increased by 10 mg every 2 to 4 days as tolerated (Table 70-8).

Selective Serotonin Reuptake Inhibitors

Efficacy

Clinical studies indicate that all SSRIs are effective in panic disorder.[20] The percentage of patients who become panic-free ranges between 60% and 80%.[20] The antipanic effect of SSRIs is delayed for at least 4 weeks, and some patients do not respond for 8 to 12 weeks.[20]

Adverse Effects

Typical antidepressant doses of SSRIs can cause side effects of insomnia, jitteriness, restlessness, and agitation, and lead to drug discontinuation in patients with panic disorder. Other adverse effects associated with SSRI use in panic disorder are listed in Table 70-6.

Dosing and Administration

Low initial doses of SSRIs are recommended (see Table 70-8) to avoid stimulatory side effects (eg, insomnia or nervousness), and should be maintained for the first week of therapy. Doses at the upper end of the dosing range can be necessary to achieve response.[21,57]

Serotonin–Norepinephrine Reuptake Inhibitors

Efficacy

Venlafaxine extended-release 75 to 150 mg/day was superior to placebo in the proportion of patients becoming free from full-symptom panic attacks. Other data support efficacy of venlafaxine in reducing the severity of anticipatory anxiety, fear, and avoidance.[57] Venlafaxine is similar in efficacy to paroxetine in patients with panic disorder and superior to placebo in a relapse prevention study.[57]

Adverse Effects

The most common adverse effects of venlafaxine extended-release in panic trials were nausea, dry mouth, constipation, anorexia, insomnia, somnolence, tremors, sweating, and sexual dysfunction.[20]

Dosing and Administration

The dosage of venlafaxine extended-release is 37.5 mg/day for the first 3 to 7 days, and then increased to a minimum of 75 mg/day (Table 70-8). Increasing the dose to 150 mg/day after initial nonresponse or partial response is recommended. A dose–response relationship was not evident in clinical trials.[32]

Benzodiazepines

Efficacy

The high-potency benzodiazepines clonazepam and alprazolam are the preferred agents.[20,21] Diazepam and lorazepam are possibly effective in treating panic disorder when taken in sufficiently

pid relief for patients in distress, but because of its short

half-life, multiple daily dosing is required and often results in profound withdrawal symptoms with missed doses.[20] Therapeutic response to benzodiazepines occurs in 1 to 2 weeks. Relapse rates of 50% or higher are common despite slow drug tapering during discontinuation of therapy.[47]

Adverse Effects

Patient acceptance of benzodiazepines usually is not a problem, and except for sedation, side effects are rarely reported (see Table 70-6).

Dosing and Administration

Doses of clonazepam can be increased by 0.25 or 0.5 mg every 3 days to 4 mg/day if needed.[41] Alprazolam can be slowly increased over several weeks to reach an ideal dose. The duration of action of immediate-release alprazolam can be as little as 4 to 6 hours with resulting breakthrough symptoms; use of the extended-release alprazolam or clonazepam will avoid this problem. Most patients require 3 to 6 mg/day of alprazolam, and some need higher doses to obtain a full therapeutic (antipanic and antiphobic) response.

Clinical Controversy…

There is an ongoing controversy about the long-term use of benzodiazepines in the treatment of anxiety and related disorders. Most treatment guidelines recommend that use of benzodiazepines be limited to short-term use because of the risk for tolerance, dose escalation, dependence, and potential abuse. In addition, recent data highlight a potential increased risk for the development of dementia with long-term use of benzodiazepines.[58] Despite these concerns, benzodiazepines are commonly prescribed in practice, and some experts argue that the benefits of long-term benzodiazepine use outweigh the potential adverse effects for most patients.

Treatment Resistance

Common reasons for treatment failures are comorbid psychiatric disorders, rapid dosage increases with resulting intolerable side effects, and underdosage.[20] All standard treatments should be tried before using augmentation strategies. In patients with a partial response to one agent, a low dose of another antipanic agent (eg, a TCA, benzodiazepine, or an SSRI) can be added.[20]

Phases of Therapy

Acute Phase

The main goal of therapy in the acute phase is reduction of symptoms (eg, resolution of panic attacks, reduction in anxiety and phobic fears, resumption of the patient's usual activities).[20,22] The duration of this phase is generally 1 to 3 months depending on the choice of drug. Therapy should be altered if there is no response after 6 to 8 weeks of an adequate dose.

The guiding principle for SSRIs and SNRIs in panic disorder is to start with low doses (approximately

one fourth to one-half of the starting doses for depression), use an adequate dose, and treat for about 12 weeks.[20,22] Adverse effects, often from too high an initial dose, can prevent achievement of an optimal dosage, compromise treatment response, and contribute to patient nonadherence.

The duration of the acute phase with benzodiazepines is approximately 1 month because response is rapid. A regular dosing schedule rather than an "as-needed" schedule is preferred for patients with panic disorder who are taking benzodiazepines, where the goal is to prevent panic attacks rather than reduce symptoms once an attack has already occurred.[20]

Maintenance Phase and Discontinuation

6 The optimal length of therapy is unknown; however, the total duration of therapy appears to be 12 to 24 months before drug discontinuation over 4 to 6 months is attempted.[20] The dose used in the acute phase is continued into the maintenance phase.[20] When drugs are discontinued too early, a high rate of relapse occurs; thus, longer periods of treatment are associated with a more sustained response. Reinstitution of drug usually results in renewed clinical response.[20] Pharmacotherapy, even of a long duration, might not prevent relapse, and many patients require long-term therapy.

The most important determinant of adherence with maintenance therapy is the tolerability of adverse events.[20] Some adverse events that are experienced short term become unbearable during long-term management (eg, sexual dysfunction and weight gain). TCAs, SSRIs (except fluoxetine), and venlafaxine can be associated with discontinuation symptoms.

The primary risk of long-term benzodiazepine use is the development of dependence and withdrawal symptoms upon discontinuation. Abuse of benzodiazepines usually is confined to patients with a personal or family history of substance or alcohol abuse.[45,46] The approach to benzodiazepine discontinuation involves a slow and gradual tapering of the dose because withdrawal symptoms and rebound anxiety may occur during discontinuation. Benzodiazepines should be tapered over 2 to 4 months at rates no higher than 10% of the dose per week.[20,47] Patients receiving benzodiazepines and antidepressants should be told not to decrease or discontinue therapy unless authorized by their clinician.[20]

Special Populations

Elderly patients with panic disorder have fewer, less intense symptoms and avoidant behavior than younger patients.[20] Youth often present with fear that they are dying or being smothered, and agoraphobia can be manifested as a fear of leaving home.[1] CBT is effective in both populations. If pharmacotherapy is used, antidepressants, especially the SSRIs, are preferred for management of panic disorder, and benzodiazepines are second-line agents because of potential problems with disinhibition in these two populations. Limited data suggest that the course of panic disorder is highly variable during pregnancy and the postpartum period. It is unclear whether uncontrolled symptoms of panic disorder affect the course or outcome of pregnancy.[20] Little evidence exists on the use of psychosocial interventions for women with panic disorder who are pregnant, breast-

feeding, or planning to become pregnant. Nonpharmacologic interventions should be considered as first-line treatment in these patients. Pharmacotherapy may also be indicated but requires careful evaluation of the potential benefits and risks.[20]

Personalized Pharmacotherapy

Research is evolving regarding pharmacogenetic properties related to benzodiazepine agents. While all benzodiazepines bind to the $GABA_A$ receptor, they have different physiochemical properties, most notably lipid solubility, which influence their pharmacokinetics, including rate of absorption and diffusion. Pharmacogenomic studies of benzodiazepines have focused on metabolizing enzymes. In particular, benzodiazepines are biotransformed by different cytochrome P450 isoforms and also by different UDP-glucuronosyltransferase subtypes. Evaluation of these factors in patients with genetic alterations in metabolism is an important part of personalized therapy. The most recent data available regarding research on the effects of pharmacogenetic properties of the benzodiazepines can be located online at The Pharmacogenomics Knowledgebase.[59]

Considerations that guide selection of the treatment modality for panic disorder include patient preference, treatment history, the presence of co-occurring medical or other psychiatric conditions, cost, and treatment availability. Psychosocial treatment in the form of CBT is recommended for patients who prefer nonpharmacologic therapy and who are able to invest the effort and time to attend weekly sessions and between-session homework exercises. Pharmacotherapy with a first-line agent is recommended for patients who prefer medications or who do not have access to or resources to engage in CBT. Combination with psychotherapy and pharmacotherapy is appropriate for patients who have failed monotherapy with medication or CBT.

Providing education about the disorder may relieve some of the symptoms of panic by helping the patient to realize that the symptoms are neither life-threatening nor uncommon. Patients should be informed regarding the lag time before a therapeutic response will occur and any problematic side effects that might affect early adherence (eg, jitteriness syndrome). Many patients are reluctant to take drugs for fear that their illness will worsen or that they will become addicted. Adverse events are often perceived as a worsening of the illness and can contribute to nonadherence or prevent necessary dosage increases. A strong therapeutic alliance between the clinician and the patient is important in supporting the patient through the aspects of the treatment that may provoke anxiety.

Evaluation of Therapeutic Outcomes

During the first few weeks of the acute phase of therapy, patients with panic disorder should be seen every 1 to 2 weeks when starting a new medication, and then every 2 to 4 weeks to adjust drug dosages based on improvement in panic symptoms and to monitor for adverse events.[20,21] After the dose is stabilized and symptoms have decreased, visits every 2 months should suffice.[22] The patient should be counseled to maintain a diary to record the date, time, frequency, duration, and intensity of panic episodes, level of anticipatory anxiety or agoraphobic avoidance, and the severity of distress and impairment related to the panic disorder. Treatment outcomes can be assessed objectively by [illegible]ale. Remission is defined as equal to or less than 3 with no or

mild agoraphobic avoidance, anxiety, disability, or depressive symptoms. Treatment response is indicated by a 40% or greater reduction in overall score.[2]

At scheduled visits, the clinician can inquire about the level of disability experienced by the patient and have the patient complete the Sheehan Disability Scale (with a goal of less than or equal to 1 point on each item). During drug discontinuation, the frequency of appointments should be increased to evaluate for emergence of potential withdrawal symptoms and monitor for relapse.

TREATMENT

Social Anxiety Disorder

Desired Outcomes

The goals of therapy in the acute phase of treatment are to reduce physiologic symptoms of anxiety (eg, tachycardia, flushing, and sweating), social anxiety, and phobic avoidance. The duration of this phase is 4 to 12 weeks, depending on the drug therapy.

The goals of therapy in the continuation phase (3-6 months) are to extend the therapeutic benefits, especially the patient's ability to participate in social activities, and improve QOL. Although the primary goal of treatment is to reduce anxiety symptoms to manageable levels, even modest reductions in avoidance and discomfort can be highly valued by patients.[19]

7 At least a 6- to 12-month medication maintenance period is recommended to maintain improvement and decrease the rate of relapse.[2,4,22] Situations suggesting a possible need for long-term treatment include the presence of unresolved symptoms or comorbidity, an early onset of disease, and a prior history of relapse.[19] The long-term goal in the treatment of SAD is remission with the disappearance of the core symptoms of social anxiety, little or no anxiety, and no functional impairment or concurrent depressive symptoms.[19,61]

General Approach

Patients with SAD should be identified early and treated aggressively.[19] Obstacles to effective treatment include patient avoidance of therapy secondary to fear and shame, treatment directed toward somatic symptoms or concurrent conditions, and financial barriers.[19] Patients with SAD often respond more slowly and less completely than patients with other anxiety disorders. Therefore, it is important to set reasonable expectations for response to therapy. Consideration of current symptoms, prior treatments, concurrent conditions, and history of substance abuse guide treatment selection.

CBT and pharmacotherapy are effective in the treatment of SAD.[2,19,60,62] Pharmacotherapy is often the most practical choice because CBT might not be available in medically underserved areas. Acute treatment outcomes for CBT and pharmacotherapy are equivalent.[2,4,19] Drug therapy is superior in reducing subjective general anxiety acutely, although CBT has a greater likelihood of maintaining

response after termination.[19,61,62]

There are no data to predict which patients will respond best to pharmacotherapy, CBT, or a combination, or maintain gains after discontinuing pharmacotherapy. The only significant indication of treatment response in pharmacotherapy is duration of treatment.[19,60,61,62,63] Some patients elect lifelong therapy, and many are reluctant to attempt drug discontinuation because of fear of relapse.

Nonpharmacologic Therapy

Patients should be educated about SAD and support groups. Self-help group programs that focus on effective communication can benefit people with anxiety involving public speaking.

CBT consists of exposure therapy, cognitive restructuring, relaxation training techniques, and social skills training.[2,4,19,22,62] Through CBT, patients learn to overcome anxiety in social situations and alter the beliefs and responses that maintain this anxiety. Therapy usually lasts several months and often is conducted in groups.[19,62]

Clinical Controversy…

It is controversial if pharmacotherapy or psychotherapy is better treatment for patients diagnosed with SAD. Some studies have directly compared pharmacotherapy and CBT for SAD, with mixed findings depending on whether short- or long-term results were examined and what types of outcome variables were studied.

Pharmacologic Therapy

Antidepressant Therapy

8 The SSRIs and venlafaxine are beneficial for concurrent depression, and are safe when used in patients with substance abuse. Paroxetine, sertraline, fluvoxamine extended-release, and venlafaxine extended-release are approved for the treatment of SAD, and are considered first-line agents because of efficacy and tolerability (**Table 70-9**). Controlled trials comparing different SSRIs, or SSRIs and an SNRI, demonstrated equivalent efficacy between agents.[19,60,61,62] TCAs are not effective in SAD.[2,22] Evidence-based guidelines for the treatment of SAD were published by the Canadian Psychiatric Association, World Federation of Societies of Biological Psychiatry, the National Institute for Health and Care Excellence, and the British Association for Psychopharmacology.[2,4,19,22] An algorithm for the pharmacotherapy of SAD appears in **Fig. 70-3**.

TABLE 70-9 Drugs Used in the Treatment of Social Anxiety Disorder

Drug	Brand Name	Initial Dose	Usual Range (mg/day)	Comments
SSRIs				

Drug	Brand Name	Initial Dose	Usual Range (mg/day)	Comments
Citalopram	Celexa	20 mg/day	20-40	Dosage used in clinical trials; maximum dose of 40 mg limited by QT prolongation; available generically
Escitalopram	Lexapro	5 mg/day	10-20	Dosage used in clinical trials; available generically
Fluvoxamine CR	Luvox CR	100 mg	100-300	FDA-approved; available generically
Paroxetine	Paxil	10 mg/day	10-60	FDA-approved; available generically
Paroxetine CR	Paxil CR	12.5 mg/day	12.5-37.5	FDA-approved; available generically
Sertraline	Zoloft	25-50 mg/day	50-200	FDA-approved; available generically
SNRI				
Venlafaxine XR	Effexor XR	75 mg/day	75-225	FDA-approved; available generically
Benzodiazepine				
Clonazepam	Klonopin	0.25 mg/day	1-4	Dosage used in clinical trials; used as augmenting agent; available generically
MOI				
Phenelzine	Nardil	15 mg at bedtime	60-90	Dosage used in clinical trials
Alternative Agents				
Buspirone	BuSpar	10 mg twice per day	45-60	Dosage used in clinical trials; used as augmenting agent; available generically
Gabapentin	Neurontin	100 mg three times a day	900-3,600	Dosage used in clinical trials; dosage adjustment required in renal impairment
Pregabalin	Lyrica	100 mg three times a day	600	Dosage used in clinical trials; dosage adjustment required in renal impairment
Quetiapine	Seroquel	25 mg at bedtime	25-400	Dosage used in clinical trials

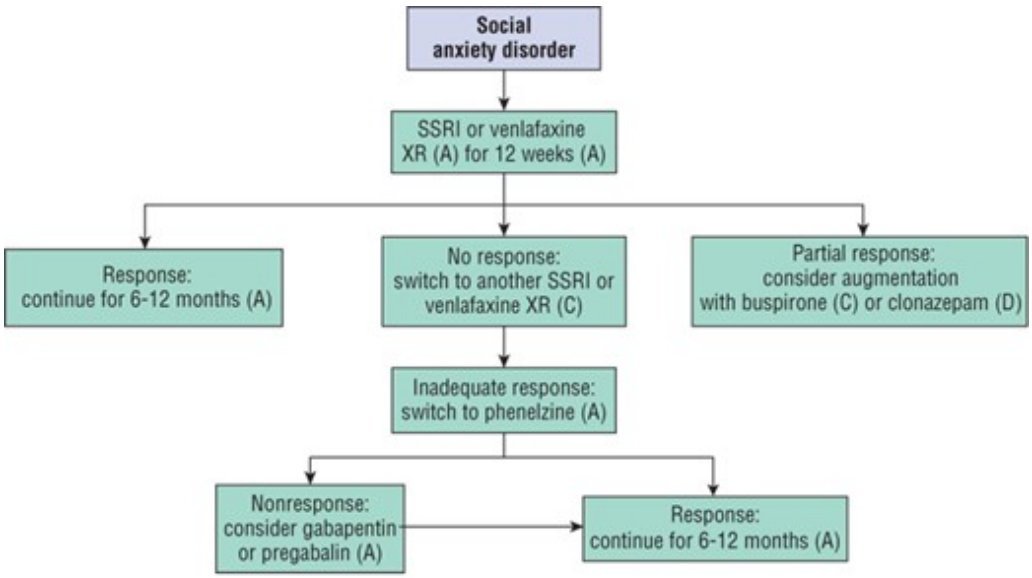
CR, controlled-release; MOI, monoamine oxidase inhibitor; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRIs, selective serotonin reuptake inhibitors; XR, extended-release.

Data from references 2, 4, 22, and 60.

FIGURE 70-3

Algorithm for the pharmacotherapy of social anxiety disorder. Strength of recommendations: A,

directly based on category I evidence (ie, meta-analysis of randomized controlled trials [RCT] or at least one RCT); B, directly based on category II evidence (ie, at least one controlled study without randomization or one other type of quasi-experimental study); C, directly based on category III evidence (ie, nonexperimental descriptive studies); D, directly based on category IV evidence (ie, expert committee reports or opinions and/or clinical experience of respected authorities); (SSRI, selective serotonin reuptake inhibitor). *(Adapted from references 2, 4, 22, and 60.)*



Selective Serotonin Reuptake Inhibitors

Efficacy

Large trials of escitalopram, fluvoxamine (immediate- and controlled-release), paroxetine, sertraline, and venlafaxine extended-release have shown efficacy and tolerability. Results of studies with fluoxetine have been inconsistent. The onset of effect was delayed 4 to 8 weeks, and maximum benefit was often not observed until 12 weeks or longer. Large relapse prevention trials with escitalopram, paroxetine, and sertraline demonstrated relapse rates of 4% to 14% with continued drug treatment, compared with 36% to 39% with placebo.[60,62]

Dosing and Administration

SSRIs should be initiated at doses similar to those used for the treatment of depression and administered as a single daily dose (see Table 70-9). If the patient suffers from comorbid panic disorder, the SSRI dose should be started at one-fourth or one-half of the dose. The dose–response curve for SSRIs tends to be relatively flat, but individual patients can require higher doses. Increase the dose as tolerated in patients who have not responded after 4 weeks of therapy.[19,60,61,62,63] When discontinuing an SSRI, the dosage should be tapered monthly (ie, decreasing sertraline by 50 mg or paroxetine by 10 mg) to reduce the risk of relapse and discontinuation symptoms.

Venlafaxine

Efficacy

The efficacy of venlafaxine extended-release was established in four double-blind, parallel-group, 12-week, multicenter, placebo-controlled, flexible-dose studies and one double-blind, parallel-group, 6-month, placebo-controlled, fixed/flexible-dose study.[32] Efficacy was assessed with the Liebowitz Social Anxiety Scale (LSAS). In these five trials, venlafaxine extended-release was significantly more effective than placebo on change from baseline to end point on the LSAS total score.[32]

Adverse Effects

Adverse effects included anorexia, dry mouth, nausea, insomnia, and sexual dysfunction (see Table 70-6).

Dosing and Administration

Additional therapeutic benefits of venlafaxine extended-release above 75 mg/day were not shown.[32] Venlafaxine should be tapered slowly (ie, decreasing by 37.5 mg/mo) to decrease the risk of relapse during discontinuation.

Alternative Agents

Benzodiazepines

Benzodiazepines are commonly used in the treatment of patients who cannot tolerate or fail to respond to antidepressants. They are not considered first-line therapy for SAD because of concerns over the adverse effects, potential for dependence, the possibility of rebound anxiety, and ineffectiveness in the treatment of depression. Clonazepam is the most extensively studied benzodiazepine for the treatment of generalized SAD.[19,60,61,62,63]

If clonazepam is prescribed, the acute phase of therapy is about 1 month. Patients should be instructed not to decrease or discontinue clonazepam without consulting their clinician because of the risks of rebound anxiety and withdrawal symptoms. Clonazepam should be gradually tapered at a rate not to exceed 0.25 mg every 2 weeks.

Anticonvulsants

Gabapentin and pregabalin were effective in controlled trials, whereas levetiracetam was ineffective.[60,61,62,63,64]

β-Blockers

β-Blockers decrease the perception of anxiety by blunting the peripheral autonomic symptoms of arousal (eg, rapid heart rate, sweating, blushing, and tremor), and they are often used to decrease

anxiety in performance-related situations.[60] For patients with performance anxiety, 10 to 80 mg of propranolol or 25 to 100 mg of atenolol can be taken 1 hour before a performance as needed. A test dose should be taken at home before the presentation to assure that β-blockade is sufficient and there are no adverse events. Controlled trials with β-blockers do not support daily use in SAD.[19]

Treatment Resistance

9 An adequate antidepressant trial usually consists of 8 to 12 weeks (at maximum dosages).[19,60,61,62,63] Subsequent options include a trial of a second SSRI or venlafaxine extended-release. Some patients experience clinical benefit during the first 4 weeks of therapy.[19,60,61,62,63] If nonresponsiveness continues, a trial of an alternative agent is warranted.

There are little data on the choice of treatments if there is a partial response to antidepressants therapy. Published studies offer preliminary support for the combination of an SSRI with a benzodiazepine, gabapentin, or pregabalin.[19,60,61,62,63]

Atypical antipsychotics and MAOIs are options in treatment-resistant SAD. Quetiapine monotherapy showed a large effect size on the Social Phobia Inventory when compared with placebo.[19,60,61,62,63] Although phenelzine is effective in 77% of patients with SAD,[2,19] dietary restrictions, potential drug interactions, and adverse effects (eg, weight gain and hypertensive crisis) have limited its use. If a patient is switched from another antidepressant to phenelzine, an appropriate washout period should be followed.

Special Populations

SAD can present in children of preschool to elementary school age. If the disorder is not treated, it can persist into adulthood and increase the risk of depression and substance abuse. CBT and social skills training are effective nonpharmacologic therapies in children.[19,60,61,62,63] Placebo-controlled and open-label trials have provided evidence of efficacy of pharmacotherapy with an SSRI or SNRI in children between ages 6 and 17 years.[2,19,60,61,62,63] Children and adolescents prescribed an SSRI or SNRI for social anxiety (or for other purposes) should be closely monitored for increased risk of suicidal ideation. Headache, nausea, drowsiness, insomnia, jitteriness, and stomachaches were reported in children receiving antidepressants.[19,60,61,62,63]

Benzodiazepines should be reserved as the last-line agents in children with SAD.[19,52] If prescribed, they should be used for the shortest time period possible. The adverse effects of benzodiazepines in children include drowsiness, oppositional behavior, disinhibition, and fatigue.

Approximately one-fifth of patients with SAD also suffer from an alcohol use disorder. Many people with SAD report that they use alcohol to cope with anxiety. Paroxetine significantly reduced social anxiety and the frequency and severity of alcohol use in patients with SAD and an alcohol use disorder.[65] MAOIs and benzodiazepines are not appropriate therapy for patients with SAD and alcohol use disorder. SSRIs are the drugs of choice.

Personalized Pharmacotherapy

Despite the availability of effective treatments for social anxiety, most adults in the United States with social anxiety do not receive mental healthcare for their symptoms. Often the symptoms that patients desire to relieve interfere with the ability to seek treatment. Patients often feel embarrassed of what others might think or say about them. It is important to develop an alliance with the patient and offer reassurance throughout the treatment process.

Certain complications may influence the choice of first-line pharmacotherapy. Comorbid depression or suicidal ideation requires careful evaluation and close monitoring. Patients with comorbid substance abuse on presentation may require postponing pharmacotherapy until after detoxification and avoidance of use of benzodiazepines as part of treatment.

Patient-specific education about treatment is important. Patients should be instructed about the gradual onset of effect, when to expect full therapeutic benefit, and that long-term therapy is required. When drug therapy is discontinued, the dosage needs to be gradually decreased over several months, and the patient should be seen more frequently to monitor for signs and symptoms of relapse or withdrawal.

It is important to remember that although pharmacotherapy usually leads to improvement in social and occupational functioning, most patients do not achieve a full remission. Many patients require additional treatment, often in the form of CBT.

There is little evidence available to predict response to pharmacotherapy for social anxiety. Variation in a functional polymorphism known to influence 5-HT reuptake is associated with SSRI response in patients with generalized SAD. In a trial that evaluated whether variation in the 5-HT transporter gene promoter (5HTTLPR) influences the efficacy of SSRIs, a trend was seen for a linear association between 5HTTLPR genotype and likelihood of response to SSRI.[66] Reduction in social anxiety symptoms during SSRI treatment was significantly associated with 5HTTLPR genotype using either the diallelic or triallelic classification.[66]

Evaluation of Therapeutic Outcomes

10 The pharmacotherapy of SAD can be monitored in three principal domains: SAD symptoms (eg, fears and physical symptoms), functionality, and well-being or overall improvement.[25,26,63] Response to pharmacotherapy in SAD is defined as a stable, clinically meaningful improvement; patients no longer have the full range of symptoms but typically continue to experience more than minimal symptoms.[25,26,63]

During the acute phase of treatment, patients should be seen weekly while the drug dosage is titrated. Once the patient responds and the dosage is stabilized, the patient can be seen monthly. Many patients report improvement during the first 4 weeks of therapy, but more than one-quarter of those who do not have a response at week 8 may have a response at 12 weeks. At each visit, the patient should be asked about adverse effects and improvement in symptoms. The patient should be

ear levels, physical symptoms, cognitions, and anxious behaviors

in actual exposures to social situations. The LSAS is a clinician-rated scale of clinical severity and change in SAD for monitoring response.[29] Patients can use the Social Phobia Inventory for self-assessment of SAD symptoms.[29] Full remission is a complete resolution of symptoms across the three SAD domains that is maintained for 3 months or a LSAS score of less than or equal to 30 points.[29]

TREATMENT

Specific Phobia

Specific phobia is considered unresponsive to drug therapy, although highly responsive to CBT. The use of benzodiazepines or paroxetine in patients who failed CBT is supported by limited data. Benzodiazepines can be detrimental in patients with specific phobias treated with CBT.[22]

CONCLUSION

Anxiety disorders are common in the population and occur concurrently with other psychiatric disorders. The proper management of anxiety disorders begins with the correct diagnosis; not all patients should receive antianxiety agents. Nonpharmacologic interventions often are effective alone or when combined with drug therapy.

There are several subtypes of anxiety disorders, and the diagnosis determines the type of drug and nonpharmacologic intervention selected. Although benzodiazepines remain the drugs of choice for situational anxiety, antidepressants have emerged as first-line therapy for GAD, panic disorder, and SAD. Benzodiazepines are reserved for use in situations requiring immediate anxiety relief during the first 2 to 4 weeks of therapy with a long-term agent such as an antidepressant. Antidepressants, including the SSRIs and SNRIs, and the benzodiazepines clonazepam and alprazolam are used extensively in patients with GAD, panic disorder, and SAD.

The long-term goal of therapy for GAD, panic disorder, and SAD is remission of core anxiety symptoms with no impairment in functionality, minimal anxiety, and no depressive symptoms. Augmentation with anticonvulsants and atypical antipsychotics show some promise in treatment-resistant cases.

Chapter 71: Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder

FIGURE 71-1

Cynthia K. Kirkwood; Sarah T. Melton; Barbara G. Wells

INTRODUCTION

KEY CONCEPTS

- 1 The short-term goal in posttraumatic stress disorder (PTSD) is reduction in core symptoms, while the long-term goal is remission.
- 2 Cognitive behavioral therapy and eye movement desensitization and reprocessing are the most effective nonpharmacologic methods to reduce symptoms of PTSD.
- 3 The selective serotonin reuptake inhibitors (SSRIs) and venlafaxine are considered first-line treatments for PTSD.
- 4 An adequate trial of SSRIs in PTSD requires appropriate dosing and duration of treatment.
- 5 Patients with PTSD who respond to pharmacotherapy should continue treatment for at least 12 months.
- 6 SSRIs are the drugs of choice for the treatment of obsessive-compulsive disorder (OCD).
- 7 Augmentation of SSRI treatment of OCD with low doses of antipsychotics may be helpful.
- 8 If an inadequate response to an SSRI for OCD occurs after 4 to 6 weeks at the maximum dose, switch to another SSRI.
- 9 Medication taper can be considered after 1 to 2 years of treatment in patients with OCD.

Traumatic or stressful events (eg, wars, terrorist attacks, torture, natural disasters, robbery, physical assault) can lead to development of posttraumatic stress disorder (PTSD). Initially diagnosed in veterans of war, PTSD is now acknowledged as a significant psychiatric illness in the civilian population and among deployed service personnel of the Afghanistan and Iraq campaigns in whom the suicide rate has escalated.[1,2] PTSD continues to be poorly recognized and diagnosed in clinical practice.[3,4] Because of its co-occurrence with anxiety disorders, depression, substance abuse, and traumatic brain injury, the overlapping symptoms can lead to diagnostic uncertainty. Advances in the science and treatment of PTSD can assist clinicians in all fields of healthcare to screen patients for a history of trauma and effectively manage PTSD if it is present.

Intrusive obsessive thoughts and compulsive ritualistic behaviors characterize obsessive-compulsive disorder (OCD). OCD can be severely debilitating and impair functioning in social, family, and work settings, with an overall decrease in quality of life (QOL). OCD is associated with an increased risk of suicide, with 15% of patients reporting a previous history of suicide attempt.[5] Increased understanding of symptom dimensions and treatment response can improve QOL in patients suffering from OCD.

EPIDEMIOLOGY

The estimated lifetime prevalence of PTSD is 8.7% in the US population.[1] Lifetime prevalence of OCD has been estimated at 2.3% in the general population.[6]

PTSD is associated with the incidence of trauma. It is estimated that approximately 60% of men and 50% of women are exposed to a life-threatening traumatic event.[7] Of these individuals 8.2% of men and 20% of women will develop PTSD. Previous exposure to a trauma and the intensity of response to the event increase the risk of PTSD. Men tend to be assaulted more frequently, but women are more likely to experience rape and sexual abuse.[7] Genetic factors can increase vulnerability to PTSD if an individual is exposed to a traumatic event. Veterans and those whose jobs increase the risk of traumatic exposure (eg, firefighters, police) have higher rates of PTSD.[1]

The epidemiology of OCD is influenced by age and gender. OCD typically begins early in life, with 25% of cases occurring by age 14.[1] Age of onset has a bimodal distribution with peaks around 10 and 21 years.[8] The onset of illness is earlier in men than in women.[6] Early age of onset has been associated with higher probabilities of comorbid anxiety disorders, oppositional defiant disorder, attention-deficit/hyperactivity disorder, and tic disorders.[9] Heredity is stronger when there is an early age of onset or comorbidity with tic disorder.[10]

ETIOLOGY

The exact etiologies of PTSD and OCD are not known. It is likely that abnormalities in several areas of brain functioning interact to cause these chronic disorders. Genetics may play a role in expression of PTSD and OCD, but environmental factors likely are also involved. A number of genetic markers for PTSD are under evaluation, including genes associated with the hypothalamic-pituitary adrenal axis

and the serotonin transporter.[11,12] A genome-wide association study did not detect any single nucleotide polymorphisms (SNPs) associated with OCD, but there was a significant enrichment of methylation quantitative trait loci (mQTLs) and frontal lobe expression of quantitative trait loci (eQTLs) in the highest ranked autosomal SNPs, suggesting that these signals may influence gene expression and perhaps the etiology of OCD.[10] Genetic etiologies of both PTSD and OCD are current research areas.

Controversy exists over the existence of a subtype of OCD characterized as a pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections (PANDAS). A relationship between the sudden onset of OCD and chronic tic disorder with an age of onset between 3 years and puberty with possible exacerbations and remissions, and a temporal association with streptococcal infection associated with symptoms of OCD or neurologic abnormalities has been proposed.[13] Although most patients with OCD do not have a streptococcal etiology, an accurate medical history regarding onset of illness is imperative because specific treatment strategies are indicated.

PATHOPHYSIOLOGY

Research findings in the areas of neuroendocrinology, neurobiology, and neuroimaging have advanced a number of theories on the pathophysiology of anxiety disorders, OCD, and PTSD. Neuroendocrine changes in the hypothalamic–pituitary–adrenal (HPA) axis are implicated in the pathophysiology of PTSD.[14] As reviewed in Chapter 70, data from neurochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain (eg, amygdala, hippocampus, thalamus, and prefrontal cortex).[14,15] Abnormal function in several neurotransmitter systems, including norepinephrine (NE), *γ*-aminobutyric acid (GABA), glutamate, dopamine (DA), and serotonin (5-HT), may affect the manifestations of anxiety disorders, OCD and PTSD.[14,16]

Neuroendocrine Theories

Neuroendocrine studies provide data that abnormalities occurring pretrauma, during trauma, and posttrauma contribute to PTSD. Normally the immediate reaction to stress occurs as an automatic response from the amygdala to the sympathetic and parasympathetic systems and the HPA axis.[14] The release of corticotropin-releasing factor (CRF) stimulates cortisol secretion from the adrenal gland. Both catecholamines and cortisol levels rise in tandem. Cortisol reduces the stress response by tempering the sympathetic reaction through negative feedback on the pituitary and hypothalamus.[14] These systems return to normal after a few hours.

Recent data implicate a role for the neuropeptides CRF and neuropeptide Y (NPY) in PTSD. Patients with PTSD have a hypersecretion of CRF but demonstrate subnormal levels of cortisol at the time of trauma and chronically.[14] Lower plasma cortisol concentrations were associated with greater severity of PTSD symptoms in nonmilitary patients.[16] Dysregulation of the HPA axis is postulated to be a risk factor for eventual development of PTSD.[14] Higher plasma concentrations of NPY were found in combat-exposed men who did not develop PTSD and could play a role in resiliency.[16]

Neurochemical Theories

Several neurotransmitters may be involved in the pathophysiology of PTSD. 5-HT, NE, and glutamate are associated with the processing of emotional and somatic contents of memories in the amygdala. The cortex and hippocampus are involved in storing the facts and related cues of memory.[16] The noradrenergic theory posits that the autonomic nervous system of anxious patients is hypersensitive and overreacts to stimuli. The alarm center, the locus ceruleus, releases NE to stimulate the sympathetic and parasympathetic nervous systems. Hyperactive noradrenergic signaling in patients with PTSD is a consistent research finding and includes increased 24-hour catecholamine excretion.[16] Glutamate signaling abnormalities may result in distortion of amygdala-dependent emotional processing under stress.[14,16] Dysregulation of the processing of sensory input and memories may contribute to the dissociative and hypervigilant symptoms in PTSD. Abnormalities of GABA inhibition may lead to increased awareness or response to stress, as seen in PTSD.[16]

Both 5-HT and DA are implicated in the pathogenesis of OCD. Selective and potent serotonergic reuptake inhibitors have consistently been shown effective for symptoms of the illness.[17] A recent meta-analysis concluded that higher doses of selective serotonin reuptake inhibitors (SSRIs) were associated with improved efficacy in the treatment of OCD.[17] DA dysregulation may contribute to some forms of OCD. Neurologic symptoms (eg, tics) are part of the clinical presentation in some patients with OCD. Tourette's disorder, a disorder of DA function, is often a concurrent disease.[1] Augmentation with antipsychotic drugs may improve symptoms in patients with OCD who are partially responsive to SSRIs.[18]

Neuroimaging Studies

Neuroimaging studies suggest that certain areas of the brain are altered by psychological trauma. In PTSD most functional neuroimaging studies have involved the amygdala, ventromedial prefrontal cortex (vmPFC), dorsal anterior cingulate cortex (dACC), and hippocampus. Findings of increased activation of the amygdala after trauma-related imagery, sounds, or smells indicate that this structure plays a role in the persistence of traumatic memory.[15] Decreased amygdala activation is correlated with resilience to PTSD and response to cognitive behavioral therapy (CBT).[15] Hypofunctioning of the vmPFC is theorized to prevent extinction in patients with PTSD and is inversely correlated with severity of symptoms.[15] Hyperresponsivity of the dACC and the insular cortex may correlate with impaired response to emotional stimuli or those that predict threat. The most consistent findings are decreased hippocampus volumes and *N*-acetylaspartate levels in patients with PTSD.[14,15] In twin studies, the unaffected twin of patients with PTSD also demonstrated smaller hippocampi compared with twins without PTSD. These findings suggest that lower hippocampal volumes in patients with PTSD are likely a precursor associated with vulnerability for subsequent development of PTSD.[14]

Neuroimaging studies suggest that dysfunction in the cortical–striatal–thalamic circuits is responsible for impulsive behavior and inability to regulate socially acceptable behaviors.[19] Drugs that decrease hyperactivity in the cortical–striatal–thalamic circuits decrease symptoms of OCD.[10] Glutamate may

play a role in OCD symptomatology.[20]

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) made several changes to the classification of anxiety and related disorders.[1] There are now individual chapters for anxiety disorders, trauma- and stress-related disorders, and obsessive-compulsive and related disorders. The movement of PTSD and acute stress disorder (ASD) from the DSM-5 anxiety disorders chapter was based on evidence that anxiety is just one of several reactions to trauma or other adverse events.[1] The DSM-5 OCD and related disorders chapter also includes hoarding disorder and trichotillomania (hair-pulling disorder). Generalized anxiety disorder, panic disorder, and social anxiety disorder are discussed in Chapter 70.

Posttraumatic Stress Disorder

Exposure to a traumatic event is required for a diagnosis of PTSD.[1] The person must have witnessed, experienced, or been confronted with a situation that involved definite or threatened death or serious injury, sexual violence, or possible harm to self or others.[1] Some examples of traumatic events include physical attacks by an intimate partner, severe traffic accidents, military combat, earthquakes, being held hostage, child sexual abuse, witnessing a murder or injury of another, and learning of a traumatic event that happened to a close family member or friend.

The resulting PTSD symptoms include persistent reexperiencing of the traumatic event, avoidance of stimuli associated with the trauma, numbing of general responsiveness, and persistent symptoms of hyperarousal. Patients must have at least one intrusion symptom, at least one symptom of avoidance of stimuli associated with the trauma, at least two symptoms of negative alterations in cognition and mood, and at least two symptoms of increased arousal.[1] Symptoms from each category need to be present for longer than 1 month and cause significant distress or impairment in functioning. Most persons diagnosed with PTSD also meet criteria for another mental disorder.[1,21]

Anxiety and dissociative symptoms (eg, absence of emotional responsiveness, derealization, inability to recall important features of the trauma) emerging within 1 month after exposure to a traumatic stressor are classified as ASD. Symptoms of ASD are experienced during or immediately after the trauma, last for at least 3 days, and resolve within 1 month.[1]

CLINICAL PRESENTATION Posttraumatic Stress Disorder Intrusion Symptoms

- Recurrent, intrusive distressing memories of the trauma
- Recurrent, disturbing dreams of the event
- Feeling that the traumatic event is recurring (eg, dissociative flashbacks)
- Physiologic reaction to or psychological distress from reminders of the trauma

Avoidance Symptoms

- Avoidance of conversations, thoughts, or feelings about the trauma
- Avoidance of people, places, or activities that are reminders of the event

Persistent Negative Alterations in Thinking and Mood

- Inability to recall an important aspect of the trauma
- Anhedonia
- Estrangement from others
- Restricted affect
- Negative beliefs about oneself
- Distorted beliefs causing one to blame others or themselves for the trauma
- Negative mood state

Hyperarousal Symptoms

- Decreased concentration
- Easily startled
- Self-destructive behavior
- Hypervigilance
- Insomnia
- Irritability or anger outbursts

Specifiers

- Dissociative symptoms: depersonalization or derealization
- With delayed expression: full criteria are not met until at least 6 months posttrauma

Data from references 1 and 21.

The age of onset and course of PTSD are variable. PTSD can occur at any age. The presentation is not predictable, because symptoms are related to the duration and intensity of the trauma, the presence of other psychiatric disorders, and how the patient deals with the trauma. Symptoms emerge soon after a traumatic event and either dissipate or chronically persist in survivors.[22] About 95% of patients who recover do so within a year, and 40% have persistent symptoms 6 years later. PTSD co-occurs with mood, anxiety, and substance use disorders. The course of illness is fluctuating, worsening with

life stressors.[22]

Obsessive-Compulsive Disorder

Patients with OCD exhibit a great variety of symptoms on presentation to clinicians. The diversity and oddity of symptoms that manifest can obscure accurate diagnosis and delay appropriate treatment of the disorder. Patients can be secretive about symptoms and purposefully refuse to report symptoms.[5] Patients can present in a seemingly incongruous manner to nonpsychiatrists for other complaints —dermatologists for eczema or chapped skin, pediatricians for parental concerns over a child's compulsive hand washing, neurologists for tics, or dentists for gum lesions from compulsive teeth brushing.

The diagnostic criteria for OCD require the presence of obsessions and/or compulsions (although most patients have both) that are severe enough to cause marked distress, to be time-consuming (occupy more than 1 h/day), or cause significant impairment in social or occupational functioning.[1] An obsession is a recurrent, persistent idea, thought, impulse, or image that is experienced as intrusive and inappropriate and produces marked anxiety. Common obsessions involve thoughts about contamination (eg, concern with germs or dirt) and repeated doubts.[1]

CLINICAL PRESENTATION Obssessive-Compulsive Disorder Obsessions

- Repetitive thoughts (eg, feeling contaminated by germs, doubting whether the stove was turned off)
- Repetitive images (eg, recurrent sexually explicit pictures)
- Repetitive urges (eg, need for symmetry or putting things in specific order, impulse to shout out obscenities in a church)

Compulsions

- Repetitive activities (eg, hand washing, checking, arranging, need to ask, need to confess)
- Repetitive mental acts (eg, counting excessively, repeating words silently, praying)

Specifiers

- Insight
    - Good or fair insight
    - Poor insight
    - Absent insight/delusional beliefs
- Related to a tic disorder

Data from references 1 and 8.

A compulsion is defined as a repetitive behavior or mental act generally performed in response to an obsession. Diagnostically, compulsive behavior is not pleasurable and is designed to prevent discomfort or the occurrence of a dreaded event that is often unknown. For example, many patients are obsessed with feelings of doubt (eg, whether a window was left unlocked), causing them marked distress and leading to repetitive checking (or compulsive behaviors). These behaviors are usually performed according to certain rules or in a stereotyped fashion. Because patients recognize their compulsive behavior as silly or senseless, they become extremely adept at denying symptoms, disguising their rituals, and concealing their illness from friends and family.[1] Individuals vary widely in their insight into the irrationality of their obsessive-compulsive symptoms.

Patients with OCD often have concurrent depression, other anxiety disorders, and substance abuse. It is a chronic illness in most patients, with severity of symptoms varying in intensity over time. Many patients with OCD have significantly impaired QOL and ability to function.[5,23]

TREATMENT

Desired Outcomes

1 The short-term goal of therapy in the management of PTSD is reduction in core symptoms (ie, intrusive reexperiencing, avoidance, and hyperarousal). Patients should also have improvements in disability, concurrent psychiatric conditions, resilience, and QOL. The long-term goal in PTSD is remission.

General Approach to Treatment

In general, patients who seek treatment acutely after a trauma and are in intense distress should receive therapy based on their presenting symptoms (eg, a nonbenzodiazepine hypnotic for difficulty sleeping). Short courses of exposure-based, trauma-focused cognitive behavioral therapy (TFCBT) can be helpful to prevent chronic PTSD in patients with ASD or acute PTSD.[21] If symptoms (eg, hyperarousal, avoidance, dissociation, sleep difficulties, or depressed mood) persist for 3 to 4 weeks and the patient experiences marked social, occupational, and/or interpersonal impairment, they can be treated with pharmacotherapy, psychotherapy, or both. Many patients with PTSD will improve substantially with pharmacotherapy but retain some symptoms. Treatment regimens usually combine psychoeducation, psychosocial support and/or treatment, and pharmacotherapy.[21,22,24]

Nonpharmacologic Therapy

Psychotherapy can be used when a patient suffers from mild symptoms, in patients who prefer not to use medications, or in conjunction with drugs in patients with severe symptoms to improve response. Patients who have experienced trauma should be educated that they can experience anxiety, depression, nightmares, and even flashbacks as a reaction to the event. Brief courses of prolonged exposure, a form of CBT, in close proximity to the traumatic event resulted in lower rates of PTSD 3

and 6 months later.[4] Single-session critical incident stress debriefing was not shown to be effective in preventing development of PTSD and actually can cause harm.[21,24]

2 Psychotherapies for treating PTSD include stress management, TFCBT, eye movement desensitization and reprocessing (EMDR), and psychoeducation.[21] Short-term reductions in symptoms can be achieved with stress management, group therapy, hypnosis, or psychodynamic therapy.[21,24] The cognitive and behavioral approaches of TFCBT and EMDR are more effective than stress management or group therapy to reduce symptoms of PTSD.[21] Psychoeducation includes information about the disease state, treatment options, and avoidance of excessive use of alcohol and other substances of abuse. Novel nonpharmacologic approaches (eg, interpersonal psychotherapy, narrative exposure therapy, imagery modification, transcranial magnetic stimulation) and delivery methods (eg, telemedicine, computer-delivered CBT) are under study.[25,26]

Pharmacologic Therapy

3 Antidepressants are the major pharmacotherapeutic treatment for PTSD. In addition to their efficacy in PTSD, these agents are also effective for concurrent depression and anxiety disorders. SSRIs and venlafaxine are the first-line pharmacotherapy of PTSD.[24,27,28] The tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) can also be effective, but they have less favorable side-effect profiles (**Table 71-1**). Both sertraline and paroxetine are approved for the acute treatment of PTSD,[29,30] and sertraline is approved for the long-term (ie, 52 weeks) management of PTSD.[30] A number of drugs can be used as augmentation agents (eg, antiadrenergic drugs and atypical antipsychotics).[27,28] Benzodiazepines are not effective for PTSD.[27,28] A number of treatment guidelines are published.[31] **Table 71-2** provides a summary of key points from the treatment guidelines for PTSD. An algorithm for the treatment of PTSD appears in **Fig. 71-1**.

TABLE 71-1 Dosing of Antidepressants in the Treatment of PTSD

Drug	Brand Name	Initial Dose	Usual Range (mg/day)	Comments
SSRIs				
Fluoxetine[a]	Prozac®	10 mg/day	10-40[b]	
Paroxetine[a]	Paxil®, Pexeva®	10-20 mg/day	20-40	Maximum dose is 50 mg/day[c]
Sertraline[a]	Zoloft®	25 mg/day	50-100	Maximum dose is 200 mg/day[c]
Other Agents				
Amitriptyline[a]	Elavil®	25 or 50 mg/day	75-200[b]	
Imipramine[a]	Tofranil®	25 or 50 mg/day	75-200[b]	
Mirtazapine[a]	Remeron®	15 mg/night	30-60[b]	

Drug	Brand Name	Initial Dose	Usual Range (mg/day)	Comments
Phenelzine[a]	Nardil®	15 or 30 mg every night	45-90[b]	
Venlafaxine extended-release[a]	Effexor XR®	37.5 mg/day	75-225[b]	

PTSD, posttraumatic stress disorder; SSRIs, selective serotonin reuptake inhibitors.

[a]Available generically.

[b]Dosage used in clinical trials but not FDA-approved.

[c]Dosage is FDA-approved.

Data from references 27, 29, and 30.

TABLE 71-2 Summary of Key Points in Treatment Guidelines for PTSD

Recommendation	Level of Evidence	Comments
First-Line Treatments		
SSRIs: Fluoxetine, paroxetine, sertraline	I	At 4 weeks if there is partial response, continue for another 4 weeks.
SNRIs: Venlafaxine	I	At 8 weeks, if no improvement, increase dose to maximum tolerated or switch to another first-line treatment
Second-Line Treatments		
TCAs: Amitriptyline, imipramine	II	The risk of adverse effects and potential for fatalities in a TCA overdose are higher than with SSRIs or SNRIs
Other: Mirtazapine	II	
Augmentation with prazosin for sleep/nightmares	II[24]	Recommended in the VA guidelines[24]
Augmentation with risperidone	II[31]	The VA guidelines[24] recommend against using risperidone as an augmenting agent secondary to metabolic adverse effects. There is insufficient evidence to support use of other atypical antipsychotics
Third-Line treatments		
MAOIs: Phenelzine	IV[31]	The VA guidelines[24] recommend phenelzine to be used cautiously (Level III)

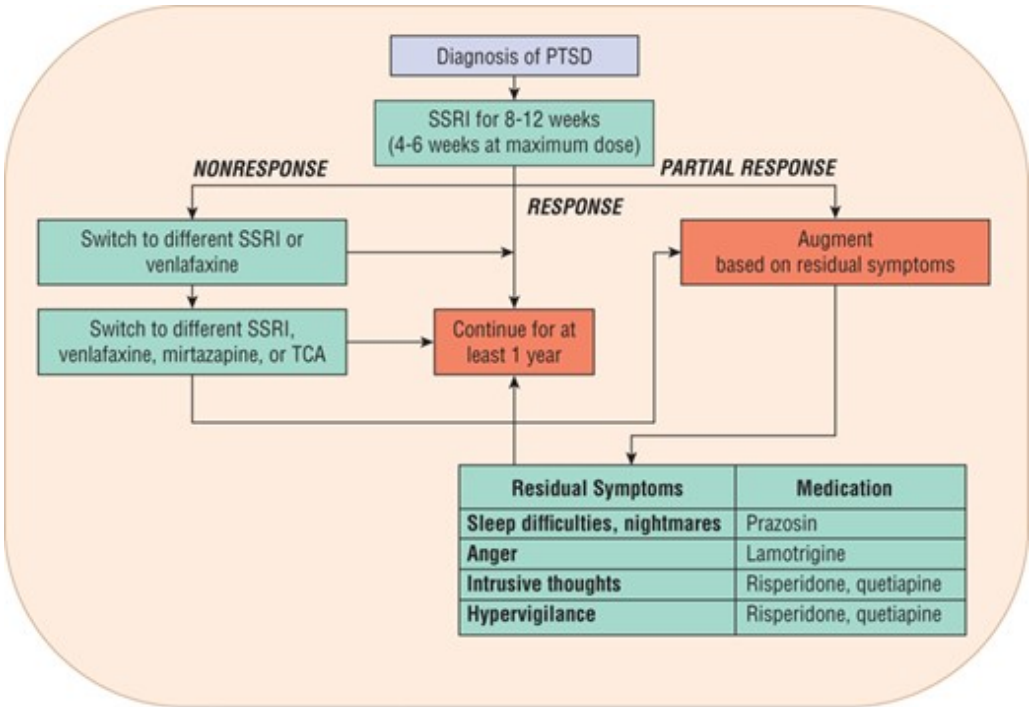
PTSD, posttraumatic stress disorder; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressant; VA, Veterans Affairs.

Levels of evidence: I, strong recommendation, full evidence from controlled trials; II, recommended, limited positive evidence from controlled trials; III, may be recommended, evidence from uncontrolled trials or case reports/expert opinion; IV, evidence is insufficient to recommend, inconsistent findings.

Data from references 24 and 27.

FIGURE 71-1

Algorithm for the pharmacotherapy of posttraumatic stress disorder (PTSD). *(Data from references 24 and 27.)*



Antidepressant Therapy

Selective Serotonin Reuptake Inhibitors

SSRIs act pharmacologically to enhance serotonergic functioning. Large prospective studies documented the efficacy of sertraline and paroxetine in the acute management of PTSD.[28] A recent meta-analysis found that SSRIs were significantly better than placebo, but the effect size was small.[32] Adverse reactions reported in patients with PTSD treated with SSRIs include gastrointestinal (GI) symptoms, sexual dysfunction, insomnia, and agitation. Long-term use of SSRIs (durations of 9-12 months) was effective in preventing relapse.[27]

Other Antidepressants

The serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine has shown efficacy in PTSD. In a 12-week, placebo-controlled trial comparing venlafaxine extended-release and sertraline, venlafaxine was effective in reducing the avoidance/numbing and hyperarousal clusters of PTSD, whereas sertraline improved all PTSD symptom clusters.[33] The remission rates for venlafaxine extended-release were 30.2% after 12 weeks[33] and 50.1% after 6 months.[34]

Other antidepressants have been studied in controlled trials. Mirtazapine was effective on global ratings of symptoms in 64% of patients with PTSD in doses up to 45 mg/day and is considered a second-line agent.[24,27] Bupropion sustained-release was not effective in patients with chronic PTSD.[21]

The TCAs amitriptyline and imipramine are also considered second-line agents, and the MAOI phenelzine is considered a third-line antidepressant if therapeutic trials of SSRIs or venlafaxine have failed. TCAs are associated with a higher burden of adverse effects compared with SSRIs (eg, daytime drowsiness, toxicity in overdose, and poor compliance).[24,27]

Alternative Drug Treatments

Atypical antipsychotics, α_1-adrenergic antagonists, antidepressants, mood stabilizers, and anticonvulsants can be used as augmenting agents for persistent symptoms, in cases of partial response to SSRI therapy after 4 to 6 weeks, or for comorbidities.[35] Data on the efficacy of atypical antipsychotics are conflicting. Overall there is a modest positive effect of risperidone and quetiapine in double-blind trials with intrusive and hypervigilance symptoms showing the most improvement.[36] A large, 6-month trial failed to show improvement in PTSD symptoms with the adjunctive use of risperidone to antidepressant therapy in military service personnel.[37]

Prazosin can be useful in some patients with PTSD. It decreased nightmares and sleep disturbances and improved the core PTSD symptoms in daily doses of 1 to 4 mg. Its presumed mechanism of action is reduction of noradrenergic transmission.[38,39] Other options for persistent sleep disturbances with less evidence include trazodone, mirtazapine, eszopiclone, and atypical antipsychotics.[39,40]

Anticonvulsants can assist in reducing impulsive anger and can also be used in patients with comorbid bipolar disorder. Some data support efficacy of lamotrigine as an augmenting agent. Data with other anticonvulsants are inconsistent.[35] The use of an anticonvulsant is not recommended as monotherapy.[24]

Special Populations

Children who experience stress and trauma (eg, sexual or physical abuse or loss of a parent) are predisposed to develop mood and anxiety disorders. SSRIs are the initial pharmacologic agents of choice in this patient population.[41] Psychotherapy is also a treatment option (eg, TFCBT).[42]

Dosage and Administration

Acute Phase

PTSD symptoms respond slowly to pharmacotherapy, and some patients never experience full resolution. SSRIs should be started 3 to 4 weeks after exposure to a trauma in patients with no improvement in their acute stress response. The initiation of an SSRI should be at a low dose with gradual titration upward toward antidepressant doses. 4 Eight to 12 weeks is an appropriate duration of antidepressant therapy to determine response.[21,24,27,43]

Continuation Phase

Many patients are undergoing psychotherapy during the continuation phase of therapy, and dosages can vary as patients deal with past traumatic experiences. During this phase, symptoms continue to improve. Six-month relapse prevention trials in patients responsive to fluoxetine or sertraline indicate low rates of relapse with SSRI therapy compared with placebo.[43]

Maintenance and Discontinuation

5 Patients with PTSD who respond to pharmacotherapy should continue treatment for at least 12 months.[21,27,43] If residual symptoms persist, drug therapy should be continued. The decision about when to discontinue therapy is based on response to therapy, presence of ongoing stresses, and adverse effects. The patient must be confident in the discontinuation plan and can require extra support throughout the process. Drug therapy should be withdrawn and tapered slowly over a period of at least 1 month to reduce the potential for relapse.

Personalized Pharmacotherapy

The choice of pharmacotherapy should be individualized to the patient's presenting symptoms. Selection of an SSRI or venlafaxine monotherapy is based on the patient's history of prior response, safety, and side-effect tolerability. When selecting an agent, the clinician should consider the potential for adverse consequences in patients with comorbid conditions (eg, anticholinergic effects and weight gain with paroxetine in patients with diabetes, obesity, or benign prostatic hypertrophy) or adverse effects (eg, insomnia with fluoxetine in patients with sleep difficulties). Increased risk of suicidality should be considered in patients taking antidepressants who are younger than 25 years. If symptoms of insomnia or nightmares continue, prazosin can be added to provide relief. Risperidone or quetiapine can be added for patients who fail to respond or have a partial response to antidepressant therapy.

Clinical Controversy…

When initiating treatment for PTSD it is unclear if pharmacotherapy should be initiated alone or in combination with psychotherapy. Currently there is insufficient evidence to guide clinicians.

Evaluation of Therapeutic Outcomes

During the acute phase of therapy, patients should be seen frequently. During months 3 to 6 of therapy, the patient can usually be seen monthly, and in months 6 to 12, visits can usually be extended to every 2 months. On each visit the patient should be asked about previously identified target symptoms of PTSD as well as other symptoms including insomnia, suicidal ideation, anger outbursts, irritability, psychosis, ongoing trauma, and disability. The Clinician-Administered PTSD Scale (CAPS) can be used by the clinician to assess symptom severity at visits.[24] A remission in patients with PTSD is defined as a 70% or greater reduction in symptoms. Patients who have a 50% response or greater reduction in symptoms are considered to have an adequate response, while those with a 25% to 50% reduction in symptoms are considered partial responders. Before deciding that a patient is not responsive to pharmacotherapy, the clinician should ensure that the medication trial has been adequate in both dose and duration.

Many patients with PTSD are sensitive to the adverse effects of drugs. They should be monitored carefully for adverse reactions that can delay the escalation of drug dosages or cause the patient distress. See Chapter 68 for details on monitoring antidepressants. Routine assessment of the metabolic profile is necessary if an atypical antipsychotic is used concurrently.[27] When pharmacotherapy is discontinued, patients should be seen more frequently and monitored carefully for signs of relapse or withdrawal.

TREATMENT

Desired Outcomes

Major goals of therapy for OCD include reduction in the frequency and severity of obsessive thoughts and time spent performing compulsive acts. Treatment for OCD generally does not completely eliminate obsessions or compulsions, but patients can feel remarkably improved with partial resolution of symptoms. Patients typically experience waxing and waning symptoms with only 20% achieving full remission.[44] Optimal treatment increases psychosocial and occupational functioning and improves overall QOL. Efforts should be made to minimize adverse drug events and prevent drug interactions.

General Approach to Treatment

It is important at the outset of therapy to identify and document the specific target symptoms for pharmacotherapy. Rating scales can be used to measure symptom severity at baseline and during treatment to ascertain the degree of improvement. The Yale-Brown Obsessive-Compulsive Scale (YBOCS) is the most widely used clinician-administered scale. A QOL scale can assist the clinician in identifying other areas to target for treatment (eg, depression and reduced physical well-being).[45,46]

The FDA has approved five antidepressants for the management of OCD: clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline. CBT and SSRIs are considered effective first-line treatment modalities.[45,46] Initial therapy may include CBT alone, SSRI monotherapy, or the combination of CBT and an SSRI, and the choice is based on clinical judgment of symptom severity and patient preferences.[45] CBT alone can be used in cooperative patients who do not desire drug therapy or

those with mild anxiety or depressive symptoms. Patients unable to participate in CBT or with a prior history of medication therapy response should be treated with SSRI monotherapy. Combined CBT and SSRIs is recommended in patients with failure on an SSRI alone or in those with severe OCD. If a combination of CBT and an SSRI is unsuccessful, another SSRI should be tried before augmentation therapy. If there is no response or partial response to combined CBT and three adequate antidepressant trials (one of which is clomipramine), augmentation with another drug and more intensive CBT can be tried.[45] Augmentation with antipsychotics has proven efficacious in some patients with partial response.[18,45]

Table 71-3 provides a summary of key points from the treatment guidelines for OCD. Although some OCD symptoms can improve over the first 4 to 6 weeks of therapy, an adequate trial of any medication is considered to be 8 to 12 weeks.

TABLE 71-3 Summary of Key Points in Treatment Guidelines for OCD

Recommendation	Level of Evidence	Comments
First-Line Treatments		
CBT alone	I	13-20 sessions
SSRI alone	I	8-12 weeks, at least 4-6 weeks at maximum tolerated dose 13-20 CBT sessions and 8- to 12-week SSRI with 4-6 weeks at maximum tolerated dose
CBT + SSRI	I	If monotherapy with CBT or SSRI alone does not provide adequate response, combination therapy with CBT + SSRI should be tried before augmentation with another pharmacologic agent
Second-Line Treatments		
Switch to another SSRI or clomipramine	I	
Augmentation with antipsychotic	II	
Third-Line Treatments		
Switch to another antipsychotic augmenting agent	II	
Augmentation of SSRI with clomipramine	III	
Maintenance and Discontinuation Phase		
After 1-2 years, gradual taper over several months	I	

Recommendation	Level of Evidence	Comments
Periodic CBT booster sessions for 3-6 months	II	

CBT, cognitive behavioral therapy; OCD, obsessive-compulsive disorder; SSRI, selective serotonin reuptake inhibitor.

Levels of evidence: I, recommended with substantial clinical confidence; II, recommended with moderate clinical confidence; III, may be recommended on the basis of individual circumstances.

Data from reference 45.

Nonpharmacologic Therapy

A number of nonpharmacologic treatments are effective for OCD. CBT with behavioral techniques (ie, exposure and response prevention [ERP]) is the most common initial nonpharmacologic treatment of choice. ERP is preferred for patients with mild symptoms, particularly children and adolescents, and in those without a psychiatric comorbidity or with a desire to avoid medications.[47] Clinicians can use motivational interviewing techniques to assist patients with treatment acceptance.[45]

Other options are deep brain stimulation (DBS) and ablative neurosurgery.[46,48] DBS is FDA-approved as a humanitarian device for severe, treatment-resistant OCD. It should not be used alone as first-line treatment but may be added to CBT or used in refractory patients. Surgery should be reserved for rare cases.[45,48] Data for the efficacy of transcranial magnetic stimulation are inconclusive.[46]

Pharmacologic Therapy

Practice guidelines for the treatment of patients with OCD were published by the American Psychiatric Association.[45,46]

6 SSRIs are considered to be the drugs of choice for patients with OCD.[45] While not FDA-approved, escitalopram has also shown efficacy in reduction of OCD symptoms.[49] Clomipramine, a TCA with strong 5-HT reuptake inhibition, has an active metabolite, desmethylclomipramine, which inhibits NE reuptake.[45,50] Meta-analytic findings of greater efficacy of clomipramine than SSRIs are not consistent with comparative trial data.[45]

Alternative Drug Treatments

Recent studies have examined novel augmentation approaches. Augmentation with the drugs that modulate the excitatory neurotransmitter glutamate (eg, riluzole, memantine, and topiramate) have shown initial promising results.[44,47] Ondansetron, dextroamphetamine, and d-cycloserine as possible augmentation agents in refractory OCD patients have had mixed results. These alternative augmenting treatments are reserved for refractory patients.[44,45]

Special Populations

Children and Adolescents

OCD affecting children and adolescents is prevalent. There are symptom and treatment similarities and differences between OCD developing earlier in life and that which develops later. Younger patients exhibit poorer insight regarding obsessions, have more obsessions involving fear of harm and separation, and possess more rituals involving family members. CBT weekly or daily and including family members has also been effective.[47] ERP is preferred as the first-line treatment for children and adolescents with milder symptom severity and less comorbidity.[47] Effects of pediatric ERP have been reported to last up to 2 years.[47] CBT and SSRI treatment are considered first-line for pediatric patients.[51]

Clomipramine, fluvoxamine, sertraline, paroxetine, and fluoxetine are approved by the FDA for treatment of OCD in children and adolescents.[45] Childhood and adult OCD appear to respond similarly to drug therapy. SSRIs are effective (50%-56% respond to the initial agent) and well tolerated in the treatment of OCD and are generally considered first-line agents.[45,51] In children, the most commonly described side effects of SSRI therapy include sedation, nausea, diarrhea, insomnia, anorexia, tremor, and hyperstimulation.[51] The starting dose of clomipramine in children is 25 mg daily in divided doses. The dose can be increased over the first 2 weeks up to 3 mg/kg or 100 mg, whichever is smaller. Over the next several weeks, the dose can be increased up to 3 mg/kg with a maximum of 200 mg daily.[50] The risk of suicidality in youth is discussed in Chapter 68.

Hepatic and Renal Disease

Clomipramine and the SSRIs are extensively metabolized in the liver, and patients with significant liver disease should be prescribed these drugs cautiously and in lower doses than those used in healthy subjects. The pharmacokinetics of sertraline is not altered in patients with significant renal dysfunction, and dosage adjustment is not necessary in these patients.[30] Increased plasma concentrations of paroxetine occur in subjects with renal impairment.[29] The initial dose of paroxetine should be reduced in patients with severe renal impairment, and upward titration should occur more slowly.[30] No dosage adjustment is necessary for patients with renal impairment receiving clomipramine.[50]

Elderly

Little information is available on treating OCD in the elderly. Selection of medication for an elderly person with OCD should be based on history of response and adverse effect profile. Treatment should be initiated with low doses in elderly patients, and doses should be increased slowly, with vigilance for emergence of adverse effects.[27,45] Because of clomipramine's sedative and anticholinergic side effects, it is not usually chosen as first-line therapy for elderly OCD patients.[45] The use of SSRIs in elderly patients is discussed in Chapter 68.

Pregnancy

Risk–benefit analysis should be made by practitioners when deciding to use pharmacotherapy options during pregnancy.[45] The use of SSRIs in pregnancy and lactation is discussed in Chapter 68.

Antidepressant Therapy

Serotonergic Antidepressants

The only potent 5-HT reuptake inhibitors consistently demonstrating efficacy in controlled trials are the TCA clomipramine and the SSRIs fluoxetine, fluvoxamine, paroxetine, and sertraline.

Current evidence indicates that 5-HT is important for the antiobsessional effects of medication.[10] SSRIs and clomipramine inhibit 5-HT reuptake into the presynaptic neuron. Inhibiting reuptake of 5-HT makes more 5-HT available to postsynaptic receptors and reduces formation of the 5-HT metabolite 5-hydroxyindoleacetic acid. Although other antidepressants, such as imipramine and amitriptyline, inhibit 5-HT reuptake, they are less potent and selective than SSRIs. Prolonged exposure to increased amounts of 5-HT after chronic antidepressant treatment (2-3 weeks) leads to altered responsiveness of postsynaptic 5-HT receptors or presynaptic autoregulatory receptors that govern 5-HT release in specific brain regions. An improvement in obsessional symptoms may correlate with plasma concentrations of clomipramine but not desmethylclomipramine, the metabolite of clomipramine with less selectivity for 5-HT reuptake inhibition.

Most experts agree that SSRIs are better tolerated than clomipramine. SSRIs are less likely to cause cardiovascular, sedative, anticholinergic, and weight-gain side effects, and to reduce the seizure threshold. Clomipramine is less likely than SSRIs to cause insomnia, akathisia, nausea, and diarrhea. Antidepressant side effects can be more severe when larger doses are used and with faster dose escalation.

Pharmacokinetics

Clomipramine is rapidly absorbed after oral administration. Maximum plasma concentrations occur within 2 to 6 hours. Clomipramine is highly protein-bound (97%) in the blood and has a half-life of 19 to 37 hours.[50] The drug is metabolized to desmethylclomipramine, which is pharmacologically active. The pharmacokinetics of SSRIs is discussed in Chapter 68.

Efficacy

SSRIs are effective in the treatment of OCD. Well-designed trials comparing these medications with placebo, head-to-head comparative trials, and meta-analyses have established that fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, and escitalopram are equally effective and that clomipramine may be somewhat more effective.[23,49] Almost half (40%-60%) of patients with OCD respond to a serotonergic antidepressant, with remission occurring in 8% to 37% of patients. Most patients continue to have symptoms that limit their functioning.[52]

Other Antidepressants

Venlafaxine, which acts as a 5-HT and NE reuptake inhibitor, may be effective for OCD.[21,47]

Augmentation with Antipsychotics

7 Augmentation of SSRI treatment with low doses of antipsychotics may be helpful. Typical antipsychotics are generally not recommended because of an increased risk for extrapyramidal symptoms.[44] One-third of treatment-refractory patients with OCD responded to antipsychotic augmentation.[44] Evidence supports augmentation with low-dose aripiprazole in a short-term efficacy trial.[53] Evidence supporting efficacy of risperidone is mixed and quetiapine is inconclusive.[46,54] The long-term use of second-generation antipsychotic augmentation resulted in modest improvement and higher rates of adverse effects (eg, sedation, weight gain, increased blood glucose).[55] The benefits and risks of using second-generation antipsychotic augmentation should be evaluated carefully.

Dosage and Administration

Table 71-4 summarizes dosing guidelines for SSRIs and clomipramine. The dose to achieve response in OCD is often higher than doses used in other indications.[45,46] If there is inadequate response to an average dose, then it should be incrementally increased to the maximum dose within 5 to 9 weeks from the start of treatment. 8 If there is an inadequate response after 4 to 6 weeks at the maximum dose, then another SSRI should be tried.[45] Eight to 12 weeks is considered an adequate trial before changing to another agent.

TABLE 71-4 Dosing of Serotonin Reuptake Inhibitors in the Treatment of OCD

Drug	Brand Name	Initial Dose	Usual Range	Comments
Citalopram[a,b]	Celexa®	20 mg daily	20-40 mg daily	Maximum dose is 40 mg in adults daily to prevent QTc prolongation; maximum dose of 20 mg daily in elderly patients, CYP2C19 poor metabolizers, or use with concurrent moderate-to-strong CYP2C19 inhibitors (eg, cimetidine, omeprazole)
Clomipramine[a]	Anafranil®	25 mg daily	100-250 mg daily	Plasma levels (clomipramine and desmethylclomipramine) should be <500 ng/mL (mcg/L; ~1.7 µmol/L) (12 hours postdose to prevent conduction delays and seizures)
Escitalopram[a,b]	Lexapro®	10 mg daily	10-20 mg daily	Doses up to 40 mg may be needed in some patients
Fluoxetine[a]	Prozac®	20 mg daily	40-60 mg daily	Doses of 80 mg or higher may be needed in some patients

Drug	Brand Name	Initial Dose	Usual Range	Comments
Fluvoxamine[a]	Luvox CR®	50 mg daily	50-200 mg daily	For initial doses use immediate-release. Doses up to 300 mg daily have been used in some patients
Paroxetine[a]	Paxil®, Pexeva®	20 mg daily	40-60 mg daily	Higher doses may be needed in some patients
Sertraline[a]	Zoloft®	50 mg daily	50-200 mg daily	Higher doses may be needed in some patients

OCD, obsessive-compulsive disorder.

[a]Available generically.

[b]Not FDA-approved for treatment of obsessive-compulsive disorder. Optimal dosing guidelines are not well established.

Data from references 29, 30, 44, and 50.

Although the appropriate maintenance dose of antidepressants is unknown, gradual dose reduction can occur in some patients without loss of efficacy.[44]

Personalized Pharmacotherapy

The choice of an SSRI for treatment is based on history of prior response, safety, and side-effect tolerability of the patient. All SSRIs are considered to be equally efficacious, but a patient may respond better to one agent over another.[45] When selecting pharmacotherapy, the clinician should consider FDA warnings (eg, QTc prolongation for citalopram), potential for adverse consequences in patients with comorbid conditions (eg, anticholinergic effects and weight gain with paroxetine in patients with diabetes, obesity, or benign prostatic hypertrophy), or adverse effects (eg, insomnia with fluoxetine in patients with sleep difficulties). Increased risk of suicidality should be considered in patients taking SSRIs who are younger than 25 years. Drug interactions should be avoided —citalopram, escitalopram, and sertraline have the least potential for inhibition of CYP450 isoenzymes (see Chapter 68).

Risks to consider with clomipramine include lethality in overdose in patients with suicidal ideation, anticholinergic effects in patients with constipation, narrow-angle glaucoma, or urinary hesitancy, and potential for seizures in patients with epilepsy. Clomipramine use is associated with the risk of QTc prolongation when used alone and in combination with other agents that prolong the QTc interval.[50]

Clinical Controversy…

Data from fixed-dose studies indicate that higher SSRI doses are more efficacious than lower doses, although there is a higher adverse effect burden. However, there are no fixed-dose studies to guide clinicians on how high to increase the dose of clomipramine. Daily doses between 75 and 300 mg have been found to be effective, but doses exceeding 250 mg daily (the approved maximum dose)

should be employed only with caution and close monitoring of plasma concentrations and QTc intervals.

Evaluation of Therapeutic Outcomes

Target symptoms of OCD should be monitored closely. The degree of response can indicate a need to modify dosage, change drug, or augment therapy. Rating scales can be used to monitor symptom response to therapy for OCD (eg, YBOCS) and changes in QOL. The clinician should inquire about and address problematic adverse effects (including the emergence of suicidal ideation) reported by the patient and the amount of time the patient spends obsessing and performing compulsions. Changes in social and occupational functioning should be assessed.

Table 71-5 details the monitoring of clomipramine pharmacotherapy in patients with OCD. Monitoring of SSRIs can be found in Chapter 68 and antipsychotics in Chapter 67. After patients have responded in the acute phase of treatment, treatment gains are maintained with maintenance-phase strategies.

TABLE 71-5 Monitoring of Patients Being Treated for OCD

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Clomipramine	Dry mouth, constipation, nausea, dyspepsia, anorexia, somnolence, tremors, dizziness, nervousness	Patient interview	Tolerance should occur in 2 weeks
	Seizures	Patient interview	
	Orthostatic hypotension, tachycardia, ECG changes	Vital signs, ECG	Obtain baseline ECG in patients >40 years and those with cardiovascular disease
	Suicidality	Patient interview	Highest risk is in patients <25 years
	Agranulocytosis, leukopenia	CBC with differential	Labs if patient complains of sore throat, fever
	Weight gain	Patient body weight	Assess at each visit
SSRIs	Nausea, vomiting, diarrhea, sexual dysfunction, headache, insomnia	Patient interview	Generally mild and short-lived
	Anxiety and agitation	Patient interview	May occur in some patients early in treatment
	Discontinuation syndrome	Patient interview	

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
	Suicidality	Patient interview	Highest risk is in patients <25 years
	QTc prolongation	ECG, electrolytes	Of most concern with citalopram doses over 40 mg daily in adults and 20 mg daily in elderly patients or in those with risk factors of patients >65 years, female sex, cardiovascular disease, hypokalemia, hypomagnesemia, or concurrent use of drugs that prolong QTc

CBC, complete blood count; ECG, electrocardiogram; OCD, obsessive-compulsive disorder; SSRI, selective serotonin reuptake inhibitor.

9 Monthly follow-up visits are recommended for at least 3 to 6 months, and a medication taper can be considered after 1 to 2 years of treatment. Medication should not be rapidly discontinued, and booster CBT sessions can reduce the risk of relapse when medication is withdrawn. The drug dosage can be decreased by 10% to 25% every 1 to 2 months with careful observation for symptom relapse.[45] Some patients require lifelong medication therapy.

Chapter 72: Sleep–Wake Disorders

FIGURE 72-1

John M. Dopp; Bradley G. Phillips

INTRODUCTION TO SLEEP

KEY CONCEPTS

- 1 Common causes of insomnia include concomitant psychiatric disorders, significant psychosocial stressors, excessive alcohol use, caffeine intake, and nicotine use.
- 2 Good sleep hygiene, including relaxing before bedtime, exercising regularly, establishing a regular bedtime and wake-up time, and discontinuing alcohol, caffeine, and nicotine, alone and in combination with drug therapy, should be part of patient education and treatments for insomnia.
- 3 Long-acting benzodiazepines should be avoided in the elderly.
- 4 Benzodiazepine-receptor agonist tolerance and dependence are avoided by using low-dose therapy for the shortest possible duration.
- 5 Obstructive sleep apnea may be an independent risk factor for the development of hypertension. When hypertension is present, it is often refractory to drug therapy until sleep-disordered breathing is alleviated.
- 6 Nasal continuous positive airway pressure (PAP) is the first-line therapy for obstructive sleep apnea, and weight loss should be encouraged in all obese patients.
- 7 Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness and rapid eye movement (REM) sleep abnormalities.
- 8 Short-acting benzodiazepine receptor agonists, ramelteon, or melatonin taken at

appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.

- Dopamine agonists are standard therapy for restless legs syndrome (RLS) but have adverse effects that require careful monitoring by patients and providers.

Approximately 70 million Americans suffer with a sleep-related problem, and as many as 60% of those experience a chronic disorder.[1] In a study by the National Institute on Aging, of 9,000 patients aged 65 years and older, more than 80% report a sleep-related disturbance.[1]

Sleep Cycles

Sleep is divided into two phases: nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Each night humans typically experience four to six cycles of NREM and REM sleep, with each cycle lasting between 70 and 120 minutes.[2] There are four stages of NREM sleep. Healthy sleep will typically progress through the four stages of NREM sleep prior to the first REM period. From wakefulness, sleep typically progresses quickly through stages 1 and 2. Stage 1 of NREM sleep is the stage between wakefulness and sleep, and individuals describe this experience as being awake, being drowsy, or being asleep. During stages 3 and 4 NREM, both metabolic activity and brain waves slow. This slow-wave sleep occurs most frequently early in the sleep period. Stages 3 and 4 sleep are called *delta sleep*, as the sleep is characterized by high-amplitude slow activity known as delta waves (0.5-3 Hz) with no eye movements and low tonic muscle activity.

REM sleep involves a dramatic physiologic change from NREM sleep, to a state in which the brain becomes electrically and metabolically activated.[2] REM occurs in bursts and is accompanied by a 62% to 173% increase in cerebral blood flow, generalized muscle atonia, bursts of bilateral REMs, poikilothermia, dreaming, and fluctuations in respiratory and cardiac rate.[2] REM cycles tend to lengthen in the later stages of the sleep cycle.[2]

Circadian Rhythm

At birth human infants spend up to 20 hours a day sleeping. At 3 to 6 months of age there is a differentiation between REM and NREM sleep. By age 3 years the ultradian sleep–wake rhythm changes to a circadian pattern. The suprachiasmatic nucleus of the brain serves as the biologic clock and paces the circadian rhythm. Although the length of a day is 24 hours, in environments devoid of light cues, the sleep–wake cycle lasts about 25 hours.[3] In midlife, there is a gradual decline in sleep efficiency and sleep time.[2] The elderly have lighter and more fragmented sleep, with intermittent arousals, shifts in the sleep stages, and a gradual reduction of slow-wave sleep.

Neurochemistry

The neurochemistry of sleep is complex, as sleep cannot be localized to either a specific area of the brain or a neurotransmitter. NREM sleep appears to be controlled by the basal forebrain, the lower brain stem to the thalamus, and hypothalamus.[3] Numerous neurotransmitters mediate NREM sleep,

including γ-aminobutyric acid (GABA) and adenosine.[3] REM sleep appears to be turned on by cholinergic cells in the mesencephalic, medullary, and pontine gigantocellular regions. REM sleep appears to be turned off by the dorsal raphe nucleus, the locus coeruleus, and the nucleus parabrachialis lateralis, the latter two of which are primarily noradrenergic. The ascending reticular activating system and the posterior hypothalamus facilitate arousal and wakefulness.[4] Dopamine has an alerting effect; decreases in dopamine promote sleepiness.[5] Neurochemicals involved in wakefulness include norepinephrine and acetylcholine in the cortex and histamine and neuropeptides such as substance P and corticotropin-releasing factor in the hypothalamus.[5,6]

Polysomnography

Sleep is typically measured and observed in sleep laboratories using an electroencephalogram (EEG), electrooculograms of each eye, electrocardiogram, electromyogram, air thermistors, abdominal and thoracic strain belts, and oxygen saturation monitor. This study is named polysomnography (PSG) and is used to assess and record variables that characterize sleep and aid in diagnosis of sleep disorders. Variables obtained during PSG include sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, arrhythmias, airflow during sleep, respiratory effort, and oxygen desaturations. Home sleep monitoring that measures variables such as electrocardiogram, oxygen saturation, airflow, and respiratory effort is also increasingly used to diagnose sleep apnea.

CLASSIFICATION OF SLEEP DISORDERS

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) classifies sleep–wake disorders into 10 categories: (1) Insomnia disorder, (2) hypersomnolence disorder, (3) narcolepsy, (4) breathing-related sleep disorders, (5) circadian rhythm sleep disorders, (6) non-REM sleep arousal disorders, (7) nightmare disorder, (8) REM sleep behavior disorder, (9) restless legs syndrome (RLS), and (10) substance- or medication-induced sleep disorder.[7]

INSOMNIA

Insomnia is the most common complaint in general medical practice.[8] It causes distress, frequently because of a fear or a feeling of not being able to fall asleep at bedtime, and can impair work-related productivity because of daytime fatigue or drowsiness. Insomnia is subjectively characterized as a complaint of difficulty falling asleep, difficulty maintaining sleep, or experiencing nonrestorative sleep.[7,8,9] Insomnia lasting less than 3 months is considered short-term, while insomnia lasting longer than 3 months is considered to be chronic.[7,9]

Epidemiology

Primary insomnia usually begins in early or middle adulthood and is rare in childhood or adolescence. Symptoms of insomnia occur in 33% to 50% of the adult population.[8] A 1-year prevalence study of insomnia in the United States reports that one-third of the individuals surveyed

complained of insomnia, and 17% reported that the symptoms were serious.[1] Conservative estimates of chronic insomnia range from 9% to 12% in adulthood and up to 20% in the elderly.[1,10] Although young adults are more likely to complain that they have difficulty falling asleep, middle-aged and elderly adults are more likely to complain that they have middle-of-the-night awakening or early morning awakening. Women complain of insomnia twice as frequently as men. Individuals who are elderly, unemployed, separated, or widowed, and those with a lower socioeconomic status report a significantly higher incidence of insomnia than the general population. Forty percent of individuals with insomnia also have a concurrent psychiatric disorder (anxiety, depression, or substance abuse).[11] A significant percentage of those with insomnia use nonprescription drugs or alcohol to self-treat.

Differential Diagnosis

Primary insomnia is considered to be an endogenous disorder caused by either a neurochemical or a structural disorder affecting the sleep–wake cycle. Individuals with primary insomnia can be light sleepers who are easily aroused by noise, temperature, or anxiety. Some studies suggest that primary insomnia is a "hyperarousal state," in that insomnia patients have increased metabolic rates compared with controls and thus take longer to fall asleep.[2] Comorbid or secondary insomnia is frequently a symptom or manifestation of another medical disorder. Evaluation of patients with a complaint of transient or short-term insomnia should focus on recent stressors, such as a separation, a death in the family, a job change, or college exams.

1 Chronic insomnia is frequently comorbid with psychiatric or medical conditions. A complete diagnostic examination should be completed in these individuals and should include routine laboratory tests, physical and mental status examinations, as well as ruling out any medication- or substance-related causes.[12] Special consideration should also be given to other sleep disorders that can have a similar presentation, including RLS, periodic limb movements of sleep (PLMS), and sleep apnea. Common causes of insomnia are listed in **Table 72-1**.

TABLE 72-1 Common Etiologies of Insomnia

Situational

- Work or financial stress, major life events, interpersonal conflicts
- Jet lag or shift work

Medical

- Cardiovascular (angina, arrhythmias, heart failure)
- Respiratory (asthma, sleep apnea)
- Chronic pain
- Endocrine disorders (diabetes, hyperthyroidism)

- Gastrointestinal (gastroesophageal reflux disease, ulcers)
- Neurologic (delirium, epilepsy, Parkinson disease)
- Pregnancy

Psychiatric

- Mood disorders (depression, mania)
- Anxiety disorders (eg, generalized anxiety disorder, obsessive-compulsive disorder)
- Substance abuse (alcohol or sedative–hypnotic withdrawal)

Pharmacologically induced

- Anticonvulsants
- Central adrenergic blockers
- Diuretics
- Selective serotonin reuptake inhibitors
- Steroids
- Stimulants

TREATMENT

Desired Outcomes

The goals of treatment of insomnia are to correct the underlying sleep complaint, consolidate sleep, improve daytime functioning and sleepiness, and avoid adverse effects from selected therapies. Drug therapy should be used in the lowest possible dose, for the shortest possible time period.

General Approach to Treatment

Therapeutic management of insomnia is initially based on whether the individual has experienced a transient, short-term, or chronic sleep disturbance. Clinical history should assess the onset, duration, and frequency of the symptoms; effect on daytime functioning; sleep hygiene habits; and history of previous symptoms or treatment.[13] Management of all patients with insomnia should include identifying the cause of the insomnia, patient education on sleep hygiene, and stress management. Any unnecessary pharmacotherapy should be eliminated.[10] Transient insomnia, which occurs as a result of an acute stressor, is expected to resolve quickly and should be treated with good sleep hygiene and careful use of sedative–hypnotics.[11] Short-term insomnia, associated with situational,

personal, or medical stress, can be treated similarly.[13] Chronic insomnia requires careful assessment for possible underlying medical causes, nonpharmacologic approaches, and careful use of sedative–hypnotics.[12]

Nonpharmacologic Therapy

2 In many cases insomnia can be treated without sedative–hypnotics. Education about normal sleep and habits for good sleep hygiene are important for all patients with insomnia. Nonpharmacologic interventions for insomnia frequently consist of short-term cognitive behavioral therapies, most commonly stimulus control therapy, sleep restriction, relaxation therapy, cognitive therapy, paradoxical intention, biofeedback, and education on good sleep hygiene (**Table 72-2**).[10,14] In patients aged 55 and older, research indicates that cognitive behavioral therapy may be more effective than pharmacologic therapy at improving certain measures of insomnia.[15,16]

TABLE 72-2 Nonpharmacologic Recommendations for Management of Insomnia

Stimulus control procedures

1. Establish regular times to wake up and to go to sleep (including weekends).
2. Sleep only as much as necessary to feel rested.
3. Go to bed only when sleepy. Avoid long periods of wakefulness in bed. Use the bed only for sleep or intimacy; do not read or watch television in bed.
4. Avoid trying to force sleep; if you do not fall asleep within 20-30 minutes, leave the bed and perform a relaxing activity (eg, read, listen to music) until drowsy. Repeat this as often as necessary.
5. Avoid blue spectrum light from television, smart phones, tablets, and other mobile devices.
6. Avoid daytime naps.
7. Schedule worry time during the day. Do not take your troubles to bed.

Sleep hygiene recommendations

1. Exercise routinely (three to four times weekly) but not close to bedtime because this can increase wakefulness.
2. Create a comfortable sleep environment by avoiding temperature extremes, loud noises, and illuminated clocks in the bedroom.
3. Discontinue or reduce the use of alcohol, caffeine, and nicotine.
4. Avoid drinking large quantities of liquids in the evening to prevent nighttime trips to the restroom.

5. Do something relaxing and enjoyable before bedtime.

Pharmacologic Therapy

Miscellaneous Agents

Antihistamines exhibit sedating properties and are included in many nonprescription sleep agents. They are effective in the treatment of mild insomnia and are generally safe.[13] Diphenhydramine and doxylamine are more sedating than pyrilamine. Patients quickly experience tolerance to sedative effects, and increasing the dose of antihistamines will not produce a linear increase in response. Antihistamines are considered to be less effective than benzodiazepines, and they have the disadvantages of anticholinergic side effects, which are especially troublesome in the elderly.[13,17]

Antidepressants are alternatives for patients with nonrestorative sleep who should not receive benzodiazepines, especially those who have depression, pain, or a risk of substance abuse. Using antidepressants for insomnia without depression is common but not well-studied, and the doses used for treating insomnia are not effective antidepressant doses.[9,13,14] Sedating antidepressants such as amitriptyline, doxepin, and nortriptyline are effective for inducing sleep continuity, although daytime sedation and side effects can be significant.[9,13] Anticholinergic activity, adrenergic blockade, and cardiac conduction prolongation can be problematic, especially in the elderly and in overdose situations.[9] Low-dose doxepin (3-6 mg) was recently Food and Drug Administration (FDA)-approved for the treatment of sleep maintenance insomnia. Mirtazapine is a sedating antidepressant that may help patients sleep, but it may also cause daytime sedation and weight gain.

Trazodone in doses of 25 to 100 mg at bedtime is sedating and can improve sleep continuity.[11] Trazodone is popular for the treatment of insomnia in patients prone to substance abuse, as dependence is not a problem with trazodone, and in patients with selective serotonin reuptake inhibitor and bupropion-induced insomnia.[11] Other side effects include carryover sedation and α-adrenergic blockade. Orthostasis can occur at any age, but it is more dangerous in the elderly. Priapism is a rare but serious side effect.[18]

Suvorexant is a recently approved dual orexinA and orexin B receptor antagonist that instead of inducing sleepiness turns off wake signaling. Suvorexant doses of 10 to 20 mg at bedtime are indicated for difficulty initiating and maintaining sleep. The most commonly reported side effect with suvorexant use is somnolence, and patients should be counseled that sleep paralysis, cataplexy, and other narcolepsy-like symptoms may rarely occur.[19]

Ramelteon is a melatonin-receptor agonist approved for the treatment of sleep-onset insomnia. It is selective for the MT1 and MT2 melatonin receptors that are thought to regulate the circadian rhythm and sleep onset. The recommended dose is 8 mg taken at bedtime to induce sleep. Although generally well tolerated, the most common adverse events reported are headache, dizziness, and somnolence. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse. It effectively treats sleep-onset difficulties in patients with chronic

obstructive pulmonary disease and sleep apnea.[20,21]

Valerian is a herbal sleep remedy that has been studied for its sedative–hypnotic properties in patients with insomnia. The mechanism of action is not fully understood but may involve increasing concentrations of GABA. The recommended dose for insomnia ranges from 300 to 600 mg. An equivalent dose of dried herbal valerian root is 2 to 3 g soaked in one cup of hot water for 20 to 25 minutes.[22]

Benzodiazepine-Receptor Agonists

The most commonly used treatments for insomnia have been the benzodiazepine-receptor agonists (BZDRAs). BZDRAs are effective as sedative–hypnotics and are FDA-labeled for the treatment of insomnia (Table 72-3). The FDA requires BZDRA labeling to include a caution regarding anaphylaxis, facial angioedema, and complex sleep behaviors (eg, sleep driving, phone calls, sleep eating, etc.). The BZDRAs consist of the newer nonbenzodiazepine $GABA_A$ agonists and the traditional benzodiazepines. All BZDRAs bind to $GABA_A$ receptors in the brain, resulting in agonist effects on GABAergic transmission and hyperpolarization of neuronal membranes. Traditional benzodiazepines have sedative, anxiolytic, muscle relaxant, and anticonvulsant properties; newer nonbenzodiazepine GABA agonists possess only sedative properties.

TABLE 72-3 Pharmacokinetics of Benzodiazepine-Receptor Agonists

Generic Name (Brand Name)	t_{max} (hours)[a]	Half-Life[b] (hours)	Daily Dose Range (mg)	Metabolic Pathway	Clinically Significant Metabolites
Estazolam (ProSom)	2	12-15	1-2	Oxidation	–
Eszopiclone (Lunesta)	1-1.5	6	2-3	Oxidation	–
				Demethylation	
Flurazepam (Dalmane)	1	8	15-30	Oxidation	Hydroxyethylflurazepam, Flurazepam aldehyde
				N-dealkylation	*N*-desalkylflurazepam[c]
Quazepam (Doral)	2	39	7.5-15	Oxidation, *N*-dealkylation	2-Oxo-quazepam, *N*-desalkylflurazepam[c]
Temazepam (Restoril)	1.5	10-15	15-30	Conjugation	–
Triazolam (Halcion)	1	2	0.125-0.25	Oxidation	–
Zaleplon (Sonata)	1	1	5-10	Oxidation	–
Zolpidem (Ambien;Intermezzo)	1.6	2-2.6	1.75-10[d]	Oxidation	–

[a]Time to peak plasma concentration.

[b]Half-life of parent drug.

[c]*N*-desalkylflurazepam, mean half-life 47 to 100 hours.

[d]Oral and sublingual dosing 5 to 10 mg; sublingual tablets for middle-of-the night dosing 1.75 to 3.5 mg (1.75 for women, 3.5 mg for men).

Benzodiazepine Hypnotics

Benzodiazepines relieve insomnia by reducing sleep latency and increasing total sleep time. They increase stage 2 sleep while decreasing delta sleep.[11] Benzodiazepine hypnotics should not be prescribed for individuals who are pregnant or who have untreated sleep apnea or a history of substance abuse. Patients should be instructed to avoid alcohol and other central nervous system (CNS) depressants.

Adverse Effects

Side effects are dose-dependent and vary according to the pharmacokinetics of the individual benzodiazepine. High doses with long or intermediate elimination half-lives have a greater potential for producing daytime sedation, psychomotor incoordination, and cognitive deficits. Most traditional benzodiazepines maintain hypnotic efficacy for 1 month. However, tolerance can develop with time.

Anterograde amnesia, an impairment of memory and recall of events occurring after the dose is taken, has been reported with most BZDRAs (it is more likely to occur with short-acting agents).[11] Rebound insomnia, characterized by increased wakefulness beyond baseline amounts that last for a few nights after abrupt discontinuation, occurs with BZDRAs. The lowest effective dosage should be used to minimize rebound insomnia and avoid adverse effects on memory.

3 Benzodiazepine half-lives are prolonged in older patients, increasing the potential for drug accumulation and the incidence of CNS side effects, including prolonged sedation and cognitive and psychomotor impairment. BZDRAs with long elimination half-lives (eg, flurazepam and quazepam) are generally not first-line agents in these patients. Benzodiazepine use is associated with increased risk of falls and hip fractures in the elderly, but since insomnia itself increases fall and fracture risk, it is unclear if benzodiazepines increase risk independent of sleep problems.[23]

Nonbenzodiazepine $GABA_A$ Agonists

Zolpidem, zaleplon, and eszopiclone are nonbenzodiazepine hypnotics that selectively bind to $GABA_A$ receptors and effectively induce sleepiness. Zolpidem has a duration of action of 6 to 8 hours.[24] It is comparable in efficacy to benzodiazepine hypnotics and is effective for reducing sleep latency and nocturnal awakenings and increasing total sleep time. It does not appear to have significant effects on next-day psychomotor performance. Sustained-release, sublingual, and reduced-strength (1.75 and 3.5 mg) formulations of zolpidem are available and are used to increase total sleep time, to reduce sleep latency, and for middle-of-the night rescue dosing, respectively.

Zolpidem is less disruptive of sleep stages than benzodiazepines. Adverse effects are dose-related and can include drowsiness, amnesia, dizziness, headache, and gastrointestinal (GI) complaints.[24]

Sleep eating during zolpidem therapy can result in significant weight gain. The recommended daily dose of zolpidem is 10 mg in male patients, or 5 mg in female patients, elderly patients and those with hepatic impairment. Because food decreases its absorption, zolpidem should be taken on an empty stomach.[25]

Zaleplon has a rapid onset of action and a half-life of 1 hour, and it is metabolized to inactive metabolites.[26] It is effective for decreasing time to sleep onset but not for reducing nighttime awakening or for increasing total sleep time.[27] Because of its short half-life, zaleplon has no effect on next-day psychomotor performance and can be used as a sleep aid for middle-of-the-night awakenings.[28] The recommended dose is 10 mg in adults and 5 mg in the elderly.[26] The most common adverse effects with zaleplon are dizziness, headache, and somnolence. There are two drug interactions of note: zaleplon plasma levels are increased when combined with cimetidine and decreased with rifampin.[24]

Eszopiclone is effective at reducing time to sleep onset, wake time after sleep onset, and number of awakenings, and increasing total sleep time and sleep quality. Eszopiclone's duration of action is up to 6 hours,[29] so it can be a good option for treatment of sleep maintenance insomnia or early morning awakenings. The most common adverse effects with eszopiclone are somnolence, unpleasant taste, headache, and dry mouth.[29] Eszopiclone is labeled for long-term use and may be taken nightly for up to 6 months.[29,30]

Other Considerations

In general, the nonbenzodiazepine hypnotics seem to be associated with less withdrawal, tolerance, and rebound insomnia than the benzodiazepine hypnotics. None of the nonbenzodiazepine $GABA_A$ agonists have significant active metabolites.

Evaluation of Therapeutic Outcomes

An algorithm for the evaluation and treatment of dyssomnias is shown in **Fig. 72-1**.[31] Patients with short-term or chronic insomnia should be evaluated after 1 week of therapy to assess for drug efficacy, adverse effects, and adherence to nonpharmacologic recommendations.

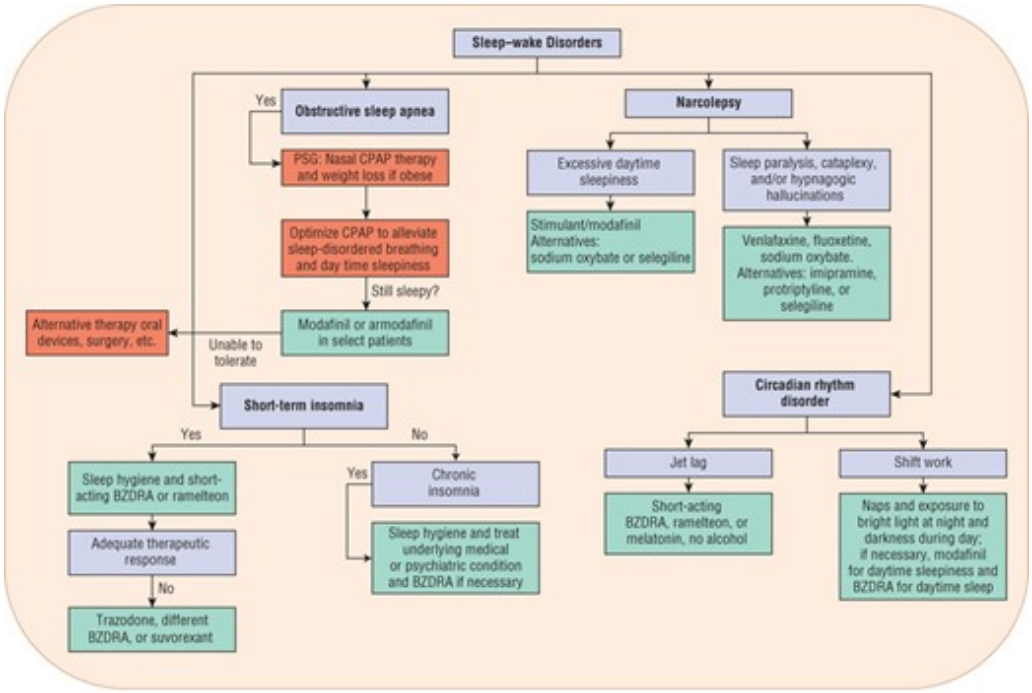
Clinical Controversy…

Population studies suggest that use of sedative–hypnotics may be associated with increased mortality. Even though causality cannot be established based on the evidence to date, these studies raise important concerns. Although the evidence does not warrant discontinuation of hypnotics, it reemphasizes the importance of using sedative–hypnotics prudently at the lowest dose possible, for the shortest duration necessary.

FIGURE 72-1

Algorithm for treatment of dyssomnias. (BZDRA, benzodiazepine-receptor agonist; CPAP, continuous

positive airway pressure.) (Reprinted with permission from Jermaine DM. Sleep disorders. In: Carter BL, Angaran DM, Lake KD, et al, eds. Pharmacotherapy Self-Assessment Program, 2nd ed. Neurology and Psychiatry. Kansas City, MO: American College of Clinical Pharmacy, 1995:146-7.)



Patients should be instructed to keep a sleep diary. The diary requires daily recording of bedtime, wake time, latency of sleep onset, number and duration of awakenings, medication ingestion, naps, and an index of sleep quality. For patients with chronic insomnia, possible medical, psychiatric, and pharmacologic causes should be identified and managed.[11] Patients with insomnia should receive education about possible medication side effects and their management.

4 Clinicians should educate patients about the concepts of tolerance, withdrawal, and rebound insomnia. Tolerance and dependence can be avoided by using hypnotics at the lowest possible dose, intermittently, and for the shortest duration possible. Patients should receive instruction about frequency of drug use and the expected duration of therapy, to help prevent development of dependence. Withdrawal symptoms can be diminished by tapering the dosage gradually.

SLEEP APNEA

Sleep apnea is a common disease, affecting 20 to 25 million Americans. It has a higher prevalence in men, particularly in African American and Hispanic populations.[32,33] Sleep apnea also occurs in children and adolescents. It is characterized by repetitive episodes of cessation of breathing during sleep followed by blood oxygen desaturation and brief arousal from sleep to restart breathing. As a result, individuals with sleep apnea experience fragmented sleep, poor sleep architecture, and periods of apnea and hypopnea. PSG is used to diagnose and quantify sleep apnea as central, obstructive, or mixed. Central sleep apnea (CSA) involves impairment of the respiratory drive, whereas OSA is caused by upper airway collapse and obstruction. Patients with mixed sleep apnea

experience both CSA and OSA. Severity of sleep apnea is determined by the number of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) episodes documented by PSG, which is expressed as the respiratory disturbance index (RDI). Mild sleep apneics have an RDI of between 5 and 15 episodes/hour, moderate 15 to 30 episodes/hour, whereas individuals with severe OSA exhibit more than 30 episodes/hour.

OSA is associated with motor vehicle accidents, depression, increased cancer risk, stroke, and cardiovascular disease.[34,35,36,37] Alleviation of sleep-disordered breathing may improve patient outcomes, particularly those related to cardiovascular disease.[37]

Obstructive Sleep Apnea

OSA is characterized by partial or complete closure of the upper airway, posterior from the nasal septum to the epiglottis, during inspiration. The reason for the loss of upper airway patency is not fully understood and is likely caused by several competing factors. Anatomical factors including neck obesity, narrow airway, and fixed upper airway lesions (eg, polyps, enlarged tonsils) can narrow the upper airway. Intraluminal negative pressure generated during each inspiration also promotes collapse of the upper airway that competes with dilating forces, primarily the pharyngeal dilator muscle. Acromegaly, amyloidosis, and hypothyroidism as well as neurologic conditions that impair upper airway muscle tone may cause OSA. The hallmarks of OSA are witnessed apneas, gasping, or both. Other recognized signs, symptoms, and considerations of sleep apnea include obesity, snoring, daytime sleepiness, family history, and hypertension.

5 OSA is increasingly linked to cardiovascular and cerebrovascular morbidity and mortality, independent of other risk factors.[37] Individuals with OSA are at risk for developing hypertension, and when hypertension is present, it is often resistant to drug therapy.[38] Alleviation of sleep-disordered breathing (with nasal continuous positive airway pressure [CPAP]) can improve blood pressure and attenuate some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.[39,40]

TREATMENT: OSA

Desired Outcomes

In the absence of an underlying cause (eg, hypothyroidism, acromegaly), alleviation of sleep-disordered breathing and prevention of associated complications are the primary goals of treatment. Nonpharmacologic measures are the treatments of choice. There is no drug therapy for OSA. However, medications that worsen sleep should be avoided. Practice parameters for the medical treatment of OSA have been published by the American Academy of Sleep Medicine.[41]

Nonpharmacologic Therapy

Positive Airway Pressure

6 Nasal positive airway pressure (PAP) during sleep is the standard treatment for most patients with OSA. PAP produces a positive pressure column in the upper airway using room air to maintain patency. A flexible tube connects the PAP machine to a mask that covers the nose.

PAP delivery may be continuous (CPAP), bilevel (providing a reduced applied pressure during expiration), or auto titrating continuous positive airway pressure therapy (AutoPAP). AutoPAP machines may be programmed to a pressure range and the machine provides individualized pressure based on breath-to-breath analysis of the necessary pressure to keep the airway open. CPAP pressure may be determined during PSG, when the pressure setting is increased (up to 20 cm H_2O) until sleep-disordered breathing is eliminated or by determining which pressure the AutoPAP machine uses 90% to 95% of the time. Barriers to PAP adherence, such as ill-fitted mask and nasal dryness, can be managed. PAP nonadherence for one night results in a complete reversal of the gains made in daytime alertness.[42] In the clinical setting, poor PAP adherence may impact blood pressure control and management in patients with OSA and hypertension.

Weight Reduction

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. OSA can predispose to weight gain, and in obese patients with mild OSA weight loss alone can be effective.[43] Individuals who are morbidly obese and have severe OSA can undergo bariatric surgery for weight loss.

Surgery

Surgical therapy (uvulopalatopharyngoplasty) opens the upper airway by removing the tonsils, trimming and reorienting the posterior and anterior tonsillar pillars, and removing the uvula and posterior portion of the palate. This is not a first-line option because it is invasive. In very severe cases tracheostomy may be necessary. This procedure can be indicated for select individuals who are morbidly obese, have severe facial skeletal deformity, experience severe drops in oxygen saturation (eg, less than 70% [0.70]), or have significant cardiac arrhythmias associated with their OSA.

Other Therapies

For individuals who experience OSA only during certain sleep positions (eg, when lying on their back), positional therapies can be effective alone but are usually used in conjunction with PAP therapy. Oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. These therapies should be considered when PAP therapy cannot be tolerated.[44]

Pharmacologic Therapy

The most important pharmacologic intervention is the avoidance of all CNS depressants (eg, alcohol, hypnotics) and drugs that promote weight gain. Weight gain worsens OSA. CNS-depressant use is potentially lethal, as it reduces the brain's reflex ability to cause a mini-arousal and resume breathing. In addition, certain CNS depressants can relax airway muscles, promoting upper airway collapse.

Medications that can cause rhinopharyngeal inflammation and cough as a side effect of therapy (ie, angiotensin-converting enzyme [ACE] inhibitor) may also worsen sleep-disordered breathing.

There is no drug therapy for OSA. In clinical trials, serotonergic agents (eg, fluoxetine, paroxetine), tricyclic antidepressants (TCAs) (ie, imipramine, protriptyline), respiratory stimulants (theophylline), medroxyprogesterone, and clonidine do not clinically improve severity of OSA. The effects of antihypertensive agents on sleep apnea are inconsistent and are likely not clinically significant.

Wake-promoting medications (eg, modafinil, armodafinil) are FDA-approved to improve wakefulness in patients who have residual excessive daytime sleepiness (EDS) while being treated with PAP. Initiation of therapy should be attempted in patients only after PAP therapy has been optimized to alleviate sleep-disordered breathing and EDS. Wake-promoting medications should be avoided in those with concomitant cardiovascular disease. In patients with concurrent rhinitis, nasal steroids are recommended for use along with PAP therapy.[41]

Evaluation of Therapeutic Outcomes

Individuals with sleep apnea should be evaluated after 1 to 3 months of treatment for improvement in alertness and daytime symptoms (eg, sleepiness, impaired memory, and irritability) and weight reduction. Individuals experiencing symptoms (eg, daytime sleepiness, snoring, loss of blood pressure control) despite PAP therapy should have PSG repeated. Symptoms can recur if patients gain weight, requiring a higher pressure setting. Conversely, PAP pressure settings can be decreased if weight loss is achieved. Patient adherence to PAP therapy can be monitored by assessing the built-in compliance meter that measures the hours used at effective pressure.

Central Sleep Apnea

CSA causes fragmented sleep and consequent daytime somnolence. However, unlike OSA, arousals from sleep are not required to initiate airflow. During PSG, there is an absence of airflow out of the mouth and nose with no activation of the inspiratory muscles. The prevalence of CSA is not well established and is less than OSA. CSA can be idiopathic but more commonly is caused by underlying autonomic nervous system lesions (eg, cervical cordotomy), neurologic diseases (eg, poliomyelitis, encephalitis, and myasthenia gravis), high altitudes, opioid abuse, and congestive heart failure. For these reasons, potential underlying causes for CSA should be evaluated and treated. For example, worsening CSA in heart failure patients can signal the need to optimize heart failure therapies. Practice parameters for the treatment of CSA have been published by the American Academy of Sleep Medicine.[45]

Drug therapy for CSA is limited and is individualized for each patient, based on underlying etiology. Acetazolamide, which induces a metabolic acidosis that stimulates respiratory drive, and theophylline, which improves severity of CSA, have been studied but have minimal effects on clinical variables.[46,47]

CLINICAL PRESENTATION Narcolepsy Symptoms

- Patients may complain of EDS and disrupted nighttime sleep; often they have some

accompanying REM sleep abnormality, sleep paralysis, cataplexy, and/or hallucinations.

Laboratory Tests

- Although not routinely tested, there is a high incidence of human leukocyte antigen (HLA) haplotypes DR2 and HLA-DQ6/DQB1 in narcolepsy.
- Cerebrospinal fluid (CSF) concentrations of hypocretin-1 can be measured to confirm a diagnosis. CSF concentrations less than 110 pg/mL (110 ng/L) positively predict narcolepsy.

Other Diagnostic Tests

- Narcolepsy is diagnosed using the multiple sleep latency test (nap test). The patient takes four to five naps in a day, and narcolepsy is diagnosed if the patient falls asleep quickly (within less than 5 minutes) and goes into REM sleep in two of those nap periods.

NARCOLEPSY

Narcolepsy is a severely debilitating neurologic disease that affects between 0.03% and 0.06% of adult Americans.[48] Despite the debilitating nature of the disease, it can be undiagnosed or misdiagnosed for years. Prevalence is equal or somewhat higher in men compared with women. It is commonly recognized in the second decade of life and increases in severity through the third and fourth decades.[48] Individuals with narcolepsy complain of EDS, and in the sleep laboratory, individuals with narcolepsy exhibit impairment of both the onset and the offset of REM and NREM sleep and have arousals and disturbed sleep during the night.

Four characteristic symptoms differentiate narcolepsy from other sleep disorders and are known as the *narcolepsy tetrad*: EDS, cataplexy, hallucinations, and sleep paralysis. Cataplexy, a sudden bilateral loss of muscle tone of varying severity and duration without the loss of consciousness, occurs in 70% to 80% of people with narcolepsy.[48] Patients can suffer subtle changes, such as jaw or head slumping, or severe weakness, such as knee buckling or collapsing to the ground. Cataplexy is often precipitated by situations characterized by high emotion (eg, laughter, anger, excitement). Cataleptic episodes can be brief, lasting seconds, or can last for several minutes. Sleep paralysis is an episodic loss of voluntary muscle tone that occurs when the individual is falling asleep or waking. Individuals are conscious but not able to move or speak. Hallucinations while falling asleep (ie, hypnagogic) and on awakening (ie, hypnopompic) are brief, dream-like experiences that intrude into wakefulness and are experienced by nearly 70% of narcoleptics. Unfortunately, these symptoms sometimes lead to an incorrect diagnosis of mental illness.[48] Cataplexy, sleep paralysis, and hypnagogic hallucinations can be caused by REM sleep disturbances.[48]

Loss of normal function of the hypocretin-orexin neurotransmitter system appears to play a central role in the pathophysiology of narcolepsy. Neurons containing hypocretin-orexin are found in the lateral hypothalamus and project to various parts of the brain that are thought to regulate sleep. In 75% of narcoleptic patients, hypocretin-orexin is undetectable in CSF.[49,50] Because narcoleptic patients have deficiencies in hypocretin-orexin–producing neurons,[51] an autoimmune process may

be responsible for the destruction of hypocretin-producing cells.[51,52] Onset of disease occurs in adolescence or adulthood, but not at birth, suggesting that environmental influences might also play a role. Molecular studies of HLA have found a high prevalence of the HLA-DR2 and HLA-DQ6/DQB1 haplotypes in narcoleptics.[53] However, the HLA-DR2 haplotype is also common in the nonnarcoleptic population and is not diagnostic.[52] There may also be a genetic component, as 3% of patients have a first-degree relative with the disorder.[49]

Clinical Controversy…

An increased risk of narcolepsy was associated with use of a 2009 H1N1 influenza vaccine used in Europe (containing a vaccine adjuvant) causing some individuals to forego influenza immunization. However, a study performed by the U.S. Centers for Disease Control and Prevention found that vaccines licensed in the United States (without adjuvants) are not associated with increased risk of narcolepsy.[54] Despite this evidence, some individuals still believe influenza immunization increases narcolepsy risk. As with autism and other disproven risks of immunization, clinicians should urge patients that narcolepsy is not a risk of influenza immunization.

TREATMENT: Narcolepsy

Desired Outcomes

The primary objective of pharmacologic treatment of narcolepsy is to reduce symptoms that adversely impact quality of life. The goal is to produce the fullest possible return of normal function for patients at work, school, home, and in social settings.

Nonpharmcologic Therapy

Nonpharmacologic management of narcolepsy includes counseling the patient and family concerning the illness to alleviate misconceptions around the individual's behavior. Good sleep hygiene should be encouraged as well as two or more scheduled daytime naps. Daytime naps lasting 15 minutes each can help the individual with narcolepsy feel refreshed.

Pharmacologic Therapy

7 Pharmacologic management of narcolepsy is focused on two primary areas: treatment of EDS and REM sleep abnormalities. Drug therapy for narcolepsy is summarized in **Table 72-4**.

TABLE 72-4 Dosing of Drugs Used to Treat Narcolepsy

Generic Name	Brand Name	Initial Dose (mg)	Usual dose (mg)	Comments
Excessive Daytime Somnolence				
Dextroamphetamine	Dexedrine	5-10	5-60	Concurrent use of amphetamines and acidic foods may reduce

Generic Name	Brand Name	Initial Dose (mg)	Usual dose (mg)	Comments
				amphetamine absorption
Dextroamphetamine/Amphetamine salts[a]	Adderall	5-20	5-60	See above
Methamphetamine[b]	Desoxyn	5-15	5-15	See above
Lisdexamfetamine	Vyvanse	20-30	20-70	Prodrug of dextroamphetamine
Methylphenidate	Ritalin	10-40	30-80	May increase risk of bleeding with concomitant warfarin therapy
Modafinil	Provigil	100-200	200-400	May reduce effectiveness of hormonal contraceptives
Armodafinil	Nuvigil	150	150-250	May reduce effectiveness of hormonal contraceptives
Sodium oxybate[c]	Xyrem	4.5 grams/night	4.5-9 grams/night	Do not use with other CNS depressants
Agents for cataplexy				
Fluoxetine	Prozac	10-20	20-80	Will see cataplexy benefits sooner than antidepressant benefits
Imipramine	Tofranil	50-100	50-250	Anticholinergic side effects
Nortriptyline	Aventyl, Pamelor	50-100	50-200	Anticholinergic side effects
Protriptyline	Vivactil	5-10	5-30	
Venlafaxine	Effexor	37.5	37.5-225	May increase blood pressure
Selegiline	Eldepryl	5-10	20-40	Doses <10 mg per day do not require dietary tyramine restrictions

CNS, central nervous system.

[a]Dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate.

[b]Not available in some states.

[c]Also is effective at treating cataplexy.

Data from references 52 and 55.

Modafinil, a racemic compound unrelated to psychostimulants, is a recognized standard treatment for EDS.[55] Armodafinil is the active R-isomer of modafinil and is also FDA-approved for treatment of EDS in narcolepsy. The precise mechanism of action of modafinil and armodafinil is not fully understood. Common adverse effects are usually mild and include headache, nausea, nervousness, anxiety, and insomnia. The dose of modafinil is between 200 and 400 mg/day, and armodafinil doses are between 150 and 250 mg/day.[56] Although both of these agents are effective in treating EDS, they lack efficacy for the treatment of cataplectic symptoms.[57]

EDS can also be treated with stimulants to improve alertness and to increase daytime performance. Dextroamphetamine and methylphenidate also have FDA approval for the treatment of narcolepsy. Methamphetamine and mixed amphetamine salts have also been used on an off-label basis. Methylphenidate and amphetamines have a fast onset of action and durations of 6 to 10 and 3 to 4 hours, respectively. The doses of methylphenidate and amphetamine formulations can range from 5 to 60 mg daily.

Stimulants improve alertness and daytime performance, and they can elevate mood and prevent sleep. Side effects can include insomnia, hypertension, palpitations, and irritability. Tolerance to long-term stimulant therapy can occur, necessitating dosage increases. Amphetamine use is associated with more likelihood of abuse and tolerance, especially when prescribed in high doses. Lisdexamfetamine is a new amphetamine prodrug rapidly absorbed and converted in the body to dextroamphetamine. It has a longer duration of action and less risk of abuse since it is active only when taken orally.

The most commonly used treatments for cataplexy are TCAs, serotonin norepinephrine reuptake inhibitors (SNRIs), and selective serotonin reuptake inhibitors (SSRIs). The mechanism of antidepressants in relieving cataplexy, hypnagogic hallucinations, and sleep paralysis can be mediated through blockade of serotonin and norepinephrine reuptake in the locus coeruleus and raphe and subsequent suppression of REM sleep.[58] Imipramine, protriptyline, clomipramine, fluoxetine, and nortriptyline are effective in approximately 80% of patients. Selegiline improves hypersomnolence and cataplexy through REM suppression and an increase in REM latency. Methylphenidate and amphetamines alone are usually ineffective for complete relief of cataplexy.

Sodium oxybate (γ-hydroxybutyrate, Xyrem) improves symptoms of EDS and decreases episodes of sleep paralysis, cataplexy, and hypnagogic hallucinations. Nightly administration of sodium oxybate changes sleep architecture to resemble normal sleep. It increases slow-wave sleep, decreases nighttime awakenings, and increases REM efficiency.[59] Sodium oxybate is available only as a liquid and is taken as two doses; one is taken at bedtime and the second dose is taken 2.5 to 4 hours later. Sodium oxybate is a potent sedative–hypnotic and should not be used concomitantly with any other sedating medications. The most common side effects include nausea, somnolence, confusion, dizziness, and incontinence.

Patients with narcolepsy should keep a diary of the frequency and severity of cataplexy, sleep paralysis, and sleep hallucinations. Patients should be evaluated regularly during medication titrations and then every 6 to 12 months to assess for adverse drug effects (eg, sleep disturbances, hypertension, and cardiovascular abnormalities). The healthcare provider should consider the benefit-to-risk ratio for the individual patient, the cost of medication, the convenience of administration, and the cost of laboratory tests when selecting narcolepsy therapies.[54] One wake-promoting agent may work better than another in an individual patient. Thus, if one agent is not effective at adequate doses, a trial with another agent should be undertaken.

CIRCADIAN RHYTHM DISORDERS

The sleep–wake cycle is under the circadian control of oscillators and can be disrupted by misalignment between an individual's biologic clock and external demands on the sleep cycle. Circadian rhythm sleep disorders usually present with either insomnia or hypersomnia, depending on the individual's performance requirements. Two commonly occurring circadian rhythm sleep disorders are jet lag and shift work sleep problems.

Jet Lag

Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Sleep disturbances typically last for 2 to 3 days but can last as long as 7 to 10 days if the time zone changes are more than 8 hours. Compared with westward travel, eastward travel is associated with a longer duration of jet lag. Jet lag leads to increased incidence of GI disturbances and a decrease in alertness and performance.

8 Treatment of jet lag includes nonpharmacologic approaches alone or in combination with drug therapy. Jet lag can be minimized in coast-to-coast travel in the United States if the duration is less than 7 days and the normal sleep–wake cycle is observed. For travel lasting longer than 7 days, jet lag severity can be lessened by 1- to 2-hour adjustments in sleep and wake times prior to departure to the destination time zone. Short-acting BZDRAs, ramelteon, and 0.5 to 5 mg melatonin, taken at appropriate target bedtimes for east or west travel, reduce jet lag and shorten sleep latency.[60]

Shift Work Sleep Disorder

Shift workers comprise approximately 20% of the workforce.[61] Night shift work causes a misalignment in the sleep–wake cycle and circadian rhythm that is associated with a decrease in alertness, performance, and quality of daytime sleep. More than 65% of workers on rotating shifts complain of insomnia, compared with only 20% who work one shift.[62] Shift workers ultimately are at risk of developing shift work sleep disorder (SWSD). SWSD is a complaint of insomnia or excessive sleepiness that occurs because of circadian sleep disruption due to working shifts during normal sleep time.[9,61] Shift workers have a higher injury rate, divorce rate, occurrence of on-the-job

sleepiness, and incidence of substance use. They may also be at increased risk of developing peptic ulcers, depression, breast cancer, and sleepiness-related accidents.[61,62,63] Night shift workers are usually in a state of permanent circadian misalignment because of the tendency to revert to conventional sleep schedules on nonwork days.[62]

Treatment for shift work sleep problems includes optimizing sleep hygiene, extending daytime sleep by sleeping in the afternoon, scheduling a 2- to 3-hour nap on days off from work, or switching to a day shift job. Short-acting BZDRAs, ramelteon, and melatonin can consolidate sleep during day sleep periods and reduce lost sleep time. Modafinil and armodafinil are FDA-approved to improve wakefulness in patients with EDS associated with SWSD. Scheduled exposure to bright lights at night and darkness in the daytime improves adaptation to night work and daytime sleep.[62]

Restless Legs Syndrome

RLS, or Ekbom syndrome, is characterized by paresthesias that are usually felt deep in the calf muscles but can also appear in the thighs and arms with the urge to keep limbs in motion. RLS occurs in both males and females, and it occurs more frequently in the elderly. It has been associated with chronic kidney disease, iron deficiency, and pregnancy. Caffeine, stress, alcohol, and fatigue can worsen symptoms. Data suggest that RLS can be caused by iron deficiency in the substantia nigra in the CNS.[64] The diagnosis of RLS is based on patient- or partner-reported symptoms and specific diagnostic criteria. Criteria required to diagnose RLS include (a) an urge to move the limbs that is usually associated with uncomfortable and unpleasant sensations, (b) symptoms that begin or worsen during rest or inactivity, (c) symptoms that are exclusively present or worse in the evening or night, and (d) symptoms that are temporarily relieved by movement.[65] The discomfort returns when the person tries to sleep, resulting in insomnia. Practice parameter recommendations for treatment of RLS are shown in **Table 72-5**.

TABLE 72-5 Evidence-Based Guidelines for Drug Therapy of RLS

Medication Recommendation[a] (Brand Name)	Strength of Recommendation[b]	Body of Evidence Level[c]
Pramipexole (Mirapex)	Standard	High
Ropinirole (Requip)	Standard	High
Levodopa and dopa decarboxylase inhibitor (Sinemet)	Guideline	High
Opioids (eg, codeine, oxycodone, hydrocodone, methadone)	Guideline	Low
Gabapentin enacarbil (Horizant)	Guideline	High
Gabapentin[d] (Neurontin)	Option	Low
Carbamazepine (Tegretol)	Option	Low
Clonidine (Catapres)	Option	Low
Supplemental iron[e]	Option	Very low

RLS, restless legs syndrome.

[a]At the time of publishing, rotigotine was not available in the United States, thus, no recommendations were made for rotigotine in the published practice parameters.

[b]"Standard" indicates recommendations for which there is high or moderate quality of evidence where the benefits clearly outweigh the harms; "Guideline" indicates low quality of evidence where benefits clearly outweigh the harms, or high or moderate quality of evidence when the benefits are closely balanced with harm/burden or there is uncertainty about the benefits/harms/burdens.

[c]Level of evidence: High, very confident in effect estimate of agent; Moderate, moderately confident in effect estimate; Low, limited confidence in effect estimate; Very low, very little confidence in effect estimate.

[d]Pregabalin is recommended similarly to gabapentin.

[e]In patients with low serum ferritin concentrations.

Data from reference 66.

9 Dopamine agonists are standard therapy for RLS but have adverse effects that require careful monitoring by patients and providers. Dopamine agonists ropinirole, pramipexole, and rotigotine are FDA-approved for RLS treatment.[66] Lower doses of dopamine agonists are used when treating RLS compared with Parkinson disease. Providers should caution patients that compulsive behaviors (eg, gambling, shopping, eating, etc) and sudden periods of extreme sleepiness may emerge during therapy with dopamine agonists. Levodopa therapy is associated with a high incidence of symptom augmentation and, because of a short half-life, might not provide relief over the entire night. Augmentation is a worsening in symptom severity, increase in symptom distribution, or emergence of symptoms earlier in the evening. Sedative–hypnotic agents can be effective in patients who have frequent awakenings from their RLS symptoms. Clonazepam at doses ranging from 0.5 to 2 mg has been most frequently studied; however, patients may experience carryover sedation because of its long duration of action. Shorter half-life sedative–hypnotics (eg, zolpidem, zaleplon) can improve sleep and reduce daytime sleepiness without carryover sedation. Opiates such as methadone 5 to 20 mg, codeine 30 to 120 mg, and oxycodone 2.5 mg are effective for patients with painful RLS. The potential for tolerance and dependence on opiate therapy should be considered. Gabapentin 300 to 900 mg near bedtime can also be considered for those with paresthetic or painful RLS symptoms.[67] Gabapentin enacarbil (Horizant) is a gabapentin prodrug that is now FDA-approved for the treatment of RLS at a dose of 600 mg taken at 5 pm. Iron studies should be completed in patients with RLS and iron supplementation initiated in those who are iron-deficient. In patients with ferritin concentrations below 50 to 75 ng/mL (µg/L), iron supplementation improves RLS symptoms.[68] Patients with RLS or PLMS should be evaluated regularly to monitor for excessive daytime somnolence, tolerance, efficacy, and adverse effects of the medication. Therapy should be monitored for adverse effects found in **Table 72-6**.

TABLE 72-6 Monitoring Patients Taking Medications for RLS and PLMS

Drug or Drug Class	Adverse Drug Reaction	Monitoring Parameter	Comments
Dopamine agonists	Compulsive behaviors	Frequency and quantity of eating, gambling, shopping, other reward behaviors	May occur at any time during therapy
Levodopa/carbidopa	Symptom augmentation	Location and timing of RLS irsymptoms	Appearance of symptoms in other areas of body and earlier in day
Gabapentin/Pregabalin	Dizziness	Subjective dizziness, falls	—
Sedative hypnotics (clonazepam, temazepam, zolpidem, etc)	Carryover sedation	Morning sleepiness, grogginess	More likely to occur with longer duration agents
Opioids (oxycodone, codeine, hydrocodone, etc)	Tolerance, constipation	Patient RLS symptoms and response to ongoing therapy	—
Oral iron therapy (ferrous sulfate, etc)	GI upset, constipation	Monitor for constipation	Prophylactic stool softeners may be necessary to reduce risk of constipation

GI, gastrointestinal; PLMS, periodic limb movements of sleep; RLS, restless leg syndrome.

Periodic Limb Movements of Sleep

RLS patients commonly have PLMS, while approximately one-third of patients with PLMS have RLS.[65] PLMS are stereotypic, repetitive, periodic movements of the legs that occur during sleep every 20 to 40 seconds and last 10 minutes to several hours.[66] The movements usually involve the big toe, but the ankle, knee, and hip can also flex. They can be terminated by a violent kick or other body movement. Often patients will be unaware of these movements and only recognize consequent insufficient sleep and morning leg cramps. A bed partner can describe PLMS. PLMS is diagnosed in the sleep laboratory using electromyogram recordings.

PLMS can occur with RLS or alone because of systemic disease (eg, renal failure) or drug therapy.[69] TCAs, SSRIs, dopaminergic antagonists, xanthines, nicotine, alcohol, and caffeine can all worsen PLMS. The treatment approach for PLMS is similar to that of RLS. If PLMS do not cause disruptions for the patient or bed partner or daytime symptoms, they may not require treatment. Symptomatic or problematic PLMS should be treated with dopaminergic medications to suppress limb movements or sedative–hypnotics to reduce awakenings and consolidate sleep.

PARASOMNIAS

Parasomnias are abnormal behavior or physiologic events that either occur during sleep or are exaggerated by sleep. Many of these disorders are considered to be disorders of partial arousal from various sleep stages. Parasomnias can be categorized as disorders of arousal (sleepwalking, sleep terrors), sleep–wake transition disorders (sleep-talking), rhythmic movement disorder, REM parasomnias (REM behavior disorder, nightmares), and miscellaneous parasomnias (enuresis, bruxism). Sleepwalking, sleep terrors, and sleep-talking predominantly occur during NREM sleep, whereas others (REM behavior disorder) occur during REM sleep.

Sleepwalking and sleep terrors are found normally in children between the ages of 4 and 12 years and usually resolve in adolescence. These disorders are increasingly recognized to also occur in adulthood, and, contrary to previous beliefs, are not related to psychological or psychiatric pathology.[70] Sleep terrors can begin in adults between the ages of 20 and 30 years. Onset of sleepwalking in adults without a childhood history of sleepwalking should prompt a search for a neurologic or substance use condition.[71] Sleepwalking and sleep terror disorder involve intrusions of wakefulness into NREM sleep during the first third of the night. In sleepwalking, individuals become ambulatory, are difficult to awaken, and are amnestic for the event. Sleep terrors involve intense fear and autonomic arousal. Individuals are difficult to awaken, inconsolable, and amnestic for the event.[71] Patients with REM behavior disorder act out their dreams, often in a violent manner, and are at risk for injury.

Treatment of sleepwalking involves protecting the individual from harm by putting safety latches on doors and windows, removing hazardous objects from bedrooms, and covering glass doors with heavy curtains. In adult patients, benzodiazepines, SSRIs, or TCAs can be beneficial therapies for sleepwalking or other NREM disorders of arousal.[70] Benzodiazepines can also be helpful in curtailing sleep terrors in adults.[71] Nightmares are anxiety-provoking dreams characterized by vivid recall. Treatment is directed at reducing stress, anxiety, and sleep deprivation. In extreme cases, low-dose benzodiazepines can be indicated. Clonazepam is the treatment of choice for REM behavior disorder. Melatonin (3-12 mg at bedtime) and pramipexole can also be an effective therapy for REM behavior disorder.[72]

PERSONALIZATION OF THERAPY

For the treatment of insomnia, the choice of a particular BZDRA can be based on its pharmacokinetic profile. When used as a single dose, extent of distribution and elimination half-life are important in predicting the duration of action. However, after multiple doses, the elimination half-life and formation of active metabolites determine the extent of drug accumulation and resultant clinical effects.[11] Advanced age, liver dysfunction, and drug interactions can prolong drug effects. The pharmacokinetic profiles of BZDRAs are summarized in Table 72-3. To individualize treatment of narcolepsy many clinicians prescribe both immediate-release and sustained-release stimulants to increase alertness throughout the day. Sustained-release stimulants are prescribed with scheduled administration times, and immediate-release stimulants can be taken as needed when the patient requires alertness (eg, driving, etc).

Chapter 73: Disorders Associated with Intellectual Disabilities

Nancy C. Brahm; Steven R. Erickson; Douglas W. Stewart

INTRODUCTION

KEY CONCEPTS

- 1 Persons diagnosed with Down syndrome (DS) can be at increased risk for medical and psychiatric comorbidities.
- 2 In persons with DS, a thorough evaluation is needed to differentiate between depression and Alzheimer disease.
- 3 Treatment plans for persons with autism spectrum disorder (ASD) focus on increasing social interactions, improving verbal and nonverbal communication, and minimizing the occurrence or impact of ritualistic, repetitive behaviors and other related mood and behavioral problems (eg, overactivity, irritability, and self-injury).
- 4 Many purported pharmacologic and nonpharmacologic treatments for ASD lack objective evidence-based support.
- 5 A structured teaching approach focusing on increasing social communication and integration with peers is needed when providing services to persons with ASD.
- 6 Nonpharmacologic interventions for sleep disturbances in children with a diagnosis of ASD should be implemented prior to pharmacotherapy considerations.
- 7 Psychopharmacologic treatment planning should include monitoring of objective, measurable, medication-responsive target behaviors, and assessment of potential adverse effects is of critical importance when treating behavioral symptoms of ASD, as the response of individuals to medication therapy is highly variable.
- 8 The use of Food and Drug Administration-approved medication for off-label indications is

an acceptable clinical practice if founded on evidence-based research and informed consent.

- 9 The level of impairment in Rett syndrome (RTT) is increasingly associated with the particular genetic mutation involved.

Intellectual disabilities (IDs) can be identified in childhood or adolescence. Current criteria for diagnosis are based on deficiencies in intellectual and adaptive functioning with an onset during the developmental period.[1] This diagnosis is made regardless of the presence or absence of concomitant medical or psychiatric disorders. In the case of mild ID, deficiencies may not be apparent in early life. Problems can be noted when the chronologic age of the child and the developmental milestones achieved by peers with similar backgrounds, cultures, socioeconomic status, and psychosocial settings differ significantly.[1] These gaps between developmental advances widen as the individual ages. Adaptive functioning deficits pose a number of challenges in treating those with an ID.

Whereas it has been estimated that a psychiatric disorder may beset approximately one-fifth of the general population in the United States,[2] the prevalence may range widely from approximately 7% to 97% for persons with an ID, largely a function of diagnostic criteria and study design.[3] Similarly, the impact of life events, the stress of these events, and limited coping skills may also contribute.[4] Underrecognition of the need for mental health services may be due to a lack of caregiver awareness of psychiatric disorders in persons with IDs and/or insufficient provider training and clinical experience with this population.[2] Additional barriers to accurate diagnosis may arise from deficits in adaptive functioning, a mechanism by which individuals effectively manage commonly encountered life demands and independence compared with nondevelopmentally disabled peers.[1] Communication deficits are a barrier-specific to this population. Furthermore, problematic behaviors that may arise limit opportunities for those with an ID to experience more social interactions and limit integration into the community.[3]

Another potential problem for the clinician assessing persons with an ID is a significant gap between receptive and expressive language skills. If not readily recognized, intellectual capabilities can be overestimated, resulting in incongruent expectations and/or abilities. In the general population, features of psychiatric illnesses are more readily identifiable, and the clinician is able to effectively interview and evaluate the patient. The term “diagnostic overshadowing” has been used to refer to clinician perceptions that behavioral problems are secondary to an ID and not the result of a psychiatric comorbidity.[5]

The term “mental retardation” is no longer used, replaced with “intellectual disability” (ID).[1] The American Association on Intellectual and Developmental Disabilities (AAIDD) supports this designation and has a definition on their Web site.[6] The change reinforces the concept that an intellectual disability is not “an absolute, invariate trait of the person” but recognizes the impart of the environment, individual supports, and personhood.[7] For this chapter, the designation “ID” will be applied to the population of individuals who require varying levels of support due to limitations in general mental abilities that result in impairment of adaptive functioning, with an onset during the developmental period, in more than one area and at home or in the community.[1] This chapter

focuses on Down syndrome (DS), autism spectrum disorder (ASD), and Rett syndrome (RTT).

DOWN SYNDROME

DS is associated with common dysmorphic features and a wide range of medical and psychiatric concerns, including a number of developmental abnormalities. Congenital heart defects, seizures, orthopedic abnormalities, sensory defects, and disorders of the eye (eg, cataracts and glaucoma), gastrointestinal (GI) tract, immune system, skin, and thyroid gland are all associated with DS. Persons diagnosed with DS also have a high probability (30%) of early onset Alzheimer disease (AD).[8] This section will focus on DS and the comorbidities of AD and leukemia.

CLINICAL PRESENTATION Intellectual Disability General

- Limitations in intellectual functioning and adaptive behavior.
- Onset before 18 years, which may also be referred to as the developmental period.

Specific Activities or Knowledge Impacted

- Limitations are considered within the framework of the individual's community, culture, and age.
- Problems in understanding and applying abstract relationships, such as problem solving, planning, and learning from experience. Standardized intelligence testing may be used to provide a numerical value and help determine limitations.
- Unable to meet developmental and sociocultural standards for personal independence and social responsibility when compared to peers of the same age and culture.
- Ongoing support(s) needed in one or more areas of daily life, such as communication and/or social participation and independent living.
- Independent living may require supports that may be needed in more than one setting: home, school/work or community and the use of long-term personalized supports will improve life functionality.
- Strengths and limitations are both present.
- The term "mental retardation" did not represent the scope of individual accomplishments of which each individual may be capable and was replaced with "ID."

Data from references 1, 6, and 7.

Epidemiology

DS is the most frequently occurring genetically based syndrome associated with an ID.[9] The incidence

ranges from 1 in 650 to 1,000 births.[9]

Etiology and Pathophysiology

The etiology of DS is the presence of an extra chromosome 21. DS, also referred to as trisomy 21, represents one of the most studied abnormal chromosomal conditions. Nondisjunction of chromosome 21 accounts for the majority of the characteristics associated with DS. Chromosomes divide and separate in a process known as disjunction during meiotic division. Failure to fully separate at this stage can result in both chromosomes remaining in the same cell, creating an abnormal number of chromosomes on each strand. The nondisjunction at chromosome 21 is strongly linked to increased maternal age. For many years, advanced maternal age has been recognized to positively correlate with an increased risk for DS, particularly over age 35 years.[9] Consideration has been given to paternal age as a potential risk factor for DS. An analysis by Steiner and colleagues found that for couples with younger fathers, the odds of having a child with DS were increased almost twofold,[10] whereas Fisch and colleagues found that older fathers in combination with older mothers, when both were 35 years or older, significantly impacted the incidence of DS.[11]

It has been theorized that two variables, lack of maternal folic acid supplementation, and genetic variability that decreases enzymatic processes in folate pathways, may negatively impact meiotic nondisjunction of chromosome 21. Questionnaire data from the National Down Syndrome Project were analyzed. No association between supplementation use and nondisjunction was found based on maternal age and ethnicity, but an association was found between older maternal age and meiosis II nondisjunction. Hollis and colleagues opined that this could explain previously reported differences in findings; additional confirmation, controlling for maternal age, is needed.[12]

Clinical Presentation and Diagnosis

The consequences of this chromosomal variance include characteristic facial features, some degree of ID, hypotonia, an increased risk for congenital heart disease, and early onset AD.[13,14] The characteristic facial features make children with DS more readily identifiable at birth. IDs range from mild to severe.[13]

For the purpose of this chapter, the term *dual diagnosis* refers to an intellectually disabled person with a comorbid psychiatric disorder.[2] Psychiatric and/or behavioral disorders, such as depression and anxiety in persons with an ID, may result from environmental variables (relocation, change in caregivers), personal variables (age, level of disability, comorbid medical conditions), and the extent to which the individual can cope. The association between life events with depression and anxiety was researched in a community-based population receiving services from three organizations (n = 988, 509 male, 479 female, mean age 61 years). Variables assessed were age, sex, ID, residential setting, and history of depression or anxiety, using a 28-item checklist for life events. Depression and anxiety instruments included the Inventory of Depressive Symptomatology Self Reports and the Glasgow Anxiety Scale of people with an Intellectual Disability. Almost all of the study population (979 of 988, 99.1%) had been exposed to at least one life event during the prior 12-month period. As

anticipated, the cohort of persons 65-years or older experienced more events.[4] The authors also found associations between major depression, generalized anxiety disorder, panic disorder, and the number of negative life events.[4]

This has implications for depression in persons with DS. A review of the literature found the majority of the information on pharmacotherapy was derived from case reports. Selective serotonin reuptake inhibitors (SSRIs) and amitriptyline have been used successfully, but desipramine was not effective.[15]

The differential diagnosis for mood disorders in all patients should include an evaluation of thyroid function. The risk of a thyroid disorder as a comorbidity in people with DS is estimated at 4% to 18%.[14] Because clinical signs and symptoms of hypothyroidism and dementia can mimic some of the features of depression, thyroid function and changes in cognition should be evaluated in patients with DS.[15]

TREATMENT

Down Syndrome

Desired Outcomes

Treatment goals in DS are to identify medical and psychiatric comorbidities, set realistic goals, and provide effective nonpharmacologic and pharmacologic interventions to improve the quality and length of life.

CLINICAL PRESENTATION Down Syndrome General

- Individual may have the characteristic physical features described below.

Diagnostic Features

- Facial features can suggest DS, but an additional diagnostic evaluation is necessary.
- Degree of ID ranges from mild to severe.
- Growth delays are common.

Common Physical Characteristics

- Hypotonia can be evident at birth.
- Facial features include flat nasal bridge and profile, with upslanted eye folds.
- The palate can be narrow and the neck thick and broad.
- Hands are characteristically short and broad.

Other Clinical Concerns

- An increased risk for congenital heart problems; a cardiac evaluation is generally done shortly after birth with periodic follow-up.
- Congenital cataracts, hearing problems, and hypothyroidism are common.
- Leukemia is often diagnosed in early childhood.
- Features of AD can present by the third or fourth decade.
- Heart problems, conditions related to AD, and leukemia are common causes of death.

Data from references 13, 14, and 17.

General Approach

Medical screenings should assess for hypothyroidism, cardiac problems, sensory impairments (including hearing loss secondary to chronic otitis media with effusion or vision defects due to congenital cataracts or glaucoma), and GI problems (including constipation and celiac disease).[14] Guidelines for health supervision and anticipatory guidance in infants, children, and adolescents with DS are available through the American Academy of Pediatrics (AAP).[14] Routine screenings are also recommended throughout life to address psychosocial changes, potential residential or vocational stressors, and the consequences of aging.[14]

Nonpharmacologic Treatments

The use of social supports for both individuals with DS and their family is known to facilitate development of functional adaptive skills.[14] Family education and development of a support network assist caregivers by providing tools and resources necessary to enable persons with DS to achieve their full potential. In the treatment of psychiatric disorders, treatment modalities useful in the general population are also applicable to those with DS. Nonpharmacologic options for depression include psychotherapy and electroconvulsive therapy (ECT).[15] Information on the effectiveness of ECT in the DS population is limited to case reports. If communication skills are adequate, psychotherapy may also be an option, including psychodynamic psychotherapy and cognitive behavior therapy (CBT). A review of the literature found that psychotherapy applicability can vary with the level of ID. For persons with mild intellectual impairment and depression, this treatment modality may be beneficial. The current behavioral therapy models are more effective in addressing specific problematic behaviors rather than the underlying emotional problems of persons with ID. Usefulness of these strategies for persons with DS and more severe ID is not known.[15]

Pharmacologic Treatments

Pharmacotherapy for the treatment of depression in patients with DS follows guidelines used in the general population. For more information on the treatment of depression, see Chapter 68.

Features of depression commonly seen in persons with DS, in order of frequency, include apathy,

disordered sleep, and changes in weight. Difficulty identifying depression in this population is impacted by the level of cognitive impairment, the ability to express abstract concepts (such as helplessness or hopelessness), and the level of adaptive functioning.[15] Clinical trials focused specifically on this population are few, and most information comes from small studies or case reports. Efficacy of SSRIs and amitriptyline is reported. If psychotic features (eg, delusions and hallucinations) are present, low-dose antipsychotic augmentation is recommended. In the studies reviewed, treatment duration was 2 to 3 years.[15]

As with treatment of depression in the general population, it is essential to ensure that the medication trial uses appropriate dose and duration of antidepressant or combination antidepressant/antipsychotic. Ruling out comorbid medical conditions that could contribute to depression is essential.

Personalized Pharmacotherapy

In addition to the chromosomal aberration and dysmorphic features associated with DS, one of the common presenting features of depression is disordered sleep. Obstructive sleep apnea rates are estimated at 50% to 75% in the DS population.[14] Daytime drowsiness and problematic behaviors may be indicative of both an affective disorder, such as depression, and a medical condition secondary to DS. A comprehensive evaluation, including the impact of obesity on sleep, is needed prior to the addition of pharmacotherapy. If pharmacotherapy is indicated, the medication list for each patient should be carefully reviewed for potential drug-drug interactions and drug-disease contraindications.

Evaluation of Therapeutic Outcomes

Assessment of therapeutic outcomes for those with DS starts with a thorough multidisciplinary evaluation to establish a baseline problem list, identification of clear therapeutic goals, and using valid pharmacotherapeutic rationale to guide medication dosing and adverse drug effect monitoring.

An in-depth list of treatment targets, both subjective and objective, is important in persons with DS to assist in evaluation of medication response. Careful monitoring for emergence of potential side effects should be regularly conducted and documented as part of ongoing assessment of medication effectiveness and to ensure that side effects are not a contributing factor to behavioral changes.

Down Syndrome and Alzheimer Disease

2 Persons with DS are at greater risk for AD, and the proportion of the population affected doubles every 5 years through age 60. By age 72, the prevalence is 67%.[16]

In adults with DS, challenging behaviors, such as aggression, stealing, loss of previous skills, and disinhibition, may be a prodromal presentation. Changes in mood and emotional stability may also present.[16] Assessing changes in functionality and cognition are problematic in this population, particularly in those with greater intellectual impairments. Early studies in this population did not specify the criteria used for diagnosing probable or possible AD. A well-delineated diagnosis of major

or mild neurocognitive disorder due to AD requires a documented decline from baseline cognitive functioning. It is recommended that baseline status be documented once before 35 years of age with reassessment annually up to every 5 years.[17] To meet the diagnostic criteria, the following are needed: baseline functioning data to assess change, functionality changes not explained by general aging, and progressive decline.[1] Accurate diagnosis requires use of an appropriate assessment scale for those with DS. Specific tools include the Dementia Scale for Down's Syndrome and the Cambridge Examination for Mental Disorders of Older People with Down's Syndrome and Others with Intellectual Disabilities.[17]

Risk factors for AD in those with DS include age, genetics, gender, estrogen, and metabolic syndrome, although information is limited in some areas. In persons older than 40 years with DS, behavior changes, such as fear, sadness, and overall regression, are the primary features of the early stages of dementia. Mood and emotional dyscontrol are reported to occur at the same time as marked adaptive functioning declines.[16] Diagnostic criteria for AD include changes in memory, language skills, and activities of daily living (ADLs). In addition, major functional declines may include behavioral disinhibition, stereotypic or ritualistic behavior, and/or apathy.[1] Information on the natural progression of cognitive changes in those with DS and AD continues to emerge.

Pathophysiology

Neuritic plaques and neurofibrillary tangles are the hallmarks of AD. A gene for amyloid-β precursor protein is located on chromosome 21.[18] The severity of ID has been theorized to significantly impact the incidence of AD, but further study is needed to validate this theory. A study of DS (n = 405) with and without dementia identified specific amyloid-β precursor proteins that might be predictors of dementia in DS regardless of age, gender, and level of ID.[18] A more extensive discussion of the pathophysiology of AD is beyond the scope of this chapter. For more information about AD, see Chapter 54.

Treatment

Down Syndrome with Alzheimer Disease

Desired Outcomes

The therapeutic goal is to maintain functioning and quality of life as close to baseline as possible for as long as possible. Approaches to therapy for persons with DS combined with AD include nonpharmacologic and pharmacologic interventions.

Nonpharmacologic Treatments

Traditionally, this population receives some level of residential living supports in either the family home or a residential facility. Depending on the level of ID, a family member, other caregiver, or residential facility staff may provide information to the clinician regarding functional status.

Pharmacologic Treatments

Pharmacologic treatments neither cure nor stop the pathologic changes associated with AD. The goals of pharmacotherapy in persons with DS and AD, as in the general population of AD patients, are to slow the decline in cognitive function and help preserve ADLs to the greatest extent possible. The use of cholinesterase inhibitors and an *N*-methyl-D-aspartate (NMDA) receptor antagonist in the DS population has been studied. Limited trial data exist on the use of memantine in persons with DS over age 40. In one prospective randomized double-blind trial (n = 88), memantine was given for 52 weeks. Inclusion criteria were a diagnosis of DS, with or without dementia, and over 40 years. Both groups declined in cognition and functional abilities.[19]

Trials of cholinesterase inhibitors to enhance learning and memory in persons with DS have had small sample sizes. One trial with promising results is a 24-week, randomized, double-blind, placebo-controlled trial of donepezil in 21 females with DS with severe ID. Treatment arms were placebo or donepezil (3 mg). The assessment instrument was a modified International Classification of Functioning, Disability and Health (ICF) scaling system. The authors reported that the ICF score improvement was significant with donepezil, and it was well tolerated.[20] For more information about pharmacotherapy treatment guidelines in AD, see Chapter 54.

Preexisting medical comorbidities, such as congenital heart defects, or concomitant pharmacotherapy may limit use of cholinesterase inhibitors in persons with DS. Clinicians are encouraged to monitor patients receiving cholinesterase inhibitors for commonly reported adverse drug effects and the potential for drug interactions.

A potential neurologic comorbidity of concern in this population is seizures, and risk increases with age. Distribution of seizure onset is trimodal, with the first peak incidence appearing before 1 year of age (40%; predominantly infantile spasms). The second peak occurs between the ages 20 and 30 years (40%). The final peak corresponds to the onset of Alzheimer-related dementia (20%).[16] Advancing age and a diagnosis of DS are independent risk factors for seizures.[17] Monitoring for new-onset seizure activity and medicating with anticonvulsants, as appropriate, are essential. For more information about epilepsy and seizure disorders, see Chapter 56.

Evaluation of Therapeutic Outcomes

Baseline functioning must be established early in adult life prior to the onset of AD, which generally occurs during the third or fourth decade of life. This is particularly crucial in individuals without expressive language skills. Follow-up evaluations should be performed before age 35 years (at least once) then annually to every 5 years.[16] If cholinesterase inhibitors are used, evaluations every 2 to 4 months (after achieving a maintenance dose) are recommended to monitor for effectiveness. Monitoring for potential medication-related side effects, including diarrhea, nausea, vomiting, insomnia, and headache, is also essential.

Down Syndrome and the Immune System

Leukemia is frequently diagnosed in DS children. The two forms more commonly encountered in DS children are acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML). The risk for ALL in a DS child is 10 times, up to 40 times, greater compared to peers in the general population and continues to be elevated until 30 years of age.[21,22] The rate of DS-AML is similarly elevated (150 times greater) in children younger than 5 years of age.[21] The most commonly identified form of DS-AML is acute megakaryoblastic leukemia (AMKL). The incidence of this disorder in DS has been identified as high as 500 times greater than in the non-DS pediatric population. Another myelodysplastic disorder almost unique to children with DS is transient abnormal myeloproliferative (TAM) disorder. A mutation in the erythroid transcription factor or GATA-binding factor 1 (GATA-1) was suspected and found between TAM and DS-AML, as TAM precedes AML in this population.[21]

In the DS population, ALL survival rates are lower than in the general pediatric population. This may be a function of differences in treatment intensity between DS and non-DS patients[22] and more chemotherapy-related toxicities, such as mucositis and cardiotoxicity, compared with non-DS children with ALL.[23] Chemotherapy-induced cardiotoxicity is of particular concern in children with DS, as 50% may have a congenital heart defect.[14] In those treated with anthracyclines, rates of cardiomyopathy are inconsistently reported.[23]

Cardiotoxicity secondary to anthracyclines in pediatric patients with diagnoses of DS and AML has been inconsistently reported. Conventional anthracycline high-dose or high-intensity regimens are associated with increased rates of cardiomyopathy in this population compared to both without DS and AML. Similar findings have been reported for youth with DS and ALL.[23] Interpretation of the literature on cardiotoxicity and anthracycline-related toxicities requires several considerations, such as population demographics. Potential confounds include age, agent used, and assessment instruments and criteria to evaluate cardiotoxicity. For example, the pediatric populations under consideration have ranged from those approximately 1 year of age to those with an average age of 6 years. In addition, some studies used different assessment methodology, making comparisons problematic.[23]

AUTISM SPECTRUM DISORDER AND AUTISM

Autism was first described by Leo Kanner in 1943 and has been historically described as early infantile autism, childhood autism, and Kanner autism.[1] Autism is not a disease but a neurodevelopmental disorder with multiple possible etiologies.[24] The onset is typically before 3 years of age and is usually, but not always, associated with some degree of ID.[1] Originally autism, or autistic disorder, was one of five behaviorally defined pervasive developmental disorders (PDDs) that included Asperger disorder, Rett syndrome (RTT), childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified (PDD-NOS). These disorders are now referred to under the single designation of ASD and are characterized by two underlying problems—impaired social interaction and communication (regarded as one conjoined problem) and restricted behavior. Further distinctions are made based on severity, which is based on the amount of support needed, challenges with social communication, restricted interests, and repetitive behaviors. Also included are specifications of with

or without an accompanying intellectual impairment.[1] There are three levels of severity, Level 1, the least severe, though Level 3, the most severe. This section will focus specifically on autism, which is characterized by severe and sustained impairments in three behavioral domains: (a) reciprocal social interaction (withdrawal or lack of interest in peers), (b) language and communication skills (limitations in the use of speech and nonverbal skills), and (c) range of interests and activities (repetitive, restricted behaviors, stereotyped mannerisms).[1,25]

Epidemiology

There has been a recent sharp increase in the reported prevalence of autism. The most recent national estimate is 1:68 children identified with ASD.[26] It is suggested that the reported increased prevalence is primarily related to changing and broadening diagnostic criteria, along with an increased index of suspicion, rather than due to an actual increased incidence, as autism is behaviorally identified, and the diagnostic boundaries are not always clear.[27,28] In addition, inclusion of individuals with diagnoses of Asperger disorder and PDD-NOS in newer studies may contribute to the increase.[28] Some behaviors (eg, stereotypies) seen in persons with autism can also be seen in nonautistic individuals. One study found children with a history of early institutionalization demonstrated more stereotypical behaviors that markedly decreased following increased interactions postplacement.[29] There is a significant impact of intellectual ability on the expression of symptoms of autism,[30] resulting in a lack of homogeneity in clinical expression of the condition. Autism is between four and five times more prevalent in males.[24] When present, ID ranges from mild to severe. The heterogeneity and early onset represent two methodologic problems for large-scale research studies.[24]

Etiology and Pathophysiology

The etiology of autism is attributed to multiple causal factors, including gene mutations, abnormalities in brain development, and genetic–environment interactions.[25] Autism may occur concomitantly with other developmental disorders that have a known genetic basis, such as RTT and fragile X syndrome.[28] Current research primarily focuses on genetics and neuropathology. Although a single genetic mutation or variant leading to autism has yet to be identified, research findings indicate that structural alterations in the genome deoxyribonucleic acid (DNA), known as copy number variations (CNVs), may be involved in ASD. Research identified a number of CNVs associated with ASDs, as this appears to be a highly heritable disorder.[31]

These findings provide support for the heterogeneity of neurodevelopmental disorders, whereby disruption represents a critical period in the development of excitatory and inhibitory neuron development. A combination of genetic and/or environmental factors, in the absence of any compensatory mechanism, may interfere with brain plasticity.[30] A meta-analysis provided some support for the theory that ASD may arise from interference in the excitatory and inhibitory balance expression and/or timing during critical periods.[32] A review of the literature found persons with autism demonstrated what was termed “unusual sensory processing.” Additional findings included (a)

a diagnosis of autism was associated with greater sensory symptoms than in other developmental disorders, (b) increased age was associated with decreased symptoms, and (c) for children there was a positive correlation between social impairment and sensory symptoms.[33]

Siblings of affected children have a significantly greater risk of having autism (3%-18.7%) than those in the general population.[34] Results from a national volunteer registry (n = 2,920 children, 1,235 families, a minimum of 1 child meeting ASD diagnostic criteria, and a minimum of 1 full sibling) found that the sibling concordance rate was 10.9%. Overall an additional 8.9% of the siblings demonstrated language delay with autistic-like speech quality.

Further support for the high heritability of the disorder was shown by additional research in this area. Sibling risk varies based on the gender of the index child: 4% versus 7% for female compared with male. If a second child is diagnosed, the risk for concordance in subsequent siblings increases to between 25% and 30%, higher than previously reported. The risk for a monozygotic twin with autism ranges from 60% to 95% that both twins will be diagnosed with autism.[35] A study of over 14,000 children diagnosed with ASD in Sweden found that ASD heritability was estimated to be 0.50, and the autistic disorder heritability was estimated to be 0.54. Interpreted, this means the heritability of ASD was estimated to be approximately 50%.[36]

Parental age was investigated as a potential risk factor for autism. While results are far from conclusive, a number of intriguing results were found. A case–control study design of a cohort of age- and sex-matched pairs (n = 68) found a significant effect linking the age of both parents and a child with a diagnosis of autism. Unadjusted parental ages were higher for both parents (paternal 4 years higher, maternal 4.8 years higher) compared with controls. After adjusting for variables, such as educational level and gestational age, the differences widened to 5.9 and 6.5 years, respectively.[37] Shelton et al found increasing paternal age was a risk factor if the mother was younger than 30 years.[38] Other work found that increasing paternal age was associated with greater risk.[39]

Environmental exposures, including toxic chemical exposure, teratogens, perinatal insults, prenatal infections,[28] and copper and zinc levels[40] are under investigation. Immunization with measles-mumps-rubella (MMR) vaccine has been investigated, and no causal association identified.[41]

Autism frequently occurs concomitantly with epilepsy[42] and may be associated with microdeletion gene defects that are also risk factors for schizophrenia and attention-deficit/hyperactivity disorder (ADHD). Examples include the association between autism, ID, schizophrenia, and seizures with microdeletions on the 15q13.3 and 1q21.1 regions.[43] Other sites also may be implicated. The two most common single gene abnormalities associated with autism are fragile X syndrome and tuberous sclerosis.[35]

The neurodevelopmental foundation of autism has sparked significant interest in early morphologic changes in brain development, particularly findings of early brain overgrowth. Head circumference at birth ranges from slightly below normal to within normal limits. This finding changes by 2 to 3 months of age when accelerated head growth occurs. The rate of growth may exceed 2 standard deviations above the average. Approximately 60% of infants diagnosed with autism compared with

6% of normal infants have this rate of accelerated head growth. The increase positively correlates to the increase in ID severity. Following this period of accelerated head growth, during which time the infant brain may achieve the size of the adult brain, deceleration or a complete cessation of head growth is noted.[24]

Accelerated brain growth may predispose the developing brain to increased vulnerability. This is consistent with the concept of plasticity, whereby development of cortical circuitry is established during critical postnatal periods. During this period of development, a balance of excitatory and inhibitory neurofunctionality occurs. It has been theorized that during this critical period if an imbalance occurs, this results in neurodevelopmental disorders, such as autism.[36] This theory is consistent with the diagnostic criteria of onset within the first 3 years, abnormalities in three major areas (socialization, communication, and repetitive behaviors[1]), and disruption in neurocircuitry development.

Dysfunction of virtually all neural systems in the brain has been proposed at some point as a potential basis of autism.[44] The neuropathologic changes noted in persons with autism are suggested to be of prenatal origin, primarily in the first 6 months of gestation.[24] Evidence has been published that suggests that autism affects a functionally diverse and widely distributed set of neural systems, making the disorder far broader in scope than a simple social interaction disorder.[44] Despite these findings, the pattern of brain abnormality appears somewhat discrete. Autism spares many perceptual and cognitive systems. A localized neural deficit can have more widespread neurofunctional implications through its influence on brain development.[44]

There is research to support abnormalities in cholinergic receptors and decreases in the nicotinic receptor binding in the cholinergic system, as well as dysfunction in the GABAergic system[42] in persons with autism. Nicotinic receptors enhance cognitive processing (ie, memory and attention) open the possibility of therapeutic intervention via cholinergic receptor modulation.[45] Approximately 25% to 60% of children with autism have elevated peripheral platelet concentrations of the neurotransmitter serotonin.[46] Studies of dopamine and catecholamine metabolites have failed to consistently show abnormalities.

Clinical Controversy…

Well-conducted case–control, cross-sectional, ecologic, and cohort studies investigating use of thimerosal, an organomercury compound previously used as a vaccine preservative, found no causal association between thimerosal-containing vaccines and the development of autism or deficits in neuropsychological function.[57] In a large sample of privately insured children with older siblings, receiving the MMR vaccine was not associated with increased risk of ASD, regardless of whether the older siblings had ASD.[58] Despite the lack of evidence, the neurotoxic effect of mercury exposure continues to be a hotly debated issue among many advocates for persons with autism. Clinicians must be well informed on this issue to educate parents and caregivers.

Clinical Presentation and Diagnosis

The differential diagnostic features of ASD are listed in **Table 73-1**. A multiple-step process has been suggested as a structured approach to diagnosis if ASD is suspected. As a spectrum disorder, the severity or level of impairment may be highly variable. This structured approach includes a determination of intellectual function and level of language development, followed by assessment of the child's behavior as it relates to chronologic age, mental age, and language age. It is important to identify relevant comorbid medical conditions and the presence of any related contributing psychosocial factors.[47]

TABLE 73-1 Comparison of Diagnostic Features of ASD and Rett Syndrome

Feature	ASD	Rett Syndrome
Age at recognition (months)	0-36	24-28
Sex ratio	M > F	F >> M
Loss of skills after initial mastery	Variable	A defining feature
Social skills	Very poor	Varies with stage
Communication skills	Usually poor	Very poor
Circumscribed interests	Variable (mechanical)	NA
Eye contact	Very poor	Varies with stage
Family history of similar problems	Sometimes	Rare
Seizure disorder	2.4%-26%	Frequent
Head growth decelerates	No	Yes
IQ range	Normal to severe ID	Severe ID
Outcome	Good to very poor	Very poor

ASD, autism spectrum disorder; F, female; IQ, intelligence quotient; M, male; NA, not applicable.

Data from references 1, 48, and 54.

Persons with autism are typically normal in physical appearance. Seizure rates among those with ASD are reported to be between 2% and 21%.[48,49] Patients with comorbid seizure disorders often have greater impairment in intellectual function.[1] Other medical comorbidities commonly reported in this population include sleep disturbances, food intolerances, and GI dysfunction.[50]

The cardinal features of autism are gross and sustained impairment of reciprocal social interaction; sustained abnormalities in verbal and nonverbal communication skills; and restricted, repetitive, and stereotypical patterns of behavior, interests, and activities.[1] These are primarily manifested as gaze aversion, little/no interest in making friends, preference for solitary activities, repetition of words/phrases, monotone voice, insistence on sameness, and a lack of awareness of other's feelings.[1,51] In most cases (approximately 75%), there is an associated diagnosis of ID, ranging from mild to profound: approximately 30% function in the mild to moderate range of ID, whereas 45% to 50% have severe to profound impairment.[47] Epidemiologic data suggest that the risk for development of autism increases as the intelligence quotient (IQ) decreases.[47] A few individuals with autism have unusual abilities called splinter functions or islets of precocity. The most significant of

these are evidenced in the autistic savant, in which the individuals can have precocity in mathematic calculations, art, music, or rote memory.[1,47]

In many instances, parents note that they were concerned about the child's lack of interest in social interactions since birth but were sure at least by 3 years of age.[1] In a controlled setting, use of an integrated model for screening was effective in diagnosing children before 36 months of age.[52] Original findings of behaviors suggesting the need for an intellectual evaluation included lack of babbling, pointing, or other gestures by 12 months, no single-word language development by 16 months, no two-word language development by 24 months of age, and loss of previously held language or social skills at any age.[28] Earlier intervention is recommended when the early signs and symptoms of autism are recognized. It is difficult to determine if autism is present in persons with severe to profound ID. A diagnosis is made in such cases when there are qualitative deficits in social and communicative skills and the specific behaviors characteristic of ASD are present.[1] A central difference is that persons with ID alone typically relate to adults in a manner consistent with their mental age, use their language to communicate with others, and present with a relatively even profile of impairments without splinter functions.[47]

Although there are no definitive biologic markers for identifying individuals with autism, a number of medical evaluations should occur at baseline, to assist in distinguishing the diagnosis as autism and to rule out other disorders. **Table 73-2** delineates the parameters to be considered in a medical evaluation for persons suspected of having autism and the rationale for the assessment.

TABLE 73-2 Medical Screening for Individuals with ASD

Parameter	Rationale
Health, medical, behavioral, and developmental history	Perform initial screening or confirm diagnosis, identify underlying cause; assess strengths and weaknesses; identify comorbidities; measure head circumference; identify resources needed
Wood's light examination	Identify depigmented macules associated with tuberous sclerosis
Hearing and vision testing	Profound hearing loss can illicit symptoms mimicking autism (receptive language deficits); most are normal
Heavy metal testing	Perform if there is a history of malnutrition, recurrent vomiting, early onset seizures, dysmorphic features, presence of ID, or developmental delays
Genetic testing for karyotype, fragile X, Rett syndrome	Benefits family for genetic counseling purposes; evaluation of siblings, if applicable; review family history for three generations
Test for inborn errors of metabolism/metabolic testing	Indicated in those with a history of lethargy, recurrent vomiting, early seizures, dysmorphic or coarse facial features, ID
CBC, thyroid function testing	CBC if anemia suspected; thyroid function tests to rule out baseline thyroid abnormality that can affect mood/activity level
EEG	Evaluate neurologic findings that cannot be explained by the diagnosis of autism alone or in the presence of developmental regression, particularly language

Parameter	Rationale
Neuroimaging	Evaluate neurologic findings that cannot be explained by the diagnosis of autism alone; identify specific neuropathologic changes associated with autism, including brain volume

ASD, autism spectrum disorder; CBC, complete blood count; EEG, electroencephalograph; ID, intellectual disability.

Data from references 28, 40, and 53.

Those individuals with autism and IQs above 70 who use communicative language by ages 5 to 7 have the best prognoses.[47] Conversely, low IQ scores and failure to develop communicative language by age 5 years correlate with a poorer long-term prognosis.[53] Outcome studies in persons with autism correlate IQ, particularly verbal IQ, with the ability to be employed and live independently.[44,54] Learning disabilities are an independent risk factor for development of behavioral problems, and 41% of children with mild, moderate, or severe learning difficulties have a significant emotional behavioral disturbance.[54] Studies indicate that high-IQ children with autism can make positive changes in communication and social domains more effectively over time. The areas less likely to improve are those related to ritualistic and repetitive behaviors.[50] Up to 80% of children diagnosed with ASD continued to experience marked impairment in social interactions as adults. Mild to moderate ID was reported for approximately 30%.[55]

In addition to the core symptoms of autism, many persons with this disorder exhibit other significant maladaptive behaviors, such as aggression to self and others. These behavioral issues can interfere with day-to-day activities and are challenging for the individual, families, and caregivers.[56]

Clinical Controversy…

Many families, clinicians, and advocates are concerned that the new diagnostic categorization will have the unintended consequence of eliminating some persons with previously diagnosed high-functioning autism (ie, formerly Asperger disorder) from eligibility for services by recognizing the essential shared features of the ASD while attempting to individualize diagnosis through dimensional descriptors. Additional study will clarify if these concerns are well founded.

Treatment

ASD

Desired Outcomes

Treatment goals in persons with a diagnosis of ASD are to address deficits in communication and social interaction using a structured approach, minimize the impact of restricted behaviors (eg, stereotypies or repetition), and facilitate behavior appropriate to the level of intellectual ability, language development, and chronologic age.

General Approach

3 The multimodal treatment plan should address (a) establishing realistic goals for educational efforts, (b) identifying the presence of behavioral target symptoms for intervention, (c) prioritizing target symptoms and comorbid conditions for intervention, (d) using specific methods of outcome monitoring of functional domains (behavioral, adaptive skills, academic skills, social interaction skills, communication skills), and (e) monitoring for efficacy and potential adverse effects of medication (if used). The National Institutes of Health (NIH) suggests that evidence-based treatment strategies include the use of both psychoeducational therapies and medications.[59] An effective, well-designed, multimodal treatment plan that is consistently executed has the most potential to positively shape the autistic individual's interaction with the environment and improve the quality of life of patients and their families.

After a thorough diagnostic evaluation, treatment planning for the individual with autism is critical to assure consistency and efficacy of interventions. With the often severe nature of the behavioral and adaptive problems, it is not surprising that many potential treatment modalities lacking an evidence basis have been proposed for persons with autism. 4 The two treatment approaches for autism with evidence-based support and clinical consensus are behavioral/psychoeducational therapies[28,60] and psychoactive medication intervention[25] as appropriate. All stakeholders (the patient, family, caregivers, educators, and clinical professionals) should be involved in the treatment planning process. Treatment decisions should be evidence-based and individualized to the specific identified needs of the individual. The potential for communication deficits often limit self-reporting of psychopathology. A multifaceted approach to information gathering should include direct observation; interviews with patient, parents, family, caregivers, and teachers; and review of the medical record, including any behavioral rating scale information.

CLINICAL PRESENTATION Autism Spectrum Disorder General

- It is a behaviorally defined disorder.
- Multifactor causality is suspected. This includes gene mutations, abnormalities in brain development, and genetic–environment interactions.
- Individuals typically present with delays or abnormalities in six or more of the symptoms below, with at least two impairments in social interactions and one each in communication and restricted interests or repetitive behaviors.

Diagnostic Features

- Significant impairment in nonverbal communication.
- Unable to develop peer relationships.
- Lack of spontaneous interactions with people or the environment.
- Developmental delays in communication.

- Inability to use expressive language appropriate to developmental level.
- Lack of developmentally appropriate play.
- Limited scope of play or interest.
- Inability to tolerate change.
- Stereotypic or repetitive, nonfunctional motor movements.

Data from references 1, 28, and 54.

4 Available evidence suggests that appropriately designed, consistently implemented educational services positively impact the acquisition of social, communicative, self-care, and cognitive skills, each of which facilitates the person's long-term success. Services, such as occupational therapy, physical therapy, and speech pathology, are often integral aspects of an overall educational plan. 5 Because of the pervasive need for sameness in routine, ongoing and consistent year-round educational programming is more effective than intermittent, episodic interventions. Effective language and communication training can lead to generalized improvements in social skills and repetitive behaviors, and thus positively impact other nonspecific, maladaptive, behavioral problems such as noncompliance, self-injury, and aggression.[61]

Nonpharmacologic Treatment

Intervention strategies, such as discrete trial training, have demonstrated improvement in challenging behaviors. Educational techniques include structuring the environment, family training, peer role modeling, and sensory integration to optimize environmental interactions.[60]

Pharmacologic Treatment

Many of the studies of psychopharmacologic interventions in persons with ASD have methodologic shortcomings, including problems in experimental design and sample size, loose or poorly defined diagnostic criteria, and many clinical outcomes that were limited in duration or of dubious clinical significance.

4 Among a number of scientifically unsupported treatments for autism is the use of complementary and alternative medicine (CAM). A study of 540 families of children with ASD found that the child/family had tried an average of seven CAM therapies.[62] Elimination diets in which casein (from dairy products) and/or gluten (from wheat products) are excluded from the diet have demonstrated no benefit. Other such purported therapies include omega-3 fatty acids and selected herbal remedies, specifically ginkgo biloba. The omega-3 trials demonstrated no significant differences between supplementation and placebo. Several of the trials reviewed had methodological problems identified. Again, utilization of ginkgo biloba or placebo as adjunctive therapy with risperidone did not show efficacy.[63]

Current research on the neurobiologic basis of autism is centered on the serotonergic, peptidergic, dopaminergic, and noradrenergic systems. This research has particular applications for insomnia in children with ASD, as the prevalence of sleep disorders has been reported to range from 44% to 83%.[64] 6 Parents commonly rate sleep disturbance as a significant clinical issue. As with nonautistic individuals, it is important to determine the underlying etiology of the sleep problem. Behavioral interventions (eg, improved sleep hygiene, eliminating maladaptive sleep habits, and parental education) should be undertaken prior to implementing pharmacotherapy. No medication has been FDA-approved for pediatric insomnia. While controlled trial data are limited, there is support for the use, safety, and effectiveness of melatonin. In a review of the literature for use of melatonin in ASD, 85% (n = 107) reported improved sleep, specifically shorter sleep onset latencies. Doses ranged from 0.75 to 6 mg. Adverse effects were mild (headaches, GI upset, dizziness).[65]

Aggression to self and others and severe tantrums are a concern, particularly with adults with ASD. In addition to inclusion of nonpharmacologic interventions, pharmacotherapy is frequently utilized. Despite limited evidence-based support, psychoactive medications have been widely used to minimize the frequency and intensity of these behaviors. 7 It is important that clinicians identify and carefully monitor specific behavioral target symptom response to avoid the practice of overprescribing psychoactive medications.

An association between dopamine dysregulation and increased aggression, including self-injury, consistent with animal models, has been proposed.[56] Such findings have led to the use of antipsychotic agents that act as dopaminergic antagonists to address aggression and self-injurious behavior. The first-generation antipsychotic agent with the most evidence for short- and long-term safety and efficacy is haloperidol. Target behaviors included impaired learning, anger, mood lability, hyperactivity, and social withdrawal. Although results for improvement in the target behaviors were greater in the antipsychotic treatment compared with the placebo group, the risk for the development of dyskinesias and the introduction of new antipsychotic medications have markedly limited haloperidol's use.[25]

As few psychopharmacologic agents have been well studied in this population, and even fewer have received FDA approval, current research is directed primarily toward the second-generation antipsychotics (SGAs). 8 Off-label use of FDA-approved medications (ie, use of an approved drug for an unapproved use) is an acceptable clinical practice when there is evidence-based support for the use of the medication and informed consent is obtained; however, there is a relative lack of robust research in this area at the present time.

Risperidone and aripiprazole are currently FDA-approved to treat the behavioral (irritability) symptoms associated with autism.[66,67] Risperidone has the most evidence-based support for treating behavioral problems associated with autism. It is FDA-approved for treatment of the following behaviors in children and adolescents with autism: aggression, self-injury, temper tantrums, and irritability.[25]

A review of the literature found both short- and long-term use (up to 1 year) of orally administered aripiprazole was effective for irritability in pediatric patients with ASD, aged 6 to 17 years. The dosage

range was 2 to 15 mg/day. In this range, aripiprazole was well tolerated with moderate side effects that resolved with continued use.[68,69,70,71] Weight gain was reported during the first 3 to 6 months, and then it plateaued.[68] The use of olanzapine is supported by limited trial data in children and adolescents with autism. Trial durations were generally short (6-8 weeks) with small numbers of participants. Positive results are generally reported in global improvement scale assessment; however, the significant weight gain and sedation noted in olanzapine trials are important considerations in weighing risk versus potential benefit.[25] A post-hoc analysis of the health-related quality of life of pediatric patients receiving aripiprazole found improved scores compared to placebo in three of five subscales, including emotional, social, and cognitive functioning.[72]

At this time there is no FDA-approved medication for the core symptoms of autism. Prior to the inclusion of pharmacotherapy for behavior as a component of the plan, utilization of a multifaceted approach is recommended.[73]

The SGAs are less likely to elicit extrapyramidal side effects than first-generation agents due to more potency at serotonin$_{2A}$ (5-HT$_{2A}$) receptors versus dopamine receptors. However, the SGAs have been implicated in weight gain in some persons with autism.[25] The potential serum prolactin elevation related to risperidone use is of concern. Elevated serum prolactin may lead to amenorrhea, galactorrhea, and osteoporosis in females and gynecomastia and sexual dysfunction in males. The minimum degree of prolactin elevation that is clinically relevant is uncertain as are the implications for long-term use in a pediatric population. If detected, strategies include evaluating the risk–benefit with continued use, reducing doses, or changing to another agent with less impact on prolactin. It is recommended that clinicians monitor for the evidence of potential risperidone-mediated prolactin elevations regardless of whether a prolactin level is obtained.[74] Additional monitoring recommendations for antipsychotic use can be found in Chapter 67.

Serotonin synthesis differs between children diagnosed with ASD and children without this diagnosis. Compared with adults, 5-hydroxytryptamine (5-HT) synthesis may peak at twice the adult level in developmentally normal children by age 5 years, whereas children with ASD have a more gradual developmental arc with a lower peak.[75] The use of SSRIs is often associated with a decrease in some of the core behavioral symptoms such as stereotypies, social withdrawal, and rigid adherence to routine. A review of the literature for citalopram,[76] escitalopram, fluoxetine, and fluvoxamine[75] found limited support for use of SSRIs to address behaviors of ASD.

Oxytocin administration has been studied using intranasal or infusion routes of administration. Oxytocin is involved in regulating social behavior in humans, and has been the subject of a number of small studies of patients with ASD. At best, data demonstrate promising effects related to repetitive behaviors and social cognition (eye gaze and emotion recognition).[77] More research is needed with adequately powered studies.

Psychostimulants have been studied in persons with autism to address hyperactivity, impulsivity, and inattention. Psychostimulants block the reuptake of dopamine and norepinephrine. It is hypothesized that ADHD represents a dysfunction in regulation of these catecholamines.[78] Study design of methylphenidate trials in persons with ASD complicates interpretation of results. Some trials were

uncontrolled, and some included children with various diagnoses. The largest and most rigorously controlled trial involved 72 participants, with 74% having a primary diagnosis of autism. In this placebo-controlled trial, methylphenidate was given in divided doses of 0.125, 0.25, and 0.5 mg/kg (morning and noon doses). In an analysis of the 66 youths completing the trial, 16 could not tolerate the 0.5 mg/kg dose phase. All three doses performed better than placebo on improving the core symptoms of ADHD according to parent and teacher ratings. Parent ratings for ADHD were better with the medium dose compared with the low dose. Teacher ratings for inattention were better with the medium dose compared with the low dose.[79] Overall, findings suggest that treatment response to psychostimulants varies and, in general, stimulants do not work as well in this population of children compared with normally developing peers.[80] The α_2-agonists, clonidine and guanfacine, have been used to treat hyperactivity and agitation in persons with autism because of their effects on inhibition of noradrenergic release and transmission. Both agents have FDA approval for treating symptoms associated with ADHD. However, as with many psychoactive medications used in the population with autism, there is a lack of methodologically sound studies supporting use of these agents. Two trials with guanfacine targeted symptoms that included inattentiveness and hyperactivity. Both reported positive outcomes. In the first (n = 80, average age of 7.7 years), guanfacine use was associated with statistically significant improvement in global functioning. In the second trial (n = 25, 20 completed), all subjects had not tolerated previous methylphenidate use. Improvement was noted on measures; some reached statistical significance.[80]

Limited data are available on the use of cholinesterase inhibitors for disruptive behaviors, such as hyperactivity and irritability. Use of donepezil for these or the core autism symptoms cannot be supported.[80] No benefit for ADHD or core symptoms was found for galantamine, and results for rivastigmine were unclear. Modification of glutamate activity in the brain may lead to improvement in various ASD-related outcomes. Use of the NMDA-receptor antagonist memantine was associated with hyperactivity. Combined with risperidone, memantine treated patients saw improvement in irritability, stereotyped behaviors, and hyperactivity.[81] Additional study is needed for this agent.

Limited support for anticonvulsants as interventions for hyperactivity and impulsivity in children with ASD was found despite the high comorbidity of seizures in this population.[80]

The current dearth of evidence-based psychopharmacologic and behavioral research in persons with autism is being addressed by a network of NIH-funded research centers, including the Research Units of Pediatric Psychopharmacology, Centers for Programs of Excellence in Autism, and Studies to Advance Autism Research and Treatment. The mission of these units is to foster well-controlled, multicenter, behavioral, and psychopharmacologic intervention studies targeting behavioral symptoms in persons with autism.

Personalized Pharmacotherapy

Aggression toward self and others and severe tantrums are a concern, particularly in adults with ASD. In addition to nonpharmacologic interventions, pharmacotherapy is frequently used. Despite limited evidence-based support, psychoactive medications have been widely used to minimize the frequency and intensity of these behaviors. Although pharmacogenomics to guide rational and targeted

pharmacotherapy would be helpful, at present this information is not available.[82] This may be in part because of the heterogeneity of the ASD population.

Pharmacogenetic research has been limited by lack of sensitive outcome assessment tools to measure the effectiveness of treatments and the presence of multiple confounding factors in studies such as age, sex, medication dosage, and treatment duration, and whether or not the study subjects were drug naïve.[83] Studies that have been conducted (primarily with risperidone) are of limited clinical utility due to small sample size, and they need to be replicated in larger populations with more diverse makeup.[83,84] However, a small study in children with ASD found that genetic variation, focused on loci that influence monoaminergic signaling, may lead to variation in response to methylphenidate.[85] Until well-conducted, reproducible study results are available to confirm the early work that has been done, using the patient's genotype to algorithmically predict a medication and dose likely to be effective and safe for a given patient with autism remains elusive.

Evaluation of Therapeutic Outcomes

7 Monitoring the safety, efficacy, and tolerability of psychopharmacologic interventions in persons with autism is imperative to minimize adverse medication-related sequelae and optimize desired therapeutic outcomes. Clinical investigators have used a variety of psychometric assessment instruments in attempts to measure changes in core symptoms.

A variety of instruments have been developed and used in clinical trials to measure symptoms, such as communication impairment, restricted interests, and repetitive behavior. A comprehensive review of many of these instruments is beyond the scope of this chapter. Pharmacotherapy in autism is usually directed toward minimizing maladaptive behaviors, such as irritability, hyperactivity, compulsive, ritualistic, and perseverative behavior, and variants of self-injurious behavior. The Aberrant Behavior Checklist was designed for assessment of behavioral changes in institutionalized individuals enrolled in pharmacotherapy trials; however, a community-based version is also available.[86,87] The Aberrant Behavior Checklist consists of 54 items divided into 5 domains: irritability, hyperactivity, stereotypic behavior, lethargy, and inappropriate speech: the lower the score in each domain, the greater the behavioral improvement. The Children's Yale-Brown Obsessive Compulsive Scale modified for pervasive developmental disorders is a validated scale sensitive to changes in repetitive behavior severity pretreatment and posttreatment.[88]

Intensive medication-related side effects monitoring and assessment is important in this population, as self-reporting may be unreliable. An instrument that is caregiver-rated such as the Monitoring of Side Effects Scale can be useful for this purpose. The Monitoring of Side Effects Scale is a multisystem, quantitative, and qualitative caregiver assessment that rates the presence or absence and severity of a variety of potential medication-related adverse effects for clinician review.[89] Signs and symptoms are written in layperson language and are listed by body area or system. As such, it is a broad-based screening tool that can be enhanced by side effect–specific scales such as those for akathisia (Barnes Akathisia Scale [BAS]), extrapyramidal effects (Simpson-Angus Scale), or tardive dyskinesia (Dyskinesia Identification System: Condensed User Scale [DISCUS]).[90,91,92]

7 Use of SGAs has been associated with increased risk of developing metabolic syndrome. Children and adults receiving these agents should be monitored for hyperglycemia, dyslipidemia, and weight gain in a manner consistent with the consensus guidelines suggested by the American Diabetes Association and the American Psychiatric Association. For monitoring guidelines, see Chapter 67.

RETT SYNDROME

In 1966, Andreas Rett, an Austrian physician, published the first paper describing this disorder in a German language journal. He documented a sequence of developmental changes affecting young girls who initially achieved normal developmental milestones and then experienced regression. The significance of these findings and worldwide interest were not fully apparent until 1981, when similar findings were published in English.[93] Seizures, autonomic dysfunction, and cardiac dysfunction are frequent comorbidities with Rett syndrome (RTT). The primary goals of treatment are to optimize quality of life.

Epidemiology

The typical, or classic, presentation of RTT affects females almost exclusively. The worldwide prevalent is estimated to be 1:10,000 to 22,000.[94]

Etiology and Pathophysiology

RTT was originally identified as a neurodevelopmental disorder originating from an X-linked dominant mutation at the Xq28 site involving the methyl-CpG-binding protein 2 (MeCP2). This represents the most commonly identified mutation in the majority (approximately 96%) of cases.[95] In-depth molecular studies found a variety of mutations on the *MECP2* gene that impact the presentation of the clinical phenotype. These mutations may provide an explanation for differences in severity, presentation, and onset and now lend credibility to RTT as a neuroprogressive disorder as well.[96]

CLINICAL PRESENTATION Rett Syndrome General features

- RTT is diagnosed primarily in females.
- Previously acquired skills are lost following apparently normal prenatal and early development.
- Seizure disorders may occur in 50% to 90% of the RTT population.

Additional Features

- Sudden death secondary to cardiac dysfunction is greater than in the general population.
- Head growth slows.
- Scoliosis may develop.

- Sleep and respiration can be problematic.
- Motor skills may vary.
- Stereotypies may occur.
- General mood disorders and behaviors consistent with anxiety and fear are common.

Data from references 94, 98, 99, and 102.

The etiology of RTT has not been fully identified. It has been determine that the loss of genetic coding of the MeCP2 protein at the Xq28 site occurs.[94] Current research focuses on identification of specific gene mutations and location of those mutations on the gene. These are increasingly linked to the presentation, severity, and outcomes of the individual.[97,98] It was once thought the MeCP2 protein was specific to brain cells. Recent research with mice models found this protein present in non-neuronal brain cells where release of a neurotoxin is theorized.[98]

Clinical Controversy…

Redefining diagnostic criteria can have significant impact on applied epidemiology, enrollment for benefit eligibility, and clinical research. Such changes should not be taken lightly. As new knowledge is created through scientific study, it may be necessary to refine diagnostic criteria to make the diagnosis more precise, the prognosis more accurate, and the population-based information more valid due to better homogeneity. RTT is a still a clinical diagnosis. Molecular biology tests may be additive or confirmatory. These tests, however, do not supersede clinical decision-making.

Clinical Presentation and Diagnosis

The clinical criteria for RTT began with the description of this constellation of aberrant behaviors, neurodevelopmental trajectory, and clinical findings. The criteria have been refined over time in order to provide consistency in population-based data collection and for clinical research purposes. Specific mutations associated with RTT were discovered in 1999, and this led to revision of criteria in 2002. More recently, a consensus panel of international clinical experts produced a new set of diagnostic criteria and nomenclature.[99]

Genetic variations have been identified that are thought to moderate the symptoms and progression of RTT, the extent of which is not fully understood. What is known is that females are predominately affected by RTT, and no causal association has been identified. An uneventful pregnancy and birth are followed by seemingly normal development with acquisition of developmentally appropriate milestones. Growth, including head circumference, is within normal limits at birth. Developmental regression appears between 6 and 18 months with the loss of previously acquired skills. Additional developmentally regressive changes have been grouped into a series of stages associated with a range of ages during which these changes occur.[96]

9 The order of symptom appearance and regressive changes associated with RTT distinguish it from other developmental disorders. Increasingly, it is believed that the developmental changes and

severity may be a function of the *MECP2* mutation (**Table 73-3**). Important features for include the onset that typically begins from approximately 6 months to 18 months of age, during which loss of previously acquired skills occur; seizures may appear. The growth rate declines, and head size decreases (microcephaly).[96] Between the ages of 1 and 4 years, developmental regression presents. During this period, indications of ID and loss of language are seen. Also noted are behavioral changes, such as loss of social interactions, and autistic-like features (eg, stereotypic hand movements). A period of pseudo-stability or a wake-up period, whereby previously lost skills, such as with communication, may partially reappear between 4 and 7 years. Scoliosis/respiratory problems, problematic sleep, and symptoms of mood changes continue. Losses in motor functionality that may be total, and autonomic fluctuations represent the final set of changes and may last for years or decades.[96] Presentations vary in terms of onset and severity. Increasingly, the specific genetic mutation and location may explain these variations.[97] Specific information was identified from a database of genotyped participations (n = 1052 with 4,940 unique contacts). Researchers isolated 16 mutation groups with 8 common point mutations.[95] Specific moderating influences for RTT features corresponded with age of onset, autonomic symptoms, seizures, and head growth.[95]

TABLE 73-3 RTT Syndrome Features

	Onset Age	Duration	Suspected Gene Mutation[a]	Characteristics
Critical point for diagnosis	6-18 months, up to 48 months	Months to years	*MECP2* *FOXG1, and* *CKDL5* *p.Arg294X* *p.Arg133Cys* *p.Arg306Cys*	Found in 90% of patients Found in 10% of patients Head growth decreases or ceases Increased social withdrawal Purposeful hand movements cease Hand use more preserved
Critical point for diagnosis	12-18 months to 4 years	Weeks to months	*CDKL5 p.R133c*	Onset of intellectual disability; may be severe Breathing irregularities Autistic features appear Early onset seizures Latest onset Seizures increase
	4-7 years	Years; may stabilize here	*R294X* *R294X, R168X*	Partial return of language skills Deterioration slows or

	Onset Age	Duration	Suspected Gene Mutation[a]	Characteristics
				ceases Variable ambulatory status Scoliosis
	>7 years old	Decades, if at all	*p.Arg306Cys* *p.Thr158Met*	Least severe Most severe Dystonias

CDKL5, cyclin-dependent kinase-like 5; *FOXG1*, forkhead box protein G1; MeCP2, methyl-CpG-binding protein 2; RTT, Rett syndrome.

[a]Unless otherwise indicated, specific mutations on the *MECP2* gene are associated with variability in the onset and/or severity of RTT developmental changes. No differentiations are made between typical and atypical RTT diagnostic criteria.

Data from references 94, 95, 96, 99, 102, and 103.

Prior to identification of specific genotypes linked to RTT features, the presence of stereotypic hand movements, social and environmental withdrawal, and irritability (including the inability to be soothed when crying) gave rise to investigating commonalities between RTT and autism. In patients with RTT, impairments in communication and environmental interactions, eye contact, and stereotypies vary and are linked to specific mutations,[95] whereas with autism, this level of genotypic specificity has not been identified.

Treatment

Rett Syndrome

Desired Outcomes

Treatment goals in RTT are to identify the characteristic developmental changes of each stage and provide effective nonpharmacologic and pharmacologic interventions as appropriate to improve quality of life.

General Approach

Treatment plans should address the physiologic changes of each stage, optimizing pharmacotherapy, as appropriate. Effective strategies require a systematic approach to (a) address the specific medical needs identified, (b) monitor the medications used as appropriate, and (c) reassess the need for continued pharmacotherapy.

Nonpharmacologic Therapy

Behavioral problems are not commonly encountered with RTT. Other considerations include evaluating for respiratory complications, such as obstructive sleep apnea with polysomnography and therapeutic interventions, if indicated.[100] Surgical intervention may be indicated to lessen the severity of scoliosis. A retrospective review of RTT patients who underwent surgery (*n* = 24, 29 surgical procedures) found preexisting RTT features, including seizure disorders, frequent upper respiratory infections, and cardiac conduction abnormalities required a high degree of intensive postoperative care.[101]

Pharmacologic Therapy

Information on pharmacotherapy for comorbidities associated with RTT comes primarily from case reports, case series, and small trials. There are currently no approved medications for the treatment of RTT.

One of the more problematic aspects of caring for RTT patients is seizures, both in terms of prevalence and treatment issues. Accurate data on the prevalence of seizure disorders are lacking, but it is estimated that up to 60% of those with RTT experience them.[102]

The International Rett Syndrome Database was used to determine if specific gene mutations influenced seizure onset and frequency. In addition to demographic data and specific health and developmental information, enrollees (*n* = 685) had a *MECP2* mutation. Researchers found the groups most affected by active seizures were between ages 7 and 12 years (49%) and 12 and 17 years (54%). Also identified were specific deletions and mutations associated with seizures activity. A large deletion was associated with the earliest onset where a *p.R133c* mutation was associated with the latest onset; active seizures were more commonly associated with either a large deletion or a *p.T158M* mutation.[103]

Antiepileptic medication usage was also extracted from the international database (*n* = 135). The most frequently used medications were valproate (47%), carbamazepine (39%), lamotrigine (30%), levetiracetam ((24%), and topiramate (19%) with 34% (*n* = 116) receiving at least one medication since seizures onset.[103] While some of the enrollees were seizure-free, 129 of 339 (38%) met criteria for drug-resistant epilepsy. Internationally, lamotrigine and valproate were more frequently used.[103]

Comorbidities, including seizures and cardiac problems, can impact drug selection. Cardiac mortality is significantly elevated in RTT. Patients with RTT have a 300-fold increase in sudden death from arrhythmias compared with the general population.[104] Causality has not been determined. Electrocardiogram (ECG) findings of QT prolongation and dyssynchronous innervations cannot account for the marked increase in mortality. Administration of medications that prolong the QT interval should be undertaken only with caution and ECG monitoring. Any pharmacotherapy should take into consideration cardiac implications and other potential adverse drug effects.

Personalized Pharmacotherapy

RTT is an X-linked dominant mutation at the Xq28 site. Mutations on this gene have been identified that may provide an explanation for differences in severity and onset for seizures and physiological variation, as well as developmental regression. Future advances in pharmacogenomics may help identify personalized pharmacotherapy for this population.

Evaluation of Therapeutic Outcomes

The most medication-responsive feature of RTT is seizure activity. Seizure frequency changes with age.[103] For more information about epilepsy and seizure disorders, see Chapter 56. Depending on the anticonvulsant used, laboratory monitoring may be needed. Seizure frequency and adverse effects should be monitored when medications are added or doses changed and at regular intervals thereafter. During the late teens and 20s, reassessing the need for continued anticonvulsant treatment is recommended, since seizures have been known to spontaneously abate in later phases of the disorder.

Chapter 74: Diabetes Mellitus

Curtis L. Triplitt; Thomas Repas; Carlos Alvarez

INTRODUCTION

KEY CONCEPTS

- 1 Diabetes mellitus (DM) is a group of metabolic disorders characterized by high blood glucose as well as altered fat and protein metabolism that results from defects in insulin secretion, insulin action (sensitivity), or both.
- 2 The incidence of type 2 DM is increasing. This has been attributed to obesity, dietary habits, and increasing numbers of people who are sedentary and genetically susceptible.
- 3 The two major classifications of DM are type 1 (insulin deficient) and type 2 (insulin resistance combined with β-cell dysfunction). They differ in clinical presentation, onset, etiology, and disease progression. Both are associated with microvascular and macrovascular complications.
- 4 Diabetes can be diagnosed by one of four criteria: (1) fasting plasma glucose ≥ 126 mg/dL (≥ 7.0 mmol/L); (2) a 2-hour value from a 75-g oral glucose tolerance test (OGTT) ≥ 200 mg/dL (more than or equal to 11.1 mmol/L); a casual plasma glucose level ≥ 200 mg/dL (≥ 11.1 mmol/L) with symptoms of diabetes; or a hemoglobin A_{1c} (HbA_{Ic}) ≥ 6.5% (≥ 0.065; ≥ 48 mmol/mol Hb). The diagnosis should be confirmed by repeat testing if obvious hyperglycemia is not present.
- 5 Goals of therapy in DM are directed toward attaining normoglycemia (or appropriate glycemic control based on the patient's comorbidities), reducing the onset and progression of diabetes-related complications, intensive therapy for associated cardiovascular risk factors, and improving quality and quantity of life.
- 6 Intensive glycemic control is paramount for reduction of microvascular complications (eg, neuropathy, retinopathy, and nephropathy). Good blood pressure control in patients with diabetes will not only reduce the risk of retinopathy and nephropathy, but also reduce cardiovascular risk.
- 7 Short-term (less than 5 years) intensive glycemic control does not lower the risk of macrovascular events—significant reductions in macrovascular complications may take 15 to 20 years. Excellent glycemic control from the time of diagnosis may result in a sustained reduction in microvascular and macrovascular risk, and has been coined metabolic memory or legacy effect.
- 8 Knowledge of the patient's quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations, and pharmacology of oral and injected antihyperglycemic agents are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.

- 9 Insulin therapy is required in Type 1 DM. Intensive basal-bolus insulin therapy or pump therapy in motivated individuals is more likely to achieve optimal glycemic outcomes. Basal-bolus therapy includes a basal insulin for fasting and a rapid acting insulin for mealtime coverage. The addition of mealtime pramlintide in patients with uncontrolled or erratic postprandial glycemia may be warranted.

- 10 Metformin should be included in the regimen for most type 2 DM patients, if tolerated and not contraindicated, due to its effectiveness, low risk of hypoglycemia, positive or neutral effects on weight, potential impact on macrovascular risk cardiovascular risk, and low cost.

- 11 Type 2 DM treatment often requires multiple therapeutic agents (combination therapy), including oral and injected antihyperglycemics to attain glycemic goals. There is a persistent reduction in β-cell function over time. The thiazolidinediones (TZDs) and the GLP-1 receptor agonists have been shown to slow, but not arrest, β-cell failure.

- 12 Aggressive management of cardiovascular risk factors in type 2 DM is necessary to reduce the incidence of cardiovascular events and death. This includes smoking cessation, use of antiplatelet therapy as well as moderate or high potency statins in most patients with DM, and treatment of hypertension.

- 13 Strategies to prevent type 1 DM have not yet been successful. Prevention strategies for type 2 DM include dietary restriction of fat, aerobic exercise for a minimum of 30 minutes 5 times a week, weight loss, and increased fiber intake. These lifestyle habits can reduce the risk of type 2 DM by 60%. No medication is currently FDA approved for the prevention of diabetes, but several have been shown to delay diabetes onset in high-risk patients.

- 14 Patient education, self-care, and adherence to therapeutic lifestyle and pharmacologic interventions are crucial for optimal outcomes. Interprofessional teams including physicians (primary care, endocrinologists, ophthalmologists, and vascular surgeons), dietitians, nurses, pharmacists, podiatrists, social workers, behavioral health specialists, and certified diabetes educators (CDEs) working together can assist persons with DM achieve optimal health outcomes.

Diabetes mellitus (DM) is a heterogeneous group of metabolic disorders characterized by hyperglycemia. It is associated with abnormalities in carbohydrate, fat, and protein metabolism and may result in chronic complications including microvascular, macrovascular, and neuropathic disorders. In 2012, an estimated 29 million Americans 20 years of age or older, roughly 12% to 14% of the population, have DM. Over one-fourth have not yet been diagnosed. An additional 86 million are at high risk for developing diabetes. The economic burden of DM approximated $245 billion in 2012. DM is the leading cause of blindness in adults aged 20 to 74 years and the leading cause of end-stage renal disease in the United States. It also resulted in approximately 73,000 lower extremity amputations in 2010. Finally, a cardiovascular event is responsible for two-thirds of deaths in individuals with type 2 DM and is the leading cause of death in type 1 DM of long-duration.[1]

Optimal management of the patient with DM will reduce or prevent complications, decrease morbidity and mortality, and improve quality of life. Research, clinical trials, and drug development efforts over the past several decades have not only improved health outcomes in patients with DM but also significantly expanded the available therapeutic options.

ETIOLOGY AND CLASSIFICATION

Diabetes mellitus is a metabolic disorder characterized by resistance to the action of insulin, insufficient insulin secretion, or both[2]. The clinical manifestation of these disorders is hyperglycemia. The vast majority of patients with DM are classified into one of two broad categories: type 1 DM caused by an absolute deficiency of insulin, or type 2 DM defined by the presence of insulin resistance and β-cell dysfunction. Women who develop diabetes during

pregnancy are classified as having gestational diabetes. Finally, uncommon types of diabetes caused by infections, drugs, endocrinopathies, pancreatic destruction, and known genetic defects are classified separately (**Table 74-1**).

TABLE 74-1 Etiologic Classification of Diabetes Mellitus[a]

1. Type 1 diabetes[b] (β-cell destruction, usually leading to absolute insulin deficiency)

Immune mediated

Idiopathic

2. Type 2 diabetes[a] (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)

3. Other specific types

Genetic defects of β-cell function

Chromosome 20q, HNF-4α (MODY1)

Chromosome 7p, glucokinase (MODY2)

Chromosome 12q, HNF-1α (MODY3)

Other rare forms

Chromosome 13q, insulin promoter factor-1 (MODY4)

Chromosome 17q, HNF-1β (MODY5)

Chromosome 2q, neurogenic differentiation 1/β-cell e-box transactivator 2 (MODY6)

Chromosome 9q, carboxyl ester lipase (MODY7)

Mitochondrial DNA

Genetic defects in insulin action

Type A insulin resistance

Leprechaunism

Rabson-Mendenhall syndrome

Lipoatrophic diabetes

Diseases of the exocrine pancreas

Pancreatitis

Trauma/pancreatectomy

Neoplasia

Cystic fibrosis

Hemochromatosis

Fibrocalculous pancreatopathy

- Endocrinopathies
  - Acromegaly
  - Cushing syndrome
  - Glucagonoma
  - Pheochromocytoma
  - Hyperthyroidism
  - Somatostatinoma
  - Aldosteronoma
- Drug or chemical induced
  - Pyriminil
  - Pentamidine
  - Nicotinic acid
  - Glucocorticoids
  - Thyroid hormone
  - Diazoxide
  - *β*-Adrenergic agonists
  - Thiazides
  - Phenytoin
  - *γ*-Interferon
  - Others
- Infections
  - Congenital rubella
  - Cytomegalovirus
  - Others
- Uncommon forms of immune-mediated diabetes
  - “Stiff-man” syndrome
  - Anti-insulin receptor antibodies
- Other genetic syndromes sometimes associated with diabetes
  - Down syndrome
  - Klinefelter syndrome
  - Turner syndrome

Wolfram syndrome

Friedreich ataxia

Huntington chorea

Laurence-Moon-Bieldel syndrome

Myotonic dystrophy

Porphyria

Prader-Willi syndrome

4. Gestational diabetes mellitus (GDM)

[a]Other rare forms may exist for all categorizations.

[b]Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not itself classify the patient.

Data from reference 2.

Type 1 Diabetes

This form of diabetes results from autoimmune destruction of the β-cells of the pancreas[2,3,4]. Evidence of β-cell autoimmunity, including islet cell antibodies (ICA), antibodies to glutamic acid decarboxylase, islet protein tyrosine phosphatase-like molecule IA2, and/or antibodies to insulin are present at the time of diagnosis in 90% of individuals. Type 1 diabetes most commonly presents in children and adolescents; however, it can occur at any age. Younger individuals typically have a more rapid rate of β-cell destruction and often present with ketoacidosis. Adults may maintain sufficient insulin secretion to prevent ketoacidosis for many years; this is referred to as latent autoimmune diabetes in adults (LADA).

Type 2 Diabetes

Type 2 DM is characterized by a combination of some degree of insulin resistance with a relative lack of insulin secretion that is insufficient to normalize plasma glucose levels, with a progressive loss of β-cell over time[2,5]. Most individuals with type 2 diabetes exhibit abdominal obesity, which is the major contributor to insulin resistance. In addition, hypertension, dyslipidemia (high triglyceride levels and low HDL-cholesterol levels), and elevated plasminogen activator inhibitor-1 (PAI-1) levels, which contributes to a hypercoagulable state, are often present. Patients with type 2 diabetes are at increased risk of developing macrovascular complications in addition to microvascular complications. Type 2 diabetes has a strong genetic predisposition and is more common in all ethnic groups other than those of European ancestry.

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is defined as glucose intolerance which is first recognized during pregnancy[2]. Hormone changes during pregnancy result in increased insulin resistance, and GDM may ensue when the mother cannot adequately compensate with increased insulin secretion to maintain normoglycemia. In most, glucose intolerance first appears near the beginning of the third trimester. However, risk assessment and intervention should begin from the first prenatal visit. If DM is diagnosed prior to pregnancy, this is not GDM, but rather pregnancy with preexisting DM. Detection is important, as therapy will reduce perinatal morbidity and mortality.

Other Specific Types of Diabetes (Less Than 5% of Diabetes)

Maturity onset diabetes of youth (MODY) is characterized by impaired insulin secretion in respond to a glucose stimulus with minimal or no insulin resistance[2]. Patients typically exhibit mild hyperglycemia at an early age, but diagnosis may be delayed. The disease is inherited in an autosomal dominant pattern with at least six different loci identified to date (MODY 2 and 3 are most common). The production of mutant insulin molecules has been identified in a few families and results in mild glucose intolerance.

Several genetic mutations have been described in the insulin receptor and are associated with insulin resistance. Type A insulin resistance is a clinical syndrome characterized by acanthosis nigricans, virilization in women, polycystic ovaries, and hyperinsulinemia. Anti-insulin receptor antibodies may block the binding of insulin. This was referred to in the past as type B insulin resistance. Endocrinopathies, pancreatic exocrine dysfunction, drugs, infections, among others may also result in hyperglycemia (see Table 74-1).

EPIDEMIOLOGY

Type 1 DM accounts for 5% to 10% of all cases of DM and is most often due to autoimmune destruction of the pancreatic β-cells[1,2,3,4,5,2]

Type 1 DM is thought to be initiated by the exposure of a genetically susceptible individual to an environmental trigger. β-Cell autoimmunity develops in less than 10% of the genetically susceptible individuals and progresses to type 1 DM in less than 1%.[3] The prevalence of β-cell autoimmunity and the incidence of type 1 DM in various populations is directly related. Sweden, Sardinia, and Finland have the highest prevalence of islet cell antibody (ICA) (3%-4.5%) and this is associated with the highest incidence of type 1 DM; 22 to 35 per 100,000.[4] The prevalence of type 1 DM is increasing, but the cause of this increase is not fully understood.

Markers of β-cell autoimmunity are detected in 14% to 33% of persons with adult-onset diabetes. This type of DM is referred to as LADA. These patients often have a poor response to oral agents and require insulin therapy much sooner than most patients with type 2 DM.[4]

Idiopathic type 1 DM is a nonautoimmune form of diabetes frequently seen in patients of African and Asian descent. These patients have periods of profound hyperglycemia and intermittently require insulin therapy.[4]

Type 2 DM accounts for up to 90% of all cases of DM. Overall the prevalence of type 2 DM in the United States is about 11.3% in persons age 20 or older; this prevalence is increasing. It is estimated that for every four persons, who are diagnosed with DM, one person remains undiagnosed.[1]

There are multiple risk factors for the development of type 2 DM, including family history (ie, parents or siblings with diabetes); obesity (ie, ≥ 20% over ideal body weight, or body mass index [BMI] ≥ 25 kg/m^2); chronic physical inactivity; race or ethnicity (see list below); history of impaired glucose tolerance, impaired fasting glucose (IFG), or hemoglobin A_{1c} (HbA_{Ic}) 5.7% to 6.4% (0.057-0.064; 39-46 mmol/mol Hb) (see diagnosis of diabetes section); hypertension (high than or equal to 140/90 mm Hg in adults); high-density lipoprotein (HDL) cholesterol ≤ 35 mg/dL (≤ 0.91 mmol/L) and/or a triglyceride level ≥ 250 mg/dL (≥ 2.83 mmol/L); history of GDM (see etiology and classification section) or delivery of a baby weighing more than 9 pounds (more than 4 kg); history of vascular disease; presence of acanthosis nigricans; and polycystic ovary disease.[5]

The prevalence of type 2 DM increases with age and varies widely among racial and ethnic populations. The prevalence of type 2 DM is especially high in Native Americans, Hispanic Americans, African Americans, Asian Americans, and Pacific Islanders. While the prevalence of type 2 DM increases with age, the disorder is increasingly being diagnosed in adolescence. The increased incidence of type DM in adolescence and young adults has been attributed to an increase in overweight/obesity and sedentary lifestyle, in addition to genetic predisposition.[2] Most cases of type 2 DM appear to be polygenetic.[2]

Gestational diabetes mellitus complicates approximately 9% of all pregnancies in the United States.[2] Most women become normoglycemic after pregnancy; however, 30% to 50% of these women develop type 2 DM later in life.

Secondary forms of DM occur due to a variety of causes.[2] MODY is due to one of six genetic defects. Endocrine disorders, such as acromegaly and Cushing syndrome, may also induce hyperglycemia. Any disease of the exocrine pancreas such as cystic fibrosis, pancreatitis, and hereditary hemochromatosis can damage β-cells and impair insulin secretion. Only 1% to 2% of all cases of DM are due to these secondary causes.

PATHOGENESIS

Diabetes mellitus is caused by derangements in the secretion of insulin, glucagon, and other hormones and results in abnormal carbohydrate and fat metabolism[2,3,4,6,7,8,9]. In the fasting state 75% of total body glucose disposal occurs in tissues, including the brain and peripheral nerves that do not require insulin. Brain glucose uptake occurs at the same rate during fed and fasting periods. The remaining 25% of glucose metabolism takes place in the liver and muscle, which is dependent on insulin. In the fasting state, approximately 85% of glucose production is derived from the liver, and the remaining amount is produced by the kidney. Glucagon, produced by pancreatic α cells, is secreted in the fasting state to oppose the action of insulin and stimulate hepatic glucose production and glycogenolysis. Glucagon and insulin secretion are closely linked. Appropriate secretion of both hormones is needed to keep plasma glucose levels normal. In the fed state, carbohydrate ingestion increases the plasma glucose concentration and stimulates insulin release from the pancreatic β-cells. The resultant hyperinsulinemia (1) suppresses hepatic glucose production, (2) stimulates glucose uptake by peripheral tissues, and (3) suppresses glucagon release (in conjunction with incretin hormones). The majority (approximately 80%-85%) of glucose is taken up by muscle. A small amount (approximately 4%-5%) is metabolized by adipocytes.[6,7,8]

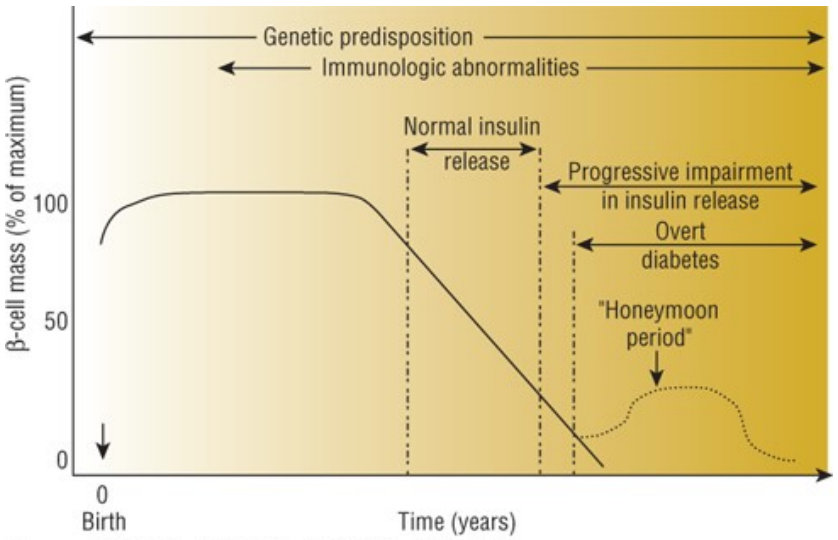
Although fat tissue is responsible for only a small amount of total body glucose disposal, it plays a very important role in the maintenance of total body glucose homeostasis. Small increases in the plasma insulin concentration exert a potent antilipolytic effect, reducing plasma-free fatty acid levels. The decline in plasma-free fatty acid concentrations results in an increased glucose uptake in muscle and indirectly reduces hepatic glucose production.

Type 1 Diabetes Mellitus

Type 1 DM results from pancreatic β-cell failure with "absolute" deficiency of insulin secretion[2,3,4,9]. Most often this is due to immune-mediated destruction of pancreatic β-cells, but rare unknown or idiopathic processes may also contribute. There often is a long preclinical period of positive autoimmune markers which progress to immune-mediated β-cell destruction with resultant hyperglycemia when 80% to 90% of the β-cells have been destroyed. After the initial diagnosis there is occasionally a period of transient remission called the "honeymoon" phase before β-cell destruction requires lifelong insulin therapy **(Fig. 74-1)**.

FIGURE 74-1

Scheme of the natural history of the β-cell defect in type 1 diabetes mellitus. *(Copyright© 2008 American Diabetes Association. From Medical Management of Type 1 Diabetes, Fifth Edition. Reprinted with permission from The American Diabetes Association.)*



In order for type 1 DM to develop, a genetically susceptible individual must be exposed to a trigger that initiates the autoimmune process and destruction of pancreatic β-cell. However, it is unknown precisely what the inciting factors are. Several triggers have been implicated including cow's milk (or lack of breastfeeding), viruses, dietary, or other environmental exposures. Vitamin D deficiency has been observed to be more prevalent in patients who develop type 1 DM. However, further study is needed to confirm whether vitamin D deficiency causes type 1 DM or whether the relationship is merely an association.[10]

The autoimmune process is mediated by macrophages and T lymphocytes with circulating autoantibodies to various β-cell antigens. The most commonly detected antibody associated with type 1 DM is the ICA. Other autoantibodies may be formed to insulin, glutamic acid decarboxylase 65, tyrosine phosphatases IA-2 and IA-2β and ZnT8 (zinc transporter 8). These antibodies are generally considered markers of disease rather than mediators of β-cell destruction. They have been used to identify individuals at risk for type 1 DM and in evaluating disease prevention strategies.[3]

More than 90% of newly diagnosed persons with type 1 DM have one or more of these antibodies, as will up to 4% of unaffected first-degree relatives. β-Cell autoimmunity may precede the diagnosis of type 1 DM by up to 13 years. Autoimmunity may remit in some individuals, or progress to absolute β-cell failure in others. Other autoimmune disorders such as Hashimoto's thyroiditis, Graves' disease, Addison's disease, vitiligo and celiac sprue are more common in patients with type 1 DM. The extent of involvement can range from no associated autoimmune disorders to polyglandular failure.

There are strong genetic linkages to the *DQA* and *B* genes as well as certain human leukocyte antigens (HLAs). Genetic polymorphisms on chromosome 6 have been associated with a higher risk of developing type 1 DM (*DR3* and *DR4*) but others are protective (*DRB1*04008-DQB1*0302* and *DRB1*0411-DQB1*0302*).[9] Additional candidate gene regions have been identified on other chromosomes as well. Because twin studies do not show 100% concordance, environmental factors, such as infectious, chemical, or dietary exposures, likely contribute to the expression of the disease.

Insulin lowers blood glucose by a variety of mechanisms, including stimulation of tissue glucose uptake, suppression of glucose production by the liver, and suppression of free fatty acid (FFA) release from fat cells.[6] The suppression of FFAs plays an important role in glucose homeostasis. Increased levels of FFAs inhibit the uptake of glucose by muscle and stimulate hepatic gluconeogenesis.[7]

Amylin is a hormone that is cosecreted from the pancreatic β-cell with insulin. Amylin is also deficient in patients with

type 1 DM secondary to the destruction of β-cells. Amylin suppresses inappropriate glucagon secretion, slows gastric emptying, and causes central satiety.

Type 2 Diabetes Mellitus

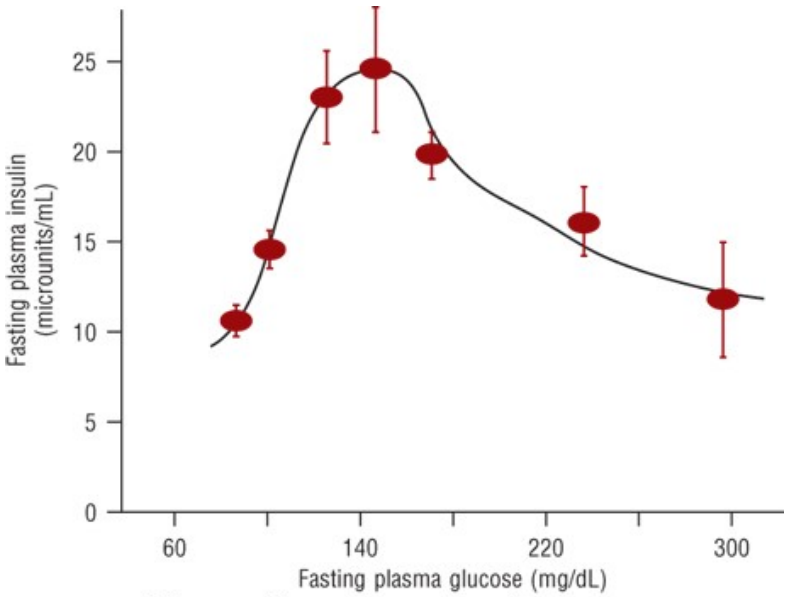
Type 2 diabetes is caused by multiple defects including: (1) impaired insulin secretion; (2) deficiency and resistance to incretin hormones; (3) insulin resistance involving muscle, liver, and adipocytes; (4) excess glucagon secretion; and (5) sodium-glucose cotransporter upregulation in the kidney[6,7,8].

Impaired Insulin Secretion

The pancreas in people with a normal-functioning β-cell is able to adjust its secretion of insulin to maintain normal plasma glucose levels[6,7,8]. In nondiabetic individuals, insulin increases in proportion to the severity of the insulin resistance and plasma glucose remains normal. Impaired insulin secretion is a hallmark finding in type 2 DM. In early β-cell dysfunction, first-phase insulin, as seen with an IV bolus of glucose, is deficient. First phase insulin involves the release of stored insulin in the β-cell and acts to "prime" the liver to nutrient intake. Without appropriate first phase insulin release, second phase insulin must compensate for the ensuing postprandial hyperglycemia in order to normalize glucose levels. When the insulin released is no longer sufficient to normalize plasma glucose, dysglycemia, including prediabetes and diabetes can ensue. β-Cell mass and function in the pancreas are both reduced. β-Cell failure is progressive, and starts years prior to the diagnosis of diabetes. People with type 2 DM lose approximately 5% to 7% of β-cell function per year. The reasons are likely multifactorial including (1) glucose toxicity; (2) lipotoxicity; (3) insulin resistance; (4) age; (5) genetics; and (6) incretin deficiency. Age results in declining β-cell responsiveness and possibly mass. High-risk ethnicity/races are predisposed to β-cell failure. Glucotoxicity occurs when glucose levels chronically exceed 140 mg/dL (7.8 mmol/L). The β-cell is unable to maintain sufficient insulin secretion and, paradoxically, releases less insulin as glucose levels increase **(Fig. 74-2)**.

FIGURE 74-2

The relationship between fasting plasma insulin and fasting plasma glucose in 177 normal weight individuals. Plasma insulin and glucose increase together up to a fasting glucose of 140 mg/dL (7.8 mmol/L). When the fasting glucose exceeds 140 mg/dL (7.8 mmol/L), the β-cell makes progressively less insulin, which leads to an overproduction of glucose by the liver and results in a progressive increase in fasting glucose. *(Reprinted from DeFronzo RA. Pathogenesis of type 2 diabetes mellitus. Med Clin N Am 2004;88:787-835, Copyright © 2004, with permission from Elsevier.)*



Incretin Hormone Deficiency/Resistance

In patients with type 2 DM, decreased postprandial insulin secretion is a result of both impaired pancreatic β-cell function and reduced stimulus from gut hormones to secrete insulin[6,7,8]. The role gut hormones play in insulin secretion is best shown by comparing the insulin response to an oral glucose load versus an isoglycemic intravenous glucose infusion. In individuals who do not have diabetes, 73% more insulin is released in response to an oral glucose load compared to an intravenous (IV) glucose load given to mimic plasma glucose levels achieved during the oral glucose load. The increased insulin secretion in response to an oral glucose stimulus is referred to as "the incretin effect" and is the result of gut hormones, stimulated by oral intake of nutrients (glucose, fat, or protein), that promote pancreatic insulin secretion. In patients with type 2 patients, this "incretin effect" is blunted with the increase in insulin secretion approximately half of that seen in nondiabetic individuals. It is now known that two hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), are responsible for over 90% of the increased insulin secretion seen in response to an oral glucose load. Patients with type 2 DM remain sensitive to GLP-1 but GIP levels are normal or elevated in type 2 DM, which suggests that some individuals may be resistant to its effect.

Glucagon-like peptide-1 is secreted from the L-cells, found in the distal intestinal and colon mucosa, in response to mixed meals. Since GLP-1 levels rise within minutes of food ingestion, neural signals and possibly proximal gastrointestinal tract receptors stimulate GLP-1 secretion. The insulinotropic action of GLP-1 is glucose dependent, enhancing insulin secretion only when glucose concentrations are higher than 90 mg/dL (5.0 mmol/L). In addition to stimulating insulin secretion, GLP-1 suppresses glucagon secretion, slows gastric emptying, and reduces food intake by increasing satiety. These effects of GLP-1 combine to limit postprandial glucose excursions. GIP is secreted by K-cells in the intestine and may have a role with insulin secretion when glucose levels are near normal. It may also act as an insulin sensitizer in adipocytes. However, GIP has no effect on glucagon secretion, gastric motility, or satiety. The half-life GLP-1 and GIP are short (less than 10 minutes). Both hormones are rapidly inactivated by dipeptidyl peptidase-4 (DPP-4), an enzyme that removes two N-terminal amino acids. As patients progress from normoglycemic to type 2 DM, GLP-1 levels decrease as glucose values increase. However, it is unlikely to be a primary defect that causes diabetes in the majority of patients with type 2 DM. A small percentage of patients have the transcription factor 7-like 2 (TCF7L2) gene defect, which is associated with decreased β-cell response to GLP-1 and likely contributes to their risk of diabetes.

Insulin Resistance

Resistance to the actions of insulin in the liver contributes significantly to excess hepatic glucose production[6,7,8]. In patients with type 2 DM with mild to moderate fasting hyperglycemia (140-200 mg/dL, 7.8-11.1 mmol/L), basal hepatic glucose production is increased by approximately 0.5 mg/kg/min. Consequently, during the overnight sleeping hours the liver of an 80-kg person with diabetes with modest fasting hyperglycemia adds an additional 35 g of glucose to the systemic circulation. This increase in fasting hepatic glucose production is the cause of fasting hyperglycemia. In the postprandial state, the liver inappropriately continues hepatic glucose output. Therefore, patients with type 2 DM have two sources of glucose in the postprandial state, one from the diet and one from continued glucose production from the liver. These sources of glucose may result in marked hyperglycemia.

Peripheral skeletal muscle is the major site of postprandial glucose disposal and approximately 80% of total body glucose uptake occurs in skeletal muscle. In response to a physiologic increase in plasma insulin concentration, muscle glucose uptake increases linearly, reaching a plateau value of 10 mg/kg/min. Even in lean type 2 DM, the onset of insulin action in muscle is delayed by approximately 40 minutes, and the ability of insulin to stimulate glucose uptake in leg muscle is reduced by 50%. Impaired intracellular insulin signaling (secondary messenger system) is a well established abnormality, with notable impairments at almost every step of activation due to insulin resistance, lipotoxicity, and glucotoxicity. The compensatory hyperinsulinemia required to overcome impaired insulin signaling can activate an alternative pathway through MAP kinase, which may be involved in atherosclerosis. Mitochondrial dysfunction may also play a role in muscle insulin resistance. Mitochondrial function and/or density appear to be lower in type 2 DM. This may result in less energy expenditure and an increased risk of dysfunction with high-fat diets.

In obese nondiabetic people as well as patients with type 2 DM, fasting plasma FFA levels are increased and fail to suppress after glucose ingestion. Chronically elevated plasma FFA concentrations can impair insulin secretion and lead to insulin resistance in muscle and liver. FFAs are stored as triglycerides in adipocytes and serve as an important energy source during conditions of fasting. Insulin is a potent inhibitor of lipolysis and restrains the release of FFAs from the adipocyte by inhibiting the hormone-sensitive lipase enzyme. In addition to FFAs that circulate in plasma in increased amounts, patients with type 2 DM have increased stores of intracellular fat products in muscle and liver. This increased fat content correlates closely with the presence of insulin resistance in these tissues. FFA products interfere with multiple steps in the insulin signaling cascade as well as increase β-cell apoptosis. Excess lipolysis from fat can also contribute to gluconeogenesis indirectly through glycerol and FFA substrate use as well as increase a number of proinflammatory cytokines.

Weight gain leads to insulin resistance in most individuals. Obese individuals who do not have diabetes often have the same degree of insulin resistance as lean type 2 DM patients. Obese but metabolically normal patients do exist (6%-30%) as well as patients who are not obese but metabolically abnormal. Thus, obesity does not automatically result in insulin resistance.

The term *visceral adipose tissue* (VAT) refers to fat cells located within the abdominal cavity and includes omental, mesenteric, retroperitoneal, and perinephric adipose tissue. VAT has been shown to correlate with insulin resistance and explain much of the variation in insulin resistance seen. VAT represents 20% of fat in men and 6% of fat in women. Central obesity can most easily be assessed using waist circumference, which is a good surrogate marker for VAT. VAT fat tissue has been shown to have a higher rate of lipolysis than subcutaneous fat, resulting in an increase in FFA production. These fatty acids are released into the portal circulation and drain into the liver, where they stimulate the production of very-low-density lipoproteins and decrease insulin sensitivity in peripheral tissues and increase the risk for nonalcoholic fatty liver disease.

Visceral adipose tissue also produces a number of adipocytokines, such as tissue necrosis factor-α, interleukin 6, angiotensinogen, plasminogen activator inhibitor-1, and resistin—all of which contribute to insulin resistance, hypertension, and hypercoagulability. These factors drain into the portal circulation and reduce insulin sensitivity in peripheral tissues. The fat cell also has the capability of producing at least one adipocytokine that improves insulin sensitivity: adiponectin. Unfortunately, adiponectin levels decline as an individual becomes more obese. Adiponectin decreases hepatic glucose production, improves hepatic insulin sensitivity, and increases fatty acid oxidation in muscle.

Excess Glucagon Secretion

Type 2 DM patients fail to suppress glucagon in response to a meal and may even have a paradoxical rise in glucagon levels[6,7,8]. Two main factors contribute: (1) GLP-1 resistance/deficiency; and (2) insulin resistance and/or deficiency, which directly suppress glucagon. Thus, hepatic insulin resistance, hyperglucagonemia, and GLP-1 deficiency result in excessive production of glucose by the liver.

Sodium-Glucose Cotransporters

Ninety percent of the filtered glucose is reabsorbed by sodium glucose cotransporter-2 (SGLT2), a high-capacity, low-affinity transporter[8]. The remaining approximately 10% is reabsorbed by SGLT1. In normal healthy people, the renal threshold for glucosuria is at a plasma glucose value of approximately 180 mg/dL (approximately 10.0 mmol/L). In chronic hyperglycemia, such as in diabetes, the renal threshold is increased to 220 to 240 mg/dL (12.2-13.3 mmol/L) before glucosuria appears. The reason for the increased reabsorption of glucose by proximal renal tubular cells is likely due to SGLT2 receptor over expression, as evidenced by SGLT2 mRNA and protein content regulated in renal proximal tubule cells. Excess reabsorption of this glucose may worsen hyperglycemia.

Metabolic Syndrome

The metabolic syndrome is a constellation of metabolic abnormalities that includes insulin resistance and confers a higher risk for cardiovascular disease (CVD)[11]. Patients with the metabolic syndrome are 5-times more likely to develop type 2 DM, if they do not already have type 2 DM. The metabolic syndrome does not identify synergism among identified risk factors, but rather additive risk, leading many to question its relevance as a clinical identity beyond the identification of a cluster of risk factors commonly occurring together. It may be useful to “package” risk factors into the metabolic syndrome to encourage aggressive management. The most recent definition of the metabolic syndrome was adopted by multiple organizations in 2009 and involves having central obesity, which is ethnically defined, in combination with at least two abnormal values from glucose, lipid, and/or blood pressure values (See: www.idf.org/metabolic-syndrome).

CLINICAL PRESENTATION

The clinical presentations of type 1 DM and type 2 DM are different[2,3,5]. Most patients (75%) develop type 1 DM before age 20 years, but it can develop at any age. Individuals with type 1 DM are often thin and are prone to ketoacidosis if insulin is withheld or under conditions of severe physiological stress. Symptoms such as polyuria, polydipsia, polyphagia, weight loss, and lethargy are common at the time of initial presentation. In the outpatient setting, some patients present with vague complaints of weight loss and fatigue but other symptoms may not be apparent unless a comprehensive history is taken. Twenty percent to 40% of patients with type 1 DM present with diabetic ketoacidosis (DKA) after several days of polyuria, polydipsia, polyphagia, and weight loss. This presentation is more common in patients from disadvantaged socioeconomic backgrounds. Rarely, type 1 DM is diagnosed in an asymptomatic patient who has a first degree family member with type 1 DM and has been closely monitored, or by casual laboratory glucose value.

Patients with type 2 DM often present without symptoms, but the presence of microvascular complications at the time of diagnosis suggest that many patients have had hyperglycemia for years. Often patients with type 2 DM are diagnosed during routine blood testing or screening. Lethargy, polyuria, nocturia, and polydipsia can be seen at diagnosis in some patients with type 2 diabetes, but significant weight loss is less common. Most patients with type 2 DM are overweight or obese. Classical clinical presentation characteristics should be used in conjunction with laboratory data to properly classify patients (see also Classical Clinical Presentation of Diabetes Mellitus Table).

CLINICAL PRESENTATION Diabetes Mellitus[a]

Favorite Table | Download (.pdf) | Print

Characteristic	Type 1 DM	Type 2 DM
Age	<30 years[b]	>30 years[b]
Onset	Abrupt	Gradual
Body habitus	Lean	Obese or history of obesity
Insulin resistance	Absent	Present
Autoantibodies	Often present	Rarely present
Symptoms	Symptomatic[c]	Often asymptomatic
Ketones at	Present	Absent[d]
Need for insulin therapy	Immediate	Years after therapy diagnosis
Acute complications	Diabetic ketoacidosis	Hyperosmolar hyperglycemic state
Microvascular complications at diagnosis	No	Common
Macrovascular complications at or before diagnosis	Rare	Common

[a]*Clinical presentation can vary widely.*

[b]*Age of onset for type 1 DM is generally <20 years of age, but can present at any age. The prevalence of type 2 DM in children, adolescents, and young adults is increasing. This is especially true in ethnic and minority children.*

[c]*Type 1 may present acutely with symptoms of polyuria, nocturia, polydipsia, polyphagia, and weight loss.*

[d]*Type 2 children and adolescents are more likely to present with ketones, but after the acute phase may be treated with oral agents. Prolonged fasting can also produce ketones in individuals.*

Screening

Type 1 Diabetes Mellitus

The prevalence of type 1 DM is low in the general population[2]. Due to the acute onset of symptoms in most individuals, screening for type 1 DM in the asymptomatic general population is not recommended. Screening for β-cell autoantibody status in high-risk family members may be appropriate. However, such screening is most often recommended in the context of clinical trials for the prevention of type 1 DM.

Type 2 Diabetes Mellitus

The American Diabetes Association (ADA) recommends screening for type 2 DM in adults who are overweight (BMI more than 25 kg/m^2, Asian-American BMI more than 23 kg/m^2) and have at least one other risk factor for the development of type 2 DM[2,5]. Risk factors include: physical inactivity, first degree relative with diabetes or high risk ethnicity/race, women who delivered a baby heavier than 9 lb (heavier than 4 kg) or have a history of GDM, hypertension, high triglycerides, low HDL, women with polycystic ovary syndrome, diagnosed with prediabetes, presence of acanthosis nigricans, or a history of CVD. Age is a risk factor for type 2 DM and adults without risk factors should be screened starting at age 45 years. The recommended screening tests are a fasting plasma glucose, HbA_{Ic}, or 2-hour OGTT. The optimal time between screening tests is not known, and the index of suspicion for the presence of diabetes should guide the clinician. Repeat testing every 3 to 5 years is cost-effective.[5]

Children and Adolescents

Despite a lack of clinical evidence to support widespread testing of children for type 2 DM, it is clear that more children and adolescents are developing type 2 DM[2,5,12]. Based on expert opinion, the ADA recommends screening

overweight (defined as BMI more than 85th percentile for age and sex, weight for height more than 85th percentile, or weight more than 120% of ideal) youths who have at least two of the following risk factors: a family history of type 2 diabetes in first- and second-degree relatives; Native Americans, African Americans, Hispanic Americans, and Asians/South Pacific Islanders; those with signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome, or small for gestational age birthweight); or maternal history of diabetes or GDM during the child's gestation be screened. Screening should be done every 3 years starting at 10 years of age or at the onset of puberty if it occurs at a younger age.

Gestational Diabetes

Risk assessment for GDM should occur at the first prenatal visit[2,5,13]. Due to the increasing incidence of obesity and undiagnosed DM, it is reasonable to screen women with risk factors for the development of diabetes as soon as feasible. If the initial screening is negative they should undergo retesting at 24 to 28 weeks of gestation. Screening for GDM may be done in one of two ways: (1) a standard 75-g OGTT or (2) a nonfasting 50-g glucose tolerance test. With the standard 75-g OGTT, the diagnosis of GDM is confirmed when fasting, 1-hour, 2-hour, and/or 3-hour glucose values are greater or equal to cut-off values. If a nonfasting 50-g glucose tolerance test is performed, a fasting 100-g glucose tolerance test must be performed if the 1-hour value is elevated. Different glycemic cut-offs and criteria identify more or fewer patients with GDM and this may influence outcomes (**Table 74-2**).

TABLE 74-2 Screening for and Diagnosis of Gestational Diabetes Mellitus (GDM)

Strategies for Diagnosis of Gestational Diabetes

1. "One-step" 75-g OGTT

2. "Two-step" approach with a 50-g (nonfasting) screen followed by a 100-g OGTT for those who screen positive

1. Screening for and Diagnosis of GDM with a 75-g glucose load[1]

One abnormal value = diagnostic of GDM

Time	**Plasma Glucose**
Fasting	≥92 mg/dL (≥5.1 mmol/L)
1 hour	≥180 mg/dL (≥10.0 mmol/L)
2 hours	≥153 mg/dL (≥8.5 mmol/L)

2. Two-Step Strategy: Screening for and Diagnosis of GDM

Step 1: Perform a 50-g glucose load test (nonfasting), with plasma glucose measurement at 1 h, at 24-28 weeks of gestation in women not previously diagnosed with overt diabetes.

1 hour values ≥140 mg/dL[2] (≥7.8 mmol/L)

Step 2: The 100-g OGTT should be performed when the patient is fasting.

The diagnosis of GDM is made if *at least two* of the following four plasma glucose levels (measured fasting and 1 h, 2 h, 3 h after the OGTT) are met or exceeded

Carpenter/Coustan		**National Diabetes Data Group**	
Time		**Time**	
Fasting	95 mg/dL (5.3 mmol/L)	Fasting	105 mg/dL (5.8 mmol/L)
1 hour	180 mg/dL (10.0 mmol/L)	1 hour	190 mg/dL (10.5 mmol/L)
2 hours	155 mg/dL (8.6 mmol/L)	2 hours	165 mg/dL (9.2 mmol/L
3 hours	140 mg/dL (7.8 mmol/L)	3 hours	145 mg/dL (8.0 mmol/L)

[1]Should be performed at 24-28 weeks gestation unless the patient has overt diabetes. The test should be done in the

morning after an 8- to 14-hour fast.

[2]The ACOG recommends a lower threshold of 135 mg/dL (7.5 mmol/L) in high-risk ethnic populations with higher prevalence of GDM; some experts also recommend 130 mg/dL (7.2 mmol/L).

Adapted from American Diabetes Association. Diagnosis and Classification of Diabetes. *Diabetes Care* 2015;38(Suppl 1):S8-S16.

DIAGNOSIS OF DIABETES

The diagnosis of diabetes requires the use of glycemic cut points that discriminate patients with normal glucose hemostasis from patients with diabetes[2,5]. The cut points are meant to reflect the level of glucose above which microvascular complications have been shown to increase. Cross-sectional studies have shown a consistent increase in the risk of developing retinopathy at a fasting glucose level above 99 to 116 mg/dL (5.5-6.4 mmol/L), at a 2-hour postprandial level above 125 to 185 mg/dL (6.9-10.3 mmol/L), and an HbA_{Ic} above 5.9% to 6.0% (0.059-0.060; 41-42 mmol/mol Hb). Current diagnostic criteria are slightly above these cut points (**Table 74-3**).

TABLE 74-3 Criteria for the Diagnosis of Diabetes Mellitus[a]

1. HbA_{Ic} ≥6.5% (≥0.065; ≥48 mmol/mol Hb). The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay.[a]
2. Fasting plasma glucose ≥126 mg/dL (≥7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.[a]
3. Two-hour plasma glucose ≥200 mg/dL (≥11.1 mmol/L) during an OGTT. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.[a]
4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose concentration ≥200 mg/dL (≥11.1 mmol/L).

[a]In the absence of unequivocal hyperglycemia, criteria 1 to 3 should be confirmed by repeat testing.

If a National Glycohemoglobin Standardization Program method is used, the HbA_{Ic} is the logical test for the diagnosis of diabetes as it measures glycemic exposure over the past 2 to 3 months, in contrast to a single-day, single-point glucose measurement. In addition, patients do not need to fast and the HbA_{1c} is easily monitored. An HbA_{Ic} of 6.0% to 6.4% (0.06-0.064; 42-46 mmol/mol Hb) denotes a tenfold increase in risk of developing diabetes, but does not consistently identify patients with IFG or impaired glucose tolerance. There are slight racial differences in normal HbA_{Ic} levels. One-third fewer individuals with diabetes are identified using the HbA_{1C} more than or equal to 6.5% (more than 0.065; more than 48 mmol/mol Hb) threshold versus an FPG more than or equal to 126 mg/dL (more than 7.0 mmol/L), yet providers may be more likely to diagnose diabetes from an HbA_{1C} than from an elevated FPG level. The ADA continues to recommend three other glucose criteria for the diagnosis of DM in nonpregnant adults (see Table 74-3). If the patient has symptomatic hyperglycemia, reconfirming the diagnosis by one of the above criteria is not required.

People at high risk of diabetes can be diagnosed by plasma glucose or HbA_{1c} criteria. As shown in **Table 74-4**, IFG is a plasma glucose of at least 100 mg/dL (5.6 mmol/L) but less than 126 mg/dL (7.0 mmol/L). Impaired glucose tolerance (IGT) is defined as a 2-hour glucose value more than or equal to 140 mg/dL (more than or equal to 7.8 mmol/L) but less than 200 mg/dL (11.1 mmol/L) during a 75 g-OGTT.

TABLE 74-4 Categorizations of Abnormal Glucose Status

Fasting plasma glucose (FPG)

Impaired fasting glucose (IFG)

- 100-125 mg/dL (5.6-6.9 mmol/L)

Diabetes mellitus[a]

- FPG ≥126 mg/dL (≥7.0 mmol/L)

Two-Hour postload plasma glucose (oral glucose tolerance test)

Impaired glucose tolerance (IGT)

- Two-hour postload glucose 140-199 mg/dL (7.8-11.0 mmol/L)

Diabetes mellitus[a]

- Two-hour postload glucose ≥200 mg/dL (≥11.1 mmol/L)

HbA_{Ic}

Increased risk of diabetes mellitus

- HbA_{Ic} 5.7%-6.4% (0.057-0.064; 39-46 mmol/mol Hb)

Diabetes mellitus[a]

- HbA_{Ic} ≥6.5% (≥0.065; ≥48 mmol/mol Hb)

[a]Diagnosis to be confirmed if not unequivocal hyperglycemia (see Table 74-3).

Serial measurements, at clinician-defined intervals, can help to identify patients moving toward diabetes, and those who are stable. Patients who have even minor increases in glucose or HbA_{Ic} values over time should be followed closely as these are likely the patients who will progress to DM. The HbA_{Ic} measurement can be affected by anemias and several hemoglobinopathies, which would necessitate the use of one of the plasma glucose criterion in these individuals. More information about HbA_{Ic} assay interference can be found at: http://www.ngsp.org/interf.asp.

TREATMENT

Desired Outcome

The primary goals of DM management are to reduce the risk for microvascular and macrovascular disease complications, to ameliorate symptoms, to reduce mortality, and to improve quality of life[14,15]. Early diagnosis and treatment to near-normal glycemia reduces the risk for developing microvascular disease complications, but aggressive management of cardiovascular risk factors including smoking cessation, treatment of dyslipidemia, intensive blood pressure control, and antiplatelet therapy are needed to reduce the likelihood for developing macrovascular disease. Hyperglycemia also contributes to poor wound healing by compromising white blood cell function and altering capillary function. DKA and hyperosmolar hyperglycemic state (HHS) are severe manifestations of poor diabetes control, almost always requiring hospitalization. Minimizing weight gain and hypoglycemia, especially severe hypoglycemia, are also therapeutic goals and may necessitate altering glycemic goals. Evidence-based guidelines, published by the ADA, may help in the attainment of these goals (**Table 74-5**).

TABLE 74-5 Selected American Diabetes Association Evidence-Based Recommendations[a]

Recommendation Area	Specific Recommendation	Evidence Level[b]
Screening for diabetes	Screen overweight or obese at any age; screen those without risk factors beginning at age 45 years.	B
	To screen for diabetes an FPG, 2-hour 75-g OGTT, or HbA_{Ic} are appropriate.	B
	Interval between screenings should be individualized based on risk, or every 3 years.	C
Monitoring	Home blood glucose monitoring is recommended for patients on multidose insulin or pump therapy at least prior to meals and snacks, and before events such as driving.	B
	Patients on other therapeutic interventions, including oral agents may perform home blood glucose monitoring, but ongoing instruction to patient on how to adjust therapy based on monitoring must be in place.	E
	Quarterly HbA_{Ic} in individuals not meeting glycemic goals, twice yearly in individuals meeting glycemic goals, should be performed.	E
	In adults, measure fasting lipid profile at least annually.	B
	At least once a year, quantitatively assess urinary albumin (eg, urine albumin-to-creatinine ratio [UACR]) and estimated glomerular filtration rate (eGFR) in patients with type 1 diabetes duration of ≥5 years and in all patients with type 2 diabetes.	B
	All patients should be screened for diabetic peripheral neuropathy (DPN) starting at diagnosis of type 2 diabetes and 5 years after the diagnosis of type 1 diabetes at least annually thereafter, using simple clinical tests, such as a 10-g monofilament.	B
	A dilated eye examination should be performed within 5 years of diagnosis in type 1 DM, and shortly after diagnosis in type 2 DM, with follow-up every year, or every 2-3 years as recommended by an eye specialist.	B
Glycemic goals	HbA_{Ic} goal for nonpregnant adults in general is <7% (<0.07; <53 mmol/mol Hb).	B
	HbA_{Ic} goal should be individualized, with <6.5% (<0.065; <48 mmol/mol Hb) if achieved without significant hypoglycemia or adverse effects in younger, long-life expectancy, and no CVD patients.	B
	Less stringent HbA_{Ic} goal (<8% [<0.08; <64 mmol/mol Hb]) may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, or in difficult to reach goal patients despite adequate therapy.	B
	Hospital: Critically ill: 140-180 mg/dL (7.8-10.0 mmol/L) (A), or more stringent guidelines down to 110-140 mg/dL (6.1-7.8 mmol/L) if without hypoglycemia (C). Noncritically ill: No clear evidence but in general premeal BG <140 mg/dL (<7.8 mmol/L) and random BG <180 mg/dL (<10.0 mmol/L) (C). A basal plus correction insulin regimen is the preferred treatment for patients with poor oral intake or who are taking nothing by mouth (NPO). An insulin regimen with basal, nutritional, and correction components is the preferred treatment for patients with good nutritional intake (A).	See text
Treatment		
Prevention of type 2 diabetes	Patients with IGT (A), IFG (E), or an A_{1C} of 5.7%-6.4% (0.057-0.064; 39-46 mmol/mol Hb) (E) should be referred to an intensive diet and physical activity behavioral counseling program targeting loss of 7% of body weight and increasing moderate-intensity physical activity (such as brisk walking) to at least 150 min/wk.	See text

Recommendation Area	Specific Recommendation	Evidence Level[b]
	Metformin may be considered with IGT (A), IFG (E), or an A_{1C} 5.7%-6.4% (0.057-0.064; 39-46 mmol/mol Hb) (E), especially in obese, <60-year-old patients, and women with prior GDM.	See text
Medical nutrition therapy	Weight loss is recommended for all insulin-resistant/overweight or obese individuals. Either low-carbohydrate, low-fat calorie restricted diets, or Mediterranean diets may work.	A
	In individuals with type 2 diabetes, ingested protein appears to increase insulin response without increasing plasma glucose concentrations. Therefore, carbohydrate sources high in protein should not be used to treat or prevent hypoglycemia.	B
	Saturated fat should be <7% (<0.07; <53 mmol/mol Hb) of total calories.	B
	Monitoring carbohydrate intake by carbohydrate counting, exchanges, or experienced estimation is recommended to achieve glycemic goals.	B
	Routine supplementation with antioxidants, such as vitamins E and C is not advised due to lack of efficacy	A
	A Mediterranean-style eating pattern, rich in monounsaturated fatty acids, may benefit glycemic control and CVD risk factors and can therefore be recommended as an effective alternative to a lower-fat, higher-carbohydrate eating pattern.	B
Physical activity	150 min/wk of moderate intensity exercise spread over at least 3 days and with no more than 2 days without exercise.	A
	Resistance training of large muscle groups should be ≥2 times/wk.	A
Blood pressure	Systolic blood pressure should be treated to <140 mm Hg.	A
	Diastolic blood pressure should be treated to <90 mm Hg.	A
	Lower goals systolic blood pressure <130 mm Hg and/or diastolic blood pressure <80 mm Hg may be appropriate for some, such as younger patients, if attained without undue treatment burden.	B
	Lifestyle intervention for elevated blood pressure consists of weight loss, if overweight or obese; a Dietary Approaches to Stop Hypertension (DASH)-style dietary pattern including reducing sodium and increasing potassium.	B
	Initial drug therapy should be with an ACEi or ARB; if intolerant to one, the other should be tried.	C
Nephropathy	In treatment of nonpregnant patients with modest (30-299 mg/day) (C), or higher levels (≥300 mg/day) (A) of urinary albumin excretion, either ACE inhibitors or ARBs are recommended.	See text
Dyslipidemia	If lipids are abnormal, annual monitoring is reasonable, if the LDL-C ≤100 mg/dL (≤2.59 mmol/L) upon screening, recheck every 5 years at a minimum is reasonable	E
	Lifestyle modification focusing on the reduction of saturated fat, trans fat, and cholesterol intake; increase omega-3 acids, viscous fiber, and plant stanols/sterols; weight loss if indicated, and increase physical activity should be recommended	A
	For patients with diabetes aged <40 years with additional CVD risk factors, consider using moderate or high-intensity statin (C)	See text
	For patients with diabetes aged 40-75 years without additional CVD risk factors, consider using moderate-intensity statin (A)	
	If with additional risk factors, high-intensity statin (B)	

Recommendation Area	Specific Recommendation	Evidence Level[b]
	For patients with diabetes aged 75 years without additional risk factors consider using moderate intensity statin (B)	
	If with additional risk factors, high-intensity statin (B)	
Antiplatelet Therapy	Use aspirin (75-162 mg daily) for secondary cardioprotection.	A
	Use aspirin (75-162 mg) for primary prevention in type 1 or 2 DM if the 10-year risk of CVD is ≥10%, the patient is >50 (men) or >60 (women) with at least one additional major CVD risk factor is present.	C
Hospitalized Patients	Critically ill: By IV insulin protocol(E); Noncritically ill: scheduled subcutaneous insulin with basal, nutritional, and correction coverage (A)	See text
Psychosocial	Include assessment of the patient's psychological and social situation as an ongoing part of the medical management of diabetes.	B

[a]Based on American Diabetes Association Practice Recommendations. Other evidence-based recommendations available.[8]

[b]Evidence levels:

A = Clear evidence from well-conducted, generalizable, randomized controlled trials that are adequately powered.

B = Supportive evidence from well-conducted cohort studies or well-conducted case-control study.

C = Supportive evidence from poorly controlled or uncontrolled studies or conflicting evidence with weight of evidence supporting intervention.

E = Expert consensus or clinical experience.

General Approach to Treatment

Appropriate care requires setting goals for glycemia, blood pressure, and blood cholesterol; monitoring for complications; making appropriate food choices and maintaining a healthy weight; engaging in regular physical activity; selecting and using medications wisely; and performing self-monitoring of blood glucose (SMBG) with periodic laboratory assessment of the aforementioned parameters[14,5] Glucose control alone is not sufficient.[15]

Initial Evaluation

A thorough medical history and identification of the specific type and duration of diabetes, characteristics of onset (eg, DKA or asymptomatic), dietary and weight history, social history, medication history including current and past medications for DM, current regimen including medications, diet, physical activity, and adherence should be obtained[14]. Hospitalization history, hypoglycemia (frequency, cause, and timing), and diabetes-related complications should be documented. Laboratory evaluation should include, at a minimum, an HbA_{1C}, lipid profile, liver function tests, thyroid stimulating hormone, serum creatinine and electrolytes, and a urine analysis for microalbuminuria. In type 1 DM, consider screening for celiac disease by measuring tissue transglutaminase or antiendomysial antibodies. A physical examination and pertinent data should include the measurement of all vital signs, weight or body mass index, blood pressure, thyroid palpation, cardiovascular and carotid auscultation, and a skin examination including assessment for acanthosis nigricans (type 2 DM) or vitiligo (type 1 DM). In addition, a foot examination, including screening for impaired sensation detection with a 10 gram-force monofilament, should be performed.

Nonpharmacologic Therapy

Medical Nutrition Therapy

Medical nutrition therapy is a cornerstone of treatment for all patients with DM[5,12,14,4] It is imperative that patients understand the interrelationships between carbohydrate intake, medications, and glucose control. A healthy meal plan that is moderate in carbohydrates and low in saturated fat (less than 7% of total calories) with all of the essential vitamins and minerals is recommended. The amount (grams) and type of carbohydrates (using the glycemic index is controversial), whether accounted for by exchanges or carbohydrate counting, should be considered. All foods can be a part of a healthy meal plan. It is not appropriate to chastise patients for eating sweets. If a healthy weight and normal glucose goals can be maintained, there is no reason to deny food choices. For individuals with type 1 DM, the focus is on physiologically regulating insulin administration with a balanced diet to achieve and maintain a healthy body weight. Overweight or obese patients with type 2 DM often require caloric restriction to promote weight loss. Portion size and the frequency of food intake must be addressed. Helping the patient adopt healthier eating behaviors that leads to sustained weight loss over time is more important than a specific diet. Financial and cultural food issues must also be considered. Discourage bedtime and between-meal snacks, set realistic goals, determine what the patient is willing to change, and follow-up to see how and if those changes occurred. A diet lower in fat is recommended for patients with CVD and avoiding a high protein diet in patients with nephropathy may be appropriate.[14]

Physical Activity

Most patients with DM benefit from regular physical activity[14,16]. Aerobic exercise improves insulin sensitivity, modestly improves glycemic control in the majority of individuals, reduces cardiovascular risk, contributes to weight loss or maintenance, and improves well-being. Patients should choose activities that they enjoy and are likely to do at regular intervals. Start exercise slowly in previously sedentary patients. It is unclear if asymptomatic patients should be screened for CVD prior to beginning an exercise regimen. The ADA does not currently recommend screening asymptomatic individuals. Screening is reasonable in patients with long-standing disease (DM more than or equal to 10 years), multiple cardiovascular risk factors, microvascular disease (especially renal disease), or evidence of atherosclerotic disease. If the patient has uncontrolled hypertension, autonomic neuropathy, insensate feet, or proliferative retinopathy, restrictions on recommended activities are recommended. Physical activity goals include at least 150 min/wk of moderate (50%-70% maximal heart rate) intensity exercise spread over at least 3 days a week with no more than 2 days between activity. In addition, resistance/strength training is recommended at least 2 times a week so long as the patient does not have proliferative diabetic retinopathy (PDR).[16]

Patient Education

It is not appropriate to give patients with DM brief instructions and a few pamphlets[14,17,15,17] Diabetes education, not only at the time of initial diagnosis but also at ongoing intervals over a lifetime, is critical. The American Association of Diabetes Educators (AADE) has developed the AADE7 self-care behaviors. The behaviors include healthy eating, being active, monitoring, taking medication, problem solving, reducing risk, and healthy coping. The patient must be involved in the decision-making process and have a strong working knowledge of the disease and associated complications. Emphasize that complications can be prevented or minimized with good glycemic control and managing risk factors for CVD. Motivational interviewing techniques have been shown to be effective. Briefly, this involves asking open-ended questions that encourage patients to identify and acknowledge barriers that hinder achieving health goals, and then work to address them with the educator's guidance.

Health professionals with formal training and experience in diabetes education can become certified. Certified Diabetes Educators (CDEs) must document their experience providing patient education and pass a certification examination. An increasing number of nurses, pharmacists, dietitians, and physicians are becoming a CDE. Formal diabetes education programs often employ several health professionals including CDEs. Accredited diabetes education program can receive payment through Medicare and private health insurance plans. The AADE and ADA accredit diabetes education programs.

Pharmacological Therapy

Although nonpharmacological therapy is the cornerstone of treatment for all patients with DM, insulin is required for type 1 DM and nonpharmacological therapy alone is rarely sufficient for type 2 DM[18,19]. Until 1995, only two treatment options were available—insulin and sulfonylureas. Since 1995, a number of new oral and injectable antidiabetic therapies have become available. These medications are often used in combination. Selecting the most appropriate pharmacological treatment approach has become increasing complex and a number of factors must be considered.

In type 1 DM, the insulin regimen should be tailored to the patient's lifestyle. This almost always involves a basal-bolus treatment strategy based on SMBG readings. This can be accomplished by using either multiple daily injections (MDI) or a continuous subcutaneous insulin infusion (CSII), also known as an insulin pump. When MDI or insulin pump therapy does not fit into the patient's lifestyle or is too complicated, a twice daily regimen using premixed insulins can be used. Some patients may require glucagon suppression therapy, as the hormone amylin is also deficient in patients with type 1 DM.

Intensive lifestyle changes in patients with type 2 DM after 10 years of follow-up failed to improve cardiovascular outcomes in the The Look Action for Health in Diabetes (Look AHEAD) trial.[20] Moreover, intensive lifestyle changes alone failed to achieve good glycemic control in the majority of patients. These findings reiterate the need for early use of antihyperglycemic medications in conjunction with diet and exercise in patients with type 2 DM.

Currently, nine classes of oral agents are approved for the treatment of type 2 diabetes: α-glucosidase inhibitors, biguanides, meglitinides, peroxisome proliferator activated receptor γ agonists (commonly called thiazolidinediones [TZDs] or glitazones), DPP-4 inhibitors, SGLT2 inhibitors, dopamine agonists, bile acid sequestrants, and sulfonylureas. Oral antidiabetic agents are often grouped according to their glucose-lowering mechanism of action. Biguanides and TZDs are often categorized as insulin sensitizers due to their ability to reduce insulin resistance. Sulfonylureas and meglitinides are often categorized as insulin secretagogues because they enhance endogenous insulin release. Three classes of injectable agents are also available for the treatment of type 2 diabetes: human insulins and insulin analogs, GLP-1 receptor agonists, and amylinomimetics.

Drug Treatments of Choice

Type 1 DM must be treated with insulin, though adjunct medications may improve glycemic control[18,19]. The optimal regimen for the treatment of type 2 DM is undetermined. Most patients with type 2 DM are initially treated with metformin due its long track record of use in clinical practice, efficacy, weight neutrality, low risk of hypoglycemia, and low cost. Common alternatives to metformin if intolerance or contraindicated include sulfonylureas, DPP-4 inhibitor, GLP-1 receptor agonist, or SGLT2 inhibitor. If the HbA_{1c} is more than 1% to 1.5% (0.01-0.015; 11-16 mmol/mol Hb) above goal, early dual therapy may be warranted. A patient with type 2 DM experiencing symptomatic hyperglycemia at the time of diagnosis should initially be treated with insulin therapy and transitioned to oral therapy or a GLP-1 receptor agonist once good glycemic control has been achieved. Type 2 DM patients who are mildly symptomatic (ie, without significant weight loss), may be started on early dual therapy. When selecting a treatment regimen medication, several factors in addition to contraindications and potential side effects should be considered. The agent's mechanism of action and efficacy to lower blood glucose to goal as well as its impact on fasting versus postprandial blood glucose must be considered. Additionally, the medication's long-term safety, ease-of-use, and cost should be discussed with the patient. Non-glycemic effects on weight, lipids, cardiovascular outcomes and risk factors, and even the perceived β-cell preservation/effects may sway the treatment selection.

Type 1 Diabetes Mellitus

All patients with type 1 DM require insulin[18]. However, how insulin is delivered should be based on the patient's preferences and lifestyle behaviors as well as clinician preferences and available resources.

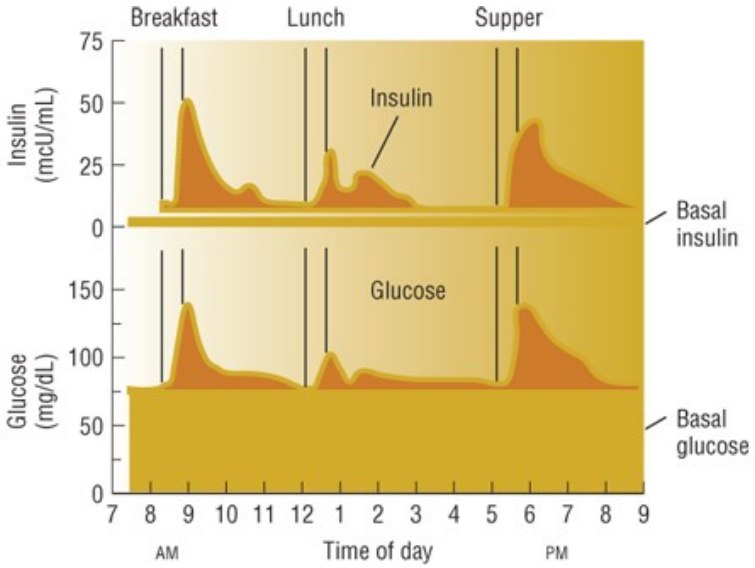
Historically, after the discovery of insulin by Banting and Best in 1921, frequent injections of regular insulin, the only insulin then available, were given to control the symptoms of hyperglycemia. Subsequently developed insulin formulations, including neutral protamine Hagedorn (NPH), lente, and ultra-lente, were suspensions of regular insulin that had a delayed onset and longer duration of action. These "long-acting" insulins enabled many patients to use only one or two injections each day. Prior to the 1980s, SMBG and HbA_{Ic} testing were not available. Patients and practitioners had no idea how well the blood glucose was controlled. Treatment was based on symptoms of hyperglycemia and hypoglycemia, which are easily misinterpreted by patients, and by measuring glucose in the urine. Neither symptoms nor urine glucose provide an accurate picture of glycemia. Moreover, while the renal threshold for glucose is relatively predictable in young healthy subjects, it is highly variable in older patients, heart failure, and patients with renal disease. Urine glucose levels will vary with time above the renal threshold, and a significant temporal lag in appearance should be expected versus blood glucose values. The advent of SMBG and HbA_{Ic} testing in the 1980s truly revolutionized the treatment of diabetes. SMBG enabled patients to rapidly determine their blood glucose and make ongoing adjustments in the insulin regimen. The HbA_{1c} provided a measure of glycemic control over the previous 3 months that correlated with the risk of long-term complications. Modern diabetes management would be impossible without these two tools.

Contemporary management of type 1 DM attempts to match carbohydrate intake with glucose-lowering processes, most commonly insulin, as well as with physical activity. The goal is to allow the patient to live as normal a life as possible.

Normal physiologic secretion of insulin can be divided into a relatively constant background level of insulin ("basal") during the fasting and postabsorptive period, with prandial spikes of insulin after eating ("bolus" or "prandial") (**Fig. 74-3**). Insulin sensitivity and insulin secretion are not constant throughout the day, however, which renders the concept of stable basal insulin requirements inaccurate. Attempting to emulate normal secretion of insulin is a useful paradigm for understanding and applying insulin treatment for the management of type 1 DM. The timing of insulin onset, peak, and duration of effect must match meal patterns and exercise schedules to achieve near-normal blood glucose values throughout the day. One or two injections daily of any one insulin formulation will in no way mimic normal physiology, and therefore is unacceptable.

FIGURE 74-3

Relationship between insulin and glucose over the course of a day and how various insulin and amylinomimetic regimens could be given. (A, Afreeza; A, aspart; CS-II, continuous subcutaneous insulin infusion; D, detemir or degludec; G, glargine; GLU, glulisine; L, lispro; N, NPH; P, pramlintide; R, regular.)



Intensive insulin therapy regimens

	7 AM (meal)	11 AM (meal)	5 PM (meal)	Bedtime
1. 2 doses,[a] R or rapid acting + N	R, L, A, GLU + N		R, L, A, GLU + N	
2. 3 doses, R or rapid acting + N	R, L, A, GLU + N	R, L, A, GLU	R, L, A, GLU + N	
3. 4 doses, R or rapid acting + N	R, L, A, GLU	R, L, A, GLU	R, L, A, GLU	N
4. 4 doses, R or rapid acting + N	R, L, A, GLU + N	R, L, A, GLU	R, L, A, GLU	N
5. 4 doses,[b] R or rapid acting + long acting	R, L, A, GLU	R, L, A, GLU	R, L, A, GLU	G or D[b] (G may be given anytime every 24 hours)
	← Adjusted basal →			
6. CS-II pump	Bolus	Bolus	Bolus	
7. 3 prandial doses pramlintide added to regimens above	P	P	P	

[a]Many clinicians may not consider this intensive insulin therapy.
[b]May be given twice a day in type 1 DM = 5 doses.

The simplest regimens that can approximate physiologic insulin release use “split-mixed” injections consisting of a morning dose of an intermediate acting insulin such as NPH and a “bolus” rapid-acting insulin or regular insulin prior to the morning and evening meals. The morning intermediate-acting insulin dose provides basal insulin during the day and provides “prandial” coverage for the midday meal. The evening intermediate-acting insulin dose provides basal insulin throughout the evening and overnight. If patients are very compulsive about timing of meals and carbohydrate intake, such a strategy may be acceptable. However, the majority of patients are not sufficiently predictable in their schedule or food intake to achieve “tight” glucose control with this approach.

Moreover, achieving good glycemic control overnight without causing nocturnal hypoglycemia can be a challenge using a twice daily split-mixed insulin regimen. Moving the evening NPH dose to bedtime may improve glycemic

control and reduce the risk of nocturnal hypoglycemia. This can be a useful approach in those who decline or are unable to implement more intense insulin regimens. However, most patients with type 1 DM need an approach which also allows greater flexibility.

"Basal-bolus" regimens using MDI attempts to replicate normal insulin physiology with a combination of intermediate- or long-acting insulin to provide the basal component, and a rapid-acting insulin to provide prandial coverage. Several long-acting insulins can be used to provide the basal insulin component, including insulin detemir, glargine, or degludec. These long-acting insulin analogues are the most convenient means of providing basal coverage for most patients with type 1 DM. Bolus or prandial insulin can be provided by either regular insulin or one of the rapid-acting insulin analogs: lispro, aspart, or glulisine. The rapid onset and short duration of action of the rapid-acting insulin analogs more closely replicate normal physiology than does regular insulin. The patient reported convenience of injecting at a meal has made rapid acting insulins very popular, though trials comparing regular insulin to rapid acting insulins have found only modest improvements in glycemic control and the risk of hypoglycemia. When using a basal-bolus regimen, the patient determines the dose of the bolus insulin to be administered based on the preprandial SMBG, anticipated carbohydrate intake from the meal, and anticipated physical activity in the next 3 to 4 hours, as exercise may reduce insulin requirements. Many patients start with a fixed dose of insulin prior to meals and then learn how to adjust the insulin dose using an "adjusted insulin scale" or a "correction factor" based on the premeal glucose readings. Patients on more advanced regimens learn to adjust the bolus insulin dose based on anticipated carbohydrate intake and physical activity.

The "correction factor" is the approximate plasma glucose lowering effect of 1 unit of short-acting insulin in mg/dL. To calculate a patient's correct factor for regular insulin, 1,500 is divided by the total daily insulin dose in number of units that the patient currently uses. For rapid-acting insulin analogs, 1,700 or 1,800 is used when calculating the correction factor. For example, if a patient is currently taking 40 units of basal insulin and 12 units of rapid-acting insulin prior to three meals, the total daily insulin dose is 76 units. Using this calculation, 1,700 divided by 76 equals 22. Thus each unit of rapid acting insulin analog will lower the plasma glucose approximately 22 mg/dL (1.2 mmol/L). In order to make insulin dose calculations easier for the patient to determine, this would be rounded to either 20 mg/dL or 25 mg/dL per 1 unit of insulin (1.1 mmol/L or 1.4 mmol/L per 1 unit of insulin). Follow-up review of ongoing blood glucose data permits more precise individualization of the correction factor.

Carbohydrate counting is an effective tool for determining the amount of rapid acting insulin that should be injected for each meal. Instead of using a fixed dose of rapid acting insulin before meals, patients can self-adjust their dose based on either estimated grams of carbohydrates or carbohydrate "choices" that will be consumed. Patient who estimate the grams of carbohydrates in their meals commonly use the "insulin to carb ratio" to determine their bolus dose. One method of calculating the insulin to carb ratio is to use 500 divided by the total daily dose of insulin. For regular insulin, 450 may be used in this calculation. For example, if the patient's total daily insulin dose is 76 units, the calculation would be 500 divided by 76 which equals 7 g of carbohydrates. Thus 1 unit of rapid-acting insulin will cover approximately 7 g of carbohydrate. This is a starting point, and to make the calculation by the patient easier, the number may be rounded. Review of follow-up BG data before and 2 hours after meals will enable more precise determination of an individual's insulin to carbohydrate ratio. Although food charts give rough estimates of the amount of carbohydrate in different foods, patients often learn to adjust the mealtime insulin doses based on their own individual response to different food items.

In type 1 DM, approximately 50% of total daily insulin replacement should be in the form of basal insulin and the other 50% in the form of bolus insulin, divided between meals. If the patient's basal: bolus ratio is not close to this recommendation, the regimen should be reassessed. For patients with type 1 DM who are just starting insulin therapy, the initial total daily dose is usually between 0.5 and 0.6 units/kg/day. The basal insulin dose should be 50% of total dose and empirically the prandial insulin doses should be 20% of total dose prior to breakfast, 15% prior to lunch, and 15% prior to supper, though these doses should be adjusted based on the patient's eating habits. Most patients with type 1 DM patients require between 0.5 and 1 unit/kg of insulin each day. If the patient requires significantly higher amounts of insulin, this suggests the patient may be insulin resistance or have insulin antibodies.

Continuous subcutaneous insulin infusion or insulin pumps using a rapid-acting insulin analog is the most sophisticated and precise method for insulin delivery. In highly motivated patients, CSII is more likely to achieve excellent glycemic control than MDI. CSII can calculate recommended bolus doses of insulin based on carbohydrate intake. Insulin pump therapy may also be paired to continuous glucose monitoring (CGM), which allows calculation of a correction insulin dose, as well as alert the patient to hypoglycemia and hyperglycemia. The patient must still know if the pump calculations are correct. "Close-loop" CSII, where the pump automatically makes insulin-dosing decisions and appropriately adjusts the infusion to keep blood glucose values normalized, is currently in long-term trials. For now, patient's must still verify that the calculated bolus dose and basal infusion rates are appropriate. Another advantage of pump therapy is that the basal insulin infusion rate can be varied throughout the day. These features enable more precise insulin dosing and help patients to achieve better glycemic control.

Despite these advantages, insulin pumps require even greater attention to detail and more frequent SMBG than does a basal-bolus MDI regimen.[21] CSII is merely a tool. Thus if the patient is not well controlled or unwilling to actively adjust insulin dose when using injections, it is very unlikely that the patient will achieve superior control on a pump. CSII initiation and adjustment should be made by an experienced clinician. CSII requires a frank discussion with the patient about the demands of using CSII as well as setting appropriate expectations. Finally, patients need extensive training on how to use and maintain their pump.

All patients treated with insulin should be instructed how to recognize and treat hypoglycemia. Many patients experiencing hypoglycemia are tempted to over treat episodes of hypoglycemia resulting in rebound hyperglycemia. To minimize this problem, patients should be advised to follow the "rule of 15." If hypoglycemia is identified, the patient should consume 15 g of simple carbohydrate. Examples include consuming 8 oz (approximately 240 mL) orange juice, 8 oz (approximately 240 mL) of milk, 4 glucose tablets, or 1 tube of glucose gel and then retest their BG 15 minutes later. If the blood glucose remains less than 70 mg/dL (3.9 mmol/L), the patient should repeat the rule of 15 until their BG is has normalized.

At each visit, patients with type 1 DM should be questioned about hypoglycemia including the frequency and severity of hypoglycemic episodes. Any hypoglycemia requiring assistance of another person, a visit to an emergent or urgent care facility, or hospitalization should be documented and steps to prevent these episodes in the future should be taken.

Some patients with type 1 DM will develop hypoglycemic unawareness. Hypoglycemic unawareness may result from autonomic neuropathy or when the patient has frequent episodes of hypoglycemia. Patients who lose the warning signs of hypoglycemia appear to have a lower set point for the release of counterregulatory hormones. The loss of warning signs of hypoglycemia is a relative contraindication to continued intensive therapy. In such situations, hypoglycemic awareness may be restored by reducing or adjusting the insulin dose to scrupulously avoiding hypoglycemic episodes.

For children and pubescent adolescents, glycemic goals may need to be tempered with the risks of hypoglycemia. **Table 74-6** lists glycemic goals.[22]

TABLE 74-6 Glycemic Goals of Therapy by Organization[8]

Biochemical Index	ADA	AACE/ACE
Hemoglobin A_{1c}	<7% (<0.07; <53 mmol/mol Hb)[a]	≤6.5% (≤0.065; ≤48 mmol/mol Hb)
Preprandial plasma glucose	80-130 mg/dL (4.4-7.2 mmol/L)	<110 mg/dL (<6.1 mmol/L)
Postprandial plasma glucose	<180 mg/dL[b] (<10 mmol/L)	<140 mg/dL (<7.8 mmol/L)

Framework for ADA Plasma Glucose and HbA_{Ic} Goals in Older Adults

Patient characteristics/ health status	Rationale	Reasonable A_{1C} goal^	Fasting or preprandial glucose (mg/dL)	Bedtime glucose (mg/dL)
Healthy (few coexisting chronic illnesses, intact cognitive and functional status)	Longer remaining life expectancy	<7.5% (<0.075; <58 mmol/mol Hb)	90-130 (5.0-7.2 mmol/L)	90-150 (5.0-8.3 mmol/L)
Complex/intermediate (multiple coexisting chronic illnesses* or 2+ instrumental ADL impairments or mild-to-moderate cognitive impairment)	Intermediate remaining life expectancy, high treatment burden, hypoglycemia vulnerability, fall risk	<8.0% (<0.08; <64 mmol/mol Hb)	90-150 (5.0-8.3 mmol/L)	100-180 (5.6-10.0 mmol/L)
Very complex/poor health (long-term care or end-stage chronic illnesses** or moderate-to-severe cognitive impairment or 2+ ADL dependencies)	Limited remaining life expectancy makes benefit uncertain	<8.5% (<0.085; <69 mmol/mol Hb)	100-180 (5.6-10.0 mmol/L)	110-200 (6.1-11.1 mmol/L)

AACE, American Association of Clinical Endocrinologists; ACE, American College of Endocrinology; ADA, American Diabetes Association; DCCT, Diabetes Control and Complications Trial.

[a]Assay should be National Glycohemoglobin Standardization Program (NGSP) certified measurement and DCCT standardized. More stringent glycemic control may be appropriate if accomplished without significant hypoglycemia or adverse effects. Less stringent HbA_{Ic} goals may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, at-risk elderly, dementia, or in younger children.

[b]Postprandial glucose measurements should be made 1-2 hours after the beginning of the meal, generally the time of peak levels in patients with diabetes.

[c]Vulnerability to hypoglycemia and relatively low risk of complication prior to puberty considered. Adolescents and young adults may have adult goals if without developmental and psychological issues, and if without excessive hypoglycemia.

^A lower A_{1C} goal may be set for an individual if achievable without recurrent or severe hypoglycemia or undue treatment burden.

*Coexisting chronic illnesses are conditions serious enough to require medications or lifestyle management and may include arthritis, cancer, congestive heart failure, depression, emphysema, falls, hypertension, incontinence, stage 3 or worse chronic kidney disease, myocardial infarction, and stroke. By "multiple," we mean at least three, but many patients may have five or more (6).

**The presence of a single end-stage chronic illness, such as stage 3-4 congestive heart failure or oxygen-dependent

lung disease, chronic kidney disease requiring dialysis, or uncontrolled metastatic cancer, may cause significant symptoms or impairment of functional status and significantly reduce life expectancy.

Insulin allergies are uncommon with human insulin. In most patients, local reactions will dissipate over time. If mild reactions at the site of injection occur, assess the patient's injection technique. Many times the patient is injecting cold insulin, which causes vasodilation around the injection site. For some patients a different type or source of insulin may alleviate the problem. If the allergic reaction does not improve or is systemic, insulin desensitization protocols are available.

Lipohypertrophy can occur in some patients with long-standing type 1 DM. Some patients give their insulin injections in the same site repeatedly to minimize discomfort; over time this can result in lipohypertrophy. Lipohypertrophy can sometimes be seen on physical examination and by palpating injection sites. Because insulin absorption from an area of lipohypertrophy is unpredictable, the patient must avoid insulin injections into these areas. Lipoatrophy, due to local adipocyte destruction, is uncommon but can be seen at injections sites as well.

When a patient taking insulin struggles to achieve good glycemic control, several issues should be explored including the overzealous use of insulin, injection site selection, and injection technique. The answer to all high blood glucose readings is not necessarily more insulin. Hyperglycemia can be due to too little insulin or it could be due to a "rebound" from low glucose and over treatment with excessive amounts of carbohydrate. Fastidious blood glucose testing or selected use of CGM can assist in differentiating the two problems. There is variability of insulin absorption from injection to injection and from site to site which may cause wide glucose swings. The most consistent absorption of insulin is from the abdominal wall. Patients are encouraged to take all their injections in the abdomen. If the patient is unable or unwilling to follow this advice, then systematic site rotation is the next preferable option. The patient should always give the insulin injection in the same region of the body and at the same time of the day each day. When in doubt, always re-evaluate the patient's injection technique including proper insulin dose, injecting the insulin dose, and testing blood glucose. Sometimes simple errors result in unpredictable glycemic control.

Asymptomatic erratic gastric emptying can severely hinder the ability to match the insulin to the meals. A gastric emptying study if suspected is appropriate. Type 1 DM patients who continue to have erratic postprandial glycemic control despite a careful evaluation for proper insulin use may benefit from addition of the amylinomimetic pramlintide. Pramlintide is taken prior to each meal and can modestly improve postprandial blood glucose control. It is not a substitute for bolus insulin, however. Moreover, pramlintide cannot be mixed with insulin requiring the patient to take an additional injection at each meal. When pramlintide is initiated, the dose of prandial insulin should be reduced by 30% to 50%, to prevent hypoglycemia. Pramlintide is then titrated based on gastrointestinal adverse effects and postprandial glycemic goals. Injecting pramlintide prior to the meal and the rapid acting insulin shortly after the meal may better match the postprandial increase in glucose due to delayed gastric emptying. The patient must be cognizant of the risk of hypoglycemia, gastrointestinal side effects, and how to minimize the risk of both.

Islet cell and whole pancreas transplantation is occasionally used in patients who require immunosuppressive therapy for other reasons, such as renal transplants. Many patients are able to stop insulin or only require a sulfonylurea or GLP-1 agonist to maintain good glycemic control. However, within 2 years following a pancreas transplant, 80% or more will need to reinitiate some form of insulin therapy.

Type 2 Diabetes Mellitus

Pharmacotherapy for type 2 DM has changed dramatically in the last few years with the addition of several new drug classes and recommendations to achieve individualized glycemic control[19,22,23,24]. Symptomatic patients may initially require treatment with insulin or combination therapy. All patients are treated with therapeutic lifestyle modification. Patients with HbA_{Ic} of 7.5% (0.075; 58 mmol/mol Hb) or less are usually treated with an antihyperglycemic agent which is unlikely to cause hypoglycemia. Those with HbA_{Ic} more than 7.5% but less than 8.5% (more than 0.075 but less than 0.085; more than 58 but less than 69 mmol/mol Hb) could be initially treated with a single agent, or combination therapy. Patients with higher initial HbA_{Ic} will require two agents or insulin. All therapeutic decisions

should consider the needs and preferences of the patient, if medically possible.[19,23]

The best oral therapy regimen for patients with type 2 DM is widely debated. Based on the results of the UKPDS and safety record, obese patients without contraindications are often started on metformin which is titrated to 2,000 mg/day. Metformin will also work in nonobese patients with type 2 DM; however, this population is more likely to be insulinopenic, necessitating medications that may increase insulin secretion. In the UKPDS, metformin use in obese type 2 DM patients reduced total mortality, but this study was before statin use, tight blood pressure control, and widespread recommendations on the use of antiplatelet therapy. The long-term durability of the glycemic response produced by metformin is suboptimal and patients will often require additional therapy over time. An insulin secretagogue, such as a sulfonylurea, is often added second. While sulfonylureas are less expensive than other add-on therapies, they have several potential drawbacks including weight gain and hypoglycemia. Moreover, the sulfonylureas do not produce a durable glycemic response. Better choices include DPP-4 inhibitors, GLP-1 receptor agonist and SGLT2 inhibitors but each has therapeutic and safety limitations as well. TZDs produce a more durable glycemic response and are unlikely to cause hypoglycemia, but weight gain, fluid retention and the risk of new onset heart failure as well as other long-term safe concerns have limited their use by many clinicians in recent years. Glycemic goal-oriented therapy meaning the intervention should be sufficient to achieve the glycemic goal. **Figure 74-4** is a consensus algorithm by the ADA and the European Association for the Study of Diabetes.[23] Another commonly quoted type 2 DM treatment algorithm is published by the American Association of Clinical Endocrinologists/American College of Endocrinologists (AACE/ACE) (See: www.aace.com/publications). Both treatment guidelines recommend individualization of pharmacotherapy; however, the AACE/ACE algorithm directs clinicians to a specific medication based on level of evidence, glycemic lowering, hypoglycemia risk, side effects, and effects on weight. The ADA algorithm does not recommend one medication over another, but list these attributes next to the mediation for consideration by the clinician. One noted difference is that sulfonylureas are placed as a "last" choice in the AACE/ACE algorithm, whereas ADA places sulfonylureas as a potential second line agent.

FIGURE 74-4

Antihyperglycemic Therapy Recommendations in Type 2 Diabetes. General Recommendations. *(Data from reference 20.)*

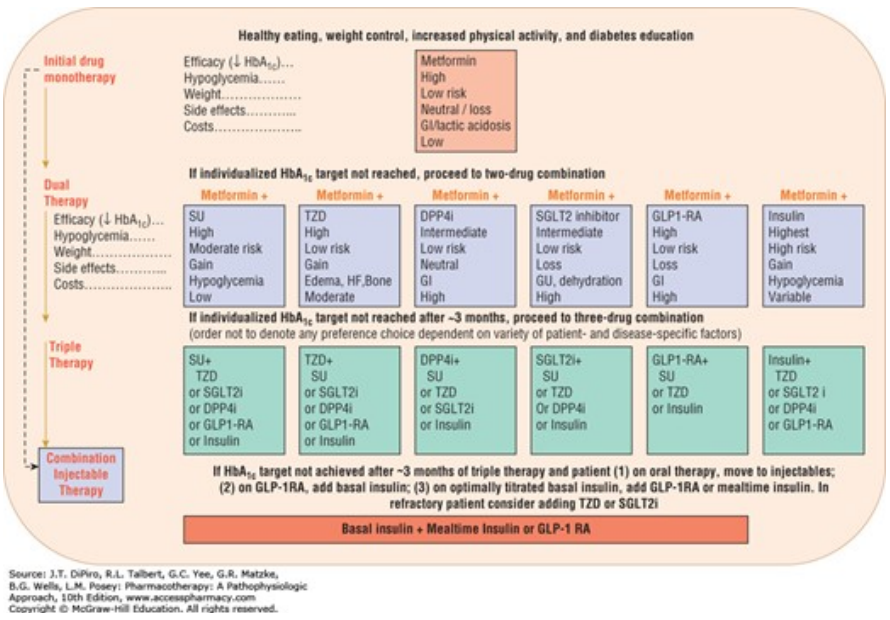

Table 74-6 provides a framework for HbA_{Ic} goal individualization. Treatment selection should be based on multiple factors. Consider some simple questions to guide therapy: (1) How long has the patient had diabetes? If the patient has had diabetes for several years, due to progress failure of β-cell function, the patient is more likely to require insulin therapy. (2) Comorbidities? If the patient has multiple comorbidities, CVD, dementia, life expectancy,

depression, osteoporosis, heart failure, recurrent genitourinary (GU) infections, some medications may be poor choices based on their potential side effects. In addition, certain comorbidities should "loosen" the HbA_{Ic} goal.[22] (3) What is the amount of glucose lowering required to achieve the goal? Each oral agent and GLP-1 receptor agonist has limits on HbA_{Ic} reduction, though most medications produce a more robust reduction with a higher baseline HbA_{Ic}. (4) Is the primary problem elevated post-prandial BG readings? Fasting BG readings? Or both? If the patient's postprandial BGs are the primary reason for poor control, pick a medication that addresses postprandial blood glucose excursions. Conversely, if the patient's fasting BG reading is consistent elevated, a medication that addresses fasting BG would be a better choice. (5) Adverse effect profile? Contraindications, hypoglycemia potential, and tolerability are based on the current status of the patient; (6) Motivation, resources, and potential difficulties with adherence should also influence treatment selection. (7) Age? If the patient is an older adult, the risk of hypoglycemia and other adverse effects increases and life expectancy diminishes. These factors should influence medication choices and HbA_{1c} goals. (8) Non-glycemic effects? CVD reduction with medications, lipid effects, blood pressure effects, weight, and durability of HbA_{1c} reduction may all influence the decision. See Table 74-6 for a framework for HbA_{Ic} goal individualization.

β-Cell function is greatly diminished (by 50%-80%) by the time type 2 DM is diagnosed. Preserving β-cell function and arresting the progressive nature of type 2 DM would be a paradigm changing approach to treatment. However, the currently available medications slow, but do not arrest progression. It appears unlikely any one drug class will arrest β-cell failure, necessitating combination therapy. The combination of a TZD and GLP-1 receptor agonist is logical as TZDs reduce apoptosis of β-cells and GLP-1 receptor agonists augment pancreatic function. Two-year data in newly diagnosed patients given metformin, pioglitazone, and exenatide demonstrate near normal HbA_{1c} values.[25]

Nearly all patients with type 2 DM ultimately become relatively insulinopenic necessitating insulin therapy. Patients with type 2 DM often transition to insulin by using a bedtime injection of an intermediate- or long-acting basal insulin while continuing to use oral agents or GLP-1 receptor agonists for control during the day. This strategy is associated with less weight gain, equal efficacy, and lower risk of hypoglycemia when compared to starting prandial insulin or split-mix twice daily insulin regimens.[26] Patients who use a basal insulin should be monitored for hypoglycemia by asking about nocturnal sweating, poor sleep, nightmares, palpitations, and tremulousness as well as SMBG. Inadequate control with basal or bedtime insulin often presents with an HbA_{1c} above goal despite an FPG that is near goal. This is often due to rising postprandial glycemia throughout the day. Using a "basal plus" strategy, where a dose of bolus insulin is given prior to the largest meal of the day or the meal with the largest glucose excursion, may be simpler to implement than MDI. When prandial insulin is added to the evening meal, a reduction in the bedtime basal insulin dose may be warranted.[27] An alternative to starting a prandial insulin is to add a GLP-1 receptor agonist. If a biphasic mixed insulin is used, such as 70/30 NPH/Regular mix insulin, Humalog Mix 75/25 or Mix 50/50 or Novolog Mix 70/30, they should be given twice daily before the first and third meal. If adequate control is not achieved, a third dose of mix insulin may be given with the mid-day meal. This not only allows for better prandial coverage but also increases the risk of hypoglycemia. Premix insulins are not as flexible because the doses of the two insulin types cannot be independently changed.

Patients commonly adjust the wrong dose of insulin when high or low SMBG values are encountered. For a typical 2-injection regimen of premix insulin, if the pre-evening meal glucose is out of range, the morning insulin dose must be adjusted. Similarly, if the morning fasting glucose is out of range, the evening dose must be adjusted.[19]

Given that insulin resistance is commonplace in patients with type 2 DM, the insulin doses required to achieve good glycemic control are typically between 0.7 and 2.5 units/kg and sometimes more. Algorithms for insulin therapy in patients with type 2 diabetes have been developed by the Texas Diabetes Council (See: www.tdctoolkit.org/algorithms-guidelines), ADA[23], and AACE (See: www.aace.com/publications) **(Fig. 74-5)**.

Select Landmark DM Clinical Trials

In the Diabetes Complications and Control Trial (DCCT)[28] type 1 DM subjects were treated with intensive therapy—3+ injections of insulin daily or insulin pump, with frequent SMBG and alteration of insulin therapy based on SMBG results, plus frequent contact with a health professional or conventional therapy—one or two injections per day. After 6.5 years, retinopathy, neuropathy, and nephropathy were significantly reduced in the intensive group, though hypoglycemia was more common. In the United Kingdom Prospective Diabetes Study (UKPDS)[29] more than 5,000 patients with newly diagnosed type 2 DM were enrolled. Patients were followed for an average of 10 years. The study assessed "conventional therapy" (no drug therapy unless the patient was symptomatic or had FPG more than 270 mg/dL [more than 15.0 mmol/L]), versus intensive therapy starting with either sulfonylureas or insulin, aimed at keeping the fasting plasma glucose less than 108 mg/dL (less than 6.0 mmol/L). A subset of obese patients was studied using metformin as the primary therapeutic agent. Microvascular complications, primarily retinopathy, were reduced. At the conclusion of the DCCT and UKPDS trials, willing subjects in both trials continued to be followed over time to ascertain long-term micro- and macrovascular outcomes. In the follow-up of the DCCT, called the Epidemiology of Diabetes Interventions and Complications (EDIC),[31,32] continued micro- and new macrovascular benefit were seen despite similar HbA_{1c} values in the intensive and conventional treatment groups after study termination. Microvascular benefits were maintained for 10 to 15 years, and macrovascular events were significantly reduced. Similar results have been reported in the UKPDS follow-up trial in type 2 DM.[33] The ACCORD,[34] ADVANCE,[35] and VADT[36] were three trials that reported no benefit after 5 years of improved/intensive glycemic control for the reduction of macrovascular complications in patients with long-standing type 2 DM.

Special Populations

Children and Adolescents with Type 2 DM

Type 2 DM is increasing in adolescence[12,37,1]. Obesity and physical inactivity seem to be particular culprits in the pathogenesis of this disease. Given the many years that the patient will have to live with diabetes, and recent evidence that the timeline for microvascular complications may mimic that of older adults, extraordinary efforts should be expended on lifestyle modification measures in an attempt to normalize glucose levels. Failing that strategy, the only FDA approved oral agent for use in children (10-16 years of age) is metformin. Unfortunately, the durability of the response to metformin monotherapy is poor in many adolescents. Sulfonylureas are also commonly used. TZDs improved glycemic control when added to metformin therapy but are not currently FDA approved for use in children. DPP-4 inhibitors and the GLP-1 receptor agonists, while attractive options, have not been adequately studied in children. Insulin therapy continues to be the standard of care when glycemic goals cannot be achieved or maintained with metformin and sulfonylurea. In adolescent females, the possibility of future pregnancy should be considered. Screening and recommendations for treatment of hypertension, dyslipidemia, nephropathy, retinopathy, hypothyroidism, and celiac disease are available.

Older Adults with DM

Elderly patients with newly diagnosed with DM present a different therapeutic challenge[38]. Consideration of the risks of hypoglycemia, the extent of comorbidities including severe microvascular disease, CVD, dexterity, self-care, nutritional status, social support, falls risk, mental status, and life expectancy should all influence glycemic goals and treatment selection (see Table 74-6). Avoidance of hypoglycemia, especially severe hypoglycemia is appropriate, but hyperglycemia that may exacerbate comorbidities should also be avoided.[22] Elderly patients may have an altered presentation of hypoglycemia as they lose adrenergic symptoms due to loss of autonomic nerve function as they age. This may cause neuroglycopenic symptoms to appear shortly after identification of hypoglycemia. DPP-4 inhibitors, shorter-acting insulin secretagogues, low-dose sulfonylureas, or α-glucosidase inhibitors may be used. Age-related decline in renal function may preclude metformin therapy, but lower doses may be used if the estimated glomerular filtration rate (eGFR) is consistently above 30 mL/min/1.73 m^2. SGLT2 inhibitor efficacy declines as renal function declines, thus most elderly patients may not have the same response as younger adults. SGLT2 inhibitors may also increase the frequency of voiding, cause possible orthostatic changes and increased falls risk. A higher risk of distal extremity fracture from falls with older adults has been documented with canagliflozin. Falls and fracture risk must be considered with TZDs which also tend to be extremity fractures from falls. DPP-4 inhibitors or α-glucosidase inhibitors are oral medications, which may be advantageous in older adults due to a low risk of hypoglycemia. Simple insulin regimens with daily basal insulin may be appropriate for glycemic control in elderly patients, especially if tight glycemic control is not the goal.

Clinical Controversy… Glycemic Goal Setting in Older Adults.

The US population continues to age[38,88,89,90]. The ACCORD,[34] ADVANCE,[35] and VADT[36] enrolled older adults with multiple cardiovascular risk factors. All three studies failed to show a benefit in terms of CVD. Indeed, more people died in the ACCORD, resulting in early termination of the study. ADVANCE reported improvement in nephropathy outcomes. Diabetes in older adults is complicated by clinical and functional heterogeneity. Patients may be relatively healthy, independent living adults or, at the other end of the spectrum, require assistance with activities of daily living, have multiple comorbidities as well as cognitive impairments. What is the optimal goals and medication therapy for these individuals?

Clinical trial data in patient over 65 years of age for most medications are lacking. Many clinicians have decided that insulin, especially basal insulin, is a reasonable choice in this age group, and that metformin if not contraindicated is reasonable. In the new ADA guidelines, a patient-centered approach is recommended. It is unlikely that most patients would choose basal insulin as their initial intervention if asked. Also, the cost for basal insulin is significant, and one must ask if it is truly the most cost-effective choice. Severe hypoglycemia must be avoided in this population, as it has been associated with a higher risk of death 1 year following the incident. In addition, poor self-care behaviors, visual

acuity, and dexterity may be of concern.

Medications that do not cause hypoglycemia may be advantageous in this population. Metformin, if not contraindicated, continues to be an excellent first choice. As renal function declines,[54] using metformin in a reduced dose is also reasonable. DPP-4 inhibitors are well tolerate and GLP-1 receptor agonist may help the patient lose weight. Both may be cost prohibitive and GLP-1 receptor agonists may be inappropriate for patients with GI symptoms or gastroparesis. Alpha glucosidase inhibitors are also very safe but gas and GI tolerability can be problematic. The optimal treatment goals and approaches for older adults remain elusive.

Gestational DM and Pregnancy with Preexisting Diabetes

Gestational DM is diagnosed during pregnancy[2,5,13,22]. The adverse outcomes associated with GDM include birth defects, miscarriage, cesarean section delivery, maternal preeclampsia/eclampsia, preterm delivery, neonatal hypoglycemia, shoulder dystocia, birth injury, and hyperbilirubinemia. Medical nutritional therapy to minimize wide fluctuations in blood glucose is of paramount importance. Intensive educational efforts are usually necessary. Pregnant women without DM maintain plasma glucose concentrations between 50 and 130 mg/dL (2.8 and 7.2 mmol/L). Normoglycemia is the goal, and failure to maintain this despite dietary interventions often will necessitate medication use. Goals during therapy are *minimally* a preprandial goal of less than or equal to 90 mg/dL (less than or equal to 5.0 mmol/L), and either a 1-hour postprandial plasma glucose levels less than or equal to 120 mg/dL (less than or equal to 6.7 mmol/L) or 2-hour postprandial plasma glucose levels less than or equal to 110 mg/dL (less than or equal to 6.1 mmol/L). Ketosis should also be avoided as much as possible.

In patients who have preexisting type 1 or type 2 DM who become pregnant, premeal, bedtime, and overnight SMBG should be 60 to 90 mg/dL (3.3-5.0 mmol/L), with a peak postprandial SMBG of 100 to 120 mg/dL (5.6-6.7 mmol/L). HbA_{Ic} during pregnancy should ideally be less than 6% (0.06; 42 mmol/mol Hb), but SMBG is the method of choice for monitoring glycemic control. Titration of insulin and switching to more complicated regimens that are guided by SMBG results is recommended. The safety of basal insulins other than NPH is still debated, but detemir has been rated pregnancy category B since 2012, and basal insulin use in GDM is increasing. Insulin pump therapy can be considered. In highly motivated patients, CSII can achieve excellent glycemic control and can be quickly adjusted.

Both metformin and glyburide have been studied as alternatives to insulin therapy. Glyburide was not detected in the cord serum of any infant in one study, whereas metformin crosses the placenta. Further study is needed prior to routinely recommending them in GDM, but in patients for whom the complexity of insulin is too difficult or refuses insulin, glyburide or metformin use is justified. Patients with gestational DM should be evaluated approximately 6 weeks after delivery to ensure that normal glucose tolerance has returned. The lifetime risk for the development of type 2 DM is 30% to 50%, making periodic reassessment of former GDM patients warranted.

Clinical Controversy… Oral agents in Pregnancy

The use of oral antidiabetes agents for the management of gestational diabetes or type 2 DM during pregnancy continues to be controversial. For those patients who fail to maintain optimal glycemic control during pregnancy with diet and lifestyle modification, the next step has traditionally been to use insulin therapy. More recently, however, some clinicians have begun using oral agents including sulfonylureas and metformin in patients with GDM or type 2 DM during pregnancy.

A randomized, open-label, controlled trial evaluated the efficacy of glyburide compared to insulin initiated after 11 weeks of gestation.[81] The control of blood glucose compared to insulin therapy was similar, with less hypoglycemia in the glyburide group. There was not any evidence of significant difference in complications, including cord-serum insulin concentrations, incidence of macrosomia (birth weight more than or equal to 4,000 g), caesarean delivery, or neonatal hypoglycemia between regimens. Glyburide was not detected in the cord serum of any infant. However, this study limited enrollment of 11 weeks of gestation and beyond, therefore no conclusions can be made regarding teratogenicity from using glyburide in the first trimester of pregnancy.

A retrospective cohort study of 10,682 women with GDM who required medical therapy, however, revealed that babies born to women with GDM who were managed on glyburide were more likely have macrosomia and to be admitted to the intensive care unit compared to those treated with insulin therapy.[82] A more recently published large cohort evaluated 110,879 patients diagnosed with GDM in a US insurance claims database. Patients treated with glyburide had significantly more admissions to the NICU, respiratory distress, and macrosomia.[83]

A study of 751 women with GDM randomly assigned subjects at 20 to 33 weeks of gestation to open treatment with metformin and supplemental insulin, if required, or insulin therapy. This study did not find any increased rate of preeclampsia or other perinatal complications with metformin use compared with insulin.[84] Subsequently there have been a number of meta-analyses which revealed no differences in maternal or neonatal outcomes with the use of glyburide or metformin compared to the use of insulin in women with GDM.[85,86] Finally, a 2015 meta-analysis comparing metformin with glyburide found that metformin was associated with less maternal weight gain, lower birth weights, less macrosomia, and fewer large for gestational age infants. Failure rate was higher with metformin than glibenclamide.[87]

The current guidelines of the American Diabetes Association continue to recommend insulin therapy as the preferred treatment for managing women with gestational diabetes or type 2 DM in pregnancy who fail to achieve optimal control with diet and lifestyle modification alone.[39] Neither metformin or glyburide have formal FDA-approval for the management of diabetes in pregnancy.

Preconception Care for Women

An increasing prevalence of DM has been noted in reproductive-age women[13,39]. Prepregnancy planning is mandatory. Organogenesis is largely completed within the first 8 weeks of pregnancy—well before good glycemic control can be achieved in the absence of preconception planning. Unfortunately, major congenital malformations due to poor glucose control in the first trimester of pregnancy remain the leading cause of mortality and serious morbidity in infants of mothers with type 1 or type 2 DM. For women with DM controlled by lifestyle measures alone, conversion to insulin as soon as the pregnancy is confirmed is appropriate. Patients previously treated with insulin may need intensification of their regimen to achieve therapeutic goals. Normal pregnancy is associated with a decrease in the BG concentration as glucose is diverted to the fetus. During precontraception planning, all drugs should be reviewed for safety. Drugs with known teratogenicity, such as ACE inhibitors and statins, should be stopped or substituted.

Sick Days

Acute self-limited illness rarely presents a major problem for patients with type 2 DM, though following a reasonable sick day plan in severe illness may avoid urgent care visits from dehydration. Type 2 DM patients should perform SMBG more often, especially if medications that may cause hypoglycemia are administered. Sick day management for patients with type 1 DM is more challenging. While caloric intake generally declines, insulin sensitivity also decreases. Thus it often requires greater amounts of insulin to control BG during periods of acute illness. Patients need to increase the frequency of SMBG, check urine ketones, use of short-acting insulin, and should consume 120 to 150 g of carbohydrates per day. Patients should continue their usual insulin regimen and use supplemental rapid-acting insulin based on SMBG results. Additional insulin may be needed if ketonuria develops. Ketone testing should be done if two consecutive plasma glucose readings are above 250 mg/dL (13.9 mmol/L) or if vomiting occurs, as this may be a sign of ketosis. Sugar and electrolyte solutions, such as sports drinks, can be used to maintain hydration and provide electrolytes if there are significant gastrointestinal or urinary losses. They also provide glucose to keep the patient from developing hypoglycemia. However, if the patient BG remains consistently elevated, the patient should abstain from sugary drinks and increase intake of sugar-free liquids.

Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Diabetic ketoacidosis and hyperosmolar hyperglycemic state are true emergencies[9,18,40]. In patients with type 1 diabetes, ketoacidosis is usually precipitated by the patient omitting insulin, or an acute illness with subsequent increase in counter-regulatory hormones such as cortisol, catecholamines, glucagon, and growth hormone. Infection is a common cause of DKA and should be thoroughly explored. Patients with DKA may be alert, stuporous, or comatose at presentation. The hallmark diagnostic laboratory values for DKA include hyperglycemia, anion gap acidosis, and large ketonemia or ketonuria. Patient with HHS present quite similarly but typically have much higher plasma glucose, elevated serum osmolality, and little to no ketonuria or ketonemia. HHS typically evolves over several days to weeks, whereas DKA evolves much quicker. Patients with DKA or HHS have fluid deficits of several liters as well as significant sodium and potassium deficits. Restoration of intravascular volume with normal saline, followed by hypotonic saline to replace free water, potassium supplements, and insulin given by continuous IV infusion to restore the patient's metabolic status are the cornerstones of therapy. Treatment with bicarbonate to correct the acidosis is generally not needed and may be harmful, especially in children. Treatment of the inciting medical condition is also vital. Hourly bedside monitoring of glucose and frequent monitoring (every 2-4 hours) of potassium is essential. A flow sheet is helpful in tracking the fluid and insulin therapies and laboratory parameters in these patients. Metabolic improvement is manifested by an increase in the serum bicarbonate or pH. Constant infusion of a fixed dose of insulin and the administration of IV glucose when the blood glucose level decreases to less than 250 mg/dL (less than 13.9 mmol/L) is preferable to titration of the insulin infusion based on the glucose level. The latter strategy may delay clearance of the ketosis and prolong treatment. Rapid correction of the glucose, a drop greater than 75 to 100 mg/dL/h (4.2-5.6 mmol/L/h), is not recommended because it has been associated with cerebral edema, especially in children. The insulin infusion should be continued until the urine ketones clear and the anion gap closes. Intramuscular regular insulin or subcutaneous insulin lispro or aspart given every 1 to 2 hours can be utilized rather than an insulin infusion in patients without hypoperfusion. Long-acting insulin should be given 1 to 3 hours prior to discontinuing the insulin infusion. Serum phosphorus usually starts high and plummets to lower-than-normal levels. Replacing phosphorus, while not unreasonable, is of questionable benefit. Fluid administration alone will reduce the glucose concentration, so a decrement in glucose values does not necessarily mean that the patient's metabolic status is improving. Patients may develop hyperchloremic metabolic acidosis with treatment if they have been given large volumes of normal saline in the course of their treatment. However, this does not require any specific treatment.

Hyperosmolar hyperglycemic state usually occurs in older patients with type 2 DM or in younger patients with prolonged hyperglycemia and dehydration or significant renal insufficiency. Occasionally patients with previously undiagnosed type 2 DM present with HHS. Large ketonemia is usually not seen because residual insulin secretion suppresses lipolysis. However, ketones from prolonged fasting may be present. Infection or another medical illness is the usual precipitant. Fluid deficits are often greater and BG concentrations higher—sometimes greater than 1,000 mg/dL (55.5 mmol/L)—in patients with HHS when compared to patients with DKA. Blood glucose should be lowered very gradually with hypotonic fluids and low-dose insulin infusions (1-2 units/h). Mortality is high with HHS.

Hospitalization for Intercurrent Medical Illness

Patients on oral agents may need transient therapy with insulin to achieve adequate glycemic control during a hospitalization[41,42,44]. It is prudent to stop metformin in all patients who arrive in acute care settings as contraindications to metformin are prevalent in hospitalized patients. In patients requiring insulin, patients should receive scheduled doses of insulin with additional short-acting insulin. "Sliding-scale" insulin regimens which withhold insulin when the BG is lower than a predetermined threshold should be discouraged, as it is notorious for not controlling glucose and for sometimes resulting in therapeutic misadventures, with wide fluctuations of BG often recorded. In-hospital mortality is increased in many hyperglycemic conditions. At least one study documented a reduction in mortality in type 2 diabetes patients with acute MIs who receive constant IV insulin during the acute phase of the event to maintain near-normal glucose concentrations. Similar mortality improvements have been documented in some intensive care unit settings using IV insulin and tight glucose control. However, the Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial did not find a benefit from tight glycemic control in the ICU setting.[43] Thus, glycemic goals for hospitalized patients have been relaxed in recent years. The ADA and AACE released a joint consensus statement regarding inpatient glycemic

control stating that glucose control measures should be implemented if the blood glucose is ≥ 180 mg/dL (10.0 mmol/L), and maintained between 140 and 180 mg/dL[4] (7.8 and 10.0 mmol/L). For noncritically ill patients there are no large outcome trials. Reasonable blood glucose goals for these patients are less than 140 mg/dL (7.8 mmol/L) premeal and less than 180 mg/dL (10.0 mmol/L) random.[22] Many protocols for IV insulin infusion are currently available and clinicians should use a well-established protocol. Point of care (POC) plasma glucose accuracy, especially in an ICU setting, has been controversial. The FDA has asked for improved accuracy from POC glucose meters to be approved for use in the hospital setting. Discharge planning is also important. Approximately one third of patients who develop hyperglycemia during a hospitalization will have newly diagnosed diabetes and another one third will likely have prediabetes. Obtaining an HbA_{1C} upon admission or prior to discharge can help determine who needs follow-up care.

Perioperative Management

Patients who require surgery may experience worsening of glycemia similar to those admitted to hospital for a medical illness[22]. Acute stress increases counter-regulatory hormones. Therapy should be individualized based on the type of DM, nature of the surgical procedure, previous therapy, and metabolic control prior to the procedure. Patients on oral agents may need to be transiently switched to insulin to control blood glucose. In patients requiring insulin, scheduled doses of insulin or continuous insulin infusions are preferred. For patients who can eat soon after surgery, basal insulin continuation is warranted. The time-honored approach of giving one-half of the patient's usual morning NPH or basal insulin dose with dextrose 5% in water intravenously is acceptable, with resumption of scheduled insulin, perhaps at reduced doses, within the first day. Patients receiving basal-bolus insulin therapy can continue receiving their usual dose of long acting insulin while holding the premeal bolus doses until the patient eats. For patients requiring more prolonged periods without oral nutrition following major surgeries, such as coronary artery bypass grafting and major abdominal surgery, continuous IV infusion insulin is preferred. However, "tight" perioperative glucose control has not proven to improve outcomes. Use of IV insulin infusion has been shown to reduce postoperative deep sternal wound infections in patients following coronary artery bypass grafting. Metformin should be discontinued temporarily after any major surgery until it is clear that the patient is hemodynamically stable and normal renal function is documented.

Human Immunodeficiency Virus (HIV) Patients and Diabetes

Patients living with HIV are at higher risk for the development of type 2 DM[45]. This risk may be related to HIV infection, concomitant infections such as hepatitis C, and medications often used to treat HIV and its comorbidities. Pentamidine, commonly used for *Pneumocystis Carinii* pneumonia infections, is a β-cell toxin and may cause some patients to develop hypoglycemia from insulin release followed by hyperglycemia. Megestrol, used as an appetite stimulant, can have glucocorticoid-like effects and cause hyperglycemia in some patients. Protease inhibitors, used to manage HIV, can worsen insulin sensitivity, decrease the ability of the β-cell to secrete insulin, and worsen lipotoxicity. Long-term use of stavudine also increases the risk of developing diabetes. Redistribution of fat from subcutaneous to the visceral compartment from medication or HIV infection caused by medications or HIV infection, also increases the risk of developing diabetes. Metformin is the drug of choice for HIV patients as weight gain can be minimized. Stavudine, zidovudine, and didanosine may cause lactemia, especially upon long-term use. It may be advisable to check lactate levels in patients taking this medications prior to metformin use. If lactate levels are greater than 2 times normal, alternative therapy should be considered. If excess visceral adiposity is noted, a TZD, which redistributes fat back to subcutaneous adipose tissue and causes visceral fat apoptosis may be considered. Drugs that promote weight loss should also be considered. Significant drug-drug interactions may also be present.

Prevention of Diabetes Mellitus

Efforts to prevent type 1 DM with niacinamide, injected insulin, or oral insulin therapy were all unsuccessful[5]. Anti-CD3 and anti-CD20 monoclonal antibodies and a GAD vaccine delayed, but not stop β-cell destruction in type 1 DM.

DiaPep277® development was halted as data from the full cohort analysis was negative. Low vitamin D levels has been associated with a higher the risk of developing type 1 DM and vitamin D supplementation in high risk patients continues to be of interest but has not yet been shown to be effective.

The "4 lifestyle pillars" for the prevention of type 2 diabetes are to decrease weight, increase aerobic exercise, increase fiber, and decrease fat intake. The Diabetes Prevention Program (DPP) confirmed that modest weight loss and regular physical activity can have a dramatic impact on insulin sensitivity and prevent the development of type 2 diabetes in patients with impaired glucose tolerance.[46] The study, which was originally planned to be ongoing for 5 years, was stopped early after 2.8 years. Patient assigned to the lifestyle arm of the study developed diabetes at a rate of 5% per year compared to an 11% per year rate in the usual care group, a 58% reduction. The exercise program involved walking 30 minutes 5 days each week. The mean weight loss was only 8 pounds (3.6 kg). A third arm of the DPP randomized subjects to metformin therapy 850 mg twice daily. Metformin therapy reduced the risk of developing type 2 DM by 31% when compared to usual care and resulted in a 4-pound (1.8 kg) weight loss. Interestingly, young and overweight individuals on metformin had a greater reduction in the risk of developing diabetes than normal weight and older study patients. Diet and exercise interventions were effective regardless of age or weight. The DREAM trial evaluated rosiglitazone and/or ramipril treatment for the delay or prevention of type 2 DM in impaired glucose tolerant subjects.[47] Rosiglitazone 8 mg daily, over approximately 3 years, reduced the incidence of type 2 diabetes by 60%. The ACT Now trial used pioglitazone 45 mg daily in patients with IGT and found a 72% reduction in the risk of development of diabetes over 2.4 years.[48] Low dose metformin and rosiglitazone combination have also shown to significantly reduce the risk of progression to diabetes. Acarbose reported a 25% reduction in the risk of type 2 DM in the STOP NIDDM study and may be most effective in populations who consume a diet high in whole grains such as rice. Liraglutide at 1.8 mg daily and at the obesity approved dose of 3.0 mg daily have been shown to decrease progression to type 2 DM.

All diabetes medications available for the prevention of diabetes, once discontinued, do not appear to have residual effects on β-cell function. Thus patients must continue the medication to "prevent" diabetes, thus raising the question about whether medications are merely early treatment. It should be noted that no pharmacologic agents are currently FDA approved for the prevention of type 2 diabetes. The ADA recommends metformin in conjunction with lifestyle changes in younger obese patients who have an HbA_{Ic} more than 6% (0.06; 42 mmol/mol Hb) and dyslipidemia, hypertension, or a family history of diabetes.[5]

Drug Class Information

Insulin

Endogenously produced insulin is cleaved from the larger proinsulin peptide in the β-cell to the active peptide of insulin and inactive C-peptide[18,19,49]. All commercially available insulin preparations contain only the active insulin peptide. Characteristics that are commonly used to categorize insulin preparations include source, strength, onset, and duration of action. Some insulin preparations, known as insulin analogs, have had amino acids substitutions in the insulin molecule that are designed to impart physiochemical and pharmacokinetic advantages. **Table 74-7** summarizes available insulin preparations.

TABLE 74-7 Available Insulin Preparations and other Injectables

Generic Name	Manufacturer	Analog[a]	Administration Options	Room Temperature[b] Expiration
Rapid-acting insulins				
Humalog (insulin lispro)	Lilly	Yes	Insulin pen 3-mL, 3-mL and 10-mL vial, or 3-mL pen cartridge	28 days

Generic Name	Manufacturer	Analog[a]	Administration Options	Room Temperature[b] Expiration
NovoLog (insulin aspart)	Novo Nordisk	Yes	Insulin pen 3-mL, 10-mL vial, or 3-mL pen cartridge	28 days
Apidra (insulin glulisine)	Sanofi	Yes	Insulin pen 3-mL, 10-mL vial	28 days
Short-acting insulins				
Humulin R (regular) U-100	Lilly	No	10-mL vial, 3-mL vial	28 days
Novolin R (regular)	Novo Nordisk	No	10-mL vial	42 days
Intermediate-acting insulins				
NPH				
Humulin N	Lilly	No	3-mL and 10-mL vial, Insulin pen 3-mL	Vial: 31 days; pen: 14 days
Novolin N	Novo Nordisk	No	10-mL vial	42 days
Long-acting insulins				
Lantus (insulin glargine)	Sanofi	Yes	10-mL vial, Insulin pen 3-mL	28 days
Levemir (insulin detemir)	Novo Nordisk	Yes	10-mL vial, Insulin pen 3-mL	42 days
Tresiba (insulin degludec)	Novo Nordisk	Yes	Insulin pen 3-mL	56 days
Premixed insulins				
Premixed insulin analogs				
Humalog Mix 75/25 (75% neutral protamine lispro, 25% lispro)	Lilly	Yes	10-mLvial, Insulin pen 3-mL	Vial: 28 days; pen: 10 days
Novolog Mix 70/30 (70% aspart protamine suspension, 30% aspart)	Novo Nordisk	Yes	10-mL vial, Insulin pen 3-mL	Vial: 28 days; pen: 14 days
Humalog Mix 50/50 (50% neutral protamine lispro/50% lispro)	Lilly	Yes	10-mL vial, Insulin pen 3-mL	Vial: 28 days; pen:10 days
NPH-regular combinations				
Humulin 70/30	Lilly	No	3-mL and 10-mL vial, Insulin pen 3-mL	Vial: 31 days; pen: 10 days
Novolin 70/30	Novo Nordisk	No	10-mL vial	42 days
Concentrated insulins				
Regular insulin (U-500)	Lilly	No	20-mL vial, Insulin pen 3-mL	Vial: 40 days, pen: 28 days
Humalog (U-200 insulin lispro)	Lilly	Yes	Insulin pen 3-mL	28 days
Toujeo (U-300 insulin glargine)	Sanofi	Yes	Insulin pen 1.5-mL	42 days
Tresiba (U-200 insulin degludec)	Novo Nordisk	Yes	Insulin pen 3-mL	56 days
Inhaled insulin				
Afrezza (Technosphere insulin)	Mannkind	No	4 unit and 8 unit cartridges	Sealed-unopened blister card/strip 10 days Opened- 3 days

[a]All diabetes injectables available in the US are now made by human recombinant DNA technology. An insulin analog is a modified human insulin molecule that imparts particular pharmacokinetic advantages.

[b]Room temperature defined as 59-86°F (15-30°C). All products are good until expiration date on product if unopened and stored correctly.

Insulin is available in several concentrations containing 100 units/mL (U-100), 200 units/mL (U-200), 300 units/mL (U-300), or 500 units/mL (U-500). The most commonly used insulin preparation is the U-100 concentration. Concentrated insulins containing more than 100 units/mL are generally reserved for individuals that require larger doses of insulin to control their diabetes. For some patients with type 1 diabetes who require extremely low doses of insulin, U-100 insulin may be diluted in order to accurately measure the necessary insulin doses. Diluents, instructions on dilution, and empty vials can be obtained from the manufacturers.

Historically, insulin was extracted from either beef or pork pancreases. Today recombinant DNA technology is exclusively used to manufacture insulin. Eli Lilly and Sanofi currently use a non-pathogenic strain of *Escherichia coli* to synthesize insulin; whereas Novo Nordisk uses *Saccharomyces cerevisiae*, or bakers' yeast.

Purity of insulin refers to the amount of proinsulin and other impurities present in the insulin product. Prior to 1980, most insulin products contained impurities (300-10,000 parts per million [ppm]) that sometimes caused local skin reactions as well as systemic antibody production. Today all recombinant DNA human insulin and insulin analogs contain less than 1 ppm of proinsulin.

When given by subcutaneous injection, regular crystalline insulin naturally associates into a hexameric (six insulin molecules) structure when zinc is present. Before absorption through a blood capillary can occur, the hexamer dissociates first into dimers and then monomers. This principle is the premise for additives such as protamine and extra zinc, which strengthen the hexamer interaction, prolonging onset, peak, and duration. Lispro, aspart, and glulisine insulin preparations dissociate more rapidly to monomers due to the substitution of amino acids on the β-chain of insulin resulting in a more rapid onset, peak, and duration of action when compared to regular insulin. Lispro (B-28 lysine and B-29 proline human insulin; monomeric) insulin has two amino acids transposed, aspart (B-28 aspartic acid human insulin; monomeric and dimeric) insulin has one amino acid substitution, and glulisine (B-3 lysine and B-29 glutamic acid) has two substitutions. Proteins are insoluble near their isoelectric point and the analog insulin glargine takes advantage of this property to prolong absorption. In comparison to human regular insulin, with an isoelectric point of 5.4, insulin glargine (A-21 glycine, B-30a-arginine, B-30a L-arginine, and B-30b L-arginine human insulin) has an isoelectric point of 6.8. In the vial, glargine is buffered to a pH of 4, a pH at which it is highly soluble, resulting in a clear colorless solution. When injected into the neutral pH of the body, it rapidly forms microprecipitates that slowly dissolve into dimers and monomers which can then be absorbed. The result is a long-acting insulin product with a duration of action of approximately 24-hours. The long-acting analog insulin detemir, in contrast, attaches a 14-carbon fatty acid at the B-29 position and removes the B-30 amino acid. This allows the fatty acid side chain to bind to interstitial albumin at the SQ injection site. In addition, stronger hexamer associations are form. Once detemir dissociates from albumin at the injection site and enters the blood, it is again binds to albumin, further prolonging its action. Insulin degludec, another long-acting insulin analog, has threonine at position B-30 removed and a 16-carbon fatty acid conjugated to lysine at position B-29 with a glutamic acid spacer. When injected, insulin degludec molecules reorganize from dihexamers to multihexamers that remain in solution at physiologic pH. Slow release of zinc ions from the multihexamers leads to a slow release of insulin degludec monomers.

The pharmacokinetics of insulin products given by subcutaneous injection are characterized by their onset, peak, and duration of action (**Table 74-8)**. Absorption of insulin from a subcutaneous depot is dependent on several factors, including source of insulin, concentration of insulin, additives to the insulin preparations (eg, zinc and protamine), blood flow to the area (rubbing of injection area, increased skin temperature, and exercise in muscles near the injection site may enhance absorption), and injection site. The absorption of regular and NPH insulin is most rapid from abdominal fat, slower from posterior upper arms and lateral thigh area, and slowest from superior buttocks area. The abdomen provides the most consistent absorption for insulin. Insulin analogs appear to retain their kinetic profile at all sites of injection. U-500 regular insulin has an onset similar to U-100 regular insulin, but a delayed peak and a longer duration of action when compared to U-100 regular insulin. The pharmacokinetic profile of U-500 is more similar to NPH. NPH insulin is a suspension. Variability in the absorption and dose due to improper mixing of the

suspension by the patient or healthcare provider prior to administration can lead to a labile glucose response. NPH insulin and all suspension based insulin preparations should be inverted or rolled gently at least 20 times to fully suspend the insulin prior to each use. Detemir at low doses (less than 0.3 units/kg) should be dosed twice daily, whereas insulin glargine and insulin degludec are dosed daily. Technosphere insulin is a dry powder of human recombinant DNA regular insulin which is inhaled and absorbed through pulmonary tissue. Inhaled insulin has rapid absorption into the blood stream and reaches maximum concentrations in 12 to 15 minutes. The bioavailability is 21% to 30% compared to regular subcutaneous insulin. Patients with asthma, COPD, and smokers should not use technosphere insulin. There is also a higher risk of provoking bronchospasm with technosphere insulin.

TABLE 74-8 Pharmacokinetics of Select Insulins Administered Subcutaneously

Type of Insulin	Onset (Hours)	Peak (Hours)	Duration (Hours)	Maximum Duration (Hours)	Appearance
Rapid acting					
Aspart	15-30 min	1-2	3-5	5-6	Clear
Lispro	15-30 min	1-2	3-4	4-6	Clear
Glulisine	15-30 min	1-2	3-4	5-6	Clear
Technosphere[a]	5-10 min	0.75-1	~3	~3	Powder
Short-acting					
Regular	0.5-1.0	2-3	4-6	6-8	Clear
Intermediate acting					
NPH	2-4	4-8	8-12	14-18	Cloudy
Long acting					
Detemir	~2 hours	—[b]	14-24	20-24	Clear
Glargine (U-100)	~2-3 hours	—[b]	22-24	24	Clear
Degludec	~2 hours	—[b]	30-36	36	Clear
Glargine (U-300)	~2 hours	—[b]	24-30	30	Clear

[a]Technosphere insulin is inhaled.

[b]Glargine is considered "flat" though there may be a slight peak in effect at 8-12 hours, and with detemir at ~8 hours, but both have exhibited peak effects during comparative testing, and these peak effects may necessitate changing therapy in a minority of type 1 DM patients. Degludec and U-300 insulin glargine appears to have less peak effect compared to U-100 insulin glargine.

The half-life of an IV injection of regular insulin is about 9 minutes. Changes in the IV insulin infusion rates will reach steady state in approximately 45 minutes. The pharmacokinetics of other soluble insulin preparations (lispro, aspart, glulisine, and glargine) given intravenously are similar to IV regular insulin. Thus they have no advantages over IV regular insulin but they are more expensive.

Insulin is degraded in the liver, muscle, and kidney. Liver deactivation is 20% to 50% in a single passage through the liver. Approximately 15% to 20% of insulin metabolism occurs in the kidney. This may explain the lower insulin dosage requirements and longer duration of activity observed in patients with endstage renal disease.

The connection between high insulin levels (hyperinsulinemia), insulin resistance, and cardiovascular events incorrectly leads some clinicians to believe that insulin therapy may cause macrovascular complications. Endogenous hyperinsulinemia in the setting of insulin resistance has been linked to increased cardiovascular events. However, hyperinsulinemia due to exogenous insulin use did not increase the risk of adverse macrovascular outcomes in the UKPDS or DCCT studies. Nor did basal insulin use in the Outcome Reduction with Initial Glargine Intervention trial increase cardiovascular risk.[50]

The most common adverse effects reported with insulin are hypoglycemia and weight gain. Hypoglycemia is more common in patients on intensive insulin therapy regimens. Patients with type 1 DM experience more hypoglycemic events when compared to type 2 DM patients who use insulin. In the UKPDS study, performed over 10 years in patients with type 2 DM, the percentage of patients that needed third party assistance due to a severe hypoglycemic reaction was 2.3%. In the DCCT study which enrolled patients with type 1 DM, tighter control increased the risk of severe hypoglycemia threefold when compared to conventional therapy. Moreover, insulin use is associated with an increased risk of hospitalizations in older adults based on public health surveillance data.[51]

Minimizing the risk of hypoglycemia for patients using insulin should include education about the signs and symptoms of hypoglycemia (tachycardia, tremulousness, and often, sweating), proper treatment of hypoglycemia, and blood glucose monitoring. Patient with neuroglycopenic symptoms may experience confusion, agitation, and eventually a loss of consciousness which may progress to coma. SMBG is essential for those on insulin, and is particularly important in patients with hypoglycemia unawareness. Patients with hypoglycemia unawareness should temporarily raise their glycemic goals and check their blood glucose level prior to any activities that require them to be alert and oriented (eg, driving and certain sports). Treatment of hypoglycemia dictates ingestion of carbohydrates. Glucose is preferred. If the patient is unconscious, IV glucose or glucagon injection should be given. Glucagon increases glycogenolysis in the liver and may be given in any situation in which IV glucose cannot be rapidly administered. A glucagon kit should be prescribed and readily available to all patients on insulin who have a history of severe hypoglycemia or at high risk for such events. Family and close friends of the patient should be educated regarding the reconstitution and injection of glucagon. It can take 10 to 15 minutes for the injection to start raising glucose levels and patients often vomit. It is important to position the patient on the side with the head tilted slightly downward to avoid aspiration.

Weight gain predominantly occurs in truncal fat and is dose dependent. Weight gain is undesirable in most type 2 DM patients, but may beneficial in underweight patients with type 1 DM. Weight gain can be minimized using physiologic insulin replacement strategies or combining insulin therapy with other medications that mitigate weight gain or promote weight loss (eg, metformin and GLP-1 receptor agonists).

The most common pulmonary adverse effect in patients receiving technosphere inhaled insulin was cough and upper respiratory infections. Technosphere insulin use in COPD and asthma is contraindicated due to bronchospasm risk. Technosphere insulin use has been associated with a small decline in pulmonary function. Specifically, the forced expiratory volume in 1 second declined by approximately 40 mL in clinical trials. This effect appears to be reversible after drug discontinuation. Technosphere insulin patients should have spirometry tests performed at baseline, 6 months, and annually thereafter. If a 20% reduction or greater in forced expiratory volume in 1 second is observed, technosphere insulin should be discontinued.

While much less common today in people using insulin, two forms of lipodystrophy still occur. Lipohypertrophy is caused by repeated injections into the same injection site. Due to insulin's anabolic actions, fat accumulates at the injection site and absorption at this site becomes variable. Lipoatrophy, in contrast, is due to insulin antibodies or allergic type-reactions that destroy the fat at the site of injection. Routinely rotating injection sites prevents these problems from developing and, when a lipodystrophy is detected, its use as an injection site should be avoided.

Several large studies using administrative data found an association between insulin glargine and cancer.[52] However, several other large database studies and meta-analysis have shown no such association. These conflicting results are likely due to patient selection. *In vivo* a metabolite of glargine is mostly present which has similar affinity for IGF-1 as regular insulin. In addition, the prospective, randomized Outcome Reduction with Initial Glargine Intervention trial reported no difference in cancer risk or cardiovascular events with low dose insulin glargine use over approximately 6 years.[50]

There are no significant drug-drug interactions with insulin but other medications may affect glucose control. Detemir theoretically could have albumin binding site interactions, but it occupies a very small percentage of total albumin binding sites. **Table 74-9** lists common medications known to alter BG.

TABLE 74-9 Medications That May Affect Glycemic Control[a]

Drug	Effect on Glucose	Mechanism/Comment
ACE inhibitors	Slight reduction	Improves insulin sensitivity
Alcohol	Reduction	Reduces hepatic glucose production
α-Interferon	Increase	Decreases insulin sensitivity/induces counterregulatory hormones
Atypical antipsychotics	Increase	Decrease insulin sensitivity; weight gain
Calcineurin inhibitors	Increase	Decrease insulin secretion
Diazoxide	Increase	Decreases insulin secretion, decreases peripheral glucose use
Diuretics (thiazides)	Increase	May increase insulin resistance and/or decrease insulin secretion, K^+ change may be in part responsible
Glucocorticoids	Increase	Impairs insulin action
Fluoroquinolones	Increase/Decrease	Unclear, potential drug interaction with sulfonylureas or change in insulin secretion
Nicotinic acid	Increase	Impairs insulin action, increases insulin resistance
Oral contraceptives	Increase	Unclear
Pentamidine	Decrease, then increase	Toxic to β-cells; initial release of stored insulin, then depletion
Phenytoin	Increase	Decreases insulin secretion
Protease inhibitors (PI)	Increase	Worsen insulin resistance/decreases 1st phase insulin release or increases lipotoxicity. Dependent on PI
β-Blockers	May increase	Decreases insulin secretion
Ranolazine	Decrease	Improves oxidative glucose disposal
Salicylates	Decrease	Inhibition of I-κ-B kinase-β (IKK-beta) (only high doses, eg, 4-6 g/day)
Sympathomimetics	Slight increase	Increased glycogenolysis and gluconeogenesis

[a]This list is not inclusive of all medications reported to cause glucose changes.

The dose of insulin must be individualized. In type 1 DM, the average daily requirement for insulin is 0.5 to 0.6 units/kg, with approximately 50% being delivered as basal insulin, and the remaining 50% dedicated to meal coverage. During the honeymoon phase, it may fall to 0.1 to 0.4 units/kg. During acute illness or with ketosis or states of relative insulin resistance, the need for higher dosages is common. In type 2 DM, a higher dosage is required for those patients with significant insulin resistance. Dosages vary widely depending on degree of insulin resistance and concomitant antihyperglycemic medication use. Patients initiating inhaled insulin and are insulin naïve should start with 4 units (4 unit cartridge) before each meal. Patients transitioning from a premixed formulation of subcutaneous insulin that includes both rapid-acting and intermediate or long-acting insulin should start with a dose that is 50% of the patient's previous total daily dose, divided across 3 meals.

U-500 regular insulin is reserved for use in patients with extreme insulin resistance. It is most often given two or three times a day. It is recommended to prescribe U-500 regular in a pen device. Extreme caution to avoid errors must be exercised when prescribing and dispensing U-500 regular in a vial. The prescription of U-500 should be written to include both the number of units and the volume (mL). For safety reasons, the dose should be administered using a tuberculin syringe. In an individual prescribed 120 units three times a day before meals, this prescription would be written as follows: "U-500 regular insulin inject 120 units (0.24 mL) subcutaneously three times daily before meals." The markings of one unit of a U-100 insulin syringe equals 5 units of U-500 regular. If an insulin syringe must be used, the same prescription as described above would be written as follows: "U-500 regular insulin: inject 120 units (24 units as measured by the unit markings of a U-100 syringe) subcutaneously three times daily before meals."

Table 74-7 outlines manufacturer-recommended expiration dates for insulin products when stored at room temperature (59-86°F [15-30°C]). For financial reasons, patients may attempt to use insulin preparations longer than the expiration dates. Careful attention must be paid to monitoring for deterioration of glycemic control and signs of clumping, precipitates, and discoloration in the insulin vial or pen cartridge.

Biguanides

Metformin is the only biguanide available in the United States[19,23,53,54]. Metformin enhances insulin sensitivity in the liver and to a lesser degree in peripheral (muscle) tissues. This allows for an increased uptake of glucose into these insulin-sensitive tissues. All the mechanisms of how metformin accomplishes glucose reduction are still being investigated, though adenosine 5′-monophosphate–activated protein kinase activity, tyrosine kinase activity enhancement, increased adenosine 5′-monophosphate, and partial inhibition of the mitochondrial respiratory chain are involved. Metformin may also reduce glucagon dependent glucose release from the liver. Metformin has no direct effect on the β-cell, but insulin concentrations are reduced due to improved insulin sensitivity.

Metformin is often the drug of choice in patients with type 2 DM due to its efficacy, low cost, positive pleiotropic effects, and manageable side effect profile. Metformin consistently reduces HbA_{Ic} levels by 1.5% to 2.0% (0.015-0.02; 16-22 mmol/mol Hb) and FPG levels by 60 to 80 mg/dL (3.3-4.4 mmol/L) in drug naïve patients with A_{1C} values approximately 9% (approximately 0.09; approximately 75 mmol/mol Hb), and can reduce FPG levels when they are extremely high (more than 300 mg/dL [more than 16.7 mmol/L]). Metformin may be useful in overweight or obese patients, causing a modest (2-3 kg) weight loss. Metformin also has positive effects on several components of the insulin resistance syndrome. Metformin decreases plasma triglycerides and low-density lipoprotein cholesterol (LDL-C) by approximately 8% to 15%, and modestly increases high-density lipoprotein cholesterol (HDL-C) (2%). Metformin reduces levels of PAI-1. Meta-analysis has shown that metformin may also lower the risk of pancreatic, colon, and breast cancer in type 2 DM patients.

The durability of A_{1C} reduction is fair—many patients will require additional antihyperglycemic therapy within 5 years. Early combination therapy, especially with medications that have a low risk of hypoglycemia, is recommended if the HbA_{1C} is > 8.5%. Metformin can be added to any other antihyperglycemic therapy, and is often continued when insulin therapy is initiated. This reduces the insulin dose requirements as well as the risk of hypoglycemia.

Metformin reduced macrovascular complications in obese subjects in the UKPDS.[30] Metformin significantly reduced all-cause mortality and risk of stroke versus intensive treatment with sulfonylureas or insulin. Metformin also reduced diabetes-related death and myocardial infarctions versus the conventional treatment arm of the UKPDS. Metformin causes gastrointestinal side effects, including abdominal discomfort, stomach upset, and/or diarrhea in approximately 30% of patients. These side effects are usually mild in nature and can be minimized with slow dose titration. Gastrointestinal side effects tend to be transient, lessening in severity over several weeks. Patients should take metformin with or immediately after meals. When initiating therapy, it is important to use a dose that is unlikely to cause gastrointestinal symptoms, typically 500 mg given with the largest meal. The dose is then increased in 500 mg increments over several weeks. Approximately 5% to 10% of patients cannot tolerate metformin despite the slow dose titration. Extended-release metformin may lessen some of the GI side effects.

The target dose for metformin is 1,000 mg BID or 2,000 mg daily if the extended release product is used. The minimal effective dose of metformin is 1,000 mg/day (**Table 74-10**). Approximately 80% of the glycemic-lowering effect may be seen at 1,500 mg daily.

TABLE 74-10 Oral Agents for the Treatment of Type 2 Diabetes Mellitus

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
Sulfonylureas							
							Hypoglycemia: half-life directly related to risk of hypoglycemia. Longer half-life gives higher risk Hypoglycemia may be prolonged by alcohol intake
						Metabolized in liver; metabolite potency equal to parent compound; renally eliminated	Renal insufficiency, hepatic impairment, or elderly—start low dose
Acetohexamide (Y)	Dymelor		250	125-250	1,500	First-generation sulfonylureas, which bind to proteins ionically, are more likely to cause drug–drug interactions than second-generation sulfonylureas, which bind nonionically. Drugs that are inducers or inhibitors of CYP450 2C9 should be monitored carefully when used with a sulfonylurea[50]	Chlorpropamide should not be used in renal insufficiency or the elderly Hyponatremia—chlorpropamide and tolbutamide—especially at high doses Risk factors: >60 years old, female, on thiazide diuretics Weight gain: 1-2 kg Disulfiram reactions: reported with tolbutamide and chlorpropamide in patients consuming

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
							alcohol
Chlorpropamide (Y)	Diabinese	250/day	250	100	500	Metabolized in liver; also excreted unchanged renally	
Tolazamide (Y)	Tolinase	250/day	100-250	100	1,000	Metabolized in liver; metabolite less active than parent compound; renally eliminated	
Tolbutamide (Y)	Orinase	500-1,000 BID	1,000-2,000	500-1,000	3,000	Metabolized in liver to inactive metabolites that are renally excreted	
Glipizide (Y)	Glucotrol	5-10/day	5	2.5-5	40	Metabolized in liver to inactive metabolites. ALL: CYP2C9 strong inhibitors	Hypoglycemia: half-life directly related to risk of hypoglycemia. Longer half-life gives higher risk Renal insufficiency, hepatic impairment, or elderly—start low dose Weight gain: 1-2 kg Do Not use in LADA patients, may hasten need for insulin therapy
Glipizide (Y)	Glucotrol XL	5-10/day	5	2.5-5	20	Slow-release form; do not cut tablet	
Glyburide (Y)	DiaBeta Micronase	5-10/day	5	1.25-2.5	20	Metabolized in liver; elimination 1/2 renal, 1/2 feces. Two active metabolites. Low dose in renal insufficiency	
Glyburide, micronized (Y)	Glynase	6/day	3	1.5-3	12	Better absorption from micronized preparation	
Glimepiride (Y)	Amaryl	4/day	1-2	0.5-1	8	Metabolized in liver to inactive metabolites. Start lower dose in renal insufficiency	

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
Glinides							
Nateglinide (Y)	Starlix	120 with meals	120 with meals	120 with meals	120 mg 3 times a day	Rapidly absorbed and short half-life (1-1.5 hours) Nateglinide is predominantly metabolized by CYP2C9 (70%) and CYP3A4 (30%) to less active metabolites. Glucuronide conjugation then allows rapid renal elimination. No dosage adjustment is needed in moderate to severe renal insufficiency Caution with gemfibrozil with trimethoprim —Increased and prolonged hypoglycemic reactions are possible and have been documented	Dose is 120 mg with significant meals. (0-30 minutes prior). 60 mg dose has little efficacy Weight gain of 2-3 kg has been noted with repaglinide, whereas weight gain with nateglinide appears to be <1 kg
Repaglinide (Y)	Prandin	2-4 with meals	0.5-1 with meals	0.5-1 with meals	16	Repaglinide is highly protein bound, and is mainly metabolized by oxidative metabolism and glucuronidation. The CYP3A4 and 2C8 system is involved with metabolism Moderate to severe renal insufficiency does not affect repaglinide, but moderate to severe hepatic impairment may	Repaglinide—may adjust dose based on size of carbohydrate in meal. Hypoglycemia is the main side effect. Consider starting a lower dose of repaglinide
Biguanides							
Metformin (Y)	Glucophage	2 g/day	500 mg twice a day	Assess renal function	2,550	Metformin is not metabolized and does not bind to plasma proteins. Metformin is eliminated by renal tubular secretion and	

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
						glomerular filtration. Half-life of plasma metformin is 6 hours, but red blood cells are a second compartment of distribution for metformin, delivering an effective half-life of 17 hours. The main depot of metformin is in the splanchnic tissue, specifically the large intestine Cimetidine competes for renal tubular secretion May increase metformin levels	
Metformin ER (Y)	Glucophage XR	Sam as above	500-1,000 mg with evening meal	Assess renal function	2,550		Take full dose with evening meal or may split dose; may consider trial if intolerant to immediate release
Metformin solution	Riomet	Same as above	500 mg daily	Assess renal function	2,000		Metformin is indicated in >10 years olds
Thiazolidinediones							
Pioglitazone (Y)	Actos	15-30/day	15	15	45	Pioglitazone is primarily metabolized by CYP2C8, a lesser extent by CYP3A4 (17%), and by hydroxylation/oxidation. The majority of pioglitazone is eliminated in the feces with 15%-30% appearing in urine as metabolites. Two active metabolites (M-III and M-IV) are present which have longer half-lives than	Fluid retention effects: Peripheral edema, fluid overload, dilutional anemia, worsening macular edema, contribute to weight gain Weight gain: can be substantial in some patients —average is 1-4

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
							kg- in general ½ is fluid, but other half is increase in fat Contraindicated in New York Heart Association Class 3 and 4 heart failure
						parent compound No dosage adjustment in moderate to severe renal disease, though edema must be monitored Pioglitazone dose is recommended to be limited to 15 mg daily in combination with gemfibrozil	Fractures of distal extremities in postmenopausal women—fracture of wrists, fingers, ankles and toes may occur Bladder cancer: excess of 3 in 10,000 patient-year (from 7 to 10 in 10,000) risk of bladder cancer with pioglitazone at 5 years. Eight and ten year data showed no association Anovulatory women may resume ovulation if caused by insulin resistances
Rosiglitazone (N)	Avandia	2-4/day	2-4	2	8 mg/day or 4 mg twice a day	Rosiglitazone is metabolized by CYP2C8, and to a lesser extent by CYP2C9, and also by *N*-demethylation and hydroxylation. Two-thirds is found in urine and one-third in feces	

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
						Highly (>99%) bound to albumin No dosage adjustment in moderate to severe renal disease, though edema must be monitored	
α-Glucosidase inhibitors							
Acarbose (Y)	Precose	50 with meals	25 mg 1-3 times a day	25 mg 1-3 times a day	25-100 mg 3 times a day	Acarbose-Metabolites absorbed and eliminated in bile. Slow titration key for tolerability. With meals Miglitol—Eliminated renally after absorption	Start 25 mg at one meal—preferably a low carbohydrate meal, increase dose as tolerated Only effective in complex carbohydrate diets Based on early, reversible ALT elevations, acarbose maximum dose of 50 mg 3 times a day for patients ≤60 kg or 100 mg 3 times a day for patients >60 kg Gastrointenstinal-urgency, diarrhea, flatulence, bloating, abdominal discomfort If hypoglycemia within 2 hours of ingestion—use glucose of high amounts of fructose —complex

							carbohydrate absorption will be delayed
Miglitol (Y)	Glyset	50 with meals	25 mg 1-3 times a day	25 mg 1-3 times a day	25-100 mg 3 times a day		
Sodium Glucose Cotransporter-2 inhibitors							
Canagliflozin (N)	Ivokana	300/day	100-300 mg daily	100 mg daily	300 mg daily	Renal dosing—see text Glucuronidated into two inactive metabolites Systemic exposure to canagliflozin is increased in patients with renal impairment; however, the efficacy is reduced in patients with renal impairment due to the reduced filtered glucose load Canagliflozin—weak P-glycoprotein inhibitor—digoxin levels may need to be monitored. Rifampin—UGT inducer—significantly reduces canagliflozin levels. Use alternative drug	Adverse Effects Apply for the Class: Genital urinary infections—more common in women and men Women with recurrent history at highest risk Postural hypotension can occur due to the potential glucose-induced diuresis and hypovolemia If the patient is on loop diuretics, reduction or discontinuation will be necessary. Thiazide diuretics usually do not need adjustment unless on high doses for diuresis. Reduction in antihypertensives, if blood pressure is normal, may be necessary Rare cases of euglycemic

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
							diabetic ketoacidosis have been reported. Caution in severe, acute illness, in first 2 weeks of therapy, and in LADA or type 1 DM use, which is currently off-label
Dapagliflozin (N)	Farxiga	5/day	2.5-5 mg daily	2.5 mg daily	5 mg daily	Renal dosing—see text Dapagliflozin is highly protein bound (>90%) and only 2% is cleared by the kidneys. It is mostly glucuronidated by UGT in the liver to both an inactive (majority) and active (<1%) metabolites. The active metabolite is not produced in dapagliflozin doses below 50 mg	
Empagliflozin (N)	Jardiance	25/day	10-25 mg daily	10 mg daily	25 mg daily	Renal dosing—see text Empagliflozin is mostly glucuronidated Rifampin—UGT inducer significantly reduces empagliflozin levels—use alternative drug[59]	
Dipeptidyl Peptidase-4 inhibitors							
Sitagliptin (N)	Januvia	100/day	100 mg daily	25-100 mg daily based on renal function	100 mg daily	50 mg daily if estimated creatinine clearance >30 to <50 mL/min (>0.5 to <0.83 mL/s); 25 mg if creatinine clearance <30 mL/min (<0.5 mL/s) Sitagliptin is metabolized approximately 20% by	Overall well tolerated medications Most common side effects include: Headache

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
							Nasopharyngitis Upper respiratory infection Urticaria/rash /facial edema—1% Rare cases of Stevens-Johnson syndrome have been reported Severe joint pain has also very rarely been reported. The mechanism is currently unknown
						CYP450 3A4 with some CYP450 2C8 Neither an inhibitor nor inducer, but is a p-glycoprotein substrate, but had negligible effects on digoxin and cyclosporine A, increasing the AUC by only 30%	Saxagliptin: Small reduction in absolute lymphocyte count (0.5%-1.5%). If prolonged infection is noted—consider stopping the medication[52] Saxagliptin and alogliptin: Increased risk of heart failure on package insert
Saxagliptin (N)	Onglyza	5/day	5 mg daily	2.5-5 mg daily based on renal function	5 mg daily	2.5 mg daily if creatinine clearance <50 mL/min (<0.83 mL/s) or if on strong inhibitors of CYP3A4/5 1 active metabolite 5 hydroxy saxagliptin—½ as potent as saxagliptin

			Nonelderly	*Elderly*			
						Metabolism by CYP3A4 and strong inhibitors/inducers will affect levels Saxagliptin is a substrate for p-glycoprotein substrate, but is neither an inhibitor nor inducer. Rifampin, an inducer, can decrease active levels by 50%	
Linagliptin (N)	Tradjenta	5/day	5 mg daily	5 mg daily	5 mg daily	Not substantially eliminated by renal, found in feces. Do not use with strong inducer of CYP3A4/p-glycoprotein Excreted unchanged, mostly through bile. Renal excretion less than 5% Linagliptin is a weak to moderate inhibitor of CYP3A4, and a substrate for p-glycoprotein	
Alogliptin (N)	Nesina	25 mg/day	25 mg daily	25 mg	25 mg	12.5 mg CrCl <60 mL/min (<1 mL/s), 6.25 mg <30 mL-15 mL/min (<0.5-0.25 mL/s) ~75% eliminated unchanged in urine No significant drug–drug interactions	
Bile Acid Sequestrants							
Colesevelam (N)	Welchol	3.75 g/day	6 tablets daily or 3 tablets BID 1.875 g BID or 3.75 g daily	6 tablets daily or 3 tablets BID 1.875 g BID or 3.75 g	3.75 g/day	Colesevelam binds bile in the gut Absorption drug–drug interactions: levothyroxine, glyburide, and oral contraceptives	Dosing-six 625-mg tablets daily (total dose/day = 3.75 g), may be split into 3 tablets 2 times a day if desired or 3.75-g

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
						Phenytoin, warfarin, digoxin, and fat-soluble vitamins(A, E, D, K) have postmarketing reports of altered absorption. Any fat soluble drug may be affected	oral suspension packet, dosed daily, or a 1.875-g oral suspension packet dose twice daily
				daily		Medications suspected of an interaction should be moved at least 4 hours prior to dosing the colesvelam	Not recommended if triglycerides are ? 300 mg/dL (3.39 mmol/L)
Dopamine Agonist							
Bromocriptine mesylate (N)	Cycloset	3.2-4/day	1.6-4.8 mg daily	1.6-4.8 mg daily	4.8 mg daily	Bromocriptine is a quick release formulation Bioavailability may be increased ~50% if given with a meal. Peak plasma concentration is about 1 hour if taken without food, but with food it is 90-120 minutes Only ~7% reaches the systemic circulation due to gastrointestinal-based metabolism and first-pass metabolism Bromocriptine is extensively metabolized by the CYP3A4 pathway, and the majority (~95%) is excreted in the bile. The half-life is approximately 6 hours. Plasma exposure is increased in females by approximately 18%-30%, but no dosage adjustment is currently recommended Drug–drug interactions: Bromocriptine is	Bromocriptine is dosed with 0.8-mg tablets administered within 2 hours of waking from sleep daily with food. From 0.8 mg daily, the dose may be increased weekly based on response and side effects by 0.8-mg tablet increments, to a maximum of 4.8 mg daily (0.8 mg × 6 tablets) If miss window to administer in AM, skip dose. Nausea, vomiting, fatigue, headache, and dizziness, asthenia, dizziness, constipation, and constipation were all common side effects. 24% of

Drug Name (Generic Version Available? Y = yes, N = no)	Brand Name	Usual Dose (mg)	Recommended Starting Dosage (mg/day)		Maximal Dose (mg/day)	Pharmacokinetics/Drug Interactions	Major Adverse Events
			Nonelderly	*Elderly*			
						extensively metabolized by CYP3A4 and strong inhibitors or inducers may change bromocriptine levels. As bromocriptine is highly protein bound, it may increase the unbound fraction of other highly protein bound drugs Drug-disease interactions: Antipsychotics and psychotic disorders as they decrease dopamine activity, atypical antipsychotics, as they may decrease the effectiveness of bromocriptine, and ergot-based therapy for migraines as bromocriptine may increase migraine and ergot related nausea and vomiting Sympathomimetic drugs: case reports of hypertension and tachycardia when administered together	patients eventually stopped therapy—most side effects "reappear" for a few days when the dose is increased Risk of orthostatic hypotension: blood pressure and symptoms of orthostasis should be closely monitored Somnolence can occur in about 5% of patients as well—caution with activities/driving

Metallic taste, due to metformin in salivary secretions and hypoglycemia during intense exercise, has been documented. Metformin may cause vitamin B_{12} deficiency and B_{12} levels or methylmalonic acid should be measured if a deficiency is suspected. Peripheral neuropathy, a microvascular complication that is common in diabetes, could manifest or worsen with B_{12} deficiency. Vitamin B_{12} supplementation by sublingual, oral, or injection easily treats this deficiency.

Metformin partially blocks the mitochondrial respiratory chain, and has been associated with lactic acidosis. The risk of developing lactic acidosis with metformin use appears to be exceedingly small but moderate to severe renal insufficiency increases metformin serum concentrations and lactic acid production. Any disease state that increases lactic acid production or decreases lactic acid removal may predispose the patient to developing lactic acidosis. Tissue hypoperfusion states such as congestive heart failure, severe lung disease, shock, or septicemia, as well as severe liver disease or chronic alcohol abuse, all increase the risk of lactic acidosis. The clinical presentation of lactic acidosis is

often nonspecific flu-like symptoms. The diagnosis is therefore made by laboratory confirmation of high lactic acid levels and acidosis.

Metformin is renally excreted and secreted and accumulates in patients with renal insufficiency. FDA product labeling for metformin in renal insufficiency has recently changed. Many organizations around the world, including the ADA, recommend that safe metformin use should be based on the patient's eGFR, rather than strict serum creatinine cut offs. When the eGFR is < 60 monitor renal function every 3 to 6 months, < 45 but ≥ 30 limit the dose to 50% of maximal dose and monitor renal function closely, and when eGFR < 30 mL/min/1.73 m^2 stop metformin.[54] Due to the risk of acute renal failure when IV contrast dye is used during imaging procedures, metformin therapy should be withheld starting the day of the procedure and resumed 2 to 3 days later, if normal renal function has been documented. It need not be withheld for days prior to the procedure.

Caution should be exercised in patients with hepatic impairment, which is poorly defined. It is unclear when lactic acid metabolism is impaired in liver dysfunction, but metabolism is normal at least until severe liver dysfunction. Most clinicians will inappropriately stop metformin with mildly elevated liver transaminases but it is reasonable to stop metformin when tests of liver function are affected such as bilirubin or the prothrombin time, or when liver transaminases are 5 to 10 times normal. Metformin use without lactic acidosis in patients with Child-Pugh C or Model for End-Stage Liver scores sufficient to require transplant have been reported. Survival may be prolonged in patients with advanced liver disease due to prevention of hepatocellular carcinoma.

Glucagon-Like Peptide 1 Receptor Agonists

All GLP-1 receptor agonists (GLP1-RAs) enhance insulin secretion in a glucose-dependent manner, suppress inappropriately high postprandial glucagon secretion resulting in decreased hepatic glucose production, increase satiety, slow gastric emptying, and promote weight loss[19,23,53,54,55,56]. All GLP1-RAs result in pharmacologic levels of GLP-1 activity, which results in the gastric emptying effect, weight loss, and additional insulin/glucagon effect.

The average HbA_{Ic} reduction observed with GLP1-RAs receptor agonists depend on baseline glycemic control and the product used. Once weekly extended release exenatide resulted in significantly greater reductions in HbA_{1c} compared to twice daily exenatide (–1.6% vs –0.9% [–0.016 vs –0.009; –18 vs –10 mmol/mol Hb]) as well as fasting plasma glucose (–35 mg/dL vs –12 mg/dL [–1.9 vs –0.7 mmol/L]).[57] Liraglutide and dulaglutide reduce HbA_{Ic} approximately 0.4% (0.004; 4 mmol/mol Hb) greater than twice-daily exenatide. Albiglutide appeared to be slightly less effective than liraglutide.[58] Exenatide twice daily significantly decreases postprandial glucose excursions, but has only a modest effect on fasting plasma glucose values. Longer-acting GLP1-RAs lower fasting and postprandial plasma glucose levels similarly. Due to their longer half-life, they suppress glucagon overnight, which improves the fasting plasma glucose.

GLP-1 receptor agonists place in therapy is unclear. The ADA and AACE/ACE guidelines both recommend GLP1-RAs as second-line therapy. AACE/ACE emphasizes it as a drug that should be used in most patients as a second or third line drug. In contrast, ADA places it as a second-line drug, but does not emphasize it over other second-line medication choices. It is logical to use a GLP1-RA instead of basal insulin if the A_{1C} is less than 9% (0.09; 75 mmol/mol Hb), the patient is overweight or obese, and is not symptomatic from hyperglycemia.

These factors and favorable effects of long-term β-cell function lead many diabetologists to frequently use this class. Often cited issues are management of side effects, perceived risk of pancreatitis, injection device issues, and clinician comfort with basal insulin. GLP1-RAs increase satiety. The average weight loss with twice daily exenatide observed in clinical trials was 1 to 2 kg over 30 weeks without dietary advice being given to patients. Long-term, open-label follow-up studies of exenatide therapy show continued and sustained weight loss over 3 years. Exenatide extended release has similar weight reduction. Liraglutide produced slightly more weight loss than exenatide formulations in clinical trials. Albiglutide and dulaglutide resulted in less weight loss relative to other GLP1-RAs. It has been speculated this may be due to their molecular size, which may penetrate the CNS less efficiently.

Lixisenatide, approved in Europe, reported no cardiovascular benefit in a cardiovascular secondary prevention trial.

There was no significant reduction in myocardial infarction, stroke, heart failure, or death.[59] Liraglutide was used in a large cardiovascular trial and reported positive results.

The most common adverse effects associated with GLP1-RAs are gastrointestinal. Adverse effects appear to be dose-related with all GLP1-RAs, so dose titration is recommended. Gastrointestinal adverse effects appear to decrease over time, though the incidence among agents will differ slightly. Withdraw rates in clinical trials of twice daily exenatide or liraglutide were 5% to 10%. Discontinuation rates due to GI side effects with the longer-acting GLP1-RAs were 2% to 5%.

The nausea produced by the GLP1-RA is directly linked to their effect on gastric emptying. Tachyphylaxis occurs over time to this effect in most patients. Long-acting preparations tend to have less impact on gastric emptying, and thus a slightly lower risk of nausea, compared to twice daily exenatide. Patients should be instructed to eat slowly and stop eating when satiated otherwise nausea may worsen or cause vomiting. GLP1-RAs enhance insulin secretion in a glucose-dependent manner, thus hypoglycemia is uncommon when combined with metformin, DPP-4 inhibitors, SGLT2 inhibitors, or a TZD. However, when combined with a sulfonylurea or insulin, hypoglycemia may occur.

Antibody formation to GLP1-RAs may occur. Antibodies not reduce efficacy or increase side effects with most GLP1-Ras; however, neutralizing antibodies may attenuate the glycemic lowering effects of exenatide extended release in up to 6% of patients. Local injection site reactions were also more common in antibody positive patients. Hypersensitivity reactions, including anaphylaxis and angioedema, have been reported with most GLP1-RAs.

GLP-1 receptor agonist has been associated with cases of acute pancreatitis, but no causal relationship has been established. While additional study is needed, it should be noted that (1) patients with type 2 DM are at inherently higher risk for developing pancreatitis; (2) GLP1-RAs may mask the initial signs of pancreatitis, including nausea, vomiting, and abdominal pain; and (3) large database studies have not linked GLP1-RAs use to a higher incidence of acute pancreatitis. In a patient with a history of pancreatitis, the benefits must be weighed against the potential risks. A GLP1-RA should not be used in patients with chronic pancreatitis. If a patient reports abdominal pain, nausea, and repeated vomiting, it is best to discontinue therapy temporarily and confirm that the symptoms are not a sign of a more serious underlying problem.

Longer acting GLP1-RAs are contraindicated in patients with a history of medullary thyroid carcinoma or multiple endocrine neoplasia type 2 due to a risk of medullary thyroid carcinoma. This contraindication is based on rodent model data that reported a higher risk of C-cell tumors of the thyroid. Rodents may not be the ideal model to study this effect as they express a high number of GLP-1 receptors on thyroid C-cells. The expression of GLP-1 receptors in the thyroid of humans is minimal. Rodents also have a higher baseline prevalence of C-cell tumors compared to humans. Though there have been case reports of medullary thyroid carcinoma, no increased incidence has been reported and no causality has been established. There is no contraindication in patients with a history of other types of thyroid cancers such as papillary or follicular.

The injection device for each GLP1-RA product is different and patients must be instructed how to use the product. Dosing of twice daily exenatide (Byetta) should begin with 5 mcg BID, and titrated to 10 mcg BID in 1 month or when tolerability allows and if warranted for glycemic control. Twice daily exenatide should be injected subcutaneously up to 60 minutes before the morning and evening meals. If the patient does not eat breakfast, they may take the first injection of the day at lunch. The peak effect of twice daily exenatide is at approximately 2 hours, so anecdotally the patient may get better appetite suppression if injected an hour prior to the meal. Extended release exenatide (Bydureon) is a 2 mg suspension injected subcutaneously every 7 days without regard to meals. No dose titration is needed and steady state is attained at 6 to 8 weeks after treatment initiation. Extended release exenatide requires a multistep process to mix the powder in a diluent prior to injection.

The initial dose of liraglutide is 0.6 mg daily. This is a nontherapeutic dose used to minimize side effects. Liraglutide is then increased to 1.2 mg daily when GI side effects have dissipated. Patients may be continued on the 1.2-mg dose or increased to the maximum dose of 1.8 mg daily, which may provide some additional HbA_{1c} lowering and slightly more weight loss. Dosing should not be confused with liraglutide approved for weight loss. The maximum dose

approved for weight loss is 3.0 mg daily whereas the maximum dose of 1.8 mg daily is approved for treatment of type 2 DM. Liraglutide comes in a pen device that can deliver all three doses.

Dulaglutide and albiglutide should be started at the lowest dose and increased to their maximum dose over time to improve gastrointestinal tolerability. For GLP1-RAs administered weekly, if a dose is missed it should be taken as soon as possible but not within 3 days of the next dose. If it is 3 days or less until the next dose, skip the dose and take the next dose on the regularly scheduled date. Caution should be used in moderate to severe renal impairment, as gastrointestinal side effects of all GLP1-RAs are more frequent, which can result in acute renal failure or injury.

Storage, pharmacokinetic and product information can be found in **Table 74-11**.

TABLE 74-11 Available GLP-1 Receptor Agonists and Amylinomimetics

Generic Name	Administration Options	Room Temperature[b] Expiration	Pharmacokinetics/Drug Interactions[a]	Major Adverse Events
Glucagon like peptide-1 agonists				
Exenatide (Byetta)	5 mcg and 10 mcg pen, 60 doses/pen Dosed twice daily at or before meals	30 days (≤77°F [≤25°C])	Pharmacokinetics: 53% homology to GLP-1, t_{max} ~2 hours, and duration of action 4-6 hours Drug Interactions: Caution with warfarin: May increase INR Delayed Gastric Emptying may delay absorption of medication. Move 1 hour before or at least 3 hours after injection	Nausea >35% Vomiting/diarrhea 10%, respectively Start with 5 mcg BID Expect recurrence of GI with increase in dose to10 mcg BID. Inject closer to meals to limit nausea, but maximal satiety may be achieved by injecting 1-2 hours prior to food intake Drug Class Warning: -Pancreatitis
Exenatide (Bydureon)	2 mg single use pen device, 2 mg vial with separate diluent, single-use system Dosed weekly	30 days (≤77°F [≤25°C])	Pharmacokinetics: Exenatide embedded in microspheres slowly release over 10 weeks upon injection. Levels gradually increase with each weekly injection. 6-8 weeks to steady-state Attains therapeutic levels at week 2 Drug Interactions: See exenatide	Slightly less nausea and vomiting versus twice daily exenatide Drug Class Warning: -Pancreatitis -Long-acting GLP-1 agonist-do not use in medullary thyroid CA, MEN2
Liraglutide (Victoza)	3-mL pen, Delivers 0.6 mg, 1.2 mg, or 1.8 mg dose Dosed daily	30 days	Pharmacokinetics: 97% homology to GLP-1 A C-16 fatty acid (palmitic acid) self-associates into heptamers, prolonging half-life to 13 hours T_{max} is reached 8-12 hours after	Nausea: 1.2 mg—10%-30% Nausea: 1.8 mg—15%-40% Vomiting: 5% Diarrhea: 8%-15% Stay on titration dose of 0.6 mg (nontherapeutic dose)

Generic Name	Administration Options	Room Temperature[b] Expiration	Pharmacokinetics/Drug Interactions[a]	Major Adverse Events
			injection with steady state in 3 days Drug Interactions: Delay in gastric emptying may affect absorption of other medications	daily until GI side effects dissipate. Then increase dose to 1.2 mg daily Drug Class Warning: -Pancreatitis -Long-acting GLP-1 agonist-do not use in medullary thyroid CA, MEN2
Albiglutide (Tanzeum)	30 mg and 50 mg single use pen Dosed weekly	4 weeks (≤86°F [≤30°C])	Pharmacokinetics: Recombinant fusion protein consists of two copies of a 30 amino acid sequence of a modified human GLP-1 (fragment 7-36) which is fused to human albumin. Fragment 97% homology to GLP-1, Half-life: 5 days. May not penetrate CNS Drug Interactions: Delay in Gastric Emptying may affect absorption of other medications	Nausea 9%-15% Vomiting 5%-12% Diarrhea 12% Drug Class Warning: -Pancreatitis -Long-acting GLP-1 agonist-do not use in medullary thyroid CA, MEN2
Dulaglutide (Trulicity)	0.75 mg and 1.5 mg single use pen (0.5 mL) 0.75 mg and 1.5 mg single use prefilled syringe (0.5 mL) Dosed weekly	14 days (≤86°F [≤30°C]))	Pharmacokinetics: Two identical disulfide-linked chains, each containing a modified human GLP-1 analog (90% homology to GLP-1) covalently linked to a modified human immunoglobulin G4 heavy chain fragment Half-life: 5 days Drug Interactions: Delay in Gastric Emptying may affect absorption of other medications	Nausea: 0.75 mg—8%-18% Nausea-1.5 mg—17%-28% Vomiting 3-5%, but as high as 17% with 1.5 mg dosing Diarrhea: 8%-17% Drug Class Warning: -Pancreatitis -Long-acting GLP-1 agonist-do not use in medullary thyroid CA, MEN2
Amylinomimetic				
Pramlintide (Symlin)	1.5 mL pen: delivers 15, 30, 45, or 60 mcg dose; 2.7 mL pen: delivers 60 or 120 mcg dose Dosed with each meal	30 days	Pharmacokinetics: The t_{max} is approximately 20 minutes. The $t_{1/2}$ is approximately 45 minutes, Metabolized by kidneys, One active metabolite (2-37 pramlintide) has a similar half-life as the parent compound. No accumulation seen in	Dosing: type 1 DM start at 15 mcg before meals, may increase as tolerated, most can advance dose to 30-45 mcg before meals Type 2 DM- start with 60 mcg before meals, most

Generic Name	Administration Options	Room Temperature[b] Expiration	Pharmacokinetics/Drug Interactions[a]	Major Adverse Events
				advance to 120 mcg before meals
			renal insufficiency. Injection into the arm—not recommended	Nausea: type 1 DM > type 2 DM
			Drug Interactions:	Vomiting: type 1 DM > type 2 DM
			Pramlintide may delay gastric emptying	Severe hypoglycemia possible: decrease prandial insulin 30%-50% prior to initiation

CNS, central nervous system; GI, gastrointestinal; $t_{1/2}$, half-life of medication; t_{max}, time at maximum concentration.

[a]All diabetes injectables available in the US are now made by human recombinant DNA technology. An insulin analog is a modified human insulin molecule that imparts particular pharmacokinetic advantages.

[b]Room temperature defined as 59-86°F (15-30°C). All products are good until expiration date on product if unopened and stored correctly.

Sulfonylureas

Sulfonylureas enhancement insulin secretion by binding to a specific sulfonylurea receptor (SUR1) on pancreatic β-cells[19,23,53,54]. Binding closes an adenosine triphosphate-dependent K^+ channel, leading to decreased potassium efflux and subsequent depolarization of the membrane. Voltage-dependent Ca^{+2} channels open and allow an inward flux of Ca^{+2}. Increases in intracellular Ca^{+2} bind to calmodulin on insulin secretory granules, causing translocation of secretory granules of insulin to the cell surface and resultant exocytosis of the granule of insulin. Elevated secretion of insulin from the pancreas travels via the portal vein and subsequently suppresses hepatic glucose production.

Sulfonylureas are classified as first-generation and second-generation agents. The classification schemes are based on relative potency. First-generation agents are lower in potency relative to the second-generation drugs: glimepiride, glipizide, and glyburide (see Table 74-10). When given in equipotent doses, all sulfonylureas are equally effective at lowering blood glucose. On average, HbA_{Ic} will fall 1.5% to 2% (0.015-0.02; 17-22 mmol/mol Hb) in drug-naïve patients, with fasting plasma glucose reductions of 60 to 70 mg/dL (3.3-3.9 mmol/L), but is dependent on baseline values and duration of diabetes.

Sulfonylureas are the second most prescribed oral drugs for the treatment of type 2 DM. However, their place in therapy is controversial. Based on their extensive track record of safety and effectiveness, many clinicians feel comfortable using them in patients with type 2 DM. Diabetologists often avoid using sulfonylureas and instead use DPP-4 inhibitors or SGLT2 inhibitors. The ADA[23] and AACE/ACE[54] have very different stances on sulfonylurea use. The ADA algorithm recommends sulfonylurea use equally to other second line treatments. The AACE/ACE algorithm lists sulfonylureas as an option, but only after other medications with a low risk of hypoglycemia. Soon after sulfonylureas are taken, a robust reduction in HbA_{1c} is seen, but long-term durability is poor in most patients. Sulfonylureas cause a tachyphylaxis to their insulin secretion effect on the β-cell. *In vitro* testing of β-cells has reported depolarization of the cell, resulting in its inability to secrete insulin. Whether this effect is reversible is unclear. Clinically this is recognized by the deterioration of HbA_{1c}. Sulfonylureas are low cost medications.

Sulfonylureas have been showed to reduce the microvascular complications associated with type 2 DM in several studies.[29] Whether sulfonylureas reduce or increase macrovascular events is controversial. The UKPDS reported no significant benefit or harm in newly diagnosed type 2 DM patients given sulfonylureas over 10 years. However, the University Group Diabetes Program study documented higher rates of coronary artery disease in type 2 patients given tolbutamide, when compared with patients given insulin or placebo. This study has been widely criticized. Some sulfonylureas bind to the SUR-2A receptor that is found in cardiac tissue. Binding to the SUR-2A receptor has been implicated in blocking ischemic preconditioning via K^+ channel closure in the heart. Recent meta-analyses have conflicting conclusions. One analysis found that sulfonylureas increased CVD risk and another found a reduced risk.

The most common side effect of sulfonylureas is hypoglycemia. The pretreatment fasting plasma glucose is a strong predictor of hypoglycemic potential. The lower the FPG is upon initiation, the greater likelihood for hypoglycemia. Those who skip meals, exercise vigorously, or lose substantial amounts of weight are also more prone to experiencing hypoglycemia. A lower dose should initially be used in high-risk patients, in addition, hypoglycemia on low-dose sulfonylureas may dictate a switch to therapy with a low risk of hypoglycemia. Severe hypoglycemia on sulfonylureas would warrant the same intervention.

Weight gain is common with sulfonylureas—typically 1 to 2 kg. Many patients report having a sulfa allergy, but cross reactivity with sulfonylureas is very rare. However, if the patient has a history of anaphylaxis type reactions to sulfa, it may be best to use a different class of medication.

The usual starting dose and maximum dose of sulfonylureas are summarized in Table 74-10. The dosage can be titrated as soon as every 2 weeks based on fasting plasma glucose values (use a longer interval with chlorpropamide) to achieve glycemic goals. Immediate-release glipizide's maximal dose is 40 mg/day, but its maximal effective dose is about 10 to 15 mg per day. Indeed, the maximal effective dose of sulfonylureas is typically 60% to 75% of the stated maximum dose.

Dipeptidyl Peptidase 4 Inhibitors (DPP-4 Inhibitors)

Several DPP-4 inhibitors are approved by the FDA including sitagliptin, saxagliptin, linagliptin, and alogliptin[19,23,53,54,55]. The DPP-4 inhibitors prolong the half-life of endogenously produced GLP-1 and GIP. GIP levels are normal in patients with type 2 DM and may play a role in stimulating insulin secretion. GIP has no effect on glucagon. However, levels of GLP-1 are deficient in patients with type 2 DM. As these agents block nearly 100% of the DPP-4 enzyme activity for at least 12 hours, normal physiologic, nondiabetic GLP-1 levels are achieved. DPP-4 inhibitors significantly reduce inappropriately elevated postprandial glucagon and improve β-cell response to hyperglycemia. This results in reduction of glucose levels without increase in hypoglycemia when used as monotherapy. These drugs do not alter gastric emptying and do not cause nausea or have significant effects on satiety. DPP-4 inhibitors have a neutral impact on weight.

The average reduction in HbA_{Ic} seen with a DPP-4 inhibitor is 0.7% to 1% (0.007-0.01; 8-11 mmol/mol Hb) when used at maximum doses. DPP-4 inhibitors have a shallow dose-response curve. These drugs are well tolerated, and the dose not need to be titrated. DPP-4 inhibitors may have greater glucose lowering efficacy in patients of Asian descent.[60] DPP-4 inhibitors are considered second line therapy in ADA algorithm and fourth-line therapy in the AACE/ACE though they may be used sooner if other medications have intolerances. Potential advantages of the DPP-4 inhibitors include once daily dose, oral administration, weight neutrality, low risk of hypoglycemia, and they are well tolerated. They may be used in older adults with moderate to severe renal insufficiency and with CVD. However, their ability to lower BG is modest and they are expensive.

The DPP-4 enzymes metabolize a wide variety of peptides including neuropeptide Y, growth hormone-releasing hormone, vasoactive intestinal polypeptide, and others. DPP-4 plays an important role for T-cell activation. Theoretically the inhibition of DPP-4 could be associated with adverse immunologic reactions. To date, however, there has been no evidence of clinically relevant changes in immune function.[61] Reducing the dose of alogliptin, saxagliptin, or sitagliptin, based on renal function is appropriate, as only 100% of the enzyme can be inhibited, and long-term

exposure to higher levels in humans has not been extensively studied.

Recent long-term cardiovascular outcome studies have found no increased in the risk of mortality, myocardial infarction, or other major CV events with alogliptin, saxagliptin, or sitagliptin.[62,63,64] However, the risk of hospitalization for heart failure was increased with saxagliptin and equivocal with alogliptin. A meta-analysis showed no increased risk of mortality, MI, or cerebrovascular events; however, the risk of heart failure was increased in patients treated long-term with DPP-4 inhibitors.[65] In April 2015, the US FDA advisory committee recommended making changes to labeling for both saxagliptin and alogliptin, to include information about increased risk of hospitalization for heart failure. See Table 74-10 for information about dosing DPP-4 inhibitors.

Sodium-Glucose Cotransporter-2 Inhibitors

Several SGLT2 inhibitors have been approved by the FDA including canagliflozin, dapagliflozin, and empagliflozin[19,23,53,54,66]. The reabsorption of glucose in the proximal tubule of the kidney from the filtered urine into renal tubular epithelial cells is facilitated by a family of ATP-dependent proteins, the sodium-glucose cotransporters (SGLT). By inhibiting SGLT2, the renal tubular threshold for glucose reabsorption is lowered and glucosuria occurs at lower levels of plasma glucose concentrations. SGLT2 inhibition lowers blood glucose through an insulin-independent mechanism. Although SGLT2 inhibitors block the reabsorption of 90% of the filtered glucose load, which could theoretically result in up to 170 g loss of glucose/day in the urine, urinary glucose excretion (UGE) does not exceed 75 to 85 g per day or less than 50% of the filtered glucose load. The reason for this is that SGLT1 never has to work at its maximal capacity. When presented with the excess glucose, SGLT1 can reabsorb up to 30% to 40% of the filtered glucose load. Thus, when SGLT2 is inhibited, SGLT1 instantaneously can augment its reabsorption of glucose and blunt the glucosuric effect of the SGLT2 inhibitor. Since glucose reabsorption in the proximal tubule is coupled with sodium reabsorption, SGLT2 inhibitors promote mild sodium depletion (for 1-2 days after start of therapy) and intravascular water.

The SGLT2 inhibitors reduce the HbA_{1c} by 0.5% to 1% (0.005-0.01; 5-11 mmol/mol Hb) and can be used as either monotherapy or add-on therapy. They appear to be more efficacious if the patient has higher baseline HbA_{1c} values. In addition, increased UGE leads to the loss of 200 to 300 kcal/day (840-1,260 kJ/day), which may contribute to 1 to 5 kg of weight loss. Visceral fat loss is responsible for the weight reduction rather than muscle mass loss. SGLT2 inhibitors modestly reduce SBP by 3 to 4 mm Hg and DBP by 1 to 2 mm Hg. Modest changes in lipid profiles have been described in clinical trials of SGLT2 inhibitors. SGLT2 inhibitors' are unlikely to cause hypoglycemia unless combined with medications such as sulfonylureas, meglitinides, or insulin.

Empagliflozin has demonstrated CV risk reduction in a dedicated CV outcomes trial (EMPA-REG OUTCOME).[67] Empagliflozin, when added to standard of care, reduced a composite of CV death (including fatal stroke and fatal MI) (HR 0.86, 95.02% CI 0.74-0.99), all-cause mortality (HR 0.68 95% CI 0.57-0.82) and death from CV causes (HR 0.62 95% CI 0.49-0.77) after a follow-up of 5 years. Canagliflozin (CANVAS) and dapagliflozin (DECLARE-TIMI 58) are currently being studied in CV trials with results due in 2018 and 2019, respectively.

In the ADA algorithm, the SGLT2 inhibitors are considered a second-line therapy and in the AACE/ACE algorithm as third-line treatment choice. Older adults and patients with stage 4 or 5 chronic kidney disease are not optimal candidates for SGLT2 inhibitors. Older adults typically have diminished renal function and, because they may have poor thirst response, they are predisposed to dehydration. Concomitant diuretic use may cause orthostatic hypotension and electrolyte abnormalities. Renal impairment decreases the efficacy of the SGLT2 inhibitors. As GFR declines, the amount of glucose that reaches the proximal tubule declines. SGLT2 inhibitors lower HbA_{1c} approximately 0.4% to 0.5% (0.004-0.005; 4-5 mmol/mol Hb) when GFR is 30 to 45 mL/min/1.73 m^2 (0.29-0.43 mL/s/m^2).

The mechanism of action and osmotic diuresis with SGLT inhibitors may affect several laboratory tests. LDL-C and HDL-C increase slightly with SGLT2 inhibitors. Hemoconcentration from diuresis can result in a 2% to 3% increase in

hematocrit. Urinary analysis will always be positive for glucose due to the mechanism of action. Additionally, the 1,5-anhydroglucitol (1,5-AG) assay, commonly known as Glycomark®, will give falsely lowered results, which may falsely indicate higher postprandial glycemia. Its use is not recommended during SGLT2 inhibitor therapy.

The most common adverse effect is GU infections. Yeast GU infections are most common, and there is a slight increase in urinary tract infections. GU infections occur more frequently in women and uncircumcised men, but led to discontinuation in less than 1% of patients in the clinical trials. Lowering the dose of a SGLT2 inhibitor will not decrease the risk of a GU infection. It is important to tell all patients, male and female, about the signs and symptoms of GU infections. Greater than 10% of people with diabetes will have asymptomatic bacteriuria at any given time, thus routine urinary analysis is not recommended. Pyelonephritis and urosepsis were not more common in SGLT2 inhibitors trials, but the FDA required SGLT2 inhibitors to add both risks to their labels based on postmarketing surveillance data. Symptomatic hypotension may occur more frequently in patients with an eGFR less than 60 mL/min/1.73 m^2. If the patient takes a loop diuretic, discontinuation will be necessary. If the patient has a compelling need for the loop diuretic, an alternate medication class may be necessary. Thiazide diuretics usually do not need adjustment unless on high doses for diuresis.

The SGLT2 inhibitor's mechanism is insulin independent and less likely to cause hypoglycemia unless combined with medications such as sulfonylureas, meglitinides, or insulin.

Cases of euglycemic DKA have been reported. Most cases have been in patients with type 1 diabetes, which is not a currently approved use by the FDA.[67] Risk factors include: dehydration, any insulinopenic patient including LADA, type 1 DM, or long-standing type 2 DM, or serious intercurrent illness. It is advisable to make sure the patient is well hydrated prior to treatment initiation, temporarily stop the drug if a serious illness is encountered, and to not decrease the insulin dose prospectively when it is initiated. Dapagliflozin has been associated with bladder tumors and patients with a prior or active history of bladder cancer should not use this medication. It is likely a chance finding, but surveillance continues. Canagliflozin has been associated with a 30% higher risk of bone fracture after more than 1 year usage. Canagliflozin trials enrolled an older population and these patients are at higher risk of developing orthostatic hypotension. Many of the fractures were distal fractures of the upper extremities after a fall. After 2 years of treatment, a 0.3% to 1% placebo-subtracted reduction in hip and lumbar at the hip and lumbar spine were noted on dual-energy x-ray absorptiometry. Mechanisms may involve changes in phosphorus reabsorption, increases in parathyroid hormone, or weight loss.

Canagliflozin should be initiated at 100 mg orally daily and may be titrated up to 300 mg daily. Patients with an eGFR between 45 and 60 mL/min/1.73 m^2 should receive no more than 100 mg of canagliflozin. Canagliflozin use is not recommended to start or continue therapy when the eGFR is consistently less than 45 mL/min/1.73 m^2. Dapagliflozin should be started at 5 mg daily and may be titrated to 10 mg orally daily in patients that require additional glycemic control. Renal function should be assessed and dapagliflozin should not be started or continued in patients with an eGFR consistently less than 60 mL/min/1.73 m^2. Empagliflozin may be started at 10 mg orally daily and titrated to 25 mg daily as tolerated. Therapy should not be started or it should be discontinued if patients have an eGFR consistently less than 45 mL/min/1.73 m^2 (see Table 74-10).

Clinical Controversy… Diabetes Drugs and Regulatory Approval:

Diabetes mellitus (DM) is a major risk factor for cardiovascular disease (CVD) with 65% of people with DM dying of CVD. Prior to the EMPA-REG study there was no conclusive evidence that any glucose lowering therapy decreased CVD risk or death.[67] Most drugs were developed and approved based solely on their glucose lowering ability. HbA_{1c} has been used as the principal surrogate marker of DM treatment effectiveness, primarily because reducing hyperglycemia has demonstrated benefits on DM symptoms and on the incidence of microvascular complications.[77] The degree of hyperglycemia as reflected by HbA_{1c} is correlated with the incidence and prevalence of cardiovascular complications and death.[78] However, despite lowering HbA_{1c}, rosiglitazone was associated with an increased risk of myocardial infarction and death in a 2007 meta-analysis.[69] This led to restrictions put in place by the FDA on the use

of rosiglitazone. Large, randomized clinical trials of "intensive" vs "standard" glucose control failed to demonstrate CVD benefit, further clouding the narrative that lower blood glucose using antihyperglycemic agents decrease CVD events.[34,35,36] Given the aggregate of these data that demonstrated either a neutral or increased effect on CVD events, the FDA issued a Guidance for Industry in 2008 recommending that new DM agents be assessed for CVD safety prior to approval. This approach has been criticized for its perceived increased burden to achieve approval for new drugs.[79] However, it has been noted that there has been an increase in novel DM agents over the last decade.[80] It is also important to note the invalidation of HbA_{1c} as a surrogate for CVD and the significance of investigating the CV effects of these drugs independent of their glucose lowering abilities.

Thiazolidinediones

Thiazolidinediones are also referred to as TZDs or glitazones[19,23,53,54]. Pioglitazone and rosiglitazone are the two currently FDA approved TZDs for the treatment of type 2 DM (see Table 74-10). TZDs work by binding to the peroxisome proliferator activator receptor-γ (PPAR-γ), which are primarily located on fat cells and vascular cells. The concentration of these receptors in the muscle is very low, but improvement in mitochondrial function through changes in lipotoxicity, glucotoxicity, and possibly binding of mitochondrial membrane proteins occurs. TZDs enhance insulin sensitivity at muscle, liver, and fat tissues indirectly. TZDs cause preadipocytes to differentiate into mature fat cells in subcutaneous fat stores. Small fat cells are more sensitive to insulin and more able to store FFAs. This allows a flux of FFAs out of the plasma, visceral fat, and liver into subcutaneous fat, a less insulin-resistant storage tissue. Muscle intracellular fat products, which contribute to insulin resistance, also decline. TZDs also effect adipokines (eg, angiotensinogen, tissue necrosis factor-α, interleukin 6, plasminogen activator inhibitor-1), which can positively affect insulin sensitivity, endothelial function, and inflammation. Of particular note, adiponectin is reduced with obesity and diabetes, but is increased with TZD therapy, which improves endothelial function, insulin sensitivity, and has a potent antiinflammatory effect.

Pioglitazone and rosiglitazone reduce HbA_{Ic} values approximately 1.0% to 1.5% (11-16 mmol/mol Hb) and reduce FPG levels by 60 to 70 mg/dL (3.3-3.9 mmol/L) at maximal doses. Glycemic-lowering onset is slow and maximal effects may not be seen until 3 to 4 months of therapy. It is important to inform patients of this fact and that they should not stop therapy even if minimal changes in SMBG are initially seen. Pioglitazone consistently decreases plasma triglyceride levels by 10% to 20%, whereas rosiglitazone tends to have a neutral effect. LDL-C concentrations tend to increase with rosiglitazone 5% to 15%, but do not significantly increase with pioglitazone. Both appear to convert small, dense LDL particles, which have been shown to be more atherogenic, to large, buoyant LDL particles, which may be less atherogenic. Any increase in LDL cholesterol, however, is of concern. Both drugs increase HDL, though pioglitazone may raise it more than rosiglitazone.

The ADA algorithm recommends the TZDs as a second-line treatment choice for type 2 DM. The AACE/ACE algorithm list them as a fifth line choice. Although the TZDs are very effective insulin sensitizers, they can cause edema, new onset or worsening of preexisting heart failure, and fractures. In addition, TZD use has been linked in the past to bladder cancer. Many clinicians, inappropriately, believe that the cardiovascular risk associated with rosiglitazone use also applies to pioglitazone. As all side effects with TZDs are dose related, starting with a low dose and seeing if a patient will respond is reasonable. This may be 3 to 6 months on pioglitazone 15 mg daily before a decision about efficacy is made. Low dose pioglitazone may be used when high dose insulin is necessary, though edema and weight gain must be followed carefully.

Macrovascular complications with TZDs are controversial. In the PROactive study, pioglitazone 45 mg was added to standard therapy in patients who had experienced a cardiovascular event or had peripheral vascular disease.[68] After 3 years of treatment, there was no difference in the primary endpoint but the secondary endpoint (all-cause mortality, nonfatal myocardial infarction, or stroke) was reduced 16% (P = 0.027). Pioglitazone has also been shown to decrease the risk of recurrent strokes, but this was in a nondiabetic population. Also of note, patients in the pioglitazone group were more likely to be hospitalized for heart failure, though this did not increase mortality. Several published meta-analysis of rosiglitazone reported higher myocardial infarction (MI) rates, but none have reported a higher risk

of mortality.[69] A prospective, multicenter, open-label noninferiority trial in 4,447 patients of rosiglitazone added to background metformin or sulfonylurea versus the active comparator metformin plus sulfonylurea found that rosiglitazone was noninferior to the comparator for all CV outcomes except heart failure. A nonsignificant increase in risk for MI (HR, 1.14; 95% CI, 0.80-1.63) as well as a nonsignificant reduction in stroke (HR, 0.72; 95% CI, 0.49-1.05) were reported. On subset analysis, previous ischemic heart disease trended toward a higher risk (HR, 1.26; CI, 0.95-1.68; P = 0.055).[70] Most studies with rosiglitazone trend toward, but do not reach, statistically significant increases in ischemic events.

Retention of fluid leads to several possible side effects with TZDs. The etiology of the fluid retention has not been fully elucidated, but appears to include peripheral vasodilation and improved insulin sensitization at the kidney with a resultant increase in renal sodium and water retention. Resultant effects from water retention may include peripheral edema, heart failure, hemodilution of hemoglobin and hematocrit, and weight gain. Peripheral edema is reported in 4% to 5% of patients using TZD monotherapy but the incidence of edema is significantly increased (more than 15%) when a TZD is used in combination with insulin. TZDs are contraindicated in patients with New York Heart Association Class III and IV heart failure, and great caution should be exercised when given to patients with Class I and II heart failure. Edema is dose related and if not severe, a reduction in the dose as well as use of spironolactone, triamterene, or amiloride may allow the continuation of therapy in the majority of patients. Rarely, TZDs have been reported to worsen macular edema of the eye.

Weight gain, which is also dose related, can be seen with both rosiglitazone and pioglitazone. Mechanistically, both fluid retention and fat accumulation play a part in explaining the weight gain. Average weight gain varies but a 4-kg weight gain is not uncommon. Rarely, a patient will gain large amounts of weight in a short period of time, and this may necessitate discontinuation of therapy.

Thiazolidinediones have also been associated with an increased fracture rate in the upper and lower limbs of postmenopausal women. These fractures are not osteoporotic in the classic sense, and do not occur in common osteoporosis fracture sites such as spine or hip. Most occur in wrists, forearms, ankles, or feet. TZDs may increase the risk of a fracture by 25%. The underlying pathophysiology is speculative, but may relate to TZDs effect on the pluripotent stem cell and shunting of new cells to fat instead of osteocytes as well as altering osteoblasts/osteoclasts. It would be prudent to consider a patient's risk factors for fractures if a TZD is being considered.

The risk of bladder cancer is controversial. Bladder tumors have been noted in rodent models using TZDs, which prompted a10-year observational study with pioglitazone. The study reported an excess of 3 in 10,000 patient-year risk of bladder cancer after 5 years of pioglitazone use. Eight and ten year data using the same database showed no association. Excess risk, if present, appears to be mostly in men and smokers, and is dose and duration associated. Mechanisms are speculative, but may involve microcrystals of the drug in the bladder which cause chronic irritation.

Premenopausal anovulatory patients may resume ovulation on TZDs due to their insulin sensitizing effects. Adequate pregnancy and contraception precautions should be explained to all women capable of becoming pregnant.

The recommended starting dosages of pioglitazone is 15 to 30 mg once daily and for rosiglitazone it is 2 to 4 mg once daily. Dosages may be increased after 3 to 4 months based on the response to treatment and side effects. The maximum dose and maximum effective dose of pioglitazone is 45 mg and 8 mg once daily for rosiglitazone. To minimize side effects, the lowest effective dose should be used.

α-Glucosidase Inhibitors

Currently, there are two α-glucosidase inhibitors approved by the FDA, acarbose and miglitol[19,23,53,54]. α-Glucosidase inhibitors competitively inhibit maltase, isomaltase, sucrase, and glucoamylase in the small intestine, delaying the breakdown of sucrose and complex carbohydrates. There is no malabsorption of these nutrients, but merely a delay their absorption. The net effect from this action is to reduce the postprandial blood glucose rise. Distal intestinal degradation of undigested carbohydrate by the gut flora results in gas, CO_2 and methane, as well as production of

short-chain fatty acids, which may stimulate glucagon like peptide-1 release from intestinal L-cells.

Postprandial glucose concentrations are reduced by 40 to 50 mg/dL (2.2-2.8 mmol/L) while fasting glucose levels are relatively unchanged. The overall glucose lowering effect of the α-glucosidase inhibitors in terms of HbA_{Ic} is 0.3% to 1% (0.003-0.01; 3-11 mmol/mol Hb). Patients near target HbA_{Ic} levels with near-normal fasting plasma glucose levels but high postprandial SMBG are candidates for therapy. The ADA does not list the class on their treatment algorithm, but the AACE/ACE algorithm considers them an alternative medication that can be used when other medications may be contraindicated or the patient has intolerances. Data from China have reported that acarbose is as effective as metformin in patients consuming high carbohydrate diet from mostly rice. It has also been shown to prevent type 2 DM. The STOP-NIDDM study in subjects with impaired glucose tolerance documented a significant reduction in the risk of cardiovascular events, though the total number of events were very small.[71] No large cardiovascular study confirming these preliminary results has been completed. For information about dosing α-glucosidase inhibitors see Table 74-10.

Short-Acting Insulin Secretagogues

By binding a site adjacent to sulfonylurea receptor, nateglinide and repaglinide stimulate insulin secretion from the β-cells of the pancreas[19,23,53,54]. Repaglinide and nateglinide both require the presence of glucose to stimulate insulin secretion. As glucose levels diminish to normal, stimulated insulin secretion diminishes. As monotherapy, both nateglinide and repaglinide significantly reduce postprandial glucose excursions and reduce HbA_{Ic} by approximately 0.8% to 1% (0.008-0.01; 9-11 mmol/mol Hb). This class of agents is not listed on the ADA algorithm but is consider a less favorable choice on the AACE/ACE treatment algorithm. DPP-4 inhibitors and SGLT2 inhibitors have largely taken the place of this class due to a low risk of hypoglycemia and daily dosing with similar or more robust glycemic reductions. Nateglinide or repaglinide may be used in patients with renal insufficiency, and may be a good option for those with erratic meal schedules. Multiple daily dosing may decrease adherence. For dosing and adverse reaction data see Table 74-10.

Amylinomimetics

Pramlintide is an antihyperglycemic agent used in patients currently treated with insulin[19,23,53,54]. Pramlintide is a synthetic analog of amylin, a neurohormone cosecreted from the β-cells with insulin. Amylin is very low or absent in type 1 DM, and lower than normal in patients with a long duration of type 2 DM. Pramlintide suppresses inappropriately high postprandial glucagon secretion, increases satiety, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition.

The average HbA_{Ic} reduction is approximately 0.6% (0.006; 7 mmol/mol Hb) in patients with type 2 DM. By improving satiety, pramlintide may reduce the number of calories a patient eats at a meal. The 120-mcg dose produced an average weight loss of 1.5-kg weight in patients with type 2 DM on insulin. In patients with type 1 DM, the average reduction in HbA_{Ic} was 0.4% to 0.5% (0.004-0.005; 4-5 mmol/mol Hb). In type 2 DM patients on basal insulin, adding pramlintide instead of prandial insulin resulted in similar efficacy and no weight gain. When pramlintide is injected before the meal, gastric emptying may delay absorption of mealtime nutrients. This may necessitate delaying the rapid-acting insulin dose until the conclusion of the meal. Pramlintide is not considered on the AACE/ACE or ADA algorithm. GLP-1 RAs and DPP-4 inhibitors have become the classes of choice to decrease inappropriate glucagon.

The most common adverse effects associated with pramlintide are gastrointestinal. Nausea occurs in approximately 20% of patients with type 2 DM and 40% to 50% of patients with type 1 DM. The higher rate of nausea in patient with type 1 DM is likely related to the near absolute amylin deficiency, and thus sensitivity or perhaps number, of amylin receptors. Vomiting or anorexia occurs in approximately 10% of patients with type 1 and type 2 DM. Gastrointestinal adverse effects decrease over time and are dose related, thus starting with a low dose and slowly titrating as tolerated is recommended. Pramlintide alone does not cause hypoglycemia, but when used in patients on insulin hypoglycemia can occur. The risk of severe hypoglycemia early in therapy is highest in patients with type 1 DM, with a twofold

increase in risk of severe hypoglycemic reactions. It is imperative that the prandial insulin dose, if used, be reduced 30% to 50% when pramlintide is initiated. This will minimize severe hypoglycemic reactions.

Pramlintide dosing is different in patient with type 1 and type 2 DM. In type 2 DM, the starting dose is 60 mcg prior to meals, and is titrated to the maximally recommended 120-mcg dose as tolerated and warranted based on postprandial plasma glucose concentrations. In type 1 DM, dosing starts at 15 mcg prior to meals, and can be titrated up in 15-mcg increments to a maximum of 60 mcg prior to each meal, if tolerated. Most type 1 DM patients are able to tolerate 30 to 45 mcg prior to meals. Snacks may also be covered with pramlintide. Storage information can be found in Table 74-11.

Bile Acid Sequestrants

Currently, the only bile acid sequestrant approved for the treatment of type 2 DM is colesevelam[19,23,53,54]. Colesevelam acts in the intestinal lumen to bind bile acid, decreasing the bile acid pool for reabsorption. It is unclear how colesevelam reduces BG. Possible mechanisms include effects on the farnesoid X and TGR5 receptors within the intestine as well as effects on farnesoid X receptor within the liver. There is evidence that colesevelam may affect the secretion of GLP-1 and GIP.

Hemoglobin A_{1C} reductions from baseline were approximately 0.4% (0.004; 4 mmol/mol Hb) when a dose of 3.8 g/day is given as add-on therapy to metformin, sulfonylureas, or insulin. The fasting plasma glucose was modestly reduced about 5 to 10 mg/dL (0.3-0.6 mmol/L). Colesevelam is not mentioned on the ADA algorithm but is considered an alternative medication on the AACE/ACE algorithm. Colesevelam also reduces LDL-C cholesterol in patients with type 2 DM. A 12% to 16% reduction in LDL-C was reported from baseline LDL-C concentrations of approximately 105 mg/dL (approximately 2.72 mmol/L). Triglycerides increased when combined with sulfonylureas or insulin, but not with metformin. Colesevelam is weight neutral and has a low risk of hypoglycemia. Colesevelam has been used in pediatric patients (10-17 years of age) for cholesterol reduction, but not type 2 DM. Although colesevelam lowers plasma glucose and LDL-C, it has not been proven to prevent cardiovascular morbidity or mortality. Patients with type 2 DM patients who need a small reduction in A_{1C} as well as additional LDL-C lowering would be candidates for this agent. See Table 74-10 for dosing and adverse reactions.

Dopamine Agonists

Bromocriptine mesylate is FDA approved for the treatment of type 2 DM[19,23,53,54]. Bromocriptine used for type 2 DM is a quick release formulation of the dopamine agonist. The exact mechanism by which bromocriptine improves glycemic control is unknown. Low hypothalamic dopamine levels, especially upon waking are augmented, which may decrease sympathetic tone and output. These effects are speculated to improve hepatic insulin sensitivity and decrease hepatic glucose output. In clinical trials, bromocriptine mesylate reduced HbA_{Ic} by a 0.3% to 0.6% (0.003-0.006; 3-7 mmol/mol Hb). Bromocriptine's target population for use is unclear. The ADA algorithm does not mention bromocriptine but the AACE/ACE treatment algorithm lists bromocriptine as an alternative medication in combination with other agents.

The effects of bromocriptine on macrovascular events have been explored in a safety trial. Bromocriptine decreased a composite cardiovascular endpoint. After 1 year of treatment, the composite outcome occurred in 37 (1.8%) bromocriptine treated subjects versus 32 (3.2%) subjects who received usual care (HR 0.6; 95% CI 0.35-0.96). See Table 74-10 for adverse effects and dosing.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring for Complications

The ADA recommends screening for complications at the time of diagnosis of DM[14,22]. Current recommendations

continue to advocate yearly dilated eye examinations in type 2 DM and an initial dilated eye examination in the first 3 to 5 years in type 1 DM, then yearly thereafter. Less frequent eye examinations, every 2 to 3 years, may be appropriate if the patient has no evidence of retinopathy and is at low risk of developing eye disease. The patient's blood pressure should be assessed at each visit. The feet should be examined at each visit including palpation of distal pulses and a visual inspection for skin integrity, calluses, and deformities. Pedal sensory loss due to polyneuropathy should screened for annually using the 10-g force Semmes-Weinstein monofilament. Screening for nephropathy should done at the time diagnosis in patients type 2 DM and 5 years after diagnosis if the patient has type 1 DM with urine microalbumin. Yearly testing for lipid abnormalities is appropriate if the patient is on lipid lowering therapy. It is generally accepted that a thyroid stimulating hormone concentration be measured in patients with type 1 DM and LADA as thyroid abnormalities are more common in DM.

Glycemic Goals and HbA_{1C}

Controlled clinical trials provide ample evidence that glycemic control is paramount in reducing microvascular complications in both type 1 DM[28] and type 2 DM[22,29]. HbA_{Ic} measurements are the gold standard for following long-term glycemic control for the previous 2 to 3 months. Other strategies such as measurement of fructosamine, which measures all glycated plasma proteins, or a glycated albumin test may be necessary to assess diabetes control in patients with altered red blood cell lifespan. Fructosamine measures glucose control over 2 to 3 weeks. Unfortunately, fructosamine measures are not as reliable as the HbA_{1c} due to significant intra-patient variability. Moreover, the correlation between fructosamine measurements and the risk complications from diabetes is unknown—thus fructosamine goals have not been established.

The HbA_{Ic} goal recommended by the ADA is < 7% (0.07; 53 mmol/mol Hb) in most adults. The AACE/ACE guidelines recommend < 6.5% (0.065; 48 mmol/mol Hb). Both guidelines recommend that treatment goals need to be individualized. Less stringent HbA_{Ic} goals may be appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, and in patients who are frail, have dementia, or have limited social or financial resources. Less stringent goals should also be used for younger children (see Table 74-6). More aggressive glycemic goals should be considered in patients who are newly diagnosed and younger using treatments that are less likely to cause hypoglycemia, weight gain, and other adverse effects.

The estimated average glucose (eAG) is correlated with HbA_{Ic} readings and now is regularly reported below HbA_{Ic} value by most laboratories. For example, an HbA_{Ic} of 7% (0.07; 53 mmol/mol Hb), correlates with an eAG of 154 mg/dL (8.5 mmol/L). Similarly, the International Federation of Clinical Chemistry (IFCC) recommends a standardize approach to report the HbA_{Ic} using mmol/mol Hb. For example, an NGSP HbA_{Ic} of 7.0% (0.07) is reported as 53 mmol/mol Hb.[22]

Self-Monitored Blood Glucose and Continuous Glucose Monitoring

Self-monitored blood glucose is a tool that provides an opportunity to intervene when an SMBG value is obtained and increases patient safety by detecting hypoglycemia so that it can be treated[14,22]. In general, SMBG frequency should match how frequently medication changes are needed to achieve glycemic control as well as the risk of hypoglycemia.

Frequent SMBG is necessary to achieve near-normal blood glucose concentrations if insulin is used. Assessment for hypoglycemia, hyperglycemia, adjustment of prandial doses of insulin, to administer corrective doses of insulin, to see how a change in diet, exercise or to check accuracy of continuous glucose monitors are but a few of the reasons a patient may need to perform SMBG. This is particularly true in patients with type 1 DM. The optimal frequency of SMBG for patients with type 2 DM on oral agents is unknown and its role controversial. What is clear is that patients must be empowered to change their therapeutic regimen in response to test results, or testing SMBG will not be useful.

Alternate site testing performed on the palm, forearm, or the thigh may improve adherence to SMBG recommendations, but only some BG test strips are designed for alternative site testing. Alternative sites tend to have less nerve endings than fingertips and may be more comfortable for a patient. However, glucose readings from alternative site testing will lag behind fingertip capillary blood by 20 to 30 minutes. Therefore, alternate site testing is discouraged in any situation where immediate action will be needed based on the glucose reading, such as testing for hypoglycemia or in patients with hypoglycemia unawareness, wide fluctuations in SMBG, or when the blood glucose is changing rapidly, such as after a meal.

Choosing an appropriate meter depends on the patient's dexterity, eye acuity, strip cost, and desired features. Insurance coverage often influences meter choice due to strip cost. Demonstrate to and then have the patient confirm SMBG technique. Each meter has specifications for hematocrit, elevation, and temperature tolerances for optimal operation.

Continuous glucose monitoring (CGM) is useful in select patients. CGM measures interstitial glucose, which lags behind capillary SMBG. CGM can be useful in patients with frequent episodes of hypoglycemia, hypoglycemic unawareness, and nocturnal hypoglycemia. CGM can be used to identify glucose patterns and evaluate patients with higher or lower than expected HbA_{Ic} results. CGM must be calibrated after insertion of a new sensor and every 12 hours thereafter with SMBG readings. Alarms need to be properly set and a new sensor must be placed every 3 to 7 days. The ADA currently recommends that CGM can be considered in adults with type 1 DM who are at least 25 years of age and those younger than 25 years of age who can demonstrate adherence to its use.[5] CGM data can be transmitted to insulin pumps which can then make recommendations to the patient to adjust insulin doses.

Treatment of Concomitant Conditions and Complications

Retinopathy

Patients with established retinopathy should see an ophthalmologist or optometrist trained in diabetic eye disease[72]. A dilated eye examination is required to fully evaluate the retina. Early background retinopathy may reverse with improved glycemic control and optimal blood pressure control. More advanced retinopathy will not fully regress with improved glycemia. Aggressive reductions in blood glucose may acutely worsen retinopathy. Diabetic retinopathy is caused by microcirculation ischemia coupled with inappropriate growth factor release. Laser photocoagulation has markedly improved sight preservation in diabetic patients and is extensively used in patients with macular edema and proliferative retinopathy. Intravitreal anti-vascular endothelial growth factor (VEGF) therapy has also been shown to be highly effective for sight preservation. Both bevacizumab, used off-label, and ranibizumab are anti-VEGF monoclonal antibodies, and aflibercept is a VEGF decoy receptor. People with diabetes also have a higher rate of cataracts and open-angle glaucoma.

Neuropathy

Neuropathy in diabetes can generally be placed into three categories: (1) peripheral neuropathy, (2) autonomic neuropathy, and (3) focal neuropathies[72,73]. Distal, symmetrical, peripheral neuropathy is the most common complication seen in type 2 DM patients in outpatient clinics. Paresthesias, perceived hot or cold, numbness, or pain are the predominant symptoms. The feet are involved far more often than the hands as it affects longer nerves first and progresses proximally. Improved glycemic control is the primary treatment and may alleviate some of the symptoms. If neuropathy is painful, symptomatic pain treatment is indicated, though it will not change the course of the neuropathy. No medication has been shown to be superior to another for pain relief. Treatment with low-dose tricyclic antidepressants, gabapentin, pregabalin, carbamazepine, duloxetine, venlafaxine, topical capsaicin, tramadol, and nonsteroidal antiinflammatory drugs may be considered. If these are unsuccessful, patients often are sent to a pain clinic or neurologist for further evaluation. Duloxetine and pregabalin are FDA approved for this indication. The numb variant of peripheral neuropathy is not treated with medications, but may lead to pressure areas on the foot and subsequent ulceration.

Clinical manifestations of diabetic autonomic neuropathy may include resting tachycardia, exercise intolerance, orthostatic hypotension, constipation, gastroparesis, erectile dysfunction, anhidrosis, heat intolerance, gustatory sweating, dry skin, impaired neurovascular function, and hypoglycemic unawareness. Gastroparesis can be a severe and debilitating complication of DM. Improved glycemic control, discontinuation of medications that slow gastric motility, and the use of metoclopramide for only a few weeks at a time or low dose erythromycin may be helpful. Gastric pacemakers can be considered if symptoms are severe and persistent. Domperidone, though not FDA approved, is available outside of the United States and may be useful. The hallmark of diabetic diarrhea is its nocturnal occurrence. A differential versus celiac disease, exocrine insufficiency, and gut bacterial overgrowth should be considered. Diabetic diarrhea frequently responds to a 10- to 14-day course of an antibiotic such as doxycycline or metronidazole. In more unresponsive cases, octreotide may be useful. If a patient develops orthostatic hypotension, antihypertensive agents should be stopped and dietary sodium intake should be liberalized. Some patients may require pharmacologic treatment for orthostatic hypotension with mineralocorticoids or adrenergic agonist agents. In severe cases, supine hypertension may be extreme, mandating that the patient sleep in a sitting or semirecumbent position. Patients with cardiac autonomic neuropathy are at a higher risk for silent MI and sudden cardiac death. Erectile dysfunction is common in diabetes, and initial treatment should include a trial of one of the phosphodiesterase type 5 inhibitors prior to referral. People with diabetes often require the highest doses of these medications to have an adequate response. Sudomotor dysfunction may cause reduced sweating and dry, cracked skin. Use of hydrating creams and ointments is needed. Autonomic neuropathy may also result in gustatory sweating after eating, which may be treated with antiperspirants or anticholinergic drugs. Hypoglycemic unawareness requires the patient to avoid hypoglycemia, as the body will slowly increase the glycemic level at which it will signal the autonomic signals.

Focal neuropathies are uncommon, but occur more often in older patient with poorly controlled diabetes. Diabetic amyotrophy, which is characterized by a proximal thigh muscle pain and weakness, is one of the most debilitating. In addition, cranial nerve III, IV, and VI neuropathies, as well as Bell's palsy occur more frequently in patients with diabetes. The clinical presentation can be quite dramatic, but the course is usually self-limited, and partial or full recover occurs in a few weeks to months. Carpal tunnel syndrome, caused by radial nerve entrapment in wrist, is also more common in people with diabetes, and tarsal tunnel syndrome may cause foot paresthesias.

Microalbuminuria and Nephropathy

Diabetes mellitus, particularly type 2 DM, is the biggest contributor statistically to the development of end-stage renal disease in the United States[72,74,1] The ADA recommends a screening urinary analysis for albumin at the time of diagnosis in persons with type 2 DM. In type 1 DM, microalbuminuria rarely occurs before puberty. Screening individuals with type 1 DM should begin with puberty and after 5 years' disease duration. There are three methods for assessing microalbuminuria: (1) measurement of the urine albumin:creatinine ratio can be determined in a random spot collection, preferably the first morning void. (2) 24-hour timed collection—more cumbersome but more accurate; and (3) timed (eg, 4- or 10-hour overnight) collection. Microalbuminuria on a spot urine specimen is defined as a ratio of 30 to 300 mg/g (3.4-34 mg/mmol) albumin:creatinine. On timed collections, microalbuminuria is defined as 30 to 300 mg/24 h or an albumin excretion rate of 20 to 200 mcg/min. Due to day-to-day variability, microalbuminuria should be confirmed on at least two of three samples over 3 to 6 months unless the results are unequivocally positive. Additionally, when assessing urine protein or albumin, conditions that may cause transient elevations in urinary albumin excretion should be excluded. These conditions include intense exercise, recent urinary tract infections, hypertension, short-term hyperglycemia, heart failure, and acute febrile illness.

In type 2 DM, the presence of microalbuminuria is a strong risk factor for macrovascular disease and is frequently present at the time of diagnosis. Microalbuminuria is a weaker predictor for future end-stage kidney disease in type 2 versus type 1 DM. Glucose and blood pressure control are important for preventing and retarding the progression of nephropathy. ACE inhibitors and ARBs, considered first-line treatment modalities, have shown efficacy in preventing the clinical progression of renal disease in patients with diabetes. Using a combination of agents to block the renin-angiotensin aldosterone system—for example using an ACE inhibitor with an ARB, aldosterone receptor blockers, or direct renin inhibitors—has not been shown to improve outcomes and may increase adverse effects. Diuretics

frequently are necessary due to the volume-expanded state of the patient and are recommended second-line therapy. The ADA currently recommends less than 140/90 mm Hg in patients with nephropathy but lower blood pressures values, if they can be safely obtained, may lower the risk further. Three or more antihypertensives are often needed to reach goal blood pressures.

Peripheral Arterial Disease and Foot Ulcers

Claudication and nonhealing foot ulcers are common in patients with type 2 DM[72]. Smoking cessation, correction of lipid abnormalities, good glycemic control, and antiplatelet therapy are important strategies in treating peripheral arterial disease. Cilostazol may be useful for reducing symptoms in select patients. Revascularization is successful in selected patients; however, small vessel disease that cannot be bypassed is common in diabetes. Local debridement and appropriate footwear are vitally important in the early treatment of foot lesions. In more advanced lesions, multiple treatments including grafts, topical wound healing, and hyperbaric treatments may be necessary. Foot examinations each visit and a yearly Semmes-Weinstein 10 gram-force monofilament test to assess for loss of protective sensation can be used to identify high-risk patients that need further podiatric evaluation.

Coronary Heart Disease

The risk for coronary heart disease (CHD) is 2 to 4 times greater in diabetic patients than in nondiabetic individuals[74,75]. CHD is the major source of mortality in patients with DM. Addressing multiple CV risk factor—lipids, hypertension, smoking cessation, and antiplatelet therapy—will reduce macrovascular events. The ADA recommends aspirin therapy in all patients who have established CV disease. If the patient is allergic to aspirin, clopidogrel may be used. The ADA currently recommends antiplatelet therapy for primary prevention of a CV event if the patient's 10-year risk of CVD is at least 10%, or in women and men at least 50 years old with an additional risk factor. β-Blocker therapy supplies an even greater protection from recurrent CHD events in patients with diabetes than in nondiabetic subjects. Therefore, β-blockers should not be avoided in patients with diabetes. Masking of hypoglycemic symptoms can be a problem in some patients with type 1 DM but this risk can be managed with proper glycemic control interventions (see also the Chapter on Ischemic Heart Disease).

The Collaborative Atorvastatin Diabetes Study (CARDS) randomized patients with diabetes and no documented CVD to atorvastatin 10 mg daily (n = 1,428) or placebo (n = 1,410). The trial was stopped early when the primary efficacy endpoint of major cardiovascular events was reduced by 37% (P = 0.001). All-cause death was reduced 27% (P = 0.059). The Heart Protection Study randomized 5,963 patients age more than 40 years with diabetes and total cholesterol more than 135 mg/dL (3.49 mmol/L). A significant 22% reduction (95% CI, 13-30) in the event rate for major cardiovascular events was seen with simvastatin 40 mg/day. This was evident even at lower LDL-C levels (less than 116 mg/dL [less than 3.00 mmol/L]), and suggests that approximately 30% to 40% reduction in LDL-C levels regardless of starting LDL-C levels may be appropriate. The ADA recommends statin therapy, regardless of baseline lipid or LDL-C levels in patients with overt CVD or without documented CVD who are over the age of 40 and have CVD risk factors besides diabetes.

Low-density lipoprotein cholesterol has been the primary target of therapy for years. However, more recently the AHA/ACC 2013 guidelines[76] recommend that rather than aiming for specific LDL-C targets, decision for treatment should be based on CV risk. In people with type 1 or type 2 diabetes who are ages 40-75 years, the decision whether to use moderate or high intensity statin should be based on risk. Those who have established CVD and/or an estimated 10-year risk of more than 7.5% (more than 0.075; more than 58 mmol/mol Hb) should be treated with high intensity statin; all others may be treated with moderate intensity statin (**Table 74-12**). High intensity statins include atorvastatin 40 to 80 mg day or rosuvastatin 20 to 40 mg day. Moderate intensity statin therapy includes atorvastatin 10 to 20 mg; rosuvastatin 5 to 10 mg; simvastatin 20 to 40 mg; pravastatin 40 to 80 mg; lovastatin 40 mg; and fluvastatin XL 80 mg. Caution is advised when beginning statins in women of child bearing age because statins may cause birth defects.

TABLE 74-12 Recommendations for Statin Treatment in People with Diabetes

Age (Years)	Risk Factors	Recommended Statin Dose*	Monitoring with Lipid Panel
	None	None	
<40	CVD risk factor(s)**	Moderate to High	Annually as needed to monitor for adherence
	Overt CVD ***	High	
	None	Moderate	
40-75	CVD risk factor(s) **	High	As needed to monitor for adherence
	Overt CVD***	High	
	None	Moderate	
>75	CVD risk factor(s)**	Moderate to High	As needed to monitor for adherence
	Overt CVD***	High	

*In addition to lifestyle therapy.

**CVD risk factors include LDL cholesterol ≥100 mg/dL (≥2.59 mmol/L), high blood pressure, smoking, and overweight and obesity.

***Overt CVD includes those with previous cardiovascular events or acute coronary syndromes.

American Diabetes Association 2015 Clinical Practice Recommendations. Cardiovascular disease and risk management. Diabetes Care 2015;38(Suppl. 1):S49 -S57. Copyright and all rights reserved. Material from this publication has been used with the permission of American Diabetes Association.

After a statin is initiated for CV risk reduction, extremely elevated triglycerides may require additional pharmacological therapy. Improved glycemic control, weight loss, and exercise will also have a positive impact on serum triglycerides. Patients with marked hypertriglyceridemia (≥ 500 mg/dL [5.65 mmol/L]) are at risk for pancreatitis. Efforts to reduce triglycerides with improved glycemic control, elimination of other secondary causes (including medications), and the use of fibrates, omega-3 fatty acid, or niacin can be used.

The routine use of fibrates in patients with diabetes is controversial. The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) was conducted in patients with type 2 DM and failed to show a CV benefit from fenofibrate 200 mg daily when compared to placebo. In a subgroup analysis, subjects without CVD at baseline appeared to have a significant reduction in CVD events. The lipid arm of the ACCORD also randomized patient to fenofibrate or placebo. Fenofibrate did not significantly lower cardiovascular events. Niacin in combination with a statin failed to improved CVD outcomes in patients with diabetes as well.

Hypertension

The role of hypertension in increasing microvascular and macrovascular risk in patients with DM has been confirmed in the UKPDS[74]. The ADA has loosened their goals for blood pressure (less than 140/80 mm Hg) in patients with DM based the results of the ACCORD study. The ACCORD blood pressure arm studied type 2 DM patients, with a goal of achieving a systolic blood pressure of either less than 120 mm Hg (achieved 119 mm Hg) or less than 140 mm Hg (133 mm Hg achieved). The lower pressure group did not have lower CVD or renal outcomes, but did have a lower risk of stroke. A goal of less than 130 mm Hg can still be considered in younger patients, patients at high risk of a stroke or if renal disease is present. ACE inhibitors and ARBs are generally recommended for initial therapy, as they have shown to be cardioprotective, and likely have special renal protective effects. Many patients require multiple agents, on average three, to attain the BP goals. Diuretics and calcium channel blockers frequently are useful as second and

third agents. African Americans receive renoprotection from ACE inhibitors or ARBs, but they lower blood pressure less than other agents in this population. For this reason, combination therapy with a diuretic or calcium channel blocker be considered as first-line therapy in African Americans. After initial therapy, which agent to add next remains controversial.

SUMMARY

A comprehensive care plan for the patient with DM will not only include strategies to achieve optimal glycemic control aimed at appropriate glycemic goals but will also screen, prevent, and manage microvascular and macrovascular complications. Current Health Plan Employer Data and Information Set (HEDIS), performance measures published by the National Committee for Quality Assurance (NCQA) recognize that quality care includes targets for glycemia, lipids, and hypertension. Publicly reported quality measures indicate that we are moving closer to these targets. Glycemic control is paramount in managing type 1 or type 2 DM. It requires frequent assessment and adjustments in diet, exercise, and pharmacologic therapies. The HbA_{Ic} should be measured twice a year in patients meeting treatment goals on a stable therapeutic regimen.[14] Quarterly assessments are recommended for those whose therapy has changed or who are not meeting glycemic goals. A fasting lipid profile should be obtained as part of an initial assessment and to determine if statin therapy has reduced LDL cholesterol as expected. Documenting foot examinations (each visit), urine albumin (annually), dilated eye examinations (yearly or more frequently) are also important. People with diabetes should receive the influenza vaccine annually and the pneumococcal vaccines and the hepatitis B vaccine series. Screening and mitigating cardiovascular risks—including smoking cessation and antiplatelet therapy—are components of preventive medicine strategies. Utilizing an integrated electronic health record, standardized progress notes, and flow sheets can assist the clinician determine whether the patient has met these standards of care. As with many chronic diseases, adherence to dietary recommendation, physical activity, and medications is a challenge for most patients. Frequent follow-up, patient education, and simplification of medication regimens using combination products are helpful (**Table 74-13**). Many patients do not take medications due to side effects and perceived risks. Frequent monitoring and patient engagement in the decision-making process is needed (**Table 74-14**).

TABLE 74-13 Available Combination Antihyperglycemic Products[a]

Medication	Combined with:	Trade Name
Metformin and/or metformin extended release	Pioglitazone	Actoplus Met
	Rosiglitazone	Avandamet
	Sitagliptin	Janumet
	Saxagliptin	Kombiglyze XR
	Linagliptin	Jentadueto
	Alogliptin	Kazano
	Glyburide	Glucovance
	Glipizide	Metaglip
	Repaglinide	Prandimet
	Canagliflozin	Invokamet
	Dapagliflozin	Xigduo XR
	Empagliflozin	Synjardy

Medication	Combined with:	Trade Name
Linagliptin	Empagliflozin	Glyxambi
Glimepiride	Pioglitazone	Duetact
	Rosiglitazone	Avandaryl
Pioglitazone	Alogliptin	Oseni

[a]at time chapter written.

TABLE 74-14 Drug Monitoring for Diabetes Mellitus Medications[a]

Medication Class	Adverse Drug Reaction	Monitoring Parameters	Comments
Alpha-glucosidase inhibitors	Gastrointestinal (GI) upset	Gas, bloating, loose stools	Titrate, take in less carbohydrate
Bile Acid Sequestrants	Constipation	Bowel movement frequency	Drink H_2O, Don't use if history of bowel obstruction
	Raises triglycerides	Triglycerides	Not recommended TG >500 mg/dL (>5.65 mmol/L)
Biguanides	Gastrointestinal distress	Reflux, nausea, vomiting, stomach upset, loose stools	Take with food and titrate dose, split doses, consider extended release
	Lactic Acidosis	High anion gap on electrolyte panel, hypoxic states, renal function, impaired liver function	Lactate levels not measured, but can be if suspected toxicity
DPP-4 inhibitors	Hypersensitivity/Angioedema and exfoliating dermatologic skin reactions	Skin rash, signs/symptoms of angioedema	Risk factors, such as history of angioedema, possibly ACE inhibitor use, and past history of severe dermal drug reactions should be explored
	Pancreatitis	Amylase, Lipase, abdominal pain with nausea/vomiting	Discontinue, look for underlying causes
SGLT2 inhibitors	GU infections,	Signs/symptoms	Monitor eGFR and blood pressure, adjust diuretics SE may be more pronounced over first 2 weeks
	Dehydration/Orthostatic	Blood pressure, syncopal symptoms, eGFR	
	UTI	Signs/symptoms	
Dopamine agonists	Hypotension	Syncopal symptoms	Usually worse for first days of dosage change. Decrease/stop antihypertensives
	Worsening psychiatric issues	Signs/symptoms of underlying mental illness	Avoid use with antipsychotics
	CNS effects	Mental alertness/asthenia /fatigue/headache	Titrate slowly
	Gastrointestial side effects	Nausea	Titrate slowly
Thiazolidinediones	Heart failure/pulmonary edema	Signs/symptoms of heart failure, increased BNP, weight	Discontinue

Medication Class	Adverse Drug Reaction	Monitoring Parameters	Comments
	Peripheral edema	Peripheral edema measures	Limit dose, consider diuretic (see text), or discontinue
	Weight gain	Weight	Consider if weight is fluid or likely caloric intake
	Peripheral fractures	None except fracture	Avoid use in osteoporosis and osteopenia
Sulfonylureas	Hypoglycemia	Self-monitored blood glucose	Consider dosing
Meglitinides	Hypoglycemia	Self-monitored blood glucose	Adjustment
GLP-1 receptor agonists	Gastrointestinal	Nausea/vomiting	Titrate slowly, avoid in gastroparesis
	Pancreatitis	Amylase, Lipase, abdominal pain with nausea/vomiting	Discontinue, look for underlying causes
	C-cell tumors of thyroid	None recommended, calcitonin	Do not use in at risk populations (MEN2 or MTC)
Amylinomimetic	Gastrointestinal upset	Nausea/vomiting	Titrate slowly, avoid in gastroparesis
Insulin	Hypoglycemia	Self-monitored blood glucose

AACE	American Association of Clinical Endocrinologists
AADE	American Association of Diabetes Educators
ACCORD	Action to Control Cardiovascular Risk in Diabetes
ACE	angiotensin-converting enzyme
ACE	American College of Endocrinologists
ADA	American Diabetes Association
ADVANCE	Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation
AHEAD	Action for Health in Diabetes
ALT	alanine aminotransferase
ARB	angiotensin-receptor blockers
BG	blood glucose
BMI	body mass index
BNP	brain natriuretic peptide
CARDS	Collaborative Atorvastatin Diabetes Study
CDE	certified diabetes educator
CGM	continuous glucose monitoring
CHD	coronary heart disease
CVD	cardiovascular disease
CSII	continuous subcutaneous insulin infusion

CYP450	cytochrome P450
DCCT	Diabetes Control and Complications Trial
DKA	diabetic ketoacidosis
DM	diabetes mellitus
DPP-4	dipeptidyl peptidase-4
DPP	Diabetes Prevention Program
eAG	estimated average glucose
EDIC	Epidemiology of Diabetes Interventions and Complications
eGFR	estimated glomerular filtration rate
FDA	Food and Drug Administration
FFA	free fatty acid
FIELD	Fenofibrate Intervention and Event Lowering in Diabetes
GCT	glucose challenge test
GDM	gestational diabetes mellitus
GIP	glucose-dependent insulinotropic polypeptide
GLP-1	glucagon-like peptide-1
GLP1-RA	GLP-1 receptor agonist
GU	genitourinary
Hb	hemoglobin
HbA_{Ic}	hemoglobin A_{Ic}
HDL-C	high-density lipoprotein cholesterol
HHS	hyperosmolar hyperglycemic state
HLA	human leukocyte antigen
ICA	islet cell antibody
IFCC	International Federation of Clinical Chemistry
IFG	impaired fasting glucose
IGT	impaired glucose tolerance
INR	international normalized ratio
IV	intravenous
LADA	latent autoimmune diabetes in adults
LDL-C	low-density lipoprotein cholesterol
MAP	mitogen activated protein
MDI	multiple daily injections
MEN2	multiple endocrine neoplasia type 2
MODY	maturity onset diabetes of youth
NGSP	National Glycohemoglobin Standardization Program
NHANES III	The Third National Health and Nutrition Evaluation Survey
NPH	neutral protamine Hagedorn
OGTT	oral glucose tolerance test
PAI-1	activator-1 plasminogen-inhibitor
PDR	proliferative diabetic retinopathy
POC	Point of care
PPAR-γ	peroxisome proliferator activator receptor-γ

SGLT	sodium glucose cotransporter
SUR	sulfonylurea receptor
SMBG	self-monitoring of blood glucose
TZD	thiazolidinedione
UGE	urinary glucose excretion
UKPDS	United Kingdom Prospective Diabetes Study
VADT	Veterans Affairs Diabetes Trial
VAT	visceral adipose tissue
VEGF	vascular endothelial growth factor

Chapter 75: Thyroid Disorders

Jacqueline Jonklaas; Michael P. Kane

INTRODUCTION

KEY CONCEPTS

- 1 Thyrotoxicosis is most commonly caused by Graves' disease, which is an autoimmune disorder in which thyroid-stimulating antibody (TSAb) directed against the thyrotropin receptor elicits the same biologic response as thyroid-stimulating hormone (TSH).
- 2 Hyperthyroidism may be treated with antithyroid drugs such as methimazole (MMI) or propylthiouracil (PTU), radioactive iodine (RAI: sodium iodide-131 [^{131}I]), or surgical removal of the thyroid gland; selection of the initial treatment approach is based on patient characteristics such as age, concurrent physiology (eg, pregnancy), comorbidities (eg, chronic obstructive lung disease), and convenience.
- 3 MMI and PTU reduce the synthesis of thyroid hormones and are similar in efficacy, although their dosing ranges differ by 10-fold. Overall, PTU may have a greater incidence of side effects.
- 4 Response to MMI and PTU is seen in 4 to 6 weeks and therefore β-blocker therapy may be concurrently initiated to reduce adrenergic symptoms. Maximal response is typically seen in 4 to 6 months; treatment usually continues for 1 to 2 years, and therapy is monitored by clinical signs and symptoms and by measuring the serum concentrations of TSH and free thyroxine (T_4).
- 5 Adjunctive therapy with β-blockers controls the adrenergic symptoms of thyrotoxicosis but does not correct the underlying disorder; iodine may also be used adjunctively in preparation for surgery and acutely for thyroid storm.
- 6 Many patients choose to have ablative therapy with ^{131}I rather than undergo repeated courses of MMI or PTU treatment; most patients receiving RAI eventually become hypothyroid and require thyroid hormone supplementation.
- 7 Hypothyroidism is most often due to an autoimmune disorder known as *Hashimoto's*

thyroiditis.

- 8 The drug of choice for replacement therapy in hypothyroidism is levothyroxine.
- 9 Studies of combination therapy with levothyroxine and liothyronine have not shown reproducible benefits. This approach to treatment of hypothyroidism requires further study.
- 10 Monitoring of levothyroxine replacement therapy is achieved by observing clinical signs and symptoms and by measuring the serum TSH level. An elevated TSH indicates under-replacement; a suppressed TSH indicates over-replacement.

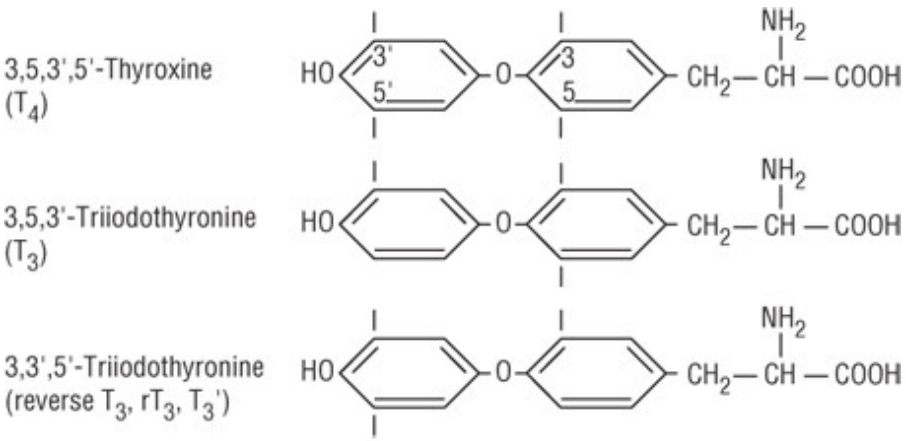
Thyroid hormones affect the function of virtually every organ system. In a child, thyroid hormone is critical for normal growth and development. In an adult, the major role of thyroid hormone is to maintain metabolic stability. Substantial reservoirs of thyroid hormone in the thyroid gland and blood provide constant thyroid hormone availability. In addition, the hypothalamic–pituitary–thyroid axis is exquisitely sensitive to small changes in circulating thyroid hormone concentrations, and alterations in thyroid hormone secretion maintain peripheral free thyroid hormone levels within a narrow range. Patients seek medical attention for evaluation of symptoms due to abnormal thyroid hormone levels or because of diffuse or nodular thyroid enlargement.

Thyroid Hormone Synthesis

The thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) (**Fig. 75-1**) are formed within thyroglobulin (TG), a large glycoprotein synthesized in the thyroid cell. Because of the unique tertiary structure of this glycoprotein, iodinated tyrosine residues present in TG are able to bind together to form active thyroid hormones.

FIGURE 75-1

Structure of thyroid hormones.



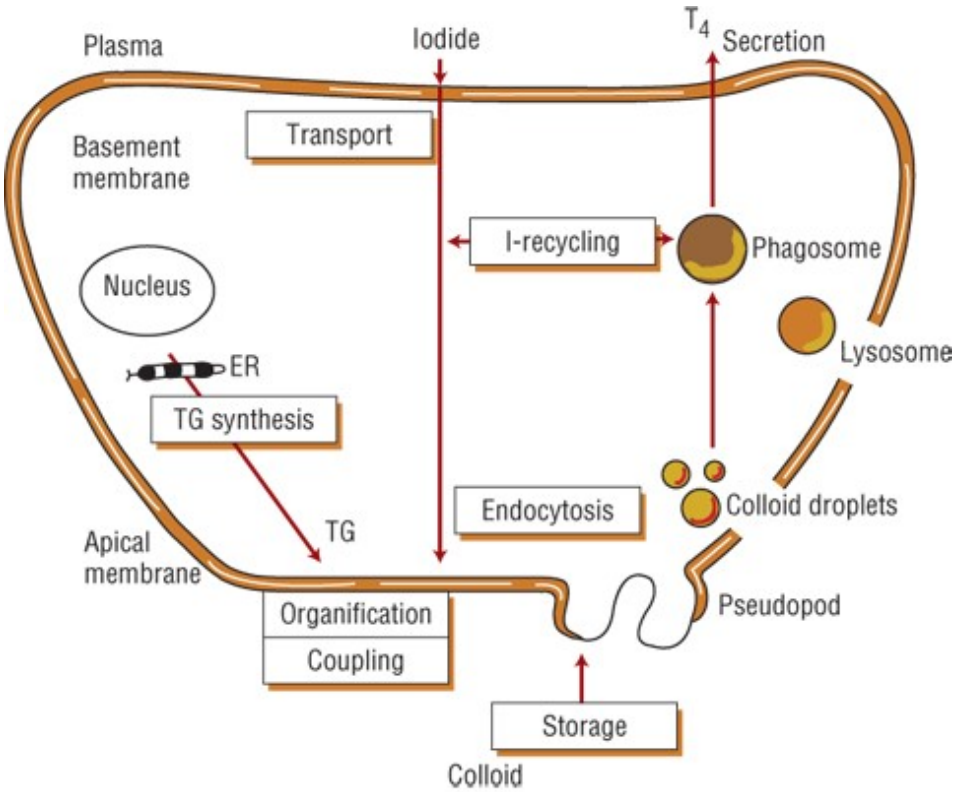
Iodide is actively transported through the basolateral membrane via a Na^+/I^- symporter from the extracellular space into the thyroid follicular cell against an electrochemical gradient, driven by the coupled transport of sodium.[1] Structurally related anions such as thiocyanate (SCN^-), perchlorate (ClO_4^-), and pertechnetate (TcO_4^-) are competitive inhibitors of iodine transport.[1] In addition, bromine, fluorine, and, under certain circumstances, lithium block iodide transport into the thyroid (**Table 75-1**). Inorganic iodide that enters the thyroid follicular cell is ushered through the cell to the apical membrane, where it is transported into the follicular lumen by pendrin, and possibly other transport proteins.[1] Located on the luminal side of the apical membrane, thyroid peroxidase oxidizes iodide and covalently binds the organified iodide to tyrosine residues within TG (**Fig. 75-2**). It is interesting that although salivary glands and the gastric mucosa are able to actively transport iodide, they are unable to effectively incorporate iodide into proteins given the lack of similar oxidizing machinery.

TABLE 75-1 Thyroid Hormone Synthesis and Secretion Inhibitors

Mechanism of Action	Substance
Blocks iodide transport into the thyroid	Bromine Fluorine Lithium (?)
Impairs organification and coupling of thyroid hormones	Thionamides Sulfonamide (?) Salicylamide (?) Antipyrine (?)
Inhibits thyroid hormone secretion	Iodide (large doses), lithium

FIGURE 75-2

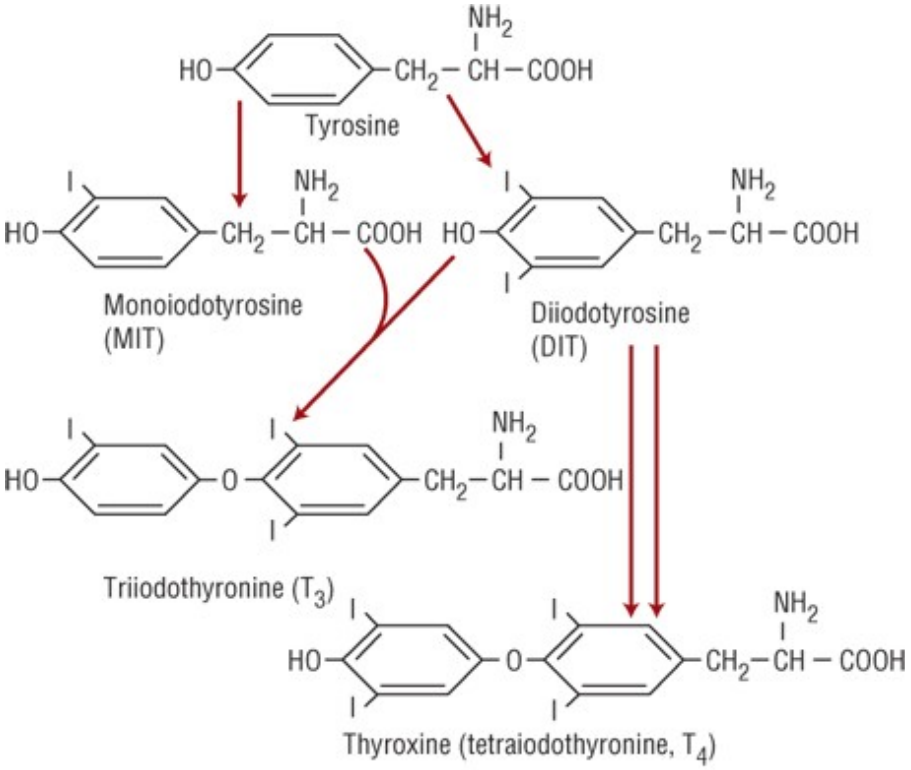
Thyroid hormone synthesis. Iodide is transported from the plasma, through the cell, to the apical membrane, where it is organified and coupled to the thyroglobulin (TG) synthesized within the thyroid cell. Hormone stored as colloid reenters the cell through endocytosis and moves back toward the basal membrane, where thyroxine (T_4) is secreted.



The iodinated tyrosine residues monoiodotyrosine (MIT) and diiodotyrosine (DIT) combine to form iodothyronines (**Fig. 75-3**). Thus, two molecules of DIT combine to form T_4, whereas MIT and DIT constitute T_3. In addition to its role in iodine organification, the hemoprotein thyroid peroxidase also catalyzes the formation of iodothyronines (coupling).

FIGURE 75-3

Scheme of coupling reactions. After tyrosine is iodinated to form monoiodotyrosine (MIT) or diiodotyrosine (DIT) (organification of the iodine), MIT and DIT combine to form triiodothyronine (T_3) or two molecules of DIT combine to form thyroxine T_4.



Iodine deficiency causes an increase in the MIT:DIT ratio in TG and leads to a relative increase in the production of T_3.[2] Because T_3 is more potent than T_4, the increase in T_3 production in iodine-deficient areas may be beneficial. The thionamide drugs used to treat hyperthyroidism inhibit thyroid peroxidase and thus block thyroid hormone synthesis.

Thyroglobulin is stored in the follicular lumen and must reenter the cell, where the process of proteolysis liberates thyroid hormone into the bloodstream. Thyroid follicles active in hormone synthesis are identified histologically by columnar epithelial cells lining a follicular lumen, which is depleted of colloid. Inactive follicles are lined by cuboidal epithelial cells and are replete with colloid. Both iodide and lithium block the release of preformed thyroid hormone, through poorly understood mechanisms.

T_4 and T_3 are transported in the bloodstream primarily by three proteins: (1) thyroxine-binding globulin (TBG), (2) transthyretin (TTR), and (3) albumin. It is estimated that 99.96% of circulating T_4 and 99.5% of T_3 are bound to these proteins. However, only the unbound (free) thyroid hormone is able to diffuse into the cell, elicit a biologic effect, and regulate thyroid-stimulating hormone (TSH; also known as *thyrotropin*) secretion from the pituitary. Multiple functions have been ascribed to these transport proteins, including (a) assuring minimal urinary loss of iodide, (b) providing a mechanism for uniform tissue distribution of free hormone, and (c) transport of hormone into the central nervous system.

Whereas T_4 is secreted solely from the thyroid gland, less than 20% of T_3 is produced in the thyroid. The majority of T_3 is formed from the breakdown of T_4 catalyzed by the 5′-monodeiodinase enzymes

found in extrathyroidal peripheral tissues. Because the binding affinity of nuclear thyroid hormone receptors (TRs) is 10 to 15 times higher for T_3 than for T_4, the deiodinase enzymes play a pivotal role in determining overall metabolic activity. Three different monodeiodinase enzymes are present in the body. Of the enzymes that catalyze 5′-monodeiodination, type I enzymes are present in peripheral tissues such as the liver and kidney, whereas type II enzymes are found in the CNS, pituitary, and thyroid. Type III enzymes, found in the placenta, skin, and developing brain, inactivate T_4 and T_3 by deiodinating the inner ring at the 5 position. The principal characteristics of these enzymes are listed in **Table 75-2**. T_4 may also be acted on by the enzyme 5′-monodeiodinase to form reverse T_3, but this accounts for a small component of hormone metabolism. Polymorphisms in the deiodinase genes may prove to be of clinical significance. For example, a polymorphism in the type I deiodinase leading to increased activity seems to be associated with an increased circulating ratio of free T_3 to free T_4.[3] Reverse T_3 has no known biologic activity. T_3 is removed from the body by deiodinative degradation and through the action of sulfotransferase enzyme systems converting to T_3 sulfate and 3,3-diiodothyronine sulfates, thus facilitating enterohepatic clearance. Thyronamines are derivatives of thyroid hormone that are present in low concentrations in human serum.[4] The most studied thyronamine, 3-iodothyronamine, can theoretically be made from T_4 by decarboxylation and deiodination. Administration of pharmacologic amounts of 3-iodothyronamine to animals has profound effects on temperature regulation and cardiac function, and shifts fuel metabolism from carbohydrates to lipids. However, a possible physiologic role for thyronamines has yet to be determined, although altered levels may be associated with some disease states.[4]

TABLE 75-2 Properties of Iodothyronine 5′-Deiodinase Isoforms

Property	Type I	Type II	Type III
Susceptibility to propylthiouracil	High	Low	Low
Tissue localization	Thyroid, liver, kidney	Pituitary, thyroid, CNS, brown adipose tissue	Placenta, developing brain, skin
Preferred substrate	rT_3 and T_3	T_4 and rT_3	T_3 and T_4
Physiologic or pathophysiologic role	Clearance of rT_3 and T_3, predominant extrathyroidal source of T_3 in hyperthyroidism	Intracellular T_3 production, especially for brain in hypothyroidism or iodine deficiency, and maintenance of plasma T_3	Clearance of T_3 and T_4
Developmental expression	Expressed latest in development; predominant deiodinase in adult	Expressed second; especially high in brain and brown adipose tissue	Expressed first; high in developing brain; may be important for fetal thyroid hormone metabolism

rT_3, reverse T_3; T_3, triiodothyronine; T_4, thyroxine.

Thyroid Hormone Regulation and Action

The growth and function of the thyroid are stimulated by activation of the thyrotropin receptor by TSH.[5] The receptor belongs to the family of G-protein–coupled receptors. The thyrotropin receptor is coupled to the α subunit of the stimulatory guanine-nucleotide–binding protein ($G_s\alpha$), activating adenylate cyclase and increasing the accumulation of cyclic adenosine monophosphate. Through this mechanism, TSH stimulates the expression of Na^+/I^- symporter, TG, and thyroid peroxidase genes as well as increases apical iodide efflux. Somatic activating mutations in the receptor are commonly seen in autonomously functioning thyroid nodules.[6] Rarely, germline-activating mutations of the TSH receptor have been reported in kindreds with Leclere's syndrome, and thyrotoxicosis can result from germline-activating mutations in G-protein signaling in McCune-Albright syndrome. Conversely, thyrotropin resistance results from point mutations that prevent TSH binding, leading to abnormalities in the thyrotropin receptor–adenylate cyclase system and congenital hypothyroidism.[5] Individuals with this abnormality have high levels of TSH but decreased TG levels and a normal or small gland.

Thyroid hormone nuclear receptors regulate the transcription of target genes in the presence of physiologic concentrations of T_3.[7] Unlike most other nuclear receptors, TRs also actively regulate gene expression in the absence of hormone, typically resulting in an opposite effect. TRs translocate from the cytoplasm to the nucleus, interact in the nucleus with T_3, and target genes and other proteins required for basal and T_3-dependent gene transcription. TRs exist in several isoforms, including TRβ1, TRβ2, and TRα1.[7] Thyroid hormone has different actions in different tissues based on tissue-specific expression of the different TR isoforms. There is interest in developing thyroid hormone analogs that selectively activate specific TR isoforms. Such agents could theoretically have targeted desirable effects such as stimulating energy expenditure without having adverse effects on other tissues.[8]

The production of thyroid hormone is regulated in two main ways. First, thyroid hormone is regulated by TSH secreted by the anterior pituitary. The secretion of TSH is itself under negative feedback control by the circulating level of free thyroid hormone and the positive influence of hypothalamic thyrotropin-releasing hormone (TRH). Second, extrathyroidal deiodination of T_4 to T_3 is regulated by a variety of factors including nutrition, nonthyroidal hormones, ambient temperatures, drugs, and illness.

EPIDEMIOLOGY—THYROTOXICOSIS

Thyrotoxicosis results when tissues are exposed to excessive levels of T_4, T_3, or both.[9] Hyperthyroidism, which is one cause of thyrotoxicosis, refers specifically to overproduction of thyroid hormone by the thyroid gland. In the National Health and Nutrition Examination Survey (NHANES) III, 0.7% of those surveyed who were not taking thyroid medications and had no history of thyroid disease had subclinical hyperthyroidism (TSH less than 0.1 milli-international unit/L, and T_4 normal), and 0.5% had "clinically significant" hyperthyroidism (TSH less than 0.1 milli-international unit/L, and T_4 more than 13.2 mcg/dL).[10] The prevalence of suppressed TSH values peaks in people aged 20 to 39, declines in those 40 to 79, and increases again in those 80 or older. Abnormal TSH levels were

more common among women than among men.

ETIOLOGY/PATHOPHYSIOLOGY—THYROTOXICOSIS

If the clinical history and examination do not provide pathognomonic clues to the etiology of the patient's thyrotoxicosis, measurement of the radioactive iodine uptake (RAIU) is critical in the evaluation (**Table 75-3**). The normal 24-hour RAIU ranges from 10% to 30% with some regional variation that is due to differences in iodine intake. An elevated RAIU indicates endogenous hyperthyroidism, that is, the patient's thyroid gland is actively overproducing T_4, T_3, or both. Conversely, a low RAIU in the absence of iodine excess indicates that high levels of thyroid hormone are not a consequence of thyroid gland hyperfunction but are likely due to thyroiditis or hormone ingestion. The importance of differentiating endogenous hyperthyroidism from other causes of thyrotoxicosis lies in the widely different prognosis and treatment of the diseases in these two categories. Therapy of thyrotoxicosis associated with thyroid hyperfunction is mainly directed at decreasing the rate of thyroid hormone synthesis, secretion, or both. Such measures are ineffective in treating thyrotoxicosis that is not the result of endogenous hyperthyroidism, because hormone synthesis and regulated hormone secretion are already at a minimum.

TABLE 75-3 Differential Diagnosis of Thyrotoxicosis

Increased RAIU[a]	Decreased RAIU
TSH-induced hyperthyroidism	Inflammatory thyroid disease
TSH-secreting tumors	Subacute thyroiditis
Selective pituitary resistance to T_4	Painless thyroiditis
Thyroid stimulators other than TSH	Ectopic thyroid tissue
TSAb (Graves' disease)	Struma ovarii
hCG (trophoblastic diseases)	Metastatic follicular carcinoma
Thyroid autonomy	Exogenous sources of thyroid hormone
Toxic adenoma	Medications containing thyroid hormone or iodine
Multinodular goiter	Food sources containing thyroid gland

hCG, human chorionic gonadotropin; RAIU, radioactive iodine uptake; TSAb, thyroid-stimulating antibody; TSH, thyroid-stimulating hormone.

[a]The RAIU may be decreased if the patient has been recently exposed to excess iodine.

CLINICAL PRESENTATION Thyrotoxicosis General

- Signs and symptoms of thyrotoxicosis affect multiple organ systems. Patients often have symptoms for an extended time period before the diagnosis of hyperthyroidism is made.

Symptoms

- The typical clinical manifestations of thyrotoxicosis include nervousness, anxiety, palpitations,

emotional lability, easy fatigability, menstrual disturbances, and heat intolerance. A cardinal sign is loss of weight concurrent with an increased appetite.

Elderly patients are more likely to develop atrial fibrillation with thyrotoxicosis than younger patients. The frequency of bowel movements may increase, but frank diarrhea is unusual. For the elderly patient and for the patient with very severe disease, anorexia may be present as well. Palpitations are a prominent and distressing symptom, particularly in the patient with preexisting heart disease. Proximal muscle weakness is common and is noted on climbing stairs or in getting up from a sitting position. Women may note their menses are becoming scanty and irregular. Extremely thyrotoxic patients may have tachycardia, heart failure, psychosis, hyperpyrexia, and coma, a presentation described as thyroid storm.[27]

Signs

- A variety of physical signs may be observed including warm, smooth, moist skin, exophthalmos (in Graves' disease only), pretibial myxedema (in Graves' disease only), and unusually fine hair. Separation of the end of the fingernails from the nail beds (onycholysis) may be noted. Ocular signs that result from thyrotoxicosis include retraction of the eyelids and lagging of the upper lid behind the globe when the patient looks downward (lid lag). Physical signs of a hyperdynamic circulatory state are common and include tachycardia at rest, a widened pulse pressure, and a systolic ejection murmur. Gynecomastia is sometimes noted in men. Neuromuscular examination often reveals a fine tremor of the protruded tongue and outstretched hands. Deep tendon reflexes are generally hyperactive. Thyromegaly is usually present.

Diagnosis

- Low TSH serum concentration. Elevated free and total T_4 and T_3 serum concentrations, particularly in more severe disease.
- Elevated radioactive iodine uptake (RAIU) by the thyroid gland when hormone is being overproduced; suppressed RAIU in thyrotoxicosis due to thyroid inflammation (thyroiditis).

Other Tests

- Thyroid-stimulating antibodies (TSAbs)
- TG
- Thyrotropin receptor antibodies

Causes of Thyrotoxicosis Associated with Elevated RAIU

TSH-Induced Hyperthyroidism

To better understand these syndromes, we must first review TSH biosynthesis and secretion. TSH is synthesized in the anterior pituitary as separate α- and β-subunit precursors. The α subunits from

luteinizing hormone (LH), follicle-stimulating hormone (FSH), human chorionic gonadotropin (hCG), and TSH are similar, whereas the β subunits are unique and confer immunologic and biologic specificity. Free β subunits are devoid of receptor binding and biologic activity and require combination with an α subunit to express their activity. Criteria for the diagnosis of TSH-induced hyperthyroidism include (a) evidence of peripheral hypermetabolism, (b) diffuse thyroid gland enlargement, (c) elevated free thyroid hormone levels, and (d) elevated or inappropriately "normal" serum immunoreactive TSH concentrations. Because the pituitary gland is extremely sensitive to even minimal elevations of free T_4, a "normal" or elevated TSH level in any thyrotoxic patient indicates the inappropriate production of TSH.

TSH-Secreting Pituitary Adenomas

TSH-secreting pituitary tumors occur sporadically and release biologically active hormone that is unresponsive to normal feedback control.[11] The mean age at diagnosis is around 40 years, with women being diagnosed more than men (8:7). These tumors may co-secrete prolactin or growth hormone; therefore, the patients may present with amenorrhea/galactorrhea or signs of acromegaly. Most patients present with classic symptoms and signs of thyrotoxicosis. Visual field defects may be present due to impingement of the optic chiasm by the tumor. Tumor growth and worsening visual field defects have been reported following antithyroid therapy because lowering of thyroid hormone levels is associated with loss of feedback inhibition from high thyroid hormone levels.

Diagnosis of a TSH-secreting adenoma should be made by demonstrating lack of TSH response to TRH stimulation, inappropriate TSH levels, elevated α-subunit levels, and radiologic imaging; given the lack of routine availability of TRH, the other three criteria are essential. Note that some small tumors are not identified by MRI. Moreover, 10% of "normal" individuals may have incidental pituitary tumors or other benign focal lesions noted on pituitary imaging.

Transsphenoidal pituitary surgery is the treatment of choice for TSH-secreting adenomas. Pituitary gland irradiation is often given following surgery to prevent tumor recurrence. Dopamine agonists and octreotide have been used to treat tumors, especially those that co-secrete prolactin.

Pituitary Resistance to Thyroid Hormone

Resistance to thyroid hormone is a rare condition that can be due to a number of molecular defects, including mutations in the TRβ gene. Pituitary resistance to thyroid hormone (PRTH) refers to selective resistance of the pituitary thyrotrophs to thyroid hormone. As nonpituitary tissues respond normally to thyroid hormone, patients experience the toxic peripheral effects of thyroid hormone excess. About 90% of patients studied have an appropriate increase in TSH in response to TRH; conversely, the TSH will be suppressed by T_3 administration.

Patients with PRTH require treatment to reduce their elevated thyroid hormone levels. Determining the appropriate serum T_4 level is difficult because TSH cannot be used to evaluate adequacy of therapy. Any reduction in thyroid hormone carries the risk of inducing thyrotroph hyperplasia. Ideally, agents that suppress TSH secretion could be used to treat these individuals. Glucocorticoids, dopaminergic drugs, somatostatin and its analogs, and thyroid hormone analogs with reduced

metabolic activity have all been tried, but with relatively little benefit. β-Blocker therapy can also be used. Triiodothyroacetic acid (TRIAC), an agent that is devoid of thyromimetic properties on peripheral tissues, but blocks the secretion of TSH, has been used to treat this condition. However, it is not available in the United States. Given the ability of retinoid X receptor ligands to inhibit TSH production, drugs such as bexarotene may have therapeutic benefit in PRTH.

Graves' Disease

1 Graves' disease is an autoimmune syndrome that usually includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos, and, less commonly, pretibial myxedema and thyroid acropachy (**Fig. 75-4**).[9,12] Graves' disease is the most common cause of hyperthyroidism, with a prevalence estimated to be 3 per 1,000 population in the United States. Hyperthyroidism results from the action of thyroid-stimulating antibodies (TSAbs), which are directed against the thyrotropin receptor on the surface of the thyroid cell. When these immunoglobulins bind to the receptor, they activate downstream G-protein signaling and adenylate cyclase in the same manner as TSH. Autoantibodies that react with orbital muscle and fibroblast tissue in the skin are responsible for the extrathyroidal manifestations of Graves' disease, and these autoantibodies are encoded by the same germline genes that encode for other autoantibodies for striated muscle and thyroid peroxidase. Clinically, the extrathyroidal disorders may not appear at the same time that hyperthyroidism develops.

FIGURE 75-4

Features of Graves' disease. (A) Facial appearance in Graves' disease; lid retraction, periorbital edema, and proptosis are marked. (B) Thyroid dermopathy over the lateral aspects of the shins. (C) Thyroid acropachy. *Reproduced with permission from Fauci AS, Kasper DL, Longo DL, et al., eds. Harrison's Principles of Internal Medicine. 16th ed. New York: McGraw-Hill; 2005:2114.*

There is now compelling evidence that heredity predisposes the susceptible individual to development of clinically overt autoimmune thyroid disease in the setting of appropriate environmental and hormonal triggers. A role for gender in the emergence of Graves' disease is suggested by the fact that hyperthyroidism is approximately eight times more common in women than in men. Other lines of evidence support a role for heredity. First, there is a well-recognized clustering of Graves' disease within some families. Twin studies in Graves' disease have revealed that a monozygotic twin has a 35% likelihood of ultimately developing the disease compared with a 3% likelihood for a dizygotic twin, resulting in estimation that 79% of the predisposition to Graves' disease is genetic.[13] Second, the occurrence of other autoimmune diseases, including Hashimoto's thyroiditis, is also increased in families of patients with Graves' disease. Third, several studies have demonstrated an increased frequency of certain human leukocyte antigens (HLAs) in patients with Graves' disease. Differing HLA associations have been identified in the various ethnic groups studied. In whites, for example, the relative risk of Graves' disease in carriers of the HLA-DR3 haplotype is between 2.5 and 5, whereas lesser associations have been reported for HLA-B8 and the HLA-DQA*0501 allele.[14] Several gene loci have been associated with autoimmune thyroid diseases such as Graves' disease. It is thought that these susceptibility genes interact with environmental triggers to induce thyroid disease through epigenetic effects.[15]

The thyroid gland is diffusely enlarged in the majority of patients with Graves' disease and is commonly 40 to 60 g (two to three times the normal size). The surface of the gland is either smooth or bosselated, and the consistency varies from soft to firm. For patients with severe disease, a thrill

may be felt and a systolic bruit may be heard over the gland, reflecting the increased intraglandular vascularity typical of hyperplasia. Whereas the presence of any of the extrathyroidal manifestations of this syndrome, including exophthalmos, thyroid acropachy, or pretibial myxedema, in a thyrotoxic patient is pathognomonic of Graves' disease, most patients can be diagnosed on the basis of their history and examination of their diffuse goiter (see Fig. 75-4). An important clinical feature of Graves' disease is the occurrence of spontaneous remissions, albeit uncommon. The abnormalities in TSAb production may decrease or disappear over time.

The results of laboratory tests in thyrotoxic Graves' disease include an increase in the overall hormone production rate with a disproportionate increase in T_3 relative to T_4 (**Table 75-4**). In an occasional patient, the disproportionate overproduction of T_3 is exaggerated, with the result that only the serum T_3 concentration is increased (T_3 toxicosis). The saturation of TBG is increased due to the elevated levels of serum T_4 and T_3. As a result, the concentrations of free T_4 and free T_3 are increased to an even greater extent than are the measured serum total T_4 and T_3 concentrations. The TSH level will be suppressed or undetectable due to negative feedback by elevated levels of thyroid hormone at the pituitary.

TABLE 75-4 Thyroid Function Tests in Different Thyroid Conditions

	Total T_4	**Free T_4**	**Total T_3**	**TSH**
Normal	4.5-10.9 mcg/dL	0.8-2.7 ng/dL	60-181 ng/dL	0.5-4.7 milli-international units/L
Hyperthyroid	↑↑	↑↑	↑↑↑	↓↓*
Hypothyroid	↓↓	↓↓	↓	↑↑*
Increased TBG	↑	Normal	↑	Normal

*primary thyroid disease.

For the patient with symptomatic disease, measurement of the serum free T_4 concentration, total T_4, total T_3, and the TSH value will confirm the diagnosis of thyrotoxicosis. If the patient is not pregnant or lactating, a 24-hour RAIU should be obtained if there is any diagnostic uncertainty, for example, recent onset of symptoms or other factors suggestive of thyroiditis. An increased RAIU documents that the thyroid gland is inappropriately utilizing the iodine to produce more thyroid hormone at a time when the patient is thyrotoxic.

Thyrotoxic periodic paralysis is a rare complication of hyperthyroidism commonly observed in Asian and Hispanic populations.[16] It presents as recurrent proximal muscle flaccidity ranging from mild weakness to total paralysis. The paralysis may be asymmetric and usually involves muscle groups that are strenuously exercised before the attack. Cognition and sensory perception are spared, whereas deep tendon reflexes are markedly diminished. The condition is characterized by hypokalemia and low urinary potassium excretion. Hypokalemia results from a sudden shift of potassium from extracellular to intracellular sites rather than reduced total body potassium. High-carbohydrate loads and exercise provoke the attacks. Treatment includes correcting the hyperthyroid state, potassium administration, spironolactone to conserve potassium, and propranolol to minimize intracellular shifts. Some patients with this condition have a mutation in the inwardly rectifying potassium channel

Kir2.6.[17]

Trophoblastic Diseases

Human chorionic gonadotropin is a stimulator of the TSH receptor and may cause hyperthyroidism. The basis for the thyrotropic effect of hCG is the structural similarity of hCG to TSH (similar α subunits and unique β subunits). For patients with hyperthyroidism caused by trophoblastic tumors, serum hCG levels usually exceed 300 units/mL and always exceed 100 units/mL. The mean peak hCG level in normal pregnancy is 50 units/mL. On a molar basis, hCG has only 1/10,000 the activity of pituitary TSH in mouse bioassays. Nevertheless, this thyrotropic activity may be very substantial for patients with trophoblastic tumors, whose serum hCG concentrations may reach 2,000 units/mL.

Toxic Adenoma

An autonomous thyroid nodule is a discrete thyroid mass whose function is independent of pituitary and TSH control. The prevalence of toxic adenoma ranges from about 2% to 9% of thyrotoxic patients, and depends on iodine availability and geographic location. Toxic adenomas are benign tumors that produce thyroid hormone. They arise from gain-of-function somatic mutations of the TSH receptor or, less commonly, the $G_s\alpha$ protein; more than a dozen TSH receptor mutations have been described.[6] These nodules may be referred to as *toxic adenomas*, or "hot" nodules, because of their persistent uptake on a radioiodine thyroid scan, despite suppressed uptake in the surrounding non-nodular gland (**Fig. 75-5**). The amount of thyroid hormone produced by an autonomous nodule is mass related. Therefore, hyperthyroidism usually occurs with larger nodules (ie, those more than 3 cm in diameter). Older patients (older than 60 years) are more likely (up to 60%) to be thyrotoxic from autonomous nodules than are younger patients (12%). There are many reports of isolated elevation of serum T_3 in patients with autonomously functioning nodules. Therefore, if the T_4 level is normal, a T_3 level must be measured to rule out T_3 toxicosis. If autonomous function is suspected but the TSH is normal, the diagnosis can be confirmed by a failure of the autonomous nodule to decrease its iodine uptake during exogenous T_3 administration sufficient to suppress TSH. Surgical resection, thionamides, percutaneous ethanol injection, and radioactive iodine (RAI) ablation are treatment options, but since thionamides do not halt the proliferative process in the nodule, definitive therapies are recommended. Ethanol ablation may be associated with pain and damage to surrounding extrathyroidal tissues, limiting its acceptance in the United States. It has been hypothesized that sublethal radiation doses received by the surrounding non-nodular thyroid tissue during RAI therapy of toxic nodules may lead to induction of thyroid cancer. However, thyroid cancer has rarely been associated with RAI therapy, and newer studies suggest hyperthyroidism itself, rather than RAI therapy, as being associated with non-thyroid malignancies.[18] An autonomously functioning nodule, if not large enough to cause thyrotoxicosis, can often be managed conservatively without therapy.

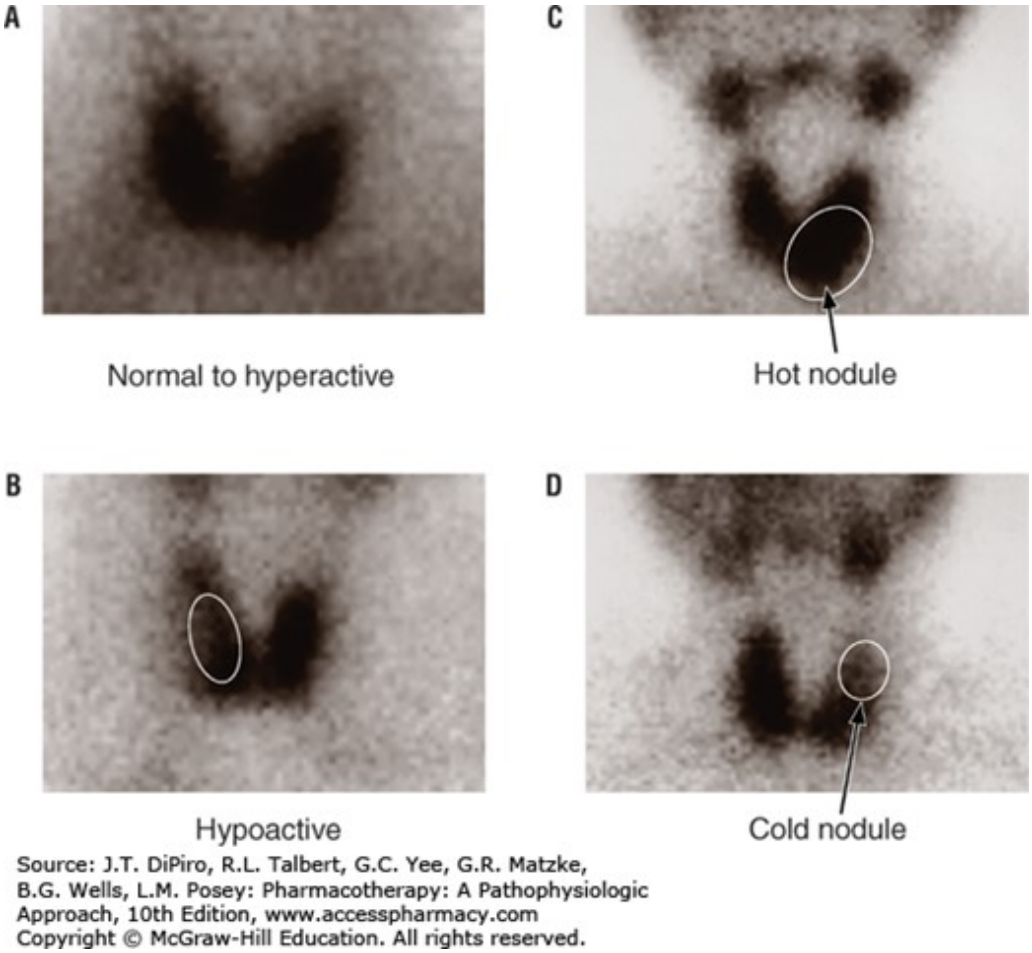
single nodule, the "hot nodule." (D) Decreased thyroid ^{125}I uptake in an isolated region, the "cold nodule." *Reproduced with permission from Molina PE. Endocrine Physiology. 2nd ed. New York: McGraw-Hill; 2006:90. Images courtesy of Dr. Luis Linares, Memorial Medical Center, New Orleans, LA.*



Multinodular Goiters

In multinodular goiters (MNGs), follicles with autonomous function coexist with normal or even nonfunctioning follicles. The pathogenesis of MNG is thought to be similar to that of toxic adenoma: diffuse hyperplasia caused by goitrogenic stimuli, leading to mutations and clonal expansion of benign neoplasms. The functional status of the nodule(s) depends on the nature of the underlying mutations, whether activating such as TSH receptor mutations or inhibitory such as ras mutations. Thyrotoxicosis in an MNG occurs when a sufficient mass of autonomous follicles generates enough thyroid hormone to exceed the needs of the patient. It is not surprising that this type of hyperthyroidism develops insidiously over a period of several years and predominantly affects older individuals with long-standing goiters. The patient's complaints of weight loss, depression, anxiety, and insomnia may be attributed to old age. Any unexplained chronic illness in an elderly patient presenting with an MNG calls for the exclusion of hidden (silent) thyrotoxicosis.[19] Current third-generation TSH assays are able to detect subclinical hyperthyroidism.

A thyroid scan will show patchy areas of autonomously functioning thyroid tissue intermixed with hypofunctioning areas. When the patient is euthyroid, therapy is based on the need to reduce goiter size due to mass-related symptoms such as dysphagia. Doses of thyroid hormone sufficient to

suppress TSH levels may slow goiter growth or cause some degree of shrinkage, but, in general, suppression therapy for nodular disease is inadequate to address mass effect. The preferred treatment for toxic MNG is RAI or surgery. Surgery is usually selected for younger patients and patients in whom large goiters impinge on vital organs. Alternatively, percutaneous injection of 95% ethanol has also been used to destroy single or multinodular adenomas with a 5-year success rate approaching 80%.

Causes of Thyrotoxicosis Associated with Suppressed RAIU

Subacute Thyroiditis

Painful subacute (granulomatous or de Quervain) thyroiditis often develops after a viral syndrome, but rarely has a specific virus been identified in thyroid parenchyma.[20] A genetic predisposition exists, with markedly higher risk for developing subacute thyroiditis for patients with HLA-Bw35. Systemic symptoms often accompany the syndrome, including fever, malaise, and myalgia, in addition to those symptoms due to thyrotoxicosis. Typically, patients complain of severe pain in the thyroid region, which often extends to the ear on the affected side. With time, the pain may migrate from one side of the gland to the other. On physical examination, the thyroid gland is firm and exquisitely tender. Signs of thyrotoxicosis are present.

Thyroid function tests typically run a triphasic course. Initially, serum T_4 levels are elevated due to release of preformed thyroid hormone from disrupted follicles. The 24-hour RAIU during this time is less than 2% due to thyroid inflammation and TSH suppression by the elevated T_4 level. As the disease progresses, intrathyroidal hormone stores are depleted, and the patient may become mildly hypothyroid with an appropriately elevated TSH level. During the recovery phase, thyroid hormone stores are replenished, and serum TSH concentration gradually returns to normal. Recovery is generally complete within 2 to 6 months. Most patients remain euthyroid, and recurrences of painful thyroiditis are extremely rare. The patient with painful thyroiditis should be reassured that the disease is self-limited and is unlikely to recur. Thyrotoxic symptoms may be relieved with β-blockers. Nonsteroidal anti-inflammatory agents will usually relieve the pain. Occasionally, prednisone (30-40 mg daily) must be used to suppress the inflammatory process. Antithyroid drugs are not indicated because they will not be effective as they do not decrease the release of preformed thyroid hormone.

Painless Thyroiditis

Since its description in 1975, painless (silent and lymphocytic) thyroiditis has been recognized as a common cause of thyrotoxicosis and may represent up to 15% of cases of thyrotoxicosis in North America. In the setting of development of lymphocytic thyroiditis during the first 12 months after the end of pregnancy, the condition is also called *postpartum thyroiditis*. The etiology is not fully understood and may be heterogeneous, but evidence indicates that autoimmunity underlies most cases. There is an increased frequency of HLA-DR3 and DR5 in patients with painless thyroiditis; non-endocrine autoimmune diseases are also more common. Histologically, diffuse lymphocytic infiltration is generally identified. The triphasic course of this illness mimics that of subacute thyroiditis. Most patients present with mild thyrotoxic symptoms. Lid retraction and lid lag are

present, but exophthalmos is absent. The thyroid gland may be diffusely enlarged, but thyroid tenderness is absent.

The 24-hour RAIU will typically be suppressed to less than 2% during the thyrotoxic phase of painless thyroiditis. Anti-TG and antithyroid peroxidase antibody (anti-TPOAb) levels are elevated in more than 50% of patients. Patients with mild hyperthyroidism and painless thyroiditis should be reassured that they have a self-limited disease, although patients with postpartum thyroiditis may experience recurrence of the disease with subsequent pregnancies. As with other thyrotoxic syndromes, adrenergic symptoms may be ameliorated with propranolol or metoprolol. Antithyroid drugs, which inhibit new hormone synthesis, are not indicated because they do not decrease the release of preformed thyroid hormone. A small proportion of patients may have recurrent episodes of thyroiditis, or may develop permanent hypothyroidism.[20]

Struma Ovarii

Struma ovarii is a teratoma of the ovary that contains differentiated thyroid follicular cells and is capable of making thyroid hormone. This extremely rare cause of thyrotoxicosis is suggested by the absence of thyroid enlargement in a thyrotoxic patient with a suppressed RAIU in the neck and no findings to suggest thyroiditis. The diagnosis is established by localizing functioning thyroid tissue in the ovary with whole-body RAI (sodium iodide-131 [^{131}I]) scanning. Interestingly, struma ovarii without associated hyperthyroidism is much more common than struma ovarii associated with hyperthyroidism. Because the tissue is neoplastic and potentially malignant, combined surgical and radioiodine treatment of malignant struma ovarii for both monitoring and therapy of relapse is the recommended treatment.

Thyroid Cancer

In widely metastatic differentiated papillary or follicular carcinomas with relatively well-preserved function, sufficient thyroid hormone can be synthesized and secreted to produce thyrotoxicosis. In most instances, a previous diagnosis of thyroid malignancy has been made. The diagnosis can be confirmed by whole-body ^{131}I scanning. Treatment with ^{131}I is generally effective at ablating functioning thyroid metastases.

Exogenous Thyroid Hormone

Thyrotoxicosis factitia was described in the recent American Thyroid Association guidelines on the management of hyperthyroidism as "all causes of hyperthyroidism due to ingestion of thyroid hormone."[9] This category includes hyperthyroidism produced by the intentional ingestion of exogenous thyroid hormone. Obesity is the most common non-thyroidal disorder for which thyroid hormone is inappropriately used, but thyroid hormone has been used for almost every conceivable problem from menstrual irregularities and infertility to hypercholesterolemia and baldness. There is little evidence to suggest that treatment with thyroid hormone is beneficial for such conditions in euthyroid individuals.[21] Obviously, thyrotoxicosis factitia can also occur when too large a dose of thyroid hormone is employed for conditions in which it is likely to be beneficial, such as differentiated

thyroid carcinoma. In addition to this iatrogenic cause, accidental ingestion such as may occur with pediatric ingestion or pharmacy error. Rarely, thyrotoxicosis factitia is caused by the purposeful and secretive ingestion of thyroid hormone by patients (usually with a medical background) who wish to obtain attention or lose weight.

Thyroid hormone may also be accidentally ingested in food sources. Reports of thyrotoxicosis in Minnesota and Nebraska in 1980s were attributed to ingestion of ground beef contaminated by bovine thyroid glands.[22,23] More recently thyrotoxicosis due to porcine thyroid tissue in meat products has been reported in Spain and Uruguay.[24]

Thyrotoxicosis factitia should be suspected in a thyrotoxic patient without evidence of increased hormone production, thyroidal inflammation, or ectopic thyroid tissue. The RAIU uptake is at low levels because the patient's thyroid gland function is suppressed by the exogenous thyroid hormone. Measurement of plasma TG is a valuable laboratory aid in the diagnosis of thyrotoxicosis factitia. TG is normally secreted in small amounts by the thyroid gland; however, when thyroid hormone is taken orally, TG levels tend to be lower than the normal range. In other entities characterized by a low RAIU, such as thyroiditis, leakage of preformed thyroid hormone results in elevated TG levels. If a history of thyroid hormone ingestion is elicited or deduced, exogenous thyroid hormone should be withheld for between 4 and 6 weeks, and thyroid function tests repeated to document that the euthyroid state has been restored. Rarely, thyroid hormone analogs or metabolites may be the drug of abuse, detection of which may be difficult with standard thyroid hormone assays. For example, tiratricol (TRIAC), an endogenous metabolite of T_3 that has been used for weight loss and paradoxically by body builders, will suppress TSH at high enough doses and may cross-react in many T_3 immunoassays; thus, thyrotoxicosis factitia due to tiratricol abuse may be misinterpreted as T_3 toxicosis, and also lead to serious side effects.[25]

Medications Containing Iodine

Amiodarone may induce thyrotoxicosis (2%-3% of patients), overt hypothyroidism (5% of patients), subclinical hypothyroidism (25% of patients), or euthyroid hyperthyroxinemia, depending on the underlying thyroid pathology or lack thereof.[26] Because amiodarone contains 37% iodine by weight, approximately 6 mg/day of iodine is released for each 200 mg of amiodarone, 1,000 times greater than the recommended daily amount of iodine of 150 mcg/day. As a result of this iodine overload, iodine-exacerbated thyroid dysfunction commonly occurs among those patients with preexisting thyroid disease: thyrotoxicosis in patients with hyperthyroidism or euthyroid nodular autonomy and hypothyroidism in patients with autoimmune thyroid disease. In contrast to hyperthyroidism with increased synthesis of thyroid hormone induced by amiodarone (type I), destructive thyroiditis with leakage of TG and thyroid hormones also occurs (type II), typically among individuals with otherwise normal glands. The two types of amiodarone-induced thyrotoxicosis may be differentiated using color flow Doppler ultrasonography. Such distinction is critically important, given the therapeutic implications of the two syndromes: type I amiodarone-induced hyperthyroidism responds somewhat to thionamides, whereas type II may respond to glucocorticoids.[26] Obviously, RAI therapy is inappropriate in type I due to the drug-induced iodine excess, and in type II due to lack of increased hormone synthesis. The manifestations of amiodarone-induced thyrotoxicosis may be atypical

symptoms such as ventricular tachycardia and exacerbation of underlying chronic obstructive pulmonary disease, both of which are significant given the severe underlying cardiac pathology that led to the use of amiodarone in the first place. Amiodarone also directly interferes with type I 5′-deiodinase, leading to reduced conversion of T_4 to T_3 and hyperthyroxinemia without thyrotoxicosis.[26]

TREATMENT

Thyrotoxicosis

2 Three common treatment modalities are used in the management of hyperthyroidism: surgery, antithyroid medications, and RAI (**Table 75-5**).

TABLE 75-5 Treatments for Hyperthyroidism Caused by Graves' Disease

Treatment	Advantages	Disadvantages	Comment
Methimazole (PTU second-line therapy)	Noninvasive Low initial cost Low risk of permanent hypothyroidism Possible remissions due to immune effects	Low cure rate (average 40%-50%) Adverse drug reactions Drug compliance Permanent hypothyroidism almost inevitable Might worsen ophthalmopathy	First-line treatment in children, adolescents, and pregnancy Initial treatment in severe cases or preoperative preparation
Radioactive iodine (^{131}I)	Cure of hyperthyroidism Lowest cost, before adjustment for quality of life	Pregnancy must be deferred for 6-12 months; no breast-feeding Small potential risk of exacerbation of hyperthyroidism	Best treatment for toxic nodules and toxic multinodular goiter
Surgery	Rapid, effective treatment, especially in patients with large goiters	Most invasive Least costly in long term after quality-of-life adjustment Permanent	Potential choice in pregnancy if major side effect from antithyroid drugs Potential complications (recurrent laryngeal nerve damage, hypoparathyroidism)

Treatment	Advantages	Disadvantages	Comment
		hypothyroidism	Useful when coexisting suspicious nodule present
		Pain, scar	Option for patients who refuse radioiodine

Desired Outcomes

The overall therapeutic objectives are to eliminate the excess thyroid hormone and minimize the symptoms and long-term consequences of hyperthyroidism.

General Approach to Treatment

Therapy must be individualized based on the type and severity of hyperthyroidism, patient age and gender, existence of nonthyroidal conditions, and response to previous therapy.[28,29] For example, patients with swallowing or breathing difficulties due to impingement of the esophagus or trachea are generally taken for surgical removal of the thyroid. Clinical guidelines for the treatment of hyperthyroidism have been published.[9] Selected recommendations from these guidelines are shown **(Table 75-6)**.

TABLE 75-6 Selected Recommendations from the American Thyroid Association Hyperthyroidism Guidelines[9]

Recommendation number	Question	Recommendation	Grading
8	If ^{131}I therapy is chosen (*for GD*), how should it be accomplished?	Sufficient radiation should be administered in a single dose (typically 10-15 mCi) to render the patient with GD hypothyroid.	Strong recommendation; moderate quality
13	If antithyroid drugs are chosen as initial management of GD, how should the therapy be managed?	Methimazole should be used in virtually every patient who chooses antithyroid drug therapy for GD, except during the first trimester of pregnancy when propylthiouracil is preferred, in the treatment of thyroid storm, and in patients with minor reactions to methimazole who refuse radioactive iodine therapy or surgery.	Strong recommendation; moderate quality
24	If thyroidectomy is chosen for treatment of GD, how should it be accomplished?	If surgery is chosen as the primary therapy for GD, near-total or total thyroidectomy is the procedure of choice.	Strong recommendation; moderate quality

Recommendation number	Question	Recommendation	Grading
35	If ^{131}I therapy is chosen (*for TMNG*), how should it be accomplished?	For radioactive iodine treatment of TMNG, sufficient radiation should be administered in a single dose to alleviate hyperthyroidism.	Strong recommendation; moderate quality
36	If ^{131}I therapy is chosen (*for TA*), how should it be accomplished?	For radioactive iodine treatment of TA, sufficient radiation to alleviate hyperthyroidism should be administered in a single dose.	Strong recommendation; moderate quality
40	If surgery is chosen (*for TMNG*), how should it be accomplished?	If surgery is chosen as treatment for TMNG, near-total or total thyroidectomy should be performed.	Strong recommendation; moderate quality
42	If surgery is chosen (*for TA*), how should it be accomplished?	If surgery is chosen as the treatment for TA, an ipsilateral thyroid lobectomy, or isthmusectomy if the adenoma is in the thyroid isthmus, should be performed.	Strong recommendation; moderate quality
72	How should hyperthyroidism in pregnancy be managed?	GD during pregnancy should be treated with the lowest possible dose of antithyroid drugs needed to keep the mother's thyroid hormone levels slightly above the normal range for total T_4 and T_3 values in pregnancy and the TSH suppressed. Free T_4 estimates should be kept at or slightly above the upper limit of the nonpregnant reference range. Thyroid function should be assessed monthly, and the antithyroid drug dose adjusted as required.	Strong recommendation; low quality

GD, Graves' disease; ^{131}I, radioactive I-131; TMNG, toxic multinodular goiter; TA, toxic adenoma, SH = subclinical hyperthyroidism.

Nonpharmacologic Therapy

Surgical removal of the hypersecreting thyroid gland became feasible in 1923 when Plummer discovered that iodine reduced the gland's vascularity, making this definitive procedure possible. Surgery should be considered for patients with a large thyroid gland (more than 80 g), severe ophthalmopathy, and a lack of remission on antithyroid drug treatment. In case of cosmetic issues or pressure symptoms, the choice in MNG stands between surgery, which is still the first choice, and radioiodine therapy if uptake is adequate. In addition to surgery, the solitary nodule, whether hot or

cold, can be treated with percutaneous ethanol injection therapy. For hot nodules, radioiodine is the therapy of choice.[9] Appropriate preparation of the patient for thyroidectomy includes methimazole (MMI) until the patient is biochemically euthyroid (usually 6-8 weeks), followed by the addition of iodides (500 mg/day) for 10 to 14 days before surgery to decrease the vascularity of the gland. Propranolol for several weeks preoperatively and 7 to 10 days after surgery has also been used to maintain a pulse rate of less than 90 beats/min. Combined pretreatment with propranolol and 10 to 14 days of potassium iodide also has been advocated.

The overall complication rate when surgery is performed for MNG by an experienced endocrine surgeon is low.[30] If subtotal thyroidectomy, or an operation that attempts to maintain euthyroidism, is performed for Graves' disease, there is a risk of recurrence of hyperthyroidism that is directly related to remnant size. Near total thyroidectomy is generally recognized as the procedure of choice for patients with Graves' disease.[9] The complication rates of surgery for Graves' disease are low when surgery is performed by a high-volume thyroid surgeon. Surgical complications include hypoparathyroidism (up to 2%) and laryngeal nerve injury (up to 1%). Formal cost-effective analysis indicates that a total thyroidectomy may be the most cost-effective method for managing hyperthyroidism when considering outcomes in quality-adjusted life-years.[31]

Pharmacologic Therapy

Antithyroid Medications

Thionamide Drugs

Two drugs within this category, MMI and PTU, are approved for the treatment of hyperthyroidism in the United States.[32] They are classified as thioureylenes (thionamides), which incorporate an N–C–S=N group into their ring structures.

Mechanism of Action

MMI and PTU share several mechanisms to inhibit the biosynthesis of thyroid hormone.[33] These drugs serve as preferential substrates for the iodinating intermediate of thyroid peroxidase and divert iodine away from potential iodination sites in TG. This prevents subsequent incorporation of iodine into iodotyrosines and ultimately iodothyronine ("organification"). Second, they inhibit coupling of MIT and DIT to form T_4 and T_3. The coupling reaction may be more sensitive to these drugs than the iodination reaction. Experimentally, these drugs exhibit immunosuppressive effects, although the clinical relevance of this finding is unclear. For patients with Graves' disease, antithyroid drug treatment has been associated with lower TSAb titers and restoration of normal suppressor T-cell function. However, perchlorate (ClO_4^-), which has a different mechanism of action, also decreases TSAbs, suggesting that normalization of the thyroid hormone level may itself improve the abnormal immune function. PTU inhibits the peripheral conversion of T_4 to T_3. This effect is dose related and occurs within hours of PTU administration. MMI does not have this effect. Over time, depletion of stored hormone and lack of continuing synthesis of thyroid hormone results in the clinical effects of these drugs.

Pharmacokinetics

Both antithyroid drugs are well absorbed (80%-95%) from the gastrointestinal tract, with peak serum concentrations about 1 hour after ingestion. The plasma half-life ranges of PTU and MMI are 1 to 2.5 and 6 to 9 hours, respectively, and are not appreciably affected by thyroid status. Urinary excretion is about 35% for PTU and less than 10% for MMI. These drugs are actively concentrated in the thyroid gland, which may account for the disparity between their relatively short plasma half-lives and the effectiveness of once-daily dosing regimens even with PTU. Approximately 60% to 80% of PTU is bound to plasma albumin, whereas MMI is not protein bound. MMI readily crosses the placenta and appears in breast milk. Older studies suggested that PTU crosses the placental membranes only one tenth as well as MMI; however, these studies were done in the course of therapeutic abortion early in pregnancy. Newer studies show little difference between fetal concentrations of PTU and MMI, and both are associated with elevated TSH in about 20% and low T_4 in about 7% of fetuses.[34]

Dosing and Administration

MMI is available as 5 and 10 mg tablets and PTU as 50 mg tablets. MMI is approximately 10 times more potent than PTU. Initial therapy with MMI is given in two or three divided doses totaling 30 to 60 mg/day. PTU is given in dose ranges from 300 to 600 mg daily, usually in three or four divided doses. Although the traditional recommendation is for divided doses, evidence exists that both drugs can be given as single daily doses. Patients with severe hyperthyroidism may require larger initial doses, and some may respond better at these larger doses if the dose is divided. The maximal blocking doses of MMI and PTU are 120 and 1,200 mg daily, respectively. Once the intrathyroidal pool of thyroid hormone is reduced and new hormone synthesis is sufficiently blocked, clinical improvement should ensue. Usually within 4 to 8 weeks of initiating therapy, symptoms will diminish and circulating thyroid hormone levels will return to normal. At this time the tapering regimen can be started. Changes in dose for each drug should be made on a monthly basis, because the endogenously produced T_4 will reach a new steady-state concentration in this interval. Typical ranges of daily maintenance doses for MMI and PTU are 5 to 30 mg and 50 to 300 mg, respectively.

If the objective of therapy is to induce a long-term remission, the patient should remain on continuous antithyroid drug therapy for 12 to 24 months. Antithyroid drug therapy induces permanent remission rates of 10% to 98%, with an overall average of about 40% to 50%.[35] This is much higher than the remission rate seen with propranolol alone (22%-36%). Patient characteristics for a favorable outcome include older patients (older than 40 years), low T_4:T_3 ratio (less than 20), a small goiter (less than 50 g), short duration of disease (less than 6 months), no previous history of relapse with antithyroid drugs, duration of therapy 1 to 2 years or longer, and low TSAb titers at baseline or a reduction with treatment.[33] A 2012 study provides preliminary evidence that a new assay that has better specificity for detection of antibodies that stimulate the TSH receptors, without detecting coexistent blocking antibodies, may be a useful predictor of remission of Graves' disease.[36]

It is important that patients be followed every 6 to 12 months after remission occurs. If a relapse occurs, alternate therapy with RAI is preferred to a second course of antithyroid drugs. Relapses seem to plateau after about 5 years and eventually 5% to 20% of patients will develop spontaneous

hypothyroidism. There has been interest in whether concurrent administration of T_4 with thionamide therapy for thyrotoxicosis and subclinical hyperthyroidism can reduce autoantibodies directed toward the thyroid gland and improve remission rate. In a Japanese study, adjunctive treatment with T_4 was associated with a 20-fold reduction in the recurrence rate of Graves' disease compared with the recurrence rate seen for patients treated with antithyroid drugs alone.[37] Attempts to reproduce these results in American and European patients with Graves' disease have failed to show any delay or reduction in the recurrence of Graves' disease with T_4 administration, and this approach is generally not recommended because of the higher rates of side effects seen with the larger doses of antithyroid drugs needed with this regimen.[9]

Subclinical hyperthyroidism is defined as the finding of a serum TSH below the lower limit of the reference range combined with free T_4 and T_3 concentrations that are normal. Subclinical hyperthyroidism is associated with an increased risk of atrial fibrillation, and may be associated with increased all-cause mortality. Some studies show an increased risk of hip fractures in postmenopausal women with subclinical hyperthyroidism. Most practitioners agree that treatment of older patients (greater than 65 years) with TSH values below 0.1 milli-international unit/L is reasonable. In patients who are younger or have TSH values of 0.1 to 0.4 milli-international unit/L a decision whether to treat the patient for mild hyperthyroidism or to monitor thyroid function depend on the patient's cardiovascular risk factors and bone health.[9,38]

Adverse Effects

Minor adverse reactions to MMI and PTU have an overall incidence of 5% to 25% depending on the dose and the drug, whereas major adverse effects occur in 1.5% to 4.6% of patients receiving these drugs.[32] Pruritic maculopapular rashes (sometimes associated with vasculitis based on skin biopsy), arthralgias, and fevers occur in up to 5% of patients and may occur at greater frequency with higher doses and in children. Rashes often disappear spontaneously but, if persistent, may be managed with antihistamines.

One of the most common side effects is a benign transient leukopenia characterized by a white blood cell (WBC) count of less than 4,000/mm^3. This condition occurs in up to 12% of adults and 25% of children, and sometimes can be confused with mild leukopenia seen in Graves' disease. This mild leukopenia is not a harbinger of the more serious adverse effect of agranulocytosis, so therapy can usually be continued. If a minor adverse reaction occurs with one antithyroid drug, the alternate thiourea may be tried, but cross-sensitivity occurs for about 50% of patients.[32]

Agranulocytosis is one of the serious adverse effects of thiourea drug therapy and is characterized by fever, malaise, gingivitis, oropharyngeal infection, and a granulocyte count less than 250/mm^3.[32] These drugs are concentrated in granulocytes, and this reaction may represent a direct toxic effect rather than hypersensitivity. This toxic reaction has occurred with both thioureas, and the incidence varies from 0.5% to 6%. It is higher for patients over age 40 receiving an MMI dose greater than 40 mg/day or the equivalent dose of PTU, is linked to HLA class II genes containing the DRB1*08032 allele, and is more frequent with initial MMI doses of 30 mg compared with 15 mg.[39] Agranulocytosis usually develops in the first 3 months of therapy. Because the onset is sudden, routine WBC count

monitoring has not been recommended. Colony-stimulating factors have been used with some success to restore cell counts to normal, but it is unclear how effective this form of therapy is compared with routine supportive care. Peripheral lymphocytes obtained from patients with PTU-induced agranulocytosis undergo transformation in the presence of other thionamides, suggesting that these severe reactions are immunologically mediated and patients should not receive other thionamides. Aplastic anemia has been reported with MMI and may be associated with an inhibitor to colony-forming units. Once antithyroid drugs are discontinued, clinical improvement is seen over several days to weeks. Patients should be counseled to discontinue therapy and contact their physician when flu-like symptoms such as fever, malaise, or sore throat develop. In addition, many clinicians will concomitantly provide an order for a complete blood cell count (with WBC count differential) when prescribing MMI or PTU therapy. If the patient becomes ill and is unable to reach the provider, the patient can still visit the nearest laboratory to have potential agranulocytosis evaluated.

Arthralgias and a lupus-like syndrome (sometimes in the absence of antinuclear antibodies) have been reported in 4% to 5% of patients. This generally occurs after 6 months of therapy. Uncommonly, polymyositis, presenting as proximal muscle weakness and elevated creatine phosphokinase, has been reported with PTU administration. Gastrointestinal intolerance is also reported to occur in 4% to 5% of patients. Hypoprothrombinemia is a rare complication of thionamide therapy. Patients who have experienced a major adverse reaction to one thiourea drug should not be converted to the alternate drug because of cross-sensitivity.[9]

Older reports suggested that congenital skin defects (aplasia cutis) may be caused by MMI and carbimazole, although a registry review from the Netherlands could not find an association between maternal use of these drugs and skin defects. Several serious congenital malformations including tracheoesophageal fistulas and choanal atresia have been observed with MMI and carbimazole but not PTU use during pregnancy.[40,41] Thus, PTU has traditionally been considered the drug of choice throughout pregnancy for women with hyperthyroidism, because of concerns about the possible teratogenic effects of MMI. However, currently heightened concerns about the greater risk of hepatotoxicity with PTU when compared to MMI have led to the recommendation that PTU no longer be considered a first-line drug, except during the first trimester of pregnancy.[9] The issue of choice of antithyroidal agent during pregnancy has been further complicated by a recent study that suggested that fetuses exposed to either MMI or PTU during gestation may have increased risk of drug-induced fetal malformations.[42]

Hepatotoxicity can be seen with both MMI and PTU with a prevalence of approximately 1.3%. At moderate doses, some authors have found that initial hepatic enzyme elevations eventually normalize in most patients with continued therapy. PTU-induced subclinical liver injury is common and is usually transient and asymptomatic. Thus, it has generally been thought that therapy with PTU may be continued with caution in the absence of symptoms and hyperbilirubinemia. However, a 1997 literature review documented 49 cases of hepatotoxicity. Twenty-eight cases were associated with PTU use, and 21 cases were associated with MMI use. The hepatotoxicity was associated with seven deaths and three deaths in the PTU and MMI groups, respectively. There did not appear to be a relationship between the dose or duration of thionamide treatment and outcome. During the past 20

years of PTU use in the United States, 22 adults developed severe hepatotoxicity leading to 9 deaths and 5 liver transplants. The risk of this complication was greater in children (1:2,000) than in adults (1:10,000).[43] A recent reanalysis of data reported to the FDA from 1982 to 2008 found that toxicity in children was generally related to higher doses of PTU and that toxicity in both children and adults was associated with therapy lasting more than 4 months in duration.[44] In light of such evidence, it has been recommended by the American Thyroid Association and the FDA that PTU not be considered as first-line therapy in either adults or children.[9,45] One of three exceptions includes the first trimester of pregnancy, when the risk of MMI-induced embryopathy may exceed that of PTU-induced hepatotoxicity. Other exceptions include intolerance to MMI and thyroid storm.

Iodides

Iodide was the first form of drug therapy for Graves' disease. Its mechanism of action is to acutely block thyroid hormone release, inhibit thyroid hormone biosynthesis by interfering with intrathyroidal iodide utilization (the Wolff-Chaikoff effect), and decrease the size and vascularity of the gland. This early inhibitory effect provides symptom improvement within 2 to 7 days of initiating therapy, and serum T_4 and T_3 concentrations may be reduced for a few weeks. Despite the reduced release of T_4 and T_3, thyroid hormone synthesis continues at an accelerated rate, resulting in a gland rich in stored hormones. The normal and hyperfunctioning thyroid soon escapes from this inhibitory effect within 1 to 2 weeks by decreasing the active transfer of iodide into the gland. Iodides are often used as adjunctive therapy to prepare a patient with Graves' disease for surgery, to acutely inhibit thyroid hormone release and quickly attain the euthyroid state in severely thyrotoxic patients with cardiac decompensation, or to inhibit thyroid hormone release following RAI therapy. However, large doses of iodine may exacerbate hyperthyroidism or indeed precipitate hyperthyroidism in some previously euthyroid individuals (Jod-Basedow disease). This Jod-Basedow phenomenon is most common in iodine-deficient areas, particularly for patients with preexisting nontoxic goiter. Iodide is contraindicated in toxic MNG.

Potassium iodide is available either as a saturated solution (SSKI), which contains 38 mg of iodide per drop, or as Lugol's solution, which contains 6.3 mg of iodide per drop. The typical starting dose of SSKI is 3 to 10 drops daily (120-400 mg) in water or juice. There is no documented advantage to using doses in excess of 6 to 8 mg/day. When used to prepare a patient for surgery, it should be administered 7 to 14 days preoperatively. As an adjunct to RAI, SSKI should not be used before, but rather 3 to 7 days after RAI treatment, so that the radioactive iodide can concentrate in the thyroid. The most frequent toxic effects with iodide therapy are hypersensitivity reactions (skin rashes, drug fever, rhinitis, and conjunctivitis), salivary gland swelling, "iodism" (metallic taste, burning mouth and throat, sore teeth and gums, symptoms of a head cold, and sometimes stomach upset and diarrhea), and gynecomastia.

Other compounds containing organic iodide have also been used therapeutically for hyperthyroidism. These include various radiologic contrast media that share a triiodoaminobenzene and monoaminobenzene ring with a propionic acid chain (eg, iopanoic acid and sodium ipodate). The effect of these compounds is a result of the iodine content inhibiting thyroid hormone release as well as competitive inhibition of 5'-monodeiodinase conversion related to their structures, which resemble

thyroid analogs. Unfortunately, these extremely useful agents are no longer available in the United States.

Adrenergic Blockers

Because many of the manifestations of hyperthyroidism are mediated by β-adrenergic receptors, β-blockers (especially propranolol) have been used widely to ameliorate symptoms such as palpitations, anxiety, tremor, and heat intolerance. Although β-blockers are quite effective for symptom control, they have no effect on the urinary excretion of calcium, phosphorus, hydroxyproline, creatinine, or various amino acids, suggesting a lack of effect on peripheral thyrotoxicosis and protein metabolism. Furthermore, β-blockers neither reduce TSAb nor prevent thyroid storm. Propranolol and nadolol partially block the conversion of T_4 to T_3, but this contribution to the overall therapeutic effect is small in magnitude. Inhibition of conversion of T_4 to T_3 is mediated by d-propranolol, which is devoid of β-blocking activity, and l-propranolol, which is responsible for the antiadrenergic effects, has little effect on the conversion.

β-Blockers are usually used as adjunctive therapy with antithyroid drugs, RAI, or iodides when treating Graves' disease or toxic nodules; in preparation for surgery; or in thyroid storm. The only conditions for which β-blockers are primary therapy for thyrotoxicosis are those associated with thyroiditis. The dose of propranolol required to relieve adrenergic symptoms is variable, but an initial dose of 20 to 40 mg four times daily is effective (heart rate less than 90 beats/min) for most patients. Younger or more severely toxic patients may require as much as 240 to 480 mg/day because there seems to be an increased clearance rate for these patients. β-Blockers are contraindicated for patients with decompensated heart failure unless it is caused solely by tachycardia (high output). Nonselective agents and those lacking intrinsic sympathomimetic activity should be used with caution for patients with asthma and bronchospastic chronic obstructive lung disease. β-Blockers that are cardioselective and have intrinsic sympathomimetic activity may have a slight margin of safety in these situations. Other patients in whom contraindications exist are those with sinus bradycardia, those receiving monoamine oxidase inhibitors or tricyclic antidepressants, and those with spontaneous hypoglycemia. β-Blockers may also prolong gestation and labor during pregnancy. Other side effects include nausea, vomiting, anxiety, insomnia, light-headedness, bradycardia, and hematologic disturbances.

Antiadrenergic agents such as centrally acting sympatholytics and calcium channel antagonists may have some role in the symptomatic treatment of hyperthyroidism. These drugs might be useful when contraindications to β-blockade exist. When compared with nadolol 40 mg twice daily, clonidine 150 mcg twice daily reduced plasma catecholamines, whereas nadolol increased both epinephrine and norepinephrine after 1 week of treatment. Diltiazem 120 mg given every 8 hours reduced heart rate by 17%; fewer ventricular extrasystoles were noted after 10 days of therapy, and diltiazem has been shown to be comparable to propranolol in lowering heart rate and blood pressure.

Radioactive Iodine

Although other radioisotopes have been used to ablate thyroid tissue, ^{131}I is considered to be the

agent of choice for Graves' disease, toxic autonomous nodules, and toxic MNGs.[9] RAI is administered as a colorless and tasteless liquid that is well absorbed and concentrates in the thyroid. ^{131}I is a β- and γ-emitter with a tissue penetration of 2 mm and a half-life of 8 days. Other organs take up ^{131}I, but the thyroid gland is the only organ in which organification of the absorbed iodine takes place. Initially, RAI disrupts hormone synthesis by incorporating into thyroid hormones and TG. Over a period of weeks, follicles that have taken up RAI and surrounding follicles develop evidence of cellular necrosis, breakdown of follicles, development of bizarre cell forms, nuclear pyknosis, and destruction of small vessels within the gland, leading to edema and fibrosis of the interstitial tissue. Pregnancy is an absolute contraindication to the use of RAI since radiation will be delivered to the fetal tissue, including the fetal thyroid.

β-Blockers may be given any time without compromising RAI therapy, accounting for their role as a mainstay of adjunctive therapy to RAI treatment. If iodides are administered, they should be given 3 to 7 days after RAI to prevent interference with the uptake of RAI in the thyroid gland. Because thyroid hormone levels will transiently increase following RAI treatment due to release of preformed thyroid hormone, patients with cardiac disease and elderly patients are often treated with thionamides prior to RAI ablation. For patients with underlying cardiac disease, it may be necessary to reinstitute antithyroid drug therapy following RAI ablation. The standard practice is to withdraw the thionamide 4 to 6 days prior to RAI treatment and to reinstitute it 4 days after therapy is concluded. Administering antithyroid drug therapy immediately following RAI treatment may result in a higher rate of post-treatment recurrence or persistent hyperthyroidism. Pretreatment with PTU may lead to higher rates of treatment failure, but this does not appear to be the case with MMI pretreatment. Use of lithium, as adjunctive therapy to RAI therapy, has multiple benefits of increasing the cure rate, shortening the time to cure, and preventing post-therapy increase in thyroid hormone levels.[46] Lithium is likely to achieve these effects by increasing RAI retention in the thyroid and inhibiting thyroid hormone release from the gland.

Corticosteroid administration will blunt and delay the rise in antibodies to the TSH receptor, TG, and thyroid peroxidase while reducing T_3 and T_4 concentrations following RAI. Bartalena et al. found no progression in ophthalmopathy for patients receiving prednisone after RAI (0% worsened) compared with 3% worsening in those receiving MMI, and 5% worsening in those receiving RAI alone.[47] Theoretically, if shared thyroidal and orbital antigen is involved in the pathogenesis of Graves' ophthalmopathy, antigen released with RAI treatment could aggravate preexisting eye disease. There is some disagreement as to what degree of ophthalmopathy should be considered a contraindication to RAI. However, in those with moderate or severe orbitopathy it seems reasonable to delay RAI until the patient's eye disease has been stable.

Destruction of the gland attenuates the hyperthyroid state, and hypothyroidism commonly occurs months to years following RAI.[9,33] The goal of therapy is to destroy overactive thyroid cells, and a single dose of 4,000 to 8,000 rad results in a euthyroid state in 60% of patients at 6 months or less. The remaining 40% become euthyroid within 1 year, requiring two or more doses. It is advisable that a second dose of RAI be given 6 months after the first RAI treatment if the patient remains hyperthyroid.[9] Variables that predict an unsuccessful outcome of RAI include gender (men are less likely to develop hypothyroidism), race, the size of the thyroid (euthyroidism is less likely in large

glands), severity of disease, and perhaps a higher level of TSAb. In a recent study, predictors of successful treatment with RAI included higher ablative dose, female gender, lower free T_4 levels at diagnosis, and absence of a palpable goiter.[48] The acute, short-term side effects of ^{131}I therapy are minimal and include mild thyroidal tenderness and dysphagia. Concern over increased risk of mutations and congenital defects now appears to be unfounded because long-term follow-up studies have not revealed increased risk for these complications.[49] In some studies examining the risk of malignancies after RAI therapy, there seems to be a small but significant increase in the risk of cancer of the small bowel and thyroid.[49] Although RAI is very effective in the treatment of hyperthyroidism, long-term follow-up from Great Britain suggests that among patients with hyperthyroidism treated with RAI, mortality from all causes and mortality resulting from cardiovascular and cerebrovascular disease and fracture are increased.

A common approach to Graves' hyperthyroidism is to administer a single dose of 5 to 15 mCi (80-200 μCi/g of tissue). The optimal method for determining ^{131}I treatment doses for Graves' hyperthyroidism is unknown, and techniques have varied from a fixed dose to more elaborate calculations based on gland size, iodine uptake, and iodine turnover.[9] In a trial of 88 patients with Graves' disease, no difference in outcome was seen among high or low, fixed or adjusted doses. Thyroid glands estimated to weigh more than 80 g may require larger doses of RAI. Larger doses are likely to induce hypothyroidism and are seldom given outside the United States due to the imposition of stringent safety restrictions. For example, in the United Kingdom, a nursery school teacher is advised to stay out of school for 3 weeks following a 15 mCi dose of ^{131}I.

Thyrotoxicosis—Controversy…

When treating pregnant women with hyperthyroidism the recommendation has been to use PTU in the first trimester to avoid teratogenesis and to switch to MMI for the remainder of pregnancy to avoid hepatotoxicity. Recent data suggest that birth defects may have a similar incidence in fetuses exposed to PTU, compared with those who are exposed to MMI. Future studies will help to determine the drug of choice for treating hyperthyroidism during pregnancy, and whether one drug should be maintained for the duration of pregnancy.

Special Populations

Graves' Disease and Pregnancy

Inappropriate production of hCG is a cause of abnormal thyroid function tests during the first half of pregnancy, and hCG can cause either subclinical (normal T_4 and suppressed TSH) or overt hyperthyroidism. This is because the homology of hCG and TSH leads to hCG-mediated stimulation through the TSH receptor. A recent study showed that at hCG concentrations greater than 400 international units/mL, TSH levels were invariably suppressed and free T_4 levels were generally above the normal range. Most patients with hCG greater than 200 international units/mL did not have symptoms of hyperthyroidism. The variability of the thyrotropic potency of hCG is believed to depend on its carbohydrate composition.

Recently, two very comprehensive guidelines have been published by the American Thyroid Association and the Endocrine Society regarding the management of thyroid disease during pregnancy.[50,51] Hyperthyroidism during pregnancy is almost solely caused by Graves' disease, with approximately 0.1% to 0.4% of pregnancies affected. Although the increased metabolic rate is usually well tolerated in pregnant women, two symptoms suggestive of hyperthyroidism during pregnancy are failure to gain weight despite good appetite and persistent tachycardia. There is no increase in maternal mortality or morbidity in well-controlled patients; however, postpartum thyroid storm has been reported in about 20% of untreated individuals. Fetal loss is also more common, due to the facts that spontaneous abortion and premature delivery are more common in untreated pregnant women, as are low-birth-weight infants and eclampsia. Transplacental passage of TSAb may occur, causing fetal as well as neonatal hyperthyroidism. An uncommon cause of hyperthyroidism is molar pregnancy; women present with a large-for-dates uterus and evacuation of the uterus is the preferred management approach.

Because RAI is contraindicated in pregnancy and surgery is usually not recommended (especially during the first trimester), antithyroid drug therapy is usually the treatment of choice for hyperthyroidism. MMI readily crosses the placenta and appears in breast milk.

Propylthiouracil has been considered the drug of choice during the first trimester of pregnancy, with the lowest possible doses used to maintain the maternal T_4 level in the high-normal range.[43,45] During this period the risk of MMI-associated embryopathy is believed to outweigh that of PTU-associated hepatotoxicity. To prevent fetal goiter and suppression of fetal thyroid function, PTU is usually prescribed in daily doses of 300 mg or less and tapered to 50 to 150 mg daily after 4 to 6 weeks. PTU doses of less than 200 mg daily are unlikely to produce fetal goiter.[34] During the second and third trimesters, when the critical period of organogenesis is complete, MMI has been thought to be the drug of choice because of the greater risk of hepatotoxicity with PTU.[43,45] However, a recent study has raised the question of whether this strategy of switching thionamides, and thus exposing the fetus to both drugs, is the optimum approach.[42] Thionamide doses should be adjusted to maintain free T_4 within 10% of the upper normal limit of the nonpregnant reference range. During the last trimester, TSAbs fall spontaneously, and some patients will go into remission so that antithyroid drug doses may be reduced. A rebound in maternal hyperthyroidism occurs in about 10% of women postpartum and may require more intensive treatment than in the last trimester of pregnancy. For example, a study of patients who were euthyroid after thionamide discontinuation and subsequently became pregnant showed a relative risk of 4.26 for relapse of hyperthyroidism occurring 4 to 8 months after delivery.[52]

Neonatal and Pediatric Hyperthyroidism

Following delivery, some babies of hyperthyroid mothers will be hyperthyroid due to placental transfer of TSAbs, which stimulates thyroid hormone production in utero and postpartum. This is likely if the maternal TSAb titers were quite high. The disease is usually expressed 7 to 10 days postpartum and treatment with antithyroid drugs (PTU 5-10 mg/kg/day or MMI 0.5-1 mg/kg/day) may be needed for as long as 8 to 12 weeks until the antibody is cleared (immunoglobulin G half-life is about 2 weeks). Iodide (potassium iodide one drop per day or Lugol's solution one to three drops

per day) and sodium ipodate may be used for the first few days to acutely inhibit hormone release.

Childhood hyperthyroidism has classically been managed with either MMI or PTU. Long-term follow-up studies suggest that this form of therapy is quite acceptable, with 25% of a cohort experiencing remission every 2 years.[53] Again, current recommendations suggest use of MMI as a first-line agent in both adults and children.[9]

Thyroid Storm

Thyroid storm is a life-threatening medical emergency characterized by decompensated thyrotoxicosis, high fever (often more than 39.4°C [more than 103°F]), tachycardia, tachypnea, dehydration, delirium, coma, nausea, vomiting, and diarrhea.[27] Although Graves' disease and less commonly toxic nodular goiter are usually the underlying thyrotoxic pathology,[54] at least two cases of subacute thyroiditis leading to thyroid storm have been reported.

Precipitating factors for thyroid storm include infection, trauma, surgery, RAI treatment, and withdrawal from antithyroid drugs. Although the duration of clinical decompensation lasts for an average duration of 72 hours, symptoms may persist up to 8 days. With aggressive treatment, the mortality rate has been lowered to 20%. The following therapeutic measures should be instituted promptly: (a) suppression of thyroid hormone formation and secretion, (b) antiadrenergic therapy, (c) administration of corticosteroids, and (d) treatment of associated complications or coexisting factors that may have precipitated the storm. Specific agents used in thyroid storm are outlined in **Table 75-7**. PTU in large doses may be the preferred thionamide because, in addition to interfering with the production of thyroid hormones, it also blocks the peripheral conversion of T_4 to T_3. However, β-blockers and corticosteroids will serve the same purpose. A theoretical advantage of MMI is that it has a longer duration of action. If patients are unable to take medications orally, the tablets can be crushed into suspension and instilled by gastric or rectal tube or given IV. Iodides, which rapidly block the release of preformed thyroid hormone, should be administered after thionamide is initiated to inhibit iodide utilization by the overactive gland. If iodide is administered first, it could theoretically provide substrate to produce even higher levels of thyroid hormone.

TABLE 75-7 Drug Dosages Used in the Management of Thyroid Storm

Drug	Regimen
Propylthiouracil	900-1,200 mg/day orally in four or six divided doses
Methimazole	90-120 mg/day orally in four or six divided doses
Sodium iodide	Up to 2 g/day IV in single or divided doses
Lugol's solution	5-10 drops three times a day in water or juice
Saturated solution of potassium iodide	1-2 drops three times a day in water or juice
Propranolol	40-80 mg every 6 hours
Dexamethasone	5-20 mg/day orally or IV in divided doses
Prednisone	25-100 mg/day orally in divided doses
Methylprednisolone	20-80 mg/day IV in divided doses

Drug	Regimen
Hydrocortisone	100-400 mg/day IV in divided doses

Antiadrenergic therapy with the short-acting agent esmolol is preferred, both because it may be used in the patient with pulmonary disease or at risk for cardiac failure and because its effects may be rapidly reversed.[55] Corticosteroids are generally recommended, although there is no convincing evidence of adrenocortical insufficiency in thyroid storm, and the benefits derived from steroids may be caused by their antipyretic action and their effect of stabilizing blood pressure.[27] General supportive measures, including acetaminophen as an antipyretic (do not use aspirin or other nonsteroidal anti-inflammatory agents because they may displace bound thyroid hormone), fluid and electrolyte replacement, sedatives, digitalis, antiarrhythmics, insulin, and antibiotics, should be given as indicated. Plasmapheresis and peritoneal dialysis have been used to remove excess hormone (and to remove thyroid-stimulating immunoglobulins in Graves' disease) when the patient has not responded to more conservative measures, although these measures do not always work.

An analysis was undertaken to identify cases of thyroid storm occurring in Japan during the period 2004 to 2008.[54] The mortality rate was approximately 10% in the group of 282 patients identified. The most common trigger of the thyrotoxicosis was discontinuation or irregular use of antithyroidal agents. The most common cause of death was either multiorgan failure or congestive heart failure.

EVALUATION OF THERAPEUTIC OUTCOMES—THYROTOXICOSIS

After therapy (surgery, thionamides, or RAI) for hyperthyroidism has been initiated, patients should be evaluated on a monthly basis until they reach a euthyroid condition. Clinical signs of continuing thyrotoxicosis (tachycardia, weight loss, and heat intolerance, among others) or the development of hypothyroidism (bradycardia, weight gain, and lethargy, among others) should be noted. β-Blockers may be used to control symptoms of thyrotoxicosis until the definitive treatment has returned the patient to a euthyroid state. If T_4 replacement is initiated, the goal is to maintain both the free T_4 level and the TSH concentration in the normal range. Once a stable dose of T_4 is identified, the patient may be followed up every 6 to 12 months.

A common, potentially confusing clinical situation should be mentioned. Some patients may have TSH concentrations that continue to be suppressed despite having free T_4 concentrations that become normal or low. For patients with long-standing hyperthyroidism, the pituitary thyrotrophs responsible for making TSH become atrophic. The average amount of time required for these cells to resume normal functioning is 6 to 8 weeks. Therefore, if a thyrotoxic patient has his or her free T_4 concentration lowered rapidly, before the thyrotrophs resume normal function, a period of "transient central hypothyroidism" will be observed. In addition, autoimmune mechanisms may also play a role, with a slower TSH recovery in patients with higher titers of thyroid-binding inhibitory immunoglobulins.

EPIDEMIOLOGY—HYPOTHYROIDISM

Hypothyroidism is defined as the clinical and biochemical syndrome resulting from decreased thyroid hormone production.[56] Overt hypothyroidism occurs in 1.5% to 2% of women and 0.2% of men, and its incidence increases with age. In the Third National Health and Nutrition Examination Survey (NHANES III), levels of serum TSH and total T_4 were measured in a representative sample of adolescents and adults (age 12 or older). Among 16,533 people who neither were taking thyroid medication nor reported histories of thyroid disease, 3.9% had subclinical hypothyroidism (serum TSH more than 4.5 milli-international units/L, and T_4 normal), and 0.2% had "clinically significant" hypothyroidism (TSH more than 4.5 milli-international units/L, and T_4 less than 4.5 mcg/dL).[10]

ETIOLOGY—HYPOTHYROIDISM

The vast majority of patients have primary hypothyroidism due to thyroid gland failure due to chronic autoimmune thyroiditis. Special populations with higher risk of developing hypothyroidism include postpartum women, individuals with a family history of autoimmune thyroid disorders and patients with previous head and neck or thyroid irradiation or surgery, other autoimmune endocrine conditions (eg, type 1 diabetes mellitus, adrenal insufficiency, and ovarian failure), some other nonendocrine autoimmune disorders (eg, celiac disease, vitiligo, pernicious anemia, Sjögren's syndrome, and multiple sclerosis), primary pulmonary hypertension, and Down's and Turner's syndromes. Secondary hypothyroidism due to pituitary failure is uncommon but should be suspected in a patient with decreased levels of T_4 and inappropriately normal or low TSH levels. Most patients with secondary hypothyroidism due to inadequate TSH production will have clinical signs of more generalized pituitary insufficiency, such as abnormal menses and decreased libido, or evidence of a pituitary adenoma, such as visual field defects, galactorrhea, or acromegaloid features, but isolated TSH deficiency can be congenital or acquired as a result of autoimmune hypophysitis.[57] Generalized (peripheral and central) resistance to thyroid hormone is extremely rare.

PATHOPHYSIOLOGY—HYPOTHYROIDISM

Table 75-8 outlines the causes of hypothyroidism. These causes fall into two broad categories involving dysfunction of the thyroid gland itself, or dysfunction at the level of the pituitary or hypothalamus.

TABLE 75-8 Causes of Hypothyroidism

Primary hypothyroidism
Hashimoto's disease
Iatrogenic hypothyroidism
Less Common:
Iodine deficiency
Enzyme defects

Thyroid hypoplasia

Goitrogens

Secondary hypothyroidism

Pituitary disease

Hypothalamic disease

Chronic Autoimmune Thyroiditis

7 Autoimmune thyroiditis (Hashimoto's disease) is the most common cause of spontaneous hypothyroidism in the adult.[56] Patients may present either with goitrous thyroid gland enlargement and mild hypothyroidism or with thyroid gland atrophy and more severe thyroid hormone deficiency. Both forms of autoimmune thyroiditis probably result from cell- and antibody-mediated thyroid injury. The bulk of evidence suggests that the presence of specific defects in suppressor T-lymphocyte function leads to the survival of a randomly mutating clone of helper T lymphocytes, which are directed against normally occurring antigens on the thyroid membrane. Once these T lymphocytes interact with thyroid membrane antigen, B lymphocytes are stimulated to produce thyroid antibodies.[58]

Antithyroid peroxidase (antimicrosomal) antibodies are present in virtually all patients with Hashimoto's thyroiditis and appear to be directed against the enzyme thyroid peroxidase.[59] These antibodies are capable of fixing complement and inducing cytotoxic changes in thyroid cells. Antibodies that are capable of stimulating thyroid growth through interaction with the TSH receptor may occasionally be found particularly in goitrous hypothyroidism; conversely, antibodies that inhibit the trophic effects of TSH may be present in the atrophic type.

Iatrogenic Hypothyroidism

Iatrogenic hypothyroidism follows exposure to destructive amounts of radiation (radioiodine or external radiation) or surgery. Hypothyroidism occurs within 3 months to a year after ^{131}I therapy in most patients treated for Graves' disease. Thereafter, it occurs at a rate of approximately 2.5% each year. External radiation therapy to the region of the thyroid using doses of greater than 2,500 centigray (cGy) for therapy of neck carcinoma also causes hypothyroidism. This effect is dose dependent, and more than 50% of patients who receive more than 4,000 cGy to the thyroid bed develop hypothyroidism. Total thyroidectomy causes hypothyroidism within 1 month. Excessive doses of thionamides used to treat hyperthyroidism can also cause iatrogenic hypothyroidism.

Other Causes of Primary Hypothyroidism

Iodine deficiency, enzymatic defects within the thyroid gland, thyroid hypoplasia, and maternal ingestion of goitrogens during fetal development may cause cretinism. Early recognition and treatment of the resultant thyroid hormone deficiency is essential for optimal mental development.[60]

Large-scale neonatal screening programs in North America, Europe, Japan, and Australia are now in place.[61] The frequency of congenital hypothyroidism in North America and Europe is 1 per 3,500 to 4,000 live births. In the United States, there are racial differences in the incidence of congenital hypothyroidism, with whites being affected seven times as frequently as blacks.

In the adult, hypothyroidism is rarely caused by iodine deficiency and goitrogens. Iodine ingestion in the form of expectorants can lead to hypothyroidism. In sensitive persons (particularly those with autoimmune thyroiditis), the iodide blocks the synthesis of thyroid hormone, leading to an increased secretion of TSH and thyroid enlargement. Thus, both iodine excess and iodine deficiency can cause decreased secretion of thyroid hormone. An example of a goitrogen that can induce hypothyroidism is raw bok choy.[62] Several medications can cause hypothyroidism, including lithium, amiodarone, interferon-alfa, interleukin-2, tyrosine kinase inhibitors, and perchlorate.

Pituitary Disease

Thyroid-stimulating hormone is required for normal thyroid secretion. Thyroid atrophy and decreased thyroid secretion follow pituitary failure. Pituitary insufficiency may be caused by destruction of thyrotrophs by either functioning or nonfunctioning pituitary tumors, surgical therapy, external pituitary radiation, postpartum pituitary necrosis (Sheehan's syndrome), trauma, and infiltrative processes of the pituitary such as metastatic tumors, tuberculosis, histiocytosis, and autoimmune mechanisms.[63,64] In all these situations, TSH deficiency most often occurs in association with other pituitary hormone deficiencies. The identification of secondary hypothyroidism due to bexarotene use has led to recognition of the role of rexinoids and retinoids to cause dysregulation of TSH production.[65,66]

Note that pituitary enlargement in hypothyroidism does not invariably indicate the presence of a primary pituitary tumor. Pituitary enlargement is seen in patients with severe primary hypothyroidism due to compensatory hyperplasia and hypertrophy of the thyrotrophs.[67] With thyroid hormone replacement therapy, serum TSH concentrations decline, indicating that the TSH secretion is not autonomous, and the pituitary resumes a more normal configuration. These patients are easily separated from patients with primary pituitary failure by measuring a TSH level.

Hypothalamic Hypothyroidism

Thyrotropin-releasing hormone deficiency also causes a rare form of central hypothyroidism. In both adults and children it may occur as a result of cranial irradiation, trauma, infiltrative diseases, or neoplastic diseases.

CLINICAL PRESENTATION General

- Hypothyroidism can lead to a variety of end-organ effects with a wide range of disease severity, from entirely asymptomatic individuals to patients in coma with multisystem failure. In the adult, manifestations of hypothyroidism are varied and nonspecific. In the child, thyroid hormone deficiency may manifest as growth or intellectual retardation.

Symptoms

- Common symptoms of hypothyroidism include dry skin, cold intolerance, weight gain, constipation, and weakness. Complaints of lethargy, depression, fatigue, exercise intolerance, or loss of ambition and energy are also common but are less specific. Muscle cramps, myalgia, and stiffness are frequent complaints of hypothyroid patients. Menorrhagia and infertility may present commonly in women.

Signs

- Objective weakness is common, with proximal muscles being affected more than distal muscles. Slow relaxation of deep tendon reflexes is common. The most common signs of decreased levels of thyroid hormone include coarse skin and hair, cold or dry skin, periorbital puffiness, and bradycardia. Speech is often slow and the voice may be hoarse. Reversible neurologic syndromes such as carpal tunnel syndrome, polyneuropathy, and cerebellar dysfunction may also occur. Galactorrhea may be found in women.

Diagnosis

- In primary hypothyroidism, TSH serum concentration should be elevated. In secondary hypothyroidism, TSH levels may be within or below the reference range; when TSH bioactivity is altered, the levels reported by immunoassay may even be elevated.

- Free and/or total T_4 and T_3 serum concentrations should be low.

Other Tests

- TPOAbs and anti-TG antibodies are likely to be elevated in autoimmune thyroiditis.

CLINICAL PRESENTATION—HYPOTHYROIDISM

Thyroid hormone is essential for normal growth and development during embryonic life. Uncorrected thyroid hormone deficiency during fetal and neonatal development results in mental retardation and/or cretinism. Both in children and adults, there is slowing of physical and mental activity, as well as of cardiovascular, gastrointestinal, and neuromuscular function.

A rise in the TSH level is the first evidence of primary hypothyroidism. Many patients will have a free T_4 level within the normal range (compensated or subclinical hypothyroidism) with few, if any, symptoms of hypothyroidism. As the disease progresses, the free T_4 concentration will drop below the normal level. Interestingly, because of TSH stimulation, thyroidal production will shift toward greater amounts of T_3, and thus T_3 concentrations will often be maintained in the normal range in spite of a low T_4. As the hypothyroidism continues to progress, the T_3 concentration will eventually become low too. The RAIU is not a useful test in the evaluation of a hypothyroid patient, as it may be low, normal, or even elevated. For most hypothyroid patients with pituitary disease, serum TSH concentrations are generally low or normal. A serum TSH concentration in the normal range is clearly

inappropriate if the patient's T_4 is low.

TREATMENT

Hypothyroidism

Most cases of hypothyroidism result from progressive and permanent damage to the thyroid gland. Replacement of thyroid hormone is the cornerstone of treatment.

Desired Outcomes

The goals of therapy are to restore normal thyroid hormone concentrations in tissue, provide symptomatic relief, prevent neurologic deficits in newborns and children, and reverse the biochemical abnormalities of hypothyroidism.

General Approach to Treatment

Levothyroxine (l-thyroxine, T_4) is considered to be drug of choice for treatment of hypothyroidism (**Table 75-9**).[21,68] Other commercially available thyroid preparations can be obtained but are not considered preferred therapy. Available thyroid preparations are synthetic (l-thyroxine, liothyronine, and liotrix) or natural in origin (ie, desiccated thyroid). The preparations containing both T_4 and T_3 (liotrix, desiccated thyroid) have relatively high proportions of T_3 and may cause thyrotoxicosis.[21,69] Liothyronine is a short-acting preparation that requires dosing multiple times a day in order to achieve stable hormone concentrations.[70] The availability of sensitive and specific assays for total and free hormone levels as well as TSH now allows precise dose titration to allow adequate replacement without inadvertent overdose. The response of TSH to TRH had been advocated for use by some in order to "fine tune" thyroid replacement, but this is not necessary if the third-generation chemiluminometric assays for TSH, which have detection limits of about 0.01 milli-international unit/L, are used. Clinical guidelines for the management of hypothyroidism have been published by the American Thyroid Association and the American Association of Clinical Endocrinologists in 2012.[68] More recent guidelines (2014) sponsored by the American Thyroid Association provide specific treatment recommendations and critically examine the use of combination therapy with T_4 and T_3[21] (**Table 75-10**).

TABLE 75-9 Thyroid Preparations Used in the Treatment of Hypothyroidism

Drug/Dosage Form	Content	Relative Dose	Comments/Equivalency
Thyroid USP			
Armour Thyroid, Nature-Throid, and Westhroid (T_4:T_3 ratio approximately 4.2:1); Armour, 1 grain = 60 mg; Nature-Throid and	Desiccated pork thyroid gland	1 grain (equivalent to 74 mcg [~60-100] mcg of T_4)	High T_3:T_4 ratio; inexpensive

Drug/Dosage Form	Content	Relative Dose	Comments/Equivalency
Westhroid, 1 grain = 65 mg. Doses include 1/4, 1/2, 1, 2, 3, 4, and 5 grain tablets			
Levothyroxine			
Synthroid, Levothroid, Levoxyl, Levo-T, Unithroid, and other generics 25, 50, 75, 88, 100, 112, 125, 137, 150, 175, 200, 300 mcg tablets; Tirosint 13-150 mcg liquid in gelatin capsule; 200 and 500 mcg per vial injection	Synthetic T_4	100 mcg	Stable; predictable potency; generics may be bioequivalent; when switching from natural thyroid to l-thyroxine, lower dose by one half grain; variable absorption between products; half-life = 7 days, so daily dosing; considered to be drug of choice
Liothyronine			
Cytomel 5, 25, and 50 mcg tablets	Synthetic T_3	33 mcg (~equivalent to 100 mcg T_4)	Uniform absorption, rapid onset; half-life = 1.5 days, rapid peak and troughs
Liotrix			
Thyrolar 1/4-, 1/2-, 1-, 2-, and 3-grain tablets	Synthetic T_4:T_3 in 4:1 ratio	Thyrolar 1 = 50 mcg T_4 and 12.5 mcg T_3	Stable; predictable; expensive; risk of T_3 thyrotoxicosis because of high ratio of T_3 relative to T_4

TABLE 75-10 Selected Recommendations from the American Thyroid Association Hypothyroidism Guidelines[21]

Recommendation Number	Question	Synopsis or Paraphrase of Recommendation	Grading
1a	Is levothyroxine monotherapy considered to be the standard of care for hypothyroidism?	Levothyroxine is recommended as the preparation of choice for the treatment of hypothyroidism due to its efficacy in resolving the symptoms of hypothyroidism.	Strong recommendation, moderate quality
1b	What are the clinical and biochemical goals for levothyroxine replacement in primary hypothyroidism?	Levothyroxine replacement therapy has three main goals. These are (i) to provide resolution of the patients' symptoms and hypothyroid signs, (ii) to achieve normalization of serum thyrotropin and, (iii) to avoid overtreatment.	Strong recommendation, moderate quality
2b	Are there situations in which therapy with	Although there are preliminary small studies suggesting that	Weak recommendation,

Recommendation Number	Question	Synopsis or Paraphrase of Recommendation	Grading
	levothyroxine dissolved in glycerin and supplied in gelatin capsules may have advantages over standard levothyroxine?	levothyroxine dissolved in glycerin and supplied in gelatin capsules may be better absorbed than standard levothyroxine, the present lack of controlled long-term outcome studies does not support a recommendation for the use of such preparations in these circumstances.	low quality
4a	What factors determine the levothyroxine dose required by a hypothyroid patient for reaching the appropriate serum thyrotropin goal?	When deciding on a starting dose of levothyroxine, the patient's weight, lean body mass, pregnancy status, etiology of hypothyroidism, degree of thyrotropin elevation, age, and general clinical context, should all be considered.	Strong recommendation, moderate quality
4b	What is the best approach to initiating and adjusting levothyroxine therapy?	Thyroid hormone therapy should be initiated as an initial full replacement or as partial replacement with gradual increments in the dose titrated upward using serum thyrotropin as the goal. Dose adjustments should be made, with thyrotropin assessment 4-6 weeks after any dosage change.	Strong recommendation, moderate quality
9b	What approach should be taken in patients treated for hypothyroidism who have normal serum thyrotropin values but still have unresolved symptoms?	A minority of patients with hypothyroidism, but normal serum thyrotropin values, may perceive a suboptimal health status of unclear etiology. Acknowledgment of the patients' symptoms and evaluation for alternative causes is recommended in such cases.	Weak recommendation, low quality
12	In adults requiring thyroid hormone replacement treatment for primary hypothyroidism, is treatment with thyroid	We recommend that levothyroxine be considered as routine care for patients with primary hypothyroidism, in preference to use of thyroid	Strong recommendation, moderate quality

Recommendation Number	Question	Synopsis or Paraphrase of Recommendation	Grading
	extracts superior to treatment with levothyroxine alone?	extracts. High-quality controlled long-term outcome data are lacking to document superiority of this treatment compared to levothyroxine therapy.	
13b	In adults requiring thyroid hormone replacement treatment for primary hypothyroidism, is combination treatment including levothyroxine and liothyronine superior to the use of levothyroxine alone?	There is no consistently strong evidence of superiority of combination therapy over monotherapy with levothyroxine. Therefore, we recommend against the routine use of combination treatment with levothyroxine and liothyronine as a form of thyroid replacement therapy in patients with primary hypothyroidism.	Weak recommendation, moderate quality
13c	In adults requiring thyroid hormone replacement treatment for primary hypothyroidism who feel unwell while taking levothyroxine, is combination treatment including levothyroxine and liothyronine superior to the use of levothyroxine alone?	For patients with primary hypothyroidism who feel unwell on levothyroxine therapy alone, there is currently insufficient evidence to support the routine use of a trial of a combination of levothyroxine and liothyronine therapy outside a formal clinical trial or N- of-1 trial, due to uncertainty in long-term risk benefit ratio of the treatment.	Insufficient evidence
14	Are there data regarding therapy with triiodothyronine alone, either as standard liothyronine or as sustained release triiodothyronine, that support the use of triiodothyronine therapy alone for the treatment of hypothyroidism?	Although short-term outcome data in hypothyroid patients suggest that thrice-daily synthetic liothyronine may be associated with beneficial effects on parameters such as weight and lipids, longer-term controlled clinical trials are needed before considering synthetic liothyronine therapy for routine clinical use.	Strong recommendation, moderate quality

Strong recommendation: Benefits clearly outweigh risks and burden or risks and burden clearly outweigh benefits.

Weak recommendation: Benefits finely balanced with risks and burden.

Quality of evidence: High, moderate, or low.

Pharmacologic Therapy

Levothyroxine is the drug of choice for thyroid replacement and suppressive therapy because it is chemically stable, relatively inexpensive, active when orally administered, free of antigenicity, and has uniform potency. Whereas T_3 is the biologically more active form of thyroid hormone, levothyroxine administration results in a pool of thyroid hormone that is readily and consistently converted to T_3; in this regard, levothyroxine may be thought of as a prohormone. The ability of levothyroxine to achieve normal T_3 concentrations was illustrated in a study of recently athyreotic patients in whom levothyroxine monotherapy produced similar T_3 levels to those documented prior to the patient's thyroidectomy.[71] Several other studies, however, suggest that athyreotic individuals taking T_4 may have low or low-normal T_3 levels.[72,73,74]

Liothyronine (T_3) is chemically pure with known potency and has a shorter half-life of 1.5 days. Although it can be used diagnostically in the T_3 suppression test, T_3 has some clinical disadvantages, including a higher incidence of cardiac adverse effects, higher cost, and difficulty in monitoring with conventional laboratory tests. If used, T_3 needs to be administered three times a day and it may take a prolonged period of adjustment to achieve stable euthyroidism.[70] Liotrix is a combination of synthetic T_4 and T_3 in a 4:1 ratio. It is chemically stable and pure and has a predictable potency. The major limitations to this product are high cost and lack of therapeutic rationale, because most T_3 is peripherally converted from T_4. In addition, the T_4:T_3 ratio is much higher than the 14:1 molar ratio produced by the thyroid gland in humans.

9 Trials comparing levothyroxine alone with a combination of levothyroxine plus partial replacement with liothyronine (T_3) have generally shown that combinations of T_4 + T_3 are no better than T_4 alone. At least 13 such trials with varying designs have been performed to date.[21] Four of these trials have found that patients expressed a preference for combination therapy. By way of illustration, in one trial of combination therapy, Clyde et al.[75] compared levothyroxine alone for treatment of primary hypothyroidism with combination therapy using levothyroxine plus liothyronine. These investigators demonstrated no beneficial changes in body weight, serum lipid levels, hypothyroid symptoms as measured by a health-related quality-of-life questionnaire, and standard measures of cognitive performance.[75] As discussed in recent guidelines,[21] three meta-analyses and a systematic review have also suggested no benefits.[76,77,78,79] A secondary analysis, however, suggested that individuals harboring a specific deiodinase polymorphism may have a poorer psychological response to levothyroxine therapy and a better response to combination therapy with both T_4 and T_3. However, no prospective study investigating whether the presence of these polymorphisms affects satisfaction with replacement therapy has yet been reported.[80]

A recent study conducted in rats suggested impairment of type 2 deiodinase activity in the whole body during levothyroxine monotherapy due to deiodinase inactivation, compared with maintenance

of deiodinase activity in the hypothalamus.[81] The lesser activation in the hypothalamus lead to efficient T_3 production in the hypothalamus and normalization of TSH before T_3 normalized in the rest of the body. Accompanying the inactivation of type 2 deiodinase in other tissues, lower serum T_3 and higher T_4/T_3 ratios were seen in rats during monotherapy with L-thyroxine, compared with combination therapy employing a subcutaneous slow release T_3 pellet. Clinical trials of a slow release T_3 preparation, other than a pharmacokinetic study of T_3 sulfate in profoundly hypothyroid individuals,[82] has yet to be conducted.

Desiccated thyroid has historically been derived from pig, beef, or sheep thyroid glands, although pigs are currently the usual source. The *United States Pharmacopeia*, requires thyroid USP to contain 38 mcg (±15%) of L-thyroxine and 9 mcg (±10%) of liothyronine for each 60 to 65 mg (one grain). Thyroid USP, as an animal protein-derived product, may be antigenic in allergic or sensitive patients. Even though desiccated thyroid is inexpensive, its limitations preclude it from being considered as a drug of choice for hypothyroid patients.

Hypothyroidism—Controversy…

A small percentage of patient taking levothyroxine do not feel well despite their treatment. Trials of combination therapy have generally not shown improved patient outcomes. Recent animal data examining inactivation of deiodinases in specific tissues suggest that sustained delivery of T_3 may have different tissue effects, compared with intermittent delivery of T_3. Future trials of a sustained release T_3 preparation are eagerly awaited.

Pharmacokinetics

The half-life of levothyroxine is approximately 7 days. This long half-life is responsible for a stable pool of prohormone and the need for only once-daily dosing with levothyroxine. Older studies with levothyroxine suggested that bioavailability was low and erratic; however, this product has been reformulated, and the average bioavailability improved to approximately 80%.[83] Different levothyroxine preparations contain different excipients such as dyes and fillers. The bioavailabilities of Synthroid, Levoxyl, and generic levothyroxine preparations were compared in a blinded, randomized, four-way crossover trial.[84] The study was sponsored by the manufacturers of Synthroid, who have challenged the authors' conclusions that the levothyroxine preparations are bioequivalent and should be interchangeable for the majority of patients. However, because the relationship between T_4 concentration and TSH is not linear, very small changes in T_4 concentration can lead to substantial changes in TSH, which is a more accurate reflection of hormone replacement status. Currently, the FDA mandates that L-thyroxine bioequivalency testing be done using normal volunteers (600 mcg in the fasted state) and three baseline free T_4 concentrations be used to correct for endogenous T_4 production. Bioequivalency is based on the area under the curve (AUC) and maximum concentration (C_{max}) of T_4 out to 48 hours. Approximately 70% of the AUC is derived from endogenous production. TSH is not considered, and it is now very clear that T_4 is too insensitive as a measure of bioequivalency.[85,86] To avoid overtreatment and undertreatment, once a product is selected, therapeutic interchange should be discouraged. Currently, there are several levothyroxine products

available, and a number of permutations for interchange are available considering that there are AB1, AB2, AB3, and AB4 products available, and since no reference listed drug is mandated in bioequivalency testing.

Adverse Effects

Serious untoward effects are unusual if dosing is appropriate and the patient is carefully monitored during initial treatment. A cross-sectional study showed that of a population of 1,525 individuals taking levothyroxine, 40% actually had abnormal TSH values.[87] A recent study showed that 57% of individuals 65 years or older receiving thyroid hormone treatment had abnormal TSH values.[88] Both of these studies suggest failure to keep a patient's TSH at goal is common. Levothyroxine replacement in athyreotic hypothyroid patients restores systolic and diastolic left ventricular performance within 2 weeks, and the use of levothyroxine may increase the frequency of atrial premature beats but not necessarily ventricular premature beats. Excessive doses of thyroid hormone may lead to heart failure, angina pectoris, and myocardial infarction; rarely, the latter may be caused by coronary artery spasm. Allergic or idiosyncratic reactions can occur with the natural animal-derived products such as desiccated thyroid, but these are extremely rare with the synthetic products used today. The 0.05 mg (50 mcg) Synthroid tablet is the least allergenic (due to a lack of dye and few excipients) and should be tried for the patient suspected to be allergic to thyroid hormone tablets.

Hyperremodeling of cortical and trabecular bone due to hyperthyroidism leads to reduced bone density and may increase the risk of fracture. Compared with normal controls, excess exogenous thyroid hormone results in histomorphometric and biochemical changes similar to those observed in osteoporosis and untreated hyperthyroidism.[89,90] The risk for this complication seems to be related to the dose of levothyroxine, patient age, and gender. Markers for bone turnover include urinary *N*-telopeptides, pyridinoline crosslinks of type I collagen, osteocalcin, and bone-specific alkaline phosphatase. When doses of levothyroxine are used to suppress TSH concentrations to below-normal values (eg, less than 0.3 milli-international unit/L) in postmenopausal women, this adverse effect is more likely to be seen. Cortical bone is affected to a greater degree than trabecular bone at suppressive doses of I-thyroxine. In contrast, it appears to be much less likely in men and in premenopausal women. Maintaining the TSH between 0.7 and 1.5 milli-international units/L does not alter bone mineral density in premenopausal women. Although not all studies have shown consistent results, a recent cohort study suggests that there is no adverse effect on bone density with treatment with I-thyroxine to achieve a normal TSH.[91]

Drug-Drug and Drug-Food Interactions

The time to maximal absorption of levothyroxine is about 2 hours and this should be considered when T_4 concentrations are determined. Ingestion of I-thyroxine with food can impair its absorption.[21,92] This can potentially affect the TSH concentration achieved if levothyroxine timing with respect to food is varied.[93] Mucosal diseases, such as celiac sprue, diabetic diarrhea, and ileal bypass surgery, can also reduce absorption. Cholestyramine, calcium carbonate, sucralfate, aluminum hydroxide, ferrous sulfate, soybean formula, dietary fiber supplements, and espresso coffee may also

impair the absorption of levothyroxine from the gastrointestinal tract (reviewed extensively in recent treatment of hypothyroidism guidelines[21]). Acid suppression with histamine blockers and proton pump inhibitors may also reduce levothyroxine absorption.[94] Drugs that increase nondeiodinative T_4 clearance include rifampin, carbamazepine, and possibly phenytoin. Selenium deficiency and amiodarone may block the conversion of T_4 to T_3.

Several non-randomized studies have suggested that liquid formulations of levothyroxine or formulations in which the levothyroxine is dissolved in glycerin and encased in a gelatin capsule may circumvent the impaired absorption of levothyroxine that may occur with tablet preparations. For patients receiving enteral feeding, liquid levothyroxine added directly to the feeding tube was associated with a similar serum TSH to that seen in another group of patients in whom the feeding was interrupted in order to administer crushed tablets.[95] The former procedure was found to be more convenient by providers. In a study of patients taking proton pump inhibitors, switching to an oral solution was associated with a decrease in serum TSH from a mean of 5.4 milli-international units/L to 1.7 milli-international units/L, suggesting better absorption of the liquid preparation in these patients.[96] A study of patients with gastritis who had a stable serum TSH while taking levothyroxine tablets and were then switched to a lower dose of levothyroxine gel capsules, showed that two-thirds of patients had a similar TSH on the lower dose, again suggesting better absorption of the gel capsule formulation.[97] Another study suggested that the serum TSH achieved by levothyroxine gel capsules was not affected by the timing with respect to breakfast.[98] If the findings of these studies are bolstered by randomized controlled studies in the future, these levothyroxine formulations may prove very convenient for hypothyroid patients.

Dosing and Administration

Recent studies suggest that the average maintenance dose of levothyroxine for most adults is about 125 mcg/day.[56] The replacement dose of levothyroxine is affected by body weight. Estimates of weight-based doses for replacement in hypothyroid patients include 1.6 and 1.7 mcg/kg/day.[21] There is, however, a wide range of replacement doses, necessitating individualized therapy and appropriate TSH monitoring to determine an adequate but not excessive dose.

In addition to alleviation of symptoms, the goal of treatment for patients with hypothyroidism is to maintain the patient's TSH within the normal range. Some clinicians are of the opinion that the traditional reference range of approximately 0.5 to 4.5 milli-international units/L includes at its upper end some individuals who have unrecognized thyroid disease.[99] Thus, some believe that the reference range should be modified downward to 0.5 to 3.5 milli-international units/L or even 0.5 to 2.5 milli-international units/L.[100] If this premise is accepted, both the TSH values that trigger l-thyroxine treatment and the TSH treatment goal could potentially be altered. There are cogent arguments on both sides of the issue. Those who suggest maintaining current reference ranges believe that lowering the upper limit of the reference range could result in treating many individuals with thyroid hormone who would not necessarily benefit from such treatment.[101] Those who favor narrowing the reference range suggest that additional patients would, in fact, derive benefit from thyroid hormone treatment.[100] TSH reference ranges also differ for different populations, such as

those who are pregnant, specific ethnic groups, and older individuals.[21]

The required dose of levothyroxine is dependent on the patient's age[102] and the presence of associated disorders, as well as the severity and duration of hypothyroidism.[21] Most patients will require approximately 1.7 mcg/kg/day once they reach steady state for full replacement. Dose requirement may be better estimated based on ideal body weight, rather than actual body weight.[103] In patients with long-standing disease and older individuals without known cardiac disease, therapy should be initiated with 50 mcg daily of levothyroxine and increased after 1 month. The recommended initial daily dose for older patients with known cardiac disease is 25 mcg daily titrated upward in increments of 25 mcg at monthly intervals to prevent stress on the cardiovascular system. Some patients may experience an exacerbation of angina with higher doses of thyroid hormone. Although the TSH is an indicator of underreplacement or overreplacement, clinicians often fail to alter the dose based on TSH values clearly outside of the normal range.

Patients with subclinical or mild hypothyroidism (seen more commonly in the elderly and women) have no or few signs or symptoms, normal serum T_3 and T_4 concentrations, and an elevated basal TSH concentration.[38] The prevalence of this disorder in the NHANES III study was found to be 4.3%.[10] Untreated individuals with moderate degrees of subclinical hypothyroidism and negative TPOAb may revert to euthyroidism during followup.[104] Increased mortality may be associated with moderate, but not mild subclinical hypothyroidism.[105] Spontaneous recovery of thyroid function and uncertainties about which patient groups may benefit from therapy contribute to the debate about treatment of subclinical hypothyroidism. Although the treatment of subclinical hypothyroidism is controversial, patients presenting with marked elevations in TSH (more than 10 milli-international units/L) and high titers of TPOAb or prior treatment with ^{131}I may be most likely to benefit from treatment. It should be noted that some studies find that only one of four treated patients experienced improvement. Other patients who may improve with replacement include those with mild symptoms of hypothyroidism and depression. Reduction of events due to ischemic heart disease was only observed in younger patients in one study.[106] If treatment is pursued, reasonable goals in this situation would be to maintain serum T_4 and T_3 levels in the normal range and reduce TSH to a value of 0.5 to 2.5 milli-international units/L in younger patients and 4 to 6 milli-international units/L in older patients.[38]

Once euthyroidism is attained, the daily maintenance dose of levothyroxine does not fluctuate greatly. As patients age, the dosing requirement may be reduced.[21,102] Third-generation TSH assays improved the accuracy with which thyroid hormone replacement can be monitored. The TSH concentration is the most sensitive and specific monitoring parameter for adjustment of levothyroxine dose. Plasma TSH concentrations begin to fall within hours and are usually normalized within 2 weeks, but they may take up to 6 weeks for some patients, depending on the baseline value. Both TSH and T_4 concentrations are used to monitor therapy, and they should be checked every 6 weeks until a euthyroid state is achieved.[21,68] Laboratory assessment of thyroid function should be performed approximately 6 weeks after levothyroxine dose initiation or change. This time frame allows achievement of steady state, as the half-life of levothyroxine is approximately 1 week. Serum T_4 concentrations can be useful in detecting noncompliance, malabsorption, or changes in levothyroxine product bioequivalence. An elevated TSH concentration indicates insufficient

replacement. The appropriate dose maintains the TSH concentration in the normal range. T_4 disposal is accelerated by nephrotic syndrome, other severe systemic illnesses, and several antiseizure medications (phenobarbital, phenytoin, and carbamazepine) and rifampin. Pregnancy increases the T_4 dose requirement for 75% of women, probably because of factors such as increased degradation by the placental deiodinase, increased T_4 pool size, and transfer of T_4 to the fetus. The etiology of hypothyroidism also affects the magnitude of the dosage increase.[107] Initiating postmenopausal hormone replacement therapy increases the dose needed in 35% of women, perhaps due to an increased circulating TBG level. Patient noncompliance with prescribed T_4, the most common cause of inadequate treatment, might be suspected for patients with a dose that is higher than expected, variable thyroid function test results that do not correlate well with prescribed doses, and an elevated serum TSH concentration with serum free T_4 at the upper end of the normal range, which can suggest improved compliance immediately before testing, with a lag in the thyrotropin response.

For patients with central hypothyroidism caused by hypothalamic or pituitary failure, the serum TSH cannot be used to assess adequacy of replacement. Alleviation of the clinical syndrome and restoration of serum T_4 to the normal range are the only criteria available for estimating the appropriate replacement dose of l-thyroxine. Keeping free T_4 values in the upper part of the normal laboratory reference range is a reasonable approach,[108] with modification of this goal to the middle of the normal range in older patients or patients with comorbidities. Concurrent use of dopamine, dopaminergic agents (bromocriptine), somatostatin or somatostatin analogs (octreotide), and corticosteroids suppresses TSH concentrations in individuals with primary hypothyroidism and may confound the interpretation of this monitoring parameter.[21,68]

TSH-suppressive levothyroxine therapy can be given to patients with nodular thyroid disease and diffuse goiter, and to patients with a history of thyroid irradiation. It is also usually given to patients with papillary or follicular thyroid cancer. The rationale for suppression therapy is to reduce TSH secretion, which promotes growth and function of abnormal thyroid tissue. However, such management, other than for patients with thyroid cancer or with elevated TSH levels, is quite controversial. Some clinicians rarely recommend or use such therapy; others will recommend a trial of levothyroxine as suppressive therapy in some patients. Three meta-analyses concluded that suppressive therapy for nodules was associated with a small decrease in nodule growth,[109] a statistically nonsignificant reduction in nodule growth,[110] and a significant reduction in nodule growth with longer-term treatment.[111] l-thyroxine may be given in nontoxic MNG to suppress the TSH to low-normal levels of 0.5 to 1 milli-international unit/L if the baseline TSH is more than 1 milli-international unit/L. Goiter size and thyroid volume may be reduced with suppression therapy. Diffuse goiter associated with autoimmune thyroiditis may also be treated with levothyroxine to reduce goiter size and thyroid volume. If suppressive therapy with levothyroxine is pursued, the age, gender, and menopausal status of the patient need to be considered, along with the risk of cardiac arrhythmias and reduced bone mineral density. Levothyroxine suppression therapy is of benefit to all but the lowest-risk thyroid cancer patients and is generally used in the management of patients with differentiated thyroid cancer, with the TSH goal being influenced by the patient's thyroid cancer stage and other risk factors.[112,113] Current guidelines from the American Thyroid Association suggest suppressing the TSH to below 0.1 milli-international unit/L in higher-risk patients, but keeping TSH

around the lower limit of normal (0.1-0.5 milli-international unit/L) in low-risk patients.[114]

Hypothyroidism—Controversy...

There is currently controversy about when subclinical thyroid disease should be treated. This is based on uncertainty about benefits and risks with respect to symptom relief, cardiovascular outcomes, and mortality. Generally the decision to treat is affected by patient age, comorbidities, and degree of TSH elevation.

Special Populations

Myxedema Coma

Myxedema coma is a rare consequence of decompensated hypothyroidism.[27,115] Clinical features include hypothermia, advanced stages of hypothyroid symptoms, and altered sensorium ranging from delirium to coma. Mortality rates of 60% to 70% necessitate immediate and aggressive therapy. Traditionally, the initial treatment has been IV bolus levothyroxine 300 to 500 mcg.[21] However, as deiodinase activity is markedly reduced, impairing T_4 to T_3 conversion, initial treatment with IV T_3, or a combination of both hormones has also been advocated.[27] Glucocorticoid therapy with IV hydrocortisone 100 mg every 8 hours should be given until coexisting adrenal suppression is ruled out.[21] All therapies must be administered parenterally as cessation of gastrointestinal peristalsis occurs, preventing absorption of orally administered medications. Consciousness, lowered TSH concentrations, and improvement in vital signs are expected within 24 hours. Maintenance doses of levothyroxine are typically 75 to 100 mcg given IV until the patient stabilizes and oral therapy is begun. Supportive therapy must be instituted to maintain adequate ventilation, blood pressure, and body temperature, and ensure euglycemia. Any underlying disorder, such as sepsis or myocardial infarction, obviously must be diagnosed and treated.

Congenital Hypothyroidism

In congenital hypothyroidism, full maintenance therapy should be instituted early to improve the prognosis for mental and physical development.[116,117] The average maintenance dose in infants and children depends on the age and weight of the child. Several studies demonstrate that aggressive therapy with levothyroxine is important for normal development, and current recommendations are for initiation of therapy as soon as possible after birth at a dose of 10 to 15 mcg/kg/day.[61,118] This dose is used to keep T_4 concentrations at about 10 mcg/dL within 30 days of starting therapy and is associated with improved IQs in treated infants. The dose is progressively decreased to a typical adult dose as the child ages, the adult dose being given in the age range of 11 to 20 years.[118]

Hypothyroidism During Pregnancy

Hypothyroidism during pregnancy leads to an increased rate of stillbirths and possibly lower neuropsychological scores in infants born of women who received inadequate replacement during pregnancy.[50,119] Thyroid hormone is necessary for fetal growth and must come from the maternal

side during the first 2 months of gestation. Although liothyronine may cross the placental membrane slightly better than levothyroxine, the latter is considered the drug of choice. The objective of treatment is to decrease TSH to normal, based on the normal reference range for pregnancy. Current guidelines suggest a TSH below 2.5 milli-international units/L during the first trimester and a TSH below 3 milli-international units/L during the remainder of pregnancy.[50,51] Based on elevated TSH levels during pregnancy, it was found in one study that the mean dose of levothyroxine had to be increased by 48% to decrease TSH into the normal range. However, in individual women the dosage increase needed may vary from approximately 10% to 80%. Increased production of binding proteins, a marginal decrease in free hormone concentration, modification of peripheral thyroid hormone metabolism, and increased T_4 metabolism by the fetal-placental unit all may contribute to increased thyroid hormone demand. As these changes regress after delivery the need for increased levothyroxine will decline.[50,51] Up to 60% of women need to have levothyroxine dose adjustment during pregnancy. Upward adjustment will usually be needed by the eighth week of pregnancy. The etiology of the hypothyroidism affects the magnitude of the required increase in levothyroxine dose.[107] After delivery the levothyroxine dose can be reduced based on T_4 concentrations and measurement of TSH, typically about 6 to 8 weeks after delivery. Many patients can return to their pre-pregnancy dose requirement.

EVALUATION OF THERAPEUTIC OUTCOMES —HYPOTHYROIDISM

Patients with idiopathic hypothyroidism and Hashimoto's thyroiditis on optimal thyroid hormone replacement therapy should have TSH and free T_4 serum concentrations in the normal range.[21] Those who are being treated for thyroid cancer should have TSH suppressed to low levels, with the appropriate TSH concentration being determined based on the patient's risk of recurrence or progression, and TG should be undetectable.[119] Given the half-life of T_4 of 7 days, the appropriate monitoring interval is no more often than 4 weeks. The signs and symptoms of hypothyroidism should be improved or absent (see Clinical Presentation of Hypothyroidism discussed earlier), although it may take several months for the full benefit of therapy to manifest.

CONCLUSION—HYPOTHYROIDISM

Untreated hypothyroidism is a devastating disease that if unrecognized eventually progresses into myxedema coma in the absence of any endogenous thyroid reserve. Levothyroxine is a readily available and efficacious hormone that rapidly reverses the biochemical and clinical abnormalities that characterize hypothyroidism. Serum TSH and thyroid hormone levels are useful measures for adjusting the levothyroxine dose during therapy. Until regeneration of thyroid cells from pluripotent stem cells has been fully realized, levothyroxine is the most effective treatment for this common disorder.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

AUC	area under the curve
cGy	centigray
C_{max}	maximum concentration
ClO_4^-	perchlorate
DIT	diiodotyrosine
FSH	follicle-stimulating hormone
$G_s\alpha$	the α subunit of the stimulatory guanine-nucleotide–binding protein
hCG	human chorionic gonadotropin
HLA	human leukocyte antigen
^{131}I	sodium iodide-131
l-thyroxine	levothyroxine
LH	luteinizing hormone
MIT	monoiodotyrosine
MMI	methimazole
MNG	multinodular goiter
NHANES III	Third National Health and Nutrition Examination Survey
PRTH	pituitary resistance to thyroid hormone
PTU	propylthiouracil
RAI	radioactive iodine
RAIU	radioactive iodine uptake
SCN^-	thiocyanate
SSKI	saturated solution of potassium iodide
T_3	triiodothyronine
T_4	thyroxine
TBG	thyroxine-binding globulin
TBPA	thyroid-binding prealbumin
TcO_4^-	pertechnetate
TG	thyroglobulin
TPOAb	thyroid peroxidase antibodies
TR	thyroid hormone receptor
TRH	thyrotropin-releasing hormone
TRIAC	triiodothyroacetic acid
TSAb	thyroid-stimulating antibody
TSH	thyroid-stimulating hormone
TTR	transthyretin

Chapter 76: Adrenal Gland Disorders

Andrew Y. Hwang; Steven M. Smith; John G. Gums

INTRODUCTION

KEY CONCEPTS

- 1 Glucocorticoid secretion from the adrenal cortex is stimulated by adrenocorticotropic hormone (ACTH) or corticotropin that is released from the anterior pituitary in response to the hypothalamic-mediated release of corticotropin-releasing hormone (CRH).
- 2 To ensure the proper treatment of Cushing syndrome, diagnostic procedures should (a) establish the presence of hypercortisolism and (b) discover the underlying etiology of the disease.
- 3 The rationale for treating Cushing syndrome is to reduce the morbidity and mortality resulting from disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities.
- 4 The treatment of choice for both ACTH-dependent and ACTH-independent Cushing syndrome is surgery, whereas pharmacologic agents are reserved for adjunctive therapy, refractory cases, or inoperable disease.
- 5 Pharmacologic agents that may be used to manage the patient with Cushing syndrome include steroidogenesis inhibitors, adrenolytic agents, neuromodulators of ACTH release, and glucocorticoid-receptor blocking agents.
- 6 Spironolactone, a competitive aldosterone-receptor antagonist, is the drug of choice in bilateral adrenal hyperplasia (BAH)–dependent hyperaldosteronism.
- 7 Addison disease (primary adrenal insufficiency) is a deficiency in cortisol, aldosterone, and various androgens resulting from the loss of function of all regions of the adrenal cortex.
- 8 Secondary adrenal insufficiency usually results from exogenous steroid use, leading to hypothalamic–pituitary–adrenal (HPA)–axis suppression followed by a decrease in ACTH release,

and low levels of androgens and cortisol.

- Virilism results from the excessive secretion of androgens from the adrenal gland and often manifests as hirsutism in females.

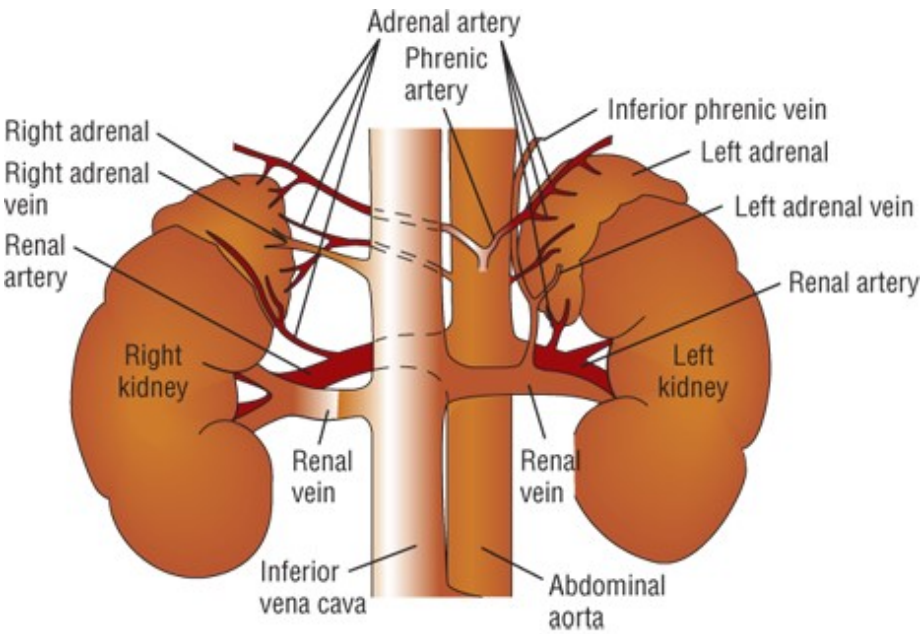
The adrenal glands were first characterized by Eustachius in 1563. After Addison identified a case of adrenal insufficiency in humans, adrenal anatomy and physiology flourished. Most of the work done in the early and mid-1900s centered on the glucocorticoid cortisol. With the discovery of aldosterone by Simpson and Tait in 1952, adrenal pharmacology turned toward the mineralocorticoid. Conn[1] followed with his classical description of primary aldosteronism (PA) in 1955, and numerous clinicians and investigators have continued to explore the variety of disease processes promoted through the adrenal gland.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY

The adrenal glands are located extraperitoneally to the upper poles of each kidney (**Fig. 76-1**). On average, each adrenal gland weighs 4 g and is 2 to 3 cm in width and 4 to 6 cm in length. The gland is fed by small arteries from the abdominal aorta and renal and phrenic arteries. Drainage of the adrenal gland occurs via the renal vein on the left and the inferior vena cava on the right.

FIGURE 76-1

Anatomy of the adrenal gland.

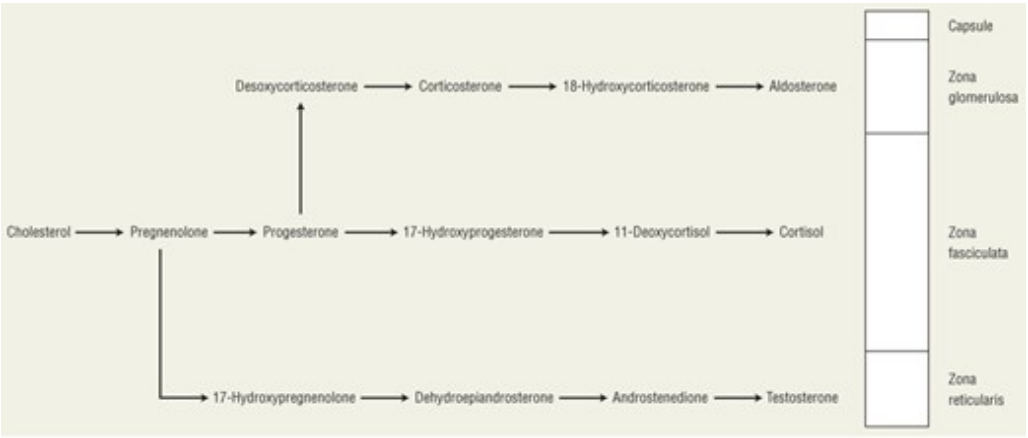


The adrenal medulla occupies 10% of the total gland and is responsible for the secretion of catecholamines. The adrenal cortex accounts for the remaining 90% and is responsible for the

secretion of three types of hormones (**Fig. 76-2**) from three separate zones.

FIGURE 76-2

Hormone synthetic pathways in relation to the zones of the adrenal cortex.



The zona glomerulosa accounts for 15% of the total adrenal cortex and is responsible for mineralocorticoid production, of which aldosterone is the principal end product. Aldosterone maintains electrolyte and volume homeostasis by altering potassium and magnesium secretion and renal tubular sodium reabsorption. The zona fasciculata, the middle zone, makes up 60% of the cortex, is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex, and is responsible for adrenal androgen production. The androgens, testosterone and estradiol, are the major end products and influence the reproductive system in addition to modulating primary and secondary sex characteristics.

Hormone Production and Metabolism

Adrenal steroid hormone synthesis begins with the conversion of cholesterol to pregnenolone by cytochrome P450 (CYP) enzymatic side-chain cleavage. Following this rate-limiting step, pregnenolone is converted to various 19- and 21-carbon steroids, depending on the enzymatic capabilities within each zone of the cortex. Androgenic properties predominate in the 19-carbon steroids, whereas mineralocorticoid and glucocorticoid properties manifest in the 21-carbon steroids.

Aldosterone production is initiated by the 21-hydroxylation of progesterone to form deoxycorticosterone. Subsequently, aldosterone synthase converts deoxycorticosterone to aldosterone through the intermediary, corticosterone. The zona glomerulosa preferentially produces aldosterone for three main reasons. First, the zona glomerulosa lacks 17α-hydroxylase activity and therefore can only convert pregnenolone to progesterone. Second, in contrast to the other zones, cells in the zona glomerulosa possess aldosterone synthase activity, which catalyzes the terminal steps in aldosterone synthesis. Lastly, cells of the zona glomerulosa display a greater number of

angiotensin II receptors than cells of the other zones. Binding of angiotensin II to these receptors provides the stimulus for initiating the aldosterone biosynthesis cascade. Thus, aldosterone synthesis is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the zona fasciculata or reticularis.

Cortisol is produced from pregnenolone via four successive hydroxylations. These hydroxylations occur primarily in the zona fasciculata, although the zona reticularis is also capable of producing glucocorticoids.

Androgens, produced primarily in the zona reticularis and less commonly in the zona fasciculata, have a 19-carbon structure and serve as precursors to more potent analogues produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, these synthesized quantities are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in **Table 76-1**.

TABLE 76-1 Rates of Adrenal Production and Plasma Concentrations of Various Steroids

Steroid	24-Hour Secretion (mg)	Plasma Concentration
Aldosterone	0.15	2-9 ng/dL (supine, normal-sodium diet)
Androstenedione	2.2-2.5	50-250 ng/dL
Corticosterone	1-4	2.4 ± 1.5 ng/dL (female) 4.2 ± 2.2 ng/dL (male)
Cortisol	8-25	0-25 µg/dL
11-Deoxycorticosterone	0.60	2-19 ng/dL
11-Deoxycortisol	0.40	12-158 ng/dL
Progesterone	0	<20 ng/dL (female)[a] 300-2,000 ng/dL (female)[b] <20-140 ng/dL (male)
Testosterone (total)	0.23 (female)	6-86 ng/dL (female) 270-1,070 ng/dL (male)

[a]Follicular phase of menstrual cycle.

[b]Luteal phase of menstrual cycle.

Glucocorticoid metabolism occurs in the liver and is responsible for converting inactive steroids to active metabolites, as well as modifying active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone,

metabolism is necessary for conversion to the active prednisolone and cortisol, respectively.

Following metabolic conversion, glomerular filtration is primarily responsible for eliminating endogenously produced glucocorticoids. The half-life of cortisol is 70 to 120 minutes, whereas aldosterone exhibits extremely high intrinsic clearance and a corresponding half-life of only 15 minutes.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs known to enhance steroid clearance include phenytoin, phenobarbital, rifampin, and mitotane. Likewise, diseases such as hyperthyroidism and renal disease can enhance steroid clearance. In contrast, drugs such as estrogens and estrogen-containing oral contraceptives reduce steroid clearance. Similarly, liver disease, age, pregnancy, hypothyroidism, anorexia nervosa, protein–calorie malnutrition, and renal disease are associated with reduced steroid clearance.

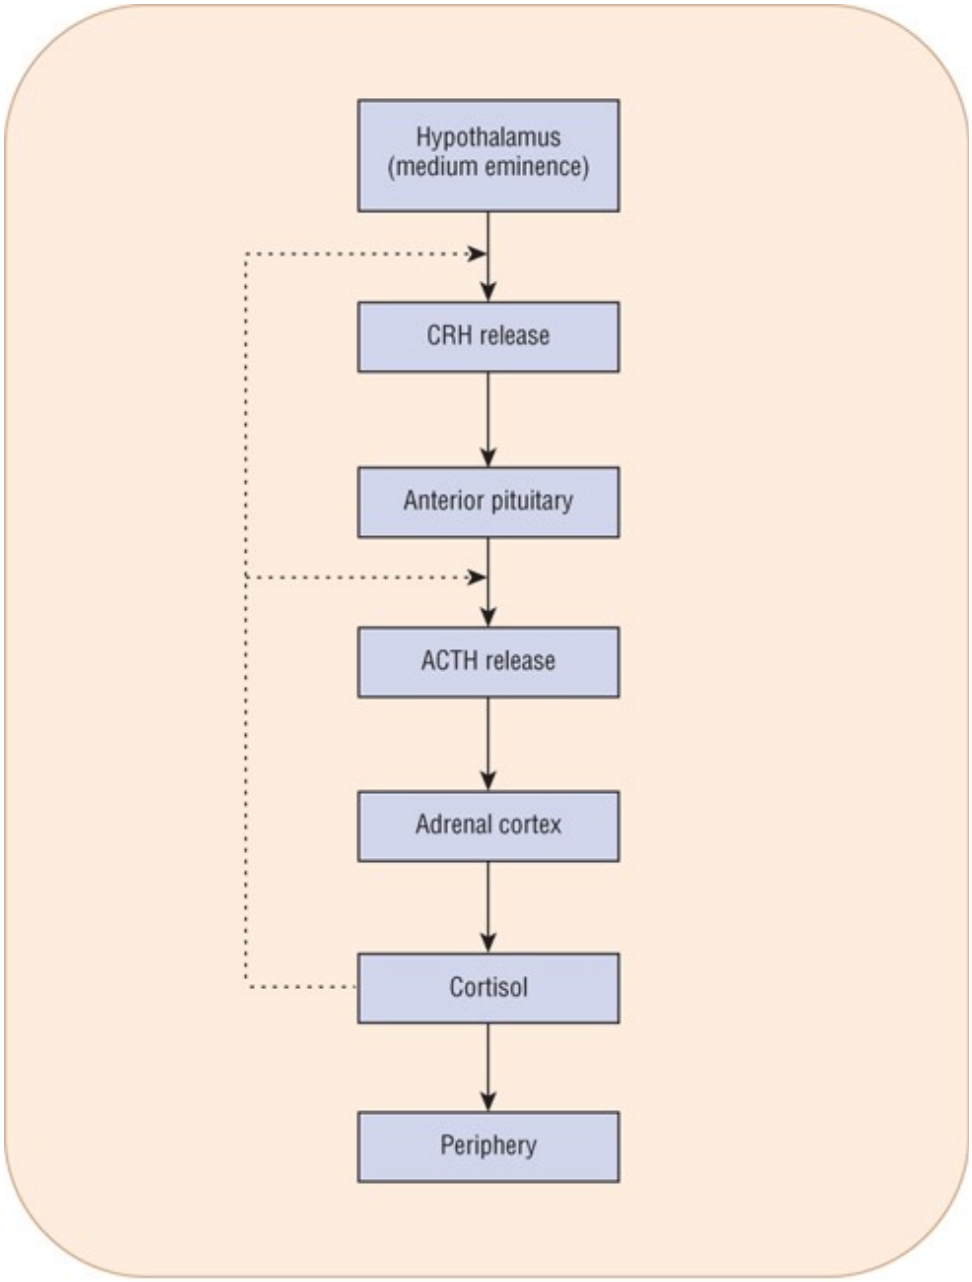
Plasma glucocorticoids are bound to one of three plasma proteins in varying degrees. Corticosteroid-binding globulin (CBG), albumin, and α_1-glycoprotein are capable of binding glucocorticoids, with CBG being the principal binding protein. Steroid binding serves as a reservoir for steroids in their inactive state and more than 95% of cortisol is normally bound in this fashion. This binding prevents glucocorticoid activity at receptor-activating sites. Therefore, a final but important variable in altered plasma concentration of free (active) steroids is concentration of plasma proteins.

Regulation of Hormone Secretion

1 Glucocorticoid secretion is regulated by the pituitary hormone, adrenocorticotropic hormone (ACTH [also known as corticotropin]). Under normal conditions, ACTH is released from the anterior pituitary in response to corticotropin-releasing hormone (CRH), which is secreted by the median eminence of the hypothalamus (**Fig. 76-3**). Vasopressin and oxytocin have weak ACTH-releasing activity through binding to the inferior V_3 receptor. CRH, in combination with vasopressin and oxytocin, stimulates greater ACTH secretion than each hormone individually.

FIGURE 76-3

Negative feedback system involved in the regulation of cortisol secretion under normal conditions. (ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.)



Additionally, histochemical studies have demonstrated that certain neurotransmitters, such as serotonin and norepinephrine, can stimulate production of CRH or ACTH directly. After release, ACTH stimulates the adrenal gland to release cortisol and, to a lesser extent, aldosterone and androgens. The rising cortisol concentration inhibits the secretion of CRH and ACTH through a negative feedback mechanism. In addition, leptin, an adipocyte hormone, can have an inhibitory effect on hypothalamic–pituitary–adrenal (HPA) activity.

Adrenal androgens are regulated in a similar fashion to cortisol. When plasma androgen reaches sufficient concentrations, production is terminated via a negative feedback loop. Androgen release is increased during puberty and in women with hirsutism. Adrenal androgen release decreases with age and in fasting states, including anorexia nervosa.

In contrast to cortisol and adrenal androgens, regulation of aldosterone secretion is considerably more complex. The renin–angiotensin system regulates aldosterone secretion through both intrarenal and extrarenal mechanisms. Renin production and subsequent aldosterone secretion is stimulated by blood pressure lowering (due to volume depletion), erect posture, salt depletion, β-adrenergic stimulation, and CNS excitation (see Chapter 13). Renin production is inhibited by salt loading, angiotensin II, vasopressin, potassium, calcium, blood pressure increases, and a variety of drugs. The renin-mediated production of angiotensin II is the initial stimulus for aldosterone synthesis. Additionally, angiotensin II can be acted on by aminopeptidase and converted to angiotensin III. Both angiotensin II and III are capable of stimulating the zona glomerulosa to secrete aldosterone. Following aldosterone secretion, increases in renal sodium and water retention as well as blood pressure occur, thereby turning off the stimulus for renin release.

HYPERFUNCTION OF THE ADRENAL GLAND

Adrenal disorders can be categorized as hyperfunction or hypofunction of the adrenal gland. Hyperfunction of the adrenal gland generally involves excess production of adrenal hormones, most notably cortisol, resulting in Cushing syndrome, or aldosterone, resulting in hyperaldosteronism.

Cushing Syndrome

In 1932, Cushing first described a syndrome of pituitary basophilism that attracted national attention. Until this time, no definitive diagnosis existed for patients with unexplained central obesity, cutaneous striae, osteoporosis, weakness, hypertension, diabetes mellitus, and congestion. Cushing emphasized that the disease was of a pituitary origin. Ten years later, Albright focused his attention on the "sugar hormone," which he believed originated from the adrenal cortex.[2]

After the development of a method for measuring urinary steroids, Daughaday discovered elevated steroids in the urine of patients with Cushing syndrome. Finally, the end product was identified, and Cushing syndrome was correctly explained as an excess of cortisol in the plasma (hypercortisolism).

Etiology

Cushing syndrome results from the effects of supraphysiologic levels of glucocorticoids originating either from exogenous administration or, less commonly, from endogenous overproduction by the adrenal glands. Excess glucocorticoids are produced in response to overproduction of ACTH (ACTH-dependent) or by abnormal adrenocortical tissues regardless of ACTH stimulation (ACTH-independent). ACTH-dependent Cushing syndrome (≈80% of all Cushing syndrome cases) usually originates from overproduction of ACTH by the pituitary gland, which chronically stimulates the adrenal glands causing bilateral adrenal hyperplasia (BAH). Approximately 85% of these cases are caused by pituitary adenomas (Cushing disease). Ectopic ACTH-secreting tumors and nonneoplastic corticotropin hypersecretion, possibly secondary to excess CRH production, account for the remainder of ACTH-dependent causes.[3] Ectopic ACTH syndrome refers to excessive ACTH production resulting from an endocrine or nonendocrine tumor, usually of the pancreas, thyroid, or lung. Small-cell carcinoma of the lung will lead to ectopic ACTH secretion in 0.5% to 2% of cases, whereas

bronchial carcinoid tumors are usually the most common.[4] Distinguishing between the various etiologies requires a careful history and pertinent laboratory work (**Table 76-2**).

TABLE 76-2 Various Etiologies of Cushing Syndrome and Their Respective Differences

	Pituitary-Dependent	Ectopic ACTH Syndrome	Adrenal Adenoma	Adrenal Carcinoma
Course	Slow	Rapid	Slow	Rapid
Symptoms	Mild to moderate	Atypical	Mild to moderate	Severe
Dominant sex/age	Female/male	Male	None noted	Children
Virilization	+	+	+	+++
Abdominal mass	0	0	0	++
Plasma ACTH concentration	Slightly elevated	High	Low	Low
Dexamethasone suppression test	≥50% suppression	No suppression	No suppression	No suppression
Iodocholesterol scan	Bilateral uptake	Bilateral uptake	Unilateral	None

ACTH, adrenocorticotropic hormone.

The remaining 20% of Cushing syndrome cases are ACTH-independent and divided almost equally between adrenal adenomas and adrenal carcinomas, with rare cases caused by macronodular hyperplasia, primary pigmented nodular adrenal disease, and McCune-Albright syndrome.[3,5] The majority of adrenal cortex tumors are benign adenomas. Adrenal carcinoma is found more often in children than in adults with Cushing syndrome.

Clinical Presentation

Patients with Cushing syndrome commonly present (>90% of patients) with central obesity and facial rounding. In addition, approximately 50% of patients will exhibit some peripheral obesity and fat accumulation. Fat accumulation in the dorsocervical area (buffalo hump) can be associated with major weight gain, whereas increased supraclavicular fat pads are more specific for Cushing syndrome. Striae are usually present along the lower abdomen and take on a red to purple color. Traditionally, hypertensive complications have been major contributors to the morbidity and mortality of Cushing syndrome. Hypertension is diagnosed in 75% to 85% of patients, with diastolic blood pressures greater than 119 mm Hg noted in over 20% of patients.[6] In addition, glucose intolerance is present in 60% of patients. Thus, many patients meet diagnostic criteria for the metabolic syndrome and have a corresponding increased risk of coronary heart disease (CHD) and stroke. Screening for Cushing syndrome in this population and in patients with uncontrolled diabetes mellitus has been suggested,[7,8] particularly when these conditions surface at an unusually early age.[9] However, screening all patients with type 2 diabetes is likely not cost-effective.[10]

CLINICAL PRESENTATION Cushing Syndrome General

- The most common findings, which are present in 90% of patients, are central obesity and facial rounding.

Symptoms

- Approximately 65% and 58% of patients complain of myopathies and muscular weakness, respectively.

Signs

- Peripheral obesity and fat accumulation is found in 50% of patients.
- Facial plethora is caused by an underlying atrophy of the skin and connective tissue and is seen in approximately 84% of patients.
- Patients often are described as having moon faces with a buffalo hump.
- Hypertension is seen in 75% to 85% of patients.
- Psychiatric changes can occur in as many as 55% of patients.
- Approximately 50% to 60% of patients will develop Cushing syndrome–induced osteoporosis. Of these, 40% will present with back pain and 20% will progress to compression fractures of the spine.
- Gonadal dysfunction is common with amenorrhea seen in up to 75% of females.
- Excess adrenal and ovary androgen secretion is responsible for 80% of females presenting with hirsutism.

Laboratory Tests

- A midnight plasma cortisol, late-night salivary cortisol, 24-hour urinary free cortisol (UFC), and/or low-dose dexamethasone suppression test (DST) will establish the presence of hypercortisolism.

Other Diagnostic Tests

- The plasma ACTH test, metyrapone stimulation test, CRH stimulation test, or inferior petrosal sinus sampling (IPSS) will help determine the etiology.

Diagnosis

2 The diagnosis of Cushing syndrome involves two steps: (a) establishing the presence of hypercortisolism, which is relatively easy, and (b) differentiating between etiologies, which can be challenging (**Fig. 76-4**).[5,8,11] The presence of hypercortisolism can be established via one or more of the following tests: 24-hour UFC, midnight plasma cortisol, late-night salivary cortisol, or the low-dose DST (using 1 mg dexamethasone for the overnight test or 0.5 mg/6 h for the classic 2-day

study). However, because these tests cannot determine the etiology of Cushing syndrome, other tests and procedures will be subsequently employed. Such tests can include any of the following: plasma ACTH via immunoradiometric assay (IRMA) or radioimmunoassay (RIA); adrenal vein catheterization; metyrapone stimulation test; adrenal, chest, or abdominal computed tomography (CT); CRH stimulation test; inferior petrosal sinus sampling (IPSS); jugular venous sampling (JVS); cavernous sinus sampling; and pituitary magnetic resonance imaging (MRI). High-dose DST has been used in the past, but is no longer recommended due to its poor specificity and limited diagnostic value. Other possible tests and procedures include insulin-induced hypoglycemia, somatostatin receptor scintigraphy, the desmopressin stimulation test, the naloxone CRH stimulation test, the loperamide test, the hexarelin stimulation test, and radionuclide imaging.[5,6,8,11,12,13,14,15,16] **Table 76-3** summarizes some of the tests used to diagnose Cushing syndrome.

FIGURE 76-4

Algorithm for diagnosing Cushing syndrome. (ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; CT, computed tomography; DST, dexamethasone suppression test; IPSS, inferior petrosal sinus sampling; JVS, jugular venous sampling; MRI, magnetic resonance imaging.)

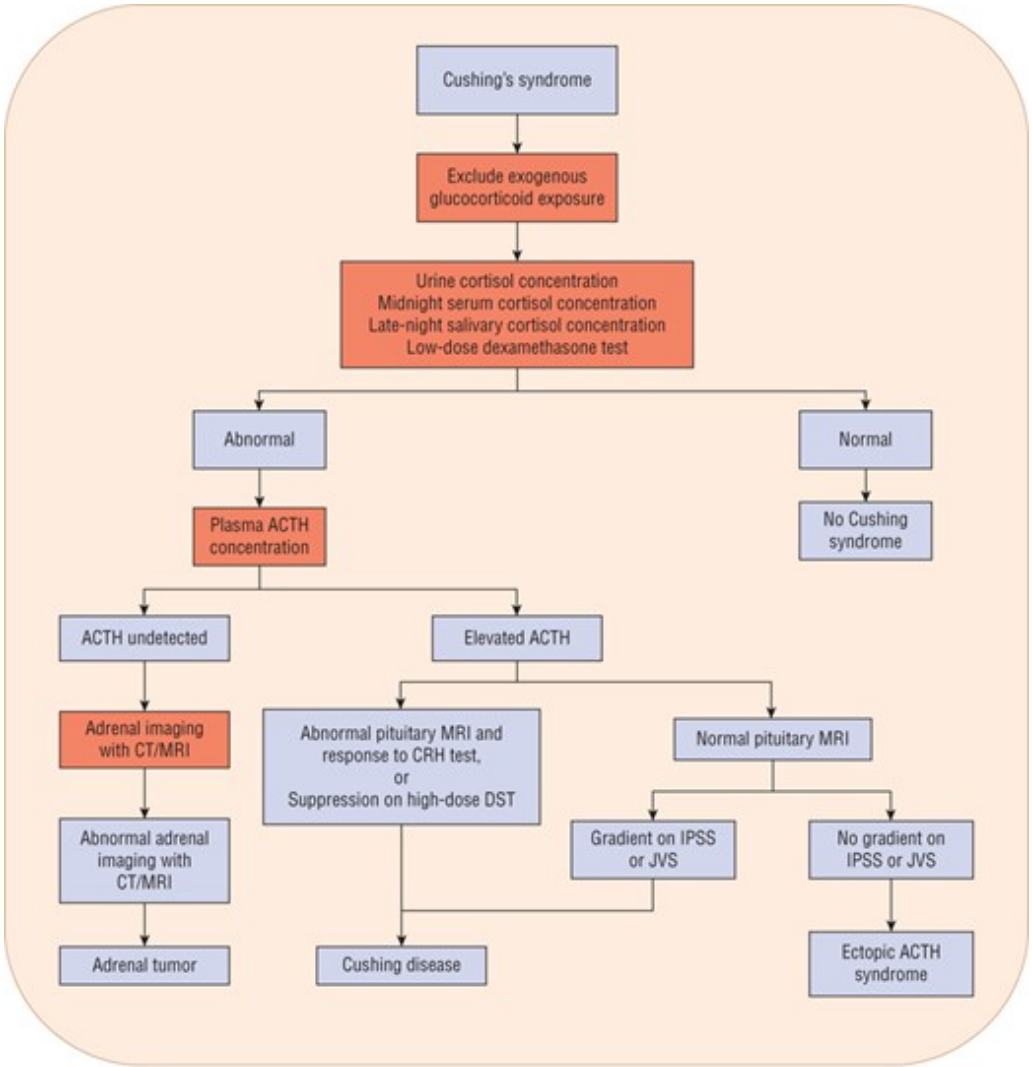


TABLE 76-3 Summary of Tests Used to Diagnose Cushing Syndrome

Test	Normal	Hyperplasia	Adenoma	Carcinoma
Plasma				
Cortisol (µg/dL, am/pm)	5-25/5-15	↑/↑↑	↑↑/↑↑	↑↑↑/↑↑↑
After low-dose DST	↓	↔	↔	↔
After high-dose DST	↓	↓/↔	↔	↔
ACTH (pg/mL)	6-76	↑↑	↓	↓
Urine				
Cortisol (µg/24 hours)	20-90	↑↑	↑↑	↑↑↑
Saliva				
Cortisol (µg/dL, PM)	Assay-dependent	↑↑	↑↑	↑↑↑

ACTH, adrenocorticotropic hormone; DST, dexamethasone suppression test.

Data from Kratz A, Ferraro M, Sluss PM, Lewandrowski KB. Laboratory reference values. N Engl J Med *2004;351(15):1548–1563. Copyright © 2004 Massachusetts Medical Society. All rights reserved.*

Elevated UFC concentrations are highly suggestive of Cushing syndrome, especially values fourfold greater than the upper limit of normal.[3,13] In contrast to plasma measurements of cortisol, UFC measures only unbound cortisol. Consequently, the UFC test is unaffected by conditions and medications that alter CBG levels. Normal reference values for UFC are 20 to 90 µg per 24-hour period. A twofold to threefold increase in urine cortisol is not uncommon in the patient with hyperfunction of the adrenal gland. Starvation, hydration from water loading (≥5 L/day), alcoholism, and acute stress are all capable of elevating urine cortisol concentrations. Likewise, elevated UFC results can occur during therapy with topical steroids, carbamazepine, and fenofibrate depending on the type of UFC test. Conversely, renal impairment (creatinine clearance [CrCl] of <60 mL/min) can falsely lower UFC concentrations. Because other pathologic conditions can increase the amount of free cortisol, additional tests may be warranted to confirm the diagnosis, or the diagnostic evaluation should be repeated when the acute stress has resolved. Of all urinary measures, UFC is the most useful assessment for patients with suspected Cushing syndrome.[8,13,15]

In healthy individuals, cortisol release follows a circadian rhythm whereby serum cortisol concentration peaks around 8:00 am and thereafter declines by 60% to 80%, reaching a nadir between 3:00 and 4:00 am. This rhythm is lost in the patient with Cushing syndrome. Although many patients with Cushing syndrome will have serum cortisol values in the high normal range if the serum is assayed in the morning, only 3.4% will have normal values if measured late at night.[17] Thus, a midnight serum cortisol greater than 7.5 µg/dL (>1.8 µg/dL if the patient is sleeping) is a highly sensitive assay for Cushing syndrome. However, this test is cumbersome and rarely recommended because it requires that patients be admitted for more than 48 hours to avoid false-positive responses secondary to the stress of hospitalization. An alternative assay is the measurement of late-night salivary cortisol. Salivary cortisol is highly correlated with free serum cortisol and independent of salivary flow rates. Moreover, salivary cortisol concentration reflects changes in serum cortisol within minutes. Salivary cortisol can be considered an acceptable alternative to UFC because of its convenience, stability (1 week), accuracy, and reproducibility. Unfortunately, normal reference ranges are assay-dependent, and cutoff points vary among institutions.[18,19]

In the overnight DST, 1 mg of dexamethasone is administered at 11:00 pm. The following morning at 8:00 am fasting plasma cortisol is obtained for analysis. This supraphysiologic dose of dexamethasone suppresses ACTH stimulation and cortisol production in healthy individuals. In contrast, the negative feedback loop is ineffective in patients with Cushing syndrome who generally exhibit a morning cortisol concentration above 5 µg/dL. Some patients with Cushing syndrome administered the overnight DST can slightly suppress cortisol and using 1.8 µg/dL as a cutoff can increase sensitivity, but at the expense of reduced specificity.[20] Therefore, the overnight DST is useful only as a screening tool for Cushing syndrome. Drugs that induce or inhibit CYP3A4 metabolism can significantly alter dexamethasone concentration, increasing the likelihood of false-positive and false-negative DSTs. Concurrent measurements of dexamethasone concentration with cortisol may improve the accuracy of testing for patients on CYP3A4-modifying drugs, although dexamethasone assays are not widely available. Also noteworthy, pregnancy and estrogen use (including oral contraceptives) increase CBG levels and frequently elicit false-positive results.[13] Consequently, UFC testing is preferred over DST in these patient populations.

The first test used to determine the etiology of Cushing syndrome is the plasma ACTH test. Plasma ACTH concentrations can be measured via RIA or IRMA.[12] In ACTH-dependent Cushing syndrome, ACTH can be normal or elevated. Very high levels of ACTH favor ectopic production. In contrast, ACTH values generally are low (<5 pg/mL) in ACTH-independent (adrenal) Cushing syndrome. Furthermore, ACTH levels can appear artificially low in some ectopic ACTH-producing tumors because ACTH can be secreted as an active prohormone that is not detected by the assay.

IPSS offers the highest sensitivity and specificity of any test in differentiating the etiology of Cushing syndrome. This technique requires catheterization of both petrosal sinuses with serial measurements of ACTH in each sinus and a peripheral vein after administration of CRH. A central-to-peripheral ACTH gradient is diagnostic for Cushing disease, whereas no gradient indicates ectopic ACTH production. Complications, such as venous thromboembolism, brain stem vascular damage, high cost, and technical expertise, can limit use of this test.[12] JVS uses the same concept as IPSS, is less invasive, and produces fewer complications; however, sensitivity is compromised.

Abnormal adrenal anatomy is effectively identified using high-resolution CT scanning and MRI.[21] Nodules as small as 1 to 1.5 cm on the adrenal cortex are easily identified by CT. With the use of thin-section scanning, nodules as small as 3 to 5 mm can be visualized.[22] Importantly, adrenal incidentalomas (masses observed incidentally on imaging) are prevalent in 5% to 10% of the general population. These masses may be functional (secreting), requiring intervention, or nonfunctional (nonsecreting), requiring only periodic observation. For this reason, abnormal imaging results are unable to conclusively diagnose adrenal disease when used alone. Nonadrenal imaging studies may be useful for identifying ectopic sources of ACTH secretion in patients for whom IPSS has ruled out Cushing disease.

Differential Diagnosis

Iatrogenic (exogenous) Cushing syndrome is the most common form of the disease. Therefore, all patients exhibiting hypercortisolism should undergo a comprehensive history and evaluation assessing medication use before laboratory testing is performed to identify endogenous causes. Iatrogenic Cushing syndrome can occur from administration of oral, inhaled, intranasal, intra-articular, and topical glucocorticoids, as well as progestins such as medroxyprogesterone acetate and megestrol acetate.[23] Disease severity correlates with exogenous glucocorticoid potency, dose, frequency, route, and treatment duration. Moreover, patients taking CYP3A4 inhibitors concomitantly with a glucocorticoid can be at higher risk of developing iatrogenic Cushing syndrome.[24,25] If exogenous glucocorticoids are being taken, the plasma cortisol concentration can increase, while the corticosterone concentration remains low.[17]

In the absence of any known exogenous causes, the clinician will need to differentiate the syndrome from other syndromes, such as pseudo-Cushing syndrome, that mimic true Cushing syndrome. Patients with obesity, chronic alcoholism, depression, and acute illness of any type can present with certain features of Cushing syndrome. However, these patients may lack true Cushing syndrome. For example, depressed patients, although mimicking the urinary steroid abnormalities of Cushing syndrome, will not resemble a cushingoid patient in appearance. In chronic alcoholism, steroid

laboratory panels generally return to baseline after ceasing alcohol intake. And obese patients often will have normal cortisol concentrations on both serum and urinary screening. Thus, identifying true cases of Cushing syndrome requires a comprehensive history in combination with laboratory and possibly imaging assessment.

Treatment

Desired Outcomes

3 If left untreated, Cushing syndrome is associated with high morbidity and mortality due to associated disorders such as hypertension, diabetes mellitus, cardiovascular disease, and electrolyte abnormalities. These disorders limit the survival of the patient with Cushing syndrome to 4 to 5 years following initial diagnosis. The desired outcomes of treatment are to limit such detrimental outcomes and return the patient to a normal functional state by removing the source of hypercortisolism while minimizing pituitary or adrenal deficiencies.

4 The treatment of choice for both ACTH-dependent and ACTH-independent Cushing syndrome is surgical resection of any offending tumors.[3,11] However, several secondary pharmacologic treatment plans are available, depending on the etiology of the disease (**Table 76-4**).[3,26,27,28,29] These pharmacologic options are generally reserved as second-line treatment in patients who are not surgical candidates, and may also be used in preoperative patients, or as adjunctive therapy in postoperative patients awaiting response. Rarely, monotherapy is used as a palliative treatment when surgery is not indicated.

TABLE 76-4 Possible Treatment Options in Cushing Syndrome Based on Etiology

	Treatment	
Etiology	**Nondrug**	**Drug**
Ectopic ACTH syndrome	Surgery, chemotherapy, irradiation	Metyrapone Ketoconazole Mitotane
Pituitary-dependent	Surgery, irradiation	Metyrapone Mifepristone Cabergoline Pasireotide
Adrenal adenoma	Surgery, postoperative replacement	Ketoconazole
Adrenal carcinoma	Surgery	Mitotane

ACTH, adrenocorticotropic hormone.

5 Pharmacotherapy of Cushing syndrome (dosing and monitoring parameters can be found in **Tables 76-5** and **76-6**, respectively)[3,28,29] can be divided into four categories based on the anatomic site of action of the agent: (1) steroidogenesis inhibitors, (2) adrenolytic agents, (3) neuromodulators of ACTH release, and (4) glucocorticoid-receptor blocking agents.[26,27]

TABLE 76-5 Drug Dosing in the Treatment of Cushing Syndrome

Drug	Brand Name	Initial Dose	Usual Range	Special Populations	Comments
Cabergoline	Dostinex®, 0.5 mg tablets	0.5 mg once weekly	0.5-7 mg once weekly		Maximum: 7 mg/week
Etomidate	Amidate®, 2 mg/mL solution	0.03 mg/kg IV bolus	0.1-0.3 mg/kg/hr infusion		Maximum: 0.3 mg/kg/hr infusion; titrate based on serum cortisol concentration
Ketoconazole	Nizoral®, 200 mg tablets	200 mg once or twice a day	200-1,200 mg/day, divided twice a day	Contraindicated in patients with hepatic disease	Maximum: 1,600 mg/day; CYP3A4 substrate and inhibitor (strong)
Metyrapone	Metopirone®, 250 mg tablets	0.5-1 g/day, divided every 4-6 hours	1-2 g/day, divided every 4-6 hours		Maximum: 6 g/day; CYP3A4 inducer
Mifepristone	Korlym®	300 mg once daily, increased by 300 mg/day every 2-4 weeks	600-1,200 mg/day	Do not exceed 600 mg/day in mild to moderate hepatic impairment; avoid in severe hepatic impairment. Do not exceed 600 mg/day in renal impairment	Maximum: 1,200 mg/day not to exceed 20 mg/kg/day
Mitotane	Lysodren®, 500 mg tablets	0.5-1 g/day, increased by 0.5-1 g/day every 1-4 weeks	1-4 g/day		Maximum: 12 g/day (most patients unable to tolerate >8 g/day). Take with food to decrease GI effects
Pasireotide	Signifor®, 0.3, 0.6, 0.9 mg/mL	0.6-0.9 mg twice daily	0.3-0.9 mg twice daily	Reduce dose in hepatic impairment	Maximum: 1.8 mg/day

Drug	Brand Name	Initial Dose	Usual Range	Special Populations	Comments
	solutions				

CYP, cytochrome P450 enzyme; GI, gastrointestinal.

TABLE 76-6 Drug Monitoring in the Treatment of Cushing Syndrome

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Cabergoline	Nausea, dizziness, headache, nasal congestion, constipation, psychiatric symptoms, valvulopathy	Echocardiogram	
Etomidate	Sedation, pain at injection site, hypotension, myoclonus, nausea, vomiting	Frequent sedation scoring initially, serum potassium, serum cortisol	
Ketoconazole	GI upset, dermatologic reactions; elevated hepatic transaminases, hepatotoxicity (rare)	Liver function tests, including ALT/AST, total bilirubin, ALP, prothrombin time, and INR testing	Approximately 10% will experience reversible LFT elevations; recent FDA restrictions on fungal infection indications
Metyrapone	Androgenic effects (hirsutism, acne, etc), blood pressure and electrolyte abnormalities, nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, allergic rash	Blood pressure, electrolytes	
Mifepristone	Hypokalemia, nausea, fatigue, headache, peripheral edema, dizziness, endometrial hyperplasia	Serum potassium, pregnancy testing, pelvic ultrasound	Abortifacient; rule out pregnancy in women of childbearing potential
Mitotane	GI upset, nausea, diarrhea, lethargy, somnolence, CNS disturbances	UFC and urinary steroid production, serum potassium	GI upset in up to 80%; GI and CNS effects appear to be dose-dependent
Pasireotide	Nausea, diarrhea, cholelithiasis, increased hepatic transaminases, hyperglycemia, sinus bradycardia, QT prolongation	Serum glucose, glycohemoglobin A1c, liver function tests	Only available as a subcutaneous injection; expensive

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CNS, central nervous system; FDA, Food and Drug Administration; GI, gastrointestinal; INR, international normalized ratio; LFT, liver function tests; UFC, urinary free cortisol.

Steroidogenesis Inhibitors

As their name implies, steroidogenesis inhibitors block the production of cortisol. This class includes metyrapone, ketoconazole, and etomidate. Metyrapone inhibits 11β-hydroxylase, the enzyme responsible for converting 11-deoxycortisol to cortisol. Following administration, a sudden decrease in cortisol concentration occurs within hours and prompts a compensatory rise in plasma ACTH concentrations. As ACTH increases and blockage of cortisol synthesis persists, adrenal steroidogenesis efforts are shunted toward androgen production. Consequently, metyrapone is associated with significant androgenic side effects, including hirsutism and increased acne, making it less ideal for women. In addition, metyrapone blocks aldosterone synthesis and causes the accumulation of aldosterone precursors, which exhibit weak mineralocorticoid activity. Blood pressure and electrolyte perturbations can ensue, depending on the level of circulating 11-deoxycortisol and the degree of aldosterone inhibition. Additional adverse effects, including nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, and allergic rash, have been reported following administration, but are often signs of overtreatment.[26,27,30] Metyrapone is currently available through the manufacturer only for compassionate use.

The imidazole derivative antifungal, ketoconazole, effectively inhibits steroidogenesis via multiple mechanisms when used in large doses. In contrast to the quick onset of metyrapone, the benefits of ketoconazole therapy are achieved only after several weeks of therapy. In addition to lowering serum cortisol levels, ketoconazole exhibits antiandrogenic activity attributable to its inhibition of multiple CYP enzymes as well as 11β-hydroxylase and 17α-hydroxylase.[26] This activity may be beneficial in women with Cushing syndrome, but can cause gynecomastia and hypogonadism in men. Sustained therapy with ketoconazole also imparts beneficial effects on serum cholesterol profiles, including lowering total and low-density lipoprotein (LDL) cholesterol levels. Ketoconazole induces a reversible elevation of hepatic transaminases in approximately 10% of patients.[31] However, concerns have been raised over the risk of severe hepatotoxicity associated with ketoconazole use. In July 2013, the US Food and Drug Administration (FDA) significantly changed the labeling of oral ketoconazole, removing various indications for fungal infections and recommending that oral ketoconazole not be used as first-line therapy for fungal infections. Similarly, the European Medicines Agency has recently recommended complete removal of oral ketoconazole from European Union markets. These changes were based largely on data in patients with fungal infections, who require lower doses of ketoconazole. However, few data are available on the incidence of severe hepatotoxicity with ketoconazole at the higher doses used in Cushing syndrome. Consequently, monitoring during treatment with ketoconazole should include liver function at baseline, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin, alkaline phosphatase (ALP), prothrombin time, and international normalized ratio (INR) testing, according to FDA recommendations. In addition, weekly monitoring of serum ALT should be continued throughout therapy with ketoconazole. In general, ketoconazole should be avoided in patients with preexisting hepatic disease. Additional common adverse effects include gastrointestinal (GI) discomfort and dermatologic reactions.

Ketoconazole may be used concomitantly with metyrapone to achieve synergistic reductions in cortisol levels. Because these drugs differ in their onset of action, coadministration allows for more

complete suppression of cortisol synthesis. Moreover, the antiandrogenic actions of ketoconazole therapy may offset the androgenic potential of metyrapone, thus attenuating a major limitation of metyrapone monotherapy.

The anesthetic etomidate is an imidazole derivative similar to ketoconazole that inhibits 11β-hydroxylase.[26] Inhibition of aldosterone synthase and antiproliferative effects on adrenal cortical cells may also play a role.[32] Etomidate is available only in a parenteral formulation and is therefore limited to patients with acute hypercortisolemia requiring emergency treatment or in preparation for surgery. Low doses of etomidate are often sufficient to suppress cortisol synthesis, thus potentially avoiding some of the adverse effects observed with higher doses used in anesthesia. However, close monitoring is recommended to avoid excess sedation with this agent.[32] Frequent monitoring of serum cortisol is also advised to prevent hypocortisolemia. Replacement corticosteroid doses may be necessary if complete blockade of cortisol is desired.

Adrenolytic Agents

Mitotane is a cytotoxic drug that structurally resembles the insecticide dichlorodiphenyltrichloroethane (DDT). Mitotane inhibits the 11-hydroxylation of 11-desoxycortisol and 11-desoxycorticosterone in the adrenal cortex, resulting in a net inhibition of cortisol and corticosterone synthesis. Similar to ketoconazole, mitotane takes weeks to months to exert beneficial effects. Sustained cortisol suppression occurs in most patients (~80%) and may persist following discontinuation of therapy in up to one-third of patients. Because of its cytotoxic nature, mitotane degenerates cells within the zona fasciculata and reticularis, resulting in atrophy of the adrenal cortex. The zona glomerulosa is minimally affected during acute therapy but can be damaged during long-term treatment.[28,29]

Importantly, mitotane can induce significant neurologic and GI side effects and patients should be monitored carefully or hospitalized when initiating therapy. Nausea and diarrhea are common adverse effects that occur at doses greater than 2 g/day and can be avoided by gradually increasing the dose and/or administering the agent with food. Most patients are unable to tolerate doses exceeding 8 g/day. Approximately 80% of patients treated with mitotane develop lethargy and somnolence, and other central nervous system (CNS) adverse drug reactions occur in approximately 40% of patients. Furthermore, significant but reversible hypercholesterolemia and prolongation of bleeding times can result from mitotane use.[26,27] Mitotane increases production of CBG resulting in artifactually elevated plasma cortisol; thus, UFC and urinary steroid production should be monitored to assess response to therapy.[26] If necessary, steroid replacement therapy can be given. However, because mitotane also increases extra-adrenal metabolism of exogenously administered corticosteroids (especially hydrocortisone), higher steroid replacement doses may be required. In select patients, supplemental androgen therapy also may be necessary.

Neuromodulatory Agents

Pituitary secretion of ACTH is normally mediated by various neurotransmitters, including serotonin, γ-aminobutyric acid (GABA), acetylcholine, and the catecholamines. Although ACTH-secreting pituitary tumors (Cushing disease) self-regulate ACTH production to some degree, these

neurotransmitters are still capable of promoting pituitary ACTH production. Consequently, agents that target these neurotransmitters have been proposed for the treatment of Cushing disease. Such agents include cyproheptadine, ritanserin, ketanserin, bromocriptine, cabergoline, valproic acid, octreotide, lanreotide, pasireotide, rosiglitazone, and tretinoin. However, with the exception of pasireotide, none of these drugs have demonstrated consistent clinical efficacy in the treatment of Cushing disease.

Cyproheptadine, a nonselective serotonin-receptor antagonist and anticholinergic drug, can decrease ACTH secretion in some patients with Cushing disease. However, side effects, including sedation and weight gain, significantly limit the use of this drug. Likewise, selective serotonin type 2-receptor antagonists, including ritanserin and ketanserin, have demonstrated limited efficacy. Owing to their poor efficacy and high relapse rates, these drugs should be avoided except in nonsurgical candidates refractory to more conventional treatments.

Dopamine D_2-receptor agonists, including bromocriptine and cabergoline, initially reduce ACTH secretion in as many as half of all patients with Cushing disease. This action occurs through activation of inhibitory D_2 receptors that are expressed in approximately 80% of pituitary adenomas.[33] Reductions in ACTH levels are often minor and rarely sustained with long-term bromocriptine therapy. Cabergoline exhibits a higher specificity and affinity for D_2 receptors as well as a prolonged half-life compared with bromocriptine. These differences may explain the greater response rates observed with cabergoline monotherapy; however, a sustained response occurs in only 30% to 40% of patients.[34,35] Although generally well-tolerated, side effects associated with cabergoline include nausea, orthostasis, headache, nasal congestion, constipation, nightmares, vivid dreams, and psychosis. The risk of cabergoline-associated cardiac valvulopathy (observed with higher doses used to treat Parkinson disease) has not been well-studied in lower doses typically used for treatment of Cushing disease.[36]

The somatostatin analogues octreotide and lanreotide generally are ineffective in reducing ACTH secretion in Cushing disease. These two agents primarily target somatostatin receptor subtype 2 (sst_2), whereas pituitary adenomas predominantly express sst_5. Pasireotide, a recently approved somatostatin analogue, exhibits a high affinity for sst_1, sst_2, sst_3, and, especially, sst_5 receptor subtypes. In a phase 3 study of 162 adults with Cushing disease and an elevated UFC level, pasireotide administered at 600 or 900 µg injected subcutaneously twice daily reduced the median UFC by 50% by month 2; levels remained stable for the duration of the 12-month study. Pasireotide was especially effective at normalizing UFC concentrations in patients whose baseline UFC was less than five times the upper limit of normal. Clinical signs and symptoms of Cushing disease were also improved as were blood pressure, weight, LDL cholesterol, and quality of life. Side effects were mostly GI in nature, although 73% of subjects experienced an adverse event related to hyperglycemia; preexisting diabetes mellitus or impaired glucose tolerance increased the risk for these events. Notably, glycated hemoglobin A1c increased by an average of 1.4%. Gallstones were also rarely seen with six subjects undergoing cholecystectomy.[37]

Since coexpression of D_2 and sst_5 receptors is common in adrenocorticotropin-secreting adenomas, the combination of pasireotide and cabergoline may produce synergistic effects in reducing cortisol

levels.[3] Limited data suggest that step-wise addition of cabergoline and ketoconazole in patients unresponsive to pasireotide may achieve normalization of UFC in the majority of patients; however, additional studies are needed to confirm the efficacy of this combination therapy. Potential drug-drug interactions exist with the combination of pasireotide and ketoconazole, and thus, the combination should be used with caution.[38,39]

Glucocorticoid-Receptor Blocking Agents

Mifepristone is a potent progesterone- and glucocorticoid-receptor antagonist that inhibits dexamethasone suppression and increases endogenous cortisol and ACTH levels in normal subjects.[26,30] Clinical experience and trial data in Cushing syndrome suggest that mifepristone is highly effective in reversing the manifestation of hypercortisolism, including hyperglycemia, hypertension, and weight gain.[40] Consequently, mifepristone has an FDA-approved indication for treatment of endogenous Cushing syndrome in patients who have type 2 diabetes or glucose intolerance, and who are not eligible for or have had poor response to surgery. However, because of its novel site of action, mifepristone induces a compensatory rise in ACTH and cortisol. Consequently, efficacy and toxicity monitoring must rely on clinical signs rather than laboratory assessments. Common adverse effects of mifepristone include fatigue, nausea, headache, arthralgia, peripheral edema, endometrial thickening (with or without vaginal bleeding), and significant reductions in serum potassium. Oral potassium supplementation or spironolactone can be effective in mitigating the latter adverse effect, although high doses may be required.[40]

Close monitoring of 24-hour UFC and serum cortisol is essential to detect treatment-induced adrenal insufficiency. Steroid secretion should be monitored with all of these drugs except mifepristone and steroid replacement given as needed. Whatever the choice, pharmacologic therapy in pituitary-dependent disease is mainly centered around patient stabilization prior to surgery or in patients waiting for potential response to other therapies.

Clinical Controversy…

The traditional strategy for suppressing hypercortisolism in Cushing disease consists of titrating medications to achieve normal cortisol levels. However, some clinicians advocate a “block and replace” strategy, whereby greater doses of medications are used to completely suppress endogenous cortisol production, followed by administration of physiologic doses of glucocorticoids to treat adrenal insufficiency.

Nonpharmacologic Therapy

Surgery

The treatment of choice for Cushing disease is transsphenoidal resection of the pituitary tumor.[3,11,29,30,41] The advantages of this procedure include preservation of pituitary function, low complication rate, and high clinical improvement rate. The overall cure rate of histologically proven microadenomas (tumor diameter <10 mm) approaches 90%, whereas remission rates for macroadenomas (tumor diameter ≥10 mm) generally do not exceed 65%.

For persistent disease following transsphenoidal surgery or when tumor-specific surgery is not possible, several second-line treatment options are available and should be tailored toward the individual patient.[29] In the case of persistent disease following transsphenoidal surgery, repeat surgery may be performed, particularly in patients with evidence of incomplete resection or pituitary lesion on imaging.[29] Although overall remission rates are lower with subsequent procedures, remission can be achieved rapidly when compared to alternative second-line treatments.[29] Alternatively, radiotherapy may be preferred for tumors invading the dura or cavernous sinus because these tumors respond poorly to surgical intervention.[42] Radiotherapy provides clinical improvement in approximately 50% of patients within 3 to 5 years, but increases the risk for pituitary-dependent hormone deficiencies (hypopituitarism).

Laparoscopic adrenalectomy is often preferred in patients with unilateral adrenal adenomas for whom transsphenoidal surgery and pituitary radiotherapy have failed or cannot be used.[3,11,30] Bilateral adrenalectomy rapidly reverses hypercortisolism. However, patients can develop Nelson syndrome, an aggressive pituitary tumor that secretes high quantities of ACTH, which causes hyperpigmentation. Because Nelson syndrome occurs in as many as 30% of bilateral adrenalectomy cases, patients should undergo regular MRI scans and ACTH level assessments. Additionally, these patients require lifelong glucocorticoid and mineralocorticoid supplementation.

Adrenal Adenoma

Surgical resection of benign adrenal adenoma is associated with relatively few side effects and a high cure rate (95%). The contralateral gland in the patient with adrenal adenoma is usually atrophic; therefore, steroid replacement is needed both perioperatively and postoperatively. **Table 76-7** outlines an approach to steroid replacement for three separate routes of hydrocortisone. Therapy should be continued for 6 to 12 months following surgery. Before replacement therapy is discontinued, recovery of the adrenal axis can be assessed by measuring the morning (8 am) cortisol concentration. The cortisol concentration should exceed 20 µg/dL before discontinuing exogenous steroids.[23]

TABLE 76-7 Alternative Steroid Replacement Regimens in the Adrenal Adenoma Patient

	Hydrocortisone Dose (mg)		
Time	**IV**	**IM**	**po**
Operation day	300	50 before surgery and 50 after surgery	
Postoperative day 1	200	50 every 12 hours	
Postoperative day 2	150	50 every 12 hours	
Postoperative day 3	100	50 every 12 hours	
Postoperative day 4		50 every 12 hours	25 every 6 hours
Postoperative day 5		25 every 12 hours	25 every 6 hours[a]
Postoperative day 7			25 every 6 hours
Postoperative days 8-10			25 every 8 hours
Postoperative days 11-20			25 every 12 hours

	Hydrocortisone Dose (mg)		
Time	**IV**	**IM**	**po**
Postoperative days 21+			20 at 8 am 10 at 4 pm

po, orally.

[a]Add fludrocortisone 0.05-2 mg orally once daily starting on postoperative day 5. Adjust dose based on blood pressure, body weight, and serum electrolytes.

Adrenal Carcinoma

Unlike the benign adenoma patient, those with adrenal carcinoma generally have an unfavorable outcome with surgical resection.[11] Often the complete tumor cannot be excised, leaving the patient with some degree of symptoms and extra-adrenal involvement. Radiotherapy can be used if metastases are discovered. In the patient with adrenal carcinoma who is not a surgical candidate, the focus of treatment is on palliative pharmacologic intervention.

Mitotane may be used in inoperable functional and nonfunctional adrenal carcinoma or as adjuvant therapy in surgical patients with a high risk of relapse and may prolong survival by 2 to 3 years.[43] However, mitotane induces tumor regression in fewer than 20% of patients.[44] Metyrapone and ketoconazole can be given as adjunctive treatment to attempt control of steroid hypersecretion. 5-Fluorouracil also has been used in combination therapy.

Ectopic Adrenocorticotropic Hormone Syndrome

In ectopic ACTH syndrome, ACTH-secreting tumors may exist in a variety of sites, including thymic, pulmonary, appendiceal, pancreatic, and thyroid tissues. Locating these sites is often difficult, but essential for determining an appropriate treatment strategy. Surgical resection is the most effective treatment option for these patients, but only approximately 10% to 30% of patients are cured following surgery due to high rates of metastatic disease or occult tumors. The remaining 70% to 90% receive postoperative medication.

Pharmacologic management with steroidogenesis inhibitors is effective in patients with ectopic ACTH syndrome and may be used as primary treatment in patients with occult or metastatic ectopic ACTH syndrome.[29] Mitotane has been used in this setting; however, its side-effect profile generally limits its use. Mifepristone and somatostatin analogues also have been reported to reduce the clinical signs of ectopic ACTH syndrome.[45]

Additional tumor-directed therapy can include systemic chemotherapy, interferon α, chemoembolization, radiofrequency ablation, and radiation therapy.[42] If all else fails, bilateral adrenalectomy can prevent the downstream effects (eg, steroidogenesis) of high levels of tumor ACTH secretion.

Clinical Controversy...

Steroidogenesis inhibitors can be used as primary treatment of hypercortisolism due to ectopic ACTH-secreting tumors. However, a direct-targeted therapy has been suggested for the treatment of ectopic ACTH-secreting tumors given that these tumors may express functional sst_2 and D_2 receptors. Despite limited evidence indicating their efficacy, medications that target these receptors, such as pasireotide or cabergoline, may reduce ACTH secretion and, thus, normalize cortisol concentration. Limited evidence exists regarding their efficacy in these tumors and their role in therapy remains to be determined.

Personalized Pharmacotherapy

Several factors may limit the ability to personalize pharmacotherapy in patients with Cushing syndrome. First, few rigorous studies have compared the various pharmacologic options used in Cushing syndrome. Apart from the benefits seen with pasireotide in patients with modestly elevated UFC and the use of mifepristone in patients with concomitant hyperglycemia, data are limited in terms of clinical predictors of disease response to these agents. Second, virtually nothing is known of the pharmacogenomic predictors of individual patient response in these disease states. Finally, because most agents are used off-label, scarce data exist on agent-specific pharmacokinetic parameters in this patient population.

With these limitations in mind, drug selection is determined according to the etiology of Cushing syndrome, individual patient factors, and cost. Once the etiology has been correctly identified, gender should be considered since some pharmacologic options (steroidogenesis inhibitors in particular) used in Cushing syndrome affect the sex hormones. Specifically, metyrapone is a clear second choice in women due to a high incidence of hirsutism, whereas ketoconazole may be a secondary choice in men due to drug-induced gynecomastia and hypogonadism. During pregnancy, metyrapone is commonly used, while mifepristone must be avoided. Additionally, women desiring pregnancy within the next 5 years should avoid mitotane as this agent is stored in adipose tissue for up to several years following discontinuation. Preexisting medication profiles should be considered also, since many of the pharmacologic options can inhibit (eg, ketoconazole) or induce (eg, metyrapone) important CYP isoenzymes such as 3A4.

Ultimately, pharmacotherapy is guided by patient response and several agents may need to be tried sequentially to elicit a substantial response. Combination therapy may be more effective and better tolerated than monotherapy in some patients, but studies on what constitutes the most appropriate drug regimens are lacking.

Hyperaldosteronism

Excess aldosterone secretion is categorized as either primary or secondary hyperaldosteronism.[46,47,48,49] In PA, the stimulation for aldosterone secretion arises from within the adrenal gland. Conversely, extra-adrenal stimulation is classified as secondary aldosteronism.

Primary Aldosteronism

Etiology

The most common causes of PA include BAH (65%) and aldosterone-producing adenoma (APA; otherwise known as Conn syndrome) (30%). Other rare causes include unilateral (primary) adrenal hyperplasia, adrenal cortex carcinoma, renin-responsive adrenocortical adenoma, and three forms of familial hyperaldosteronism (FH): FH type I, also known as glucocorticoid-remediable aldosteronism (GRA); FH type II, also known as familial occurrence of adenoma or hyperplasia type II; and FH type III.[46,48,49]

Clinical Presentation

PA is present in approximately 10% of the general hypertensive population and is a leading cause of secondary hypertension and apparent resistant hypertension. The disease is more common in women than in men, and diagnosis usually occurs between the third and sixth decades of life. Signs and symptoms can include arterial hypertension, which is often moderate to severe and resistant to pharmacologic intervention, as well as hypokalemia (10%-40% of PA patients), muscle weakness, fatigue, and headache. These features are nonspecific for PA and many patients are asymptomatic. Historically, hypokalemia was considered a requisite feature for PA diagnosis; however, normokalemia exists frequently in patients and should not obviate concern for PA.

CLINICAL PRESENTATION Primary Aldosteronism Symptoms

- Patients may complain of muscle weakness, fatigue, paresthesias, and headache.

Signs

- Hypertension
- Tetany/paralysis
- Polydipsia/nocturnal polyuria

Laboratory Tests

- A plasma-aldosterone-concentration–to–plasma-renin-activity (PAC–to–PRA) ratio, or aldosterone-to-renin ratio (ARR) greater than 30 and a PAC greater than 15 is suggestive of PA.
- Common laboratory findings include suppressed renin activity, elevated plasma aldosterone concentration (PAC), hypernatremia (>142 mEq/L), hypokalemia, hypomagnesemia, elevated bicarbonate concentration (>31 mEq/L), and glucose intolerance.

Confirmatory Tests

- Oral or IV saline loading, fludrocortisone suppression test (FST), and genetic testing

Diagnosis

Diagnostic confirmation of PA is obtainable through screening, confirmatory tests, and subtype differentiation (**Fig. 76-5**). As in Cushing syndrome, discovery of the underlying etiology ensures

proper treatment. **Table 76-8** lists the various abnormalities that must be ruled out when suspicion of hyperaldosteronism is high.

FIGURE 76-5

Algorithm for the diagnosis of primary aldosteronism. (ARR, aldosterone-to-renin ratio; APA, aldosterone-producing adenoma; AVS, adrenal venous sampling; BAH, bilateral adrenal hyperplasia; CT, computed tomography; FH-1, familial hyperaldosteronism type 1; FST, fludrocortisone suppression test; HTN, hypertension; PAC, plasma aldosterone concentration.)

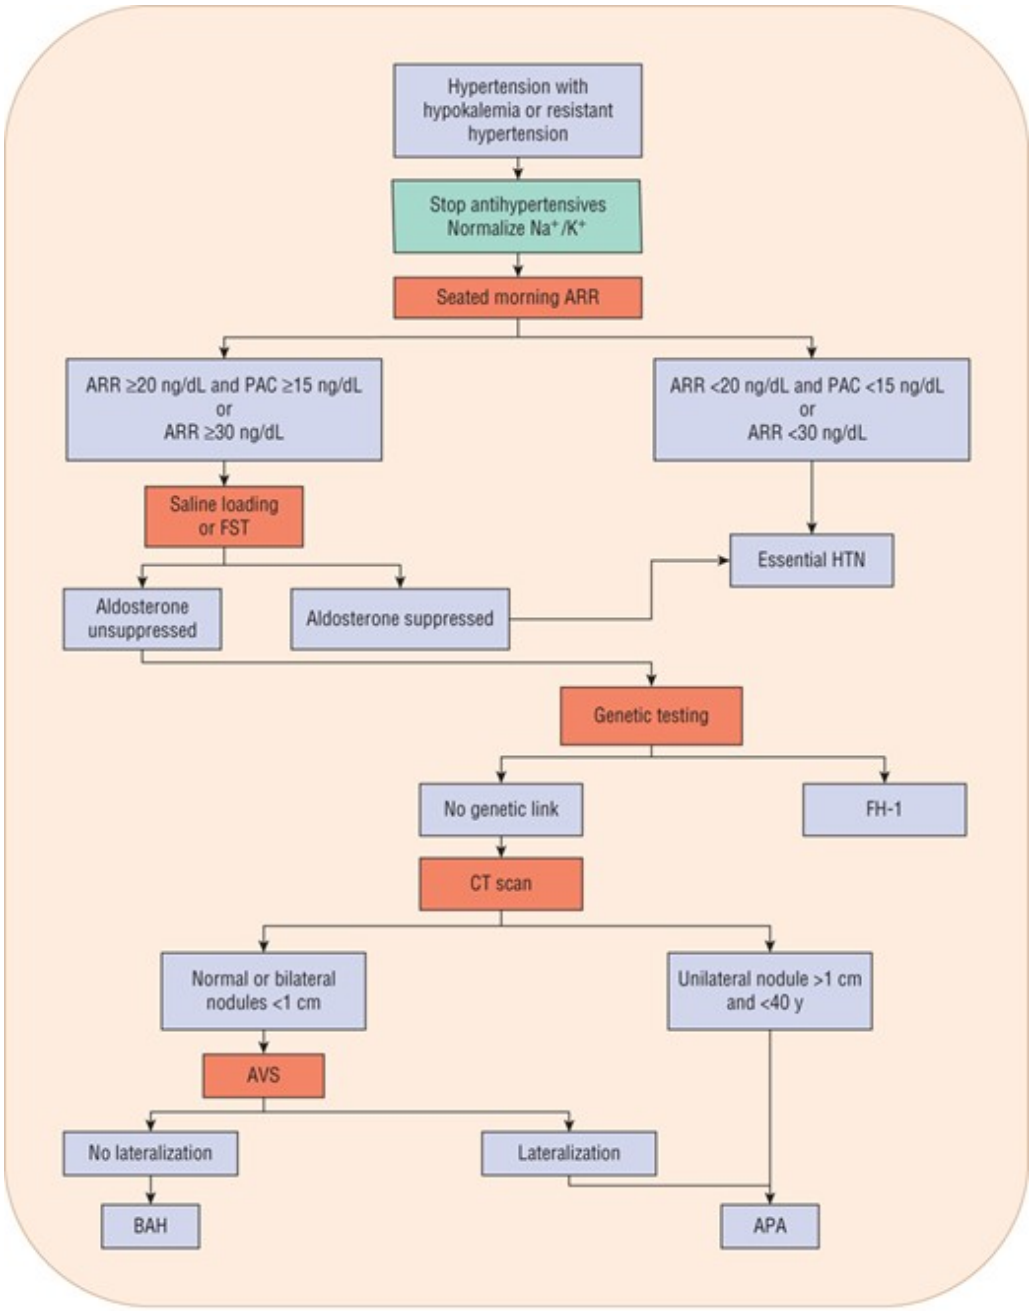

TABLE 76-8 Differential Diagnosis of Primary Aldosteronism

Disease	Plasma Renin Activity	Plasma Aldosterone Concentration	Blood Pressure
Primary aldosteronism	Low	High	High
Edematous disorders	High	High	Normal
Malignant hypertension	High	High	High
Congenital adrenal hyperplasia	Low	Low	High
Cushing syndrome	Low to normal	Low to normal	High
Liddle syndrome	Low	Low	High
Bartter syndrome	High	High	Low to normal
Licorice ingestion	Low	Low	High
Low-renin essential hypertension	Low	Low to normal	High

Initial diagnosis is made through proper screening of patients with suspected PA. Such patients include those with blood pressure greater than 160/100 mm Hg, appreciating that the prevalence of PA increases with hypertensive severity, and those with resistant hypertension. Screening for PA is most often done by using the PAC-to-PRA ratio, otherwise known as the ARR. An elevated ARR is highly suggestive of PA; however, an optimal cutoff ratio remains elusive because testing conditions (posture, time, current drug therapy, recent dietary salt intake), patient characteristics, and variable levels of specificity and sensitivity among assays can significantly alter test results.[50] ARR cutoffs of 20 to 40 or 30 with an aldosterone concentration greater than 15 ng/dL are used most often.[47,50,51,52]

Following a positive ARR screening test, confirmatory testing must be performed to exclude any false-positive cases. Confirmatory tests include the oral sodium loading test, saline infusion test, FST, and the captopril challenge test. Although individual tests can vary in sensitivity, specificity, and reliability, any test can be used depending on patient- and institution-specific considerations. FST generally is considered the most reliable, but requires hospitalization. Prior to performing these tests, potassium must be normalized and renin–angiotensin–aldosterone system (RAAS) inhibitors should be temporarily discontinued, if possible. Positive tests indicate autonomous aldosterone secretion under inhibitory pressures and are diagnostic for PA. After diagnosis, patients with confirmed PA before age 20 or with a family history of PA or strokes before age 40 should undergo genetic testing for GRA.[50]

Differentiating between an APA and BAH is imperative to formulate a proper treatment plan. Most adenomas are singular and small (<1 cm) and occur more often in the left adrenal gland than the right. Patients with APA generally have more severe hypertension, more profound hypokalemia, and higher plasma and urinary aldosterone concentrations compared with patients with BAH. Adrenal venous sampling (AVS) provides the most accurate means of differentiating unilateral from bilateral forms of PA. However, AVS is expensive, invasive, and frequently unavailable. CT scanning can detect most adenomas, although an incidentaloma can occasionally cause confusion. If CT scanning is inconclusive, AVS is performed to characterize lateralization.[47,53,54,55]

The underlying abnormality in BAH remains a mystery, but some investigators believe that a hormone factor stimulates the zona glomerulosa, resulting in increased sensitivity to angiotensin II. In contrast to those with an APA, patients with BAH are able to maintain control of the renin–angiotensin system, with little effect following doses of ACTH.

Therapeutic Management

BAH-Dependent Aldosteronism

Aldosterone-receptor antagonists are the treatment of choice in bilateral cases of PA (drug dosing and monitoring parameters can be found in **Tables 76-9** and **76-10**, respectively). Spironolactone, a nonselective aldosterone-receptor antagonist, competes with aldosterone for binding at the aldosterone receptor, thus preventing the negative downstream effects of aldosterone-receptor activation. Additionally, spironolactone is capable of inhibiting aldosterone synthesis within the adrenal gland; however, the magnitude of this inhibition is relatively small and the effect only occurs at doses above those recommended in the clinical setting.[56] Spironolactone is available in oral form, with most patients responding to doses between 25 and 400 mg/day. The clinician should wait 4 to 8 weeks before reassessing the patient for urinary electrolytes and blood pressure control. Adverse effects of spironolactone are dose-dependent and include GI discomfort, impotence, gynecomastia, menstrual irregularities, and hyperkalemia. Gynecomastia and menstrual irregularities observed with spironolactone therapy arise from activity at androgen and progesterone receptors and inhibition of testosterone biosynthesis. Additionally, because salicylates increase the renal secretion of canrenone, the active metabolite of spironolactone, patients should be advised to avoid concomitant therapy with salicylates. In patients intolerant of spironolactone, alternative options include eplerenone and amiloride.[48,49,57,58,59]

TABLE 76-9 Drug Dosing in the Treatment of Hyperaldosteronism

Drug	Brand Name	Initial Dose	Usual Range	Special Populations	Comments
Amiloride	Midamor®, 5 mg tablets	5 mg twice daily	20 mg/day in two divided doses	CrCl 10-50 mL/min: reduce dose by 50%; CrCl <10 mL/min: CI	Maximum: 30 mg/day
Eplerenone	Inspra®, 25 and 50 mg tablets	50 mg once daily	100-300 mg/day in single or divided doses; titrate at 4- to 8-week intervals	CrCl <30 mL/min: CI	Maximum: 300 mg/day
Spironolactone	Aldactone®, 25, 50, and 100 mg tablets	25 mg once daily	100-400 mg/day in single or divided doses; titrate at 4- to 8-week intervals	CrCl 10-50 mL/min: extend dosing interval to once daily; CrCl <10 mL/min: CI	Maximum: 400 mg/day

CI, contraindicated; CrCl, creatinine clearance.

TABLE 76-10 Drug Monitoring in the Treatment of Hyperaldosteronism

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Amiloride	Electrolyte abnormalities (hyperkalemia), hypotension, nausea, vomiting, diarrhea, headache	Serum creatinine, serum potassium, blood pressure	Electrolyte abnormalities (hyperkalemia) more pronounced with reduced renal function
Eplerenone	Electrolyte abnormalities (hyperkalemia), hypotension, dizziness, headache; gynecomastia and menstrual irregularities are uncommon	Serum creatinine, serum potassium, blood pressure	Electrolyte abnormalities (hyperkalemia) more pronounced with reduced renal function. CYP3A4 substrate; avoid use with potent CYP3A4 inhibitors
Spironolactone	GI discomfort, impotence, gynecomastia, menstrual irregularities, electrolyte abnormalities (hyperkalemia), hypotension	Serum creatinine, serum potassium, blood pressure	Electrolyte abnormalities (hyperkalemia) more pronounced with reduced renal function

CYP, cytochrome P450 enzyme; GI, gastrointestinal.

Eplerenone is a selective aldosterone-receptor antagonist with high affinity for the aldosterone receptor and low affinity for androgen and progesterone receptors. Consequently, eplerenone elicits fewer sex steroid–dependent effects than spironolactone. Recent data suggest that eplerenone reduces blood pressure less than spironolactone in patients with PA, although long-term data comparing these agents are lacking.[60] Eplerenone dosing starts at 50 mg daily, with titration to 50 mg twice a day; some patients may require total daily doses as high as 200 to 300 mg.[57] Titration should occur at 4- to 8-week intervals. In addition, eplerenone is a substrate of CYP3A4 and should not be taken with potent CYP3A4 inhibitors. Eplerenone is the preferred aldosterone antagonist during pregnancy since spironolactone can cause ambiguous genitalia in a male fetus.[61]

Amiloride, a potassium-sparing diuretic, is dosed at 5 mg twice a day up to 30 mg/day if necessary. Amiloride is less effective than spironolactone and patients often require additional therapy to adequately control blood pressure. Additional second-line options include calcium channel blockers, ACE inhibitors, and diuretics such as chlorthalidone, although all lack outcome data in PA.[55,58] However, some agents (eg, diuretics, calcium channel blockers) can promote a reactive rise in PRA, ultimately leading to increased aldosterone levels and potentially worsening PA. A prudent strategy would be to use these agents only in combination with RAAS inhibitors to mitigate the downstream aldosterone effects of any increase in PRA.

Aldosterone synthase inhibitors, currently under development, may offer additional therapeutic options in the future.

APA-Dependent Aldosteronism

The treatment of choice for APA-dependent aldosteronism remains laparoscopic resection of the

adenoma.[62] Nearly 100% of patients show blood pressure improvement while 30% to 72% are permanently cured.[59,63] Because APAs are small and often occur in multiples, resection should target the entire adrenal gland. In successful cases, blood pressure control is achieved in 1 to 3 months. Medical management can be efficacious in this population if surgery is contraindicated. However, medical management may be significantly more expensive than unilateral resection.

Glucocorticoid-Remediable Aldosteronism

Glucocorticoids are very effective in treating GRA.[42] Low doses of long-acting glucocorticoids are used (0.125-0.5 mg/day of dexamethasone or 2.5-5 mg/day of prednisone) because complete suppression of ACTH-stimulated aldosterone release is unnecessary. Spironolactone, eplerenone, and amiloride are alternative treatment options.[47]

Secondary Aldosteronism

Secondary aldosteronism results from an appropriate response to excessive stimulation of the zona glomerulosa by an extra-adrenal factor, usually the renin–angiotensin system. Excessive potassium intake can promote aldosterone secretion, as can oral contraceptive use, pregnancy (aldosterone secretion 10 times normal by the third trimester), and menses. Congestive heart failure, cirrhosis, renal artery stenosis, and Bartter syndrome also can lead to elevated aldosterone concentrations.

Treatment of secondary aldosteronism is dictated by etiology. Control or correction of the extra-adrenal stimulation of aldosterone secretion should resolve the disorder. Medical therapy with spironolactone is the mainstay of treatment until an exact etiology can be located.

HYPOFUNCTION OF THE ADRENAL GLAND

Hypofunction of the adrenal gland can affect any or all adrenal hormones, depending on the etiology of the disorder. However, hypofunction does not always lead to insufficient production of adrenal hormones as might be expected. As described further, some types of adrenal hypofunction can lead to excess production of certain hormones.

Addison Disease

7 Primary adrenal insufficiency, or Addison disease, most often involves the destruction of all regions of the adrenal cortex. Deficiencies arise in cortisol, aldosterone, and the various androgens and levels of CRH and ACTH increase in a compensatory manner. In developed countries, autoimmune dysfunction is responsible for most cases (80%-90%), whereas tuberculosis predominates as the cause in developing countries. Approximately 50% of patients with autoimmune etiologies present with one or more concomitant autoimmune disorders, usually involving other endocrine organs. Autoimmune thyroid disorders (eg, Hashimoto thyroiditis or Graves disease) are the most common, but the ovaries, pancreas, parathyroid gland, and organs of the GI system can also be affected. This polyglandular failure syndrome, termed autoimmune polyendocrine syndrome (APS), is associated with the idiopathic etiology only and has not been seen with adrenal insufficiency

associated with tuberculosis or other invasive diseases. Medications that inhibit cortisol synthesis (ketoconazole) or accelerate cortisol metabolism (phenytoin, rifampin, phenobarbital) can also cause primary adrenal insufficiency.[64]

8 Secondary insufficiency is characterized by reduced glucocorticoid production secondary to decreased ACTH levels. Low levels of ACTH most commonly result from exogenous steroid use, leading to suppression of the HPA axis and decreased release of ACTH, resulting in impaired androgen and cortisol production. These effects occur with oral, inhaled, intranasal, and topical glucocorticoid administration.[65,66,67] Moreover, mirtazapine and progestins, such as medroxyprogesterone acetate and megestrol acetate, have been reported to induce secondary adrenal insufficiency.[68,69] Chronic suppression also can result in atrophy of the anterior pituitary and hypothalamus, impairing recovery of function if the exogenous steroid is reduced. Endogenous secondary insufficiency can occur with tumor development in the hypothalamic–pituitary region. Secondary disease classically presents with normal concentrations of mineralocorticoids since the zona glomerulosa is controlled by the renin–angiotensin system rather than ACTH levels.

Approximately 90% of the adrenal cortex must be destroyed before adrenal insufficiency symptoms will occur.[70] Specific etiologies for both primary and secondary insufficiency are listed in **Table 76-11**. Adrenal hemorrhage can result from multiple etiologies including traumatic shock, coagulopathies, ischemic disorders, and other situations of severe stress, but septicemia is the most common. Symptoms include truncal pain, fever, shaking, chills, hypotension preceding shock, anorexia, headache, vertigo, vomiting, rash, psychiatric symptoms, abdominal rigidity or rebound, and death in 6 to 48 hours if not treated. The most common organisms found on autopsy are *Neisseria meningitidis*, *Pseudomonas aeruginosa*, *Streptococcus pneumoniae*, Group A *Streptococcus*, and *Haemophilus influenzae*.[70,71]

TABLE 76-11 Etiologies of Primary and Secondary Adrenal Insufficiency

Primary Insufficiency	Secondary Insufficiency
Slow onset	Craniopharyngioma
Acquired immunodeficiency syndrome	Cure of Cushing syndrome
Adrenomyeloneuropathy	Empty sella syndrome
Adrenoleukodystrophy	Tumors of the third ventricle
Amyloidosis	Histiocytosis
Autoimmune adrenalitis[a]	Hypothalamic tumors
Bilateral adrenalectomy	Hypopituitarism
Congenital adrenal hypoplasia	Long-term corticosteroid administration
Hemochromatosis	Lymphocytic hypophysitis
Isolated glucocorticoid deficiency	Pituitary surgery, radiation, or tumor
Metastatic neoplasia	Sarcoidosis
Systemic fungal, bacterial, or viral infections, tuberculosis[b]	Medications—progestins and glucocorticoid discontinuation

Primary Insufficiency	Secondary Insufficiency
Medications—ketoconazole, etomidate, rifampin, phenytoin, phenobarbital	Postpartum pituitary necrosis
Fast onset	Necrotic or bleeding pituitary macroadenoma
Adrenal thrombosis, hemorrhage, sepsis, trauma, or necrosis	Head trauma, lesions of the pituitary stalk, pituitary or adrenal surgery for Cushing syndrome

[a]Accounts for approximately 70% of cases.

[b]Accounts for approximately 20% of cases.

Diagnosis

Distinguishing Addison disease from secondary insufficiency is difficult; however, the following guidelines may be helpful:

1. Hyperpigmentation, commonly found in areas of skin exposed to increased friction, is seen only in Addison disease because of excess secretion of ACTH and other proopiomelanocortin (POMC) peptides that induce melanocyte-stimulating hormone production. Secondary adrenal insufficiency is fundamentally characterized by deficient ACTH and POMC peptide secretion and a corresponding low level of melanocyte-stimulating hormone production. In fact, some patients with secondary insufficiency may exhibit pale-colored skin secondary to hypopigmentation.

2. Aldosterone secretion usually is preserved in secondary insufficiency.

3. Weight loss, dehydration, hyponatremia, hyperkalemia, and elevated blood urea nitrogen are common in Addison disease.

4. Addison disease will have an abnormal response to the short corticotropin stimulation test. Plasma ACTH levels are usually elevated (400-2,000 pg/mL) in primary insufficiency, versus low to normal (5-50 pg/mL; see Table 76-3) in secondary insufficiency. A normal corticotropin stimulation test does not rule out secondary adrenal insufficiency, particularly in mild cases.

The short corticotropin stimulation test, also known as the cosyntropin stimulation test, can be used to assess patients suspected of hypocortisolism. Patients are given 250 µg of synthetic ACTH IV or intramuscularly, with serum cortisol measured at baseline and 30 to 60 minutes after the injection. A resulting cortisol concentration ≥18 µg/dL (500 nmol/L) rules out adrenal insufficiency.[72] Because 250 µg represents a massive supraphysiologic dose, this test can elicit normal, elevated cortisol responses in some cases of mild secondary insufficiency. Thus, some suggest that higher cutoff values (≥22 µg/dL [≥600 nmol/L]) should be used to prevent false-negative test results.[73] Alternatively, a low-dose corticotropin stimulation test, using 1 µg of synthetic ACTH, can achieve equivalent results to the standard test and is more sensitive in establishing the diagnosis of secondary insufficiency.[74] Other tests include the insulin hypoglycemia test, the metyrapone test, and

the CRH stimulation test.[75,76]

The standard cutoffs described above are of limited use in acutely ill patients.[77] Severe infection, trauma, burns, illnesses, or surgery can increase cortisol production by as much as a factor of 6, making the recognition of adrenal insufficiency in this population extremely difficult. In the critically ill, a random cortisol concentration below 15 µg/dL (415 nmol/L) is suggestive of adrenal insufficiency, whereas a concentration greater than 34 µg/dL (940 nmol/L) suggests that adrenal insufficiency is unlikely.[77] For patients who fall between these two values, a poor response to corticotropin (<9 µg/dL [250 nmol/L] increase in plasma cortisol from baseline at 30 or 60 minutes) indicates the possibility of adrenal insufficiency and a need for corticosteroid supplementation.[77] A severe hypoproteinemic patient (albumin <2.5 g/L) will have markedly lower CBG, which can underestimate the actual free fraction of cortisol. These patients may benefit from measurement of free cortisol, although the assay may not be routinely available.[64,76]

Therapeutic Management

Treatment of Addison disease must include adequate patient education, so that the patient is aware of treatment complications, expected outcome, consequences of missed doses, and drug side effects. The agents of choice are hydrocortisone, cortisone, and prednisone, administered twice daily with the treatment objective being the establishment of the lowest effective dose while mimicking the normal diurnal adrenal rhythm.[72] Usually a twice-daily dosing schedule is adequate with the dose depending on the agent used.

Endogenous cortisol production varies between 5 and 10 mg/m^2/day.[78] Hence, the classic 12 to 15 mg/m^2/day rule for cortisol supplementation can be excessive in most patients. Recommended starting doses to properly mimic endogenous cortisol production are 15 to 25 mg of hydrocortisone daily, which is roughly equal to 25 to 37.5 mg of cortisone acetate or 2.5 mg of prednisone.[64,78] The majority of the dose (67%) is given in the morning, whereas the remainder (33%) is given 6 to 8 hours later to duplicate the normal circadian rhythm of cortisol production. Recent data also suggest that continuous infusion of glucocorticoids delivered via infusion pump may provide a more physiological circadian maintenance of ACTH and cortisol concentration when compared to conventional oral replacement.[79] Since no laboratory test adequately determines the appropriateness of dosing, the patient's symptoms should be monitored every 6 to 8 weeks to assess proper glucocorticoid replacement.

In primary insufficiency, fludrocortisone acetate can be used to supplement mineralocorticoid loss. For most patients, a dose of 0.05 to 0.2 mg by mouth once a day is adequate to maintain volume status. If parenteral therapy is needed, 2 to 5 mg of deoxycorticosterone trimethylacetate in oil intramuscularly every 3 to 4 weeks can be substituted. Mineralocorticoid replacement attenuates the development of hyperkalemia, but may be unnecessary in some primary cases because glucocorticoids, particularly at large doses, also bind to mineralocorticoid receptors. For example, a daily dose of hydrocortisone 40 to 50 mg has similar mineralocorticoid effects to 0.1 mg of fludrocortisone. Adverse effects must be monitored closely and include gastric upset, edema, hypertension, hypokalemia, insomnia, excitability, and diabetes mellitus. In addition, patient weight,

blood pressure, and electrocardiogram should be monitored regularly.[75,76]

Clinical Controversy…

The primary source of dehydroepiandrosterone (DHEA) and androgens in women is the adrenal cortex. DHEA is converted to more potent androgens and estrogens in the periphery. Consequently, women with adrenal insufficiency can have decreased libido. DHEA, available as a dietary supplement, has been advocated as an option for female patients with adrenal insufficiency complaining of decreased libido and low energy. However, clinical trial data surrounding the benefits of DHEA are conflicting, and the general consensus on routine recommendation in clinical practice is currently lacking.

Most adrenal crises occur secondary to glucocorticoid dose reduction or lack of stress-related dose adjustments. Patients receiving corticosteroid replacement therapy should receive an additional 5 to 10 mg of hydrocortisone shortly before strenuous activities such as exercise.[75,76] Likewise, during times of severe physical stress such as febrile illnesses or injury, patients should be instructed to double their daily dose until recovery.[76,80] For major trauma, surgery, or in critically ill patients, larger doses—up to 10 times the usual daily dose—may be required.[76] Parenteral therapy should be used for patients experiencing diarrhea or vomiting. In patients with concomitant, newly diagnosed, or uncontrolled hypothyroidism, thyroid replacement should take place only after adequate glucocorticoid replacement as euthyroidism can trigger an adrenal crisis by accelerating cortisol metabolism.[72]

The end point of therapy is difficult to assess in most patients, but a reduction in excess pigmentation is a good clinical marker. The development of features of Cushing syndrome indicates excessive replacement. Treatment of secondary adrenal insufficiency is identical to primary disease treatment, except that mineralocorticoid replacement usually is unnecessary. Patient education is paramount with emphasis placed on the medication regimen and adrenal crisis prevention.

Acute Adrenal Insufficiency

Adrenal crisis, or Addisonian crisis, is characterized by an acute adrenocortical insufficiency and represents a true endocrine emergency. Anything that increases adrenal requirements dramatically can precipitate an adrenal crisis. Stressful situations, surgery, infection, and trauma all are potential triggering events, especially in the patient with some underlying adrenal or pituitary insufficiency. The most common cause of adrenal crisis is HPA-axis suppression brought on by abrupt withdrawal of chronic glucocorticoid use.

CLINICAL PRESENTATION Adrenal Insufficiency Symptoms

- Patients commonly complain of weakness, weight loss, GI symptoms, craving for salt, headaches, memory impairment, depression, and postural dizziness.
- Early symptoms of acute adrenal insufficiency also include myalgias, malaise, and anorexia. As the situation progresses, vomiting, fever, hypotension, and shock will develop.

Signs

- Increased pigmentation
- Hypotension (postural)
- Fever
- Decreased body hair
- Vitiligo
- Features of hypopituitarism (amenorrhea and cold intolerance)

Laboratory Tests

- The short cosyntropin stimulation test can be used to assess patients suspected of hypercortisolism.

Other Diagnostic Tests

- Other tests include the insulin hypoglycemia test, the metyrapone test, and the CRH stimulation test.

Treatment of adrenal crisis involves the administration of parenteral glucocorticoids. Hydrocortisone is the agent of choice owing to its combined glucocorticoid and mineralocorticoid activity. Hydrocortisone is initially administered at a dose of 100 mg IV through rapid infusion, followed by a continuous infusion (usually 10 mg/h) or intermittent bolus of 100 to 200 mg every 24 hours.[64,76,81] Intravenous administration is continued for 24 to 48 hours, at which time if the patient is stable, oral hydrocortisone can be administered at a dose of 50 mg every 6 to 8 hours, followed by tapering to the individual's chronic replacement needs. Fluid replacement often is required and can be accomplished with dextrose 5% in normal saline solution (D_5NS) at a rate to support blood pressure. During initial treatment for adrenal crisis, mineralocorticoid replacement generally is unnecessary because of hydrocortisone's mineralocorticoid activity. If hyperkalemia is present after the hydrocortisone maintenance phase, additional mineralocorticoid supplementation can be achieved with 0.1 mg of fludrocortisone acetate daily.

Patients with adrenal insufficiency should be instructed to carry a card or wear a bracelet or necklace, such as MedicAlert, that contains information about their condition. Additionally, patients should have easy access to injectable hydrocortisone or glucocorticoid suppositories in case of an emergency or during times of physical stress, such as febrile illness or injury.[64]

Hypoaldosteronism

Hypoaldosteronism is rare and usually associated with low-renin status (hyporeninemic hypoaldosteronism), diabetes, complete heart block, or severe postural hypotension, or it can occur postoperatively following tumor removal. Hypoaldosteronism can be part of a larger adrenal

insufficiency or a stand-alone defect. In nonselective hypoaldosteronism, generalized adrenocortical insufficiency is the most likely etiology (see Addison Disease). In selective hypoaldosteronism, insufficient aldosterone levels are precipitated by a specific defect in the stimulation of adrenal aldosterone secretion, with 21-hydroxylase deficiency being most common. Pseudohypoaldosteronism results from a defect in peripheral aldosterone action, whether from increased peripheral resistance or a reduced number of functional aldosterone receptors.

Laboratory analysis reveals hyponatremia, hyperkalemia, or both. Patients often will present with hyperchloremic metabolic acidosis. In most cases, the deficiency is in mineralocorticoid production and replacement with fludrocortisone in a dose of 0.1 to 0.3 mg is usually effective. Patients should be monitored for blood pressure response as well as electrolyte status.

Congenital Adrenal Hyperplasia

Because many enzyme systems are needed to complete the complex cholesterol-to-cortisol pathway, enzyme deficiencies can lead to disruptions of the normal cascade of events (see Fig. 76-2). This group of enzyme disorders is collectively referred to as congenital adrenal hyperplasia because of the resultant chronic adrenal gland stimulation that occurs following enzyme deficiency.[76,82,83] The most frequent cause of congenital adrenal hyperplasia is steroid 21-hydroxylase deficiency, accounting for more than 90% of cases. Any enzyme deficiency is capable of affecting any one or all three of the steroid pathways. Therefore, treatment focuses on replacement of the deficient hormone, psychological support, and surgical repair of the external genitalia in most female patients.[84] Six of the most common enzyme deficiencies are outlined briefly in **Table 76-12**.

TABLE 76-12 Congenital Adrenal Hyperplasia

Enzyme Deficiency (Disorder)	Symptoms	Laboratory Tests	Comments
21-Hydroxylase (nonvirilizing CAH)	Enlarged female genitalia and adrenal gland (caused by cholesterol)	All steroids are low in blood and urine	Poor prognosis for infants
17-Hydroxylase (nonvirilizing CAH)	Hypertension usually present	Low concentrations of cortisol and estrogens	Mineralocorticoid replacement not necessary
21-Hydroxylase (virilizing CAH)	Pubertal irregularities (acne, early pubic hair, voice lowering, and increased muscularity); mature normally with replacement	High progesterone, renin, 17-hydroxyprogesterone, and ACTH; low cortisol, sodium, and aldosterone	Most common form of CAH (90% of total), incidence of 1:10,000; monitor growth velocity, bone age, renin, and 17-hydroxyprogesterone

Enzyme Deficiency (Disorder)	Symptoms	Laboratory Tests	Comments
11-Hydroxylase (virilizing CAH)	Hypertension secondary to high deoxycortisol and virilism from androgen excess; mistaken for Cushing, but no glucose intolerance	Low plasma cortisone and aldosterone; high ACTH and MSH concentrations	Second most common form of CAH (9% of total), incidence of 1:100,000; final step in biosynthesis of corticosterone and cortisol; found only in adrenal cortex
3-Hydroxysteroid dehydrogenase (mixed CAH)	Both cortisol and aldosterone deficiencies	Decreased aldosterone, cortisol, estrogens, and androgens; increased pregnenolone and cholesterol	Defect affects both adrenals and gonads
18-Hydroxysteroid dehydrogenase (corticosterone methyloxidase deficiency)	Hypotension	Restricted to zona glomerulosa; sole aldosterone defect; hyponatremia, hyperkalemia, increased renin	Mineralocorticoid replacement without glucocorticoid replacement

ACTH, adrenocorticotropic hormone; CAH, congenital adrenal hyperplasia; MSH, melanocyte-stimulating hormone.

Adrenal Virilism

9 Virilism, excessive secretion of androgens from the adrenal gland, commonly occurs as a result of congenital enzyme defects. Depending on the enzyme deficiency, patients accumulate excess levels of a variety of androgens, most notably testosterone. The condition affects women more often than men, with hirsutism being the dominant feature. Additional coexisting features can include voice deepening, acne, increased muscle mass, menstrual abnormalities, clitoral enlargement, redistribution of body fat and loss of female body contour, breast atrophy, and hair recession and crown balding.[85]

Treatment of virilism centers on suppression of the pituitary–adrenal axis with exogenous glucocorticoids. In adults, the usual steroids used are dexamethasone (0.25-0.5 mg), prednisone (2.5-5 mg), or hydrocortisone (10-20 mg).[86]

Hirsutism

Women presenting with hirsutism exhibit excess terminal hair growth in an androgen-dependent distribution. Such growth has obvious cosmetic consequences, but also can adversely affect quality of

life and psychological well-being.[87] Most cases of hirsutism occur in women with some degree of excess androgen production. Androgen excess can be derived from either the ovaries or the adrenal glands, or rarely from pituitary disorders. Polycystic ovarian syndrome (PCOS) is responsible for most cases of ovarian excess and is the most common cause of hirsutism overall.[88] Congenital adrenal hyperplasia accounts for 5% of cases while adrenal and ovarian tumors cause hyperandrogenemia in 0.2% of women.

Cosmetic approaches generally are tried first, with repeated photoepilation offering the greatest long-term success.[89] If these approaches are unsuccessful, subsequent treatment should include pharmacologic intervention. Oral contraceptives are the treatment of choice in most hirsute women, particularly in those requiring concurrent contraception. If oral contraceptives are used, a progestin with low androgen activity (norethindrone, ethynodiol diacetate) or antiandrogenic activity (drospirenone) should be chosen. Other antiandrogens, including spironolactone and finasteride, can supplement or replace oral contraceptive therapy in women who cannot or choose not to conceive. Antiandrogens can take 6 to 12 months to alleviate hirsutism and treatment should be continued for 2 years, followed by a slow dose reduction.[90] Dexamethasone (and other glucocorticoids) can be modestly effective if the androgen source is adrenal, but can induce cushingoid symptoms even at doses of 0.5 mg/day.

Gonadotropin-releasing hormone can be an effective adjunct or alternative to oral contraceptives if the source of androgen is ovarian. However, these products generally are not recommended due to excessive costs, injectable-only routes of administration, and adverse effects resulting from estrogen deficiency. Additionally, insulin sensitizers, such as metformin or thiazolidinediones, can show modest improvement in women with PCOS, but their routine use is not recommended.[88]

Eflornithine hydrochloride, an irreversible ornithine decarboxylase inhibitor, moderately reduces the rate of hair growth but does not remove hair already present. The drug is available as a topical cream applied as a thin layer to the affected area twice daily, at least 8 hours apart. Reduction in unwanted hair can be noted within 6 to 8 weeks with a maximal effect at 8 to 24 weeks; therapy must be continued indefinitely to prevent hair regrowth.[86,90] Skin irritation can occur that resolves on discontinuation.

PRINCIPLES OF GLUCOCORTICOID ADMINISTRATION

Originally, the term *glucocorticoid* was given to these agents to describe their glucose-regulating properties. However, carbohydrate metabolism is only one of the myriad effects exhibited by steroids. The activity produced by these drugs is a function of the receptor activated (glucocorticoid vs mineralocorticoid), the location of the receptor, as well as the agent and dose prescribed.

The mechanism of action of glucocorticoids is complex and not fully known. The glucocorticoid enters the cell through passive diffusion and binds to its specific receptor. Between 5,000 and 100,000 receptors exist in each cell. Steroids exhibit various binding affinities to the vast number of receptors in almost every tissue and therefore elicit a wide variety of biologic effects.

Following receptor binding, a structural change occurs in the receptor, known as *activation*. After activation, the receptor–steroid complex binds to deoxyribonucleic acid sites in the cell called *glucocorticoid response elements* (GREs). This binding alters nearby gene expression and stimulates, or in some cases, inhibits transcription of specific mRNAs. Consequently, the resulting protein, which produces the stimulatory or inhibitory glucocorticoid action, varies according to the tissue and cell type in which the glucocorticoid receptor exists.

Pharmacokinetic properties of the glucocorticoids vary by agent and route of administration. In general, most orally administered steroids are well absorbed. Water-soluble agents are more rapidly absorbed following intramuscular injection than are lipid-soluble agents. Intravenous administration is recommended when a quick onset of action is needed. A summary of these agents is provided in **Table 76-13**.

TABLE 76-13 Relative Potencies of Glucocorticoids

Glucocorticoid	Antiinflammatory Potency	Equivalent Potency (mg)	Approximate Half-Life (min)	Sodium-Retaining Potency
Cortisone	0.8	25	30	2
Hydrocortisone	1	20	90	2
Prednisone	3.5	5	60	1
Prednisolone	4	5	200	1
Triamcinolone	5	4	300	0
Methylprednisolone	5	4	180	0
Betamethasone	25	0.6	100-300	0
Dexamethasone	30	0.75	100-300	0

In addition to causing iatrogenic Cushing syndrome, systemic steroids can lead to increased susceptibility to infection, osteoporosis, sodium retention with resultant edema, hypokalemia, hypomagnesemia, cataracts, peptic ulcer disease, seizures, and generalized suppression of the HPA axis. Long-term complications tend to be insidious and less likely to respond to steroid withdrawal.

Suppression of the HPA axis is a major concern whenever systemic steroids are tapered or withdrawn. Single doses of glucocorticoids can prevent the axis from responding to major stressors for several hours. In general, steroid administration at a high dose for long periods of time causes suppression of the axis. However, the possibility of suppression occurs any time the patient is exposed to supraphysiologic steroid doses.[23,91] Symptoms of steroid withdrawal resemble those seen in a patient with adrenocortical deficiency.

A variety of recommendations for steroid tapering are available.[23,92,93,94] In general, patients who have been on long-term steroid therapy will need to be gradually withdrawn toward physiologic doses over months. On average, the normal adult produces approximately 10 to 30 mg of cortisol per day with the peak concentration occurring around 8:00 am. As the steroid or steroid-equivalent dose approaches the 20- to 30-mg level, the taper should be slowed and the patient checked for axis

function. The primary modes to test HPA integrity are the ACTH test, either high or low dose, or a morning (8:00 am) serum cortisol. A normal morning serum cortisol (>20 µg/dL) or a normal ACTH test indicates that daily steroid maintenance therapy may be discontinued. If morning serum cortisol is between 3 and 20 µg/dL, the ACTH or CRH stimulation test can be useful in the assessment of pituitary–adrenal function.[23] A morning cortisol less than 3 µg/dL indicates axis suppression and the need for continued replacement therapy. Suppression can persist for up to a year in some patients. Caution should be used to prevent disease exacerbation during the steroid taper and to avoid the need for another course of high-dose steroids.

Alternate-day therapy (ADT) regimens have been promoted as a means to lessen the impact of prolonged steroid administration.[23,94] ADT theoretically minimizes the hypothalamic–pituitary suppression as well as some of the adverse effects seen with once-daily therapy. This hypothetical advantage may be especially pertinent in treating children and young adults, in whom growth suppression is a major concern. ADT is not recommended for initial management, but rather in the management of the stabilized patient who needs long-term therapy. The patient is exposed to "on" and "off" days, with the "on" day dose gradually increased corresponding with a dose-reduction in the "off" day dose over a period of 14 days. After 2 weeks, no medication is taken on "off" days. Not all patients will have equivalent disease control on ADT, and it should be avoided in certain indications.[23,94]

EVALUATION OF THERAPEUTIC OUTCOMES

Successful glucocorticoid therapy involves counseling and monitoring the patient, as well as recognizing complications of therapy (**Table 76-14**). The risk-to-benefit ratio of glucocorticoid administration should always be considered, especially with concurrent disease states such as hypertension, diabetes mellitus, peptic ulcer disease, and uncontrolled systemic infections.

TABLE 76-14 Factors in Successful Glucocorticoid Therapy

Monitoring	Glucose concentrations (serum and urine)
	Electrolytes (serum and urine)
	Ophthalmologic examinations
	Stool tests for occult blood loss
	Growth and development (children and adolescents)
Counseling	Take with food to minimize GI discomfort
	Never discontinue medication on your own; check with your physician; gradual dose reduction is usually necessary
	Carry or wear medical identification indicating that you are on long-term glucocorticoid therapy

	Dosage increases can be necessary at times of increased stress (surgery or emergency treatments)
	Be aware of potential side effects (ie, visual disturbances, bruising, and delayed wound healing)
	What to do if you miss a dose: If your dosing schedule is:
	Every other day: Take as soon as possible if remembered that morning. If not remembered until later, skip that day. Take the next morning, and then skip the following day
	Every day: Take as soon as possible, but skip if almost time for the next dose. Never double doses
Recognizing complications	Early in therapy and essentially unavoidable: insomnia, enhanced appetite, weight gain
	Common in patients with underlying risk factors: hypertension, diabetes mellitus, peptic ulcer disease
	Long-term intense treatment: cushingoid habitus, hypothalamic pituitary–adrenal suppression, impaired wound healing
	Delayed and insidious: cataracts, atherosclerosis
	Rare and unpredictable: psychosis, glaucoma, pancreatitis

Data from references 95 and 96.

Chapter e77: Pituitary Gland Disorders

Joseph K. Jordan; Amy Heck Sheehan; Karim Anton Calis

INTRODUCTION

KEY CONCEPTS

- 1 Pharmacologic therapy for acromegaly should be considered when surgery and irradiation are contraindicated, when there is poor likelihood of surgical success, when rapid control of symptoms is needed, or when other treatments have failed to normalize growth hormone (GH) and insulin-like growth factor-1 (IGF-1) serum concentrations.
- 2 Pharmacotherapy for acromegaly using dopamine agonists provides advantages of oral dosing and reduced cost compared to somatostatin analogs and pegvisomant. However, dopamine agonists effectively normalize IGF-1 serum concentrations in only 10% of patients. Therefore, somatostatin analogs remain the mainstay of therapy.
- 3 Blood glucose concentrations should be monitored frequently in the early stages of somatostatin analog therapy for acromegaly.
- 4 Pegvisomant appears to be the most effective agent for normalizing IGF-1 serum concentrations. However, further study is needed to determine the long-term safety and efficacy of this agent for the treatment of acromegaly.
- 4 Recombinant GH is currently considered the mainstay for treatment of children with growth hormone-deficient short stature. Prompt diagnosis of growth hormone deficiency (GHD) and initiation of replacement therapy with recombinant GH is crucial for optimizing final adult heights.
- 5 All GH products are generally considered to be equally effective. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg/wk.
- 6 Pharmacologic agents that antagonize dopamine or increase the release of prolactin can induce hyperprolactinemia. Discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalizes serum prolactin concentrations.

- 7 Cabergoline appears to be more effective than bromocriptine for the medical management of prolactinomas and offers the advantage of less-frequent dosing and fewer adverse effects.
- 8 Although preliminary data do not suggest cabergoline has significant teratogenic potential, cabergoline is not recommended for use during pregnancy, and patients receiving cabergoline who plan to become pregnant should discontinue the medication as soon as pregnancy is detected.
- 10 Pharmacologic treatment of panhypopituitarism includes the use of glucocorticoids, thyroid hormone, sex steroids, and recombinant GH, where appropriate, as lifelong replacement therapies.

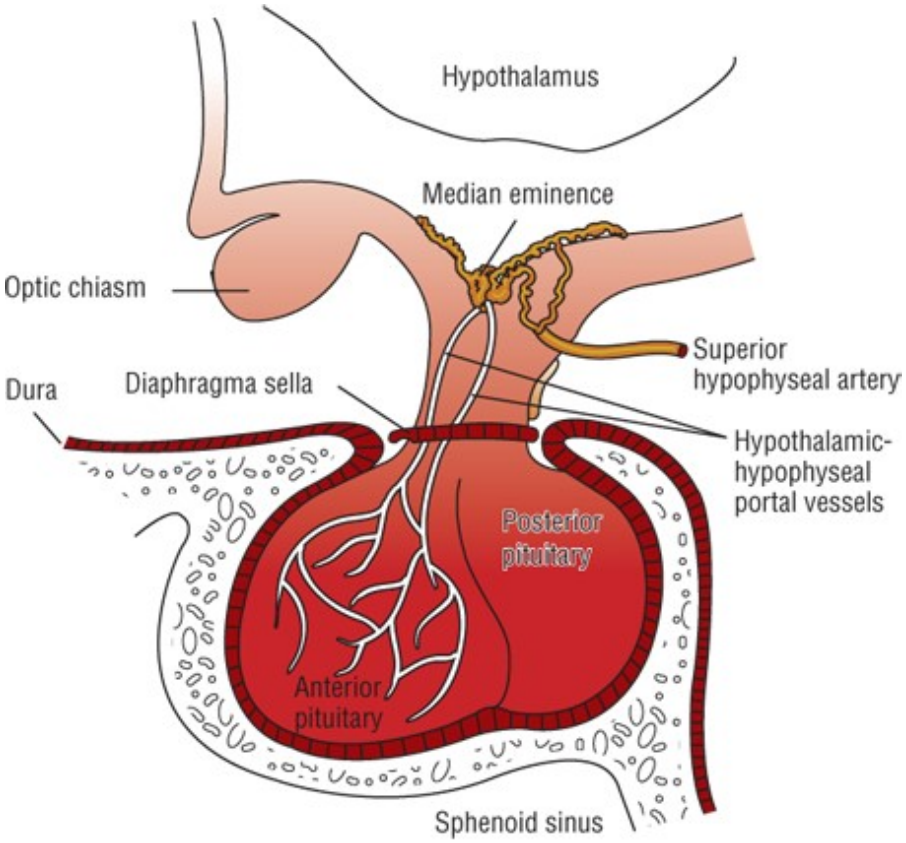
In the 1950s, Geoffrey Harris and his colleagues uncovered the physiologic importance of pituitary hormones and proposed the theory of neurohormonal regulation of the pituitary by the hypothalamus.[1] Today the pituitary gland is recognized for its essential role in body homeostasis, and for this reason it is often referred to as the *master gland*. The hypothalamus and the pituitary gland are closely connected, and together they provide a means of communication between the brain and many of the body's endocrine organs. The hypothalamus uses nervous input and metabolic signals from the body to control the secretion of pituitary hormones that regulate growth, thyroid function, adrenal activity, reproduction, lactation, and fluid balance.

ANATOMY AND PHYSIOLOGY

The hypothalamus (**Fig. e77-1**) is a small region at the base of the brain that receives autonomic nervous input from different areas of the body to regulate limbic functions, food and water intake, body temperature, cardiovascular function, respiratory function, and diurnal rhythms. In addition, the hypothalamus controls the release of hormones from the anterior and posterior regions of the pituitary gland. Neurons in the hypothalamus produce vasopressin and oxytocin and make many hormone-releasing factors that stimulate or inhibit the release of trophic hormones. At the base of the hypothalamus, a projection known as the *median eminence* is rich with nerve axons and blood vessels and provides both chemical and physical connections between the hypothalamus and the pituitary gland.

FIGURE e77-1

Pituitary gland.



The pituitary gland, also referred to as the *hypophysis*, is located at the base of the brain in a cavity of the sphenoid bone known as the *sella turcica*. The pituitary is separated from the brain by an extension of the dura mater known as the *diaphragma sellae*. The pituitary is a very small gland, weighing between 0.4 and 1 g in adults. It is divided into two distinct regions: the anterior lobe, or adenohypophysis; and the posterior lobe, or the neurohypophysis (see Fig. e77-1).

The posterior pituitary gland secretes two major hormones: oxytocin and vasopressin (antidiuretic hormone) (**Table e77-1**). Oxytocin release from the posterior pituitary causes contraction of the smooth muscles in the breast during lactation. It also plays a role in uterine contraction during parturition. Vasopressin is essential for proper fluid balance and acts on the renal collecting ducts to conserve water. Oxytocin and vasopressin are synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. The posterior pituitary gland contains the terminal nerve endings of these two nuclei as well as specialized secretory granules that release hormones in response to appropriate signals. Loss of anterior pituitary function does not necessarily affect the release of vasopressin or oxytocin because these hormones actually are synthesized in the hypothalamus.

TABLE e77-1 Pituitary Hormones

Hormone	Stimulated by	Inhibited by	Physiologic Effects
Anterior Pituitary Hormones			
GH	*Physiologic*	*Physiologic*	

Hormone	Stimulated by	Inhibited by	Physiologic Effects
	GH-releasing hormone		
	Ghrelin		
	ADH	Somatostatin	
	GABA	Elevated IGF-1	
	Norepinephrine	Growth hormone	Stimulates IGF-I production
	Dopamine	Progesterone	IGF-I and GH promote growth in all body tissues
	Serotonin	Glucocorticoids	
	Estrogen	Postprandial hyperglycemia	
	Sleep	Elevated free fatty acids	
	Stress		
	Exercise		
	Pharmacologic	*Pharmacologic*	
	α-Adrenergic agonists (eg, clonidine)	Dopamine antagonists (eg, phenothiazines)	
	β-Adrenergic antagonists (eg, propranolol)	α-Adrenergic antagonists (eg, phentolamine)	
	Dopamine agonists (eg, bromocriptine)	β-Adrenergic agonists (eg, isoproterenol)	
	GABA agonists (eg, muscimol)	Serotonin antagonists (eg, methysergide)	
Prolactin	*Physiologic*	*Physiologic*	
	TRH	Dopamine	Lactation
	VIP	GABA	
	Estrogen		
	Serotonin		
	Histamine		
	Endogenous opioids		
	Pregnancy and nursing		
	Pharmacologic	*Pharmacologic*	
	Dopamine antagonists (eg, phenothiazines, haloperidol, methyldopa)	Dopamine agonists (eg, L-dopa, bromocriptine, pergolide, cabergoline)	

Hormone	Stimulated by	Inhibited by	Physiologic Effects
	Opiates Estrogens H_2-antagonists (eg, cimetidine) MAO inhibitors		
ACTH	CRH	Elevated cortisol	Glucocorticoid effects Pigmentation
TSH	TRH Estrogens Norepinephrine Serotonin	Thyroxine Triiodothyronine Somatostatin Glucocorticoids Dopamine	Iodine uptake and thyroid hormone synthesis
LH	*Physiologic* GnRH *Pharmacologic* Clomiphene	Estradiol Testosterone Fasting	Ovulation Maintains corpus luteum
FSH	*Physiologic* GnRH Menopause Ovarian disorders *Pharmacologic* Clomiphene	Estradiol Inhibin Fasting	Ovarian follicle development Stimulates estradiol and progesterone
Posterior Pituitary Hormones			
Vasopressin (ADH)	Hyperosmolality Volume depletion	Hypervolemia Hypoosmolality	Acts on renal collecting ducts to prevent diuresis
Oxytocin	Parturition Suckling		Uterine contraction Milk ejection

ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, γ-aminobutyric acid; GH, growth hormone; GnRH,

gonadotropin-releasing hormone; IGF-1, insulin-like growth factor-1; LH, Luteinizing hormone; MAO, monoamine oxidase; TSH, thyroid-stimulating hormone; TRH, thyrotropin-releasing hormone; VIP, vasoactive intestinal peptide.

From references 2,3,4.

Unlike the posterior pituitary, the release of anterior pituitary hormones is not regulated by direct nervous stimulation but rather is controlled by specific hypothalamic-releasing and inhibitory hormones. The median eminence of the hypothalamus contains a large number of capillaries that converge to form a network of veins known as the *hypothalamic–hypophyseal portal circulation*. Inhibiting and releasing hormones synthesized in the neurons of the hypothalamus reach the anterior pituitary via the hypothalamic–hypophyseal portal vessels to control release of anterior pituitary hormones. Although there is a direct arterial blood supply to the anterior pituitary lobe, the hypothalamic–hypophyseal portal vessels provide the primary blood supply (see Fig. e77-1). In contrast to the posterior pituitary, the anterior pituitary lobe is extremely vascular and has the highest rate of blood flow of all body organs.

The specialized secretory cells of the anterior pituitary lobe secrete six major polypeptide hormones (see Table e77-1). These include growth hormone (GH) or somatotropin, adrenocorticotropic hormone (ACTH) or corticotropin, thyroid-stimulating hormone (TSH) or thyrotropin, prolactin, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The release of these hormones is regulated primarily by hypothalamic-releasing and inhibiting hormones. Thyrotropin-releasing hormone (TRH) stimulates anterior pituitary release of TSH and prolactin, corticotropin-releasing hormone (CRH) stimulates anterior pituitary release of ACTH, growth hormone-releasing hormone (GHRH) stimulates anterior pituitary release of GH, and gonadotropin-releasing hormone (GnRH) stimulates anterior pituitary release of LH and FSH. Hypothalamic release of somatostatin inhibits release of GH, and hypothalamic release of dopamine (prolactin inhibitory hormone) inhibits the secretion of prolactin. Prolactin differs from the other anterior lobe hormones in that an inhibiting factor, rather than a stimulating factor, is primarily responsible for controlling its secretion. In the absence of hypothalamic input, an excess of prolactin is produced, whereas a deficiency state of other anterior pituitary hormones results. Physiologic regulation and action of anterior and posterior pituitary hormones are summarized in Table e77-1.[2,3,4]

Destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, GH deficiency, and hypoprolactinemia. The formation of certain types of pituitary tumors may result in pituitary hormone excess. Pituitary tumors may physically compress the pituitary and prevent the release of trophic hypothalamic factors that regulate pituitary hormones. In this chapter, the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, short stature, hyperprolactinemia, and panhypopituitarism are discussed.

GROWTH HORMONE

GH has direct anti-insulin effects on lipid and carbohydrate metabolism. GH decreases utilization of glucose by peripheral tissues, increases lipolysis, and increases muscle mass. GH also stimulates gluconeogenesis in hepatocytes, impairs tissue glucose uptake, decreases insulin-receptor sensitivity,

and impairs postreceptor insulin action. The growth-promoting effects of GH are largely mediated by insulin-like growth factors (IGFs) also known as *somatomedins*. GH stimulates the formation of IGF-1 in the liver as well as in other peripheral tissues. This anabolic peptide acts as a direct stimulator of cell proliferation and growth. There are two types of IGFs: IGF-1 and IGF-2. IGF-1 regulates growth to some extent before, and largely after, birth. In contrast, IGF-2 is thought to primarily regulate growth in utero.[5] GH is secreted by the anterior pituitary in a pulsatile fashion, with several short bursts that occur mostly at night. Because of the short half-life of GH in the plasma (~30 minutes), measurements of circulating GH concentrations throughout the waking hours usually are very low or undetectable. Daytime GH pulses are most likely to occur after meals, following exercise, or during periods of stress. The greatest amount of GH secretion occurs during the night within the first 1 to 2 hours of slow-wave sleep (stage III or IV). Secretion of GH is lowest during infancy, increases slightly during childhood, reaches its peak during adolescence, and then begins to gradually decline during the middle-age years.[3]

Growth Hormone Excess

Acromegaly is a pathologic condition characterized by excessive production of GH. This is a rare disorder that affects approximately 50 to 70 adults per million.[6] Gigantism, which is even more rare than acromegaly, is the excess secretion of GH prior to epiphyseal closure in children.[7] Patients diagnosed with acromegaly are reported to have a two- to threefold increase in mortality, usually related to cardiovascular, respiratory, or neoplastic disease.[7,8,9,10] Most patients are middle-aged at the time of diagnosis, and this disorder does not appear to affect one sex to a greater extent than the other. The most common cause of excess GH secretion in acromegaly is a GH-secreting pituitary adenoma, accounting for over 95% of all cases.[7] Rarely, acromegaly is caused by ectopic GH-secreting adenomas, GH cell hyperplasia, excess GHRH secretion, or is a manifestation of multiple endocrine neoplasia syndrome type 1, McCune–Albright syndrome, or the Carney complex, all very rare hypersecretory endocrinopathies.[7,8,9]

The clinical signs and symptoms of acromegaly develop gradually over an extended period of time. In fact, because of the subtle and slowly developing changes in physical appearance caused by GH excess, most patients are not definitively diagnosed with acromegaly until 7 to 10 years after the presumed onset of excessive GH secretion.[9] Excessive secretion of GH and IGF-1 adversely affects several organ systems. Almost all acromegalic patients will present with physical signs and symptoms of soft-tissue overgrowth. **Table e77-2** summarizes the classic clinical presentation of patients with acromegaly.[7,8,9] Some patients with acromegaly present with only a few of these classic signs and symptoms, making recognition of this disease extremely difficult.

TABLE e77-2 Clinical Presentation of Acromegaly

General
The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over 7 to 10 years
Symptoms

The patient may complain of symptoms related to local effects of the GH-secreting tumor, such as headache and visual disturbances. Other symptoms related to elevated GH and IGF-1 concentrations include excessive sweating, neuropathies, joint pain, and paresthesias

Signs

The patient may exhibit coarsening of facial features, increased hand volume, increased ring size, increased shoe size, an enlarged tongue, and various dermatologic conditions

Laboratory tests

The patient's GH concentration will be >1 µg/L (>45 pmol/L) following an OGTT and IGF-1 serum concentrations will be elevated. Glucose intolerance may be present in up to 50% of patients

Additional clinical sequelae

- Cardiovascular diseases such as hypertension, coronary heart disease, cardiomyopathy, and left ventricular hypertrophy are common in patients with acromegaly
- Osteoarthritis and joint damage develop in up to 90% of acromegalic patients
- Respiratory disorders and sleep apnea occur in up to 60% of acromegalic patients
- Type 2 diabetes develops in approximately 25% of acromegalic patients
- Patients with acromegaly may have an increased risk for development of esophageal, colon, and stomach cancer

GH, growth hormone; IGF-1, insulin-like growth factor-1; OGTT, oral glucose tolerance test.

From references 7,8,9.

The diagnosis of acromegaly is based on a combination of diagnostic tests and clinical signs and symptoms. Random measures of plasma GH levels are not usually dependable because of the pulsatile pattern of release. However, some clinicians exclude diagnosis of acromegaly in the presence of a random GH below 0.4 µg/L (less than 18 pmol/L) and IGF-1 that is normal for age and sex.[7,8,9] The oral glucose tolerance test (OGTT) is commonly used as an important diagnostic tool. Postprandial hyperglycemia inhibits the secretion of GH for at least 1 to 2 hours. Therefore, an oral glucose load would be expected to suppress GH concentrations. However, patients with acromegaly continue to secrete GH during the OGTT. Because GH stimulates the production of IGF-1, serum IGF-1 concentrations can also be measured to aid in the diagnosis of acromegaly. Circulating IGF-1 is cleared from the body at a much slower rate than is GH, and measurements can be collected at any time of the day to identify patients with GH excess.[7,8,9] Current criteria for the diagnosis of acromegaly include failure of GH suppression less than 1 µg/L (less than 45 pmol/L) following an OGTT in the presence of elevated IGF-1 serum concentrations (strong recommendation, moderate quality of evidence).[7,8,11] With the development of more sensitive GH and IGF-1 assays, the American

Association of Clinical Endocrinologists (AACE) suggests lowering the cutoff for GH suppression to less than 0.4 µg/L (less than 18 pmol/L) although other groups still support a cutoff of less than 1 µg/L based on concerns of requisite sensitivity of many assays.[7,8,11] Insulin-like growth factor 1 binding protein 3 (IGFBP-3) also can be measured because it is positively regulated by GH and binds to circulating IGF-1 with high affinity. This test may prove useful in the future in monitoring response to therapy but, at present, AACE does not recommend IGFBP-3 measurement for the purpose of clinical management.[8] Computed tomography and magnetic resonance imaging (MRI) of the pituitary are important diagnostic tests to confirm the presence of a pituitary adenoma.[7,8,11]

TREATMENT

The primary treatment goals for patients diagnosed with acromegaly are to reduce GH and IGF-1 concentrations, improve the clinical signs and symptoms of the disease, and decrease mortality.[7,8,11,12,13,14] Many clinicians define biochemical control of acromegaly as suppression of GH concentrations to less than 1 µg/L (less than 45 pmol/L) after a standard OGTT in the presence of normal IGF-1 serum concentrations, although some argue for a lower cutoff GH value of 0.4 µg/L (18 pmol/L) due to the availability of more sensitive test methods.[13] The treatment of choice for most patients with acromegaly is transsphenoidal surgical resection of the GH-secreting adenoma (strong recommendation, moderate quality evidence).[7,8,11,12,13] Postsurgical cure rates have been reported to range from 50% to 90%, depending on the type of adenoma and the expertise of the neurosurgeon.[7,8,13,14] Complications of transsphenoidal surgery are relatively infrequent and include cerebrospinal fluid leak, meningitis, arachnoiditis, diabetes insipidus, and pituitary failure.[8] For patients who are poor surgical candidates, those who have not responded to surgical or medical interventions, or others who refuse surgical or medical treatment, radiation therapy may be considered. Radiation, however, may require several years to relieve the symptoms of acromegaly.

Because neither radiation therapy nor surgery will cure all patients with acromegaly, adjuvant drug therapy is often needed to control symptoms.[7,8,11,12]

Pharmacologic Therapy

1 Drug therapy should be considered primary therapy for acromegalic patients who prefer medical therapy, are poor surgical candidates, or when there is a poor likelihood of surgical success. Drug therapy should be considered adjunctive therapy in the presence of persistent disease after surgery (strong recommendation, high quality evidence).[7,8] Pharmacologic treatment options include dopamine agonists, somatostatin analogs, and the GH-receptor antagonist pegvisomant. Dopamine agonists such as bromocriptine and cabergoline are effective in a small subset of patients and provide the advantages of oral dosing and reduced cost. Somatostatin analogs are more effective than dopamine agonists, reducing GH concentrations and normalizing IGF-1 in approximately 50% to 60% of patients. Pegvisomant, a GH-receptor antagonist, is highly effective in normalizing IGF-1 concentrations in up to 97% of patients in the first year and in 60% over 5 years.

Dopamine Agonists

2 In normal healthy adults, dopamine agonists cause an increase in GH production. However, when these agents are given to patients with acromegaly, there is a paradoxical decrease in GH production. Most clinical experience with the use of dopamine agonists in acromegaly is with bromocriptine or cabergoline. Other agents such as pergolide, quinagolide, and lisuride also have been used but are not available in the United States. Bromocriptine and cabergoline are semisynthetic ergot alkaloids that act as dopamine-receptor agonists. Most trials assessing the efficacy of bromocriptine in the treatment of acromegaly were conducted in the 1970s and early 1980s and determined that bromocriptine was effective in suppressing mean serum GH levels to less than 5 µg/L (less than 225 pmol/L) in approximately 20% of patients.[15] While only 10% of patients experience normalization of IGF-1 concentrations with bromocriptine therapy, more than 50% of patients treated with bromocriptine experience improvement in symptoms of acromegaly.[8,15] According to AACE guidelines, cabergoline appears to be used more commonly than bromocriptine.[8] A meta-analysis of 15 studies concluded that cabergoline as monotherapy was effective in normalizing IGF-1 levels in 34% of patients and resulted in normalization of IGF-1 levels in 52% of patients when added to a somatostatin analog in those unresponsive to somatostatin analog monotherapy.[16]

In the United States, bromocriptine is commercially available as 0.8 and 2.5-mg oral tablets and 5-mg oral capsules. The 0.8-mg tablet is only indicated for adjunctive therapy in type 2 diabetes mellitus. In acromegalic patients, significant reductions in GH concentrations are observed within 1 to 2 hours of oral dosing. This effect persists for at least 4 to 5 hours. An overall clinical response in acromegalic patients typically occurs after 4 to 8 weeks of continuous bromocriptine therapy. For treatment of acromegaly, bromocriptine is initiated at a dose of 1.25 mg (1/2 of a 2.5-mg tablet) at bedtime and is increased by 1.25-mg increments every 3 to 4 days as needed. Doses as high as 86 mg/day have been used for treatment of acromegaly, but clinical studies have shown that dosages more than 20 to 30 mg daily do not offer additional benefits in the suppression of GH. When used for treatment of acromegaly, the duration of action of bromocriptine is shorter than that for treatment of hyperprolactinemia. Therefore, the total daily dose of bromocriptine should be divided into three or four doses.

Cabergoline is commercially available as 0.5 mg tablets. Use in acromegaly is considered off-label, and dosing is typically initiated at 0.5 mg twice weekly and increased as needed to 0.5 mg every other day. Doses up to 7 mg/wk (0.5 mg twice daily) have been reported in trials.

The most common adverse effects of dopamine agonist therapy include central nervous system (CNS) symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal (GI) effects such as nausea, abdominal pain, or diarrhea also are very common. Some patients may need to take dopamine agonists with food to decrease the incidence of adverse GI effects. Most adverse effects are seen early in the course of therapy and tend to decrease with continued treatment.[8,15] Dopamine agonists may cause thickening of bronchial secretions and nasal congestion. Rare cases of psychiatric disturbances, pleural diseases, and an erythromelalgic syndrome (painful paroxysmal dilation of the blood vessels in the skin of the feet and lower extremities) have been reported with dopamine agonist use. These conditions appear to be associated with higher doses and prolonged duration of therapy.[8,15]

Dopamine agonists are not FDA-approved for use during pregnancy. However, surveillance of women who took dopamine agonists throughout pregnancy does not suggest that dopamine agonists are associated with an increased risk for birth defects.[17] If a woman becomes pregnant while taking dopamine agonists, the risks and benefits of therapy should be fully considered. In most cases, the benefits of successful therapy outweigh the risks, and dopamine agonist therapy should be continued if it is effective in improving symptoms and reducing elevated GH concentrations.

Other dopamine agonists that have been used to treat acromegaly include pergolide, lisuride, and quinagolide. Pergolide is no longer commercially available, and lisuride and quinagolide are not commercially available in the United States. Because of the potential cost advantages and convenience of oral administration, dopamine agonists are often considered for treatment of acromegaly prior to initiation of somatostatin analogs. The Endocrine Society guidelines suggest a trial of a dopamine agonist in acromegalic patients with mild signs and symptoms and modest elevations in serum IGF-1.[7] (weak recommendation, low quality evidence) However, the availability of long-acting somatostatin analogs has made these agents more attractive for first-line treatment of acromegaly.

Somatostatin Analogs

Octreotide, lanreotide, and pasireotide are long-acting somatostatin analogs that are more potent in inhibiting GH secretion than endogenous somatostatin.[18] The Endocrine Society suggests somatostatin analogs as initial adjuvant medical therapy in patients with significant disease (weak recommendation, low quality evidence) and as primary therapy in patients who cannot be cured by surgery or are poor surgical candidates.[7] (weak recommendation, moderate quality evidence). These agents also suppress the LH response to GnRH; decrease splanchnic blood flow; and inhibit secretion of insulin, vasoactive intestinal peptide (VIP), gastrin, secretin, motilin, serotonin, and pancreatic polypeptide. Pasireotide is a somatostatin analog that has a broader affinity for somatostatin receptor subtypes than octreotide or lanreotide. The binding to additional subtypes of somatostatin receptors may result in greater GH inhibition compared to octreotide or lanreotide and efficacy of pasireotide in the presence of octreotide or lanreotide-resistant adenomas.[18]

Octreotide (Sandostatin) injection is commercially available in the United States for subcutaneous or IV administration. A long-acting intramuscular formulation of octreotide (Sandostatin LAR) is available for monthly administration. An investigational oral formulation of octreotide administered as monotherapy was effective in maintaining control of IGF-1 and GH serum concentrations in patients previously well controlled with an injectable formulation.[19] In addition to the treatment of acromegaly, octreotide has many other therapeutic uses, including the treatment of carcinoid tumors, vasoactive intestinal peptide-secreting tumors (VIPomas), GI fistulas, variceal bleeding, diarrheal states, and irritable bowel syndrome.

The efficacy of octreotide for treatment of acromegaly was initially determined by two major multicenter trials.[20,21] These studies demonstrated that drug therapy with octreotide suppresses mean serum GH concentrations to less than 5 µg/L (less than 225 pmol/L) and normalizes serum IGF-1 concentrations in 50% to 60% of acromegalic patients and reduces the clinical signs and

symptoms of acromegaly. In a 6-month multicenter trial, 70% of patients experienced significant relief of headaches.[21] In some patients, relief of headache symptoms occurred within minutes of octreotide administration. In addition, middle-finger circumference was reduced significantly, and 50% to 75% of patients experienced improvement in symptoms of excessive perspiration, fatigue, joint pain, and cystic acne. Long-term follow-up of patients treated with octreotide LAR for up to 9 years showed octreotide therapy to be safe and effective for long-term use in acromegalic patients.[22] Octreotide also has been shown to improve the cardiovascular manifestations of acromegaly and to halt pituitary tumor growth, with some patients experiencing tumor regression.[23] Data from more recent studies indicate that shrinkage of pituitary tumor mass during octreotide therapy occurs in approximately 50% of patients.[24]

The pharmacodynamic effects of long-acting octreotide are similar to those of subcutaneously administered octreotide. Single monthly doses of long-acting octreotide have been shown to be at least as effective as daily doses of subcutaneous octreotide administered in divided doses three times daily in normalizing IGF-1 levels and maintaining suppression of mean serum GH concentrations.[25] Trials evaluating the efficacy of long-acting octreotide in acromegalic patients who previously had responded to subcutaneously administered octreotide have reported sustained suppression of GH concentrations to less than 5 µg/L (less than 225 pmol/L) and normalization of IGF-1 in patients following 1 year of therapy.[25]

Response to long-term therapy with octreotide is related to the presence and increased quantity of functioning somatostatin receptors located in the pituitary adenoma. Identification of patients who most likely will respond to octreotide, prior to initiation of therapy, is important when considering the high cost of this medication and the inconvenience of subcutaneous or intramuscular drug administration. Suppression of serum GH concentrations after a single 50-µg dose of octreotide has been used to predict a favorable long-term response to octreotide therapy but reliability of this test is not universally accepted.[7,26]

The initial dose of octreotide for treatment of acromegaly is usually 100 µg administered three times daily followed by either titration to a maximum of 1,500 µg/day or transition to long-acting octreotide.[8] Some clinicians recommend a starting dose of 50 µg every 8 hours, then increasing the dose to 100 µg every 8 hours after 1 week, to improve the patient's tolerance of adverse GI effects. The dose can be increased by increments of 50 µg every 1 to 2 weeks based on mean serum GH and IGF-1 concentrations. Patients who experience a significant rise in GH prior to the end of the 8-hour dosing interval may benefit from decreasing the dosing interval to every 4 to 6 hours. Although doses as high as 1,500 µg/day have been used, doses greater than 600 µg daily generally do not offer additional benefits, and most patients are adequately managed with 100 to 200 µg three times daily.[8] Patients who have been maintained on subcutaneous octreotide for at least 2 weeks and have shown response to therapy can be converted to the long-acting depot form of octreotide. The initial dose of long-acting octreotide is 20 mg administered intramuscularly in the gluteal region every 28 days. Steady-state serum concentrations are not obtained until after 3 months of therapy. Therefore, dosage adjustments for long-acting octreotide should not be considered until after this time. Some patients may require additional subcutaneous injections during the initial dose-titration phase in order to control symptoms. In patients who achieve more than 50% reduction in GH levels to 30 mg

every 4 weeks, some may have added response to a higher-dose regimen of 60 mg every 4 weeks.[27]

Lanreotide (Somatuline Depot) is commercially available in the United States for monthly, deep subcutaneous administration. In addition to acromegaly, lanreotide is also indicated for the treatment of gastroenteropancreatic neuroendocrine tumors (GEP-NETs). The efficacy of this preparation of lanreotide for the treatment of acromegaly has been evaluated in several prospective multicenter clinical trials involving treatment-naïve and treatment-experienced patients who were switched from intramuscular octreotide LAR or intramuscular lanreotide LA to monthly deep subcutaneous lanreotide.[28] These studies have determined that deep subcutaneous lanreotide suppresses mean serum GH concentrations to less than 5 µg/L (less than 225 pmol/L) and normalizes serum IGF-1 concentrations in acromegalic patients to a similar extent as octreotide LAR and lanreotide LA. A 4-year follow-up of 23 patients treated with monthly deep subcutaneous lanreotide reported the drug to be well tolerated during long-term therapy with mean serum GH concentrations less than 5 µg/L (less than 225 pmol/L) in 62% of patients and normalization of serum IGF-1 concentrations in 43% of patients.[29] Analyses of trials investigating the effects of lanreotide on pituitary tumor mass have shown shrinkage in the majority of patients, and the response appears to be more prevalent in treatment-naïve patients and in patients with macroadenomas.[28,30] Well-designed trials directly comparing the efficacy of intramuscular octreotide LAR to deep subcutaneous lanreotide are currently lacking. However, these two agents are generally regarded to have comparable efficacy.[7,8] Lanreotide (Somatuline Depot) is commercially available in the United States as 60-, 90-, and 120-mg prefilled syringes. In contrast to octreotide LAR and pasireotide, lanreotide injection does not need to be reconstituted prior to administration. The initial recommended dose of lanreotide is 90 mg given by deep subcutaneous injection in the superior external quadrant of the buttock every 28 days. Injection sites should be alternated between the left and right side. The initial dose should be reduced to 60 mg every 28 days for patients with moderate or severe renal or hepatic impairment. After 3 months of therapy, the dose may then be titrated based on serum GH concentrations, serum IGF-1 concentrations, and control of clinical signs and symptoms of acromegaly.[28] Long-acting deep subcutaneous lanreotide injection in doses more than 120 mg every 28 days has not been studied. Extended dosing intervals of up to every 8 weeks are currently under investigation.[31]

Pasireotide (Signifor LAR) for the treatment of acromegaly is commercially available in the United States in the form of a monthly intramuscular injection. Another formulation of pasireotide (Signifor) is approved for treatment of Cushing disease as a twice daily subcutaneous injection. The efficacy of the long-acting pasireotide formulation has been evaluated in both drug-naïve patients and those inadequately controlled on long-acting octreotide or lanreotide.[32,33,34,35] In drug-naïve acromegalic patients, drug therapy over 12 months with pasireotide suppressed mean serum GH concentrations to less than 2.5 µg/L and normalized serum IGF-1 concentrations in 38% compared to 23% with octreotide.[33] An extension study of up to 25 months noted long-term biochemical control (GH less than 2.5 µg/L and normal IGF-1) in 48% with pasireotide compared with 45% with octreotide.[34] In patients inadequately controlled with octreotide or lanreotide, drug therapy with pasireotide over a 24-week period resulted in biochemical control (GH less than 2.5 µg/L and normal IGF-1) in 15% to 20% of patients.[35]

The initial recommended dose of pasireotide is 40 mg given by intramuscular injection every 28 days. The initial dose should be reduced to 20 mg every 28 days for patients with moderate or severe hepatic impairment. After 3 months of therapy, the dose may be titrated based on serum GH concentrations, serum IGF-1 concentrations, and control of clinical signs and symptoms of acromegaly. Doses of pasireotide exceeding 60 mg every 28 days are not recommended.[32] The most common adverse effects of somatostatin analog therapy are GI disturbances such as diarrhea, nausea, abdominal cramps, malabsorption of fat, and flatulence.[25,28,32] GI adverse effects occur in approximately 75% of patients but usually subside within 10 to 14 days of continued treatment. Octreotide has been reported to cause injection-site pain (4%-31%), conduction abnormalities and arrhythmias (9%), subclinical hypothyroidism (2%-12%), biliary tract disorders (4%-50%), and abnormalities in glucose metabolism (2%-18%). Lanreotide has been reported to cause injection-site reactions (9%), sinus bradycardia (3%), hypertension (5%), biliary tract disorders (20%), and abnormalities in glucose metabolism (7%). The incidence of adverse effects with pasireotide is similar to octreotide and lanreotide with the exception of a higher incidence of hyperglycemia (61%-67% vs 25%-30%) often requiring treatment with antidiabetes medications (38%-39% vs 6%).

Somatostatin analogs also inhibit cholecystokinin release and gallbladder motility, predisposing patients to the development of cholelithiasis.[36] The development of gallstones is a long-term adverse effect of somatostatin analog therapy and is largely dependent on geographic factors, dietary habits, and length of therapy. The incidence of gallstones in acromegalic patients receiving octreotide and lanreotide increases with length of therapy and has been reported to range from 20% to 50%.[25,28,32] However, most patients are asymptomatic, and the diagnosis of cholelithiasis usually is made following an ultrasonographic study that is not prompted by patient symptoms. It has been estimated that only 1% of patients will develop symptomatic gallstones during 1 year of octreotide treatment.[36] Because somatostatin analog-induced gallstones usually are present without clinical symptoms, prophylactic cholecystectomy or medical therapy with ursodeoxycholic acid for acromegalic patients with asymptomatic gallstones usually is not recommended. A small number of studies have suggested that the incidence of gallstone development may be lower with long-acting octreotide compared to subcutaneous octreotide.[25] However, further studies are needed to confirm this observation.

3 The effect of somatostatin analogs on glucose metabolism in patients with acromegaly is multifactorial. Decreases in serum GH concentrations induced by somatostatin analogs should result in decreased hepatic gluconeogenesis and increased insulin-receptor sensitivity. However, somatostatin analogs also decrease insulin secretion and increase IGFBP-1, which is known to inhibit the insulin-like effects of IGF-1. In addition, somatostatin analogs delay the GI absorption of glucose, which may further alter glucose metabolism in acromegalic patients.[38] Small studies conducted in acromegalic patients receiving octreotide have reported improvement in insulin sensitivity as well as impaired insulin secretion.[39] Risk factors associated with worsening glucose tolerance included female sex and elevated baseline insulin values. Although somatostatin analogs appear to have a beneficial effect on glucose tolerance in most patients, glucose determinations should be obtained frequently in the early stages of therapy in all acromegalic patients.

Growth Hormone Receptor Antagonist

4 Pegvisomant (Somavert) is a genetically engineered GH derivative that binds to, but does not activate, GH receptors and inhibits IGF-1 production. This agent is different from other medications used in the management of acromegaly because it does not inhibit GH production; rather, it blocks the physiologic effects of GH on target tissues. Therefore, GH concentrations remain elevated during therapy, and response to treatment is evidenced by a reduction in IGF-1 concentrations. Unlike somatostatin analogs, the pharmacologic activity of pegvisomant does not depend on the presence and quantity of somatostatin receptors in the pituitary tumor.[40] Studies evaluating the clinical efficacy of pegvisomant in acromegalic patients have reported a dose-dependent normalization of IGF-1 concentrations in 54% to 89% of patients after 12 weeks of therapy and in 97% of patients after 1 year of therapy.[40,41] Significant improvements in the clinical signs and symptoms of acromegaly were reported and persisted throughout the 1-year treatment period.[41] An ongoing, international postmarketing surveillance registry (ACROSTUDY) reported normalization of IGF-1 serum concentrations in 63% of patients treated with pegvisomant over 5 years of therapy. Investigators note that failure to maintain IGF-1 normalization may reflect suboptimal dosing strategies or more advanced disease than reported in the original studies.[42]

Adverse effects include injection-site pain, GI complaints such as nausea and diarrhea, and flu-like symptoms. Significant elevations in hepatic aminotransferase concentrations, which are generally reversible upon discontinuation of the drug, have been reported.[43] As a result, hepatic function tests should be monitored very closely during therapy as outlined in the product labeling, and the drug should be used with caution in patients with baseline elevations in hepatic aminotransferase concentrations. GH concentrations may increase significantly during the first 6 months of therapy. Tumor growth has been reported in a small number of patients and there are theoretical concerns that the lack of GH feedback regulation on tumors that lead to persistently elevated GH concentrations may stimulate tumor growth or result in other long-term adverse effects. Results of the ongoing ACROSTUDY suggest that the rate of tumor growth of 3.2% is comparable to the background rate in acromegaly, and the incidence of hepatic aminotransferases greater than three times upper limit of normal is low (2.5%).[42]

Pegvisomant is commercially available in the United States for daily subcutaneous use. The first dose should be administered under the supervision of a physician as a 40-mg loading dose. Subsequent doses are self-administered by the patient starting at a dose of 10 mg daily. The dose can be adjusted in 5-mg increments based on serum IGF-1 concentrations every 4 to 6 weeks.[43]

Based on the available data, pegvisomant appears to be among the most effective agents for normalizing IGF-1 serum concentrations. Current guidelines for acromegaly management suggest pegvisomant therapy for patients who have failed to achieve normalization of IGF-1 serum concentrations with other treatments or as the initial adjuvant medical therapy.[7,8,11]

Combination Therapy

Several small studies have suggested that combination therapy with somatostatin analogs, dopamine agonists, or pegvisomant may be more beneficial than monotherapy with either drug alone.[7,8] Several of these trials have used doses lower than those typically used for monotherapy in order to try to minimize the risk of additive adverse effects. The Endocrine Society recommends the addition of pegvisomant or cabergoline in patients with inadequate response to a somatostatin analog.[7] (weak recommendation, low quality of evidence) Because of the potential for additive adverse effects, combination therapy should be considered as a therapeutic option only for refractory patients who have not fully responded to monotherapy.[7,8]

Personalized Pharmacotherapy

While several biomarkers have been studied in pituitary tumors, the prognostic value of these in predicting response to therapy is still unclear.[44] The genetics of GH and its receptors have been well-studied.[45] At this time, the data are most abundant with pegvisomant. As pegvisomant acts at the GH receptor, researchers have investigated response to GH receptor variants. In patients with exon 3-deleted GH receptors, lower doses and fewer months were needed to obtain IGF-1 normalization.[46] However, recommendations regarding how therapy can be individualized to maximize patient benefit are not yet available.[7,8,46]

Clinical Controversy…

Some clinicians advocate the use of somatostatin analogs prior to surgery in order to improve comorbidities that may complicate surgery. However, sufficient evidence is lacking.[47]

Conclusions

Acromegaly is a chronic debilitating disease characterized by excess GH secretion most commonly caused by a GH-secreting pituitary adenoma. Transsphenoidal surgical resection of the adenoma is the current treatment of choice for most patients with acromegaly. Patients who are poor surgical candidates may receive radiation therapy or long-term pharmacologic therapy. Drug therapy options within the United States for acromegaly include dopamine agonists, somatostatin analogs, and pegvisomant. **Figure e77-2** shows a treatment algorithm for the management of acromegaly.[7,8]

Growth Hormone Deficiency

Short stature is a condition that is commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group.[48] It has been estimated that more than 1.8 million children in the United States can be characterized as having short stature.[48] Short stature is a very broad term describing a condition that may be the result of many different causes. A true lack of GH is among the least common causes and is known as GHD short stature. Absolute GH deficiency is a congenital disorder that can result from various genetic abnormalities, such as GHRH deficiency, GH gene deletion, and developmental disorders including pituitary aplasia or hypoplasia.[48] GH insufficiency is an acquired condition that can result from hypothalamic or pituitary tumors (or their neurosurgical treatment), cranial irradiation, head trauma, pituitary infarction, and various types of CNS infections. In addition, psychosocial deprivation, hypothyroidism, poorly controlled diabetes mellitus, treatment of precocious puberty with LH-releasing hormone agonists, and pharmacologic agents such as glucocorticoids, methylphenidate, and dextroamphetamine may induce transient GH insufficiency.[48]

Short stature also occurs with several conditions that are not associated with a true GH deficiency or insufficiency. These conditions include intrauterine growth restriction; constitutional growth delay; malnutrition; malabsorption of nutrients associated with inflammatory bowel disease, celiac disease, and cystic fibrosis; chronic renal failure; skeletal and cartilage dysplasia; and genetic syndromes such as Turner syndrome.[48,49] In addition, many children are diagnosed with idiopathic or normal variant

short stature. These patients have heights that are significantly lower than the third percentile but present with normal GH serum concentrations and no specific underlying explanation for short stature.[49]

Children with congenital GHD usually are born with an average birth weight. Decreases in growth velocity generally become evident between the ages of 6 months and 3 years.[48] In contrast, GH insufficiency may arise at any age during growth and development. The clinical characteristics of GHD or GH-insufficient children are listed in **Table e77-3**.[48]

TABLE e77-3 Clinical Presentation of Short Stature

General

- The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and sex.

Signs

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature may also present with central obesity, prominence of the forehead, and immaturity of the face.

Laboratory tests

- The patient will exhibit a peak GH concentration <10 µg/L (<450 pmol/L) following a GH provocation test. Reduced IGF-1 and concentrations may be present.
- Because GH deficiency may be accompanied by loss of other pituitary hormones, hypoglycemia, and hypothyroidism may be noted.

GH, growth hormone.

From references 48 and 49.

Several factors must be considered in the diagnosis of GH deficiency or insufficiency. Standard epidemiologic growth charts developed by the National Center for Health Statistics typically are used to determine the percentile of anthropometric measurements, such as height, weight, and head circumference. Pubertal stage typically is determined using the Tanner method. Bone age is determined according to published standards, and growth velocity is calculated to determine the patient's height velocity percentile using standard growth-velocity charts.[48,49] GH deficiency is rarely seen in the absence of delayed skeletal maturation and decreased growth velocity. In addition, several different provocative stimuli that induce GH secretion may be used diagnostically to determine GH status. Common provocative pharmacologic GH stimuli include insulin-induced hypoglycemia, clonidine, L-dopa, arginine, glucagon, and GHRH.[48] Traditionally, a subnormal GH response during childhood is arbitrarily defined as a peak GH serum concentration less than 10 µg/L

(less than 450 pmol/L) during a 2-hour period after administration of one of these agents.[48] However, a lower cutoff may be used for the peak GH response, depending on the specific assay and GH reference product used. For prepubertal and early pubertal patients (Tanner stage less than III), priming with sex hormones to improve the specificity of GH provocation tests is often considered. Some patients exhibit clinical signs of GH deficiency, subnormal growth velocity, and delayed bone age despite GH levels that are within normal limits after provocative testing. This makes diagnosis in this group of patients very difficult. Diagnosis based on GH stimulation tests becomes further complicated because of the paucity of data reporting the normal range of GH concentrations after provocative testing in healthy children and the fact that commercial GH and IGF-1 assays currently available may not be equivalent. Although a gold standard for diagnosis of GHD does not exist, treatment is generally recommended for children who have "idiopathic short stature" and pass GH provocative testing but have most of the following criteria: height greater than 2.25 standard deviations below the mean for age; subnormal growth velocity; delayed bone age; low serum IGF-1 and/or IGFBP-3; and other clinical features consistent with GH deficiency.[50] Ultimately, careful consideration of multiple factors by a pediatric endocrinology specialist is required to correctly diagnose GH deficiency. Of note, more than half of children diagnosed with GH deficiency are found to secrete normal quantities of GH and IGF-1 in adulthood.[51]

TREATMENT

Pharmacologic Therapy

The treatment of GH deficiency with pituitary-derived human GH was first reported in the late 1950s. The National Hormone and Pituitary Program was founded by the National Institutes of Health in 1963 to coordinate the collection of human pituitary glands and purification of GH for administration to children with GH deficiency. In 1985, three deaths linked to Creutzfeldt–Jakob disease (CJD) were identified in young individuals who were previously treated with human pituitary GH. An evaluation of National Hormone and Pituitary Program data identified 26 cases of fatal CJD in a cohort of 6,107 patients who received treatment with human pituitary-derived GH in the United States between 1963 and 1985.[52] Cadaveric pituitary GH was withdrawn from the US market because of the strong likelihood that CJD was transmitted through contaminated human pituitary-derived hormone. Shortly after the withdrawal of human pituitary GH, the FDA approved the first recombinant DNA-derived GH for treatment of GH insufficiency. Prior to the introduction of recombinant GH, the number of individuals who received treatment for GH insufficiency was relatively small because of the limited availability of human pituitary tissue for GH extraction. Currently, with the widespread availability of recombinant GH products, a large number of children can receive GH replacement therapy at higher doses.

Clinical Controversy…

Many pediatric endocrinologists in the United States believe that GH therapy is appropriate treatment in certain patients with non-GHD short stature. However, given the high cost of therapy and small increases in height, use of GH in this patient population remains controversial.

Recombinant Growth Hormone

5 Recombinant GH is currently considered the mainstay of therapy for treatment of GHD short stature. GH replacement therapy in children with documented GHD short stature produces a significant improvement in growth velocity within the first year of therapy and significantly improves final adult height.[53,54] The initial increase in growth velocity often is referred to as *catch-up growth*. Most of the initial studies evaluating the efficacy of GH therapy in GHD children were conducted for short periods of time in small numbers of patients and information about the long-term outcome of GH therapy was limited. Initial data suggested that final adult height is not substantially improved, with an average final adult height reported to be two standard deviations below the population mean.[55,56] Although these results were disappointing, it is important to note that a substantial percentage of patients included in these studies initially had received human pituitary GH in relatively low doses because of its limited availability. In addition, current GH dosing regimens with regard to frequency of administration have changed, making these data difficult to interpret and apply to the patients who are receiving GH replacement therapy today. Recent studies evaluating the adult height of children who received only recombinant GH therapy with currently recommended dosing regimens suggest that current recombinant GH therapy has a greater impact on final adult height than previously reported.[54,55,56] These studies have reported average final adult heights ranging from 0.5 to 1.7 standard deviations below the population mean. Initiation of therapy at an early chronologic age, prior to the onset of puberty, is associated with a more favorable increase in final height.[48,53,54,55,56] Therefore, prompt diagnosis of GH deficiency and early initiation of replacement therapy with recombinant GH are crucial factors in optimizing the final adult height of children with GH deficiency.

Recombinant GH has been shown to increase the short-term growth rate in pediatric patients with chronic renal insufficiency, Turner syndrome, idiopathic short stature, Prader–Willi syndrome, short stature homeobox gene (SHOX) deficiency, Noonan syndrome, and children born small for gestational age (SGA), and is approved by the FDA for treatment of growth failure associated with these conditions. GH is also FDA-approved for treatment of adult GH deficiency, short bowel syndrome in patients receiving specialized nutritional support, and acquired immunodeficiency syndrome wasting syndrome. When used in adult patients, the recommended dosage of recombinant GH is significantly lower than the dosage used in pediatric patients. Adult patients with GH deficiency during childhood must have the diagnosis of GHD confirmed when they are adults. Long-term GH therapy in GHD adults significantly decreases body fat, increases muscle mass, and improves exercise capacity.[51] GH therapy in adults has not been definitively shown to improve the cardiac risk profile or bone mineral density, but it does appear to improve psychological well-being.[57] The Beers Criteria of the American Geriatrics Society recommends avoiding GH therapy except as replacement after pituitary gland removal because the risks in older adults outweigh any potential benefits.[58] Use of GH as an anabolic agent for management of acute catabolism is not recommended.[48]

The majority of short children in the United States do not have an identifiable medical cause for their condition, but with widespread availability of several recombinant GH formulations, many children have received GH therapy regardless of the underlying etiology of their short stature. The use of

recombinant GH therapy in children with non-GHD short stature, also referred to as *idiopathic short stature*, has been studied by many investigators and was approved by the FDA in 2003.[49] However, the use of GH therapy in this patient population remains controversial.[59,60] A meta-analysis of 38 clinical studies evaluating the efficacy of GH treatment in children with idiopathic short stature reported average increases in final adult height of 4 to 5 cm (1.6-2 inches) following a mean duration of therapy of 4.7 years.[61] This corresponded to an increase above the predicted final adult height of 0.56 to 0.63 standard deviations of the population mean. A more recent systematic review of GH treatment in idiopathic short stature noted that the final adult height gain is usually less than that seen in other FDA-approved conditions associated with growth failure, increasing adult height by about 4 cm. The individual response to therapy is highly variable, and further studies are needed to identify responders.[62]

Nine different recombinant GH products (somatropin) currently are available for use in the United States (Genotropin, Humatrope, Norditropin, Nutropin AQ, Omnitrope, Saizen, Serostim, Zomactin, and Zorbtive). Somatropin is composed of the same amino acid sequence as native human pituitary GH. Recombinant GH formulations must be administered by intramuscular or subcutaneous injection. Nutropin AQ, Norditropin, and Omnitrope are the only GH products available as liquid formulations. The remaining products are formulated as lyophilized powders for injection, and patients must be instructed regarding proper administration. A needle-free injection device (Zoma-Jet) is available for use with Zomactin. This device delivers a thin stream of recombinant GH that penetrates the stratum corneum and deposits into the subcutaneous tissue. This product may be particularly useful for patients who experience significant adverse effects from injections. The potency of GH products is expressed as international units per milligram (international units/mg), with 1 mg containing approximately 2.6 international units of GH. Direct comparisons between the different recombinant GH products have not been published. However, all GH products are generally considered to be equally effective and some retrospective data suggest that switching formulations during the course of treatment may not negatively impact the growth trajectory.[63] The recommended dose for treatment of GHD short stature in children ranges from 0.2 to 0.375 mg/kg/wk.[48,52] Recombinant GH can be administered daily or in equal doses six times per week, depending on the specific GH product used.[48,52] Dosing regimens with greater frequency of administration have been shown to provide more favorable short-term growth responses.[48,52] While fixed-dose strategies have historically been used, most endocrinologists suggest that adjustments in GH replacement can be made based on IGF-1 serum concentrations as appropriate for age and sex.[64,65] GH replacement therapy should be initiated as early as possible after diagnosis of GH insufficiency and continued until a desirable height is reached or growth velocity has decreased to less than 2.5 cm per year after the pubertal growth spurt. However, the suitable time point for discontinuation of therapy with growth-promoting doses remains controversial. Glucocorticoids may inhibit the growth-promoting effects of recombinant GH, and concomitant administration of androgens, estrogens, thyroid hormones, or anabolic steroids may accelerate epiphyseal closure and compromise final height.

Large databases, such as the National Cooperative Growth Study, the Kabi International Growth Study, and the Australian and New Zealand growth database (OZGROW), have been developed to collect postmarketing adverse event data associated with recombinant GH. Development of these

databases was prompted by the unexpected and tragic cases of CJD reported in patients treated with human pituitary GH. These databases are organized and maintained by pharmaceutical companies that manufacture GH products.[66,67,68] Results from the Safety and Appropriateness of Growth Hormone treatments in Europe (SAGhE) study provide additional long-term surveillance data from a noncommercial source.[68] Recombinant GH is generally well tolerated in children, and adverse effects are relatively uncommon.[66,67,68,69] A small number of patients may complain of injection-site pain or arthralgias. Idiopathic intracranial hypertension, also known as *pseudotumor cerebri*, has been reported in a very small number of children receiving GH therapy. This condition usually develops within the first 8 to 12 of weeks of treatment and presents with symptoms such as headache, blurred vision, diplopia, nausea, and vomiting.[69] The symptoms of idiopathic intracranial hypertension usually resolve after discontinuation of GH therapy, and long-term complications are rare. Cases of slipped capital femoral epiphysis have been reported in children with GHD who are receiving GH therapy.[68,69] This condition is thought to occur as a result of the increased width of the femoral plate during GH treatment, but it also has been reported in GHD children who are not receiving GH replacement. Patients with this condition typically complain of hip or knee pain. Slipped capital femoral epiphysis can be managed by an orthopedic surgeon, and GH therapy does not need to be withdrawn. Because GH is known to cause decreased insulin sensitivity, hyperglycemia and diabetes mellitus may develop.[69] Patients who have specific predisposing risk factors for diabetes mellitus are at greatest risk for this adverse effect.[66,69] Glycosylated hemoglobin concentrations should be monitored in all patients receiving GH products.[48] GH could theoretically promote the growth of various types of neoplasms and increase tumor recurrence rates in patients with a history of malignancy.[48,66,69] Guidelines recommend that GH can be safely used in those without a history of malignancy but note that current evidence is insufficient to conclude whether GH increases cancer risk or recurrence.[70] In 1988, a Japanese report indicated that children receiving GH therapy were twice as likely to develop leukemia as children who were not receiving the hormone. A more recent analysis of all collected reports of leukemia associated with GH therapy determined that these children had other leukemia risk factors (Fanconi anemia, Bloom syndrome, or history of cancer).[68] GH therapy in children without these risk factors does not appear to predispose children to develop leukemia.[68,70] Concerns have been raised from the SAGhE cohort about the possibility that childhood GH exposure may be associated with diseases that may not manifest until adulthood. Increased cardiac and cerebrovascular mortality rates were observed in adult French subjects treated with GH therapy as children but similar results were not seen in subjects from Belgium, the Netherlands, and Sweden.[68,71] The observational design of these studies makes interpretation of the findings difficult. Additionally, it should be noted that some authors have stressed the importance of using growth velocity and provocative testing in deciding whom and when to treat, and at what doses.

Recombinant Insulin-Like Growth Factor-1

Recombinant IGF-1 (mecasermin [Increlex]) is approved by the FDA for the treatment of children with short stature due to severe primary IGF-1 deficiency (defined as children with height standard deviation score ≤–3.0 plus basal IGF-1 standard deviation score ≤–3.0, plus normal or elevated GH concentration) or GH gene deletion with neutralizing antibodies to GH. Recombinant IGF-1 products

are not intended for use in subjects with secondary forms of IGF-1 deficiency, such as GH deficiency, malnutrition, hypothyroidism, or chronic treatment with pharmacologic doses of anti-inflammatory steroids. Recombinant IGF-1 products have been shown to increase growth velocity in children with short stature who have low IGF-1 serum concentrations and resistance to GH.[72,73,74] However, the efficacy of these agents is less than that reported with GH products in patients with GH deficiency.

The recommended dose of mecasermin is 0.04 to 0.12 mg/kg administered by subcutaneous injection twice daily. First year growth and long-term outcomes are best with doses more than 0.1 mg/kg/dose, adjusted for increases in weight as the patient grows. Treatment continues until epiphyseal closure or attainment of full growth potential.[72,73] Because of the insulin-like effects of these products, patients should be monitored very closely for hypoglycemia, and the drug should be initiated at the lower end of the dosage range and administered with a meal or snack. Additional adverse effects experienced by patients receiving recombinant IGF-1 products include injection-site reactions, tonsillar/adenoidal hypertrophy, lymphoid hypertrophy, coarsening facial features, anaphylaxis, headache, dizziness, and arthralgia.[72,73,74] Intracranial hypertension has been reported in a small number of patients. Additional studies are needed to elucidate the exact role of recombinant IGF-1 products in the management of short stature not caused by GH gene deletion or GH receptor defects.

Personalized Pharmacotherapy

Ongoing genetic studies are attempting to predict GH response in subjects. There is some evidence to suggest that patients with exon-3 deleted GH receptors or a specific polymorphism in the IGFBP-3 promoter gene have an enhanced response to GH therapy. However, recommendations regarding how therapy can be tailored to maximize patient benefit based on these findings are not available at this time. The large number of GHD disorders vary in phenotype and in biochemical and molecular characteristics thereby likely contributing to the variability of response reported in trials with GH or IGF-1. Given this variability, and in the absence of specific and well-validated indicators of response, therapy must be carefully individualized.[75]

Evaluation of Therapeutic Outcomes

Appropriate monitoring of therapy for GHD and non-GHD short stature includes regular assessments of height, weight, growth velocity, serum IGF-1 concentrations, and bone age every 6 to 12 months. Additional laboratory tests to monitor for potential adverse effects include serum glucose concentration and thyroid function. The dose of GH will periodically need to be increased as weight increases in growing children.

Conclusions

GH deficiency during childhood results in short stature. Replacement with recombinant GH is considered the mainstay of therapy for patients with GHD short stature, but its use for treatment of non-GHD short stature remains controversial despite FDA approval for this indication. Recombinant GH has proven to be safe for use in children and is associated with few adverse effects. Preparations

of IGF-1 may provide benefit for patients with non-GHD short stature. GH regimens can be particularly demanding and inconvenient for pediatric patients because they must be administered by subcutaneous injection. Knowledge of the long-term benefits and risks is critical to the development of rational, cost-effective treatments for patients with short stature.

PROLACTIN

Hyperprolactinemia

Prolactin is secreted in a pulsatile fashion by the lactotroph cells of the anterior pituitary, with the highest peak concentrations observed during sleep.[4] The secretion of prolactin is regulated primarily by tonic hypothalamic inhibitory effects of dopamine. As described earlier in this chapter and in Table e77-1, many factors can affect prolactin secretion. During pregnancy, prolactin serum concentrations rise substantially above normal. All other conditions characterized by excess prolactin serum concentrations, known as *hyperprolactinemia*, are considered pathologic. Hyperprolactinemia is a state of persistent serum prolactin elevation. In the absence of stress, a prolactin serum measurement above the normal range (25 µg/L ([1,090 pmol/L]) is generally considered indicative of hyperprolactinemia.[76] Hyperprolactinemia usually affects women of reproductive age.[76,77,78] The annual incidence of hyperprolactinemia in women between the ages of 24 and 35 years is approximately 24 cases per 1,000 person years.[76]

Hyperprolactinemia has several etiologies. The most common causes are benign prolactin-secreting pituitary tumors, known as *prolactinomas*, and various medications. Prolactinomas are classified according to size. Prolactin-secreting microadenomas are less than 10 mm in diameter and often do not increase in size.[77] In contrast, macroadenomas are tumors with a diameter greater than 10 mm that continue to grow and can cause invasion of surrounding tissues.[4] In the presence of a prolactinoma, the elevation in prolactin serum concentration is generally proportional to the size of the tumor, with prolactin concentrations more than 500 µg/L typically diagnostic for a macroprolactinoma.[76,77,78]

7 Any pharmacologic agent that antagonizes dopamine or increases the release of prolactin can induce hyperprolactinemia (**Table e77-4**).[79] Antipsychotic medications are the most frequently reported agents to cause hyperprolactinemia due to their potent dopamine-receptor blockade. Serotonin is a strong stimulator of prolactin secretion and antidepressants, such as selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase (MAO) inhibitors, and tricyclic and tetracyclic agents, are associated with hyperprolactinemia.[79] More recently, the $5HT_1$ receptor agonist eletriptan has been implicated as a potential cause of hyperprolactinemia.[80] Metoclopramide and domperidone, an antiemxetic available in Europe, are potent dopamine-receptor antagonists reported to induce hyperprolactinemia.[79] Hormones such as estrogen and progesterone, commonly prescribed as oral contraceptives, can stimulate lactotroph growth to promote prolactin secretion and have been implicated in drug-induced hyperprolactinemia. Although the exact mechanism of action remains to be determined, the calcium channel-blocking agent verapamil has been associated

with cases of hyperprolactinemia.[4,79] Methyldopa and reserpine, although not used frequently in clinical practice today, are antihypertensive agents that can stimulate prolactin secretion.[79] Prolactin concentrations may increase with administration of GnRH agonist such as leuprolide or goserelin.[79] Other medications rarely reported to cause hyperprolactinemia include H_2-receptor blocking agents, benzodiazepines, opioids, and protease inhibitors.[4,79] Prolactin levels do not typically rise to more than 150 µg/L (greater than 6,500 pmol/L) in most cases of drug-induced hyperprolactinemia. Measurement of serum prolactin concentrations prior to the initiation of therapy with medications known to cause prolactin elevation may obviate the need for extensive examination of pituitary function and aid with the appropriate diagnosis of drug-induced hyperprolactinemia.

TABLE e77-4 Drug-Induced Hyperprolactinemia

Dopamine antagonists
Antipsychotics
Phenothiazines
Metoclopramide
Domperidone
Prolactin stimulators
Methyldopa
Reserpine
SSRIs
$5HT_1$ receptor agonists
Estrogens
Progestins
Protease inhibitors
GnRH analogs
Benzodiazepines
Tricyclic and tetracyclic antidepressants
MAO inhibitors
H_2-Receptor antagonists
Opioids

Cocaine

Other

Verapamil

GnRH, gonadotropin-releasing hormone; MAO, monoamine oxidase; SSRIs, selective serotonin reuptake inhibitors.

Less common etiologies include CNS lesions that physically compress the pituitary stalk and interrupt tonic hypothalamic dopamine secretion, resulting in hyperprolactinemia.[76] Increased TRH concentrations in hypothyroidism can stimulate prolactin secretion and cause hyperprolactinemia. During conditions of renal or hepatic compromise, the clearance of prolactin is decreased, resulting in elevated prolactin concentrations.[76] Mutation of the prolactin receptor has also been identified as a cause of hyperprolactinemia.[77] Despite vigorous diagnostic effort, the cause of hyperprolactinemia cannot always be determined. In such cases, the condition is referred to as *idiopathic hyperprolactinemia*.[76,77] It should be noted that many physiologic factors, such as stress (including the stress of phlebotomy), sleep, exercise, coitus, and eating, also can induce transiently elevated prolactin levels.[4] Therefore, some clinicians may prefer obtaining multiple prolactin measurements to confirm the diagnosis.[76] Ideally, after an IV line is placed in the patient's arm, the patient should rest in a supine position or in a chair for 2 hours before prolactin samples are collected.

Elevated prolactin serum concentrations inhibit gonadotropin secretion and sex-steroid synthesis. Because prolactin concentrations greater than 60 µg/L (greater than 2,600 pmol/L) are associated with anovulation, women with hyperprolactinemia typically present with menstrual irregularities such as oligomenorrhea or amenorrhea and infertility.[76] In addition, approximately 40% to 80% of women with hyperprolactinemia will have galactorrhea.[76,77] The clinical presentation of patients with hyperprolactinemia is summarized in **Table e77-5**.[4,76,77]

TABLE e77-5 Clinical Presentation of Hyperprolactinemia

General

- Hyperprolactinemia most commonly affects women and is very rare in men.

Signs and symptoms

- The patient may complain of symptoms related to local effects of the prolactin-secreting tumor, such as headache and visual disturbances, that result from tumor compression of the optic chiasm.
- Female patients experience oligomenorrhea, amenorrhea, galactorrhea, infertility, decreased libido, hirsutism, and acne.

- Male patients experience decreased libido, erectile dysfunction, infertility, reduced muscle mass, galactorrhea, and gynecomastia.

Laboratory tests

- Prolactin serum concentrations at rest will be >25 µg/L (>1,090 pmol/L).

Additional clinical sequelae

- Prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreased bone mineral density and significant risk for development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

From references 4, 76, and 77.

The diagnosis of hyperprolactinemia, as defined by a single prolactin serum concentration greater than 25 µg/L (greater than 1,090 pmol/L), is relatively simple.[76] However, identifying the underlying cause of this abnormality may be more challenging. Patients with modest prolactin elevations should have multiple prolactin serum determinations to minimize the potential for detecting only transient increases in prolactin. A careful medication history is essential, and the presence of hypothyroidism, renal failure, or hepatic dysfunction should be evaluated. If the cause of hyperprolactinemia remains ambiguous, a computed tomography scan or MRI study should be performed to determine the presence of a pituitary tumor.[76,77] If an underlying cause of elevated prolactin serum concentration is not determined, the hyperprolactinemia is considered to be idiopathic.

Clinical Controversy…

For patients with antipsychotic-induced hyperprolactinemia in whom it is not feasible to withdraw the offending agent, treatment with dopamine agonists is controversial because of the potential for exacerbation of the underlying psychosis.

TREATMENT

The treatment of hyperprolactinemia depends on the underlying cause of the abnormality. In cases of drug-induced hyperprolactinemia, discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalize serum prolactin concentrations.[79] Aripiprazole, an atypical antipsychotic with partial dopamine D_2-receptor agonist activity, has recently been shown effective for managing antipsychotic-induced hyperprolactinemia as an adjunctive therapy and as a therapeutic alternative when patients have been switched from the offending agent to aripiprazole.[81] In cases for which an appropriate therapeutic alternative does not exist, medical therapy with bromocriptine or cabergoline may be carefully considered (The Endocrine Society; weak recommendation with very low quality evidence).[76] Sex-steroid replacement if clinically indicated also should be considered.[76] Treatment options for the management of prolactinomas include clinical observation, medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgical

removal of the tumor.[4,76,77,78] Because prolactin-secreting microadenomas are very small and typically do not increase in size, treatment of these tumors is primarily directed toward alleviating symptoms.[76,77,78] The goal of therapy is to normalize prolactin serum concentrations and reestablish gonadotropin secretion to restore fertility and reduce the risk of osteoporosis. In patients with asymptomatic elevations in serum prolactin, observation and close follow-up are appropriate.[76] For women with amenorrhea who do not wish to become pregnant, dopamine agonist therapy may not be necessary. In these patients, sex-steroid replacement and close follow-up may be sufficient.[76] Treatment goals are more aggressive in patients with prolactin-secreting macroadenomas because these tumors are larger and can cause invasion of local tissues with significant visual defects. Therefore, in addition to normalizing prolactin concentrations, tumor shrinkage and correction of visual defects are primary goals of treatment.

Medical therapy with dopamine agonists usually is more effective than transsphenoidal surgery for both types of pituitary prolactinomas.[4,76,77,78] Postsurgical cure rates differ depending on tumor type and expertise of the neurosurgeon. Long-term cure rates are reported to be approximately 60% for microprolactinomas and only 25% for macroprolactinomas.[4] Transsphenoidal surgery for removal of prolactinomas usually is reserved for patients who are refractory to or cannot tolerate therapy with dopamine agonists and for patients with very large tumors that cause severe compression of adjacent tissues.[4,76,77,78] Radiation therapy may require several years for effective tumor shrinkage and reduction in serum prolactin concentrations and usually is used only in conjunction with surgery.[4]

Pharmacologic Therapy

Medical therapy with dopamine agonists has proven to be very effective in normalizing prolactin serum concentrations, restoring gonadal function, and reducing tumor size and is recommended by The Endocrine Society Clinical Practice Guidelines as first-line therapy (strong recommendation with high quality evidence).[76] Cabergoline, a long-acting dopamine agonist that offers the advantage of less-frequent dosing, is the agent of choice for the medical management of prolactinomas because of its superior efficacy in comparison to bromocriptine (strong recommendation with high quality evidence).[76]

Bromocriptine

Bromocriptine was the first D_2-receptor agonist to be used in the treatment of hyperprolactinemia and had been the mainstay of therapy for over 20 years. It inhibits the release of prolactin by directly stimulating postsynaptic dopamine receptors in the hypothalamus. Hypothalamic release of dopamine (prolactin-inhibitory hormone) inhibits the release of prolactin. Decreases in serum prolactin concentrations occur within 2 hours of oral administration, with maximal suppression occurring after 8 hours and suppressive effects persisting for up to 24 hours. Medical therapy with bromocriptine normalizes prolactin serum concentrations, restores gonadotropin production, and shrinks tumor size in approximately 80% of patients with microprolactinomas and 70% of patients with macroprolactinomas.[77]

For the management of hyperprolactinemia, bromocriptine therapy typically is initiated at a dose of 1.25 to 2.5 mg once daily at bedtime to minimize adverse effects.[4] The dose can be gradually increased by 1.25-mg increments every week to obtain desirable serum prolactin concentrations. Usual therapeutic doses of bromocriptine range from 2.5 to 15 mg/day, although some patients may require doses as high as 40 mg/day. Bromocriptine usually is administered in two or three divided doses, but once-daily dosing has also been shown to be effective.

The most common adverse effects associated with bromocriptine therapy include CNS symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. GI effects such as nausea, abdominal pain, and diarrhea also are common. Bromocriptine should be administered with food to decrease the incidence of adverse GI effects. Although most of these adverse effects diminish with continued treatment, approximately 12% of patients will not tolerate the adverse effects associated with bromocriptine therapy.[78] Vaginal preparations of bromocriptine may be used in women to decrease the incidence of adverse effects associated with oral adminstration.[4,76]

Because most patients with hyperprolactinemia are women with a principal complaint of infertility, the safety of bromocriptine in pregnancy must be considered. More than 6,000 pregnancies have been reported in women who received bromocriptine throughout gestation, and an increased risk for spontaneous abortion or congenital anomalies has not been detected.[76] Although bromocriptine does not appear to be teratogenic, discontinuation of therapy as soon as pregnancy is detected is recommended because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown (The Endocrine Society; strong recommendation with low quality evidence).[4,76,77,78] In patients with macroprolactinomas undergoing rapid tumor expansion, bromocriptine therapy may need to be continued throughout pregnancy (The Endocrine Society; weak recommendation with low quality evidence).

Cabergoline

8 Cabergoline is a long-acting dopamine agonist with high selectivity and affinity for dopamine D_2-receptors. This agent is approved for treatment of hyperprolactinemia and has been shown to effectively reduce serum prolactin concentrations and tumor size in patients with both microprolactinomas and macroprolactinomas.[76] A systematic review and meta-analysis of four clinical trials comparing the efficacy of cabergoline and bromocriptine reported that cabergoline was significantly more effective in normalizing serum prolactin concentrations.[82] Cabergoline has also proved effective in patients who are intolerant of or resistant to bromocriptine, and the data suggest that cabergoline is as effective in men as in women with microprolactinomas and macroprolactinomas.[76,83]

Cabergoline is commercially available as 0.5-mg oral tablets. The initial dose of cabergoline for treatment of hyperprolactinemia is 0.25 to 0.5 mg once weekly or in divided doses twice weekly. This dose may be increased by 0.5-mg increments at 4-week intervals based on serum prolactin concentrations.[84] The usual dose is 1 to 2 mg weekly; doses more than 3 mg per week are infrequently required. However, doses as high as 12 mg weekly have been used safely in patients with

treatment-resistant prolactinomas.[85] Following oral administration, peak serum concentrations are obtained within 2 hours, and food does not affect absorption. The elimination of cabergoline from the pituitary appears to be very slow; this rate may explain the long duration of action. Cabergoline is extensively metabolized in the liver by hydrolysis, and the dose should be reduced in patients with severe hepatic failure. This drug is eliminated primarily in the feces, and the elimination half-life ranges from 79 to 155 hours in hyperprolactinemic patients.

The most common adverse effects reported with use of cabergoline are nausea, vomiting, headache, and dizziness.[77,84] These effects are similar to the adverse effects reported with bromocriptine. However, in a large comparative study evaluating bromocriptine and cabergoline, fewer patients receiving cabergoline reported adverse effects than did patients receiving bromocriptine, and only 3% of the patients in the cabergoline group withdrew from the study because of adverse effects versus 12% of patients taking bromocriptine.[86] Other adverse events associated with use of cabergoline include constipation, fatigue, anxiety, depression, and nasal congestion.[84] As with other dopamine agonists, adverse events usually occur early in therapy and subside with continued treatment. However, in one study 15% to 20% of patients receiving cabergoline experienced a recurrence of early symptoms or an onset of new symptoms after several weeks of treatment.[86] Mild-to-moderate decreases in blood pressure have been observed in up to 50% of patients taking cabergoline; however, the incidence of symptomatic orthostatic hypotension has not been significant.[84,86] Transient increases in serum alkaline phosphatase, bilirubin, and aminotransferases have been reported in small numbers of patients receiving cabergoline.[86] Newly diagnosed cardiac valve regurgitation has been reported with cabergoline use at the larger doses used in the treatment of Parkinson disease.[87] Although symptomatic cardiac valve abnormalities have not been observed with cabergoline when administered in doses used for the treatment of prolactinomas, some clinicians have recommended routine echocardiography for patients receiving long-term cabergoline treatment for prolactinomas.[76,87]

9 Use of cabergoline in pregnancy has not been extensively studied. However, several case reports of women who received cabergoline therapy during the first and second trimesters of pregnancy have not documented an increased risk of spontaneous abortion, congenital abnormalities, or tubal pregnancy.[88] However, prospective data in large numbers of pregnancies are lacking. Because of the long half-life and limited data on cabergoline use in pregnancy, current guidelines recommend that women receiving cabergoline therapy who plan to become pregnant should discontinue the medication as soon as pregnancy is detected (The Endocrine Society; strong recommendation with low quality evidence).[76]

Other dopamine agonists that have been used in the treatment of hyperprolactinemia but are not commercially available in the United States include lisuride, terguride, metergoline, dihydroergocristine, and quinagolide. Quinagolide, a D_2-receptor agonist used frequently in Europe, is dosed once daily. Quinagolide has been shown to be as effective as bromocriptine for the management of hyperprolactinemia and may be effective in the treatment of patients who are resistant to or intolerant of bromocriptine.[4]

Personalized Pharmacotherapy

Genetic predisposition to the development of hyperprolactinemia has been reported involving the D_2-receptor and hormone-related genes.[89,90] However, recommendations regarding how therapy can be individualized to maximize patient benefit are not available.

Evaluation of Therapeutic Outcomes

Prolactin serum concentrations should be monitored every 3 to 4 weeks after the initiation of any dopamine-agonist therapy to assess efficacy and appropriately titrate medication dosage.[76] In addition, symptoms such as headache, visual disturbances, menstrual cycles in women, and sexual function in men should be evaluated to assess clinical response to therapy. Once prolactin concentrations have normalized and clinical symptoms of hyperprolactinemia have resolved with dopamine-agonist therapy, prolactin serum concentrations should be monitored every 6 to 12 months. In patients receiving long-term treatment, the dose of the dopamine agonist can be gradually reduced or discontinued in some patients. For patients who have received medical therapy with dopamine agonists for at least 2 years, therapy may be tapered or discontinued if normal serum prolactin concentrations are achieved in the absence of visible tumor (The Endocrine Society; weak recommendation with low quality evidence).[76] Follow-up of such patients should include prolactin serum concentration measurements every 3 months for the first year (continued annually thereafter), with assessment of MRI findings if prolactin concentrations are elevated.

Conclusions

Hyperprolactinemia is a common disorder that can have a significant impact on fertility. Hyperprolactinemia is most commonly caused by the presence of prolactin-secreting pituitary tumors and various medications that antagonize dopamine or increase the secretion of prolactin. Available treatment options for this disorder include medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgery. In most cases, medical therapy with dopamine agonists is considered the most effective treatment. Cabergoline is the mainstay of medical therapy because it appears to be better tolerated and more effective than bromocriptine.

PANHYPOPITUITARISM

9 Panhypopituitarism is a condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary hormone deficiencies. Patients with panhypopituitarism may have ACTH deficiency, gonadotropin deficiency, GH deficiency, hypothyroidism, and hyperprolactinemia. Panhypopituitarism can be classified as either primary or secondary depending on the etiology. Primary panhypopituitarism involves an abnormality within the secretory cells of the pituitary, whereas secondary panhypopituitarism is caused by a lack of proper external stimulation needed for normal release of pituitary hormones. Some of the most common causes of panhypopituitarism include primary pituitary tumors, ischemic necrosis of the pituitary, surgical trauma, irradiation, and various types of CNS infections. Pharmacologic treatment of

panhypopituitarism is essential and consists of replacement of specific pituitary hormones after careful assessment of individual deficiencies. Replacement most often consists of glucocorticoids, thyroid hormone preparations, and sex steroids. Administration of recombinant GH also may be necessary. Patients with panhypopituitarism will need lifelong replacement therapy and constant monitoring of multiple homeostatic functions.

ACKNOWLEDGMENT

This research was supported in part by the Intramural Research Program of the National Institute of Child Health and Human Development, National Institutes of Health.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

AACE	American Association of Clinical Endocrinologists
ACTH	adrenocorticotropic hormone
CJD	Creutzfeldt–Jakob disease
CNS	central nervous system
CRH	corticotropin-releasing hormone
FSH	follicle-stimulating hormone
GEP-NETs	gastroenteropancreatic neuroendocrine tumors
GH	growth hormone
GHD	growth hormone deficiency/growth hormone-deficient)
GHRH	growth hormone-releasing hormone
GI	gastrointestinal
GnRH	gonadotropin-releasing hormone
IGF	insulin-like growth factor
IGFBP-3	insulin-like growth factor-1 binding protein-3
LH	luteinizing hormone
MAO	monoamine oxidase
MRI	magnetic resonance imaging
OGTT	oral glucose tolerance test
SAGhE	Safety and Appropriateness of Growth Hormone treatments in Europe
SGA	small for gestational age
SHOX	short stature homeobox-containing gene
SSRI	selective serotonin reuptake inhibitor
TRH	thyrotropin-releasing hormone
TSH	thyroid-stimulating hormone
VIP	vasoactive intestinal peptide

Chapter 78: Pregnancy and Lactation: Therapeutic Considerations

Kristina E. Ward

INTRODUCTION

KEY CONCEPTS

- 1 Complex physiology surrounds the process of fertilization and pregnancy progression.
- 2 Drug characteristics and physiologic changes modify drug pharmacokinetics during pregnancy, including changes in absorption, protein binding, distribution, and elimination, requiring individualized drug selection and dosing.
- 3 Although drug-induced teratogenicity is a serious concern during pregnancy, most drugs required by pregnant women can be used safely. Informed selection of drug therapy is essential.
- 4 Healthcare practitioners must know where to find and how to evaluate evidence related to the safety of drugs used during pregnancy and lactation.
- 5 Health issues influenced by pregnancy, such as nausea and vomiting, can be treated safely and effectively with nonpharmacologic treatment or carefully selected drug therapy.
- 6 Some acute and chronic illnesses pose additional risks during pregnancy, requiring treatment with appropriately selected and monitored drug therapies to avoid harm to the woman and the fetus.
- 7 Management of the pregnant woman during the peripartum period not only can encompass uncomplicated pregnancies/deliveries, but can also include a wide variety of potential complications that require use of evidence-based treatments to maximize positive maternal and neonatal outcomes.
- 8 Understanding the physiology of lactation and pharmacokinetic factors affecting drug

distribution, metabolism, and elimination can assist the clinician in selecting safe and effective medications during lactation.

A controversial and emotionally charged subject because of medicolegal and ethical implications, drug use in pregnancy and lactation is a topic often underemphasized in the education of health professionals. Clinicians are responsible for ensuring safe and effective therapy before conception, during pregnancy and parturition, and after delivery. Active patient participation is essential. Optimal treatments of illnesses during pregnancy sometimes differ from those used in the nonpregnant patient.

In many cases, medication dosing recommendations for acute or chronic illnesses in pregnant women are the same as for the general population. However, some cases require different dosing and selection of medications. Principles of drug use during lactation, although similar, are not the same as those applicable during pregnancy.

PHYSIOLOGY OF PREGNANCY

1 Fertilization and progression of pregnancy are complex, resulting in survival of only approximately 50% of embryos.[1] Because most losses occur early, usually in the first 2 weeks after fertilization, many women do not realize they were pregnant. Spontaneous loss of pregnancy later in gestation occurs in about 15% of pregnancies that survive the first 2 weeks after fertilization.[2]

Fertilization occurs when a sperm attaches to the outer protein layer of the egg, the zona pellucida, and renders the egg nonresponsive to other sperm.[3] The attached sperm releases enzymes that allow the sperm to fully penetrate the zona pellucida and contact the egg's cell membrane. The membranes of the sperm and egg then combine to create a new, single cell called a zygote. Male and female chromosomes join in the zygote, fuse to create a single nucleus, and organize for cell division.

Fertilization usually occurs in the fallopian tube.[4] The fertilized egg travels down the fallopian tube over 2 days, with cell division taking place. By day 3, the fertilized egg reaches the uterus. Cell division continues for another 2 to 3 days in the uterine cavity before implantation. Approximately 6 days after fertilization, the cell mass is termed a *blastocyst*. Human chorionic gonadotropin (hCG) now is produced in amounts detectable by commercial laboratories. Implantation begins with the blastocyst sloughing the zona pellucida to rest directly on the endometrium allowing initiation of growth into the endometrial wall. By day 10 postfertilization, the blastocyst is implanted under the endometrial surface and receives nutrition from maternal blood. On the first day of the third week postfertilization it is called an *embryo*.[4,5]

After the embryonic period (between weeks 2 and 8 postfertilization), the embryo is renamed a *fetus*. Most body structures are formed during the embryonic period, and they continue to grow and mature during the fetal period. The fetal period continues until the pregnancy reaches term, approximately 40 weeks after the last menstrual period.[5]

Gravidity is the number of times that a woman has been pregnant. A multiple birth is counted as a

single pregnancy. *Parity* refers to the number of pregnancies exceeding 20 weeks of gestation and relates information regarding the outcome of each pregnancy. In sequence, the numbers reflect (a) term deliveries, (b) premature deliveries, (c) aborted pregnancies, and (d) number of living children. A woman who has been pregnant four times; has experienced two term deliveries, one premature delivery, and one ectopic pregnancy; and has three living children would be designated G_4P_{2113}.[6,7]

Characteristics of Pregnancy

Pregnancy lasts approximately 280 days (about 40 weeks or 9 months); the time period is measured from the first day of the last menstrual period to birth. *Gestational age* refers to the age of the embryo or fetus beginning with the first day of the last menstrual period, which is about 2 weeks prior to fertilization. When calculating the estimated due date, add 7 days to the first day of the last menstrual period then subtract 3 months. Pregnancy is divided into three periods of 3 calendar months, each called a *trimester*.[6]

Early symptoms of pregnancy include fatigue and increased frequency of urination. After the first or second missed menstrual period, nausea and vomiting can occur. While commonly called *morning sickness*, it can happen at any time of the day. Nausea and vomiting usually resolve at 14 to 16 weeks of gestation. A pregnant woman can feel fetal movement in the lower abdomen at 14 to 20 weeks of gestation; multiparous women feel movement earlier than women who are primiparous. Signs of pregnancy include cessation of menses, change in cervical mucus consistency, bluish discoloration of the vaginal mucosa, increased skin pigmentation, and anatomic breast changes.[6,7]

Pharmacokinetic Changes During Pregnancy

2 Normal physiologic changes that occur during pregnancy may alter medication effects, resulting in the need to more closely monitor and, sometimes, adjust therapy. Physiologic changes begin in the first trimester and peak during the second trimester. For medications that can be monitored by blood or serum concentration measurements, monitoring should occur throughout pregnancy.

During pregnancy, maternal plasma volume, cardiac output, and glomerular filtration increase by 30% to 50% or higher, potentially lowering the concentration of renally cleared drugs.[8,9] As body fat increases during pregnancy, the volume of distribution of fat-soluble drugs may increase. Plasma albumin concentration decreases, which increases the volume of distribution of drugs that are highly protein bound. However, unbound drugs are more rapidly cleared by the liver and kidney during pregnancy, resulting in little change in concentration. Hepatic perfusion increases, which could theoretically increase the hepatic extraction of drugs. Nausea and vomiting, as well as delayed gastric emptying, may alter the absorption of drugs. Likewise, a pregnancy-induced increase in gastric pH may affect the absorption of weak acids and bases. Higher levels of estrogen and progesterone alter liver enzyme activity and increase the elimination of some drugs but result in accumulation of others.[8,9,10]

Transplacental Drug Transfer

Although once thought to be a barrier to drug transfer, the placenta is the organ of exchange for a number of substances, including drugs, between the mother and fetus. Most drugs move from the maternal circulation to the fetal circulation by diffusion.[11] Certain chemical properties, such as lipid solubility, electrical charge, molecular weight, and degree of protein binding of medications, may influence the rate of transfer across the placenta.

Drugs with molecular weights less than 500 Da readily cross the placenta, whereas larger molecules (600-1,000 Da) cross more slowly.[11] Drugs with molecular weights greater than 1,000 Da, such as insulin and heparin, do not cross the placenta in significant amounts. Lipophilic drugs, such as opioids and antibiotics, cross the placenta more easily than do water-soluble drugs. Maternal plasma albumin progressively decreases, while fetal albumin increases during the course of pregnancy, which may result in higher concentrations of certain protein-bound drugs in the fetus. Fetal pH is slightly more acidic than maternal pH, permitting weak bases to more easily cross the placenta. Once in the fetal circulation, the molecule becomes more ionized and less likely to diffuse back into the maternal circulation.[11]

DRUG SELECTION DURING PREGNANCY

Many misconceptions exist regarding the association of medications and birth defects. Although some drugs have the potential to cause teratogenic effects, most medications required by pregnant women can be used safely.

The baseline risk for congenital malformations is approximately 3% to 6%, with approximately 3% considered severe.[2,12] Medication exposure is estimated to account for less than 1% of all birth defects. Genetic causes are responsible for 15% to 25%, other environmental issues (eg, maternal conditions and infections) account for 10%, and the remaining 65% to 75% of congenital malformations result from unknown causes.[2,12]

Factors such as the stage of pregnancy during exposure, route of administration, and dose can affect outcomes.[12] In the first 2 weeks following conception, exposure to a teratogen may result in an "all-or-none" phenomenon, which could either destroy the embryo or cause no problems.[13] Organogenesis occurs during the embryonic period. As organ systems are developing, teratogenic exposures may result in structural anomalies. For the remainder of the pregnancy, exposure to teratogens may result in growth retardation, central nervous system (CNS) abnormalities, or death. Examples of medications associated with teratogenic effects in the period of organogenesis include chemotherapy drugs (eg, methotrexate and cyclophosphamide), sex hormones (eg, androgens and progestational drugs), lithium, retinoids, thalidomide, certain antiepileptic drugs, and coumarin derivatives. Other medications, such as nonsteroidal antiinflammatory drugs (NSAIDs) and tetracycline derivatives, are more likely to exhibit effects in the second or third trimester.

Medications are necessary during pregnancy for treatment of acute and chronic conditions. Identifying patterns of medication use before conception, eliminating nonessential medications and discouraging self-medication, minimizing exposure to medications known to be harmful, and

adjusting medication doses are all strategies to optimize the health of the mother while minimizing the risk to the fetus. In summary, a small number of medications have the potential to cause congenital malformations, and many can be avoided during pregnancy. In situations where a drug may be teratogenic but is necessary for maternal care, considerations related to route of administration, dosage form, and dosing may lessen the risk.

Methods and Resources for Determining Drug Safety in Pregnancy

When assessing the safety of using medications during pregnancy, evaluation of the quality of the evidence is important. Ideally, safety data from randomized, controlled trials are most desirable, but pregnant women are not usually eligible for participation in clinical trials. Other types of data commonly used to estimate the risk associated with medication use during pregnancy include animal studies, case reports, case-control studies, prospective cohort studies, historical cohort studies, and voluntary reporting systems.

Animal studies are a required component of drug testing, but extrapolation of the results to humans is not always valid.[14] Thalidomide was found to be safe in some animal models, but proved to have teratogenic effects in human offspring. The value of case reports is limited because birth defects in the offspring of women who used medication during pregnancy may occur by chance.[14] Case-control studies identify an outcome (congenital anomaly), match subjects with or without that outcome, and report how often exposure to a suspected agent occurred. Recall bias is a concern, as women with an affected pregnancy may be more likely to remember drugs used during the pregnancy than those with a normal outcome.

Cohort studies evaluate the intervention (use of a particular drug) in a group of persons and compare outcomes in a similar group of subjects without the intervention.[14,15] Prospective studies eliminate some of the problems with recall bias, but require time and large numbers of participants. Despite these disadvantages, cohort studies are often used for evaluating the effects of a drug exposure on pregnancy outcomes.

Teratology information services provide pregnant women with information about potential exposures during pregnancy and follow these women throughout the pregnancy to assess the outcomes of the pregnancy.[14] Services may publish pooled data to facilitate information sharing about medications used during pregnancy. Some pharmaceutical companies have organized voluntary reporting systems (also called pregnancy registries) for drugs used during pregnancy.

Computerized databases (eg, *www.motherisk.org*, LactMed [*www.toxnet.nlm.nih.gov*]), tertiary compendia, and textbooks with information from large cohorts of treated women offer valuable assistance. New information regarding drug use in pregnancy and lactation can be obtained from searches of the primary literature for cohort and case-control studies.

The FDA developed risk categories (ie, A, B, C, D, X, with A considered safe and X considered teratogenic) to guide clinicians regarding medication risk during pregnancy. Very few drugs are ranked as safe during pregnancy (category A) because a controlled trial is required to establish safety;

this implies that few drugs are safe. Because of multiple limitations of the risk categories, the FDA instituted new labeling requirements for drugs submitted for approval after June 30, 2015 to replace the pregnancy risk categories. Use of the new system will be phased in gradually for drugs approved after June 30, 2001. The new labeling requirements include a subsection for pregnancy that includes information about pregnancy exposure registries, a risk summary, clinical considerations, and supporting data. The lactation subsection provides information about drug use during lactation. A new subsection includes information for females and males of reproductive potential.[16]

In summary, determining drug safety during pregnancy is limited by the quality of data and the types of study designs that can be used. While information from product labeling may provide a rough estimate of risks for medication-related adverse fetal outcomes, careful evaluation of other available information sources is necessary to make decisions about medication use in pregnant women.

PRECONCEPTION PLANNING

Pregnancy outcomes are influenced by maternal health status, lifestyle, and history prior to conception. The goal of preconception care is health promotion, through modification of behavioral, biomedical, and social risks in all women of reproductive age to ensure optimal health and improve pregnancy outcomes.[17] Almost half of all pregnancies in the United States are unintended. Preconception planning is important, since some behaviors and exposures impart risk to the fetus during the first trimester, often before prenatal care is begun or even before pregnancy is detected. **Table 78-1** lists selected preconception risk factors, the potential adverse pregnancy outcomes, and management or prevention options.

TABLE 78-1 Selected Preconception Risk Factors for Adverse Pregnancy Outcomes

Preconception Risk Factor	Potential Adverse Pregnancy Outcomes	Management or Prevention Options
Use of known teratogens		
• Antiepileptic drugs	• Known teratogens; causes craniofacial, cardiac, and limb defects[a] • NTD • Fetal hydantoin syndrome	• Use lowest possible dose to maintain control • Folic acid 4 mg daily
• Isotretinoins	• Miscarriage • Known teratogen; causes CNS, craniofacial, and cardiac defects[a]	• Use effective pregnancy prevention

Preconception Risk Factor	Potential Adverse Pregnancy Outcomes	Management or Prevention Options
• Oral anticoagulants	• Fetal warfarin syndrome	• Switch to nonteratogenic anticoagulant (eg, LMWH) before becoming pregnant
Lifestyle factors		
• Alcohol misuse	• Fetal alcohol syndrome	• Cease alcohol intake before conception
• Obesity	• NTD • Preterm delivery • Diabetes, HTN, VTE • Cesarean section	• Weight loss with appropriate nutritional intake before pregnancy

• Tobacco use	• Preterm birth
	• Low birth weight
	• Spontaneous abortion
	• Increased perinatal mortality
		• Ideally, cease tobacco use before conception
		• Nonpharmacologic therapies (eg, CBT, counseling, hypnosis)
		• No consensus for NRT product, dosing, or frequency:
		  ○ Intermittent forms (eg, gum)
		  ○ Transdermal patch (limit to 16 h/day)
		• Bupropion risk may be less than risk posed by smoking; efficacy unclear
		• Varenicline safety unknown

CBT, cognitive behavioral therapy; CNS, central nervous system; HTN, hypertension; LMWH, low-molecular weight heparin; NRT, nicotine replacement therapy; NTD, neural tube defect; VTE, venous thromboembolism.

[a]List is not all-inclusive.

Data from references 17,18,19,20.

The most common major congenital abnormalities are neural tube defects (NTDs), cleft palate and lip, and cardiac anomalies. Each year in the United States approximately 1 in 1,000 infants are born with NTDs.[18] Folic acid supplementation of women substantially reduces the incidence of NTDs in their offspring. This is also true in women who have previously delivered babies with NTDs.[18] NTDs occur within the first month of conception because neural tube closure occurs during the first month of pregnancy. Folic acid supplementation between 0.4 and 0.9 mg daily is recommended throughout a woman's reproductive years, since many pregnancies are unplanned and may not be recognized until after the first month.

Use of alcohol and recreational drugs during pregnancy is associated with birth defects.[17] Of births in the United States in 2003, 10% were to mothers who smoked tobacco during pregnancy.[15] Smoking can cause preterm birth, low birth weight, and other adverse outcomes. In a systematic review of 72 trials of smoking cessation and perinatal outcomes, incidences of low birth weight and preterm birth were reduced, and birth weight increased by 54 g with smoking cessation.[19] Use of nicotine replacement during pregnancy is controversial, since its use is not supported by clinical trial data; however, nicotine replacement theoretically imparts less risk than exposure to the over 4,000 chemicals found in cigarettes.[20]

PREGNANCY-INFLUENCED ISSUES

Pregnancy causes or exacerbates conditions that pregnant women commonly experience, including constipation, gastroesophageal reflux, hemorrhoids, and nausea and vomiting. Women with pregnancy-influenced gastrointestinal (GI) issues can be treated safely with lifestyle modification or medications, many of them nonprescription. Gestational diabetes, gestational hypertension, and venous thromboembolism (VTE) have the potential to cause adverse pregnancy consequences. Gestational thyrotoxicosis (GTT) is usually self-limiting.

GI Tract

5 Constipation during pregnancy is prevalent, affecting up to 40% of women and may contribute to the development or exacerbation of hemorrhoids; hemorrhoids are more prevalent in pregnant women compared with the general population.[21,22] Moderate physical exercise and increased intake of dietary fiber and fluid should be instituted first for constipation.[22] If additional treatment is needed, supplemental fiber and/or a stool softener is appropriate. Bulk-forming agents (eg, psyllium, methylcellulose, and polycarbophil) are safe for long-term use because they are not absorbed. Osmotic laxatives (eg, polyethylene glycol, lactulose, and sorbitol) and stimulant laxatives (eg, senna and bisacodyl) can also be used. Use of magnesium and sodium salts may cause electrolyte imbalance. Castor oil and mineral oil should be avoided because they cause stimulation of uterine contractions and impairment of maternal fat-soluble vitamin absorption, respectively.[21,22,23] Data supporting other management options for hemorrhoids during pregnancy are limited. Conservative treatment (ie, high dietary fiber intake, adequate oral fluid intake, and use of sitz baths) should be

tried first. Laxatives and stool softeners can be used if conservative management is inadequate for preventing or treating constipation. Topical anesthetics, skin protectants, and astringents (eg, witch hazel) can be used for anal irritation and pain. Hydrocortisone may reduce inflammation and pruritis.[22]

Between 30% and 80% of pregnant women experience gastroesophageal reflux disease. An algorithm starting with lifestyle and dietary modifications (eg, small, frequent meals; alcohol and tobacco avoidance; food avoidance before bedtime; elevation of the head of the bed) should be used.[21,24] If symptoms are not relieved, antacids (eg, aluminum, calcium, or magnesium preparations) or sucralfate are acceptable; however, sodium bicarbonate and magnesium trisilicate should be avoided. Histamine-2 (H_2) receptor blockers can be used for patients unresponsive to lifestyle changes and antacids; evidence supports the use of ranitidine and cimetidine. Literature evaluating the use of famotidine and nizatidine is limited, but they are likely safe.[24] The use of proton pump inhibitors (PPIs) during pregnancy does not appear to increase the risk of major birth defects; most data comes from use of omeprazole.[25] Since more data and clinical experience are available for H_2 antagonists, use of PPIs should be reserved for women with inadequate response to H_2 antagonists.

Nausea and vomiting of pregnancy (NVP) is estimated to affect up to 90% of pregnant women. NVP usually begins between weeks 4 and 6 of gestation and usually resolves by weeks 16 to 20; peak symptoms occur between weeks 8 and 12.[26,27] Hyperemesis gravidarum (HG; ie, unrelenting vomiting causing weight loss of more than 5% prepregnancy weight, dehydration, electrolyte imbalance, and ketonuria) occurs in 0.5% to 2% of women.[26] Dietary modifications, such as eating frequent, small, bland meals and avoiding fatty or spicy foods, may be helpful. Applying pressure at acupressure point P6 on the volar aspect of the wrist may be beneficial. Ginger has shown efficacy for hyperemesis in randomized, controlled trials and is probably safe. Pharmacotherapeutic approaches for NVP that have shown efficacy include pyridoxine (vitamin B_6), and antihistamines (including doxylamine). The American College of Obstetricians and Gynecologists (ACOG) considers pyridoxine alone or in combination with doxylamine first-line; the combination was approved by FDA in 2013.[26] Metoclopramide and phenothiazines are generally considered safe, but may cause sedation and extrapyramidal effects, including dystonia. Conflicting data exist regarding ondansetron use. While recent studies showed no increase in risk of congenital anomalies, a large case-control study found an increased risk of oral clefts. Some suggest using metoclopramide before ondansetron.[26,27] Corticosteroids may be effective for HG; use should be reserved until after the first trimester because of a small increase in the risk of oral clefts.

Gestational Diabetes

5 Gestational diabetes mellitus (GDM) is diabetes diagnosed in the second or third trimester that is not overt diabetes.[28] It develops in about 3% to 5% of pregnant women in the United States.[29] Risks of GDM are many and include fetal loss, increased risk of major malformations, and fetal macrosomia. The American Diabetes Association and a consensus panel of the International Association of Diabetes and Pregnancy Study Groups (IADPSG) recommends universal screening of pregnant women not previously diagnosed with diabetes.[28,30] At the first prenatal visit, all women considered

high-risk for diabetes (eg, obesity, glycosuria, and strong family history of diabetes) should be screened for overt diabetes which would indicate pregestational origin. Overt diabetes occurs if the A1C is greater than or equal to 6.5% (0.065; 48 mmol/mol Hgb), fasting plasma glucose (FPG) is greater than or equal to 126 mg/dL (7.0 mmol/L), or 2-hour plasma glucose 200 mg/dL (11.1 mmol/L) or greater during an oral glucose tolerance test (OGTT), or if random plasma glucose (RPG) is greater than or equal to 200 mg/dL (11.1 mmol/L) in a patient with hyperglycemic crisis or classic hyperglycemic symptoms. If overt diabetes is not diagnosed or for women not at high-risk for diabetes, screening for GDM should occur at weeks 24 to 28 using either the one-step (75-g OGTT) or two-step (50-g, 1-hour glucose challenge test followed by a 100-g, 3-hour OGTT) method.[28] **Table 78-2** summarizes screening and diagnosis of GDM.

TABLE 78-2 Screening and Diagnosis of Gestational Diabetes Mellitus

One-Step Method		**Two-Step Method**	
	75-g OGTT[a]		
Give:	*If any plasma glucose levels are met or exceeded, GDM is diagnosed*	***Step 1***:	Give 50-g GLT[b]
			≥140 mg/dL (7.8 mmol/L)
Fasting:	≥92 mg/dL (5.1 mmol/L)	1-hr:	*If plasma glucose level is met or exceeded, proceed to Step 2*
			Give 100-g OGTT
1-hr:	≥180 mg/dL (10 mmol/L)	***Step 2***:	*If two or more plasma glucose levels are met or exceeded, GDM is diagnosed*
2-hr:	≥153 mg/dL (8.5 mmol/L)		Carpenter/Coustan Method[c]
		Fasting	95 mg/dL (5.3 mmol/L)
		1-hr	180 mg/dL (10 mmol/L)
		2-hr	155 mg/dL (8.6 mmol/L)
		3-hr	140 mg/dL (7.8 mmol/L)

GLT, glucose load test; OGTT, oral glucose tolerance test.

[a]Perform with plasma glucose measurement in fasting state. Should be performed in the morning after at least 8-hours of fasting.

[b]Perform with plasma glucose measurement in nonfasting state.

[c]Carpenter and Coustan developed diagnostic criteria for gestational diabetes that lowered diagnostic plasma glucose levels compared to the National Diabetes Data Group.

Data from references 28 and 29.

Clinical Controversy...

Insulin has traditionally been the drug of choice to treat diabetes, including gestational diabetes, during pregnancy if drug therapy is indicated. Randomized, controlled trials of glyburide and metformin use in GDM have shown efficacy and short-term safety.[31] However, long-term safety data are limited, and both agents cross the placenta. ACOG considers oral medications (specifically, glyburide and metformin) and insulin equivalent in efficacy and lists all three as appropriate first-line drug treatment of GDM.[32]

Dietary modification (medical nutrition therapy), exercise, and blood glucose monitoring is considered first-line therapy for all women who have GDM, since as many as 85% of women can achieve control with these interventions alone.[31] Self-monitoring of blood glucose four times daily (fasting, and 1 or 2 hours after each meal) is recommended until normoglycemia at which time monitoring may be modified.[32] Drug therapy should be initiated if glycemic control is not achieved with lifestyle interventions. Glycemic control is preprandial capillary glucose concentrations at or below 95 mg/dL (5.3 mmol/L) along with one of the following: a 1-hour postprandial glucose at or below 140 mg/dL (7.8 mmol/L) or a 2-hour postprandial glucose of 120 mg/dL (6.7 mmol/L) or below.[31] Human insulin is the drug of choice for diabetes management during pregnancy because it does not cross the placenta. Glyburide and metformin are alternatives, but long-term safety data are limited.[31,32] The ACOG considers insulin and oral medications (specifically, glyburide and metformin) equivalent and supports either for first-line drug therapy.[32]

Evidence supporting dietary modification, self-monitored blood glucose, exercise, and pharmacologic interventions for women with GDM is largely based on one randomized clinical trial that showed reductions in perinatal morbidity (composite of death, nerve palsy, bone fracture, and shoulder dystocia) with nutritional education, blood glucose monitoring, and insulin treatment.[32,33]

Hypertensive Disorders of Pregnancy

5 Hypertensive disorders of pregnancy (HDP) complicate approximately 10% of pregnancies. Four categories of HDP are established: (1) preeclampsia-eclampsia, (2) chronic hypertension (HTN; preexisting hypertension or developing before 20 weeks of gestation), (3) chronic HTN with superimposed preeclampsia, and (4) gestational HTN (HTN without proteinuria developing after 20 weeks of gestation.[34,35] Hypertension in pregnancy is defined as either systolic blood pressure (sBP) above 140 mm Hg or diastolic blood pressure (dBP) above 90 mm Hg based upon two or more measurements at least 4 hours apart.[34] Nondrug managements of HDP center on activity restriction, stress reduction, and exercise; however, no evidence indicates that any of these approaches improves pregnancy outcome, and prolonged bed rest may increase the risk of complications (eg, venous thromboembolic disease).[36] Use of supplemental calcium 1 to 2 g/day decreases the risk of hypertension by 35% (95% CI; 19%-47%) and preeclampsia by 55% (95% CI, 35%-69%).[37] High-risk patients (those with the lowest initial calcium intake) benefited most. The ACOG states the findings are not applicable to populations with adequate calcium intake, such as in the United States.[35] Supplemental calcium may still be appropriate for some pregnant women.[36,37] Antihypertensive drug therapy is discussed under Chronic Illnesses in Pregnancy.

While preeclampsia usually develops after 20 weeks of gestation, up to 30% of chronic and gestational hypertension are complicated by preeclampsia. Preeclampsia is a multisystem syndrome that complicates 2% to 8% of pregnancies and can cause poorer outcomes, including renal failure, maternal morbidity/mortality, preterm delivery, and intrauterine growth restriction.[38,39] Risk factors for development of preeclampsia include nulliparity, previous personal or family history of preeclampsia, prepregnancy body mass index above 30 kg/m^2, tobacco use, underlying medical conditions (eg, chronic hypertension, diabetes, antiphospholipid antibodies, autoimmune disease, renal disease), multiple gestations, and ethnicity (black greater than white or Hispanic). Maternal age over 40 years is also a potential risk factor.[39,40] Diagnosis of preeclampsia includes elevated blood pressure as with HDP, and proteinuria (300 [or more] mg/24 hours, protein/creatinine ratio of at least 0.3 mg/mg (approximately 30 mg/mmol), or urine dipstick of 1+). If proteinuria is not present, new onset of any of the following with new onset HTN is indicative of preeclampsia: thrombocytopenia (count less than 100,000/µL [100 × 10^9/L]), serum creatinine above 1.1 mg/dL (97 µmol/L) or a doubling of serum creatinine, elevated liver transaminases, pulmonary edema, or cerebral or visual symptoms.[35] Signs of more severe preeclampsia include: persistent severe headache, vomiting; hyperreflexia, chest pain or dyspnea, and HELLP (hemolysis, elevated liver enzymes, low platelets).[40,41] Treatment of hypertension in women with preeclampsia depends upon the blood pressure measurement and follows the same principles discussed under Chronic Illnesses in Pregnancy. Low-dose aspirin (60-81 mg/day) beginning late in the first trimester in women at risk for preeclampsia decreases the risk of its development by 17%, which corresponds to prevention of one preeclampsia case for every 72 at-risk women treated. Decreased rates of preterm birth (8% reduction) and fetal or neonatal death (14% reduction) also result from low-dose aspirin use.[42] The only cure for preeclampsia is delivery of the placenta.[41]

Preeclampsia may progress rapidly to eclampsia, which is the occurrence of seizures superimposed on preeclampsia. Eclampsia is a medical emergency. In high-risk women (ie, previous severe preeclampsia, renal disease, autoimmune disease, diabetes, and chronic hypertension), use of low-dose aspirin prevents one case of preeclampsia for every 19 women treated.[42] Magnesium sulfate decreases the risk of progression to eclampsia by almost 60%; it is recommended to prevent eclampsia as well as treat eclamptic seizures. The usual dose of magnesium sulfate is 4 to 6 g IV over 15 to 20 minutes followed by a 2 g/h continuous infusion; duration of use varies, but the usual duration is 24 hours. Diazepam and phenytoin should be avoided.[43]

Thyroid Abnormalities

5 Pregnant women with overt hyperthyroidism should be treated with a thioamide (ie, methimazole and propylthiouracil [PTU]), and those with overt hypothyroidism should receive thyroid replacement (ie, levothyroxine).[44]

During pregnancy, stimulation of the thyroid gland may occur because of hCG's structural similarity to thyroid-stimulating hormone (TSH; thyrotropin). In some women, gestational transient thyrotoxicosis (GTT) may result. Occurrence of GTT is often associated with HG. By 20 weeks of gestation, GTT usually resolves as production of hCG declines. Treatment with antithyroid medication

is not usually needed.[44] Nausea and vomiting can be treated as for patients without this pseudo-hyperthyroid state.

Although not all women experience postpartum thyroiditis (PPT) similarly, the typical presentation is characterized by transient hyperthyroidism during the first several months postpartum, a period of transient hypothyroidism between 4 and 8 months postpartum, and, finally, euthyroidism within 1 year. The initial hyperthyroid state usually does not require treatment; however, β-blockers (propranolol, starting at 10-20 mg daily as needed) can provide symptomatic relief of adrenergic symptoms. Because PTT is from a destructive inflammation process and not overproduction of thyroid hormone, antithyroid drugs are ineffective. Levothyroxine replacement is suggested for a total of 6 to 12 months.[44] Up to one-third of women affected by PPT develop permanent hypothyroidism.

Thromboembolism

5 The risk of VTE in pregnant women is increased by fivefold to tenfold over nonpregnant women.[45] Low-molecular-weight heparin (LMWH) is recommended over unfractionated heparin (UFH) and warfarin for treatment of acute thromboembolism during pregnancy. Treatment should be continued throughout pregnancy and for 6 weeks after delivery; the minimum total duration of therapy should not be less than 3 months. Fondaparinux and injectable direct thrombin inhibitors (eg, lepirudin and bivalirudin) should be avoided unless a severe allergy to heparin (eg, heparin-induced thrombocytopenia) is present. The novel oral anticoagulants (eg, dabigatran, rivaroxaban, and apixaban) are not recommended.[45] Warfarin is not used because it causes nasal hypoplasia, stippled epiphyses, limb hypoplasia, and eye abnormalities; the risk period appears to be between 6 and 12 weeks of gestation. CNS anomalies are associated with second- and third-trimester exposure.

Recurrent VTE is divided into three categories: low risk, intermediate risk, and high risk of recurrence. Antepartum monitoring is recommended for women with a single episode of VTE who have a low risk of recurrence (ie, one transient risk factor [eg, surgery, injury, lengthy travel, or immobility]). For intermediate risk (ie, hormone-related, pregnancy-related, or unprovoked VTE) and high risk (ie, more than one unprovoked VTE or continuous risk factors), antepartum prophylaxis with LMWH plus 6-week postpartum prophylaxis with either LMWH or warfarin is recommended. Specific recommendations for thrombophilias (eg, antiphospholipid antibodies, Factor V Leiden, protein C and S deficiencies) can be found in the American College of Chest Physicians clinical practice guidelines.[45]

Women with prosthetic heart valves should receive LMWH (twice daily) or UFH (every 12 hours) during pregnancy. LMWH should be adjusted to achieve a peak anti-Xa level at 4 hours post-subcutaneous dose, while UFH treatment should target a mid-interval aPTT at least twice the control value or an anti-Xa heparin level of 0.35 to 0.7 units/mL (0.35-0.7 kU/L).[45] After a discussion of potential risks, LMWH or UFH can be used until week 13 of gestation with subsequent substitution of warfarin until the middle of the third trimester when LMWH or UFH should be resumed. In women considered very high-risk for VTE (eg, older-generation prosthetic mitral valve, and history of thromboembolism), prevention of maternal complications, such as valve thrombosis exceeds the risk

of fetal malformation; use of warfarin is appropriate until replacement with LMWH or UFH near the end of the third trimester. High-risk women with prosthetic heart valves may also receive low-dose aspirin (75-100 mg/day).[45]

ACUTE CARE ISSUES IN PREGNANCY

In some cases, the risks associated with the acute illness are magnified during pregnancy, and early screening and treatment become critical. In other cases, such as during treatment of certain sexually transmitted infections (STIs), the urgency regarding treatment comes from an increased likelihood of infection leading to preterm labor. Occasionally, common acute care issues, such as migraine headache, improve during pregnancy.

Urinary Tract Infection

6 The most common infections in pregnant and nonpregnant women are urinary tract infections (UTIs). Typically, UTIs are characterized as asymptomatic (eg, asymptomatic bacteriuria) or symptomatic (eg, lower [cystitis] or upper [pyelonephritis]). *Escherichia coli* is the primary cause of infection in 75% to 90% of cases.[46,47] Other gram-negative rods, such as *Proteus* and *Klebsiella*, as well as Group B *Streptococcus* (GBS) account for some infections. The presence of GBS in the urine indicates heavy colonization of the genitourinary tract, increasing the risk for GBS infection in the newborn.[47]

The incidence of asymptomatic bacteriuria ranges from 2% to 10%. Untreated, bacteriuria progresses to pyelonephritis in approximately 30% of pregnant women.[46,47] While no consensus regarding screening for asymptomatic bacteriuria exists, a urine culture obtained at the first prenatal visit is appropriate; some advocate a urine culture in each trimester. Use of rapid screening tests, such as dipsticks, should be avoided because of poor performance in pregnant women.[47] Acute cystitis occurs in about 1% to 3% of pregnant women. Signs and symptoms of acute cystitis include urgency, frequency, hematuria, pyuria, and dysuria.[46]

Treatment of asymptomatic bacteriuria is necessary to prevent pyelonephritis. For asymptomatic bacteriuria, the agents of choice and treatment duration are not well defined. Treatment of acute cystitis is similar to that of asymptomatic bacteriuria. Using outcomes of cure rates, recurrent infection, incidence of preterm delivery or rupture of membranes, admission to neonatal intensive care, need for change of antibiotic, or incidence of prolonged fever, antibiotic treatment has demonstrated effectiveness in treating symptomatic UTIs (including pyelonephritis) in pregnancy. No specific treatment appears superior to other commonly used treatments.[48] Treatment courses for asymptomatic bacteriuria and cystitis of 7 to 14 days are common, but shorter courses of therapy may be sufficient.

The most commonly used antibiotics to treat asymptomatic bacteriuria and cystitis are the β-lactams (including penicillins and cephalosporins) and nitrofurantoin.[48,49] β-Lactams are not known teratogens; however, the incidence of *E. coli* resistance to ampicillin and amoxicillin limits their use as

single agents. Nitrofurantoin is not active against *Proteus* species and should not be used after week 37 in patients with glucose-6-phosphate dehydrogenase deficiency because of a theoretical risk for hemolytic anemia in the neonate. Sulfa-containing drugs can contribute to the development of newborn kernicterus; use should be avoided during the last weeks of gestation. Trimethoprim is a folate antagonist and is relatively contraindicated during the first trimester because of associations with cardiovascular malformations. Regionally, increased rates of *E. coli* resistance to trimethoprim-sulfa may limit its use. Fluoroquinolones and tetracyclines are contraindicated because of potential associations with impaired cartilage development and deciduous teeth discoloration (if given after 5 months of gestation), respectively.[49]

Patients with pyelonephritis usually present with bacteriuria and systemic symptoms of costovertebral angle tenderness, dysuria, fever, flank pain, nausea, and vomiting.[46] Complications of pyelonephritis include premature delivery, low infant birth weight, hypertension, anemia, bacteremia, and transient renal failure. Hospitalization is the standard of care for pregnant women with pyelonephritis.[46,49] Inpatient therapy has included parenteral administration of second- or third-generation cephalosporins (eg, cefuroxime and ceftriaxone), ampicillin plus gentamicin, or ampicillin-sulbactam. Switching to oral antibiotics can occur after the woman is afebrile for 48 hours; however, nitrofurantoin should be avoided because it does not achieve therapeutic levels outside of the urine. Outpatient antibiotic therapy can be considered after initial inpatient observation in women who are afebrile and less than 24 weeks of gestation. The total duration of antibiotic therapy for acute pyelonephritis is 10 to 14 days.[49] Suppression therapy with nitrofurantoin can be considered for use until week 37 of gestation.[46]

Sexually Transmitted Infections

6 Sexually transmitted infections in pregnant women range from infections that may be transmitted across the placenta and infect the infant prenatally (eg, syphilis) to organisms that may be transmitted during birth and cause neonatal infection (eg, *Chlamydia trachomatis, Neisseria gonorrhoeae*, or herpes simplex virus [HSV]) to infections that pose a threat for preterm labor (eg, bacterial vaginosis [BV]). Initial screening during the first prenatal visit is recommended for human immunodeficiency virus (HIV), hepatitis B surface antigen, and syphilis. Women younger than 25 years and older women with increased risk (eg, new sex partner, two or more sex partners, non-monogamous sex partner, or sex partner with an STI) should be screened for *C. trachomatis* and gonorrhea; women at high risk for hepatitis C should also be screened during the first prenatal visit.[50] Treatment for select STIs is summarized in **Table 78-3**.

TABLE 78-3 Management of Sexually Transmitted Infections in Pregnancy

STI	Drug Name (Brand Name)	Usual Dose	Monitoring	Comments
Bacterial vaginosis	*Recommended:* Metronidazole (Flagyl)	• 500 mg by mouth two times daily × 7 days	Follow-up testing not required if symptoms resolve	No link between intravaginal clindamycin and newborn

STI	Drug Name (Brand Name)	Usual Dose	Monitoring	Comments
	OR			
	Metronidazole 0.75% gel *Alternatives[a]:* Clindamycin (Cleocin)	• 5 g intravaginally once daily × 5 days		complications Oral or vaginal preparations can be used
Chlamydia	*Recommended:* Azithromycin (Zithromax) *Alternatives[a]:* Amoxicillin (Amoxil) Erythromycin base Erythromycin ethylsuccinate	1 g by mouth × 1 dose	Test-of-cure at 3-4 weeks after therapy completion; retest all after 3 months	Gonorrheal coinfection common; both are treated concurrently Chlamydia is asymptomatic in men and women Women below age 25 years and those at high risk should be retested in the third trimester
Genital herpes	*Recommended:* Acyclovir (Zovirax) ***OR*** Valacyclovir	400 mg by mouth three times a day 500 mg by mouth twice a day	Routine serologic testing for HSV-2 is not recommended	Start treatment at 36 weeks of gestation
Gonorrhea	*Recommended:* Ceftriaxone (Rocephin) *PLUS* Azithromycin (Zithromax)	250 mg IM × 1 dose 1 g by mouth × 1 dose	Because of high reinfection rate, repeat testing for gonorrhea 3 months after treatment	Chlamydial coinfection common; both are treated concurrently Consult with infectious disease specialist if cephalosporin allergy
Syphilis[b]				

STI	Drug Name (Brand Name)	Usual Dose	Monitoring	Comments
Primary, secondary, early latent	*Recommended:* Benzathine penicillin G (Bicillin L-A)	2.4 million units IM × 1 dose; a second dose can be given 1 week after initial dose	Nontreponemal serologic evaluation[c] at 6 and 12 months	For treatment failure or reinfection, use same drug and dose but increase to 3 weekly doses unless neurosyphilis is present
Tertiary, late latent	*Recommended:* Benzathine penicillin G (Bicillin L-A)	2.4 million units IM × 3 doses at 1-week intervals	Nontreponemal serologic evaluation[c] at 6, 12, and 24 months. CSF examination may be required	Use this regimen for late latent or latent syphilis of unknown duration
Neurosyphilis	*Recommended:* Aqueous penicillin G (Pfizerpen) *Alternative[a]:* Procaine penicillin (Wycillin, Pfizerpen-AS) *PLUS* Probenecid	3-4 million units IV every 4 hours or 18-24 million units IV continuously × 10-14 days 2.4 million units IM daily × 10-14 days 500 mg by mouth four times daily × 10-14 days	If initial elevation of leukocytes in CSF, repeat CSF examination every 6 months until normalization	Consider repeat treatment if CSF leukocytes or protein do not normalize after 2 years Use alternative regimen only if compliance can be ensured
Trichomoniasis	*Recommended:* Metronidazole	2 g by mouth × 1 dose	Rescreen HIV patients at 3 months after treatment	While tinidazole is an alternative for nonpregnant women, avoid during pregnancy

CSF, cerebrospinal fluid; IM, intramuscular; STI, sexually transmitted infection.

[a]Refer to reference 50 for specific dosing recommendations.

[b]Pregnant women with history of penicillin allergy should undergo penicillin desensitization as no proven alternatives exist.

[c]Nontreponemal evaluation consists of VDRL (Venereal Disease Research Laboratory) and RPR (rapid

plasma regain).

Data from reference 50.

Syphilis

Syphilis is caused by *Treponema pallidum*; complications are many (eg, mucocutaneous lesions, altered mental status, visual and auditory abnormalities, gumma, cranial nerve palsies). For women who live in areas with a high prevalence of syphilis, are at high risk, have not been previously tested, or had positive serology in the first trimester, additional serologic testing early in the third trimester (around 28 weeks) and at delivery is recommended.[50] With the exception of neurosyphilis, which is treated with aqueous penicillin G, the drug of choice for all stages of syphilis is benzathine penicillin G. If a penicillin allergy is present, women with IgE-mediated hypersensitivity can undergo desensitization. Penicillin effectively prevents transmission to the fetus and treats the fetus, if already infected. Treatment during the second half of pregnancy may increase the risk for preterm labor and fetal distress because a Jarisch-Herxheimer reaction may occur; however, treatment should not be withheld or delayed.[50]

Chlamydia and Gonorrhea

Chlamydia is the most commonly reported STI in the United States; complications of *C. trachomatis* include pelvic inflammatory disease (PID), ectopic pregnancy, and infertility. *C. trachomatis* infects the newborn through exposure to the infected cervix during delivery. Perinatal infection most commonly causes conjunctivitis that develops 5 to 12 days postpartum. A subacute, afebrile pneumonia with an onset at ages 1 to 3 months may occur.[50]

Gonorrhea, an STI caused by *N. gonorrhoeae*, is the second-most commonly reported notifiable infection in the United States.[50] In women, recognizable symptoms may be absent initially, but gonorrheal infection can cause PID, a known risk for infertility. Perinatal gonococcal infection results from exposure to the infected cervix during birth. Symptoms usually manifest within 2 to 5 days after delivery. Milder manifestations include rhinitis, vaginitis, and urethritis. More severe presentations include ophthalmia neonatorum and sepsis.[50] Identification and treatment of the infection in neonates is crucial, as permanent sequelae such as blindness can occur.

Antimicrobial resistance rates among *N. gonorrhoeae* are increasing which has prompted the Centers for Disease Control and Prevention to remove oral cephalosporins as a preferred treatment option.[50] Coinfection with *C. trachomatis* is common; treatment of most *N. gonorrhoeae* infections includes treatment for *C. trachomatis*.[50]

Bacterial Vaginosis and Trichomoniasis

Bacterial vaginosis and trichomoniasis are STIs characterized by vaginal discharge. BV results from the lack of normal vaginal flora (ie, *Lactobacillus* species) and replacement with anaerobic bacteria, mycoplasmas, and *Gardnerella vaginalis*.[50] It is a risk factor for premature rupture of membranes,

preterm labor, preterm birth, intraamniotic infection, and postpartum endometritis. In women at high or low risk for preterm delivery, data to support routine screening for asymptomatic BV at the first prenatal visit are equivocal.[50]

Trichomoniasis is caused by the protozoa, *Trichomonas vaginalis*. Infection with *T. vaginalis* is associated with an increased risk of premature rupture of the membranes, preterm delivery, and low birth weight. Treatment may prevent respiratory or genital infection in the neonate.[50]

Genital Herpes

Genital herpes is a chronic disease most frequently caused by herpes simplex virus-2 (HSV-2), although the number of anogenital herpes infections caused by HSV-1 is increasing. Neonatal herpes often occurs in infants born to women lacking histories of genital herpes. The risk of neonatal transmission is under 1% for women with a history of recurrent herpes at term or those who acquire herpes in the first half of pregnancy, but is 30% to 50% for women who initially acquire genital herpes near term.[50] However, because recurrent herpes occurs more commonly than new acquisition during pregnancy, it remains the cause for most cases of neonatal transmission. Prevention strategies include counseling uninfected women to avoid intercourse during the third trimester with partners having known or suspected genital herpes infection. Women with no history of orolabial herpes should avoid receptive oral sex during the third trimester with partners who have orolabial herpes. Prevention of genital herpes transmission to pregnant women using antiviral agents has not been studied.[50]

All women should be asked about symptoms of genital herpes at the time of delivery and should be examined for lesions. Women who have no symptoms (including prodromal symptoms) or lesions proceed with vaginal childbirth; however, those with evidence of an outbreak undergo cesarean section to decrease the risk of neonatal transmission.[50]

Maternal use of acyclovir during the first trimester has not demonstrated an increased risk for birth defects. Valacyclovir is an alternative, but is more expensive.[50] For initial or recurrent episodes, most women receive oral acyclovir therapy; IV acyclovir is reserved for severe infections. In women seropositive for HSV but who have not experienced an outbreak, no data suggest a treatment benefit.[50]

Headache

6 Primary headaches (eg, tension and migraine) in pregnant and nonpregnant women are the most common types of headache. Secondary headaches can also occur and include those caused by eclampsia, stroke, postdural puncture, cerebral angiopathy, and cerebral venous thrombosis.[51]

Migraine headaches are associated with estrogen fluctuations in women of childbearing age. Between 60% and 70% of pregnant women with a history of migraine headaches experience symptom improvement during pregnancy; 20% experience complete cessation. Improvement is more likely in women who have migraine without aura and in women with a history of menstrual migraine.

Women with menstrual migraine are more likely to have postpartum recurrence.[51] Tension headaches are less studied. Most women report no change in the frequency or intensity of tension headaches, and remission is possible.

Relaxation, stress management, and biofeedback are all effective nonpharmacologic treatment methods that should be attempted in pregnant women with migraines and tension headaches because these interventions pose a minimal risk. For tension headache, acetaminophen or ibuprofen can be used if nonpharmacologic treatments fail. While ibuprofen is considered safe, all NSAIDs are contraindicated in the third trimester because of the potential for premature closure of the ductus arteriosus. Aspirin should be avoided in the third trimester because, in addition to its effects on the ductus arteriosis, it can cause maternal and fetal bleeding as well as decreased uterine contractility (hence, prolonged labor). Opioids are rarely used.[51]

Pharmacologic treatment for migraines involves use of analgesics (ie, acetaminophen and ibuprofen). Opioids have been used, but may contribute to migraine-associated nausea; long-term use near term can cause neonatal withdrawal. For migraines that are not responsive to other treatments, triptans may be used; sumatriptan is the triptan of choice because for other triptans, there is relatively little information about use in pregnancy. Ergotamine and dihydroergotamine are contraindicated because of effects on uterine tone. Promethazine, prochlorperazine, and metoclopramide can be used for patients who have migraine-associated nausea.[51]

Tension-type headaches do not usually require prophylaxis. Chronic, preventive treatment is reserved for women with severe headaches (usually migraines) that are not responsive to other treatments. The agent of choice is propranolol given at the lowest effective dose. Alternatives include tricyclic antidepressants. Amitriptyline and nortriptyline (each dosed 10-25 mg by mouth daily) are preferred over the selective serotonin reuptake inhibitors (SSRI) or serotonin–norepinephrine reuptake inhibitors (SNRI) because data on safe use of these agents during pregnancy are conflicting.[51]

CHRONIC ILLNESSES IN PREGNANCY

For the majority of women and their healthcare providers, pregnancy is a new consideration for a previously diagnosed health condition. Medications used to treat the chronic illness can often be used throughout the pregnancy and during breastfeeding. See **Table 78-4** for treatment of chronic illnesses during pregnancy.

TABLE 78-4 Treatment of Chronic Illnesses in Pregnancy

Chronic Illness	Treatment	Comments
Allergic rhinitis	Intranasal corticosteroids	Budesonide and beclomethasone most widely studied intranasal corticosteroids
	Intranasal cromolyn	
	First generation antihistamines (chlorpheniramine, diphenhydramine, hydroxyzine)	Second generation antihistamines do not appear to increase fetal risk, but are less extensively studied than first generation products

Chronic Illness	Treatment	Comments
		Use of external nasal dilator, short-term topical oxymetazoline, or ICS may be preferable to oral decongestants
		Budesonide is the preferred ICS, but any may be used
Asthma	SABA (albuterol)	
Step 1 (intermittent)	SABA (albuterol)	Alternatives are cromolyn (less effective), leukotriene receptor antagonists (less experience in pregnancy), and theophylline (more potential toxicity)
Step 2 and above (persistent)	Step-appropriate ICS LABA	Systemic corticosteroids recommended to gain control in patients with most severe disease
Epilepsy	Probably Safest AEDs • Carbamazepine • Lamotrigine • Levetiracetam • Phenytoin	Polytherapy carries higher risk of major malformations than monotherapy Rates of major malformation with probably safest AEDs clusters around 2-2.5%
	Lower risk than VPA • Gabapentin • Oxcarbazepine • Zonisamide	Phenytoin, lamotrigine, and carbamazepine may cause cleft palate Phenobarbital is associated with cardiac malformations Risk for most AED-associated malformations is dose-related Emerging evidence suggests risk of structural teratogenesis with levetiracetam is low
	Significant risk greater than other AEDs • Phenobarbital • Topiramate • VPA	
HIV	Currently receiving ART: Continue current regimen if viral load is suppressed	In women currently receiving ART, antiretroviral drug resistance testing should be performed to guide ART
	AR -naïve, no evidence of	If efavirenz is part of current ART, continue use since NTDs usually occur through weeks 5-6 of

Chronic Illness	Treatment	Comments
	resistance: • Dual NRTI backbone ***PLUS*** • Ritonavir-boosted PI ***OR*** • NNRTI ***OR*** • Integrase inhibitor	gestation and pregnancy often is not recognized during that time period If ART-naïve, any regimen containing efavirenz should be initiated after first 8 weeks of pregnancy
Hypertension, chronic	Initial treatment: Labetalol Nifedipine Methyldopa	ACE inhibitors, ARBs, renin inhibitors, mineralocorticoid receptor antagonists are not recommended Atenolol has been associated with fetal growth restriction Thiazide diuretics theoretically lower the increase in plasma volume during pregnancy, but are considered second-line
Thyroid disorders	Hypothyroid Levothyroxine Hyperthyroid • PTU • Methimazole	For hypothyroidism, attain a TSH of 0.1-2.5, 0.2-3, and 0.3-3 milli-international units/L (mIU/L) in the first, second, and third trimester, respectively Use PTU in first trimester followed by switch to methimazole in second and third trimester to balance the risk of PTU-induced hepatotoxicity and methimazole embryopathy

ACE, angiotensin converting enzyme, AED, antiepileptic drug; ARB, angiotensin receptor blocker; ART, antiretroviral therapy; ICS, inhaled corticosteroid; LABA, long-acting beta agonist; NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; NTD, neural tube defects; PI, protease inhibitor; PTU, propylthiouracil; SABA, short-acting beta agonist; TSH, thyroid stimulating hormone; VPA, valproic acid.

[a]List is not all-inclusive.

Data from references 40, 44, 53,54,55, 61,62,63,64.

Allergic Rhinitis and Asthma

6 Asthma and rhinitis are common chronic illnesses in pregnancy. Asthma affects approximately 8% of pregnancies.[52] During pregnancy, almost equal proportions of patients have symptoms that worsen, improve, or remain unchanged. Diagnosis and staging of asthma during pregnancy is the

same as in nonpregnant women, although more frequent follow-up is necessary because of changes in disease severity.[53,54] Health consequences of untreated or poorly treated asthma include preterm labor, preeclampsia, intrauterine growth restriction, premature birth, low birth weight, and stillbirth; therefore, the treatment goal is to achieve and maintain control of asthma symptoms. Asthma is controlled when there are no daytime symptoms, limitations of activities, nocturnal symptoms, short-acting β_2-agonist use, or exacerbations, and there is normal pulmonary function.[54]

Risks of medication use to the fetus are lower than the risks of untreated asthma; therefore, use of medications to achieve and maintain control is warranted. Treatment recommendations are divided into multiple steps based on symptom control and follow a stepwise approach. Once control is achieved, the goal is maintenance of control at the lowest controlling step; however, stepping down may be delayed until after delivery because of the potential effects of exacerbation on pregnancy outcomes.[53,54]

Approximately 20% of all pregnancies are impacted by allergic rhinitis. Notably, nasal congestion can be caused by pregnancy because of vascular engorgement in the nasal passages and hormonal effects on mucus secretion. Treatment strategies for allergic rhinitis during pregnancy are similar to those used in nonpregnant women and include avoidance of allergens, immunotherapy, and pharmacotherapy. Immunotherapy is not contraindicated in pregnancy, but dose increases during pregnancy are not advised in order to lessen the risk for anaphylaxis.[55,56]

Diabetes

 Poorly controlled diabetes can cause fetal malformations, fetal loss, and maternal morbidity. Women with diabetes should use effective contraception until optimal glycemic control is achieved before attempting pregnancy. Additionally, diabetic retinopathy may worsen, hypertension may develop, and renal function may deteriorate during pregnancy, requiring enhanced monitoring for these target-organ problems.[31,57]

Glycemic control can change dramatically during pregnancy; frequent adjustment to management may be needed. Medical nutrition therapy and supervised physical activity programs should continue. Self-monitored blood glucose should occur before and after meals, with occasional early morning (ie, 2-4 am) measurement.[57] For patients with type 1 diabetes, human insulin may be continued. No data have shown the use of insulin detemir and insulin glargine to cause major safety concerns in pregnancy, but studies have been small and retrospective; the available evidence supports insulin detemir as the first-line long-acting insulin analogue.[58] Glyburide and metformin are now considered first-line treatments for GDM,[32] so they may be potential alternatives for treatment of type 2 diabetes during pregnancy.

Epilepsy

 Seizure frequency does not change for most pregnant women with epilepsy. Studies have demonstrated no frequency change in 54% to 80% of women with epilepsy, while decreased

frequency ranges between 3% and 24% and increased frequency ranges from 14% to 32%.[59] Seizures may become more frequent because of changes in maternal hormones, sleep deprivation, and medication adherence problems (because of perceived teratogenic risk). Another potential cause is changes in free serum concentrations of antiepileptic drugs resulting from increased maternal volume of distribution, decreased protein binding from hypoalbuminemia, increased hepatic drug metabolism, and increased renal drug clearance. A woman's clinical condition and her free serum concentrations of antiepileptic drug should be the basis for dose adjustments.

The risks of uncontrolled seizures, particularly tonic-clonic seizures, to the fetus are considered to be greater than those associated with the antiepileptic drugs. Major malformations are two to three times more likely to occur in children born to women taking antiepileptic drugs than to those who do not.[60] Major malformations with valproic acid are dose related and range from 6% to 9%; use of valproic acid should be avoided during pregnancy to minimize the risk of NTDs (eg, spina bifida), facial clefts, and cognitive teratogenicity.[61,62]

When possible, antiepileptic drug monotherapy is recommended with medication regimen optimization occurring before conception. If gradual drug withdrawal is attempted because of epilepsy remission, it should be fully completed and evaluated before trying to conceive. Medication change to avoid use of valproic acid and phenobarbital is suggested; if either is used during pregnancy because of treatment failure with other medications, the lowest effective dose should be used.[62] All women taking antiepileptic drugs should receive folic acid supplementation: 4 to 5 mg daily starting before pregnancy and continuing through at least the first trimester, but preferably through the entire pregnancy.[60,62]

Human Immunodeficiency Virus Infection

6 The rate of perinatal HIV transmission is below 2% as a result of national recommendations for universal prenatal HIV counseling and testing, antiretroviral therapy (ART) use, cesarean delivery, and breastfeeding avoidance. The primary goal for HIV-infected women who receive combination ART and desire pregnancy is to achieve sustained viral load suppression below the limits of detection before conception and throughout pregnancy. In women newly diagnosed with HIV or who have not previously received ART, ART should be initiated as soon as pregnancy is determined since risk of perinatal transmission is lower with earlier viral suppression. The treatment regimen should be selected from those suggested for nonpregnant adults, with special consideration given to the teratogenic profile of each drug. Women currently receiving ART should be continued on their regimen provided that viral suppression below the level of detection is documented.[63] For ART-naïve women, use of a three-drug combination regimen is recommended. Recommendations regarding combination ART change frequently as new data becomes available; the clinical guidelines provided at https://aidsinfo.nih.gov are the most up-to-date.

For pregnant women with HIV RNA levels above 1,000 copies/mL (1,000 × 10^3/L) approaching delivery, scheduled cesarean section at 38 weeks of gestation is recommended to reduce the risk of perinatal HIV transmission. Scheduled cesarean section is not recommended if HIV RNA levels are

1,000 copies/mL (1,000 × 10^3/L) or below because of risks for increased complications and the low rate of perinatal transmission. If maternal viral load is greater than 1,000 copies/mL (1000 × 10^3/L) or not known, IV zidovudine should be initiated with a 1-hour loading dose (2 mg/kg) followed by a continuous infusion (1 mg/kg) for 2 hours (cesarean) or until delivery (for vaginal delivery). Zidovudine IV should still be administered in the presence of resistance to oral zidovudine. Women with a viral load at or below 1,000 copies/mL (1,000 × 10^3/L or less) near delivery do not require zidovudine IV, but should continue their ART. Specific recommendations for different clinical scenarios during antepartum, intrapartum, and postpartum are provided in the clinical guidelines.[63]

Hypertension

Typically, a physiologic decrease in blood pressure occurs during the first part of pregnancy, reaching its lowest point between 16 and 18 weeks of gestation; this decrease may mask undiagnosed hypertension. By the third trimester, blood pressure usually returns to prepregnancy levels. Hypertension occurring before 20 weeks of gestation, the use of antihypertensive medications before pregnancy, or the persistence of hypertension beyond 12 weeks postpartum defines chronic hypertension in pregnancy. It is classified as mild/nonsevere (sBP 140-159 mm Hg or dBP 90-109 mm Hg) or severe (sBP 160 mm Hg or greater or dBP 110 mm Hg or greater).[64]

Chronic hypertension can cause fetal growth restriction, maternal complications, and hospital admission. Treatment of nonsevere hypertension reduces the risk of severe hypertension by 50% but does not substantially affect fetal outcomes.[65] According to ACOG, drug therapy is recommended for women with persistent chronic hypertension with a blood pressure of 160/105 mm Hg and above. If no evidence of end-organ damage is present and sBP is below 160 mm Hg and dBP is below 105 mm Hg, pharmacologic treatment is not suggested.[35] When antihypertensive medication is used, maintenance of sBP between 120 and 160 mm Hg and dBP between 80 and 105 mm Hg is recommended.[35] No international consensus on management of chronic hypertension exists; definitions and recommendations vary.

Sustained severe hypertension in pregnancy requires treatment as maternal end organ complications, such as stroke, can occur. Lowering of blood pressure should occur over a period of hours to prevent compromise of uteroplacental blood flow. Initial choice of pharmacologic agent varies, but recommended agents are parenteral labetalol and hydralazine; however, hydralazine is associated with more maternal and fetal adverse effects. Oral nifedipine may also be used. Although still commonly used, limited evidence supports the use of magnesium sulfate to lower blood pressure except when being used concomitantly for preeclampsia. Nitroprusside, diazoxide, and nitroglycerin should be reserved for refractory hypertension in an appropriately monitored environment.[38,40]

Mental Health Conditions

Psychiatric illness affects approximately 500,000 pregnancies each year according to a practice guideline reaffirmed by ACOG in 2014.[66] Anxiety disorders, including panic disorder, obsessive-compulsive disorder, generalized anxiety disorder, posttraumatic stress disorder, social anxiety

disorder, and phobias, can cause adverse maternal and fetal outcomes such as spontaneous abortion, preterm delivery, prolonged labor, and fetal distress.[66]

Depression occurs in 14% to 23% of pregnant women. Maternal depression is associated with greater risk for premature birth, low birth weight, miscarriage, and fetal growth restriction.[67] In addition to the potential impact of maternal depression on obstetric complications, untreated depression may have long-term implications for normal infant development.[66] Up to 6.4% of Americans have bipolar disorder, with men and women equally affected; the incidence in pregnancy is unclear although perinatal episodes tend toward depressive manifestations. Schizophrenia occurs in 1% to 2% of women; however, the incidence in pregnancy is unknown. Maternal schizophrenia is associated with increased risk of perinatal death, low birth weight, small-for-gestational-age infants, cardiovascular malformations, preterm delivery, stillbirth, and infant death.[66]

Up to 70% of women with mental health conditions discontinue or refuse treatment because of concerns about teratogenicity, or because of paranoid or delusional thinking.[68] Therefore, the risks and benefits of psychotropic medication use during pregnancy must be discussed with the patient. Because most psychotropic medications are used to treat more than one condition, the reader should refer to other sources for information about treatment of specific mental health diagnoses. In general, monotherapy is preferred over polytherapy even if higher doses are required.[66]

Through 2005, the use of SSRIs was considered relatively safe. Conflicting studies about the risk of cardiac malformations with paroxetine are published in the literature; if absolute risk is increased, it appears small and clinically insignificant.[67,69] Despite this association, SSRIs are not considered major teratogens, as no consistent information supports an association with structural malformations.[67] Risks with SNRIs are less defined. Use of SSRIs and SNRIs in the latter part of pregnancy is associated with persistent pulmonary hypertension of the newborn and Prenatal Antidepressant Exposure Syndrome (encompasses cardiac, respiratory, neurological, GI, and metabolic complications from drug toxicity or withdrawal of drug therapy).[68] Tricyclic antidepressants were commonly used in pregnancy before the introduction of SSRIs and are not considered major teratogens, although they have also been associated with a neonatal withdrawal syndrome when used late in pregnancy.[66,68] Importantly, women who stop taking antidepressants are more likely to relapse, which can also have implications for the well-being of the fetus.

Studies completed over 30 years ago showed an increased risk of oral clefts with diazepam use during pregnancy; these findings were not confirmed in a meta-analysis that found the absolute risk of oral cleft changed from six cases to seven cases per 10,000 exposures (0.01%).[66] Benzodiazepine use in the third trimester can cause infant sedation and withdrawal symptoms (eg, restlessness, hypertonia, hyperreflexia, tremulousness, apnea, diarrhea, and vomiting). “Floppy baby syndrome,” consisting of low Apgar scores, hypothermia, poor muscle tone, feeding difficulties, and poor temperature adaptation, has also been described.[66]

Mood stabilizers, such as lithium, lamotrigine, carbamazepine, and valproic acid, are often used to treat bipolar disorder.[66] The reader can find information related to the safety of seizure medications used for mood stabilization in the section on epilepsy. Lithium’s place in the treatment of bipolar

disorder during pregnancy is controversial because of concerns about cardiovascular anomalies, especially Ebstein's anomaly, in exposed infants.[66] A meta-analysis calculated that the risk ratio for cardiac malformations was between 1.2 and 7.7 and for all congenital malformations was between 1.5 and 3. Stated differently, the risk for Ebstein's anomaly after prenatal lithium exposure would rise from 1:20,000 to 1:1,000; it is no longer considered a major human teratogen, but careful monitoring of serum lithium concentrations along with renal and thyroid function during pregnancy is prudent.[69,70] Other reported neonatal side effects include floppy baby syndrome, nephrogenic diabetes insipidus, hypoglycemia, cardiac arrhythmias, thyroid dysfunction, polyhydramnios, and premature delivery. Lithium may cause lethargy, hypotonia, hypothermia, cyanosis, and changes in electrocardiogram in infants exposed through breastfeeding. If breastfeeding, the infant's lithium levels, thyroid function, and complete blood count should be monitored.[66]

While neither the typical nor atypical antipsychotics have been adequately studied for the risk of adverse pregnancy outcomes, the typical antipsychotics are considered to have minimum toxic or teratogenic potential. Chlorpromazine, haloperidol, and perphenazine have long histories of use during pregnancy, with no reported significant teratogenic effect.[66] Atypical antipsychotics are considered first-line treatment for schizophrenia because of their more favorable side-effect profiles and potential increased efficacy for treating negative symptoms compared with the older agents; use has increased during pregnancy. While one systematic review found no or minimal increases in risk of major malformations with atypical antipsychotics,[69] others have found a higher rate (10% vs 2%) of low-birth-weight infants with olanzapine, clozapine, quetiapine, and risperidone compared with non-exposed infants and an increased risk of cardiovascular defects.[66,69] Atypical antipsychotics can cause weight gain, gestational diabetes, and metabolic syndrome which have implications for poorer obstetric outcomes.[69]

Thyroid Disorders

6 Universal screening for thyroid disorders during pregnancy is not recommended.[44] Hypothyroidism is present in 2 to 10 per 1,000 pregnancies. Untreated hypothyroidism increases the risk of preeclampsia, premature birth, miscarriage, and growth restriction; impaired neurological development in the fetus may also occur. Causes of hypothyroidism include autoimmune diseases (eg, Hashimoto's thyroiditis), iodine deficiency (uncommon in the United States), and thyroid dysfunction following surgery or ablative therapy for previous hyperthyroidism. If hypothyroidism is present, thyroid replacement should occur. A reasonable levothyroxine starting dose is 0.1 mg/day.[44] Women receiving thyroid replacement therapy before pregnancy may have an increased dosage requirement during pregnancy. Laboratory follow-up of TSH should occur every 4 to 6 weeks during pregnancy to allow for dose titration according to TSH levels.[44]

Hyperthyroidism affects approximately 0.2% of pregnancies and is associated with fetal death, low birth weight, intrauterine growth restriction, and preeclampsia. Graves' disease accounts for 95% of hyperthyroidism in pregnancy.[44] Therapy includes the thioamides (ie, methimazole and PTU). The risks of uncontrolled hyperthyroidism outweigh the risks of the thioamides. The goal of therapy is to attain free thyroxine concentrations near the upper limit of normal to allow for dose minimization

and to limit fetal or neonatal hypothyroidism.[44] Iodine-131 is contraindicated because of the risk of thyroid damage in the fetus.

LABOR AND DELIVERY

Management of the pregnant woman during the perinatal period often requires drug therapy for pain and for potential complications.

Preterm Labor

Preterm labor occurs between 20 and 37 weeks of gestation when changes in cervical dilation and/or effacement happen along with regular uterine contractions or when the initial presentation includes regular contractions and cervical dilation of at least 2 cm.[71] Preterm birth is the leading cause of infant morbidity and mortality with an incidence that peaked in 2006 at 12.8% in the United States. Rates decreased to 11.7% in 2011, but are still double the European rate. Risk factors for preterm delivery include previous preterm delivery, infections, multiple gestation, poverty, nonwhite race, maternal complication factors (eg, smoking and use of illicit drugs or alcohol), and uterine functional causes (eg, incompetent cervix); previous pregnancy with an adverse outcome, and prior second trimester loss confer a higher risk.[72]

No adequate tests are available for monitoring and preventing preterm labor. Monitoring of uterine activity along with intensive surveillance does not minimize risk.[71] The presence of fetal fibronectin, a glycoprotein found in cervicovaginal secretions, indicates a high risk of preterm birth. Cervical shortening is also associated with preterm delivery. Fetal fibronectin determinations and cervical ultrasound have not helped to prevent preterm labor but have been useful for their negative predictive value.[71] Bed rest and hydration do not decrease the risk of preterm birth and should not be recommended routinely; they carry risks of VTE, bone demineralization, and deconditioning.

Tocolytic Therapy

The purposes of tocolytic therapy are threefold: (a) postpone delivery long enough to allow for the maximum effect of antenatal corticosteroid administration; (b) allow for transportation of the mother to a facility equipped to deal with high-risk deliveries; and (c) prolongation of pregnancy when there are underlying, self-limited conditions that can cause labor, such as pyelonephritis or abdominal surgery, that are unlikely to cause recurrent preterm labor.[71] Tocolytics are generally not utilized beyond 34 weeks of gestation. Use of tocolytics has not reduced the number of premature deliveries. The criteria for starting tocolysis are regular uterine contractions with cervical change. Tocolytic therapy should not be used in cases of previability, intrauterine fetal demise, a lethal fetal anomaly, intrauterine infection, fetal distress, severe preeclampsia, vaginal bleeding, or maternal hemodynamic instability.[71]

Four classes of tocolytics are available in the United States: β-agonists, magnesium, calcium channel blockers, and prostaglandin inhibitors (ie, NSAIDs). All four therapies prolong pregnancy between 48

hours to 1 week; however, this prolongation is not associated with a statistically significant reduction in overall rates of respiratory distress syndrome, neonatal death, or preterm birth before 37 weeks of gestation.[73,74] Prostaglandin inhibitors and calcium channel blockers may be preferable based on the probability of delaying delivery and improving neonatal outcomes.[73]

The β-agonists terbutaline and ritodrine have been used for tocolytic therapy. Ritodrine is no longer available in the United States. Relative to other agents, β-agonists have a higher incidence of maternal side effects, including hyperkalemia, arrhythmias, hyperglycemia, hypotension, and pulmonary edema. Recommended terbutaline doses vary because its use as a tocolytic agent is off-label; a commonly used dose is 250 mcg subcutaneously which may be repeated in 15 to 30 minutes for inadequate response with a maximum of 500 mcg given in a 4-hour period.[74] A black box warning was issued in 2011 recommending against oral dosing or prolonged parenteral use (beyond 48-72 hours) because of maternal cardiotoxicity and death.[71,74]

Intravenous magnesium sulfate has been used for tocolysis; however, a Cochrane review does not support its effectiveness.[74,75] Heterogeneity of study designs and results along with small treatment arms in the included studies may partially explain this finding; however, its use remains unsupported by evidence. These findings should not affect the use of magnesium sulfate for neuroprotection. The incidence of cerebral palsy is increased in premature infants. Several studies evaluating the use of IV magnesium (6 g load followed by 2 g/h continuous infusion until delivery) during preterm labor (up to 34 weeks of gestation) found the occurrence of moderate or severe cerebral palsy was decreased by 45% to 50%.[74] Maternal side effects are rare but can include pulmonary edema. At toxic levels, hypotension, muscle paralysis, tetany, cardiac arrest, and respiratory depression may occur.[74] Magnesium undergoes renal excretion; dose adjustment is required in women with impaired renal function.

Nifedipine is associated with fewer side effects than magnesium or β-agonist therapy and decreases risk of delivery within 7 days compared to β-agonists.[73,74] One concern with the use of nifedipine is its hypotensive effect and corresponding change in uteroplacental blood flow. However, a meta-analysis showed reduced neonatal morbidity with calcium channel blocker use. With the initial diagnosis of preterm labor, nifedipine loading doses range between 10 and 40 mg with subsequent dosing of 10 and 20 mg every 4 to 6 hours with dose adjustment based on patterns of preterm contractions.[74]

Nonsteroidal antiinflammatory drugs, such as indomethacin, have been used effectively for tocolysis.[71,73,74] Oral or rectal doses of 50 to 100 mg initially, followed by an oral dose of 25 to 50 mg every 6 hours for 48 hours, have been used. An increased rate of premature constriction of the ductus arteriosus has been noted in infants with indomethacin use after 32 weeks of gestation and with use exceeding 48 hours.[74] Indomethacin may be used when tocolysis is needed despite treatment with magnesium for neuroprotection because other agents, such as calcium channel blockers and β-agonists, can cause hypotension when administered concurrently with magnesium.

Other Drug Therapies for Preterm Labor Prevention

Infection is a potential cause of preterm labor. Antibiotics have been used, in addition to tocolytics and corticosteroids, to improve the outcome of preterm labor; however, a Cochrane review showed no reduction in the incidence of preterm delivery, respiratory distress syndrome, or neonatal sepsis but a trend toward increased neonatal mortality.[71] Therefore, routine use of antibiotics is not recommended. However, if a patient experiences preterm premature rupture of membranes (PPROM) before 34 weeks of gestation, prophylactic antibiotics should be initiated because a reduction in major morbidities (ie, death, respiratory distress syndrome, early sepsis, severe intraventricular hemorrhage, and necrotizing enterocolitis) was demonstrated.[76,77] A 7-day course of broad-spectrum antibiotics should be used with the intent to prolong latency, which is the time from ruptured membranes to delivery. One recommended regimen is ampicillin (2 g IV every 6 hours) plus erythromycin (250 mg IV every 6 hours) for 48 hours, followed by amoxicillin (250 mg orally three times daily) and erythromycin base (333 mg orally every 8 hours), although multiple regimens have shown benefit.[76] Amoxicillin-clavulanate is not recommended since it causes increased rates of necrotizing enterocolitis.

Progesterone administration in the setting of prior preterm birth is based upon its effects to diminish cervical ripening (softening of the cervix necessary for cervical dilation before birth), reduce uterine wall contractility, and modulate inflammation.[72] Evidence supports progesterone supplementation to prevent spontaneous preterm birth. Use of intramuscular 17-α-hydroxyprogesterone weekly (250 mg) or vaginal progesterone suppositories (100 mg) starting between weeks 16 and 24 continued through week 36 in women with a previous spontaneous preterm birth is recommended.[78]

Clinical Controversy…

Women who present with PPROM receive, among other important interventions, antibiotic prophylaxis for 7 days to prevent chorioamnionitis and neonatal sepsis. The goal is to prolong pregnancy and reduce neonatal morbidity.[76,77] However, some evidence suggests that use of antibiotic prophylaxis may have a role in women with premature rupture of the membranes presenting at 36 weeks of gestation or more to reduce occurrence of chorioamnionitis and endometritis. Results should be interpreted cautiously since the outcomes measured were secondary endpoints and analyzed through meta-analysis of studies, all of which used different antibiotic regimens.[79]

Antenatal Corticosteroids

Use of antenatal corticosteroids for fetal lung maturation to prevent respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely is supported by a Cochrane review and recommended by ACOG.[71,80] The current clinical recommendation is to administer betamethasone 12 mg intramuscularly every 24 hours for two doses or dexamethasone 6 mg intramuscularly every 12 hours for four doses to pregnant women between 24 and 34 weeks of gestation who are at risk for preterm delivery within the next 7 days.[71] Benefits from antenatal corticosteroids are believed to begin within 24 hours.

Salvage (“rescue”) treatment administered to women at risk of delivering within 7 days but who

received a previous course of therapy is also supported by a Cochrane review. Risk of respiratory distress syndrome was lower with the administration of rescue steroids compared with placebo (risk ratio 0.83, 95% confidence interval 0.75-0.91).[81]

Group B *Streptococcus* Infection

Maternal infection with GBS is associated with invasive disease in the newborn.[82,83] Women colonized with GBS have an increased risk for pregnancy loss, premature delivery, and transmission of the bacteria to the infant during delivery. Between 10% and 30% of pregnant women are colonized with GBS. The rate of invasive infection (defined as isolation of GBS from blood or other sterile body site excluding urine) in pregnant women is 0.12 per 1,000 live births (range, 0.11-0.14 per 1,000 births). The incidence of early-onset disease in neonates, although higher than in pregnant women, has declined steadily from 1.5 per 1,000 live births in 1993 to approximately 0.24 cases per 1,000 live births in 2010. The consequences of neonatal infections include bacteremia, pneumonia, meningitis, and fatality in the newborn.[83] The case-fatality rate is approximately 4%.

Recommendations for prevention of GBS infection were last updated in 2010.[83] Universal prenatal screening for GBS colonization is recommended. Antibiotics are given if the woman previously gave birth to an infant with invasive GBS disease or in the presence of GBS bacteriuria. All other pregnant women should have a vaginal/rectal culture at 35 to 37 weeks of gestation. If negative, antibiotics are not indicated. If a woman presents in labor and no screening information is available, antibiotics are given for fever greater than 100.4°F (38°C), membrane rupture at least 18 hours prior, or gestation under 37 weeks.

Penicillin G 5 million units given IV, followed by 2.5 million units given every 4 hours until delivery is the recommended treatment regimen.[83] Alternatively, ampicillin 2 g can be given IV, followed by 1 g every 4 hours. For women with penicillin allergy but not at risk for anaphylaxis, cefazolin 2 g IV, followed by 1 g every 8 hours, is recommended. In women at high risk for anaphylaxis, clindamycin 900 mg IV every 8 hours or erythromycin 500 mg IV every 6 hours is recommended. For penicillin-allergic women, GBS cultures should be sent for sensitivities. If resistant to clindamycin or erythromycin, vancomycin 1 g IV every 12 hours until delivery is appropriate.

Cervical Ripening and Labor Induction

Throughout gestation, the cervix is closed and firm. During the last few weeks of pregnancy, the cervix softens and thins to facilitate labor. This process is mediated by hormonal changes, including final mediation by prostaglandins E_2 and $F_2\alpha$, which increase collagenase activity in the cervix leading to thinning and dilation.

The rate of pregnancy induction ranges from 9.5% to 33.5%; the most common indications for induction are postdatism (beyond 42 weeks) and pregnancy-induced hypertension, which account for 80% of inductions.[84,85,86] Other reasons for induction include suspected fetal growth retardation, maternal hypertension, premature rupture of membranes with no active onset of labor, and social factors. Contraindications include placenta previa, oblique or transverse lie, pelvic structure

abnormality, prolapsed umbilical cord, and active herpes. Concerns with induction of labor are ineffective labor and side effects, such as uterine hyperstimulation, that may adversely affect the infant and increase the likelihood of cesarean section.

Scoring systems have been used to determine the likelihood of successful labor induction. The Bishop scoring system is most commonly used and is based on five parameters: cervical dilation, cervical effacement (thinning), station of the baby's head, consistency of the cervix, and position of the cervix.[84,86] A Bishop score under six indicates the need for cervical ripening while a score above eight corresponds to a likely successful vaginal delivery.

A number of nonpharmacologic methods are used for cervical ripening. Castor oil, hot baths, sexual intercourse, and nipple stimulation all have been suggested for labor induction.[87] Minimal evidence supports the efficacy of these methods. Use of a Foley catheter placed in an unfavorable cervix for ripening has been found as effective as prostaglandin E_2. Membrane stripping is safe and inexpensive.[86]

Prostaglandin E_2 analogs (eg, dinoprostone [Prepidil gel, Cervidil vaginal insert]) are commonly used for cervical ripening. Prepidil 500 mcg is administered intracervically. The dose may be repeated after 6 hours to a maximum of three doses in 24 hours.[86] After administration, the patient remains supine for 30 minutes. Cervidil contains 10 mg dinoprostone with a slower, more constant release of medication than the gel.[86] The insert is removed when labor begins or after 12 hours. Patients must be attached to a fetal heart rate monitor for the duration of Cervidil use and for 15 minutes after its removal.[87]

Misoprostol, a prostaglandin E_1 analog, is an effective and inexpensive drug for cervical ripening and labor induction. Intravaginal administration of 25 mcg misoprostol (oral tablets are split to obtain dose) given every 3 to 6 hours is at least as effective as other prostaglandin agents and results in a shorter time to delivery.[86] Oral misoprostol has been used successfully for cervical ripening and labor induction, but the evidence for safety is more extensive with intravaginal use. The most commonly encountered side effects are uterine hyperstimulation and meconium-stained amniotic fluid. Use of misoprostol is contraindicated in women with a previous uterine scar because of its association with uterine rupture, a catastrophic medical event.

Progesterone inhibits uterine contractions. Preliminary studies show that mifepristone, an antiprogesterone agent, compared with placebo results in a shorter time to delivery and fewer cesarean sections.[88] Limited information on fetal and maternal outcomes is available because of the small sample sizes.

Oxytocin is the most commonly used agent for labor induction after cervical ripening. By the end of pregnancy, the number of oxytocin receptors has increased by 300-fold.[85,87] A solution of 10 mU/mL (10 U/L) is used for infusion. Oxytocin is effective in both low-dose (physiologic) and high-dose (pharmacologic) regimens. Refer to the ACOG practice bulletin for detailed administration information.[86]

Labor Analgesia

7 The first phase of labor occurs from onset of labor to complete cervical dilation while the second phase of labor is the period of time between complete cervical dilation and delivery. During the first phase of labor, women perceive visceral pain caused by uterine contractions. Pain in the second phase of labor is associated with perineal stretching.[89]

Nonpharmacologic Approaches to Analgesia

Women who receive continuous support from nurses, midwives, childbirth educators, or doulas (lay women trained in labor support), have fewer operative vaginal deliveries, cesarean deliveries, and requests for pain medication.[90] Warm water baths provide temporary pain relief may decrease the use of pharmacologic pain treatments, but do not decrease the rate of assisted vaginal deliveries or cesarean sections; maternal and neonatal infection, and neonatal water aspiration are potential risks. Intradermal injections of sterile water in the sacral area provide short-term decreases in back pain during labor. However, requests for pain medication did not decrease in studies. Acupuncture has also been used for pain relief. Several randomized, controlled trials have shown that acupuncture decreases the need for analgesia, but more methodologically sound studies are needed. Use of audioanalgesia (music or white noise), relaxation and breathing techniques, application of heat and cold, aromatherapy, acupressure, transcutaneous electrical nerve stimulation (TENS), and hypnosis have little to no evidence of effectiveness derived from randomized, controlled trials.[89,90]

Pharmacologic Approaches to Labor Pain Management

Maternal request alone is a sufficient medical indication for labor analgesia.[91] The two main types of pharmacologic approaches in the United States are parenteral opioids and epidural analgesia.

Parenteral opioids are commonly used to alleviate labor pain.[91] In comparison with epidural analgesia, parenteral opioids have lower rates of oxytocin augmentation, result in shorter stages of labor, and require fewer instrumental deliveries and cesarean sections for fetal distress.[92]

Approximately 60% of women in the United States choose an epidural for pain relief during labor and report better pain relief than with other analgesic modalities.[92] With epidural analgesia, a catheter is introduced into the epidural space, and an opioid and/or an anesthetic (eg, fentanyl and/or bupivacaine) is administered. Combined spinal-epidural analgesia consists of injecting a single opioid bolus into the subarachnoid space to provide instant pain relief with additional use of a local anesthetic epidural; compared with traditional epidurals, combined spinal-epidural anesthesia has a slightly shorter mean time to onset of effective analgesia.[89] Patient-controlled epidural analgesia allows the patient to control the amount and timing of the anesthetic; it results in a lower total dose of local anesthetics used over the course of labor compared with continuous epidural infusions and allows a reduction in the time between onset of pain and administration of analgesia.[93]

Side effects of the regional anesthesia include hypotension, pruritus, and inability to void. Epidural analgesia is associated with prolongation of the first and second stages of labor, higher numbers of

instrumental deliveries and cesarean sections (for fetal distress), and maternal fever.[89,92] A rare complication of epidural anesthesia is puncture of the subarachnoid space leading to a severe headache, which occurs in approximately 1% of women. Other complications include hypotension, nausea, vomiting, itching, and urinary retention.[92] Low back pain has not been associated with the use of epidural analgesia.

Postpartum Hemorrhage

7 The placenta is delivered after the delivery of the baby and is referred to as the third stage of labor. Postpartum hemorrhage (PPH) is an obstetrical emergency and is a major cause of morbidity and mortality worldwide.[94] The traditional definition of PPH is loss of more than 500 mL of blood within 24 hours of a vaginal delivery or 1,000 mL after a cesarean section; however, other definitions have also been suggested. Risk factors include retained placenta, failure to progress during the second stage of labor, placenta previa, placenta accreta, lacerations, instrumental delivery, large for gestational age newborn, hypertensive disorders, labor induction, augmentation of labor with oxytocin, prior history, maternal obesity, and preeclampsia.[94]

A stepwise approach to the treatment of PPH is advised. After the exclusion of retained products of conception and cervical and vaginal lacerations, attention should be turned to the management of uterine atony if present. The most common cause of PPH is uterine atony.[94,95] Initial management should include oxytocin. Controlled traction of the cord, which involves gently pulling on the cut umbilical cord to remove the placenta, may reduce minor PPHs but early clamping and cutting of the umbilical cord has no effect on rates of PPH.[95] Administration of a uterotonic medication (intramuscular oxytocin, ergonovine, or combination) before placental delivery and instituting active management of labor after all uncomplicated vaginal deliveries result in reduced maternal blood loss, fewer cases of PPH, and less prolongation of the third stage of labor.[95] Other uterotonic agents should be used if an inadequate response is attained with oxytocin alone. Methylergonovine, carboprost, misoprostol, and dinoprostone have all been used; less evidence is available for misoprostol and dinoprostone. Some limited evidence supports use of tranexamic acid, an antifibrinolytic agent. If uterotonic drug therapies fail to control the bleeding, uterine artery embolization, intrauterine balloon catheters, or a variety of different surgical techniques can be used.[94,95]

POSTPARTUM ISSUES

Drug Use During Lactation

8 A wide variety of benefits (eg, health, nutritional, immunologic, psychological, economic, developmental, and social) are imparted by breastfeeding to infants, mothers, and the family. Women should breastfeed exclusively for 6 months and continue until at least 12 months of age while other foods are introduced.[96] Healthy People 2020 increased targets for breastfeeding to 81.9% of neonates at the time of birth and to 60.5% for infants being breastfed at 6 months.[96]

Adequate milk removal from the breast by breastfeeding or pumping is necessary to maintain or increase milk production.[97] Relactation is the process of increasing the breast milk supply for women whose milk has not "come in," who have inadequate milk production despite appropriate breastfeeding frequency or pumping, or who have weaned or never breastfed after delivery. Metoclopramide can be used if nonpharmacologic measures are ineffective because of its stimulation of prolactin secretion. The most common dose is 10 mg orally three times daily for 7 to 14 days.[97] Breast milk production may decrease after metoclopramide therapy is stopped, but production will continue if lactation has been established successfully.

Most drugs transfer into breast milk, but breastfeeding may be continued in most circumstances. Healthcare providers should encourage breastfeeding women who require medications to continue breastfeeding whenever possible. Passive diffusion is the primary mechanism for drug transfer into breast milk, but other drug-related factors influence drug transfer from maternal circulation into breast milk, including (a) degree of protein binding in maternal plasma, (b) molecular weight, (c) lipid solubility (and corresponding fat content of milk), (d) maternal plasma concentration, (e) drug half-life, and (f) drug pH.[98] The degree of protein binding to maternal plasma proteins is one of the most significant factors affecting drug transfer to breast milk; highly bound medications transfer in low amounts. Low-molecular-weight drugs passively diffuse into breast milk, but larger molecules are not likely to transfer in large amounts. Higher lipid solubility of drugs also increases the likelihood of transfer. Colostrum is secreted in the first couple of days after birth and has high quantities of immunoglobulins, maternal lymphocytes, and maternal macrophages. While greater amounts of drugs are present in colostrum, the amount received by the nursing infant is minimal because of the limited volume of colostrum produced. A greater volume of mature milk is produced, but drug transfer into mature milk is lower because of tight cell-to-cell junctions. The higher the concentration of drug in the mother's serum, the higher the concentration will be in the breast milk. As the drug is metabolized and excreted by the mother, the mother's serum concentration drops, and the drug in the breast milk may redistribute back into the mother's bloodstream. Maternal plasma pH is 7.4, while the pH of breast milk ranges between 6.8 and 7. Weak bases are not ionized in the maternal circulation and easily transfer to breast milk.[98] In the lower pH of breast milk, molecules become ionized and are less likely to diffuse back into maternal circulation ("ion trapping"). Likewise, drugs with longer half-lives are more likely to maintain higher levels in breast milk, resulting in greater exposure to the infant.

Infant-related factors may also influence the amount of drug ingested through breastfeeding. Both the frequency of feedings and the amount of milk ingested are important considerations. Exclusively breastfed infants are more likely to ingest larger amounts of drugs than older infants who receive other foods. Drugs unstable in gastric acid (aminoglycosides, PPIs, heparin, and insulin) are less likely to be absorbed by infants.[98] Finally, infants may vary in their ability to metabolize and excrete ingested medication. Premature and full-term infants may not have full renal and liver function.

Strategies for reducing the risk to the infant include selection of medications that would be considered safe for use in the infant. Drugs with shorter half-lives accumulate less, and those that are more protein bound do not cross into breast milk as well as those that are less protein bound. Drugs with lower oral bioavailability and lower lipid solubility are good choices. If the mother is using a

once-daily medication, administration before the infant's longest sleep period may be advised to increase the interval to the next feeding. For medications taken multiple times per day, administration immediately after breastfeeding provides the longest interval for back diffusion of drug from the breast milk to the mother's serum. During short-term drug therapy, the mother can pump and discard milk to preserve her milk-producing capability if the medication is not considered compatible with breastfeeding.[99,100]

Information regarding drug use during breastfeeding is available from expert committees (eg, American Academy of Pediatrics Committee on Drugs) and evidence-based textbooks or databases (eg, LactMed [*www.toxnet.nlm.nih.gov*]). All may be of assistance in determining safe and appropriate medications to use during breastfeeding.

Mastitis

Mastitis is inflammation of the breast that occurs in 3% to 20% in lactating women.[101] It can be infectious or noninfectious; the most common cause is milk stasis. Signs and symptoms include breast tenderness, redness, warmth, flulike symptoms, and fever (temperature 101.3°F [38.5°C] or greater). Risk factors for developing mastitis include breast engorgement, plugged milk ducts, oversupply of milk, and cracked nipples.[101]

Penicillin-resistant *Staphylococcus aureus* is the most common bacterial cause of mastitis; *E. coli* and *Streptococcus* have also been implicated.[101] A 10- to 14-day course of antibiotics is usually given for treatment of mastitis; penicillinase-resistant penicillins (eg, dicloxacillin, oxacillin) and cephalosporins (eg, cephalexin) are frequently prescribed. Antiinflammatory drugs, such as ibuprofen, may provide some pain relief. Application of heat may also be helpful. Affected women should be counseled to continue breastfeeding from both breasts throughout treatment and to pump if breasts are not emptied completely with feedings.[101]

Postpartum Depression

Mood disorders in the postpartum period may include postpartum blues, postpartum depression, and postpartum psychosis.[102] Postpartum blues ("baby blues") is common, usually affecting 15% to 85% of new mothers within the first 10 days of delivery, and generally does not require treatment. Symptoms include anxiety, anger, fatigue, insomnia, tearfulness, and sadness. Postpartum psychosis is more severe and can present as mania, psychotic depression, or schizophrenia but is rare, affecting less than 1% of new mothers; hospitalization is usually indicated.[102]

Postpartum depression affects up to 13% of women, with almost 5% experiencing major depression.[102] Symptoms may develop during pregnancy or up to 6 months after delivery, although the strict definition for major depressive disorder after delivery specifies symptom occurrence within 4 to 6 weeks. Psychotherapy, including interpersonal psychotherapy, cognitive behavioral therapy, and group/family therapy, has been shown effective for treatment of postpartum depression.[102]

Some evidence suggests that the benefits to the infant of breastfeeding exceed the risks of

breastfeeding from an antidepressant-treated mother with postpartum depression. In cases where pharmacotherapy is warranted, selection of medication with low transfer to breast milk is desirable.[99] Sertraline, paroxetine, fluoxetine, and nortriptyline are the most studied in the postpartum period. A Cochrane review found that SSRIs are more likely to be effective than placebo for treatment of postpartum depression, but the evidence with tricyclic antidepressants is insufficient to assess outcome.[102]

Chapter 79: Contraception

FIGURE 79-1

Sarah P. Shrader; Kelly R. Ragucci

INTRODUCTION

KEY CONCEPTS

- 1 The attitude of the patient and sexual partner toward contraceptive methods, efficacy rate, the reliability of the patient in using the method correctly (which may affect the effectiveness of the method), noncontraceptive benefits, and the patient's ability to pay must be considered when selecting a contraceptive method.
- 2 Patient-specific factors (eg, frequency of intercourse, age, smoking status, and concomitant diseases or medications) must be evaluated when selecting a contraceptive method.
- 3 Adverse effects or difficulties using the chosen method should be monitored carefully and managed in consideration of patient-specific factors.
- 4 Accurate and timely counseling on the optimal use of the contraceptive method and strategies for minimizing sexually transmitted diseases (STDs) must be provided to all patients when contraceptives are initiated and on an ongoing basis.
- 5 Emergency contraception (EC) may prevent pregnancy after unprotected intercourse or when regular contraceptive methods have failed.

Unintended pregnancy is a significant public health problem. In the United States, approximately 6 million females become pregnant each year.[1] The most recent data reveal that 37% of pregnancies are unintended, with the highest rates occurring in women aged 20 to 34 years.[1] However, teen pregnancy rates are still an issue and slow to decline; teen births account for 11% of all the births in the United States.[1] About half of all unintended pregnancies end in abortion, and 40% occur in sexually active couples who claim they used some method of contraception.[1] If the goal of

contraception—for pregnancies to be planned and desired—is to be realized, education on the use and efficacy of contraceptive methods must be improved.

ETIOLOGY AND PATHOPHYSIOLOGY

Comprehension of the hormonal regulation of the normal menstrual cycle is essential to understanding contraception in women (**Fig. 79-1**). The cycle of menstruation begins with menarche, usually around age 12 years, and continues to occur in nonpregnant women until menopause, usually around age 50 years. Factors such as race, body weight, medical conditions, and family history can affect the menstrual cycle.[2,3] The cycle includes the vaginal discharge of sloughed endometrium called *menses*. The menstrual cycle comprises three phases: (1) follicular (or preovulatory), (2) ovulatory, and (3) luteal (or postovulatory).

FIGURE 79-1

Menstrual cycle events, idealized 28-day cycle. (FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin, LH, luteinizing hormone.)

LH: 15 mIU/mL = 15 IU/L; 50-100 mIU/mL = 50-100 IU/L.

FSH: 10-12 mIU/mL = 10-12 IU/L; 25 mIU/mL = 25 IU/L.

Estrogen: 40 pg/mL = ~150 pmol/L; 250-400 pg/mL = ~920-1,470 pmol/L; 125-250 pg/mL = ~460-920 pmol/L.

Progesterone: 1 ng/mL = 3 nmol/L; 10-15 ng/mL = ~30-50 nmol/L.

Temperatures: 99°F = 37.2°C; 98°F = 36.7°C; 97°F = 36.1°C.

The Menstrual Cycle

The first day of menses is referred to as *day 1 of the menstrual cycle* and marks the beginning of the follicular phase.[2] The follicular phase continues until ovulation, which typically occurs on day 14. The time after ovulation is referred to as the *luteal phase*, which lasts until the beginning of the next menstrual cycle. The median menstrual cycle length is 28 days, but it can range from 21 to 40 days. Generally, variation in length is greatest in the follicular phase, particularly in the years immediately after menarche and before menopause.[2]

The menstrual cycle is influenced by the hormonal relationships among the hypothalamus, anterior pituitary, and ovaries.[2] The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion.[2] These GnRH bursts stimulate the anterior pituitary to secrete bursts of gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). FSH and LH direct events in the ovarian follicles that result in the production of a fertile ovum.

Follicular Phase

In the first 4 days of the menstrual cycle, FSH levels rise and allow the recruitment of a small group of follicles for continued growth and development (see Fig. 79-1).[2] Between days 5 and 7, one follicle becomes dominant and later ruptures, releasing the oocyte. The dominant follicle develops increasing amounts of estradiol and inhibin, which cause a negative feedback on the hypothalamic secretion of GnRH and pituitary secretion of FSH, causing atresia of the remaining follicles recruited during the cycle.

Once the follicle has received FSH stimulation, it must receive continued FSH stimulation or it will die.[2] FSH allows the follicle to enlarge and synthesize estradiol, progesterone, and androgen. Estradiol stops the menstrual flow from the previous cycle, thickening the endometrial lining of the uterus to prepare it for embryonic implantation. Estrogen is responsible for increased production of thin, watery cervical mucus, which will enhance sperm transport during fertilization. FSH regulates the aromatase enzymes that convert androgens to estrogens in the follicle. If a follicle has insufficient aromatase, the follicle will not survive.

Ovulation

When estradiol levels remain elevated for a sustained period of time, the pituitary releases a midcycle LH surge (see Fig. 79-1).[2] This LH surge stimulates the final stages of follicular maturation and ovulation (follicular rupture and release of the oocyte). On average, ovulation occurs 24 to 36 hours after the estradiol peak and 10 to 16 hours after the LH peak. The LH surge, which occurs 28 to 32 hours before a follicle ruptures, is the most clinically useful predictor of approaching ovulation. After ovulation, the oocyte is released and travels to the fallopian tube, where it can be fertilized and transported to the uterus for embryonic implantation. Conception is most successful when intercourse takes place from 2 days before ovulation to the day of ovulation.

Luteal Phase

After rupture of the follicle and release of the ovum, the remaining luteinized follicles become the

corpus luteum, which synthesizes androgen, estrogen, and progesterone (see Fig. 79-1).[2] Progesterone helps to maintain the endometrial lining, which sustains the implanted embryo and maintains the pregnancy. It also inhibits GnRH and gonadotropin release, preventing the development of new follicles. If pregnancy occurs, human chorionic gonadotropin prevents regression of the corpus luteum and stimulates continued production of estrogen and progesterone secretion to maintain the pregnancy until the placenta is able to fulfill this role.

If fertilization or implantation does not occur, the corpus luteum degenerates, and progesterone production declines.[2] The life span of the corpus luteum depends on the continuous presence of small amounts of LH, and its average duration of function is 9 to 11 days. As progesterone levels decline, endometrial shedding (menstruation) occurs, and a new menstrual cycle begins. At the end of the luteal phase, when estrogen and progesterone levels are low, FSH levels start to rise, and follicular recruitment for the next cycle begins.

EPIDEMIOLOGY

Contraception implies the prevention of pregnancy following sexual intercourse by inhibiting viable sperm from coming into contact with a mature ovum (ie, methods that act as barriers or prevent ovulation) or by preventing a fertilized ovum from implanting successfully in the endometrium (ie, mechanisms that create an unfavorable uterine environment). These methods differ in their relative effectiveness, safety, and patient acceptability (**Tables 79-1** and **79-2**).[2,3]

TABLE 79-1 Pregnancy and Continuation Rates for Various Pharmacologic Contraceptive Methods

Method	Pregnancy Typical Use (%)	Pregnancy Ideal Use (%)	Continuation After 1 Year (%)
Combined oral contraceptive	9	<1	71
Combined hormonal transdermal contraceptive patch	9	<1	—
Combined hormonal vaginal contraceptive ring	9	<1	—
Depot medroxyprogesterone acetate	6	<1	70
Copper IUD	<1	<1	78
Levonorgestrel IUD	<1	<1	80
Progestin-only implant	<1	<1	88

Data from references 2 and 3.

TABLE 79-2 Comparison of Methods of Nonhormonal Contraception

	Percent of Women with Pregnancy[a]

Method	Absolute Contraindications	Advantages	Disadvantages	Perfect Use	Typical Use
Condoms, male	Allergy to latex or rubber	Inexpensive STD protection, including HIV (latex only)	High user failure rate Poor acceptance Possibility of breakage Efficacy decreased by oil-based lubricants Possible allergic reactions to latex in either partner	2	18
Condoms, female	Allergy to polyurethane History of TSS	Can be inserted just before intercourse or ahead of time STD protection, including HIV	High user failure rate Dislike ring hanging outside vagina Cumbersome	5	21
Diaphragm with spermicide	Allergy to latex, rubber, or spermicide Recurrent UTIs History of TSS Abnormal gynecologic anatomy	Low cost Decreased incidence of cervical neoplasia Some protection against STDs	High user failure rate Decreased efficacy with increased frequency of intercourse Increased incidence of vaginal yeast UTIs, TSS Efficacy decreased by oil-based lubricants	6	12
Cervical cap (FemCap)	Allergy to spermicide History of TSS Abnormal gynecologic anatomy Abnormal papanicolaou smear	Low cost Latex-free Some protection against STDs FemCap reusable for up to 2 years	Cervical irritation High user failure rate Decreased efficacy with parity Cannot be used during menses	9	16[b]
Spermicides alone	Allergy to spermicide	Inexpensive	High user failure rate	18	28

			Must be reapplied before each act of intercourse May enhance HIV transmission No protection against STDs High user failure rate		
Sponge (Today)	Allergy to spermicide Recurrent UTIs History of TSS Abnormal gynecologic anatomy	Inexpensive	Decreased efficacy with parity Cannot be used during menses No protection against STDs	9[c]	12[d]

HIV, human immunodeficiency virus; STD, sexually transmitted disease; TSS, toxic shock syndrome; UTI, urinary tract infection.

[a]Failure rates in the United States during first year of use.

[b]Failure rate with FemCap reported to be 24% per package insert.

[c]Failure rate with Today sponge reported to be 20% in parous women.

[d]Failure rate with Today sponge reported to be 32% in parous women.

Data from reference 2.

The actual effectiveness of any contraceptive method is difficult to determine because many factors affect contraceptive failure. A failure in patients who use the contraceptive agent properly is considered a method failure or perfect-use failure. It is also important to consider user failure or typical-use failure rates, which are usually higher because they take into account the user's ability to follow directions correctly and consistently.[2,3]

CLINICAL PRESENTATION

Most health maintenance annual visits should include assessment of and counseling about reproductive health. Clinicians may use this opportunity to provide contraception and educate patients on prevention of sexually transmitted diseases (STDs). Traditionally, hormonal contraception is provided subsequent to breast and pelvic examinations. However, the need for the physical examination may delay access to contraception and reinforces the incorrect perception that these

methods of contraceptives are harmful. Therefore, the American Congress of Obstetrics and Gynecology (ACOG) allow provision of hormonal contraception after a simple medical history and blood pressure measurement.[4] Other preventive measures, such as pelvic and breast examinations, provision of the human papillomavirus vaccine, and screening for cervical neoplasia, can be accomplished during routine annual office visits.

TREATMENT

Desired Outcomes

The obvious goal of treatment with all methods of contraception is to prevent pregnancy. However, many health benefits are associated with contraceptive methods, including prevention of STDs (with condoms), improvements in menstrual cycle regularity (with hormonal contraceptives), improvements in certain health conditions (with hormonal contraceptives), and management of perimenopause.[2,5]

Nonpharmacologic Therapy

Periodic Abstinence

1 2 Motivated couples may use the abstinence (rhythm) method of contraception, avoiding sexual intercourse during the days of the menstrual cycle when conception is likely to occur. Physiologic changes, such as basal body temperature and cervical mucus, are used during each cycle to determine the fertile period. The major drawbacks are the relatively high pregnancy rates and avoidance of intercourse for several days during each menstrual cycle.[2]

Barrier Techniques

1 2 The effectiveness of barrier methods depends almost exclusively on motivation to use them consistently and correctly.[2] These methods include condoms, diaphragms, cervical caps, and sponges (see Table 79-2). A major disadvantage is higher failure rates than most hormonal contraceptives; thus, provision of counseling and an advanced prescription for emergency contraception (EC) are recommended for all patients using barrier methods as their primary means of contraception.

Male condoms create a mechanical barrier, preventing direct contact of the vagina with semen, genital lesions, and infectious secretions.[2] Most condoms in the United States are made of latex, which is impermeable to viruses. A small proportion are made from lamb intestine, which is not impermeable to viruses. Synthetic condoms manufactured from polyurethane are another option; these condoms are latex-free and do protect against viruses. Condoms are used worldwide as protection from STDs including human immunodeficiency virus (HIV). When condoms are used in conjunction with any other barrier method, their effectiveness theoretically approaches 98%. Spillage of semen or perforation and tearing of the condom can occur, but proper use minimizes these problems. Mineral oil-based vaginal drug formulations (eg, Cleocin, Premarin, and Monistat), lotions, or lubricants can decrease the barrier strength of latex, thus making water-soluble lubricants (eg, Astroglide and K-Y Jelly) preferable. Condoms with spermicides are no longer recommended because

they provide no additional protection against pregnancy or STDs and may increase vulnerability to HIV.2,6,7

The female condom is a prelubricated, loose-fitting polyurethane sheath, closed at one end, with flexible rings at both ends.[2] Properly positioned, the ring at the closed end covers the cervix, and the sheath lines the walls of the vagina. The outer ring remains outside the vagina, covering the labia. The pregnancy rate is reported to be higher when compared to male condoms. Male and female condoms should not be used together, as slippage and device displacement may occur.

The diaphragm, a reusable dome-shaped rubber cap with a flexible rim that is inserted vaginally, fits over the cervix in order to decrease access of sperm to the ovum. The diaphragm requires a prescription from a clinician who has fitted the patient for the correct size.[2] Its efficacy is increased when it is used in conjunction with spermicidal cream or jelly. The diaphragm may be inserted up to 6 hours before intercourse and must be left in place for at least 6 hours afterward. However, leaving it in place for more than 24 hours is not recommended due to the potential for toxic shock syndrome (TSS). With subsequent acts of intercourse, the diaphragm should be left in place, and a condom should be used for additional protection.

The cervical cap (FemCap) is a soft, deep cup with a firm round rim that is smaller than a diaphragm and fits over the cervix like a thimble.[2] The cervical cap is available in three sizes and requires a prescription from a clinician who has fitted the patient for the correct size. It should be filled with spermicide prior to insertion. The cervical cap can be inserted 6 hours prior to intercourse and should not be removed for at least 6 hours after intercourse. It can remain in place for multiple episodes of intercourse without adding more spermicide but should not be worn for more than 48 hours at a time to reduce the risk of TSS. Failure rates are higher than with other methods. Diaphragms and cervical caps do not protect against some STDs including HIV, thus condoms should also be used.

Pharmacologic Therapy

Spermicides

1 2 Spermicides, most of which contain nonoxynol-9, are chemical surfactants that destroy sperm cell walls and act as barriers that prevent sperm from entering the cervical os.[2] They are available as creams, films, foams, gels, suppositories, sponges, and tablets. Spermicides offer no protection against STDs. In fact, when used frequently (more than two times per day), nonoxynol-9 may increase the risk of transmission of HIV by causing small disruptions in the vaginal epithelium.[2,6,7] The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) do not promote products containing nonoxynol-9 for protection against STDs.

Spermicide-Implanted Barrier Techniques

1 2 The vaginal contraceptive sponge (Today) contains 1 g of the spermicide nonoxynol-9.[2] It has a concave dimple on one side to fit over the cervix and a loop on the other side to facilitate removal. After being moistened with water, the sponge is inserted into the vagina up to 6 hours before

intercourse. The sponge provides protection for 24 hours, regardless of the frequency of intercourse during this time. After intercourse, the sponge must be left in place for at least 6 hours before removal and should not be left in place for more than 24 to 30 hours to reduce the risk of TSS. Sponges should not be reused; after removal, they should be discarded. The sponge comes in one size and is available over the counter (OTC).

Hormonal Contraception

Hormonal contraceptives contain a combination of estrogen and progestin or a progestin alone. Oral contraceptive (OC) preparations first became available in the 1960s, but options have expanded to include a transdermal patch, a vaginal contraceptive ring, and long-acting injectable, implantable, and intrauterine contraceptives.

Combined hormonal contraceptives (CHCs) contain both estrogen and progestin and work primarily before fertilization to prevent conception. Progestins provide most of the contraceptive effect by thickening cervical mucus to prevent sperm penetration, slowing tubal motility, delaying sperm transport, and inducing endometrial atrophy. Progestins block the LH surge, therefore inhibiting ovulation. Estrogens suppress FSH release from the pituitary, which may contribute to blocking the LH surge and preventing ovulation. However, the primary role of estrogen in hormonal contraceptives is to stabilize the endometrial lining and provide cycle control.[2,3]

Estrogens

Three synthetic estrogens found in hormonal contraceptives available in the United States are ethinyl estradiol (EE), mestranol, and estradiol valerate. Mestranol must be converted by the liver to EE before it is pharmacologically active and is 50% less potent than EE.[2,3] Most combined OCs, transdermal patch, and vaginal ring contain estrogen at doses of 20 to 50 mcg of EE.[3]

Progestins

A variety of progestins are available in the United States, and they vary in their progestational activity and differ with respect to inherent estrogenic, antiestrogenic, and androgenic effects.[2,3] Estrogenic and antiestrogenic properties are secondary to the extent of progestins' metabolism to estrogenic substances. Androgenic activity depends on two variables: the presence of sex hormone (testosterone) binding globulin (SHBG-TBG) and the androgen-to-progesterone activity ratio. If the amount of SHBG-TBG is decreased, free testosterone levels increase, and androgenic side effects are more prominent.[3]

Considerations with Combined Hormonal Contraceptive Use

1 When selecting a CHC, clinicians are challenged by weighing the benefits and risks associated with the many formulations available. The clinician must determine if the form of contraception is appropriate based upon the patient's lifestyle and potential adherence. A complete medical examination and papanicolaou (Pap) smear are not necessary before a CHC is prescribed. A medical

history and blood pressure measurement should be obtained before prescribing a CHC, along with a discussion of the benefits, risks, and adverse effects with each patient.[2,3,8,9] For example, OCs are associated with noncontraceptive benefits, including relief from menstruation-related problems (eg, decreased menstrual cramps, decreased ovulatory pain [mittelschmerz], and decreased menstrual blood loss), improvement in menstrual regularity, and decreased iron deficiency anemia.[5] Women who take combination OCs have a reduced risk of ovarian and endometrial cancer. There is a 50% reduction in risk in women who have used OCs for 5 years or more, and protection may persist for more than 10 years post-use. Combination OCs may also reduce the risk of ovarian cysts, ectopic pregnancy, pelvic inflammatory disease, endometriosis, uterine fibroids, and benign breast disease. The CHC transdermal patch and vaginal ring are other combined hormonal options that may be more convenient for women than taking a tablet each day.

2 3 Adverse effects may hinder adherence and therefore efficacy, so they should be discussed prior to initiating a hormonal contraceptive agent.[9] Excessive or deficient amounts of estrogen and progestin are related to the most common adverse effects.[2,3,9] An important concern regarding the use of CHCs is the lack of protection against STDs. Because of their high efficacy in preventing pregnancy, patients may choose not to use condoms. In addition to public health awareness, clinicians must encourage patients to use condoms for prevention of STDs. OCs have an extensive history of safety concerns, which traditionally were related to high dose estrogen tablets. Overall, the health risks associated with pregnancy, the specific health risks associated with CHCs, and the noncontraceptive benefits of CHCs should be factored into risk-to-benefit considerations. To replace the traditional absolute and relative contraindications to the use of OCs, the CDC developed a graded list of precautions for clinicians to consider when initiating CHCs (**Table 79-3**).[8,21]

TABLE 79-3 US Medical Eligibility Criteria for Contraceptive Use: Classifications for Combined Hormonal Contraceptives

Category 4: Unacceptable health risk (method not to be used)

- Breastfeeding or nonbreastfeeding <21 days postpartum
- Current breast cancer
- Severe (decompensated) cirrhosis
- History/risk of or current deep venous thrombosis/pulmonary embolism (not on anticoagulant therapy); thrombogenic mutations
- Major surgery with prolonged immobilization
- Migraines with aura, any age
- Systolic blood pressure ≥160 mm Hg or diastolic
- Migraines without aura, age <35 (*category 3 with continued use*)
- History of pregnancy-related cholestasis
- History of high blood pressure during pregnancy
- Benign liver tumors; focal nodular hyperplasia
- Obesity
- Breastfeeding 30 days or more postpartum
- Postpartum 21-42 days without

≥100 mm Hg

- Hypertension with vascular disease
- Current and history of ischemic heart disease
- Benign hepatocellular adenoma or malignant liver tumor
- Moderately or severely impaired cardiac function; normal or mildly impaired cardiac function <6 months
- Smoking ≥15 cigarettes per day and age ≥35
- Complicated solid organ transplantation
- History of cerebrovascular accident
- SLE; positive or unknown antiphospholipid antibodies
- Complicated valvular heart disease

Category 3: Theoretical or proven risks usually outweigh the advantages

- Breastfeeding 21-30 days postpartum with or without risk factors for VTE
- Nonbreastfeeding 21-42 days postpartum with other risk factors for VTE
- Past breast cancer and no evidence of disease for 5 years
- History of DVT/PE (not on anticoagulant therapy or established on anticoagulant therapy for at least 3 months), but lower risk for recurrent DVT/PE
- Current gallbladder disease, symptomatic and medically treated
- Migraines without aura, age ≥35 (*category 4 with continued use*)
- History of bariatric surgery; malabsorptive procedures
- History of cholestasis, past COC-related
- Hypertension; systolic blood pressure 140-159 mm

other risk factors

- Nonbreastfeeding 21-42 days postpartum without risk factors for VTE
- Rheumatoid arthritis on or off immunosuppressive therapy
- Smoking and <35 years old
- Uncomplicated sold organ transplantation
- Superficial thrombophlebitis
- Stable SLE without antiphospholipid antibodies
- Unexplained vaginal bleeding before evaluation
- Uncomplicated valvular heart disease
- Use of nonnucleoside reverse transcriptase inhibitors
- Hyperlipidemia (*possibly category 3 based upon type, severity, and other risk factors*)
- Inflammatory bowel disease (*possibly category 3 for those with increased risk of VTE*)

Category 1: No restriction (method can be used)

- Thalassemia, iron deficiency anemia
- Mild compensated cirrhosis
- Benign ovarian tumors
- Benign breast disease or family history of cancer

Hg or diastolic 90-99 mm Hg

- Normal or mildly impaired cardiac function ≥6 months
- Postpartum 21-42 days with other risk factors for VTE
- Smoking <15 cigarettes per day and age ≥35
- Use of ritonavir-boosted protease inhibitors
- Use of certain anticonvulsants (phenytoin, carbamazepine, barbiturates, primidone, topiramate, oxcarbazepine, and lamotrigine)
- Use of rifampicin or rifabutin therapy
- Diabetes with vascular disease or >20 years duration (*possibly category 4 depending upon severity*)
- Multiple risk factors for arterial cardiovascular disease (older age, smoking, diabetes, and hypertension) (*possibly category 4 depending on category and severity*)

Category 2: Advantages generally outweigh theoretical or proven risks

- Age ≥40 (in the absence of other comorbid conditions that increase CVD risk)
- Sickle-cell disease
- Undiagnosed breast mass
- Cervical cancer and awaiting treatment; cervical intraepithelial neoplasia
- Family history (first-degree relatives) of DVT/PE
- Major surgery without prolonged immobilization
- Diabetes mellitus (type 1 or type 2), nonvascular disease
- Gallbladder disease; symptomatic and treated by cholecystectomy or asymptomatic
- Family history of cancer
- Schistosomiasis
- Viral hepatitis (carrier/chronic)
- Minor surgery without immobilization
- Depression
- Gestational diabetes mellitus
- Endometrial cancer/hyperplasia, endometriosis
- Epilepsy
- Gestational trophoblastic disease
- Nonmigrainous headaches (category 2 for continued use)
- History of bariatric surgery; restrictive procedures
- History of pelvic surgery
- HIV infected or high risk
- Malaria
- Ovarian cancer
- Past ectopic pregnancy
- PID
- Postabortion
- More than 42 days postpartum
- Severe dysmenorrhea
- Sexually transmitted infections
- Varicose veins
- Thyroid disorders

- Tuberculosis
- Uterine fibroids
- Use of nucleoside reverse transcriptase inhibitors
- Use of broad-spectrum antibiotics, antifungals, and antiparasitics

CHC, combined hormonal contraception; HIV, human immunodeficiency virus; VTE, venous thromboembolism; PE, pulmonary embolism; CVD, cardiovascular disease; PID, pelvic inflammatory disease.

Data from references 8 and 21.

Women Older Than 35 Years

Use of CHC in women older than 35 is controversial. Older women, especially women in their 40s, retain a level of fertility even in the perimenopausal state and can use hormonal contraception to prevent pregnancy. Formulations with lower doses of estrogen (less than 30 mcg) have increased the use of CHCs in these women. In addition to the benefit of pregnancy prevention, they may improve or decrease the chance of developing perimenopausal and menopausal symptoms and increase bone mineral density (BMD). However, the benefits of using CHCs must be weighed against the risks in women older than 35. The increased risk of venous thromboembolism (VTE) should be considered especially in perimenopausal women older than 40. Older data suggest an increased risk of myocardial infarction (MI) in older women using CHCs, although many women in these studies were current smokers and used older formulations containing higher doses (greater than 50 mcg) of estrogen. More recent data do not support the increased risk of cardiovascular disease when low-dose formulations of CHCs are used in healthy, nonobese women. Other concerns include the increased risk of ischemic stroke in women with migraines and the increased risk of breast cancer in older women.[3,8]

The risks and benefits of using CHCs in women greater than 35 must be considered on an individual basis. It is recommended that use of CHCs (with less than 50 mcg of estrogen) may be considered in healthy nonsmoking women. CHCs should not be recommended in women older than 35 years with migraine (with or without aura), uncontrolled hypertension, smoking, or diabetes with vascular disease.[3,8]

Smoking

In early studies, OCs with 50 mcg EE or more were associated with MI in women who smoked cigarettes.[2,3] The United States case-control studies have found that both nonsmoking and smoking women, regardless of age, taking OCs with less than 50 mcg EE did not have an increased risk of MI

or stroke. However, these studies included few women older than 35 years who were smokers. European studies, with a higher population of older smoking women, demonstrated an increased risk of MI in this population. Therefore, practitioners should prescribe CHC with caution, if at all, to women older than 35 years who smoke. Smoking 15 or more cigarettes per day by women in this age group is a contraindication to CHC, and the risks generally outweigh the benefits of CHC in those who smoke fewer than 15 cigarettes per day.[8] Progestin-only contraceptive methods should be considered for women in this group.

Hypertension

CHCs can cause small increases (ie, 6-8 mm Hg) in blood pressure, regardless of estrogen dosage.[3,8] This has been documented in both normotensive and mildly hypertensive women given a 30 mcg EE OC. In case-control studies of women with hypertension, OCs have been associated with an increased risk of MI and stroke. Use of low-dose CHC is acceptable in women younger than 35 years with well-controlled and frequently monitored hypertension. If a CHC-related increase in blood pressure occurs, discontinuing the CHC usually restores blood pressure to pretreatment values within 3 to 6 months.[3] Systolic blood pressure greater than or equal to 160 mm Hg or diastolic blood pressure greater than or equal to 100 mm Hg is considered a contraindication to the use of CHCs. Hypertensive women who have a systolic blood pressure 140 to 159 or diastolic blood pressure 90 to 99 mm Hg should also avoid CHCs as the risks generally outweigh the benefits. Women with hypertension who are taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may have increased serum potassium concentrations if they are also using an OC-containing drospirenone, which has antialdosterone properties.[3]

Dyslipidemia

Generally, synthetic progestins adversely affect lipid metabolism by decreasing high-density lipoprotein (HDL) and increasing low-density lipoprotein (LDL).[3,8] Estrogens tend to have more beneficial effects by enhancing removal of LDL and increasing HDL levels. Estrogens may moderately increase triglycerides. As a net result, most low-dose CHCs have no significant impact on HDL, LDL, triglycerides, or total cholesterol. CHCs containing more androgenic progestins (eg, levonorgestrel) may result in lower HDL levels in some patients. Although the lipid effects of CHCs theoretically can influence cardiovascular risk, the mechanism of increased cardiovascular disease in CHC users is believed to be due to thromboembolic and thrombotic changes, not atherosclerosis. Women with controlled dyslipidemia can use low-dose CHCs, although periodic fasting lipid profiles are recommended. Women with uncontrolled dyslipidemia (LDL greater than 160 mg/dL [4.14 mmol/L], HDL less than 35 mg/dL [0.91 mmol/L], triglycerides greater than 250 mg/dL [2.83 mmol/L]) and additional risk factors (eg, coronary artery disease, diabetes, hypertension, smoking, or positive family history) should consider an alternative method of contraception.

Diabetes

Any effect of CHCs on carbohydrate metabolism is thought to be due to the progestin component.[3,8] However, with the exception of some levonorgestrel-containing products, formulations containing

low doses of progestins do not significantly alter insulin, glucose, or glucagon release after a glucose load in healthy women or in those with a history of gestational diabetes. The new progestins are believed to have little, if any, effect on carbohydrate metabolism. CHCs do not appear to alter the hemoglobin A_{1C} values or accelerate the development of microvascular complications in women with diabetes. Therefore, nonsmoking women younger than 35 years with diabetes but no associated vascular disease can safely use CHCs. Diabetic women with vascular disease (eg, nephropathy, retinopathy, neuropathy, or other vascular disease) or diabetes of more than 20 years' duration should not use CHCs.[3,8]

Migraine Headaches

Women with migraine headaches may experience a decreased or an increased frequency of migraine headaches when using CHCs.[3,8,10] Studies have demonstrated a higher risk of stroke in women experiencing migraine with aura compared to women with simple migraine. In population-based studies, the risk of stroke in women with migraines has been elevated twofold to threefold. However, given the low absolute risk of stroke in young women (age less than 35 years), CHCs in healthy, nonsmoking women with migraine headaches without aura may still be considered.[8] Likewise, women with nonmigrainous headaches may also use CHCs without restriction. Women of any age who have migraine with aura and women over the age of 35 with any type of migraine should not use CHC.[8] Women who develop migraines (with or without aura) while receiving CHC should discontinue use and consider a progestin-only option.

Breast Cancer

Worldwide epidemiologic data from 54 studies in 25 countries (many of which studied high dose OCs) were collected to assess the relationship between OCs and breast cancer.[3] Overall, investigators noted a small increase in the relative risk of having breast cancer diagnosed while combined OCs are taken and for up to 10 years following discontinuance. There is no increased excess risk of diagnosis 10 years or more after OCs are discontinued. Cancers diagnosed in women who used combined OCs were less advanced clinically than cancers diagnosed in women who had not used OCs. Breast cancers diagnosed in ever-users were less clinically advanced than those diagnosed in never-users for up to 20 years after discontinuing OCs. Although some studies have found differences in risk of breast cancer based on the presence of *BRCA1* and *BRCA2* mutations, the most recent cohort study found no association with low-dose OCs and the presence of either mutation. The choice to use CHCs should not be affected by the presence of benign breast disease or a family history of breast cancer with either mutation. Women with current or past history of breast cancer should not use CHCs.[2,3,8]

Thromboembolism

Estrogens increase hepatic production of factor VII, factor X, and fibrinogen in the coagulation cascade, therefore increasing the risk of thromboembolic events (eg, deep vein thrombosis and pulmonary embolism). These risks are increased in women who have underlying hypercoagulable states (eg, deficiencies in antithrombin III, protein C, and protein S; factor V Leiden mutations, prothrombin G2010 A mutations) or who have acquired conditions (eg, obesity, pregnancy,

immobility, trauma, surgery, and certain malignancies) that predispose them to coagulation abnormalities.[3,8] The incidence of thromboembolism and mortality is increased threefold in current OC users compared to nonusers. However, this risk is still less than the risk of VTE incurred during pregnancy. OCs containing newer progestins, such as drospirenone, desogestrel, and norgestimate, are associated with a slightly increased risk of thrombosis.[2,3] Although the mechanism for this increased risk is unclear, it is thought that third- and fourth-generation progestins may have a greater effect on the procoagulant, anticoagulant, and fibrinolytic pathways.[2,11,12] These progestins may also be associated with increased resistance to protein C and may increase levels of sex hormone-binding globulin.[2,11,12] It is thought that continuous, higher exposure to estrogen seen with the transdermal patch or vaginal ring is the reason for an increased thromboembolic risk with these agents as well.[11] An advisory committee to the FDA decided to change the product labeling of the transdermal patch as well as products containing drospirenone to include additional information about the increased risk of thromboembolism.[13,14] In addition, the vaginal ring also has an additional precaution in the product labeling.[15] Therefore, for women who are at an increased risk of thromboembolism (eg, older than 35 years, obesity, smoking, personal or family history of venous thrombosis, prolonged immobilization), it would be prudent to first consider low-dose oral estrogen contraceptives containing older progestins or progestin-only contraceptive methods.

Clinical Controversy…

Weighing the risk versus benefit of using CHCs containing third- and fourth-generation progestins, transdermal patch, and vaginal ring to determine their place in therapy is controversial. Third-generation progestins (eg, desogestrel and norgestimate) and a fourth-generation progestin (eg, drospirenone) have been associated with a higher risk of thromboembolism. Mechanisms underlying this increased risk may include: (a) a greater effect on the procoagulant, anticoagulant, and fibrinolytic pathways than earlier generation progestins; (b) increased resistance to the anticoagulant effect of activated protein C; (c) increased levels of sex hormone-binding globulin; and (d) antiandrogenic effects of drospirenone make the CHC more estrogenic. The overall risk of VTE with older low-dose agents is 6 per 10,000 women per year (compared with 2-3 per 10,000 in nonusers). The risk increases to 10 to 15 per 10,000 women per year with drospirenone-containing OCs. Risk of VTE is also higher with the transdermal patch (10-15 per 10,000 women per year) and possibly with the vaginal ring (8 per 10,000 women per year). It is thought that continuous, higher exposure to estrogen seen with these formulations may be the cause of this increased risk. It is important to remember that regardless of contraceptive product, the risk is still lower than the risk of thromboembolism during pregnancy (17 per 10,000 women per year).

Obesity

The prevalence of obesity continues to rise each year among all age groups including women of childbearing age. It has been hypothesized that women with increased body weight have increased basal metabolic rates and induction of hepatic enzymes, leading to increased hormonal clearance and decreased serum concentrations of hormonal contraceptives. In addition, women who are obese have more adipose tissue, increasing hormonal sequestration, and decreased free hormone serum concentrations resulting in lower efficacy.[2,3] It is estimated that there is an additional two to four

pregnancies per 100 woman-years of use in overweight or obese users.[16,17] This decreased efficacy may be a particular issue with the low-dose OCs. In addition, the transdermal contraceptive patch should not be used as a first-line option in women weighing greater than 90 kg.[14] Increased pregnancy rates have not been demonstrated in obese women using depot medroxyprogesterone acetate (DMPA) or the levonorgestrel intrauterine device (IUD). It is important to note that the CDC recommends that the benefit outweighs the potential risk of decreased efficacy in obese women.[8]

Obese women are also at risk of VTE, although studies evaluating the incidence of thromboembolism in obese women taking hormonal contraceptives have produced conflicting results. With low-dose estrogen containing products, the incidence increases from 5 to 10 cases in nonusers to 15 to 30 cases in users per 10,000 women per year. At baseline, obesity doubles the risk of thromboembolism compared to someone with a normal body mass index (BMI). ACOG suggests that progestin-only hormonal contraception may be more appropriate for obese women over the age of 35 years, and women should be counseled on the risk and consider alternative contraceptive methods on an individual basis.[17] Again, it should be noted that the risk of thromboembolism during pregnancy and in the peripartum period is significantly greater than the risk with any hormonal contraceptive agent.

Systemic Lupus Erythematosus

Contraception is important in women with systemic lupus erythematosus (SLE), because the risks associated with pregnancy are high in this population. Historically, clinicians have thought that CHCs exacerbated the symptoms of SLE. It is postulated that estrogen may cause cutaneous lupus to progress to systemic lupus by promoting B-cell hyper-responsiveness and inducing or increasing autoimmunity.[3] Trials have shown that OCs with less than 50 mcg ethinyl estradiol do not increase the risk of flare among women with stable SLE and without antiphospholipid/anticardiolipin antibodies. Because 25% of women with SLE who become pregnant choose to terminate the pregnancy, effective contraception is essential for these patients. CHCs should be avoided in women with SLE and antiphospholipid antibodies or vascular complications. Progestin-only contraceptives can be used in this situation.[8]

Oral Contraceptives

1 2 With perfect-use OCs have a 99% efficacy rate, but with typical-use up to 8% of users may become pregnant (see Table 79-1).[2,3] The OCs currently available are modifications of the original products introduced in the 1960s and contain significantly less estrogen and progestin. High-dose formulations were associated with vascular and embolic events, cancers, and significant side effects, but reductions in hormone doses have been associated with fewer complications.

Monophasic OCs contain the same amounts of estrogen and progestin for 21 days, followed by 7-day placebo phase. Multiphasic pills contain variable amounts of estrogen and progestin for 21 days, also followed by a 7-day placebo phase. There are no published data demonstrating increased safety or efficacy with the multiphasic tablets compared to monophasic tablets.[2,18,19] Extended-cycle tablets and continuous combination regimens may offer some benefits for patients in terms of side effects and convenience. With combination OCs, the types and doses of estrogen and progestin

remain constant during the 21 to 24 days that active tablets are taken, though the doses and ratios of estrogens and progestins vary from one preparation to another. The inclusion of 3 additional days of active pills to shorten the pill-free interval has been shown to reduce hormone fluctuation between menstrual cycles. With extended use of OCs, active combination tablets are taken continuously for 84 days or longer followed by 7 days of inactive pills or estrogen only pills.[3] The claimed advantage of extended cycle regimens is that patients have fewer total menstrual cycles per year, which may be helpful in those with severe premenstrual syndrome. No significant differences have been found with regard to bleeding and spotting in those with extended use.[3] **Table 79-4** lists available OC products by brand name and specifies hormonal composition.[20] Progestin-only "minipills" (28 days of active hormone per cycle) are also available options. Progestin-only OCs are less effective than combination OCs and are associated with irregular and unpredictable menstrual bleeding.[2,3] Minipills must be taken every day of the menstrual cycle at approximately the same time to maintain contraceptive efficacy. If a progestin-only OC is taken more than 3 hours late, patients should use a backup method of contraception for 48 hours.[3] Minipills may not block ovulation (nearly 40% of women continue to ovulate normally), so the risk of ectopic pregnancy is higher with their use than with other hormonal contraceptives.

TABLE 79-4 Composition of Commonly Prescribed Oral Contraceptives[a]

Product	Estrogen	Micrograms[b]	Progestin	Milligrams[b]	Spotting and Breakthrough Bleeding
50 mcg Estrogen					
Ogestrel 0.5/50	Ethinyl estradiol	50	Norgestrel	0.5	4.5
Zovia 1/50	Ethinyl estradiol	50	Ethynodiol diacetate	1	13.9

Initiating an Oral Contraceptive

4 OCs may be initiated by several different methods, including on the first day of bleeding during the menstrual cycle, on the first Sunday after the menstrual cycle begins or on the fifth day after the menstrual cycle begins. The most popular "Sunday start" method is to begin pills on the first Sunday after the menstrual cycle begins, as this may provide for weekends free of menstrual periods.[2,3,9] Women should be instructed to use a second method of contraception (typically recommend condoms) for at least 7 days after initiation for maximum effectiveness. It may be preferable to have women use additional contraception for the entire first cycle, due to user failure in the first month. In the "quick start" method for initiating OCs, the patient takes the first tablet on the day of her office visit. Women should be instructed to use a second method of contraception for at least 7 days and informed that the menstrual period will be delayed until completion of the active tablets in the current OC pack. This method has been shown to be more successful in getting women to start OCs and to continue using OCs through the third cycle of use.

Postpartum Use of CHCs

In the postpartum phase, there is concern about use of CHCs because of the mother's hypercoagulability and the effects on lactation. In the first 21 days postpartum (when the risk of thrombosis is higher), estrogen-containing hormonal contraceptives should be avoided (see Table 79-3).[8,21] If contraception is required during this period, progestin-only contraceptive methods may be acceptable alternatives. It is recommended that women who are breastfeeding avoid CHCs for the first 42 days postpartum in those with risk factors for VTE and for 30 days in those without risk factors. In those women who are not breastfeeding, CHCs should be avoided for up to 42 days postpartum in those with risk factors for VTE.[21] After 42 days postpartum, there is no restriction to the use of CHCs.

Choice of Oral Contraceptive

1 2 Because all combined OCs are similarly effective in preventing pregnancy (see Table 79-1), the initial choice is based on the hormonal content and dose, preferred formulation, and coexisting medical conditions (see Table 79-3).[3,8,20] In women without coexisting medical conditions, an OC containing 35 mcg or less of EE and less than 0.5 mg of norethindrone or an equivalent is recommended (see Table 79-4).[3] This strategy is based on evidence that complications and side effects from CHC (ie, VTE, stroke, or MI) result from excessive hormonal content. Adolescents,

underweight women (less than 50 kg [110 lb]), women older than 35 years, and those who are perimenopausal may have fewer side effects with OCs containing 20 to 25 mcg of EE.[3] With nonadherence to OCs, the risk of pregnancy may be greater in women taking OCs containing less than 35 mcg of EE. Women with oily skin, acne, or hirsutism should be given low androgenic OCs.[3] Choice of agent based upon coexisting medical conditions have been previously addressed (see Table 79-3).[8,21]

It may be easier to identify/manage side effects and easier to manipulate to alter the timing of the menstrual cycle in patients taking monophasic OCs. They are preferred over multiphasic OCs upon initiation.[2,3] Extended-cycle OCs either eliminate or reduce the number of menstrual cycles per year, leading to less premenstrual symptoms and dysmenorrhea. Commercially available extended-cycle OCs are available, or monophasic 28 day OCs can be cycled by skipping the 7-day placebo phase. With continued use of extended-cycle OCs for 1 year, no significant changes in adverse effects have been noted. However, long-term studies have not been performed to assess the risk of cancer, VTE, or changes in fertility. Continuous combination regimens provide a shortened pill-free interval, from the traditional 7 days to 2 to 4 days. These various extended-cycle regimens may be beneficial for women with symptoms such as dysmenorrhea, severe premenstrual syndrome, or menstrual migraines.

Managing Oral Contraceptive Side Effects

3 Many symptoms occurring with early OC use (eg, nausea, bloating, breakthrough bleeding) improve spontaneously by the third cycle of use after adjusting to the altered hormone levels.[2,3] Women should be counseled to continue their OC for 2 to 3 months before a change is made to adjust the hormonal content unless a serious adverse effect is present. Despite the 2 to 3 month adjustment period, a large majority of women who discontinue OCs do so because of the side effects. Patient education and early reevaluation within 3 to 6 months are necessary to identify and manage adverse effects, in an effort to improve adherence. The most common adverse effect is irregular bleeding. Women on extended-cycle regimens should be counseled to expect this during the first 6 months. For women experiencing bleeding irregularities beyond the recommended time-frame, then the estrogen or progestin content may need to be adjusted.[3,9] Serious adverse effects that may occur with the use of CHCs are listed in **Table 79-5**, and common side effects and recommended monitoring are reviewed in **Table 79-6**.[2,3,9] Patients should be instructed to immediately discontinue CHCs if they experience serious warning signs, described as ACHES (abdominal pain, chest pain, headaches, eye problems, and severe leg pain).[3]

TABLE 79-5 Symptoms of a Serious or Potentially Serious Nature of Combined Hormonal Contraception

Symptom	Possible Cause
SERIOUS: Stop immediately	
Loss of vision, proptosis, diplopia, papilledema	Retinal artery thrombosis
Unilateral numbness, weakness, or tingling	Hemorrhagic or thrombotic stroke
Severe pains in chest, left arm, or neck	Myocardial infarction

Symptom	Possible Cause
Hemoptysis	Pulmonary embolism
Severe pains, tenderness or swelling, warmth or palpable cord in legs	Thrombophlebitis or thrombosis
Slurring of speech	Hemorrhagic or thrombotic stroke
Hepatic mass or tenderness	Liver neoplasm
POTENTIALLY SERIOUS: May continue with caution while being evaluated	
Absence of menses	Pregnancy
Spotting or breakthrough bleeding	Cervical endometrial or vaginal cancer
Breast mass, pain or swelling	Breast cancer
Right upper-quadrant pain	Cholecystitis, cholelithiasis or liver neoplasm
Mid-epigastric pain	Thrombosis of abdominal artery or vein, MI or PE
Migraine headache	Vascular spasm which may precede thrombosis
Severe nonvascular headache	Hypertension, vascular spasm
Galactorrhea	Pituitary adenoma
Jaundice, pruritus	Cholestatic jaundice
Depression, sleepiness	B6 deficiency
Uterine size increase	Leiomyomata, adenomyosis, pregnancy

Data from references 2 and 3.

TABLE 79-6 Monitoring Patients Taking Hormonal Contraceptives

Drug (or Drug Class)	Adverse Drug Reactions	Monitoring Parameter	Comments
Combined hormonal contraception	Nausea/vomiting	Patient symptoms	Typically improves after two to three cycles; consider changing to lower estrogenic
	Breast tenderness	Patient symptoms	
	Weight gain	Weight	
	Acne, oily skin	Visual inspection	Consider changing to lower androgenic
	Depression, fatigue	Depression screening	
	Breakthrough bleeding/spotting	Menstrual symptoms	Data are limited and conflicting
	Application site reaction (transdermal)	Visual inspection	Consider changing to higher estrogenic
		Patient symptoms	

Drug (or Drug Class)	Adverse Drug Reactions	Monitoring Parameter	Comments
	Vaginal irritation (vaginal ring)		
Depot medroxyprogesterone acetate	Menstrual irregularities	Menstrual symptoms	
	Weight gain	Weight	Typically improves after 6 months
	Acne	Visual inspection	Data are limited and conflicting
	Hirsutism	Visual inspection	
	Depression	Depression screening	Do not routinely screen with DXA
	Decreased bone density	BMD	
Levonorgestrel IUD	Menstrual irregularities	Menstrual symptoms	Typically spotting, amenorrhea
		Cramping, pain	Prophylactic NSAIDs or local anesthetic may reduce occurrence
	Insertion-related complications	Cramping, pain, spotting, dyspareunia, missing strings	IUD strings should be checked regularly by women to ensure IUD properly placed
	Expulsion		
	Pelvic inflammatory disease	Lower abdominal pain, unusual vaginal discharge, fever	Overall risk of developing is rare, but counseling on STD prevention is important
Copper IUD	See levonorgestrel IUD above	See levonorgestrel IUD above	Menstrual irregularities are typically heavier menses with copper IUD
Progestin-only implant	Menstrual irregularities	Menstrual symptoms	
	Insertion-site reactions	Pain, bruising, skin irritation, erythema, pus, fever	Typically well-tolerated and resolve without treatment, infection is rare

BMD, Bone Mineral Density; DXA, Dual Energy X-ray Absorptiometry; IUD, Intrauternine Device; STD, Sexually Transmitted Disease.

Data from references 2 and 9.

Managing Oral Contraceptive Drug Interactions

3 The effectiveness of an OC is sometimes limited by drug interactions that interfere with GI absorption, increase intestinal motility by altering gut bacteriologic flora, and alter the metabolism, excretion, or binding of the OC.[2] The lower the dose of hormone in the OC, the greater the risk that a drug interaction will compromise its efficacy. Women should be instructed to use an additional method of contraception if there is a possibility of a drug interaction altering the efficacy of the OC.[3] Although less well documented, these recommendations generally apply to patients receiving transdermal and vaginal CHC products.

Of all antibiotics, rifampin is the one with a true documented pharmacokinetic interaction.[2,8,9] Pharmacokinetic studies of other antibiotics have not shown any consistent interaction, but case reports of individual patients have shown a reduction in EE levels when OCs are taken with tetracyclines and penicillin derivatives. Women may use their OC when also taking antimicrobials other than rifampin (or derivatives) without use of an additional nonhormonal form of contraception.[8] It is important to note the difference and always recommend that women receiving concomitant rifampin (or derivatives) and OCs be counseled on the possibility for decreased efficacy and to use an additional nonhormonal form of contraception while on the combination and for at least 7 days after the rifampin therapy has been discontinued.[8] Additional recommendations suggest using an additional nonhormonal form of contraception for up to 28 days after discontinuation.[22] Some clinicians may continue to inform women of the slight risk of decreased efficacy with other antimicrobials just to be conservative, but it is not required or supported with evidence. If a woman is going to be receiving the interacting medication for more than 2 months, it is suggested to switch oral contraception to DMPA or an IUD to avoid the interaction and eliminate the need for long-term additional nonhormonal contraception. Women receiving certain anticonvulsants for a seizure disorder should be offered another form of contraception such as DMPA or IUDs rather than OCs (see Table 79-3).[8] Some anticonvulsants (mainly phenobarbital, carbamazepine, phenytoin) induce the metabolism of estrogen and progestin, inducing breakthrough bleeding and potentially reducing contraceptive efficacy. In addition, some anticonvulsants (eg, phenytoin) are known teratogens. Use of combined OCs with lamotrigine may decrease the effectiveness of lamotrigine and increase the possibility of worsening the seizure disorder. Finally, use of certain antiretroviral therapies in combination with OCs may decrease the efficacy of the OC.[8]

Patient Instructions with Oral Contraceptives

4 Many women who take OCs are not educated properly on the appropriate use of these medications. Women should be given the package insert that accompanies all estrogen products and instructed to read it. The written patient information should be supplemented with verbal information describing the mechanism of the medication, both common and serious side effects (ie, ACHES symptoms), and management of these side effects. Although several transient self-limiting side effects often occur, the patient should be aware of the danger signals that require immediate medical attention (see Table 79-5). The benefits and risks should be discussed, including the fact that OCs provide no physical barrier to the transmission of STDs, including HIV. Detailed instructions on

when to start taking the OC should be provided. Patients should be told the importance of routine daily administration to ensure consistent plasma concentrations and improve adherence.

Missed Doses of Oral Contraceptives.

Specific instructions should be given regarding what to do if a tablet is missed. The latest recommendations from the CDC strive to balance simplicity with the best evidence.[21] For women who routinely have difficulty with adhering to daily dosing, counseling regarding other options such as the vaginal ring, transdermal patch, DMPA, implants, or IUDs should be provided. If warranted, suggesting EC may also be necessary.

If one tablet is missed or late then take the tablet as soon as remembered and continue taking the rest of the tablets as prescribed (for most women that means two tablets taken on the same day). Typically no additional nonhormonal contraception methods are warranted. If two or more consecutive tablets are missed then take one missed tablet as soon as remembered and discard the remaining missed tablets. Continue taking the OC tablets as scheduled (this means two tablets may need to be taken on the same day—ie, one of the missed tablets and one of the regularly scheduled tablets). Counsel to use additional nonhormonal contraception until tablets have been taken for 7 consecutive days. If tablets were missed in the last week of hormonal tablets then omit the hormone-free interval by finishing tablets containing hormones and then starting a new pack. Counsel to use additional nonhormonal contraception until tablets have been taken for 7 consecutive days. For all scenarios when two or more consecutive tablets are missed, consider counseling on use of EC if warranted. Additional information regarding missed doses of OCs and vaginal rings or transdermal patches can be found on the CDC website.[21] It is important to remember that handling missed or late doses of progestin-only OCs are different. If a woman forgets a tablet or is more than 3 hours late then additional nonhormonal contraception should be used for 48 hours.[8]

Vomiting and Severe Diarrhea While on Oral Contraceptives

Efficacy of OCs may be decreased when vomiting or severe diarrhea occurs, and recommendations for dosing OCs in this situation have been developed.[21] The recommendations are based on theoretical concerns and are identical to missed tablet instructions. If vomiting or diarrhea occurs for less than 48 hours then no redosing of OCs is warranted. If vomiting or diarrhea persists greater than 48 hours then continue taking tablets and use additional nonhormonal contraception until tablets have been taken for 7 consecutive days after the vomiting or diarrhea subsides. If this scenario occurs during the last week of the hormonal tablets, then finish the tablets, skip the hormone-free tablets and begin a new pack. Additional nonhormonal contraception should be used until 7 consecutive days of tablets are taken without gastrointestinal symptoms. Counsel patients on use of EC if warranted.

Discontinuing Oral Contraceptives and Return of Fertility

There is no evidence that OC use decreases subsequent fertility; there are similar findings with the transdermal patch and vaginal ring.[2] The average delay in ovulation after discontinuing OCs is 1 to 2 weeks; however, delayed ovulation is more common in women with a history of irregular menses. If

amenorrhea does continue beyond 6 months, women should be counseled to see a physician for further fertility work-up.[2,3] In the past, women were counseled to allow two to three normal menstrual periods before becoming pregnant to permit the reestablishment of menses and ovulation. However, in several large cohort and case-control studies, infants conceived in the first month after discontinuation of an OC had no greater chance of miscarriage or being born with a birth defect than those born in the general population.

Transdermal Contraceptives

1 2 A CHC is available as a transdermal patch (Ortho Evra), which includes 0.75 mg of EE and 6 mg of norelgestromin, the active metabolite of norgestimate.[2,3] Comparative trials have shown the transdermal patch to be as effective as combined OCs in patients weighing less than 90 kg. Of the 15 pregnancies reported in the clinical trials, five were among women weighing more than 90 kg; therefore, this product is not recommended as a first-line option for these women.[2,3,17] 3 Some patients experience application-site reactions, but other side effects are similar to those experienced with OCs (eg, breast discomfort, headache, and nausea).[3] A warning from the manufacturer states that women using the patch are exposed to approximately 60% more estrogen than from a typical OC containing 35 mcg of EE. Evidence suggests that higher exposure to estrogen may lead to increased thromboembolic risk, and the labeling for the contraceptive patch now contains a warning of this risk.[14] The patch should be applied to the abdomen, buttocks, upper torso, or upper arm at the beginning of the menstrual cycle and replaced every week for 3 weeks (the fourth week is patch-free).[2,3] The patch releases estrogen and progestin for 9 days. If there is delayed application for less than 48 hours since patch should have been applied or detachment less than 24 hours, a new patch should be applied immediately, or the detached patch can be reapplied, with no additional nonhormonal contraception necessary. If there is delayed application for 48 hours or more since the patch should have been applied or detachment for 24 hours or more, a new patch should be applied as soon as possible, and additional nonhormonal contraception should be utilized until the patch has been worn for 7 consecutive days. If the delayed application or detachment occurs in the third patch week, the hormone-free week should be omitted and a new patch should be applied immediately.[14,21] Users have demonstrated greater adherence with the patch than with an OC, but whether this results in reduced pregnancy rates remains to be seen. The benefits of adherence must be weighed against of the risk of increased estrogen exposure and possibility of VTE.

Vaginal Rings

1 2 The vaginal contraceptive ring contains EE and etonogestrel (NuvaRing).[15] It is a 54-mm flexible ring, 4 mm in thickness. Over a 3-week period, the ring releases approximately 15 mcg/day of EE and 120 mcg/day of etonogestrel. Comparative trials have shown the vaginal ring to be as effective as combined OCs. On the first cycle of use, the ring should be inserted on or before the fifth day of the menstrual cycle, remain in place for 3 weeks, then removed for 1 week to allow for withdrawal bleeding. The new ring should be inserted on the same day of the week as it was during the last cycle, similar to starting a new OC pack on the same day of the week. If the ring has been

displaced for less than 3 hours, a new ring should be inserted as soon as possible and kept in until the scheduled removal day. No additional nonhormonal contraception is necessary. If there is a delay of 3 or more hours, a new ring should be inserted immediately and additional nonhormonal contraception should be utilized, or intercourse should be avoided until the ring has been in place for 7 consecutive days. If the delayed reinsertion occurs during the third week of ring use, a new ring can be reinserted right away to start the next 21 day cycle. There may be some spotting or vaginal bleeding. If a woman forgets to change the ring after the third week, she can simply reinsert a new ring during the fourth week and begin a new cycle. She will still be protected, and no back up protection will be necessary.[14]

3 Side effects, precautions, and contraindications for use of the hormonal ring are similar to those for all CHCs. The most commonly reported reasons for discontinuation of use were device-related issues, such as foreign-body sensation, device expulsion, and vaginal symptoms.[14] Cycle control with the vaginal ring appears to be equal or better than with combined OCs, with a low incidence of breakthrough bleeding and spotting after the second cycle of use. Patient acceptability of the delivery system has been studied, and the majority of women do not complain of discomfort in general or during intercourse.[3,14] A potential concern is the possibility of increased VTE (8 cases per 10,000 per year vs 6 cases with most CHCs) since etonogestrel is a metabolite of desogestrel which may be associated with increased risk.[23] The ring should be inserted vaginally. In contrast to diaphragms and cervical caps, precise placement is not an issue because the hormones are absorbed anywhere in the vagina. Women should be in a comfortable position, and compress the ring between the thumb and index finger and push it into the vagina. There is no danger of inserting the ring too far because the cervix will prevent it from traveling up the genital tract. Removal of the ring is performed in a similar manner; pulling it out and discarding into the foil patch (the ring should not be flushed down the toilet).[14] Patients should be discouraged from douching, but other vaginal products, including antifungal creams and spermicides, can be used.[3,14]

Injectable Progestins

Steroid hormones provide longer-term contraception when injected into the skin. Sustained progestin exposure blocks the LH surge, thus inhibiting ovulation. Should ovulation occur, progestins reduce ovum motility in the fallopian tubes. Even if fertilization occurs, progestins thin the endometrium, reducing the chance of implantation. Progestins also thicken the cervical mucus, producing a barrier to sperm penetration. This method of contraception does not provide any protection from STDs.[2,3]

1 2 Women who may benefit from injectable progestins are those who are breastfeeding, those who are intolerant to estrogens (ie, have a history of estrogen-related headache, breast tenderness, or nausea) or those with concomitant medical conditions in which estrogen is not recommended (see Table 79-3). Additionally, injectable progestins are beneficial for women with adherence issues; they have lower failure rates than CHC methods (see Table 79-1).[2,8,20]

Depot Medroxyprogesterone Acetate

1 2 It is similar in structure to naturally occurring progesterone. DMPA (Depo-Provera) is administered every 3 months either by deep intramuscular injection in the gluteal or deltoid muscle or subcutaneously in the abdomen or thigh within 5 days of onset of menstrual bleeding.[24,25] With perfect use, the efficacy of DMPA is more than 99%; however, with typical use, 3% of women experience unintended pregnancy.[2] Although these injections may inhibit ovulation for up to 14 weeks, the dose should be repeated every 3 months (12 weeks) to ensure continuous contraception. The manufacturer recommends excluding pregnancy in women with a lapse of 13 or more weeks between injections for the intramuscular formulation or 14 or more weeks between injections for the subcutaneous formulation. Depo-Provera is available as a 150 mg/mL injection vial or prefilled syringe for IM injection and Depo-SubQ Provera 104 is available as a prefilled syringe.[24,25]Administration of both formulations of DMPA requires a medical office visit; however, studies of patient self-administration of subcutaneous DMPA have demonstrated positive results.[26]

Although no adverse effects have been documented in infants exposed to DMPA through breast milk, the manufacturer recommends not initiating DMPA until 6 weeks postpartum in breastfeeding women.[24,25] However, the CDC cites a lack of evidence supporting this claim and classifies DMPA use during this timeframe as a category 1 or 2 suggesting that the benefit may outweigh the theoretical risk.[8] Women who are not breastfeeding but require contraception can receive DMPA immediately postpartum.[8] Women with sickle-cell disease are good candidates for DMPA, as studies have demonstrated a reduction in sickle cell pain crises in women using DMPA.[8] In addition, women with seizure disorders may experience fewer seizures when taking DMPA for contraception, and there is not a concern with anticonvulsants reducing the contraceptive efficacy of DMPA.[2,8] Because return of fertility may be delayed after discontinuation of DMPA, it should not be recommended to women desiring pregnancy in the near future. The median time to conception from the first omitted dose is 10 months. Sixty-eight percent of women will be able to conceive within 12 months, 83% within 15 months, and 93% within 18 months of the last injection.[2,24,25]

3 Menstrual irregularities are the most frequent adverse effects of both formulations of DMPA and are most common in the first year of use. These irregularities include spotting, prolonged bleeding, and amenorrhea; counseling women on these possibilities is important before initiation of the method.[8,9] Women who cannot tolerate prolonged bleeding may benefit from a short course of non-steroidal anti-inflammatory drugs (NSAIDs) (for 5-7 days) during the bleeding. In addition, a short course of estrogen (if no contraindications are present) for approximately 10 to 20 days. Examples of estrogen regimens to help prolonged bleeding during DMPA include one pack of low dose combined OCs, 1 mg of oral estradiol or 0.795 to 1.25 mg of oral conjugated equine estrogen.[9] The incidence of irregular bleeding decreases from 30% in the first year to 10% thereafter. After 12 months of therapy, 55% of women report amenorrhea, with the incidence increasing to 68% after 2 years.[24,25]

Other adverse effects, including breast tenderness and depression, occur less commonly. Weight gain is a concern for many women using DMPA, and the incidence and amount gained vary widely. It has been reported that weight gain averages 1 kg annually and may not resolve until 6 to 8 months after

the last injection or patients gain 5 kg on average after using DMPA for 5 years.[2,3,24,25]

Depot medroxyprogesterone acetate has been associated with short-term bone loss in younger women of reproductive age. This potential side effect may be due to lower ovarian estrogen production that occurs when gonadotropin secretion is suppressed.[2,27] Because longitudinal studies demonstrated effects on BMD, the FDA issued a black box warning for DMPA in 2004.[24,25] It states that DMPA should be continued for more than 2 years only if other contraceptive methods are inadequate. It also states that the loss of BMD seems to be greater with increasing duration of use and may not be completely reversible. However, the majority of clinicians view the effects of DMPA on BMD (which in the majority of cases is reversible) as a surrogate marker and there are no clear data that demonstrate the effects of DMPA on fracture risk.[27,28] The ACOG and CDC continue to recommend that for most patients the benefits of DMPA outweigh the risks even when used beyond 2 years of use.[8,27] ACOG does not recommend the routine screening of BMD in most patients.[27] A discussion regarding the risks and benefits of this contraceptive option is recommended prior to initiation and with prolonged use.

Long-acting Reversible Contraception (LARC)

It refers to a category of hormonal and nonhormonal contraceptives that include IUDs and implants. This type of contraception is highly efficacious in preventing pregnancy, but the effects are quickly reversible upon removal.[29] LARC does not require effort or adherence by the patient once they are inserted. Therefore, perfect-use and typical-use efficacy rates do not differ, and the efficacy rate is similar to that of surgical options such as tubal ligation (see Table 79-1).[2,29] When compared to other methods of hormonal contraception, especially OCs, LARC methods are not used as frequently in the United States. However, increased education campaigns are demonstrating effectiveness. The use of LARC increased to 7% of all women, and in women aged 25 to 34 their use is up to 11%.[30] All women should be considered potential candidates for this method.[29,31] In the past, many clinicians offered LARC only when adherence was an issue or in women with contraindications to estrogen. Due to the high efficacy rates of LARC methods, many advocates propose that increased use may decrease unintended pregnancy rates.[29]

Subdermal Progestin Implants

1 2 Nexplanon (formerly called Implanon in the United States) is a single 4-cm-long implant, containing 68 mg of etonogestrel that is placed under the skin of the upper arm using a preloaded inserter.[2,32] Clinicians must receive training from the manufacturer prior to insertion or removal of the device. The implant releases etonogestrel at a rate of 60 mcg daily for the first month, then decreases to an average of 30 mcg daily at the end of the 3 years of recommended use. The primary mechanism of action is suppression of ovulation. When ovulation is not suppressed, etonogestrel still is effective as the progestin thickens the cervical mucus and produces an atrophic endometrium. With both perfect and typical use, the efficacy rate is over 99%.[2,32] However, in overweight and obese women weighing more than 130% of their ideal body weight, the manufacturer states the possibility of decreased efficacy. However, it is noted that overweight women were excluded from studies, and

recent small studies have not demonstrated any decreased effects.[31,32]

4 The etonogestrel implant should be inserted between days 1 and 5 of the menstrual cycle in women who have not previously used hormonal contraception.[32] If it is inserted at any other time of the menstrual cycle, then it is recommended to use an additional nonhormonal contraceptive method for 7 days. Women currently taking OCs can have the implant inserted within 7 days after taking the last active OC tablet. Women currently taking progestin-only OCs should have the implant inserted without skipping any days, on the same day that the progestin-only IUD is removed, or on the day that the DMPA injection is due. After removal, fertility returns within 30 days.

3 The major adverse effect associated with Nexplanon is irregular menstrual bleeding, which led to discontinuation of the implant in 11% of patients in clinical trials.[29,32] Women should be counseled about the risk of irregular bleeding patterns so that patients will not request early removal of Nexplanon. Some women (22%) became amenorrheic with continued use, but many continued to have prolonged bleeding and spotting (18% and 34%, respectively) and frequent bleeding (7%).[9,31,32] Women who cannot tolerate prolonged bleeding may benefit from a short course of NSAIDS (for 5-7 days) during the bleeding. In addition, a short course of estrogen (if no contraindications are present) for approximately 10 to 20 days.[9] Insertion and removal complications are rare (less than 2%).[31,32] Information from the manufacturer suggests using precaution when there is potential for drug interactions in the presence of potent CYP450 inducers (eg, rifampin, phenytoin, and carbamazepine).[32] This information conflicts with CDC recommendations; those recommendations classify combining those medications with Nexplanon as a category 2, suggesting that the benefits may outweigh the theoretical risks. However, the CDC does still recommend use of additional nonhormonal contraception or switching to DMPA or an IUD.[8]

Intrauterine Devices

1 2 There are currently four IUDs available, all are T-shaped and are medicated, one with copper (ParaGard) and three with levonorgestrel (Mirena, Skyla, and Liletta). Clinicians must receive training from the manufacturer prior to insertion or removal of the IUDs. These IUDs have several possible mechanisms of action including inhibition of sperm migration, damaging ovum or disrupting transport, and possibly damaging the fertilized ovum. Due to the presence of local progestin, the Mirena, Skyla, and Liletta IUDs have additional mechanisms of endometrial suppression and thickening cervical mucus. The most recent evidence regarding the mechanisms of action demonstrate that the contraceptive activity of IUDs occurs before implanatation.[2,29] Efficacy rates with IUDs are greater than 99% with both perfect and typical use.[2,29] IUDs should not be used in the presence of current pregnancy, current pelvic inflammatory disease, current STD, puerperal or postabortion sepsis, purulent cervicitis, undiagnosed abnormal vaginal bleeding, malignancy of genital tract, uterine anomalies or fibroids distorting uterine cavity, allergy to IUD component, or Wilson's disease (for copper IUD).[33,34] The risk of pelvic inflammatory disease among IUD users is low. There are no long-term effects on fertility, and average time to return of fertility is similar to oral contracpetives.[29,31]

3 ParaGard is a highly effective IUD that can be left in place for 10 years.[2,33] A disadvantage of ParaGard is increased menstrual blood flow and dysmenorrhea; average monthly blood loss among users increased by 35% in clinical trials. Mirena, Skyla, and Liletta are the more recently approved IUDs in the United States and contain the progestin levonorgestrel.[34,35,36] Mirena releases 20 mcg of levonorgestrel daily and can be used for 5 years.[2,34] Liletta and Skyla are the most recent IUDs to be approved and release 18 mcg and 14 mcg of levonorgestrel daily, respectively.[2,35,36] They can be left in place for 3 years. Systemically absorbed levonorgestrel is minimal and considerably less than with OCs. The levonorgestrel IUD produces its effects locally via suppression of the endometrium, causing a reduction in menstrual blood loss. In contrast to the copper IUD, menstrual flow in users of the levonorgestrel IUD is decreased, and development of amenorrhea has been observed in 20% of users in the first year and 60% in the fifth year. A disadvantage of the levonorgestrel IUD is increased spotting in the first 6 months of use; women should be counseled that the spotting will decline gradually over time.[2,34] Women who cannot tolerate prolonged bleeding may benefit from a short course of NSAIDS (for 5-7 days) during the bleeding. In addition, a short course of estrogen (if no contraindications are present) could be used for approximately 10 to 20 days.[9]

Due to the local effects on the endometrium and decrease in blood loss, Mirena has an additional indication for treatment of heavy menstrual bleeding (menorrhagia).[34] Return to fertility is rapid and typically occurs within 30 days after removal of the IUD.[29] Historically, use in nulliparous and adolescent women was considered a precaution to use of an IUD. However, recent evidence, clinical experience, and expert opinion do not preclude use in these populations. Risk versus benefits should be considered, and the woman must be counseled on the efficacy and potential adverse effects.[29,37] Strong consideration of an IUD is appropriate in this population due to high efficacy rates.[37] In addition, Skyla does not include nulliparous women as a precaution, and about 40% of patients in the clinical trials were nulliparous.[36] The influence of drug interactions on the efficacy of IUDs is not a primary concern based on manufacturer and CDC recommendations.[8,34,35,36]

Clinical Controversy...

Controversy exists regarding the potential for decreased efficacy of oral emergency contraception (both levonorgestrel and ulipristal) in overweight or obese women. No large scale studies have been designed to fully resolve the controversy. Meta-analyses of limited pooled data have suggested an association with increased body weight and decreased efficacy of oral EC.[38] The data demonstrate that there may be a decline in efficacy in women weighing greater than 75 kg. There is no effect of increased body weight on efficacy of a copper IUD. This issue is controversial because oral EC is the most widely used EC method due to its accessibility.

Emergency Contraception

5 Emergency contraception is used to prevent unwanted pregnancy after unprotected or inadequately protected sexual intercourse (eg, no contraception, condom breakage, OC nonadherence, sexual assault). Pregnancy occurs when the fertilized egg is implanted into the endometrial lining. After intercourse, implantation of the fertilized egg typically takes approximately 5

days.[39] Progestin-only and progesterone receptor modulator products are approved by the FDA and recommended as first-line EC options.[2,3,39] Insertion of the copper IUD or prescribing higher doses of combined OCs (Yuzpe method) are other options but are not widely used.

Currently, the progestin-only formulation containing levonorgestrel 1.5 mg tablet × 1 dose (currently marketed in a variety of products, including Next Choice One Dose and Plan B One Step) is approved specifically for EC in the United States.[20] Studies support that the primary mechanism of action of progestin-only EC is inhibiting or delaying ovulation, and there is no evidence that there is an effect on implantation or disrupt a fertilized egg after implantation has occurred.[39] The levonorgestrel-containing EC formulation is the regimen of choice due to availability, improved tolerability, and potentially increased efficacy rates. All formulations are now offered as one dose options, to be given within 72 hours (3 days) of unprotected intercourse. However, the earlier the medication is given, the greater the efficacy and less chance of a pregnancy. Notably, there is some evidence that this regimen may be effective for up to 5 days after unprotected intercourse; but consideration of ulipristal or a copper IUD may be a better option if a woman can get access in time.[39] Levonorgestrel-containing EC products are now available without a prescription to patients of all ages in the United States.[39]

5 Ulipristal (Ella) is the newest EC product and was approved for use by the FDA in 2010. Ulipristal is a selective progesterone receptor modulator with mixed progesterone agonist and antagonist properties.[39,40] Its mechanism of action depends on the timing of administration relative to the woman's menstrual cycle.[41] The primary mechanism of action appears to be delay of ovulation. Ulipristal is available by prescription only and is available as a single dose of 30 mg taken within 120 hours (5 days) after unprotected intercourse. Evidence supports that it maintains efficacy for the full 120-hour window.[39,40] Data exist to support noninferiority of ulipristal compared to levonorgestrel-containing EC.[42]

5 Determining the exact effectiveness rate of EC is difficult; however, the range has been reported to be between 59% and 94%.[39] Evidence reported that EC may prevent an average of 75% of expected pregnancies when taken appropriately. It is recommended that women have an advanced prescription on hand or access to an OTC formulation to maximize the effectiveness of EC.

3 Common adverse effects include nausea, vomiting, and irregular bleeding.[39] Nausea and vomiting occur significantly less when progestin-only and progesterone receptor modulator EC is administered. Many women will experience irregular bleeding regardless of which EC method is used, with the menstrual period usually occurring 1 week before or after the expected time. Routine screening prior to or after receiving progestin-only and progesterone receptor modulator EC is not recommended. If a pregnancy already exists, the EC will not disrupt or harm the embryo. Additionally, there are no contraindications to the use of these methods of EC (for the Yuzpe and copper IUD methods clinicians must adhere to their contraindications and precautions). No current data regarding the safety of repeated use EC are available, but current consensus suggests that the risks are low, and women can receive multiple regimens if warranted. Appropriate counseling should be provided regarding timing of the dose, common adverse effects, and use of a regular contraceptive

method (additional nonhormonal contraceptive methods should be used after EC for at least 7 days).

Personalized Pharmacotherapy

Selecting a contraceptive method should involve the patient and clinician using a shared decision-making model. Contraceptive pharmacotherapy should be personalized for each patient, taking into account desired outcomes from a contraceptive and noncontraceptive perspective. Factors to consider include efficacy, presence of coexisting medical conditions or medications, safety, adverse effects, cost, and patient preference of the contraceptive method (eg, long-acting, short-acting, hormonal, oral, non-oral, barrier). In addition, access to timely contraception is important. The ACOG favors many strategies to improve comprehensive contraception including full coverage by the Affordable Care Act in the United States, over-the-counter access for certain hormonal contraceptives, and advanced provision or counseling regarding EC.[43] In addition, a few states have (or are in the process of obtaining) expanded scope of practice to include provision of hormonal contraception by a pharmacist working under a collaborative practice agreement.[44]

EVALUATION OF THERAPEUTIC OUTCOMES

4 Patients should receive both verbal and written instructions on the chosen method of contraception. Follow-up appointments can increase adherence and provide opportunities to address other health maintenance issues. The contraceptive outcome of pregnancy prevention can be assessed when needed by obtaining a serum or urine pregnancy test.

Monitoring of the Pharmaceutical Care Plan

Contraceptive users should receive an annual well woman exam that may include a cytologic screening (as appropriate), pelvic and breast examination. Consultation should provide routine health maintenance screening and to assess for clinical problems or adverse effects related to contraception (see Table 79-6). It is important to note that these annual screenings do not have to occur prior to prescribing hormonal contraception.

Annual blood pressure monitoring is recommended for all users of CHC. When a patient with a history of glucose intolerance or diabetes mellitus begins or discontinues the use of hormonal contraception, glucose levels must be monitored. Monitoring for the presence of adverse effects related to hormonal content or the presence of coexisting medical conditions is recommended for women using CHCs. Women using Nexplanon should be monitored annually for menstrual cycle disturbances, local inflammation, or infection at the implant site, acne, breast tenderness, headaches, and hair loss. Women using DMPA should be asked at 3-month follow-up visits about weight gain, menstrual cycle disturbances, and fractures. Women using IUDs should be asked at 1- to 3-month follow-up visits about IUD placement (checking for IUD strings to assure the IUD is still in the proper position), changes in menstrual bleeding patterns, and symptoms and protection against STDs. Clinicians should check for proper IUD positioning and symptoms of upper genital tract infection.

Finally, clinicians should monitor and when indicated screen for HIV and STDs. All women should

receive counseling about healthy sexual practices including the use of condoms to prevent the transmission of STDs when necessary.

ABBREVIATIONS

Chapter 80: Menstruation-Related Disorders

Elena M. Umland; Jacqueline Klootwyk

INTRODUCTION

KEY CONCEPTS

- 1 While a urine pregnancy test should be one of the first steps in evaluating amenorrhea, the majority of primary amenorrhea case can be attributed to either physical anomalies of the gonads, outflow tract or anomalies of the hypothalamic–pituitary axis.
- 2 For hypoestrogenic conditions associated with primary and secondary amenorrhea, estrogen (with a progestin) is provided.
- 3 Heavy menstrual bleeding (HMB) is generally caused by either systemic disorders or specific uterine abnormalities.
- 4 Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis for any woman presenting with heavy menses.
- 5 When compared to other conventional medical therapies used for HMB, the levonorgestrel intrauterine system is associated with a 61% lower discontinuation rate and 82% fewer treatment failures.
- 6 Intrauterine devices (IUDs) are considered therapeutic options in a variety of menstruation-related disorders. Guidelines from the American College of Obstetricians and Gynecologists (ACOG) indicate that both nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.
- 7 Abnormal uterine bleeding associated with ovulatory dysfunction (AUB-O) is a spectrum of disorders commonly associated with heavy or irregular bleeding from the endometrium which primarily results from a dysfunctioning menstrual system, specifically the effects of chronic unopposed estrogen.
- 8 Polycystic ovary syndrome (PCOS) can present as a variety of menstruation disorders,

including amenorrhea, HMB, and anovulatory bleeding. Although its definition continues to evolve, it is generally considered a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction.

- 9 Metformin use for anovulatory bleeding associated with PCOS is beneficial not only for managing AUB-O and positively affecting fertility but also for improving glucose tolerance and other metabolic parameters that contribute to cardiovascular risk.

- 10 The selective serotonin reuptake inhibitors (SSRIs) are first-line pharmacologic treatment options for premenstrual dysphoric disorder (PMDD).

Problems related to the menstrual cycle are exceedingly common in women of reproductive age. This chapter discusses the most frequently encountered menstruation-related difficulties: amenorrhea; heavy menstrual bleeding (HMB); abnormal uterine bleeding associated with ovulatory dysfunction (AUB-O), including polycystic ovary syndrome (PCOS); dysmenorrhea; and premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD). The need for effective treatments of these disorders stems from their negative impact on any or all of the following: quality of life, reproductive health, and long-term detrimental health effects, such as increased risk of osteoporosis with amenorrhea and cardiovascular disease with PCOS.

AMENORRHEA

Amenorrhea is described as either primary or secondary in nature. Primary amenorrhea is the absence of menses by age 16 years in the presence of normal secondary sexual development or the absence of menses by age 14 in the absence of normal secondary sexual development.[1] Secondary amenorrhea is the absence of menses for three cycles or for 6 months in a previously menstruating woman. There is a significant amount of overlap between the two. The initial evaluation of amenorrhea is often the same, regardless of age of onset, except in unusual clinical situations.[2,3]

Epidemiology

Primary amenorrhea occurs in less than 0.1% of the general population. Secondary amenorrhea, in comparison, has an incidence of 3% to 4% in the general population and occurs more frequently in women younger than 25 years with a history of menstrual irregularities and in those involved in competitive athletics.[3]

Etiology

1 While a urine pregnancy test should be one of the first steps in evaluating amenorrhea, the majority of primary amenorrhea cases can be attributed to either anomalies of the gonads or outflow tract or anomalies of the hypothalamic–pituitary axis.[1] Similarly, greater than 50% of secondary amenorrhea cases are due to the impact of disturbances of the hypothalamic–pituitary–adrenal axis or the hypothalamic–pituitary–ovarian axis.[3] Specifically, hypothalamic suppression, chronic

anovulation, hyperprolactinemia, ovarian failure, and uterine disorders.[4] Therefore, in organizing an approach to diagnosis and treatment, it is helpful to consider the organs involved in the menstrual cycle, which include the uterus, ovaries, anterior pituitary, and hypothalamus.

Pathophysiology

Each organ in the hypothalamic–pituitary–ovarian–uterine axis is of importance in determining amenorrhea's etiology and pathophysiology. Beginning with the uterus/outflow tract and progressing caudally will result in a comprehensive differential diagnosis. **Table 80-1** lists the pathophysiology of amenorrhea relative to the organ system(s) involved and the specific condition(s) that results in amenorrhea.

TABLE 80-1 Pathophysiology of Selected Menstrual Bleeding Disorders

Organ System	Condition	Pathophysiology/Laboratory Findings
Amenorrhea		
Uterus	Asherman's syndrome	Postcurettage/postsurgical uterine adhesions
	Congenital uterine abnormalities	Abnormal uterine development
Ovaries	Turner's syndrome	Lack of ovarian follicles
	Gonadal dysgenesis	Other genetic abnormalities
	Premature ovarian failure	Early loss of follicles
	Chemotherapy/radiation	Gonadal toxins
Anterior pituitary	Pituitary prolactin-secreting adenoma	↑ Prolactin suppresses the HPO axis
	Hypothyroidism	TRH causes ↑ prolactin, other abnormalities
	Medication (antipsychotics, verapamil)	↑ Prolactin suppresses the HPO axis
Hypothalamus	FHA	↓ Pulsatile GnRH secretion in the absence of other abnormalities
	Eating disorder	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss
	Exercise	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat
	Anovulation/PCOS	Asynchronous gonadotropin and estrogen production, abnormal endometrial growth
Abnormal Uterine Bleeding Associated with Ovulatory Dysfunction (AUB-O)		
Physiologic causes	Adolescence	Immaturity of the HPO axis: no LH surge
	Perimenopause	Declining ovarian function
Pathologic causes	Hyperandrogenic anovulation (PCOS)	Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance

Organ System	Condition	Pathophysiology/Laboratory Findings
	Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss)	Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH
	Hyperprolactinemia (pituitary gland tumor, psychiatric medications)	High prolactin
	Hypothyroidism	High TSH
	Premature ovarian failure	High FSH
Heavy Menstrual Bleeding (HMB)		
Hematologic	von Willebrand disease	Factor VII defect causing impaired platelet adhesion and increased bleeding time
	Idiopathic thrombocytopenic purpura	Decrease in circulating platelets, can be acute or chronic
Hepatic	Cirrhosis	Decreased estrogen metabolism, underlying coagulopathy
Endocrine	Hypothyroidism	Alterations in the HPO axis
Uterine	Fibroids	Alteration of endometrium, changes in uterine contractility
	Adenomyosis	Alteration of endometrium, changes in uterine contractility
	Endometrial polyps	Alteration of endometrium
	Gynecologic cancers	Various dysplastic alterations of endometrium, uterus, cervix

FHA, functional hypothalamic amenorrhea; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic–pituitary–ovarian axis; LH, luteinizing hormone; PCOS, polycystic ovary syndrome; TSH, thyroid-stimulating hormone; TRH, thyrotropin-releasing hormone.

Data from references 1,2,3,4,5,6,7,8,9, 14, and 17.

Uterus/Outflow Tract

For menstruation to occur, a uterus, functional endometrium, and patent vagina must be present. Several anatomic abnormalities may cause amenorrhea.[1] If primary amenorrhea is the presenting symptom, a congenital anomaly such as imperforate hymen or uterine agenesis may be present and often discovered by physical examination. An acquired condition of the genital tract, such as Asherman's syndrome or cervical stenosis, is more likely in secondary amenorrhea.

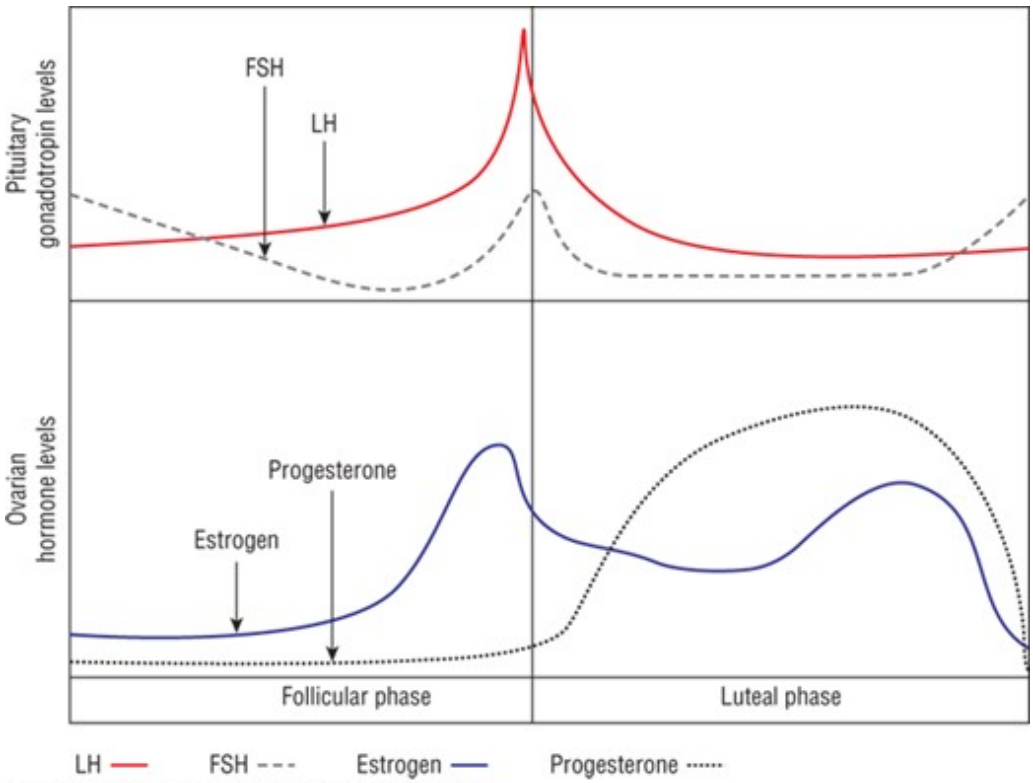
Ovaries

Normal ovarian function is critical for menstruation to occur. The ovaries must respond appropriately to follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by secreting estrogen and

progesterone in the proper sequence to influence endometrial growth and shedding (**Fig. 80-1**).

FIGURE 80-1

Hormonal fluctuations with the normal menstrual cycle. (FSH, follicle-stimulating hormone; LH, luteinizing hormone.)



Premature ovarian failure occurs when no viable follicles remain in the ovaries. This is because estrogen production is insufficient to stimulate endometrial growth in the absence of follicles. In a woman younger than 30 years, amenorrhea due to premature ovarian failure may be the result of genetic anomalies.[2]

The ovaries may play a role in amenorrhea through anovulation. Ovulation is required for the follicle (an estrogen-secreting body) to become a corpus luteum (a progesterone-secreting body). Without ovulation, the proper sequence of estrogen production, progesterone production, and estrogen/progesterone withdrawal will not occur. This can result in amenorrhea. Anovulation can occur secondary to thyroid disease, androgen excess (as in PCOS), or chronic illness.

Pituitary Gland

The anterior pituitary gland secretes FSH and LH in sequential fashion in response to hypothalamic stimulation and a complex ovarian feedback mechanism. Normal secretion of FSH and LH is altered by several endocrinologic and iatrogenic conditions, including thyroid disease, hyperprolactinemia, and dopaminergic drug administration.

Hypothalamus

The hypothalamus secretes cyclic gonadotropin-releasing hormone (GnRH), which causes the pituitary to produce FSH and LH. Disrupting this cyclic process will interrupt the hormonal cascade that results in normal menstruation. Anorexia nervosa, bulimia, intense exercise, and stress may cause hypothalamic amenorrhea. Further, recent research has confirmed the role of leptin insufficiency in causing hypogonadotropic hypogonadism leading to hypothalamic amenorrhea.[10]

Treatment

The treatment options for amenorrhea are as varied as its causes.

Desired Outcome(s)

Therapeutic modalities for amenorrhea should ensure the occurrence of normal puberty and restore the menstrual cycle. Treatment goals include bone density preservation, bone loss prevention, and ovulation restoration to improve fertility as desired. Amenorrhea from hypoestrogenism may affect quality of life via hot flash induction (premature ovarian failure), dyspareunia, and, in prepubertal females, lack of secondary sexual characteristics and absence of menarche. Treatment is targeted at reversing these effects.

CLINICAL PRESENTATION Amenorrhea General

- Although patients may be concerned about cessation of menses and implications for fertility, patients are generally not in acute distress.

Symptoms

- Patients will note cessation of menses.
- Patients may complain of infertility, vaginal dryness, or decreased libido.

Signs

- Cessation of menses for more than 6 months in women with established menstruation, absence of menses by age 16 in the presence of normal secondary sexual development, or absence of menses by age 14 in the absence of normal secondary sexual development.
- Recent significant weight loss or weight gain.
- Presence of acne, hirsutism, hair loss, or acanthosis nigrans may suggest androgen excess.

Laboratory Tests

- Pregnancy test
- Serum FSH and LH

- Thyroid-stimulating hormone
- Prolactin
- If hyperandrogenic state (ie, PCOS) is suspected, consider free and total testosterone, dehydroepiandrosterone, fasting glucose, fasting lipid panel

Other Diagnostic Tests

- Progesterone challenge to confirm functional anatomy and adequate estrogenization.
- Pelvic ultrasound to evaluate for polycystic ovaries, presence/absence of uterus, and/or structural abnormalities of the reproductive tract organs.

General Approach to Treatment

The overall success of any intervention to treat amenorrhea depends on proper identification of the disorder's underlying cause(s). Once the cause is identified, the appropriate intervention(s) can be made. For patients experiencing amenorrhea secondary to hypoestrogenic states, a diet rich in calcium and vitamin D is essential to minimize any negative impact on bone health.

Nonpharmacologic Therapy

Nonpharmacologic therapy for amenorrhea varies depending upon the underlying cause. Amenorrhea secondary to anorexia may respond to weight gain. In young women for whom excessive exercise is an underlying cause, reduction of exercise quantity and intensity are important. Cognitive behavioral therapy has been shown to restore ovarian function in women with functional hypothalamic amenorrhea (FHA).[11]

Pharmacologic Therapy

2 For hypoestrogenic conditions associated with primary or secondary amenorrhea, estrogen (with a progestin) is provided. It can be administered as an oral contraceptive (OC), conjugated equine estrogen, or estradiol patch. Estrogen therapy in this patient population reduces osteoporosis risk[12] and improves quality of life. **Table 80-2** lists therapeutic agents for amenorrhea treatment, including recommended doses. **Figure 80-2** illustrates a treatment algorithm for management of amenorrhea.

TABLE 80-2 Therapeutic Agents for Selected Menstrual Disorders

Specific Menstrual Disorder(s)	Agent(s)	Brand Name(s)	Usual Recommended Dose
Amenorrhea (primary or secondary)[1,8,13,14]	CEE	Premarin®, Cenestin®, Enjuvia®	0.625-1.25 mg by mouth daily on days 1-25 of the cycle
	Ethinyl estradiol patch	Alora®, Climara®, Estraderm®,	50 mcg/24 hours

Specific Menstrual Disorder(s)	Agent(s)	Brand Name(s)	Usual Recommended Dose
		Vivelle-Dot®	
	Combination OC	Various	30-40 mcg formulations
Amenorrhea (secondary)[13,15]	Oral MPA	Provera®	5-10 mg by mouth on days 14-25 of the cycle
	Progesterone vaginal gel	Crinone®	1.125 g of 4% gel intravaginally every other day for 6 doses; if no response, increase to 8% gel for 6 doses
	Norethindrone	Aygestin®	5 mg by mouth daily for 7-10 days
	Micronized progesterone	Prometrium®	400 mg by mouth daily for 7-10 days
Amenorrhea related to hyperprolactinemia[4,16,17]	Bromocriptine	Parlodel®, Parlodel® SnapTabs	2.5-15mg daily in two to three divided doses
	Cabergoline	Dostinex®	0.25-2 mg by mouth once weekly or in two divided doses
Anovulatory bleeding	Combination OC	Desogen 28®, Ortho-Cept 28®, Yasmin 28®, Yaz®, Beyaz®, and others Norgestrel containing: Cryselle 28®, Lo/Ovral 28®	≤35 mcg ethinyl estradiol
Dysmenorrhea[8,18,19,20]	Combination OC	Levonorgestrel containing: Levora 28®, Nordette 28®, Aviane 28®, Lessina 28® Extended-cycle: Introvale®, Quasense®, Seasonale®, Seasonique®, LoSeasonique®, Lybrel®	<35 mcg formulations + norgestrel or levonorgestrel; use of extended-cycle formulations is beneficial for this indication

Specific Menstrual Disorder(s)	Agent(s)	Brand Name(s)	Usual Recommended Dose
	Injectable MPA	Depo-Provera®, Depo-SubQ Provera 104®	150 mg intramuscularly or 104 mg subcutaneously every 12 weeks
	LNG-IUS	Mirena®	20 mcg released daily
	NSAIDs (any are acceptable); the most commonly studied/cited are included in this table	Diclofenac (Cataflam®); ibuprofen (Motrin®, Advil®), mefenamic acid (Ponstel®)	Diclofenac 50 mg by mouth three times daily; ibuprofen 800 mg by mouth three times daily; mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to four times daily as needed
		Naproxen (Naprosyn®)	Naproxen 550-mg loading dose by mouth started 1-2 days prior to menses followed by 275 mg by mouth every 6-12 hours as needed
	Celecoxib	Celebrex®	400 mg by mouth followed by 200 mg by mouth every 12 hours as needed during menses
Heavy Menstrual Bleeding [9,21,22,23,24,25,26,27,28]	Combination OC	Various	Optimal dose unknown
	LNG-IUS	Mirena®	20 mcg released daily
	Oral MPA	Provera®	5-10 mg by mouth on days 5-26 of the cycle or during the luteal phase
	Tranexamic acid	Lysteda®	1,300 mg by mouth every 8 hours once heavy bleeding begins; dose for 4-7 days as needed per cycle
PCOS-related amenorrhea and/or AUB-O [29,30]	Injectable MPA	Depo-Provera®, Depo-SubQ Provera 104®	150 mg intramuscularly or 104 mg subcutaneously every 12 weeks
	Combination OC [20,21]	Desogestrel containing: Desogen 28®, Ortho-Cept 28®	≤30 mcg ethinyl estradiol with either desogestrel, norgestimate or drospirenone
		Norgestimate	

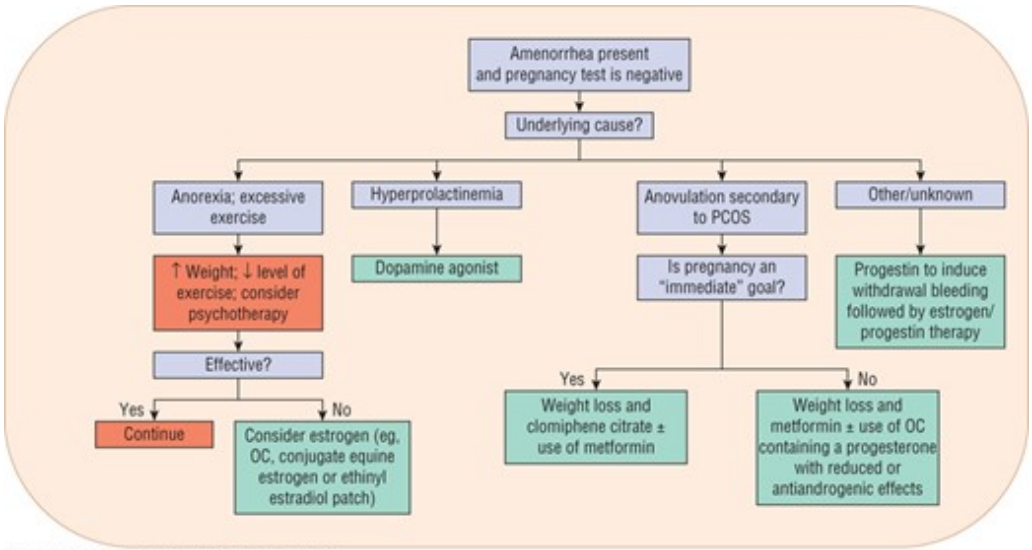
Specific Menstrual Disorder(s)	Agent(s)	Brand Name(s)	Usual Recommended Dose
		containing: OrthoTri-Cyclen Lo®	
		Drospirenone containing: Yasmin 28®, Yaz®, Beyaz®	
	Oral MPA	Provera®	10 mg by mouth for 10 days[5]
	Metformin	Glucophage®, Fortamet®, Glucophage XR®, Glumetza®	1,500-2,000 mg by mouth daily[21]
PMDD[31,32,33]	Clomipramine	Anafranil®	25-75 mg by mouth daily taken either continuously or only during the luteal phase
	Drospirenone	Yasmin 28®, Yaz®, Beyaz®	3 mg (+ ≤30 mcg ethinyl estradiol) by mouth on days 1-21 of the menstrual cycle[23]
	Leuprolide	Lupron Depot®	3.75 mg intramuscularly[22]
	SSRIs	Citalopram = Celexa®; escitalopram = Lexapro®; fluoxetine = Prozac®, Sarafem®; paroxetine = Paxil®; sertraline = Zoloft®	Citalopram 10-30 mg; escitalopram 10-20 mg; fluoxetine 10-20 mg; fluvoxamine 50 mg; paroxetine 10-30 mg; sertraline 25-150 mg; all agents are given by mouth daily and can be dosed either continuously or during the luteal phase only
	SNRIs	Venlafaxine = Effexor®, Effexor XR®; duloxetine = Cymbalta®	Venlafaxine 50-200 mg, can be dosed continuously or during the luteal phase only; duloxetine 60 mg dosed continuously

CEE, conjugated equine estrogen; LNG-IUS, levonorgestrel intrauterine system; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal anti-inflammatory drug; OC, oral contraceptive; PCOS, polycystic ovary syndrome; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitors; SNRI, serotonin norepinephrine reuptake inhibitors.

Data from references 1, 4, 8, 9, 13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33.

FIGURE 80-2

Treatment algorithm for amenorrhea. (OC, oral contraceptive; PCOS, polycystic ovary syndrome.)



When hyperprolactinemia is the cause of amenorrhea, dopamine agonists such as bromocriptine and cabergoline aid in reducing prolactin concentrations and the resumption of menses. Bromocriptine normalizes prolactin levels in 58% of affected women while cabergoline has the same effect in 85%.[16]

Amenorrhea related to PCOS-induced anovulation may respond to agents that reduce insulin resistance. Metformin for this purpose is discussed in the "abnormal uterine bleeding" section.

Progestins induce withdrawal bleeding in women with secondary amenorrhea, and several factors predict progesterone's efficacy for this purpose.[14] These factors include estrogen concentrations greater than or equal to 35 pg/mL (128 pmol/L) and endometrial thickness (greater initial thickness resulting in more withdrawal bleeding).

Progestin efficacy for secondary amenorrhea varies by formulation used. Progesterone in oil administered intramuscularly results in withdrawal bleeding in 70% of treated patients, whereas oral medroxyprogesterone acetate (MPA) induces withdrawal bleeding in 95% of treated patients.[14] Table 80-2 identifies the types and doses of progestins used for secondary amenorrhea treatment. Figure 80-2 illustrates when to consider progestin use for amenorrhea treatment.

Special Populations

Amenorrhea in the adolescent population is of concern because developmentally this is the time when peak bone mass is achieved. The cause of amenorrhea, whether primary or secondary, must be promptly identified, as amenorrhea and its related hypoestrogenism negatively affect bone development. In addition to treating or eliminating amenorrhea's underlying cause, ensuring that the patient is receiving adequate amounts of calcium and vitamin D is imperative. Estrogen replacement, typically via an OC, is important.

Drug Class Information

Table 80-3 identifies the significant pharmacologic properties of agents used for amenorrhea management which require monitoring.

TABLE 80-3 Pharmacologic Properties and Monitoring Parameters for Select Agents Used in the Management of Menstrual Disorders

Therapeutic Agent/Drug Class	Mechanism of Action/Role in Particular Menstrual Disorders	Adverse Drug Reactions	Monitoring for Expected Outcomes of Specific Menstrual Disorders	Comments
Dopamine agonists (bromocriptine and cabergoline)	Suppresses prolactin production from pituitary tumors such that resumption of normal FSH and LH production occurs	Hypotension, nausea, constipation, anorexia, Raynaud's phenomenon, fatigue, headache	Amenorrhea related to hyperprolactinemia: Baseline and weekly prolactin levels should be measured with dosage increases until resumption of menses is observed. Continue therapy for 6-12 months following return of menses and continued normalization of serum prolactin levels	Inhibits CYP3A4 and is metabolized by CYP3A4 St. John's Wort induces CP3A4; coadministration may lead to treatment failure
Clomipramine	PMDD: Exact mechanism unknown	Dry mouth, constipation, fatigue, vertigo, sweating	Reduction in or absence of initial symptoms and improved quality of life within 1-3 menstrual cycles of therapy	
Combination OCs	Exogenous estrogen and progesterone that suppresses FSH and LH production and thus inhibits ovulation Can be used to reduce menstrual flow (menorrhagia, dysmenorrhea), and control menstrual cycle (anovulatory bleeding secondary	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, GI upset, headache, peripheral edema	Amenorrhea: Resumption of menses within 1-2 months of therapy Anovulatory bleeding: Improvement in pattern of abnormal bleeding within 1-2 months of therapy Dysmenorrhea: Reduction in or absence	St. John's Wort contributes to altered menstrual bleeding Rifampin induces estrogen metabolism, possibly contributing to treatment failure Sulfa-containing drugs may

Therapeutic Agent/Drug Class	Mechanism of Action/Role in Particular Menstrual Disorders	Adverse Drug Reactions	Monitoring for Expected Outcomes of Specific Menstrual Disorders	Comments
			of pelvic pain within 1-2 months of therapy	
			Menorrhagia:	
	to hypoestrogenism)		Reduction in blood loss with menses over 1-2 months of therapy. Improvement in hemoglobin/hematocrit after 3 months of therapy compared to baseline	contribute to increased photosensitivity
CEE	Estrogen replacement for hypoestrogenic states leading to anovulatory bleeding	As noted for combination OC	Anovulatory bleeding: Improvement in pattern of abnormal bleeding within 1-2 months of therapy	Same as OCs
Drospirenone-containing OCs	Progesterone with antimineralocorticoid and antiandrogenic properties; decreases emotional lability associated with PMDD	As noted for combination OC; increased risk of hyperkalemia	PCOS-related amenorrhea or anovulatory bleeding: In addition to the improvement in the pattern of abnormal bleeding within 1-2 months of treatment, women should also experience an improvement in androgen-excess symptoms such as acne/oily skin and hirsutism	Same as OCs Coadministration of potassium-sparing diuretics or diets high in potassium may contribute to increased serum potassium concentrations, particularly in women with renal dysfunction
Ethinyl estradiol transdermal patch	Same as combination OCs and CEE	As noted for combination OC; however, lesser effects on serum cholesterol concentrations	Amenorrhea: Resumption of menses within 1-2 months of therapy	Same as OCs

Therapeutic Agent/Drug Class	Mechanism of Action/Role in Particular Menstrual Disorders	Adverse Drug Reactions	Monitoring for Expected Outcomes of Specific Menstrual Disorders	Comments
		because patch avoids first-pass metabolism		
Leuprolide	GnRH agent that contributes to suppression of FSH and LH and ultimately a reduction in estrogen and progesterone, inhibiting the normal menstrual cycle/hormonal fluctuations	Hot flashes, night sweats, headache, nausea	PMDD: Improvement in PMDD signs and symptoms within 1-2 months of therapy	
LNG-IUS	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual growth of the endometrium	Irregular menses, amenorrhea	Dysmenorrhea: Reduction in or absence of pelvic pain after 1-2 months of therapy Menorrhagia: Reduction in blood loss with menses over 1-2 months of therapy. Improvement in hemoglobin/hematocrit after 3 months of therapy compared to baseline	
MPA (oral and injectable)	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual growth of the endometrium	Edema, anorexia, depression, insomnia, weight gain or loss, increase in serum total and LDL cholesterol, may reduce HDL cholesterol	Dysmenorrhea: Reduction in or absence of pelvic pain after 1-2 months of therapy Menorrhagia: Reduction in blood loss with menses over 1-2 months of therapy. Improvement in hemoglobin/hematocrit	

Therapeutic Agent/Drug Class	Mechanism of Action/Role in Particular Menstrual Disorders	Adverse Drug Reactions	Monitoring for Expected Outcomes of Specific Menstrual Disorders	Comments
			after 3 months of therapy compared to baseline PCOS-related amenorrhea and/or anovulatory bleeding: Resumption of menses over 1-2 courses of therapy	
Metformin	Inhibits hepatic glucose production and increases sensitivity of tissues to insulin, thus reducing insulin resistance	Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis (rare)	PCOS-related amenorrhea and/or anovulatory bleeding: If desired, monitor for ovulation after 3-6 months of therapy	IV contrast dye may increase the risk of lactic acidosis; stop metformin 1 day prior and restart when renal function is normal and stabilized following the IV dye
NSAIDs	Inhibits prostaglandin release that occurs with menses, thus reducing inflammatory response contributing to dysmenorrhea	GI upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness	Dysmenorrhea: Reduction in or absence of pelvic pain within hours of initiating. Menorrhagia: Reduction in blood loss with menses over 1-2 months of therapy	
SSRIs	Exact mechanism in PMDD unknown	Sexual dysfunction (reduced libido, anorgasmia), insomnia, sedation, hypersomnia, nausea, diarrhea	Improvement in PMDD signs and symptoms observed within 1-3 months of therapy	
Tranexamic acid	Antifibrinolytic effects by reversibly	Nausea, vomiting, diarrhea, dyspepsia	Menorrhagia: Reduction in blood loss with	

Therapeutic Agent/Drug Class	Mechanism of Action/Role in Particular Menstrual Disorders	Adverse Drug Reactions	Monitoring for Expected Outcomes of Specific Menstrual Disorders	Comments
	blocking lysine binding sites on plasminogen, preventing fibrin degradation and a reduction in menstrual blood loss		menses should be noticeable with the first month of therapy. Improvement in hemoglobin/hematocrit after 3 months of therapy compared to baseline	
Venlafaxine	Exact mechanism in PMDD unknown		Improvement in PMDD signs and symptoms observed within 1-3 months of therapy	

CEE, conjugated equine estrogen; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LH, luteinizing hormone; LNG-IUS, levonorgestrel intrauterine system; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal anti-inflammatory drug; OC, oral contraceptive; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitor.

Evaluation of Therapeutic Outcomes

Table 80-3 lists the expected outcomes and specific monitoring parameters for treatment modalities used in amenorrhea management.

HEAVY MENSTRUAL BLEEDING

Heavy menstrual bleeding is the term now used to in place of menorrhagia.[9] The classical definition, however, remains the same: menstrual blood loss greater than 80 mL per cycle or menstrual bleeding lasting greater than 7 days per cycle.[9] This definition has been questioned because of difficulty quantifying menstrual loss in clinical practice. Additionally, many women with “heavy menses” but whose blood loss is less than 80 mL merit treatment consideration because of flow containment issues, unpredictably heavy flow days, or other associated symptoms.[19,37] More recently, diagnosis has also been considered based upon the impact of HMB on quality of life and social, professional, familial or sexual roles.

Epidemiology

Up to as many as 20% to 30% of women are affected by HMB,[9,21,28] and it is responsible for 12% to 15% of referrals to gynecologists.[9,21,22] In women with coagulation disorders such as von Willebrand disease or platelet dysfunction, the rates of HMB are as high as 100% and 98%, respectively.[6,38]

Etiology

While the specific cause of HMB may be unknown in up to 50% of patients, 3 HMB is generally caused by either systemic disorders or specific uterine abnormalities. 4 Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis list for any woman presenting with heavy menses.[8] Bleeding disorders including von Willebrand disease, symptomatic hemophilia, platelet dysfunction, and Factory VII and XI deficiencies must also be considered as these were found to exist in 20% of women with HMB.[8] Hypothyroidism also may be associated with heavy menses.[9,39] Specific uterine causes of HMB are more common in older childbearing women and include fibroids, adenomyosis, endometrial polyps, and gynecologic malignancies.[9] Fibroids, specifically, have been identified in as many as 40% of women with HMB.[28]

Pathophysiology

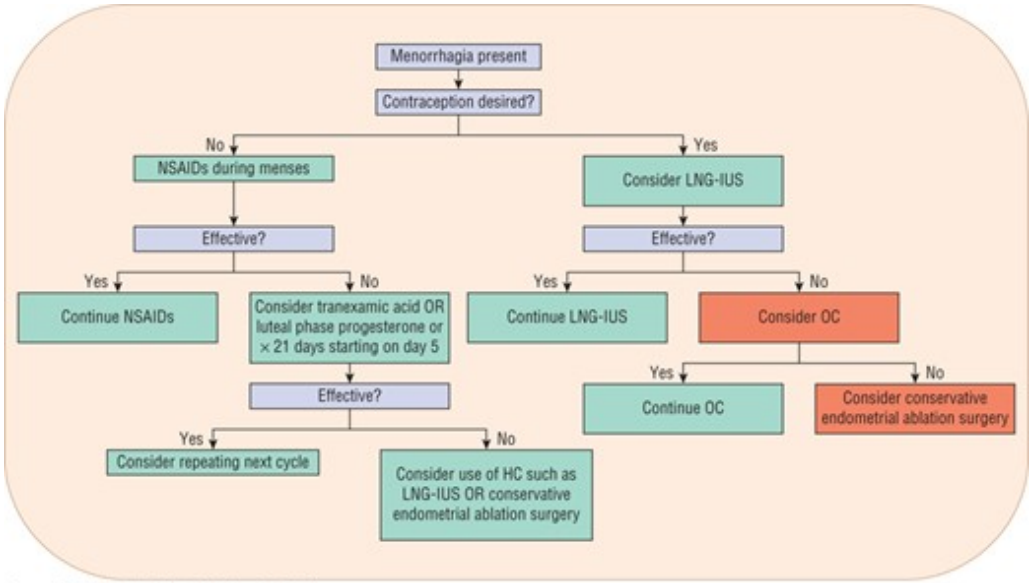
Table 80-1 lists the pathophysiology of HMB relative to the organ system(s) involved and the specific conditions that may result in HMB.

Treatment

Effective medical treatments, as opposed to surgical interventions, are recommended as the initial treatment choice for women with HMB. Table 80-2 identifies the variety of pharmacologic treatment options and their recommended dosing for HMB management. **Figure 80-3** presents an algorithm for HMB treatment.

FIGURE 80-3

Treatment algorithm for HMB. (LNG-IUS, levonorgestrel-releasing intrauterine system; NSAIDs, nonsteroidal anti-inflammatory drugs; OC, oral contraceptive; HC, hormonal cotraceptive.)



Desired Outcome(s)

Therapy for HMB should reduce menstrual flow, improve the patient's quality of life, and defer the need for surgical intervention.

General Approach to Treatment

Several treatment options exist for HMB. Initial and subsequent treatment options should be thoughtfully chosen in an effort to avoid surgery.

Nonpharmacologic Therapy

Nonpharmacologic interventions for HMB include surgical procedures that are generally reserved for patients not responding to pharmacologic treatment. These interventions vary from conservative endometrial ablation to hysterectomy.[21,37]

Pharmacologic Therapy

Among the agents used to treat HMB, the nonsteroidal anti-inflammatory drugs (NSAIDs) have the advantage of administration only during menses and are associated with a 10% to 51% reduction in blood loss[34] For women desiring to avoid pregnancy, hormonal contraception (HC) use is beneficial for HMB and should be considered as a 40% to 50% reduction in menstrual blood loss has been observed in patients treated with cyclic combined HCs.[35] The best studied HC option for HMB, and the only OC approved by the FDA for the indication of HMB is the four-phasic formulation containing estradiol valerate and dienogest.[34,36]

Another HMB treatment option is the levonorgestrel-releasing intrauterine system (LNG-IUS). This is the most effective treatment to reduce menstrual flow.[23,34,40] In particular, a 79% to 97% reduction in

blood loss has been observed with its use,[40] and its use has also resulted in postponing or cancelling scheduled endometrial ablation surgery or hysterectomy. Among women using this treatment option, only 9% eventually opted for surgery.[34] Further, its therapeutic efficacy is similar to endometrial ablation up to 2 years following treatment.[24]

Cyclic progesterone therapy for 21 days, starting on day 5 after onset of menses, results in a 37% to 87% reduction in menstrual blood loss.[28] While progesterone use provides no benefit in efficacy over other medical treatments,[28] its use may be considered in women with contraindications to estrogen.[34]

Tranexamic acid was recently approved in the United States for primary HMB treatment. Its use is associated with a significant 34% to 60% reduction in menstrual blood loss.[28,41] Compared to many of the other options, its use may be preferable among women desiring pregnancy or in whom hormonal therapy may not be appropriate.

Drug Treatments of First Choice

For women in whom pregnancy is not an immediate goal, it is reasonable to start with either an OC or the LNG-IUS. While either choice is acceptable for both nulligravid and multiparous women who desire a long-term reversible form of contraception,[35,40] cost-effectiveness data suggest LNG-IUS is the best first-line choice for women desiring contraception.[28,37] Clinical trial data illustrate a higher failure rate with the OCs (32%) compared to the LNG-IUS (11%) as the primary treatment method.[28] 5 When compared to other conventional medical therapies used for HMB, the levonorgestrel intrauterine system is associated with a 61% lower discontinuation rate and 82% fewer treatment failures.[23]

CLINICAL PRESENTATION Heavy Menstrual Bleeding General

- Patients may or may not be in acute distress.

Symptoms

- Patients may complain of heavy/prolonged menstrual flow. They also may have signs of fatigue and lightheadedness in cases of severe blood loss. These symptoms may or may not occur with dysmenorrhea.

Signs

- Orthostasis, tachycardia, and pallor may be noted, especially in cases of significant acute blood loss.

Laboratory Tests

- Complete blood count and ferritin levels; hemoglobin and hematocrit results may be low.

- If the history dictates, testing (eg, prothrombin time, activated partial thromboplastin time, international normalized ratio, von Willebrand factor antigen, Factor VIII) may be performed to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

- Pelvic ultrasound
- Pelvic magnetic resonance imaging
- Papanicolaou (Pap) smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

Alternative Drug Treatments

For women who have HMB associated with ovulatory cycles and do not desire hormonal therapy and/or contraception, NSAIDs during menses is a reasonable choice in the absence of any contraindications or GI illnesses such as peptic ulcer disease or gastroesophageal reflux disease. This choice is convenient (only taken during menses) and comparatively inexpensive. Given their side effects, reduced efficacy compared to the first-line agents, and/or cost, use of oral progesterone and depot MPA should be reserved. Tranexamic acid is another treatment option which has been associated with a significant improvement in quality of life and high patient satisfaction following three cycles of use.[27,42]

Special Populations

Although historically it was believed that IUD use should be avoided in nulliparous women, 6 guidelines from the American College of Obstetricians and Gynecologists (ACOG) indicate that both nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.[40] Therefore, any of the treatments discussed (including the LNG IUS) are options in any female presenting with HMB.

Dosage adjustment for tranexamic acid is recommended for reduced renal function. Women with serum creatinine between 1.4 and 2.8 mg/dL (124 and 248 µmol/L) should receive only 1,300 mg by mouth twice daily; women with serum creatinine between 2.9 and 5.7 mg/dL (256 and 504 µmol/L) should receive 1,300 mg by mouth once daily; those with serum creatinine above 5.7 mg/dL (504 µmol/L) should receive 650 mg by mouth once daily. Additionally, due to its potential to increase the risk for venous thromboembolism, it should be used with extreme caution in women with a history of thrombosis and should not be combined with estrogen-containing contraceptives.

Drug Class Information

Table 80-3 identifies the significant pharmacologic properties of agents used for the management of HMB that require monitoring.

Evaluation of Therapeutic Outcomes

Table 80-3 illustrates the expected outcomes and specific monitoring parameters for the treatment modalities used in HMB management.

ABNORMAL UTERINE BLEEDING WITH OVULATORY DYSFUNCTION

Abnormal uterine bleeding associated with ovulatory dysfunction (AUB-O) is a spectrum of disorders commonly associated with heavy or irregular bleeding from the endometrium which primarily results from a dysfunctioning menstrual system, specifically the effects of chronic unopposed estrogen.[7] While it does encompass bleeding patterns such as HMB and amenorrhea, this section will focus specifically on AUB-O as it relates to oligo-anovulation.

Epidemiology

One of the most common causes of AUB-O is PCOS, for which the prevalence rates range from 6% to 25%.[30] In fact, PCOS is the most common endocrine abnormality among US women of reproductive age.[43] PCOS can present as a variety of menstruation disorders, including amenorrhea, HMB, and/or AUB-O. Although its exact definition continues to evolve, it is a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction. It is a significant risk factor for the metabolic syndrome, type 2 diabetes, dyslipidemia, hypertension, and possibly cardiovascular disease.[30] PCOS is a common cause of ovulation dysfunction in adult women, with other common causes including hyperprolactinemia, hypothalamic amenorrhea, also known as hypogonadotropic hypogonadism, premature ovarian failure, and thyroid dysfunction.[2,7]

Etiology

When considering the etiology of AUB-O, the patient's age must be taken into account. As previously discussed, all patients presenting with abnormal bleeding should be evaluated for pregnancy. It is common for adolescents to experience physiologic anovulatory cycles in the first few years following menarche because their hypothalamic–pituitary–gonadal axis is still maturing. However, if regular menstrual cycles have not been established within 5 years of menarche, further evaluation for the cause, such as PCOS, should be considered.[30] Anovulatory cycles may "unmask" an underlying bleeding disorder. When irregular menses is associated with significant bleeding, an inherited bleeding disorder should be a considered as a cause, especially in adolescence.[6] Women experiencing anovulation in their reproductive years should be evaluated for pathologic causes, including PCOS, thyroid dysfunction, hyperprolactinemia, primary pituitary disease, premature ovarian failure, hypothalamic dysfunction, disordered eating, adrenal disease, and androgen-

producing tumors.[7] Women in their perimenopausal years may experience "physiologic" anovulatory cycles because of intermittently declining estrogen levels. Regardless of age, evaluation for endometrial hyperplasia and/or endometrial cancer should be considered when a woman experiences excessive bleeding with anovulatory cycles.[7,34] When considering the etiology of anovulation, it is common for several conditions to coexist (eg, PCOS and hypothyroidism), each contributing to the woman's constellation of symptoms.

Pathophysiology

Normal menstrual cycles occur through a complex interaction of the hypothalamus, pituitary gland, ovaries, and endometrium (see Fig. 80-1). In an ovulatory cycle, the ovary produces a mature, estrogen-secreting follicle in response to FSH release from the pituitary. The endometrium proliferates under the influence of this estrogen production. At a critical level of estrogen concentration, the pituitary responds by producing an "LH surge," which creates a cascade of ovarian events, culminating in ovulation. Upon oocyte release, the follicle becomes a progesterone-producing corpus luteum. The endometrium "organizes" into secretory endometrium in the presence of adequate progesterone. If conception and implantation do not occur, corpus luteum involution causes a decline in estrogen and progesterone leading to predictable, organized menstrual flow as the endometrium sloughs.

If ovulation does not occur, progesterone is not produced, and the endometrium will continue to proliferate in an "unorganized" fashion under the influence of continued estrogen production. Eventually the endometrium will become so thick that it can no longer be supported by continued estrogen production. This results in unorganized, sporadic sloughing of the endometrium, characteristic of the unpredictable and heavy bleeding associated with anovulation, which has several etiologies dependent on the patient's situation. In adolescence, hypothalamic–pituitary axis immaturity contributes to the absence of the LH surge required for ovulation. In the anorexic patient, the hypothalamus loses much of its pulsatile GnRH release, leading to low levels of FSH and LH, enough for estrogen production but not enough to induce ovulation. Oocyte decline and abnormal follicular development contribute to anovulatory cycles common among women in the perimenopause transition.[7]

Clinical Controversy… DIAGNOSIS OF PCOS IN ADOLESCENTS

The criteria for diagnosing PCOS in adolescents are controversial as the pathologic features used for the diagnosis in adults, specifically acne and irregular menses, may be normal pubertal occurrences[44]. It is difficult to ascertain that adolescent hyperandrogenism (as opposed to adult hyperandrogenism) is not a consequence of the lack of synchronicity among the hypothalamic–pituitary–ovarian (HPO) axis during prolonged anovulatory cycles that are typical during puberty. In this patient population, obesity, increased insulin and increased androgens are common, and as such, should not be used in diagnosing PCOS. More research is needed to definitively identify the appropriate diagnosis of PCOS among adolescents so that appropriate treatment(s) can be recommended.

Treatment

Optimizing therapy for AUB-O depends on accurate identification of the disorder's cause(s). The treatment options for AUB-O are wide and varied.

Desired Outcome(s)

When applicable, control of excessive bleeding in the short-term is paramount. Longer-term goals of therapy include restoring the natural cycle of orderly endometrial growth and shedding,[7,45] decreasing anovulation complications (eg, osteopenia and infertility), and improving overall quality of life. Table 80-2 identifies the agents used to manage AUB-O and their recommended doses.

General Approach to Treatment

Although the appropriate primary treatment choice for AUB-O depends on the accurate diagnosis of its cause and identification of desired outcomes, additional treatment may be necessary to manage other signs and symptoms. Medical treatment, as opposed to surgical management, to resolve AUB-O should be initiated and any underlying HMB should be managed as AUB-O is primarily an endocrinologic abnormality.[7]

CLINICAL PRESENTATION Abnormal Uterine Bleeding with Ovulatory Dysfunction General

- Patients may or may not be in acute distress.

Symptoms

- Irregular, heavy, or prolonged uterine bleeding, perimenopausal symptoms (eg, hot flashes, night sweats, and vaginal dryness).

Signs

- Acne, hirsutism, and obesity

Laboratory Tests

- Pregnancy testing
- If PCOS is suspected, consider free or total testosterone, fasting glucose, fasting lipid panel
- If perimenopause is suspected, measure FSH
- Thyroid-stimulating hormone

Other Diagnostic Tests

- Endometrial biopsy for women with risk factors for endometrial hyperplasia or malignancy
- Pelvic ultrasound to evaluate for polycystic ovaries
- If perimenopause is suspected, measure FSH

Nonpharmacologic Therapy

Nonpharmacologic treatment options for AUB-O depend on the underlying cause. In a woman of reproductive age with PCOS, moderate weight loss of 2% to 5% may result in improved menstrual regularity and ovulatory function, reduced hirsutism, increased insulin sensitivity, and improved response to fertility treatments.[46] Further, sustained weight loss has resulted in a return to ovulatory cycles in women without PCOS who experienced anovulatory cycles.[7] In women who have completed childbearing or who have not responded to medical management, endometrial ablation or resection and hysterectomy are surgical options. In the short term, ablation results in less morbidity and shorter recovery periods compared to other surgical interventions. Importantly, procedure choice involves shared decision-making with the patient.

Pharmacologic Therapy

Estrogen is the recommended treatment for managing acute severe bleeding episodes because it promotes endometrial stabilization.[47] Following its initial use to control acute bleeding episodes, therapy continuation may be necessary to prevent future occurrences. HC use fulfills this role and contributes to predictable menstrual cycles.

Hormonal contraceptives prevent recurrent AUB-O by providing a progestin and suppressing ovarian hormones and adrenal androgen production. They also, indirectly, increase sex hormone-binding globulin (SHBG) which binds androgens and reduces their circulating free concentrations. For women with high androgen levels and its related signs such as hirsutism (eg, those with PCOS), HCs containing less than or equal to 35 mcg of ethinyl estradiol and a progesterone that exhibits minimal androgenic side effects (eg, norgestimate and desogestrel) or with antiandrogenic effects (eg, drospirenone) may be desirable.[29]

Clinical Controversy… PROGESTERONE IN PCOS

Hormonal contraceptives containing antiandrogenic progesterones are very effective for managing the acne and hirsutism that accompany PCOS; they also suppress ovarian androgen production and increase SHBG, thus reducing free testosterone concentrations. Controversy regarding their use in PCOS exists secondary to their potential adverse effects on insulin resistance, glucose tolerance, vascular reactivity, and coagulability.[29] An increase in high-sensitivity C-reactive protein (a predictor of cardiovascular disease) and an increase in homocysteine levels (indicating an increased risk of cardiovascular disease) have been observed with the use of such OCs.[48] Another trial found a reduction in brachial artery flow-mediated dilatation and an increase in carotid intima-media thickness, both indicators of endothelial dysfunction, following therapy with OCs containing ethinyl estradiol and cyproterone acetate in women with PCOS.[49] Additional, longer-term clinical trials will clarify whether the benefits of these agents outweigh the risks. It has been suggested that cardiovascular risk calculators be employed as an adjunct to guidelines suggesting the use of OCs in this patient population.[50]

In women with contraindication(s) to estrogen or in whom the side effects are unacceptable,

progesterone-only products are an option. They should be strongly considered for women experiencing HMB associated with anovulatory cycles.[7] In women with PCOS, depot and intermittent oral MPA provide endometrial protection through endometrial shedding.[5] Another progesterone option is placement of the LNG-IUS,[7,51] particularly if pregnancy is not a desired outcome of treatment. Studied specifically in women over 30 years of age, use of the LNG-IUS resulted in a greater than 95% reduction in menstrual blood loss by 2 years[52] and patient satisfaction rates were greater than 80% with 74% agreeing to recommend it to other women.[52]

Metformin improves insulin sensitivity. In patients with PCOS, which contributes to reduced circulating androgen concentrations and increased ovulation rates.[30,45] These improvements occur due to the SHBG increase that occurs via increased insulin sensitivity.

9 Metformin use for AUB-O associated with PCOS is beneficial not only for managing the AUB-O and positively affecting fertility but also for improving glucose tolerance and other metabolic parameters that contribute to cardiovascular risk.[7,30]

If the treatment goal is improved fertility via ovulation induction, clomiphene citrate is another option. Treatment with 50 mg/day for 5 days can be initiated between menstrual cycle days 3 and 5. This often occurs after inducing withdrawal bleeding with a progesterone such as MPA 10 mg daily orally for 10 days. If ovulation does not occur with this dose of clomiphene, a dose of 100 mg/day is warranted. In rare instances, it may be increased by 50 mg increments up to 250 mg/day.

Drug Treatments of First Choice

As with many menstruation-related disorders, there is not one universal treatment option of first choice for AUB-O. Rather, the treatment(s) chosen depends on accurate etiologic diagnosis as well as identification of the desired treatment outcome(s).

Hormonal contraceptives are the first-choice treatment in women with AUB-O who do not desire pregnancy.[7] The use of HCs containing ethinyl estradiol and a progesterone with minimal androgenic or antiandrogenic effects is effective for cycle control and minimizing the androgenic signs and symptoms of PCOS.[29,47]

Relative to anovulation in women with PCOS, insulin-sensitizing agents such as metformin may improve ovulatory frequency and metabolic parameters. Clomiphene use may further assist in achieving ovulation induction.

More recent data provide evidence for additional benefits of metformin's use compared to clomiphene for ovulation induction.[45] When used for ovulation induction[45] as well as its use throughout pregnancy[53] in women with PCOS, metformin has also been associated with reduced miscarriage rates in this patient population.

Clinical Controversy… LETROZOLE USE FOR PCOS/AUB-O

The use of letrozole, an aromatase inhibitor, for ovulation induction has recently been examined in obese patients with PCOS, but remains controversial[54,55]. Letrozole has been shown to have statistically significant higher rates of live births (27.5% vs 19.1%) and ovulation rates (61.7% vs 48.3%) over clomiphene citrate. These patients had an average BMI of 35 kg/m^2.[54] Fetal teratogenicity is a concern with both letrozole and clomiphene. While clomiphene is FDA approved for ovulation induction in premenopausal women, letrozole is only approved for breast cancer in postmenopausal women. Additionally, a recent meta-analysis evaluating aromatase inhibitors for anovulatory bleeding in women with PCOS concluded that the evidence was of low quality and that further research is warranted.

Special Populations

Anovulatory cycles are fairly common in the perimenarchal reproductive years. Ovulation typically is established 1 year or more following menarche. AUB-O occurring in this population may be excessive. If excessive bleeding occurs, the patient should be evaluated for bleeding disorders, as the prevalence of bleeding disorders, including von Willebrand disease, prothrombin deficiency, and idiopathic thrombocytopenia purpura, in this population ranges from 5% to 24%.[6]

If identified, the specific bleeding disorders should be treated. Acute severe bleeding can be managed with high-dose estrogen. OCs containing less than or equal to 35 mcg of ethinyl estradiol is a first-line treatment in adolescents with chronic anovulation.[47]

Drug Class Information

Table 80-3 identifies the significant pharmacologic properties of agents used to treat AUB-O that require monitoring.

Personalized Pharmacotherapy

While not typically an issue among the relatively young population of patients treated with metformin for PCOS, one must be cognizant of the risk of lactic acidosis in metformin users with renal impairment. As such, this drug should be avoided in women with serum creatinine greater than 1.4 mg/dL (124 µmol/L).

Evaluation of Therapeutic Outcomes

Table 80-3 lists the expected outcomes and specific monitoring parameters for the treatment modalities used to manage AUB-O.

DYSMENORRHEA

Dysmenorrhea is one of the most commonly encountered gynecologic complaints. It is defined as crampy pelvic pain occurring with or just prior to menses. Primary dysmenorrhea implies pain in the setting of normal pelvic anatomy and physiology.[56] Secondary dysmenorrhea is associated with

underlying pelvic pathology.[57]

Epidemiology

Dysmenorrhea prevalence rates range from 16% to 90%,[57,58,59] and its presence may be associated with significant interference in work and school attendance. In addition, significant reductions in quality of life and lower overall life satisfaction and contentment ratings have been observed in women with dysmenorrhea compared to controls.[56] Risk factors include menarche before the age of 12 years, current age less than 30 years, heavy menses, nulliparity, low body mass index, and a history of sexual abuse.[57]

Etiology

For most patients, dysmenorrhea is associated with normal ovulatory cycles and normal pelvic anatomy. This is referred to as primary, or functional, dysmenorrhea. However, in approximately 10% of the adolescents and young adults presenting with painful menses, an underlying anatomic or physiologic cause exists.[57] Comparatively, secondary dysmenorrhea associated with pelvic pathology should be suspected in women over 30 years of age without a history of dysmenorrhea.[57]

Pathophysiology

The most significant mechanism for primary dysmenorrhea is the release of prostaglandins and leukotrienes into the menstrual fluid, initiating an inflammatory response and possibly vasopressin-mediated vasoconstriction.[8,19] Causes of secondary dysmenorrhea include endometriosis, current or history of pelvic inflammatory disease, uterine fibroids, and adenomyosis leiomyomata.[57] Pregnancy and miscarriage must be considered in new onset dysmenorrhea.

Treatment

Initial treatment choice is influenced by whether or not the woman desires pregnancy. Nonpharmacologic options have been studied and observed to be as effective as some existing pharmacologic options.

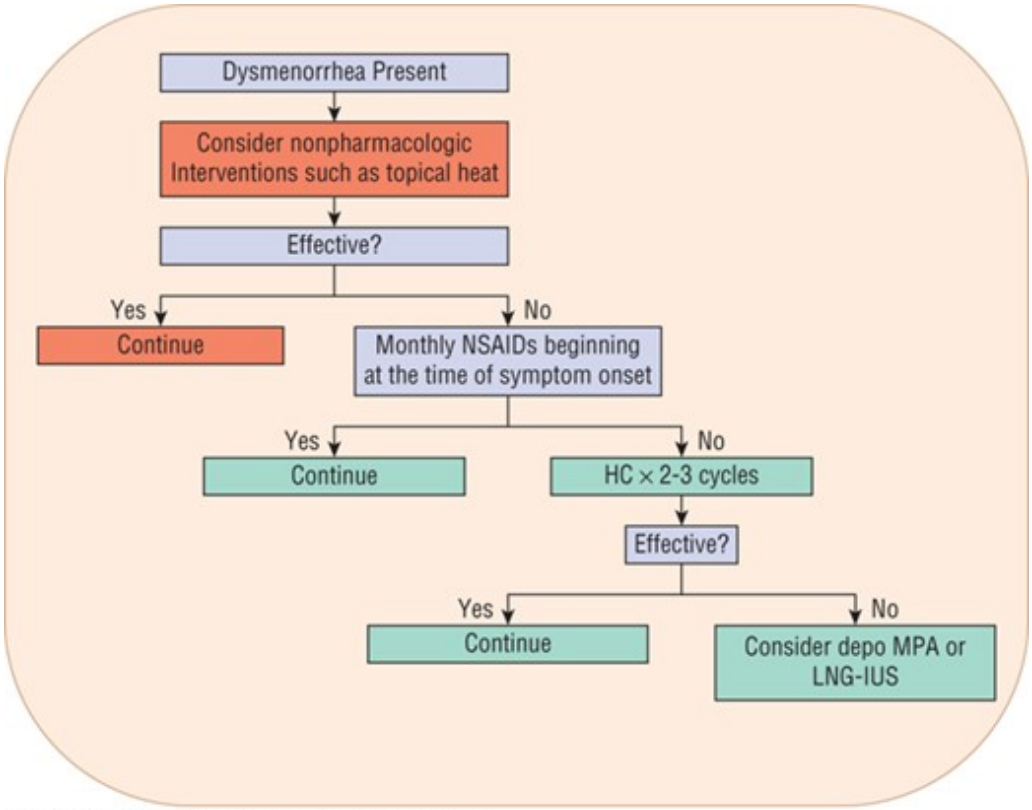
Desired Outcome(s)

Medical management of dysmenorrhea should relieve the pelvic pain, result in reducing lost school and work days, and contribute to an improved quality of life. Table 80-2 identifies the agents used to manage dysmenorrhea and their recommended doses. **Figure 80-4** shows a treatment algorithm for dysmenorrhea management.

FIGURE 80-4

Treatment algorithm for dysmenorrhea. (LNG-IUS, levonorgestrel-releasing intrauterine system; MPA, medroxyprogesterone acetate; NSAIDs, nonsteroidal anti-inflammatory drugs; HC, hormonal

contraceptive.)



General Approach to Treatment

A variety of effective treatment options for dysmenorrhea are available, including nonhormonal and hormonal pharmacologic options and noninvasive nonpharmacologic options. Treatment choice is influenced by the desire for contraception, the patient's level of sexual activity, potential for adverse effects, and cost.

CLINICAL PRESENTATION Dysmenorrhea General

- Patients may or may not be in acute distress, depending on the level of menstrual pain experienced

Symptoms

- Patients complain of crampy pelvic pain beginning shortly before or at the onset of menses. Symptoms typically last from 8 to 72 hours.
- Associated symptoms may include low back pain, headache, diarrhea, fatigue, and/or nausea and vomiting.

Laboratory Tests

- Pelvic examination should be performed to screen for sexually transmitted diseases and/or

pelvic inflammatory disease as a cause of the pain in sexually active females.

- Gonorrhea, Chlamydia cultures or polymerase chain reaction, wet mount.

Other Diagnostic Tests

- Transvaginal/pelvic ultrasound can be used to identify potential anatomic abnormalities such as masses/lesions or to detect ovarian cysts and endometriomas.

Nonpharmacologic Therapy

Several nonpharmacologic interventions are used for managing dysmenorrhea. Among these, topical heat therapy, exercise, and a low-fat vegetarian diet have been shown to reduce dysmenorrhea intensity.[57,58,60] Dietary changes may shorten dysmenorrhea duration. Topical heat application via an abdominal patch is as effective as 400 mg of ibuprofen dosed three times daily.[60,61] Because topical heat, exercise, and dietary changes do not impart systemic effects, they are associated with little to no risk compared to the pharmacologic options. Recent data is suggestive of the benefits of powdered ginger (250 mg by mouth every 6 hours) in significantly reducing the pain associated with dysmenorrhea when begun at the onset of menses.[62,63] Nonpharmacologic options that are reserved for use following a failed trial of pharmacologic interventions include transcutaneous electric nerve stimulation, acupressure, and acupuncture.[58]

Pharmacologic Therapy

Given the role of prostaglandins in dysmenorrhea pathophysiology, NSAIDs are the initial treatment of choice. These agents do not differ in efficacy. The most commonly used agents are naproxen and ibuprofen.

All NSAIDs have a propensity for causing GI distress and ulceration; their administration with food or milk minimizes these effects. In women who have a history of NSAID-induced gastric effects, the use of celecoxib, a cyclo-oxygenase-2 (COX-2) inhibitor, is an alternative.[19,20] Choice of one agent over another may be based on cost, convenience, and patient preference. Some research suggests that NSAID therapy should begin at the onset of menses or perhaps even the day before and continued around the clock instead of waiting until symptom onset. The data substantiating this are weak.[58] Acetaminophen is inferior to NSAID in treatment of this disorder.[58] If an NSAID or celecoxib use is contraindicated or not desired, hormonal agents should be considered.

Hormonal contraceptives improve dysmenorrhea by inhibiting endometrial tissue proliferation which reduces endometrial-derived prostaglandins that cause the pelvic pain.[8,58] Significant improvements in mild, moderate, and severe dysmenorrhea have been noted with HCs. Evidence supporting monophasic versus multiphase OC regimens, however, is lacking. And while the use of extended-cycle OCs would be desirable for this purpose, data illustrating their superiority over traditional monthly OCs do not currently exist.

Long-acting progesterones, such as depot MPA and the LNG-IUS, can be considered for

dysmenorrhea treatment. Their efficacy is secondary to their ability to render most patients amenorrheic within 6 to 12 months of use.[8,58] Because the pelvic pain of dysmenorrhea is related to the prostaglandins released during menses, in the setting of amenorrhea the underlying cause of dysmenorrhea is removed.

Drug Treatments of First Choice

Several factors influence the choice of first-line treatment for dysmenorrhea. If contraception is desired, then a hormonal option may be considered taking into account cost, adherence issues, and side effects. If contraception is not desired, then NSAID use would be desirable from cost and convenience standpoints. If NSAIDs are not tolerated, celecoxib could be recommended. In patients for whom OCs, NSAIDs, or celecoxib is not an option, topical heat should be considered.

Special Populations

Dysmenorrhea is common in adolescent females. The treatment measures used for adult patients are also appropriate for adolescents. Although NSAIDs, topical heat, and OCs are among the top choices, use of the levonorgestrel IUD is also an option.[40]

Drug Class Information

Table 80-3 identifies the significant pharmacologic properties for agents used to treat dysmenorrhea that require monitoring.

Evaluation of Therapeutic Outcomes

Table 80-3 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in the management of dysmenorrhea.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Premenstrual syndrome (PMS) is a constellation of symptoms including mild mood disturbances and physical symptoms occurring prior to menses and resolving with menses initiation. It is distinct from Premenstrual Dysphoric Disorder (PMDD).

Epidemiology

Up to 80% of menstruating women experience PMS symptoms.[64,65] However, a spectrum of premenstrual mood disturbances exists, and PMDD is the most severe. Approximately 3% to 9% of women have PMDD.[64,65,66]

Etiology and Pathophysiology

Premenstrual dysphoric disorder is a complex psychiatric disorder with multiple biological, psychological, and sociocultural determinants.[67] Although cyclic hormonal changes are in some way related to PMS and PMDD, the association is neither linear nor simple. When ovulation is suppressed medically or surgically, symptoms improve. Some evidence suggests that PMS and PMDD symptoms are related to low levels of the centrally active progesterone metabolite allopregnanolone in the luteal phase and/or lower cortical γ-aminobutyric acid levels in the follicular phase.[67] A number of studies suggest a link between PMS and PMDD and low serotonin levels.[67] Despite similar affective symptoms, hypothalamic–pituitary–adrenal (HPA) axis function in PMS and PMDD is distinct from that seen in major depressive disorder. Specifically, women with PMS show a decrease in stimulated HPA axis response, whereas this response is increased in women with major depressive disorder. Although several cross-cultural studies suggest that PMS physical symptoms are consistent across cultures, the negative affective symptoms are part of the negative "menstrual socialization" in western culture.[2,67]

Treatment

Women experiencing PMS and PMDD symptoms miss significantly more work and school than do controls. They also report significant impairment of their ability to participate in social activities and hobbies and in their relationships with others.[66] Given this, the need for effective treatment modalities is clear.

Desired Outcome

Premenstrual syndrome and PMDD interventions should alleviate the presenting symptoms and subsequently improve quality of life. Table 80-2 lists the various agents used in the managing PMS and PMDD and their recommended dosing.

General Approach to Treatment

A treatment modality that is minimally invasive or without systemic effects is desired for initial therapy. Key to the successful choice of pharmacologic therapy for PMS and PMDD is having the patient chart her specific symptoms for at least two menstrual cycles to assist in ruling out premenstrual exacerbation of underlying psychiatric disorders.

Nonpharmacologic Therapy

Lifestyle interventions should be started and followed for 2 months while the patient charts her symptoms. Although these interventions lack significant supporting clinical trial data, anecdotal reports of efficacy exist. Some lifestyle changes for women with mild-to-moderate premenstrual symptoms include minimizing intake of caffeine, refined sugar, and sodium and increasing exercise.[31,33] Vitamin and mineral supplements, such as vitamin B_6 (50-100 mg daily) and calcium carbonate (1,200 mg daily), may help to reduce the physical symptoms associated with PMS; however, clinical trial data is limited and/or mixed precluding a definitive conclusion regarding their use.[31,33] A clinical trial review concludes that the following options lack efficacy and safety data and

should not be recommended: herbal medicines, homeopathic remedies, dietary supplements, relaxation, massage therapy, reflexology, chiropractic treatments, and biofeedback.[68,69]

Pharmacologic Therapy

If symptoms persist after 2 months of symptom charting and lifestyle modifications, pharmacologic therapy for PMDD management is warranted. Most recent investigations have focused on the selective serotonin reuptake inhibitors (SSRIs) for this disorder.[70] Studies have revealed very positive results relative to most symptoms associated with PMDD. Other agents that have been studied and are alternatives include the selective serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine, as well as HCs and GnRH agonists.

Drug Treatments of First Choice

10 The first-line pharmacologic treatment options for PMDD are the SSRIs.[31,33,36,71] Among this class of agents, data support the use of citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. Current research evaluating the dosing of these agents continuously or only during the luteal phase has illustrated similar efficacy between the two regimens such that one regimen cannot be recommended over another.[33,36,70,71] The optimal duration of treatment is still not evident as relapse within 6 to 8 months of therapy discontinuation has been observed in at least half of all treated patients.[71] The use of paroxetine, specifically, may be questioned, as this agent has been associated with an increased risk of congenital abnormalities when taken during the first trimester of pregnancy.[31] Paroxetine use should be avoided in women of childbearing age who do not use a reliable form of contraception.

CLINICAL PRESENTATION PMDD

A summary of the American Psychiatric Association's criteria for PMDD is as follows:[2,36,67]

- Symptoms are temporally associated with the last week of the luteal phase and remit with onset of menses.
- At least five of the following symptoms are present: affective lability, anger or irritability often characterized by interpersonal conflicts, markedly depressed mood, anxiety, decreased interest in activities, fatigue, difficulty concentrating, changes in appetite, sleep disturbance, feelings of being overwhelmed, and physical symptoms, such as breast tenderness or bloating.
- One of the symptoms must be affective lability, irritability, markedly depressed mood, or anxiety.
- Symptoms interfere significantly with work and/or social relationships.
- Symptoms are not an exacerbation of another underlying psychiatric disorder.
- The criteria are confirmed prospectively by daily ratings over two menstrual cycles and must

have occurred during most menstrual cycles in the past year.

The SSRIs are efficacious in approximately 60% of treated patients compared to less than 30% of those receiving placebo.[31,71] An adequate therapeutic trial is at least two menstrual cycles.[71]

Alternative Drug Treatments

The SNRI, venlafaxine, has been studied for PMDD and, similar to the SSRIs, found to result in a 58% or greater improvement in symptoms in more than half of the treated patients.[31,33]

The use of a monophasic OC containing 20 mcg of ethinyl estradiol and 3 mg of drospirenone, a progesterone with antiandrogenic effects, improves premenstrual symptoms in women with PMDD.[32] The continuous cycle HC regimen delivering 90 mcg of levonorgestrel and 20 mcg of ethinyl estradiol daily has also been studied in controlled trials resulting in a 30% to 59% improvement in symptoms.[72] As with the SSRI and SNRI agents, optimal treatment duration is unknown, and superiority of one HC relative to another OC has not been established.

If treatment with the above options is unsuccessful, hormonal treatment with a GnRH agonist, such as leuprolide, can be considered.[31] Leuprolide improves premenstrual emotional symptoms as well as some physical symptoms, such as bloating and breast tenderness. However, its cost, the need for intramuscular administration, and its hypoestrogenism side effects (eg, vaginal dryness, hot flashes, and bone demineralization) severely limit its use.

Drug Class Information

Table 80-3 lists the significant pharmacologic properties for agents used to treat PMDD that require monitoring.

Personalized Pharmacotherapy

It is important that concomitant drug therapy of women prescribed any of the SSRIs or venlafaxine be evaluated closely for pharmacokinetic drug–drug interactions given the interface of these drugs with cytochrome P450 isoenzyme systems.

Evaluation of Therapeutic Outcomes

Table 80-3 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in PMDD management.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACOG	American College of Obstetricians and Gynecologists
AUB-O	abnormal uterine bleeding with ovulatory dysfunction

COX-2	cyclo-oxygenase-2
FHA	functional hypothalamic amenorrhea
FSH	follicle-stimulating hormone
GnRH	gonadotropin-releasing hormone
HC	hormonal contraceptive
HMB	heavy menstrual bleeding
HPA	hypothalamic–pituitary–adrenal
HPO	hypothalamic–pituitary–ovarian
IUDs	Intrauterine devices
LH	luteinizing hormone
LNG-IUS	levonorgestrel-releasing intrauterine system
MPA	medroxyprogesterone acetate
NSAID	nonsteroidal anti-inflammatory drug
OC	oral contraceptive
PCOS	polycystic ovary syndrome
PMDD	premenstrual dysphoric disorder
PMS	premenstrual syndrome
SHBG	sex hormone-binding globulin
SNRI	serotonin–norepinephrine reuptake inhibitor
SSRI	selective serotonin reuptake inhibitor

Chapter 81: Endometriosis

Deborah A. Sturpe; Kathleen J. Pincus

INTRODUCTION

KEY CONCEPTS

- 1 Endometriosis should be suspected in any woman of reproductive age with recurring cyclic or acyclic pelvic pain and/or subfertility, especially if pain does not improve with nonsteroidal anti-inflammatory drugs and hormonal contraceptives.
- 2 The etiology of endometriosis is likely multifactorial and requires a genetic or immunologic predisposition. Retrograde menstruation is the most widely accepted theory to account for displacement of endometrial tissue, although alternative theories have been proposed.
- 3 Treatment goals include improvement of painful symptoms and maintenance or improvement of fertility. Therapy is considered successful based on resolution of symptoms or achievement of pregnancy.
- 4 Both drug therapy and surgery may treat endometriosis-related pain, but infertility can be treated only with surgery or assisted reproductive techniques.
- 5 No medical therapy has been proven to be more effective than another; thus, the choice among agents is determined primarily by side-effect profile, cost, and individual patient response.
- 6 For endometriosis pain, surgical therapy is typically reserved for medical therapy failure.
- 7 Diagnosis of endometriosis can be made only via surgical visualization of lesions, not by physical examination or laboratory testing. Empiric treatment without confirmation of diagnosis is acceptable in most cases.
- 8 To help avoid loss of bone mineral density, add-back therapy should be used in any woman receiving a gonadotropin-releasing hormone agonist.

1 Endometriosis causes secondary dysmenorrhea and is associated with infertility. Presence of endometrial tissue outside the uterus is chronic and relapsing. Endometriosis treatment targets pain relief and fertility improvement.

EPIDEMIOLOGY

Endometriosis has up to a 10% estimated prevalence in the general female population.[1,2,3] Though the prevalence is substantially higher in patients with pelvic pain or infertility. Only 4% of premenopausal women presenting to primary care for nongynecologic problems have endometriosis, whereas up to 80% of adult women and 50% of adolescents with chronic pelvic pain are diagnosed with the disorder.[3,4] The incidence is 10-fold higher in women with infertility (20%-50%) compared with that in fertile women (0.5%-5%).[1,2,3,4,5] A genetic predisposition for endometriosis has also been noted, with a sixfold higher risk in women with first-degree relatives with severe endometriosis.[2,3,6,7]

ETIOLOGY

Endometriosis is characterized by findings of endometrial tissue outside the normal uterine cavity. It may be diagnosed at any age, but is most commonly found during the reproductive years (range 12-80 years, average 28 years). Risk of developing endometriosis increases with early menarche (≤11 years), shorter menstrual cycles (less than 27 days), and heavy, prolonged menstruation.[4,6,8] Conversely, higher parity and increased duration of lactation decrease the risk of endometriosis.[4,6,8] Taller, thinner women are more likely to develop endometriosis than patients with higher body weights, body mass indexes, or waist-to-hip ratios potentially due to higher follicular-phase estradiol levels.[6,8] The woman's own birth history may also relate to the risk of developing endometriosis with lower birth weights (less than 5.5 pounds [2.5 kg]), multiple fetal gestations, and in utero exposure to diethylstilbesterol conferring higher risks of future development of endometriosis potentially due to alterations in gestational exposure to hormones including estrogen.[2,6] Altered pelvic anatomy, such as Müllerian duct anomalies and cervical or vaginal outlet obstruction, also increases risk of developing endometriosis.[2,6] Regular exercise (greater than 4 h/wk), diets high in fruits and vegetables, and cigarette smoking are associated with decreased risk of endometriosis, where alcohol use, caffeine consumption, and high polychlorinated biphenyl concentrations are associated with increased risk.[4,6] Comorbid autoimmune disorders, such as rheumatoid arthritis, systemic lupus erythematosus, and autoimmune thyroid disease, are more common in cohorts of patients with endometriosis than population controls.[6,7]

Gene mutation studies suggest genes regulating inflammation, sex steroid regulation, metabolism, biosynthesis, detoxification, vascular function, and tissue remodeling may contribute to endometriosis, but no validated associations have been confirmed.[9] Alterations on chromosomes 7 and 10 have been identified in clusters of women with endometriosis.[2] It is most likely that a multitude of genetic mutations are involved with the development of endometriosis.

PATHOPHYSIOLOGY

2 Multiple theories exist to explain why endometrial tissue is present outside the uterine cavity, and the true pathophysiology is likely multifactorial.[2,7] The most widely accepted theory proposes that endometrial tissue is deposited in the peritoneal cavity by retrograde menstruation through the fallopian tubes.[2,7] However, retrograde menstruation occurs in up to 90% of women while only approximately 10% develop endometriosis, indicating that additional factors are necessary for endometrial lesions to attach, survive, and proliferate.[7] Endometrial fragments are routinely cleared by the immune system; there is currently much interest in researching the role immune deficiencies and alterations play in the development of endometriosis.[7] Endometrial tissue from women with endometriosis has been shown to be more resistant to natural killer cell lysis than endometrium from women without the disease, and women with endometriosis have been found to have impaired macrophage function.[7] Alternative theories include: inappropriate differentiation of mesothelial cells into endometrium-like tissue (coelomic metaplasia); hormonal or immunologic stimuli promoting differentiation of cells in the peritoneal lining to endometrial cells (induction theory); differentiation of stem cells from either bone marrow or the endometrial basalis layer into endometrial-like tissues (stem cell theory); and spread of menstrual tissue to distant sites through veins or lymphatic vessels (hematogenous or lymphatic spread).[2,7]

Endometriosis is a chronic inflammatory disorder that exhibits cellular proliferation, cellular invasion, and angiogenesis not unlike solid tumor malignancies.[7] Genetic alterations including upregulation of BCL-2, which inhibits cellular apoptosis, may predispose endometriotic lesion survival in certain women.[7] Endometriosis also demonstrates estrogen-dependency and progesterone resistance. Endometriotic tissue has a higher expression of aromatase enzymes and lower expression of 17-beta-hydroxysteriod dehydrogenase. Together these alterations result in increased concentrations of estrogen.[7] Endometriotic tissue also has decreased progesterone receptor expression, including an absence of certain receptor subtypes, which impairs progression from the luteal to secretory phase of menstruation.[7] Other noted genetic alterations demonstrated in patients with endometriosis included cytokines, matrix metalloproteinases, transcriptions factors, prostaglandins, and tumor suppressor genes.[2,7]

Pain associated with endometriosis results from increased concentrations of inflammatory markers, including prostaglandins and increased nerve density at lesion sites. Proinflammatory cytokines found in endometrial lesions, including tumor necrosis factor-α and interleukins 1, 6, and 8, promote lesion formation, adhesion, and infiltration and induce pain through pelvic nerve stimulation.[2,3,7,10] Prostaglandin $F_2\alpha$ induces vasoconstriction and can cause uterine contractions, a component of dysmenorrhea, while prostaglandin E_2 can induce pain through direct actions on nerves.[2] Overexpression of nerve growth factors promotes neuroangiogenesis in endometriotic tissue which leads to increased pain receptors expression; and it is hypothesized that endometriotic nerve fibers influence dorsal root neurons which increase the perception of pain.[7] Researchers have demonstrated that these nerve fibers are found significantly more often in patients with endometriosis than in those without endometriosis, in greater density in patients with higher pain scores (≥3 vs ≤20), and in

greater density in patients with deep infiltrating lesions.[11,12] The interplay between increased density of nerve fibers in endometrial lesions and increased concentrations of cytokines and prostaglandins in peritoneal fluid combines to confer significant pelvic pain in many patients. The location and depth of infiltration of endometriotic lesions impact the severity of pain symptoms.[10]

The pathophysiology for infertility in endometriosis is less well defined, especially in mild disease. In advanced endometriosis, inflammation and anatomic abnormalities such as ovarian cysts and adhesions may physically block fallopian tubes and decrease receptivity of the endometrium, thus hindering oocyte and embryo development.[2,3,13] The same inflammatory cytokines (macrophages, interlukins 1 and 6, and tumor necrosis factor-α) that lead to pain also create a hostile peritoneal environment leading to damage of sperm DNA and cell membranes.[13,14,15] Hormonal dysregulation resulting from the disease may also lead to altered endometrial receptivity and implantation, prolonged follicular phases, altered oocyte and embryo quality, or abnormal uterotubal transport which can adversely impact fertility.[13,15]

Clinical Presentation Endometriosis Symptoms

- Dysmenorrhea and infertility are the most common symptoms.
- Other symptoms include dyspareunia, menorrhagia, chronic pelvic pain (cyclic or acyclic), ovulation pain, sacral back pain, cyclic or perimenstrual bowel and bladder complaints (eg, GI disturbances, painful defecation, tenesmus dysuria, and/or hematuria), chronic fatigue, or rarely neuropathic pain.
- Some patients may be asymptomatic.

Signs

- Findings on physical examination are best observed during menstruation and may include pelvic or uterosacral ligament tenderness, enlarged ovaries, pelvic masses or nodules, or a fixed, retroverted uterus.
- Findings on laparoscopic examination may range from a few small lesions located on the ovaries, serosal surfaces, or peritoneum to large cysts called endometriomas. Lesions are often described as: “powder burn” or “gunshot” lesions; dark brown, black, or blue lesions, nodules, and cysts; and “chocolate cysts” (endometriomas containing blood).

Diagnosis

- Definitive diagnosis can be made only by direct surgical visualization of endometrial lesions; however, treatment guidelines allow for nondefinitive diagnosis in patients presenting with chronic pelvic pain provided that other causes of pain are ruled out and that pain responds to empiric therapies.
- Ultrasonography, magnetic resonance imaging, and computed tomography have much lower sensitivity for endometrial lesions, but have utility in assessing for pelvic or adnexal masses.

Disease Staging

- Severity of disease can be classified according to the American Society of Reproductive Medicine staging system (stage I [mild] to stage IV [severe]), but clinical utility of this staging system is limited because findings do not correlate with painful symptoms, nor does the staging system predict pregnancy rates. Staging may be useful in guiding decisions regarding prognosis and treatment for infertility.

Data from references 3 and 17.

TREATMENT

Endometriosis is a chronic, relapsing disease. Lifelong treatment plans must consider individual patient symptoms, goals for fertility, and impact on quality of life.[16] Various organizations, including the American College of Obstetricians and Gynecologists (ACOG), the American Society for Reproductive Medicine, the Society of Obstetricians and Gynaecologists of Canada, and the European Society of Human Reproduction and Embryology (ESHRE), have published evidence-based and/or expert opinion-based guidelines for treating endometriosis.[3,10,13,16,17] The ESHRE guideline, updated in 2014, uses structured methodology and grades recommendations based on the strength and quality of available evidence **(Table 81-1)**.[17]

TABLE 81-1 Evidence-Based Recommendations for Treatment of Endometriosis-Related Pain

Treatment Options	**Grade of Recommen-dation[a]**
CHCs	
Oral	B
Transdermal	C
Vaginal	C
Progestins	
Oral	A

Desired Outcomes

Identification of endometriosis treatment goals depends on individual patient presentation and needs. 3 4 Typical goals include minimization of associated pain, improved quality of life, and correction of associated infertility. The first two outcomes can often be achieved through use of pharmacologic therapy and surgery.[3,10,15] Infertility is nonresponsive to medical therapies; thus, surgical intervention to remove endometrial lesions coupled with various assisted reproductive techniques must be employed.[3,13] Even with such efforts, not all women with endometriosis will be able to conceive, and exact success rates are unknown due to a paucity of well-designed clinical studies.

General Approach to Treatment

Treatment of the asymptomatic patient with incidental findings of endometriosis is considered unnecessary.[17] For patients presenting with endometriosis-related pain, the foundation of therapy includes medical treatment, surgical treatment, or both. To date, no studies have directly compared medical and surgical treatment as first-line therapy. Furthermore, determining the optimal medical or surgical approach is difficult secondary to a paucity of well-designed, randomized, controlled trials

comparing options. 5 All commonly prescribed medical therapies relieve endometriosis-related pain by regressing lesions via induction of a pseudopregnancy or pseudomenopausal state, but medications do not eradicate lesions or improve fertility. The choice of initial therapy thus depends on factors such as the patient's primary complaint, the location and extent of disease, desire for future fertility, cost of therapy, contraindications to therapy, and potential side effects.[3,10,16,17] Information regarding drugs commonly prescribed for endometriosis, their dosing, side effects, and special monitoring parameters are listed in **Tables 81-2** and **81-3**. No endometriosis treatments are guaranteed to provide full relief of symptoms; consequently, analgesics such as nonsteroidal anti-inflammatory drugs or opioids are often used as adjunctive therapy for pain relief.

TABLE 81-2 Dosing of Drugs Used in Treatment of Endometriosis

Drug	Brand Name	Initial Dose	Usual Range	Other
CHCs				
CHC pill	Various (see Chapter 79)	One pill orally daily	One pill orally daily	Continuous dosing may improve efficacy
Etonogestrel/ethinyl estradiol (vaginal ring)	NuvaRing	Insert one ring monthly	Insert one ring monthly	Continuous dosing may improve efficacy
Norelgestromin/ethinyl estradiol (transdermal)	Ortho Evra	Apply one patch weekly	Apply one patch weekly	Continuous dosing may improve efficacy
Progestins				
Depot medroxyprogesterone acetate (IM or SubQ)	Depo-Provera	150 mg IM every 13 weeks	150 mg IM every 13 weeks	
	Depo-SubQ Provera	104 mg SubQ every 12-14 weeks	104 mg SubQ every 12-14 weeks	
Oral medroxyprogesterone acetate	Provera	30 mg orally daily	30-60 mg orally daily	
LNG-IUS[a]	Mirena	Single insertion for up to 5 years	Single insertion for up to 5 years	
Norethindrone acetate	Aygestin	5 mg orally daily	Titrate as needed to maximum dose 20 mg orally daily	
GnRH Agonists				
Goserelin	Zoladex	3.6 mg monthly SubQ implant	3.6 mg monthly SubQ implant	Use add-back therapy

Drug	Brand Name	Initial Dose	Usual Range	Other
Leuprolide	Lupron Depot	3.75 mg IM monthly or 11.25 mg IM every 3 months	3.75 mg IM monthly or 11.25 mg IM every 3 months	Use add-back therapy
Nafarelin	Synarel	400 µg intranasally daily, dosed as one spray in one nostril am and one spray in opposite nostril pm	May titrate to maximum 800 µg intranasally daily, dosed as one spray in each nostril twice daily	Use add-back therapy
Triptorelin	Trelstar Depot	3.75 mg IM monthly	3.75 mg IM monthly	Use add-back therapy
Androgens				
Danazol	Danocrine	100-200 mg orally twice daily	Titrate as needed to maximum 400 mg orally twice daily	
Aromatase Inhibitors				
Anastrozole	Arimidex	1 mg orally daily	1 mg orally daily	Use with CHC, progestin, or GnRH agonist
Letrozole	Femara	2.5 mg orally daily	2.5 mg orally daily	Use with CHC, progestin, or GnRH agonist

CHC, combined hormonal contraceptive; GnRH, gonadotropin-releasing hormone; IM, intramuscular; LNG-IUS, levonorgestrel-releasing intrauterine system; SubQ, subcutaneous.

[a]At this time, only Mirena has been studied in the endometriosis population. Other LNG-IUSs (Liletta and Skylar) should not be recommended until data are available to support their use.

TABLE 81-3 Monitoring Drug Therapy for Endometriosis

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
CHC pills	Nausea, vomiting, breast tenderness, weight gain, acne, oily skin, depression, fatigue, breakthrough bleeding or spotting, elevated blood pressure	Blood pressure within 3 months of starting new method	Many symptoms improve after two to three cycles of use
Etonogestrel/ethinyl estradiol (vaginal ring)	Nausea, vomiting, breast tenderness, weight gain, acne, oily skin, depression, fatigue,	Blood pressure within 3 months of starting new method	Many symptoms improve after two to three cycles of

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
	breakthrough bleeding or spotting, vaginal irritation, elevated blood pressure		use
Norelgestromin/ethinyl estradiol (transdermal)	Nausea, vomiting, breast tenderness, weight gain, acne, oily skin, depression, fatigue, breakthrough bleeding or spotting, application site reaction, elevated blood pressure	Blood pressure within 3 months of starting new method	Many symptoms improve after two to three cycles of use
Depot medroxyprogesterone acetate (IM or SubQ)	Menstrual irregularities, weight gain, acne, hirsutism, depression, decreased bone mineral density	None	Bone mineral density testing specifically not recommended at this time
Oral medroxyprogesterone acetate	Menstrual irregularities, nausea, peripheral edema Venous thromboembolism	None	
LNG-IUS	Menstrual irregularities, insertion-related complications, expulsion, pelvic inflammatory disease	None	Counsel on sexually transmitted infection prevention
Norethindrone acetate	Breast tenderness, nausea, peripheral edema Venous thromboembolism	None	
Goserelin	Acne, depression, hot flashes, mood swings, peripheral edema, vaginitis Bone mineral density loss	May consider bone mineral density testing every 1-2 years and serum lipid levels every 6 months if treatment extended beyond 12 months	Add-back therapy prevents many adverse reactions
Leuprolide	Acne, depression, dizziness, headache, hot flashes, mood swings, nausea/vomiting, triglyceride elevation, vaginitis Anaphylaxis, bone mineral density loss, venous	May consider bone mineral density testing every 1-2 years and serum lipid levels every 6 months if treatment extended beyond 12 months	Add-back therapy prevents many adverse reactions

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
	thromboembolism		
Nafarelin	Acne, headache, hot flashes, mood swings, vaginal dryness Bone mineral density loss, venous thromboembolism	May consider bone mineral density testing every 1-2 years and serum lipid levels every 6 months if treatment extended beyond 12 months	Add-back therapy prevents many adverse reactions
Triptorelin	Headache, high blood pressure, hot flashes Anaphylaxis, angioedema	May consider bone mineral density testing every 1-2 years and serum lipid levels every 6 months if treatment extended beyond 12 months	Add-back therapy prevents many adverse reactions
Danazol	Acne, peripheral edema, hirsutism, lipid abnormalities, weight gain Hepatic dysfunction	Liver function tests and serum cholesterol every 3-6 months	
Anastrozole	Arthralgias, hot flashes, myalgias, nausea, diarrhea Decreased bone mineral density	May consider bone mineral density testing every 1-2 years if treatment extended beyond 12 months	Limited adverse reaction data in premenopausal women with endometriosis
Letrozole	Arthralgias, hot flashes, myalgias, nausea, diarreha Decreased bone mineral density	May consider bone mineral density testing every 1-2 years if treatment extended beyond 12 months	Limited adverse reaction data in premenopausal women with endometriosis

CHC, combined hormonal contraceptive; IM, intramuscular; LNG-IUS, levonorgestrel-releasing intrauterine system; SubQ, subcutaneous.

Nonpharmacologic Therapy

Surgery, generally performed via laparoscopy, is used in endometriosis as both a diagnostic and a therapeutic tool.[13,17] [4] [6] Due to lack of data supporting superiority of surgical versus medical therapies in relieving endometriosis pain, surgical therapy is typically reserved for patients

experiencing medication failure or who suffer from infertility, although clinicians are encouraged to "see and treat" any symptomatic patient undergoing diagnostic surgery by removing visible lesions.[17] Women with continuing pain symptoms who do not desire pregnancy may be offered the option of hysterectomy with or without oophorectomy, although such radical surgery does not guarantee freedom from symptoms.[17]

Use of perioperative medical therapy is a source of treatment controversy. Although most experts agree that preoperative medication use does not improve surgical outcomes, the role of postoperative medical therapy is less certain.[17] The ESHRE guideline now clearly delineates between adjunctive medical therapy (used within 6 months of surgery) and secondary prevention (used later than 6 months postsurgery).[17] The guideline recommends against adjunctive therapy solely for further reduction of pain, but does acknowledge that medical therapies may be started immediately postsurgery for other indications such as contraception or menstrual cycle control.[17] For secondary prevention of dysmenorrhea after surgery, the levonorgestrel intrauterine system (LNG-IUS) or combined hormonal contraceptives (CHCs) are recommended due to equivalent efficacy and better tolerability than other therapeutic options.[17,18,19]

Clinical Controversy…

Many women seek relief of endometriosis pain through complementary and alternative methods such as electrical nerve stimulation, acupuncture, traditional Chinese medicine, and dietary therapy (particularly vitamins B_6, A, C, and E, mineral salts such as calcium, magnesium, selenium, zinc, and iron, lactic ferments, and omega-3 and omega-6 fatty acids). Reputable data to support such methods are often sparse to nonexistent, thus practice guidelines recommend against such use.[17] However, these same guidelines do recognize that such methods may be beneficial in some women. Unfortunately, it is difficult to determine who may benefit most (or least). Provided a treatment is unlikely to cause harm, it may be reasonable to support use of complementary and alternative therapies in women specifically interested in such options.

Pharmacologic Therapy

 Pharmacologic therapy is typically the first choice for treatment of endometriosis-related pain to minimize risks from multiple surgeries such as scarring and tissue adhesions.

Drug Treatments of First Choice

First-line therapy for endometriosis-associated pain typically includes oral CHCs, oral progestins (norethindrone acetate or medroxyprogesterone acetate) or the depot progestin medroxyprogesterone acetate (DMPA) since these drugs are considered as effective as, but less costly and toxic than, other pharmacologic options.[3,10,16,17] Choice among these classes and agents depends on patient characteristics such as the desire for contraception, pain pattern, contraindications, and potential side effects, as no direct comparisons are available in the literature. Long-term maintenance therapy with these agents should be considered for women achieving a

good therapeutic response.[3] 7 These drugs may be used empirically for suspected endometriosis prior to laparoscopy in patients of any age.[3,10,16,17] Despite a clear lack of efficacy data in the endometriosis population, analgesics are also recommended as adjunctive therapy to these other first-line options.[17]

Alternative Drug Treatments

Alternative choices for endometriosis pain include the LNG-IUS, transdermal or vaginal CHC, a gonadotropin releasing hormone (GnRH) agonist, or danazol.[3,16,17,20] 7 Selection is again driven primarily by patient preference, patient-specific response, side-effect profile, available dosage forms, and medication costs, since no method has been proven superior to another.[3,10,16,17] Unlike the first-line agents, either the safety of long-term use is unknown or efficacy is less well defined for these alternative options. A major concern with long-term use (greater than 6 months) of GnRH agonist is bone mineral density loss, but add-back therapy with an estrogen and progestin combination minimizes this loss along with mitigation of other bothersome side effects and has been shown to be safe for up to 10 years of use.[21,22] 8 Consequently, it is recommended to start add-back therapy on immediate initiation of GnRH agonist treatment.[3,16,17]

A pharmacologic option for endometriosis pain refractory to the aforementioned drug and nondrug methods is an aromatase inhibitor in combination with a CHC, progestin, or GnRH agonist, particularly in women with rectovaginal endometriosis.[17] Because long-term studies of aromatase inhibitors are lacking, use is reserved for refractory patients due to concern over potential long-term side effects, especially in a premenopausal population

Special Populations

Treatment of the adolescent patient with endometriosis presents a unique challenge, as these patients often present with normal physical findings and laparoscopic findings that are atypical for endometriosis; thus, endometriosis must be strongly suspected in any patient whose dysmenorrhea fails to respond to first-line agents.[16] Treatment recommendations for such patients are extrapolated from adult guidelines and generally follow the same recommendations as for adult patients.[16,20] Pertinent differences include preference for diagnostic laparoscopy after first-line medical treatment failure before initiation of alternative medical treatments and limitation of GnRH agonist therapy due to concern about drug-associated bone loss in a population that has not yet reached peak bone mineral density.[16,17,20] In at least one study, use of progestin-only add-back therapy during GnRH agonist treatment in adolescents did not fully prevent bone loss, possibly emphasizing the need to carefully consider selection of this drug class in the adolescent population and to consider routine monitoring of bone mineral density if prescribed.[23] Despite these limitations in treating adolescents, early recognition and treatment of endometriosis in this population may be critical for maintenance of quality of life and reduction of future disease-related complications.[24,25,26]

Clinical Controversy...

Treatment of vasomotor and urogenital symptoms in women with surgically induced menopause due to endometriosis may be problematic as the potential relief of menopausal symptoms must be weighed against the risk of disease reactivation upon administration of hormone therapy. Despite this risk, guidelines support use of hormone therapy in women after surgical hysterectomy-oophorectomy until the average age of menopause.[17] Although estrogen therapy alone would typically be prescribed for this patient population, endometriosis guidelines endorse use of estrogen-progestin combination therapy since risk of disease reactivation may be lowered by the addition of the progestin component. However, hormone therapy related risks are known to be greater with estrogen-progestin therapy versus estrogen therapy alone. Thus no clear guidance exists on how to best treat this patient population.

Drug Class Information

No single drug therapy has been shown to be superior to another for the treatment of endometriosis pain. Therefore, the choice of drug between and within classes is often dependent on patient factors and clinician experience.

Combined Hormonal Contraception

Effectiveness of oral CHCs in treating endometriosis pain has been demonstrated in only a small number of observational, placebo-controlled, and active-comparator trials.[17,27] Despite this overall paucity of clinical trial data, the widespread use and effectiveness of oral CHCs for other dysmenorrheas, the secondary benefits of contraception and menstrual regulation, and the good safety record of these agents leads to oral CHCs being recommended as first-line therapy.[17] There is no evidence to suggest superiority of any particular oral CHC over another, although most studies used monophasic pills. Effectiveness of the CHC patch and vaginal ring has also been demonstrated in one study.[28] Overall, the choice between CHCs should be guided by patient preference, likelihood of adherence, and cost.

Administration of CHCs may be cyclic (includes a placebo or nondrug week) or continuous. Effectiveness of continuous dosing was first demonstrated in a prospective study in which patients with recurrent postoperative dysmenorrhea were switched from cyclic to continuous CHC dosing.[29] Severity of pain was significantly reduced after the switch, and more than 80% of patients reported satisfaction with the method. In a more recent randomized, placebo-controlled trial comparing cyclic and continuous dosing of a low-dose monophasic oral contraceptive pill after laparoscopy, the continuous dosing strategy provided statistically superior improvement in pain and disease recurrence compared with both the cyclic dosing and placebo groups at 6, 12, 18, and 24 months postoperatively, while the cyclic dosing group demonstrated superiority only over placebo after 12 months of therapy.[30] One theory that may explain these findings is prevention of retrograde menstruation through induction of an amenorrheic state with continuous dosing. Based on these findings, the ESHRE guidelines recommend continuous CHC dosing as an option for patients.[17]

Progestins

Various studies have demonstrated the effectiveness of progestins in treating the pain of endometriosis. The largest body of data support use of oral norethindrone acetate, oral dienogest (not available in the United States), oral medroxyprogesterone acetate, and DMPA. As with all endometriosis treatments, active comparator studies (eg, progestin vs GnRH agonist, progestin vs danazol) have failed to demonstrate superiority of any one drug class over another.[31] There are no trials that directly compare the various progestins with one another; thus, selection of an agent must consider its dosage form, cost, and potential side effects.

One concern over use of DMPA is its potential to cause bone mineral density loss, and for this reason both the intramuscular and the subcutaneous products carry FDA black box warnings against use for more than 2 years. Despite this labeling, ACOG has stated that the concern over bone mineral density and potential fracture risk should not deter clinicians from prescribing and continuing DMPA in appropriate patients since bone loss appears to be almost completely reversible upon discontinuation of the drug.[32] Although this ACOG statement specifically addresses use of DMPA for contraception, one may surmise that the same may hold true in the endometriosis population. Prolonged delays in return to ovulation after cessation of therapy of DMPA is also concerning, thus it may not be optimal for use in women desiring future pregnancy.[16]

Levonorgestrel Intrauterine System

The LNG-IUS is an intriguing option for treating endometriosis due to its ability to locally deliver progestin to the uterine cavity, causing atrophy and pseudodecidualization of the uterine lining and endometrial cell apoptosis, without significant systemic absorption.[33] To date, almost all studies demonstrating effectiveness of the LNG-IUS have been conducted in patients previously undergoing conservative surgery, with time to insertion of the LNG-IUS varying from immediately to 5 years after surgery.[34] Effectiveness has also been shown in adolescent patients after surgery.[33] Although three LNG-IUS products are now available in the United States, only Mirena has been studied in endometriosis patients. The three systems differ in the amount of daily drug delivered, thus it cannot be assumed that the other two products (Skyla and Liletta) will demonstrate similar benefits.

Disadvantages of the LNG-IUS include potential difficulty of inserting the device into nulliparous women, a 5% expulsion rate, and the potential for growth of ovarian endometriomas since the method does not inhibit ovulation.[16]

Gonadotropin-Releasing Hormone Agonists

GnRH agonists create a functional oophorectomy via inhibition of follicle-stimulating hormone and luteinizing hormone secretion. For the first 2 to 3 weeks after initiation, GnRH agonists create a gonadotropin flare prior to receptor downregulation. This flare often causes a temporary increase in pain. Initiating therapy during the mid-luteal phase and/or overlapping the first 3 weeks of therapy with a CHC or progestin may minimize such effects, and use of analgesics during this time frame is also critical.[35] Of the four agents available for use in the United States (goserelin, leuprolide, nafarelin, and triptorelin), route of administration and cost is the primary distinguishing factor that determines choice of drug.

Pain relief with GnRH agonists is superior to placebo and comparable to other therapies such as danazol, CHCs, DMPA, and the LNG-IUS.[36] As previously noted, many clinicians now prescribe GnRH agonists indefinitely due to the fast recurrence of pain that occurs upon discontinuation and ability to avoid unwanted side effects through use of add-back therapy.

Side effects are the primary limitation of GnRH agonist use. The pharmacologically induced hypoestrogenic environment results in bone mineral density loss and vasomotor symptoms such as hot flashes, vaginal dryness, and insomnia. Without add-back therapy, loss of bone mineral density is estimated at 4% to 8% within a 6-month treatment course, and this loss continues progressively over time.[37,38]

Cost of the GnRH agonists is high. In one study, every 6-week dosing of intramuscular triptorelin was compared with its usual every 4-week dosing regimen.[39] Pain relief and serum hormone levels were equivalent between groups, suggesting that an extended interval strategy may be an option for cost savings.

Add-Back Therapy

8 Add-back therapy refers to use of pharmacologic agents in addition to GnRH agonists in order to minimize side effects (eg, hot flashes and decreased libido), improve adherence, and most importantly protect bone mineral density.[22,37] Regimens investigated for this purpose have generally included progestin monotherapy or estrogen-progestin combinations, with a recent meta-analysis and randomized, controlled trial concluding that only an estrogen-progestin combination is protective of bone mineral density loss.[38,40] Although it may seem counterintuitive to use such therapy in endometriosis patients, it appears that maintaining serum estrogen levels at less than 50 pg/mL (184 pmol/L) prevents GnRH agonist side effects while still preventing growth of new endometrial tissue.[16,22] For this reason, CHCs should not be used as add-back therapy as they will cause serum estrogen levels to exceed this threshold.[35] Instead, the estrogen and progestin doses typically used in menopausal women are more appropriate. Examples of regimens studied include oral conjungated equine estrogens 0.625 mg/day plus oral norethindrone acetate 5 mg/day, and transdermal estradiol 25 µg twice weekly plus oral medroxyprogesterone acetate 5 mg/day, and oral estradiol 2 mg/day plus oral norethindrone acetate 1 mg/day.[40]

Danazol

Danazol has been shown to be effective both empirically and after surgery compared with placebo.[41] Formerly the "gold standard" of endometriosis treatment, the popularity of danazol has decreased with the development of agents with more favorable side-effect profiles. Danazol should not be initiated in women with hyperlipidemia or liver disease. It is teratogenic; thus, barrier forms of contraception must be used.

In an effort to diminish the high rate of androgenic side effects noted with danazol while maintaining effectiveness, vaginal danazol formulations (100-200 mg/day) have been investigated in three small studies.[42,43,44] Each study was a nonrandomized, prospective trial in women who had failed other

therapies such as surgery, GnRH agonists, and the LNG-IUS. In each, improvements in dysmenorrhea, deep dyspareunia, and pelvic pain were noted without incidence of systemic side effects; thus, vaginal delivery of this drug may prove to be a viable method. Unfortunately, a vaginal formulation is not yet available in the United States.

Aromatase Inhibitors

Aromatase inhibitors are the most recent drug class to be formally added as a treatment option in endometriosis guidelines.[17] Because aromatase is a key enzyme in the conversion of adrenal androgens to estrogens, the agents diminish endometrial lesions by lowering overall estrogen concentrations by 97% to 99%.[45] Numerous case reports and retrospective, nonrandomized and noncomparative, as well as randomized comparative studies support the effectiveness of both letrozole and anastrozole in decreasing pain, improving quality of life, and reducing postoperative recurrence of disease in women refractory to other treatment efforts.[17,45,46,47,48,49,50] In all cases, the aromatase inhibitor was used in combination with a progestin, a combined oral contraceptive, or a GnRH agonist. Because most safety information for the aromatase inhibitors is derived from use in postmenopausal women with cancer, it is unknown if similar issues will be experienced by premenopausal women using these agents for endometriosis. Of particular concern is the impact of use on bone mineral density. Based on available data, it does appear that use of progestins and combined oral contraceptives in combination with the aromatase inhibitors helps limit bone mineral density loss.[45,49]

Personalized Pharmacotherapy

At this point in time, no evidence exists to suggest how to select or dose therapy for endometriosis based on pharmacogenomic, pharmacogenetic, or pharmacokinetic differences between patients. As additional understanding of the pathogenesis of endometriosis emerges, such personalized pharmacotherapy options might be realized.

EVALUATION OF THERAPEUTIC OUTCOMES

Size, number, and distribution of endometrial lesions do not correlate with pain symptoms or fertility potential; thus, therapeutic outcome monitoring should focus solely on subjective relief of symptoms.[3] Although traditional measures such as visual pain scales and symptom diaries have been used to measure treatment effectiveness, such measures do not capture overall patient satisfaction with treatment, a factor which has been correlated to treatment adherence.[51] A patient-reported outcome instrument, the Endometriosis Treatment Satisfaction Questionnaire, has been developed and validated.[51] The tool includes six items (pain before and/or during periods, pain during and/or after sex, endometriosis pain, bleeding/spotting, tolerability, overall satisfaction) that are rated by patients on a 7-point Likert scale.[51] The SF-36 has also been validated in the endometriosis population.[52]

3 Endometriosis-related pain should be relieved within 2 months of initiating medical therapy. If

symptoms persist, consideration should be given to different medical and/or surgical therapy. For endometriosis-related infertility, most experts recommend 6 months of watchful waiting after surgical intervention. If pregnancy is not achieved within that time, assisted reproductive techniques can be considered.

MENOPAUSE AND MENOPAUSAL HORMONE THERAPY

KEY CONCEPTS

- 1 The decision to use menopausal hormone therapy (MHT) and the type of formulation used must be individualized based on several factors, including the severity of menopausal symptoms and the risks of cardiovascular disease, breast cancer, osteoporotic fracture, and venous thromboembolic events (VTE).
- 2 Menopausal hormone therapy is the most effective treatment option for alleviating moderate to severe vasomotor symptoms.
- 3 Cardiovascular disease—including coronary artery disease, stroke, and peripheral vascular disease—is the leading cause of death among women, and MHT should not be used for reducing the risk of cardiovascular disease.
- 4 The risk of breast cancer associated with MHT appears to be associated with the addition of progestogen therapy to estrogen. Use of estrogen alone does not increase the risk of breast cancer.
- 5 In recently postmenopausal women who are at increased fracture risk, systemic estrogen therapy may be indicated for the prevention of osteoporotic fractures when alternate therapies are either contraindicated or cause excessive adverse effects.
- 6 Menopausal hormone therapy appears to improve depressive symptoms in symptomatic menopausal women.
- 7 Use of MHT at doses lower than those prescribed historically (ie, prior to the Women's

Health Initiative [WHI] study) appears to be effective in reducing bone loss and managing menopausal symptoms.

- 8 Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (ie, unopposed estrogen), use of systemic estrogen in women with an intact uterus must always be accompanied by a progestogen or an estrogen agonist antagonist for endometrial protection.

- 9 Premenopausal hormone therapy in young women with primary ovarian insufficiency (POI) differs markedly from MHT, and results of randomized trials conducted in menopausal women, including the WHI trial, cannot be extrapolated to premenopausal women with ovarian dysfunction.

All women undergo menopause, but every woman experiences it differently. Natural menopause occurs in stages including perimenopause (in the 5th decade), menopause, and postmenopause (1 year after menopause and beyond). Induced menopause can be experienced any time before natural menopause with bilateral oophorectomy (removal of both ovaries) or iatrogenic ablation of ovarian function (eg, chemotherapy, pelvic radiation). Symptoms of menopause can vary widely with induced menopause typically causing more severe symptoms. Due to the variability in duration, severity, and presence of menopausal symptoms among women, treatment should be individualized with treatment goals and decisions established in a shared decision making process.

Epidemiology

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity. The median age at the onset of menopause in the United States is 51 years, but can vary widely from 40 to 58 years.[1] An estimated 6,000 women in the United States reach menopause each day, and will spend approximately 40% of their lives in postmenopause.[2] It is estimated that by 2025, the number of postmenopausal women will be 1.1 billion worldwide.[1] By definition, menopause is a normal physiologic event that occurs after 12 consecutive months of amenorrhea, so the time of the final menses is determined retrospectively. Women who have undergone hysterectomy (removal of the uterus) must rely on their symptoms to estimate the actual time of menopause, but typically occurs a few years earlier than natural menopause.

Etiology

A nomenclature and staging system for the female reproductive aging continuum was developed at the Stages of Reproductive Aging Workshop (STRAW) in 2001 and revised in 2011 with the STRAW + 10 staging system.[3] The menopause transition refers to the span of time including menstrual, endocrine, and symptom changes starting with variation in menstrual cycle length and ending with the final menstrual period (FMP). Postmenopause occurs for the years beyond the FMP with stabilization of hormone levels and limited endocrine changes.

Pathophysiology

A woman is born with approximately two million primordial follicles in her ovaries. During a normal reproductive life span, she ovulates fewer than 500 times. The vast majority of follicles undergo atresia.

The hypothalamic–pituitary–ovarian axis dynamically controls reproductive physiology throughout the reproductive years. The pituitary is regulated by pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH), produced by the pituitary in response to GnRH, regulate ovarian function. These gonadotropins also are influenced by negative feedback from estradiol and progesterone. Ovarian follicular activity is reflected by the circulating concentrations of sex steroids and by peptide hormones including inhibin, activin, and anti-Mullerian hormone (AMH). AMH is a product of growing ovarian follicles, which appears to be independent of the hypothalamic–pituitary–gonadal axis. It is a principal regulator of early follicular recruitment from the primordial pool such that the concentration of AMH in blood may also reflect the nongrowing follicle population. AMH concentrations decline with age. While AMH levels may predict the median time to menopause, obtaining levels of AMH, FSH, and estradiol may be best reserved for women seeking fertility.[4] The sex steroids include estradiol, produced by the dominant follicle; progesterone, produced by the corpus luteum after maturation of the dominant ovarian follicle; and androgens, primarily testosterone and androstenedione, secreted by the ovarian stroma. Sex steroids are important for the healthy functioning of many organs, including the bones, brain, skin, and reproductive and urogenital tracts. They act primarily by regulating gene expression.

Pathophysiologic changes associated with menopause are caused by loss of ovarian follicular activity. Ovarian primordial follicle numbers decrease with advancing age, and at the time of menopause, few follicles remain in the ovary. Hence, the postmenopausal ovary is no longer the primary site of estradiol or progesterone synthesis. The postmenopausal ovary secretes primarily androstenedione. In contrast to the acute fall in circulating estrogen at the time of menopause, the decline in circulating androgens commences in the decade leading up to the average age of natural menopause and closely parallels increasing age. Whether the ovary continues to secrete testosterone after menopause remains controversial. Hypertrophy of the ovarian stroma may develop after menopause, probably secondary to high LH concentrations, thereby resulting in increased ovarian testosterone production. Alternatively, the ovaries may become fibrotic and a poor source of sex steroids. No endocrine event clearly signals the time just prior to final menses.[5]

As women age, a progressive rise in circulating FSH and a concomitant decline in ovarian inhibin-B and AMH are observed. In women who continue to experience menstrual bleeding, FSH determinations on day 2 or 3 of the menstrual cycle exceeding 10 to 12 International Units/L (10-12 IU/L) may indicate diminished ovarian reserve. Alternatively, low AMH concentrations, measured at any time in the cycle, predicts diminishing ovarian reserve. Clear elevations in serum FSH are seen in women approximately at age 40 years.[5] When ovarian function has ceased, serum FSH concentrations are greater than 40 IU/L. Menopause is characterized by a 10- to 15-fold increase in circulating FSH concentrations compared with concentrations of FSH in the follicular phase of the cycle, a fourfold to fivefold increase in LH, and a greater than 90% decrease in circulating estradiol concentrations.[5] During the perimenopause, FSH concentrations may rise to the postmenopausal

range during some cycles but return to premenopausal levels during subsequent cycles. Thus, high concentrations of FSH should not be used to diagnose menopause in perimenopausal women.

Clinical Presentation

The perimenopause commences with the onset of menstrual irregularity and ends 12 months after the last menstrual period.[3] Approximately 90% of women have 4 to 8 years of menstrual cycle changes with heavier flow of longer duration before natural menopause occurs.[1] The menstrual cycle irregularity is most often caused by the increased frequency of anovulatory cycles, but may also be due to thyroid abnormalities, hyperprolactinemia, or polycystic ovary syndrome. Women commonly experience symptoms during the perimenopause, which substantially impact their health and daily function. Vasomotor symptoms (eg, hot flushes and night sweats) occur in up to 75% of women for 6 months to 2 years, and some women have bothersome symptoms for 10 years or longer.[1] Vasomotor symptoms persist for an average 7.4 years with moderate to severe vasomotor symptoms extending in 42% of women age 60 to 65 years.[6,7] Research has shown that 25% of women experience severe vasomotor symptoms, 30% experience severe psychological symptoms (eg, depression and anxiety), and 50% report moderate to severe symptoms of sleep disturbance, joint pain, or headache, and at least one in four women have sexual dysfunction.[8,9] Genitourinary syndrome of menopause (GSM) is a collection of symptoms associated with decreased estrogen and other sex steroids that create changes to the labia majora/minora, clitoris, vestibule/introitus, vagina, urethra, and bladder.[10] Resulting symptoms include genital dryness, burning, and irritation; sexual symptoms of lubrication difficulty, discomfort or pain, and impaired sexual function; and urinary symptoms of urgency, dysuria, and recurrent urinary tract infections. Vaginal symptoms occur in an estimated 45% of women, but only 4% can identify these symptoms as vulvovaginal atrophy related to menopause.[11]

Women who experience severe symptoms, either from early in the menopause transition or from their FMP, are likely to continue to experience severe symptoms for several years.[8] The perimenopause is associated with a higher vulnerability to depression with the risk increasing from early to late perimenopause and decreasing during postmenopause.[12] Women with a history of depression are nearly five times as likely to be diagnosed with depression during the perimenopause, whereas women with no history of depression are two to four times more likely to have a diagnosis compared with premenopausal women.[12]

In addition to the symptoms of menopause, loss of estrogen production results in significant metabolic changes including effects on body composition, cognition, lipids, vascular function, and bone metabolism. The menopause transition is associated with a significant increase in central abdominal fat leading to an average weight gain during the menopausal transition of 5 pounds; however this is likely to be related to aging and lifestyle rather than menopause.[1] Skin changes including decreased thickness and elasticity, loss of collagen, and wrinkling, and hair changes including alopecia and hirsutism are also associated with menopause. Poor concentration and memory are common during the menopause transition and early postmenopause.[1] Memory performance and processing speed slightly decline during the menopausal transition, but reach premenopausal levels after menopause. It is important to note that these cognitive symptoms can be

affected by other symptoms of menopause including sleep disturbances, hot flushes, depressed mood, fatigue, and midlife stressors.

CLINICAL PRESENTATION Perimenopause and Menopause Signs

- Perimenopause: DUB as a result of anovulatory cycles (other gynecologic disorders should be excluded).
- Menopause: signs of GSM.

Symptoms

- Vasomotor symptoms (hot flushes and night sweats)
- Sleep disturbances
- Mood changes
- Problems with concentration and memory
- Vaginal dryness and dyspareunia
- Arthralgia

Laboratory Tests

- Perimenopause: FSH on day 2 or 3 of the menstrual cycle greater than 10 to 12 IU/L
- Menopause: FSH greater than 40 IU/L

Other Relevant Diagnostic Tests

- Thyroid function tests
- Iron stores
- Lipid profile

Dysfunctional uterine bleeding (DUB) may occur during the perimenopausal years because of anovulatory cycles; however, abnormal uterine bleeding always merits investigation when it cannot be simply explained by menopausal cyclical irregularity. Treatment options for DUB include insertion of an intrauterine progestin-only device, systemic progestogen therapy, or the combined oral contraceptive pill unless contraindicated.

Treatment: Menopause

Desired Outcomes

Menopause is a natural life event, not a disease. The primary goals of therapy for menopause are to

relieve symptoms and improve quality of life while minimizing adverse effects. This can be best achieved by individualizing treatment based on medical, social, and family history as well as her symptoms and quality of life goals.

General Approach to Treatment

In women with mild vasomotor symptoms, nonpharmacologic therapy can be considered. In women with moderate to severe hot flushes and vulvovaginal symptoms, menopausal hormone therapy (MHT) is the treatment of choice unless contraindicated (**Table 82-1**). Treatment of mild vulvovaginal symptoms should include nonhormonal lubricants and moisturizers. However, for some women these treatments are not effective. **Fig. 82-1** outlines an algorithm for the general management of menopausal women.

TABLE 82-1 FDA-Labeled Indications and Contraindications for Menopausal Hormone Therapy with Estrogens and Progestins

Indications	
For systemic use	Treatment of moderate to severe vasomotor symptoms (ie, moderate to severe hot flushes)
For intravaginal use (low systemic exposure)	Treatment of moderate to severe symptoms of vulvar and vaginal atrophy (ie, moderate to severe vaginal dryness, dyspareunia, and atrophic vaginitis)
Contraindications	
Absolute contraindications	Undiagnosed abnormal genital bleeding
	Known, suspected, or history of cancer of the breast
	Known or suspected estrogen- or progesterone-dependent neoplasia
	Active deep vein thrombosis, pulmonary embolism, or a history of these conditions
	Active or recent (eg, within the past year) arterial thromboembolic disease (eg, stroke, myocardial infarction)
	Liver dysfunction or disease
Relative contraindications	Elevated blood pressure
	Hypertriglyceridemia
	Impaired liver function and past history of cholestatic jaundice
	Hypothyroidism
	Fluid retention
	Severe hypocalcemia

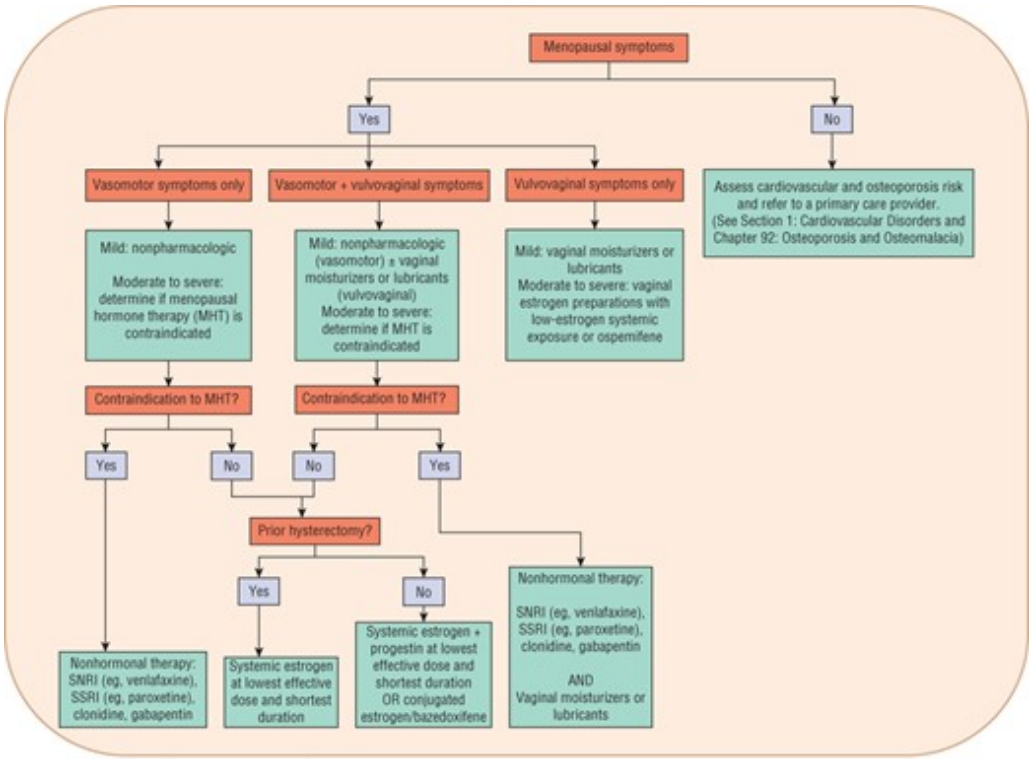
Ovarian cancer

Exacerbation of endometriosis

Exacerbation of asthma, diabetes mellitus, migraine, systemic lupus erythematosus, epilepsy, porphyria, and hepatic hemangioma

FIGURE 82-1

Algorithm for pharmacologic management of menopausal symptoms.



1 The decision to use MHT and the type of formulation used must be individualized based on several factors, including the severity of menopausal symptoms and the risks of cardiovascular disease, breast cancer, osteoporotic fracture, and venous thromboembolic events (VTE). Breast cancer risk is increased with concomitant progestogen use in menopausal women with an intact uterus.[13] VTE may also increase with higher estrogen doses and oral administration.[14,15]

The duration of therapy also needs to be individualized according to severity of symptoms, health status, and concerns regarding risks. Approved indications of MHT include treatment of moderate to severe vasomotor symptoms, moderate to severe vulvovaginal atrophy, and prevention of postmenopausal osteoporosis. For treatment of vasomotor symptoms, systemic MHT is the most effective pharmacologic intervention (see Fig. 82-1). For symptoms of vulvar and vaginal atrophy, such as vaginal dryness, intravaginal products should be considered.

Nonpharmacologic Therapy

Mild menopausal symptoms may be managed effectively with lifestyle modifications, including wearing layered clothing that can be removed or added as necessary, lowering room temperature, decreasing intake of hot spicy foods, caffeine, and hot beverages, exercise, and other good general health practices. Dietary supplements have been promoted as alternatives to MHT with conflicting results.[16]

Pharmacologic Therapy

Pharmacologic therapy is the mainstay of management of menopausal symptoms and includes both hormonal (estrogen with or without progestogen) and nonhormonal medications.

Drug Treatment of First Choice

2 Menopausal hormone therapy is the most effective treatment option for alleviating moderate to severe vasomotor symptoms. In women with an intact uterus, systemic MHT consists of an estrogen plus a progestogen or estrogen agonist/antagonist (eg, bazedoxifene) to prevent endometrial hyperplasia. In women who have undergone hysterectomy, estrogen therapy is given unopposed by a progestogen. Mild vulvovaginal symptoms may be adequately managed with nonhormonal lubricants and moisturizers.[17] However, vaginal estrogen therapy (cream, tablet, and ring) may be needed for moderate to severe vulvovaginal symptoms. Progestogen therapy for endometrial protection is not recommended with the use of low-dose vaginal estrogens (ie, those with minimal systemic exposure), but it should be noted that endometrial safety studies of vaginal estrogen therapy do not extend beyond 1 year.

Published Guidelines

A number of national and international guidelines and consensus statements on the management of menopause are available.[1,18,19,20,21,22,23] The United States Preventive Services Task Force also provides a recommendation statement on the use of MHT for the prevention of chronic medical conditions in postmenopausal women.[24]

Therapy for Perimenopausal Women

Despite a decline in fertility with age, sexually active women may become pregnant during the perimenopausal years. Furthermore, perimenopausal women can experience hot flushes despite having menstrual cycles. Combined hormonal contraceptives (containing low-dose estrogen and progestogen) provide contraception and vasomotor symptom relief. Perimenopausal women should not use estrogen-containing contraceptives if they smoke or have a history of estrogen-dependent cancer, heart disease, high blood pressure, diabetes, or thromboembolism. For perimenopausal women with DUB due to anovulatory cycles, a progestin-only intrauterine device may be a useful option. Combined hormonal contraceptives provide the additional benefit of reducing the risk of ovarian and endometrial cancer.

Menopausal hormone therapy remains the most effective treatment for moderate and severe vasomotor symptoms, impaired sleep quality, and vulvovaginal symptoms of menopause.

Vasomotor Symptoms

Fewer than 25% of women experience a menopausal transition without symptoms, whereas more than 25% suffer severe menopausal symptoms, most commonly hot flushes and night sweats. The average duration of vasomotor symptoms is 7.4 years with some women experiencing symptoms for more than 10 years.[6] Women with mild vasomotor symptoms can experience relief by lifestyle modification, and at least 25% of women in clinical trials reported significant improvement of vasomotor symptoms when taking placebo. The most effective treatment for vasomotor symptoms is MHT with 80% to 90% relief of symptoms. Benefits and risks of MHT should be weighed individually and assessed on an annual basis. The formulation, dose, and duration of therapy will also depend on patient symptoms and medical history.

Genitourinary Syndrome of Menopause

Estrogen receptors have been demonstrated in the lower genitourinary tract, and up to 50% of postmenopausal women suffer symptoms of vulvovaginal atrophy caused by estrogen deficiency. Atrophy of the vaginal mucosa results in vaginal dryness, burning, irritation, discomfort, and dyspareunia. Lower urinary tract symptoms include urethritis, recurrent urinary tract infection, urinary urgency, and frequency.

Most women with moderate-to-severe vulvovaginal symptoms require local or systemic estrogen therapy for symptom relief. Local (vaginal) estrogen delivery is preferred when vaginal symptoms are the only menopausal symptom complaint, as it minimizes systemic absorption and is more effective than oral estrogen therapy with 80% to 90% symptom relief compared to 75% with oral estrogen.[17,20] Vaginal estrogen has also been shown to improve atrophic symptoms and vaginal mucosal appearance, decrease vaginal pH, improve vaginal and/or urethral cytology, and reduce the risk of lower urinary tract symptoms and recurrent urinary tract infections possibly by modifying the vaginal flora.[17,20,25] Moderate to severe vulvovaginal symptoms can be treated with a vaginal estrogen cream, tablet, or ring; or with the selective estrogen receptor modulator (SERM) ospemifene 60 mg orally per day.[26] Ospemifene has a nearly full estrogen agonist effect in the vaginal epithelium to improve dyspareunia and has been well tolerated without breast or endometrial concerns after 1 year of use.

Dose-related adverse effects of vaginal estrogen include vulvovaginal candidiasis, vaginal bleeding, breast pain, and nausea.[17] Concomitant progestogen therapy is unnecessary when low-dose vaginal estrogen is used. It should be noted that one vaginal ring (Femring®) is known to deliver a systemic dose of estrogen.

Therapeutic response is typically attained after 2 weeks of daily estrogen use. For maintenance therapy, the frequency of administration is generally decreased to 2 to 3 times weekly.

The Women's Health Initiative (WHI) was a randomized, double-blind, placebo-controlled trial launched in 1991 to evaluate the effects of MHT on heart disease, osteoporosis, and cancer. The WHI trial had two arms: the estrogen-plus-progestin arm involving women with an intact uterus and the estrogen-alone arm involving women with a history of hysterectomy.[13,27] The combined estrogen and progestin arm included 16,608 women aged 50 to 79 years (mean age 63 years), and the estrogen-only arm enrolled 10,739 women aged 50 to 79 years (mean age 64 years). The primary outcome was incidence of coronary heart disease (CHD) (nonfatal myocardial infarction or CHD death), and the primary safety outcome was invasive breast cancer. A global index was used to summarize the balance of risks and benefits, which included the two primary outcomes plus stroke, pulmonary embolism, endometrial cancer, colorectal cancer, hip fracture, and death due to other causes. The estrogen-plus-progestin arm was terminated prematurely after only 5.2 years (the planned duration was 8.5 years) because the global index statistic supported risks exceeding benefits on the major clinical outcomes. The estrogen-only arm also was terminated early (after 6.8 years) because of excess risk of stroke. Results of the WHI trial are shown in **Table 82-2**. Upon discontinuation of the trial, participants were asked to discontinue study medication and invited to participate in a follow-up phase of the study that has resulted in multiple ancillary analyses.[28,29,30,31,32,33,34,35,36,37,38,39,40,41]

TABLE 82-2 Principal Results of the Women's Health Initiative Hormone Therapy Trial

	Estrogen + Progestogen Arm (Mean duration 5.2 years)			**Estrogen-only Arm (Mean duration 6.8 years)**		
Outcome	MHT (*n* = 8,506) No. Patients (annualized %)	Placebo (*n* = 8,102) No. Patients (annualized %)	Hazard Ratio (Nominal 95% CI)	MHT (*n* = 5,310) No. Patients (annualized %)	Placebo (*n* = 5,429) No. Patients (annualized %)	Hazard Ratio (Nominal 95% CI)

Global Index	751 (1.70)	623 (1.51)	1.15 (1.03-1.28)	692 (1.92)	705 (1.90)	1.01 (0.91-1.12)

Data from references 16 and 44.

More than a decade later, use of MHT has greatly evolved to recognize the need to individualize therapy for women based on patient specific factors (eg, age, risk factors, and goals of therapy). A summary of various clinical considerations described in the 2012 Hormone Therapy Position Statement of the North American Menopause Society is provided in **Table 82-3.**

TABLE 82-3 Summary of North American Menopause Society Position Statement on Menopausal Hormone Therapy

Symptom/Condition	Summary statement(s)
Vasomotor symptoms	Estrogen therapy (+/- progestogen) is the most effective therapy, including consequences of vasomotor symptoms such as sleep quality, irritability, difficulty concentrating, and quality of life
Vulvovaginal symptoms	Estrogen therapy is the most effective treatment for moderate to several vulvovaginal symptoms. Local therapy is recommended for sole vaginal symptoms; progestogen generally not indicated (data for up to 1 year)
Sexual function	Low-dose local estrogen therapy may improve lubrication, blood flow and vaginal sensation; however MHT is not recommended as treatment for other problems of sexual function (eg, libido, orgasmic response)
Osteoporosis	Standard-dose MHT reduces postmenopausal osteoporotic fractures (hip, vertebral, and nonvertebral) and many systemic MHT products are approved for prevention of osteoporosis. MHT is not indicated for treatment. Benefits of MHT dissipate when discontinued
Coronary heart disease	Observational and randomized control data are conflicting. Estrogen only therapy may reduce CHD risk when initiated in newly menopausal women (age 50-59 years). Estrogen + progestogen therapy initiated between ages 50 and 59 years or within 10 years of menopause does not appear to increase CHD risk. Women initiating therapy after 10 years since menopause have an increased risk of CHD. MHT is not recommended any time for coronary protection
Stroke	Increased risk of ischemic stroke (not hemorrhagic) exists with estrogen only and estrogen + progestogen use. Risk dissipates upon discontinuation
Venous thromboembolism (VTE)	Increased risk of VTE with oral MHT, but risk is rare when used between ages of 50 and 59 years. Risk increases with personal risk factors including obesity, previous history of VTE, presence of Factor V Leiden mutation. Risk

Symptom/Condition	Summary statement(s)
	dissipates upon discontinuation. The type of progestogen may impact risk. Transdermal formulations appear to have lower VTE risk than oral formulations

Data from reference 23.

Clinical Controversy…

Some authorities recommend that the duration of MHT should not exceed 5 years when estrogen and progestogen are used together because of the increased risk of breast cancer. However, in some women, vasomotor symptoms may persist for many years after menopause, and therapy for longer durations may be warranted.

Furthermore, several national and international organizations have published guidelines or position statements to outline points of consensus regarding the safe and effective use of MHT.[20,23] Overall, consensus recommendations regarding the use of MHT include:

- Menopausal hormone therapy is the most effective treatment for vasomotor symptoms in recently menopausal women (before age 60 years or within 10 years of menopause).
- Menopausal hormone therapy is effective and appropriate for prevention of osteoporosis-related fractures in recently menopausal women at risk.
- Estrogen-only therapy may decrease heart disease and all-cause mortality in 50 to 59 year-old-women with a history of hysterectomy. In this age group, combined estrogen and progestogen therapy shows similar trends for mortality, but no significant difference in CHD.
- Estrogen alone is appropriate for women after hysterectomy; additional progestogen is required when a uterus is present.
- Use of MHT should be individualized based on the severity of menopausal symptoms and personal risk factors (eg, age, time since menopause, history of VTE, stroke, ischemic heart disease, and breast cancer).
- Risk of VTE and stroke increases with oral MHT containing estrogen, but the absolute risk is low in women below 60 years of age. Based on observational studies, transdermal MHT and low-dose oral estrogen therapy appear to have a lower risk of VTE and stroke compared to standard-dose oral estrogen regimens.
- Menopausal hormone therapy is contraindicated in women with a personal history of breast cancer. The risk of MHT-related breast cancer appears to be associated with the addition of progestogen to estrogen and increases after 5 or more years of continuous combined use. However, use of estrogen alone appears to decrease rather than increase breast cancer risk.
- The lowest dose of hormone therapy should be used for the shortest possible duration to adequately manage menopausal symptoms.

Cardiovascular Disease

3 Cardiovascular disease—including coronary artery disease, stroke, and peripheral vascular disease—is the leading cause of death among women, and MHT should not be used for reducing the risk of cardiovascular disease. Menopause is associated with the development of a more adverse lipid profile, thereby increasing the risk for cardiovascular disease.

In the decade prior to the publication of the WHI results in 2002, an expectation of coronary benefit had been a major reason for use of postmenopausal hormones because observational studies indicated that women who use MHT have a 35% to 50% lower risk of CHD than nonusers. In addition, previous studies had shown that estrogen exerts protective effects on the cardiovascular system, including lipid-lowering, antioxidant, and vasodilating effects.[42] However, in the 2000s, published results of several randomized clinical trials provided no evidence of cardiovascular disease protection and even some evidence of harm with MHT.[13,43,44]

The primary findings of the estrogen plus progestogen arm of the WHI trial showed an overall increase in the risk of CHD (HR 1.29, 95% CI 1.02-1.63) among healthy postmenopausal women receiving combined estrogen–progestogen MHT compared with those receiving placebo.[13,27] The primary findings of the estrogen-only arm of the WHI trial show no effect (either increase or decrease) on the risk of CHD in women taking estrogen alone.[27] Subgroup analyses performed in the years after the WHI was first published in 2002 revealed that women who initiated MHT 10 or more years after the time of menopause tended to have increased CHD risk compared with women who initiated therapy within 10 years of menopause.[45,46] Neither estrogen alone nor estrogen plus progestogen was associated with a statistically significant effect on CHD in women aged 50 to 59 years, and MHT was associated with reduced overall mortality, although this decrease was not statistically significant.[45] More recently, subgroup analyses from the WHI that included only adherent study participants found that the risk of CHD with estrogen plus progestogen use is increased in the first 2 years of treatment, even in women aged 50 to 59 years at study entry. However, the risk of CHD in women who initiated therapy within 10 years of menopause appears to decrease after 6 years of treatment.[46] Most women who commence estrogen or estrogen plus progestogen therapy do so within the first few years of becoming menopausal.

A randomized controlled study of 1,006 recently menopausal women revealed that 10-year MHT was associated with a significantly reduced risk of cardiovascular disease.[47] In addition, studies of recently menopausal women showed that the presence and severity of hot flushes are associated with vascular endothelial dysfunction and vascular inflammation (markers of increased risk for CHD); MHT improved both of these parameters.[48,49,50]

In an attempt to resolve some of the controversy, the Kronos Early Estrogen Prevention Study (KEEPS) randomized 727 recently menopausal women (mean age 52 years and less than 3 years since FMP) to cyclic progestogen and either oral estrogen (conjugated estrogen 0.45 mg/day), transdermal estrogen (estradiol 50 mcg/day), or placebo to examine the rate of atherosclerosis.[51] During 4 years of treatment, there was no difference among the study arms on atherosclerotic progression as evidenced by carotid intima-media thickness and coronary artery calcium.

Menopausal hormone therapy should not be initiated or continued solely for the prevention of cardiovascular disease. Adherence to a healthful lifestyle (cessation of smoking, regular exercise, healthy diet, and body mass index less than 25 kg/m^2) may prevent the onset of cardiovascular disease in postmenopausal women.

In the estrogen plus progestogen arm of the WHI study, the increased risk for stroke and venous thromboembolism continued throughout the 5 years of therapy.[13] Increased risk was observed only for ischemic stroke and not for hemorrhagic stroke.[30] In the estrogen-alone arm of the study, a similar increased risk for stroke was observed.[27] After the cessation of treatment, there is no increased risk for stroke.[52,53]

Clinical Controversy ...

Data are conflicting regarding the risk of cardiovascular disease with MHT. In older women, MHT appears to increase cardiovascular disease risk, whereas in recently menopausal women with vasomotor symptoms, MHT may have a beneficial effect.

Venous Thromboembolism

Venous thromboembolism, including thrombosis of the deep veins of the legs and embolism to the pulmonary arteries, is uncommon in the general population. Women taking oral estrogen therapy have a twofold increased risk for thromboembolic events, with the highest risk occurring in the first year of use.[13,27] However, women with certain risk factors for venous thromboembolism including those with a Factor V Leiden mutation, obesity, and history of previous thromboembolic events, are at increased risk with MHT.[20] Lower doses of estrogen are associated with a decreased risk for thromboembolism as compared with higher doses. Oral administration of estrogen increases the risk of venous thromboembolism compared to the transdermal route.[14] In addition, the norpregnane progestogens, unlike micronized progesterone, appear to be thrombogenic. Currently, there is no indication for thrombophilia screening before initiating MHT. However, MHT should be avoided in women at high risk for thromboembolic events.

Breast cancer

4 The risk of breast cancer associated with MHT appears to be associated with the addition of progestogen therapy to estrogen. Use of estrogen alone does not increase the risk of breast cancer. The WHI trial found that combined estrogen plus progestogen oral therapy has an increased risk of invasive breast cancer (HR 1.26, 95% CI: 1.0-1.59) and a trend toward increasing risk with increasing duration of therapy.[13] This risk does not persist after discontinuation of hormone treatment.[52] The estrogen-only arm of the WHI trial found a decreased risk for breast cancer during the 7-year follow-up period, which persisted after discontinuation of treatment.[27,53]

In the estrogen plus progestogen arm of the WHI, the increased breast cancer risk did not appear until after 3 years of study participation.[13] The risk was seen only in women who initiated therapy within 5 years of the start of menopause but not in those who started therapy more than 5 years after

menopause.[54] The breast cancers diagnosed in women in the MHT group had similar histology and grade but were more likely to be in an advanced stage compared with women in the placebo group.[29] The risk of breast cancer returns to baseline rapidly after discontinuation of MHT.[52,54] In an unselected postmenopausal population, the Million Women Study found that current use of MHT increased breast cancer risk and breast cancer mortality (relative risk 1.66 and 1.22, respectively).[55] Increased incidence was observed for estrogen-only use (relative risk 1.30), for estrogen plus progestogen (relative risk 2), and for tibolone (relative risk 1.45). The risk for estrogen only and estrogen plus progestin therapy were higher for those who initiated treatment within 5 years of menopause compared to those who started therapy 5 or more years after menopause.[56]

For women in the United States, the lifetime risk of developing breast cancer is approximately one in eight, and the greatest incidence occurs in women older than 60 years (Chapter 129).[57] In a collaborative re-analysis of data from 51 studies evaluating 52,705 women with breast cancer and 108,411 controls, less than 5 years of combined estrogen–progestogen therapy was associated with a 15% increase in breast cancer risk, and the risk increased with longer duration (relative risk 1.35 with 5 or more years of use).[58] However, 5 years after discontinuation of MHT, the risk of breast cancer was no longer increased.[58]

Addition of progestogens to estrogen may increase breast cancer risk beyond that observed with estrogen alone.[59]

Sex-steroid deficiency during the menopause results in lipomatous involution of the breast, which is seen as decreased mammographic breast density and markedly improved radiotransparency of breast tissue. Thus, mammographic changes indicating breast cancer can be recognized more easily and earlier after the menopause. Conversely, use of MHT results in increased mammographic breast density, and increased density on mammography has been associated with higher breast cancer risk.[60]

Endometrial Cancer

The WHI trial suggests that combined oral MHT does not increase endometrial cancer risk compared with placebo (HR 0.81, 95% CI: 0.48-1.36).[35] However, estrogen alone given to women with an intact uterus significantly increases uterine cancer risk.[61] The excess risk increases with dose and duration of estrogen (10 years of unopposed estrogen increases the risk 10-fold), is apparent within 2 years of the start of treatment, and persists for many years after estrogen replacement is discontinued.[61] Estrogen-induced endometrial cancer usually is of a low stage and grade at the time of diagnosis, and it can be prevented almost entirely by progestogen coadministration.[35] The sequential addition of progestogen to estrogen for at least 10 days of the treatment cycle or continuous combined estrogen–progestogen does not increase the risk of endometrial cancer.

Lower doses of estrogen may be associated with a lower risk of endometrial hyperplasia.[62] SERMs do not result in endometrial hyperplasia. A 4-year trial of raloxifene in women with osteoporosis showed no increased risk of endometrial cancer.[63]

Ovarian Cancer

Lifetime risk of ovarian cancer is low (1.7%). The WHI trial suggested that orally administered combined MHT does not increase the risk of ovarian cancer (HR 1.58, 95% CI: 0.77-3.24).[35] An observational study reported an increased risk of ovarian cancer in women taking postmenopausal estrogen-only therapy for more than 10 years (relative risk 1.8, 95% CI: 1.1-3.0 and 3.2, 95% CI: 1.7-5.7 for 10-19 years and 20 or more years, respectively), but no increased risk of ovarian cancer among women receiving combination estrogen–progestogen therapy.[64] A recent analysis of 52 epidemiological studies suggests that ovarian cancer risk is increased in current users of MHT, even with less than 5 years of use. The increased risk appears to decrease but not completely disappear a decade after discontinuation of MHT.[65]

Lung Cancer

The WHI trial found that combined oral estrogen–progestogen therapy did not increase lung cancer incidence, but significantly increased deaths from lung cancer, mainly from nonsmall cell lung cancers (HR 1.87, 95% CI: 1.22-2.88).[66] The estrogen-only arm of the WHI trial found no increased risk for lung cancer death.[67] It should be noted that the WHI was not designed to assess lung cancer.

Osteoporosis

Postmenopausal osteoporosis is a serious age-related disease that affects millions of women throughout the world. Menopause is accompanied by accelerated bone loss, and the central role of estrogen deficiency in postmenopausal osteoporosis is well established (Chapter 93).

The WHI was the first randomized trial to demonstrate that MHT reduces the risk of fractures at the hip, spine, and wrist.[13,34] These findings are in agreement with observational data and several meta-analyses of the efficacy of MHT for reducing fractures in postmenopausal women.

Estrogen therapy reduces bone turnover and increases bone density in postmenopausal women of all ages. The protective effect persists as long as the treatment is maintained. With cessation of therapy, postmenopausal bone loss resumes at the same rate as in untreated women.[52,53] The standard bone-sparing daily estrogen dose is equivalent to 0.625 mg conjugated equine estrogen (CEE). However, lower doses of estrogen have been shown to increase bone mass to the same extent as standard-dose estrogen therapy.[68,69] Whether lower doses of estrogen are safer (eg, lower incidence of venous thromboembolism and breast cancer) remains to be proven.

5 In younger postmenopausal women who are at increased fracture risk, systemic estrogen therapy may be indicated for the prevention of osteoporotic fractures when alternate therapies are either contraindicated or cause excessive adverse effects. General protective health measures, such as regular weight-bearing exercise and avoidance of detrimental lifestyle habits such as smoking and alcohol abuse, are appropriate for all women. Some women require calcium supplementation to their usual dietary intake. Adequate vitamin D intake and/or supplementation are also needed. Appropriate risk assessment and evaluation is needed to determine appropriate treatment strategies in menopausal women. See Chapter 93 for a full discussion of osteoporosis prevention and

treatment.

Mood, Cognition, and Dementia

6 Menopausal hormone therapy appears to improve depressive symptoms in symptomatic menopausal women, most likely by relieving flushing and improving sleep. Women with vasomotor symptoms receiving MHT have improved mental health and fewer depressive symptoms compared with women receiving placebo; however, MHT may worsen quality of life in women without flushes.[70]

Clinical Controversy…

Conflicting data exist regarding the effect of MHT on well-being and quality of life. Some experts believe well-being and quality of life may be improved as a direct result of menopausal symptom relief (eg, vasomotor, vulvovaginal) while others believe there is no change in overall well-being or quality of life with MHT.

More than 33% of women 65 years and older will develop dementia during their lifetime.[71] Several observational studies have suggested that estrogen therapy may be protective against Alzheimer disease (see Chapter 54). The WHI Memory Study (WHIMS, an ancillary study of the WHI trial) evaluated the effect of MHT on dementia and cognition in 4,532 women 65 to 79 years old.[32] The study found that postmenopausal women 65 years and older taking estrogen plus progestogen therapy had twice the rate of dementia, including Alzheimer disease, than women taking placebo (HR 2.05, 95% CI: 1.21-3.48).[32] In addition, estrogen plus progestogen therapy in these women did not prevent mild cognitive impairment, a cognitive and functional state between normal aging and dementia that frequently progresses to dementia.[32] The estrogen alone arm of the WHI trial showed similar findings.[36,41]

In contrast, the Women's Health Initiative Memory Study of Younger Women (WHIMSY) found that neither estrogen plus progestogen or estrogen therapy alone confer any risk or benefit to cognitive function when taken by postmenopausal women aged 50 to 55 years old.[72] In another study, the ancillary Cognitive and Affective Study (KEEPS-Cog) of the Kronos Early Estrogen Prevention Cognitive Study (KEEPS) evaluated the effects of up to four years of MHT on cognition and mood in recently menopausal women (mean age 52.6 years and 1.4 years past FMP) with low cardiovascular risk.[73] Specifically, 693 women participated with 220 women randomized to receive 0.45 mg/day oral conjugated equine estrogens (o-CEE) plus 200 mg/day micronized progesterone (m-P) for the first 12 days of each month, 211 women randomized to receive 50 mcg/day transdermal estradiol (t-E2) plus 200 mg/day m-P for the first 12 days of each month, and 262 women randomized to receive placebo pills and patches. After a mean length of follow-up of 2.85 years for cognition outcomes, no treatment-related benefits were observed. After a mean length of follow-up for 2.76 years regarding mood outcomes, model estimates indicated that women treated with o-CEE showed improvements in depression and anxiety symptoms over the 48 months of treatment, compared to women on placebo.

Diabetes

In healthy postmenopausal women, hormone therapy appears to have a beneficial effect on fasting glucose levels in women with elevated fasting insulin concentrations.[74] Also, in women with coronary artery disease, hormone therapy reduces the incidence of diabetes by 35%.[75] Women who received estrogen plus progestogen in the WHI trial had a statistically significant 21% reduction (HR, 0.79; 95% CI, 0.67-0.93) in the incidence of type 2 diabetes requiring treatment.[76] These findings provide important insights into the metabolic effects of hormone therapy but are insufficient to recommend the long-term use of hormone therapy in women with diabetes.

Body Weight

A meta-analysis of randomized controlled trials showed that unopposed estrogen or estrogen combined with a progestogen has no effect on body weight, suggesting that hormone therapy does not cause weight gain in excess of that normally observed at the time of menopause.[77]

Gallbladder Disease

Gallbladder disease is a commonly cited complication of oral estrogen use. The WHI studies reported an increased risk for cholecystitis, cholelithiasis, and cholecystectomy among women taking oral estrogen or estrogen–progestogen therapy.[78] Transdermal estrogen is an alternative to oral therapy for women at high risk for cholelithiasis.

Estrogens

Estrogens are naturally occurring hormones or synthetic steroidal or nonsteroidal compounds with estrogenic activity. The primary indication for systemic estrogen-based MHT is the relief of moderate and severe vasomotor and vulvovaginal symptoms, and the initial dose should be the lowest effective dose for symptom control.

Adverse Effects

Common adverse effects of estrogen include nausea, headache, breast tenderness, and heavy bleeding. More serious adverse effects include increased risk for CHD, stroke, venous thromboembolism, breast cancer, and gallbladder disease. Transdermal estradiol is associated with a lower incidence of breast tenderness and deep vein thrombosis than is oral estrogen.[14,15,47]

Dosage and Administration

7 Use of MHT at doses lower than those prescribed historically (ie, prior to the WHI study) appears to be effective in reducing bone loss and managing menopausal symptoms (see Table 82-1).[68,69,79,80] Low-dose estrogen regimens include 0.3 to 0.45 mg conjugated estrogens, 0.5 mg micronized 17β-estradiol, and 0.014 to 0.0375 mg transdermal 17β-estradiol patch.[20] Topical gels, sprays, and creams are also available in low doses. Lower doses typically have fewer adverse effects and may have better overall benefit-risk profiles than standard doses. The lowest effective dose of estrogen, consistent with individualized patient treatment goals and assessment of safety and effectiveness, should be used.

Various systemically administered estrogens (typically oral and transdermal) are equally effective for replacement therapy (**Table 82-4**). Estrogens can be administered orally, percutaneously (transdermal patches and topical products), intravaginally (creams, tablets, or rings), intramuscularly, and even subcutaneously in the form of implanted pellets. The choice of estrogen delivery (product, route, and method) should be determined in consultation with the patient to ensure acceptability and enhance adherence. In general, the oral and transdermal routes are used most frequently.

TABLE 82-4 FDA-Approved Estrogen Products for Menopausal Hormone Therapy

Drug	Brand Name[a]	Initial Dose/Low Dose	Usual Dose Range	Comments
Systemic Estrogen Products (for the treatment of moderate and severe vasomotor symptoms ± urogenital symptoms)				
Oral estrogens[b]				
Conjugated equine estrogens	Premarin	0.3 or 0.45 mg once daily	0.3-1.25 mg once daily	Dosage form available as 0.3, 0.45, 0.625, 0.9, 1.25 mg
Synthetic conjugated estrogens	Cenestin, Enjuvia	0.3 mg once daily	0.3-1.25 mg once daily	Dosage form available as 0.3, 0.45, 0.625, 0.9, 1.25 mg
Esterified estrogens (75%-85% estrone + 6%-15% equilin)	Menest	0.3 mg once daily	0.3-2.5 mg once daily	Administer 3 weeks on and 1 week off Dosage form available as 0.3, 0.625, 1.25, 2.5 mg
Estropipate (piperazine estrone sulfate)	Ogen, Ortho-Est, Generics	0.75 mg once daily	0.75-6 mg once daily	Dosage form available as 0.75, 1, 5, 3, 6 mg
Estradiol acetate	Femtrace	0.45 mg once daily	0.45-1.8 mg once daily	Dosage form available as 0.45, 0.9, 1.8 mg
Micronized 17β-estradiol	Estrace Generics	1 mg once daily	1 or 2 mg once daily	Administer 3 weeks on and 1 week off Dosage form available as 1, 2 mg
Transdermal estrogens patches				
17β-estradiol	Alora	0.025 mg/day (patch applied twice weekly)[c]	0.025-0.1 mg/day (patch applied twice weekly)[c]	Dosage form available as 0.025, 0.05, 0.075, 0.1 mg/day

Drug	Brand Name[a]	Initial Dose/Low Dose	Usual Dose Range	Comments
	Climara	0.025 mg/day (patch applied twice weekly)[c]	0.025-0.1 mg/day (patch applied twice weekly)[c]	Dosage form available as 0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg/day
	Menostar	0.014 mg/day (patch applied once weekly)[c,d]	0.014 mg/day (patch applied once weekly)[c,d]	Dosage form available as 0.014 mg/day
	Estraderm	-	0.05 or 0.1 mg/day (patch applied twice weekly)[c]	Dosage form available as 0.05, 0.1 mg/day
	Minivelle, Vivelle, Vivelle Dot	0.025 mg/day (patch applied twice weekly)[c]	0.025-0.1 mg/day, 0.05 is standard dose (patch applied twice weekly)[c]	Dosage form available as 0.025, 0.0375, 0.05 (standard dose), 0.075, 0.1 mg/day
Other topical forms of estrogen				
17β-estradiol topical emulsion	Estrasorb 0.25% emulsion	–	Two pouches once daily (which delivers 0.05 mg of estradiol per day)	Apply to legs
17β-estradiol topical gel	EstroGel 0.06% metered-dose pump	–	1.25 g/day once daily (contains 0.75 mg estradiol)	Apply from wrist to shoulder
	Elestrin 0.06% metered-dose pump		1-2 unit doses once daily (1 unit dose: 0.87 g, which contains 0.52 mg estradiol)	Apply to upper arm
	Divigel 0.1% (topical once daily)	0.25 g once daily	0.25-1 g (provides 0.25-1 mg of estradiol)	Apply to upper thigh. Dosage form available as 0.25, 0.5, 1 g
17β-estradiol transdermal spray	Evamist	1 spray once daily	2-3 sprays once daily (1.53 mg of estradiol per spray)	Apply to inner surface of forearm
Implanted estrogens[e]				
Implanted 17β-estradiol	Estradiol pellets	25 mg implanted subcutaneously every 6 months	50-100 mg implanted subcutaneously every 6 months	
Vaginal estrogens				

Drug	Brand Name[a]	Initial Dose/Low Dose	Usual Dose Range	Comments
Estradiol acetate vaginal ring	Femring	12.4 mg every 3 months	12.4, 24.8 mg ring (delivers 0.05 or 0.1 mg estradiol/day)	
Intravaginal Estrogen Products (for the treatment of urogenital symptoms only/low systemic exposure)				
Conjugated equine estrogens (CEE) vaginal cream	Premarin		0.5-2 g/day (contains 0.625 mg CEE per g)	
17β-estradiol vaginal cream	Estrace		1 g/day (contains 0.1 mg estradiol per g)	
17β-estradiol vaginal ring	Estring	2 mg replaced every 90 days	2 mg ring (delivers 0.0075 mg/day) replaced every 90 days	
Estradiol hemihydrate vaginal tablet	Vagifem	10 mcg twice weekly	10 or 25 mcg twice weekly	

[a]United States brand names.

[b]Orally administered estrogens stimulate synthesis of hepatic proteins and increase circulating concentrations of sex hormone-binding globulin, which in turn may compromise the bioavailability of androgens and estrogens. Women with elevated triglyceride concentrations or significant liver function abnormalities are candidates for non-oral estrogen therapy.

[c]Do not apply estrogen patches on or near breasts. Avoid waistline as patch may rub off with tight-fitting clothing.

[d]FDA-approved for prevention of postmenopausal osteoporosis only.

[e]Not available in the United States.

Oral Estrogen

Oral conjugated equine estrogen has been available for more than 50 years. CEE is prepared from the urine of pregnant mares and is composed of estrone sulfate (50%-60%) and multiple other equine estrogens such as equilin and 17α-dihydroequilin.

Estradiol is the predominant and most active form of endogenous estrogens. A micronized form of estradiol (produced by a technique that yields extremely small particles of the pure hormone) is readily absorbed from the small intestines. When given orally, estradiol is metabolized by the intestinal mucosa and the liver during the first hepatic passage, and only 10% reaches circulation as

free estradiol. Metabolism of estrogen is partly mediated by the cytochrome P450 3A4 isoenzyme. Gut and liver metabolism converts a large proportion of estradiol to the less potent estrone. Thus, measurement of serum estradiol is not useful for monitoring oral estrogen replacement. The principal metabolites of micronized estradiol are estrone and estrone sulfate. Administration of estradiol via the oral route results in estrone concentrations that are three to six times those of estradiol. Ethinyl estradiol is a highly potent semisynthetic estrogen that has similar activity following administration by the oral or nonoral route.

Orally administered estrogens stimulate the synthesis of hepatic proteins and increase the circulating concentrations of sex hormone-binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens.

Other Routes of Estrogen Administration

Nonoral routes of estrogen administration may offer both advantages and disadvantages compared with the oral route, but long-term data are not available. Nonoral forms of estrogens bypass the GI tract and thereby avoid first-pass liver metabolism. These routes of estradiol delivery result in a more physiologic estradiol-to-estrone ratio (estradiol concentrations greater than estrone concentrations), as seen in the normal premenopausal state.

When compared with standard oral estrogen doses, transdermal therapy appears to offer no significant increase in triglycerides, C-reactive protein, sex hormone binding globulin, and blood pressure.[20,81] Transdermal estrogen has also been associated with a lower risk of deep vein thrombosis, stroke, and MI. Transdermal estrogen patches share the advantages of other nonoral estrogen routes and have the added advantage of delivering estradiol to the general venous circulation at a continuous rate. The matrix transdermal systems (estrogen in adhesive) generally are well tolerated, and fewer than 5% of women experience skin reactions. The incidence of skin irritation diminishes when the application site is rotated. Topical anti-inflammatory products (eg, hydrocortisone cream) can be applied for managing the rashes, and switching to another transdermal patch is often a viable option.

Topical gels, sprays, and emulsions are convenient forms of systemic estrogen therapy, but variability in drug absorption has been noted with some formulations. Intravaginal creams, tablets, and rings are used for treatment of urogenital (vulvar and vaginal) atrophy. Intravaginal tablets and rings are sustained-release delivery systems that can maintain adequate estradiol concentrations. While most tablets and rings provide local estrogen, one intravaginal ring product (Femring®) is designed to achieve systemic concentrations of estrogen and is also indicated for treatment of moderate to severe vasomotor symptoms. Estradiol pellets (for subcutaneous implantation), containing pure crystalline 17β-estradiol, have been available for more than 50 years. They are inserted subcutaneously into the anterior abdominal wall or buttock. Pellets are difficult to remove and may continue to release estradiol for a long time after insertion. Implantation should not be repeated until serum estradiol concentrations have fallen to values similar to those at the midfollicular phase of the menstrual cycle. Estradiol pellets are not available in the United States.

Progestogens

8 Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (ie, unopposed estrogen), use of systemic estrogen in women with an intact uterus must always be accompanied by a progestogen or an estrogen agonist antagonist (eg, bazedoxifene) for endometrial protection.[82] Some data suggest that progestins may also improve vasomotor symptoms, but their use for this purpose is not considered first line or standard therapy.[83]

Progestogens reduce nuclear estradiol receptor concentrations, suppress DNA synthesis, and decrease estrogen bioavailability by increasing the activity of endometrial 17-hydroxysteroid dehydrogenase, an enzyme responsible for converting estradiol to estrone.[61]

The first generation of progestogens included the C-19 androgenic progestogens norethindrone (also known as norethisterone), norgestrel, and levonorgestrel. More recent preparations have included the C-21 progestogens dydrogesterone and medroxyprogesterone acetate (MPA), which are less androgenic. Drospirenone, a synthetic progestogen analog of the potassium-sparing diuretic spironolactone, has both antiandrogenic and antialdosterone properties. Micronized progesterone also has become available for use in postmenopausal women. The most commonly used oral progestogens are MPA, micronized progesterone, and norethindrone acetate. The latter can be administered transdermally in the form of a combined estrogen–progestogen patch.

Adverse Effects

Common adverse effects of progestogens include irritability, weight gain, bloating, and headache. Changing from a cyclic to a continuous-combined regimen or changing from one progestogen to another may decrease the incidence or severity of untoward effects. Adverse effects of progestogens are difficult to evaluate and can vary with the agent administered. Some women experience "premenstrual-like" symptoms, such as mood swings, bloating, fluid retention, and sleep disturbance. Newer methods and routes of progestogen delivery (eg, locally by an intrauterine device that releases levonorgestrel or a progesterone-containing bioadhesive vaginal gel) may be associated with fewer adverse effects.

Dosage and Administration

Several progestogen regimens designed to prevent endometrial hyperplasia are available for use in women with an intact uterus (**Table 82-5**). Progestogens can be used continuously (resulting in endometrial atrophy) or cyclically (resulting in monthly withdrawal bleeding). For cyclic use, the progestogen must be taken for a sufficient period of time during each cycle. In general, a minimum of 12 to 14 days of progestogen therapy per month is required for complete protection against estrogen-induced endometrial hyperplasia. For women with a history of hysterectomy, use of progestogens is not indicated. However, in women with endometriosis who have had a hysterectomy, the use of a progestogen along with estrogen may minimize endometriosis exacerbations.

TABLE 82-5 Progestogen Dosing for Endometrial Protection (Cyclic Administration)

Progestogen	Brand Name	Dosage
Dydrogesterone[a]	Duphaston	10-20 mg/day for 12-14 days per calendar month (oral

Progestogen	Brand Name	Dosage
		dosage form available as 10 mg tablets)
Medroxyprogesterone acetate	Provera	5-10 mg/day for 12-14 days per calendar month (oral dosage form available as 2.5, 5, 10 mg tablets)
Micronized progesterone	Prometrium	200 mg/day for 12-14 days per calendar month (oral dosage form available as 100 and 200 mg tablets)
Norethindrone acetate	Aygestin[b]	5 mg/day for 12-14 days per calendar month (oral dosage form available as 2.5, 5 mg tablets)

[a]Not available in the United States.

[b]Not approved for postmenopausal hormone therapy in the United States.

Menopausal Hormone Therapy Regimens

Many products have been used for MHT, and most include an estrogen and a progestogen in various regimens, routes, and administration schedules. Additionally, products that combine estrogen with an estrogen agonist/antagonist are also available for once-daily dosing. Common combination MHT regimens are described in **Table 82-6**.

TABLE 82-6 Common Combination Menopausal Hormone Therapy Regimens

Regimen	Brand name	Dosage
Oral Regimens		
Conjugated equine estrogen (CEE) + medroxyprogesterone acetate (MPA)	Prempro (continuous)	0.625 mg/2.5 MPA, 0.625 mg/5 mg daily Low dose: 0.3 mg/1.5 mg, 0.45 mg/1.5 mg daily
	Premphase (continuous sequential)	0.625 mg CEE daily only in the first 2 weeks of a 4-week cycle then 0.625 mg daily CEE + 5 mg MPA daily in the last 2 weeks of a 4-week cycle
Conjugated equine estrogen (CEE) + bazedoxifene	Duavee (continuous)	0.45 mg/20 mg daily
Ethinyl estradiol (EE) + norethindrone acetate (NETA)	Generic, Femhrt (continuous)	5 mcg EE/1 mg NETA daily Low dose (Femhrt only): 2.5 mcg EE/0.5 mg NETA daily
Estradiol (E) + drospirenone (DRSP)	Angeliq (continuous)	1 mg E/5 mg DRSP daily Low dose: 0.5 mg E/0.25 mg DRSP daily

Regimen	Brand name	Dosage
Estradiol (E) + norgestimate	Prefest (estrogen/intermittent progestogen)	1 mg E daily for first 3 days then 1 mg E/0.09 mg norgestimate daily for next 3 days; this pattern is repeated continuously
Estradiol (E) + norethindrone acetate (NETA)	Activella (continuous)	1 mg E/0.5 mg NETA daily
	Mimvey (continuous)	Low-dose: 0.5 mg E/0.1 mg NETA daily 1 mg E/0.5 mg NETA daily
Transdermal Regimens		
Estradiol + norethindrone acetate patch	CombiPatch (continuous)	Continuous: 0.05/0.14 mg, 0.05/0.25 mg (apply 1 patch twice weekly)
	CombiPatch (continuous sequential)	Continuous sequential: 0.05 mg of an estradiol only patch (apply 1 patch twice weekly) in the first 2 weeks of a 4-week cycle then either dose of the CombiPatch (apply 1 patch twice weekly) in the last 2 weeks of a 4-week cycle
Estradiol (E) + levonorgestrel patch	Climara Pro (continuous)	0.045 mg E/0.015 mg/day(apply 1 patch once weekly)

CEE, conjugated equine estrogen; DRSP, drospirenone; E, estradiol; EE, ethinyl estradiol; NETA, norethindrone acetate; MPA, medroxyprogesterone acetate.

Continuous Cyclic Estrogen–Progestogen (Sequential) Treatment

Estrogen typically is administered continuously (daily). A progestogen is coadministered with the estrogen for at least 12 to 14 days of a 28-day cycle.[84] The progestogen causes scheduled withdrawal bleeding in approximately 90% of women. With this regimen, bleeding usually begins 1 to 2 days after the last progestogen dose. Occasionally, bleeding begins during the latter phase of progestogen administration.

Continuous Combined Estrogen–Progestogen Treatment

Continuous combined estrogen–progestogen administration results in endometrial atrophy and the absence of vaginal bleeding. Continuous combined MHT is more acceptable than traditional cyclic therapy. This method of treatment can be achieved by using either commercially available oral and transdermal preparations or by administering systemic estrogen along with the use of the levonorgestrel-releasing intrauterine system.

Continuous Long-Cycle Estrogen–Progestogen Treatment

This modified sequential regimen was developed to decrease the incidence of uterine bleeding. In the continuous long-cycle (or cyclic withdrawal) estrogen–progestogen regimen, estrogen is given

daily, and progestogen is given six times per year, every other month for 12 to 14 days, resulting in six periods per year. Bleeding episodes may be heavier and last for more days than withdrawal bleeding with continuous cyclic regimens. The effect of continuous long-cycle estrogen–progestogen treatment on endometrial protection is unclear.

Intermittent Combined Estrogen–Progestogen Treatment

The intermittent combined estrogen–progestogen regimen, also called *continuous-pulsed estrogen–progestogen* or *pulsed-progestogen*, consists of 3 days of estrogen therapy alone, followed by 3 days of combined estrogen and progestogen, which is then repeated without interruption. This regimen is designed to lower the incidence of uterine bleeding. It is based on the assumption that pulsed-progestogen administration will prevent downregulation of progesterone receptors that can be produced by continuous combined regimens. The lower progestogen dose induces fewer side effects and can be better tolerated. The long-term effect of intermittent combined regimens in endometrial protection is undetermined.

Bioidentical Hormones

Bioidentical hormone therapy is terminology used to describe hormone therapy formulations that are custom-prepared (ie, compounded) for individual patients.[85] Commonly compounded formulations include estrone, estradiol, estriol, progesterone, testosterone, and dehydroepiandrosterone. Although claims have been made to suggest that bioidentical hormones are safer and more "natural" alternatives to commercially available preparations, there is a paucity of evidence regarding the efficacy, safety, and pharmaceutical quality of these products.[86,87] Furthermore, saliva testing is often used to adjust hormone levels, and there is no scientific evidence to support this practice. Bioidentical hormones appear to carry the same risks as traditional hormone therapy products. Several major medical organizations, along with the FDA, have released statements to dissuade patients and clinicians from using this treatment approach.[85,86,88]

Other Treatments for Menopause-Related Symptoms

In women who have contraindications to MHT use, prefer not to take estrogen and/or progestogen, or cannot tolerate estrogen and/or progestogen administration, a number of other medications may be considered, depending on the goals of therapy.[89,90] These include the prescription medications testosterone, SERMs, and tibolone (not currently available in the United States) as well as nonhormonal prescription medications (eg, selective serotonin reuptake inhibitors).

Alternatives to estrogen for treatment of hot flushes include tibolone, selective serotonin reuptake inhibitors (eg, paroxetine and fluoxetine), dual serotonin and norepinephrine reuptake inhibitors (eg, venlafaxine), MPA, megestrol acetate, clonidine, and gabapentin (**Table 82-7**). Progestogens alone may be an option for some women (eg, those with a history of venous thrombosis), but weight gain, vaginal bleeding, and other adverse effects often limit their use. Tibolone and progestogens cannot be considered nonhormonal agents for treatment of hot flushes in women for whom MHT is contraindicated. For this group of patients, selective serotonin reuptake inhibitors such as paroxetine

mesylate and serotonin-norepinephrine reuptake inhibitors such as venlafaxine are considered by some to be a first-line therapy.[91,92,93,93] Furthermore, in breast cancer patients, evidence suggests that selective serotonin reuptake inhibitors could interfere with metabolism of endocrine therapies, such as tamoxifen via cytochrome P450 2D6 inhibition.[94] Clonidine is often effective for symptom control, but its side effects (eg, sedation, dry mouth, and hypotension) are not always well tolerated by women.

TABLE 82-7 Alternatives to Estrogen for Treatment of Hot Flushes[a]

Drug	Brand Name[b]	Initial Dose	Usual Dose Range	Comments
Tibolone[c]	Livial (not available in the United States)	2.5 mg	2.5 mg/day	Tibolone is not recommended during the perimenopause period because it may cause irregular bleeding
Venlafaxine	Effexor, Effexor XR	37.5 mg	37.5-150 mg/day	Adverse effects include nausea, headache, somnolence, dizziness, insomnia, nervousness, xerostomia, anorexia, constipation, diaphoresis, weakness, and hypertension
Desvenlafaxine	Pristiq	100-150 mg	100-150 mg/day	Adverse effects include nausea, headache, somnolence, dizziness, insomnia, xerostomia, anorexia, constipation, diaphoresis, and weakness
Paroxetine, paroxetine CR[d]	Brisdelle,[e] Paxil, Paxil CR, Pexeva	17.5 mg/day (paroxetine),[e] 10 mg/day (paroxetine), or 12.5 mg/day (paroxetine CR)	7.5 mg/day,[e] 10-20 mg/day or 12.5–25 mg/day	Adverse effects include nausea, somnolence, insomnia, headache, dizziness, xerostomia, constipation, diarrhea, weakness, and diaphoresis
Megestrol acetate	Megace	20 mg/day	20-40 mg/day	Progesterone may be linked to breast cancer etiology; also, there is concern regarding the safety of progestational agents in women with preexisting breast cancer

Drug	Brand Name[b]	Initial Dose	Usual Dose Range	Comments
Clonidine	Catapres and generic tablets (oral) Catapres-TTS (transdermal) Kapvay tablets (extended release; oral)	0.1 mg/day	0.1 mg/day	Adverse effects include drowsiness, dizziness, hypotension, and dry mouth, especially with higher doses
Gabapentin	Gralise, Neurontin	300 mg at bedtime	900 mg/day (divided in three daily doses), doses up to 2,400 mg/day (divided in three daily doses) have been studied	Adverse effects include somnolence and dizziness; these symptoms often can be obviated with a gradual increase in dosing

CR, controlled release.

[a]Treatment of postmenopausal hot flushes is an off-label indication in the United States for all medications listed except for one formulation of paroxetine (paroxetine mesylate).

[b]United States brand names.

[c]Not available in the United States.

[d]Other selective serotonin reuptake inhibitors (eg, citalopram, escitalopram, fluoxetine, and sertraline) have also been studied and may be used for the treatment of hot flushes.

[e]The brand Brisdelle contains 7.5 mg of paroxetine and is FDA-approved to treat moderate to severe vasomotor symptoms of menopause. This specific product is not FDA-approved for treating psychiatric conditions.

Data from references 131,132,133,134,135.

Androgens

Androgens have important biologic effects in women, acting both directly via androgen receptors in tissues, such as bone, skin fibroblasts, hair follicles, and sebaceous glands, and indirectly via the aromatization of testosterone to estrogen in the ovaries, bone, brain, adipose tissue, and other tissues. There is a natural decline in androgen production with aging, and pathophysiologic states affecting ovarian and adrenal function have been associated with androgen deficiency in women. The

therapeutic use of testosterone in women is controversial.

A cluster of symptoms that characterizes androgen insufficiency in women, manifested as diminished sense of well-being, persistent or unexplained fatigue, and sexual function changes such as decreased libido, decreased sexual receptivity, and decreased pleasure has been reported. However, studies designed to evaluate this have shown no relationships between serum total and free testosterone levels and either sexual function or well-being in women.[95,96] Thus, as data supporting an androgen deficiency syndrome are lacking, in 2014 the American Endocrine Society reaffirmed their recommendation against making a diagnosis of androgen deficiency in women.[95,97] However, large randomized placebo-controlled clinical trials involving naturally[98,99] and surgically[100] postmenopausal women presenting with low libido demonstrate that testosterone therapy, with and without concurrent estrogen therapy, may improve the quality of the sexual experience, with additional preliminary data in premenopausal women.[101]

Androgens should not be used during pregnancy or lactation or in women with suspected androgen-dependent neoplasia. Adverse effects from excessive dosage include virilization, fluid retention, and potentially adverse lipoprotein lipid effects, which are more likely with oral administration. There is no evidence that systemic transdermal testosterone is associated with increased cardiovascular morbidity or mortality[102] or of a significant change in the risk of invasive breast cancer.[103] However, further studies are required to determine the long-term safety of testosterone in women.

Most of the earlier studies showing clinical improvement with testosterone therapy reported supraphysiologic concentrations. Other studies have used transdermal patch therapy to achieve free testosterone concentrations in the upper normal range for young women.[100,104] Evidence regarding efficacy and safety of testosterone in women is lacking, and the generalized use of testosterone is currently not recommended.[97] In the United States, there are no testosterone products approved for use in women.

Selective Estrogen Receptor Modulators (SERMs)

Selective estrogen receptor modulators are a group of nonsteroidal compounds that are chemically distinct from estradiol. They act as estrogen agonists in some tissues, such as bone, and as estrogen antagonists in other tissues, such as breast and endometrial tissue, through specific, high-affinity binding to the estrogen receptor. Individual SERMs differ in their activity and tissue specificity resulting in varying patterns of estrogen-receptor agonism in some tissues and estrogen-receptor antagonism in others.[105]

Efficacy The ideal SERM would protect against osteoporosis and decrease the incidence of breast, endometrial, and colorectal cancer and CHD without exacerbating menopausal symptoms or increasing the risk of venous thromboembolism or gallbladder disease. To date, no SERM meets these ideals. Tamoxifen, the first-generation SERM (a nonsteroidal triphenylethylene derivative), has estrogen antagonist activity on the breast and estrogen-like agonist activity on bone and endometrium. The second-generation SERM raloxifene, a nonsteroidal benzothiophene derivative, is used to reduce the risk of postmenopausal osteoporosis and invasive breast cancer, and also for

treatment of postmenopausal osteoporosis. Raloxifene, however, has an increased incidence of hot flushes compared to placebo.[106]

The third generation SERM, bazedoxifene, in conjunction with conjugated estrogens forms a tissue-selective estrogen complex (TSEC) and is FDA-approved for use in moderate to severe vasomotor symptoms and prevention of osteoporosis.[105,107] This agent appears to have a favorable breast, endometrial, and ovarian safety profile, even after prolonged use.[108] While this TSEC has demonstrated high effectiveness for vasomotor symptoms (approximately 75% reduction),[108,109] SERMs alone do not alleviate, and may even exacerbate vasomotor symptoms, and also increase the risk for venous thromboembolism.

Ospemifene is an orally administered third generation SERM approved by the FDA for the treatment of moderate-to-severe dyspareunia from menopausal vulvar and vaginal atrophy. Ospemifene's labeling carries a boxed warning about its estrogenic effect on the endometrium: there is an increased risk of endometrial hyperplasia and endometrial cancer in a woman with a uterus who takes unopposed estrogen therapy. Ospemifene labeling includes a boxed warning about the possible risk of stroke and venous thromboembolism, and this drug has a 7.5% incidence of hot flushes.

Adverse Effects Depending on the tissue selectivity, several SERMs are associated with hot flushes and less often with leg cramps. SERMs can increase the risk of venous thromboembolism and fatal stroke to a degree similar to that of oral estrogen, but the degree of risk is product specific.[63] Common adverse effects (greater than or equal to 5%) of bazedoxifene include muscle spasms, nausea, diarrhea, dyspepsia, upper abdominal pain, oropharyngeal pain, dizziness, and neck pain. Adverse effects of ospemifene include hot flushes, vaginal discharge, muscle spasm, genital discharge, and hyperhidrosis.

Dose and Administration Conjugated estrogens/bazedoxifene is supplied as 0.45 mg/20 mg tablets and is taken once daily. Ospemifene is a 60 mg tablet taken once daily with food. Other available SERMs are also dosed orally once daily.

Tibolone

Tibolone is a gonadomimetic synthetic steroid in the norpregnane family with combined estrogenic, progestogenic, and androgenic activity. Tibolone has been used for three decades in Europe for treatment of menopausal symptoms and prevention of osteoporosis but is currently not approved in the United States. The hormonal effects of this synthetic steroid depend on its metabolism and activation in peripheral tissues. The parent compound has been described as a prodrug that is metabolized quickly in the gastrointestinal (GI) tract. It has several active metabolites, including a Δ4-isomer and 3α-OH and 3β-OH compounds. The Δ4-isomer metabolite confers significant progestogenic and androgenic properties.

Efficacy Tibolone has beneficial effects on mood and libido and improves menopausal symptoms and vaginal atrophy. Tibolone protects against bone loss and significantly reduces the risk of vertebral fractures in postmenopausal women with osteoporosis.[110] It has also been shown to decrease the

risk of breast cancer and colon cancer in healthy women aged 60 to 85 years.[110] It also appears to be more effective than conventional MHT for management of sexual dysfunction.[111]

Adverse Effects Tibolone use in elderly women has been reported to be associated with an increased risk of stroke.[110] Tibolone use is associated with breast cancer recurrence in breast cancer patients with vasomotor symptoms.[112] Tibolone lowers concentrations of total cholesterol, triglycerides, and lipoprotein (a) but may decrease high-density lipoprotein (HDL) cholesterol.[113] The Million Women Study, an observational cohort study, found a greater risk of endometrial cancer (adjusted relative risk 1.79, 95% CI: 1.43-2.25).[114] However, other randomized placebo-controlled studies have not shown an increased risk of endometrial cancer with tibolone and suggest that tibolone has an endometrial safety profile similar to continuous combined CEE and MPA.[115] The most commonly reported adverse effects of tibolone include weight gain and bloating.

Complementary and Alternative Medicine

Some women prefer to use natural remedies due to a belief that they are safer. Randomized, placebo-controlled trials of complementary and alternative therapies have been equivocal and have not established the safety and efficacy of herbal remedies, homeopathic treatments, or acupuncture for the prevention or treatment of hot flushes.

Phytoestrogens Phytoestrogens have physiologic effects in humans.[116] They are plant compounds with estrogen-like biologic activity and relatively weak estrogen receptor-binding properties. Epidemiologic studies suggest that consumption of a phytoestrogen-rich diet, which is common in traditional Asian societies, is associated with a lower risk of breast cancer.[116]

The biologic potencies of phytoestrogens vary. Most of these compounds are nonsteroidal and are less potent than synthetic estrogens. The three main classes of phytoestrogens are isoflavones, lignans, and coumestans, all of which are found in plants or their seeds.[116] The most commonly studied phytoestrogen is the isoflavone class. Genistein and daidzein are the most abundant active components of isoflavones. The concentration of isoflavones per gram of soy protein varies considerably among preparations. Also, a single plant often contains more than one class of phytoestrogen. Common food sources of phytoestrogens include soybeans (isoflavones), cereals, oilseeds such as flaxseed (lignans), and alfalfa sprouts (coumestans).

Mild estrogenic effects have been seen in postmenopausal women.[116] An early study suggested that phytoestrogen supplementation is no more effective than placebo in relieving hot flushes or other symptoms of menopause in postmenopausal women. However, a systematic review indicated that high levels of genistein extracts appear to reduce the number of daily hot flushes compared with placebo without harmful endometrial effects.[117,118] A limitation of this review is that many of the studies included were of poor quality and short duration but it is worth.

Phytoestrogens decrease low-density lipoprotein (LDL) cholesterol and triglyceride concentrations with no significant change in HDL cholesterol concentrations.[119] Furthermore, phytoestrogens have the ability to inhibit LDL oxidation and normalize vascular reactivity in estrogen-deprived primates.[119]

In addition, bone mineral density (BMD) may be improved by phytoestrogens.[116] Common adverse effects include constipation, bloating, and nausea.[120]

A recent meta-analysis reported that phytoestrogen use is not associated with increased rates of endometrial cancer, vaginal bleeding, and breast cancer.[120] Large, long-term studies are needed to further document the effects of phytoestrogens on the breast, bone, and endometrium. Furthermore, before phytoestrogens can be considered an alternative to conventional MHT in postmenopausal women, additional data are needed to clarify differences among classes of phytoestrogens, including dosing, biologic activity, safety, and efficacy.

Other Herbal Products Black cohosh (*Cimicifuga racemosa* or *Actaea racemosa*), a widely used herbal supplement, may not offer substantial benefits for relief of vasomotor symptoms.[121] A systematic review of 16 studies involving 2,027 women found insufficient evidence to support the use of black cohosh for menopausal symptoms, but further research is warranted.[122] This substance does not appear to have strong intrinsic estrogenic properties but may act through the serotonergic system. Black cohosh appears to be generally well tolerated, although hepatotoxicity has been reported. It is unclear if this is due to the herb itself or is a result of adulteration of the commercially available products.[123] The long-term effects of black cohosh are unknown. Other herbals and alternative treatments that may be used by women include dong quai, red clover leaf (contains phytoestrogens), kava, and dehydroepiandrosterone. These have not been shown to be effective in the treatment of menopausal symptoms and may carry the risk of adverse events.[124] Complementary and alternative therapies should not be recommended to treat menopausal symptoms.

Personalized Pharmacotherapy

The severity of menopausal symptoms varies widely from woman to woman. The decision to use MHT must be individualized and based on several parameters, including vasomotor and vulvovaginal symptoms, age, fracture risk, cardiovascular disease risk, breast cancer risk, and thromboembolism risk. MHT is not indicated for prevention of chronic diseases of aging. The initiation of MHT should be considered for healthy symptomatic women who are within 10 years of menopause or age younger than 60 years and who do not have contraindications to therapy.[23] The duration of estrogen–progestogen therapy is limited by the risk of breast cancer at 3 to 5 years of use; estrogen-only therapy allows for more flexibility up to 7 years.[20] It is recommended that treatment be individualized and used at the lowest effective dose for the shortest duration that is needed to relieve vasomotor symptoms.

Long-term use of MHT or initiation in older women is associated with greater risks. Once advised of increased risks associated with continuing MHT beyond age 60 years, extending therapy may be acceptable under close medical supervision. For example, in women with severe and persistent menopausal symptoms, use should not discontinued based solely on age but rather individualized based on assessment of potential risks and benefits.[22]

Estrogen therapy is the most effective treatment for moderate and severe vasomotor symptoms, impaired sleep quality, and vulvovaginal symptoms of menopause (see Fig. 82-1). A thorough

discussion of the risks and benefits of MHT should be completed with the patient so that she can weigh the risks and benefits versus alternatives and make a rational decision about whether to use MHT. For a healthy recently menopausal woman who has vasomotor symptoms, the benefits of hormonal therapy generally outweigh the risks. These benefits include the control of vasomotor symptoms, treatment of urogenital atrophy, and prevention of postmenopausal bone loss. Nonetheless, VTE and stroke are concerning short-term risks.

Menopausal hormone therapy should be tailored for optimal formulation, dose, route of delivery, and counseling should be based on age, years since menopause, and hysterectomy status. All types and routes of administration of estrogen are equally effective in relieving vasomotor symptoms and vulvovaginal atrophy.[20] A dose-dependent relationship between estrogen administration and suppression of hot flushes is well established. Some women, especially younger women, may require a higher than average dose of estrogen to suppress symptoms. On the other hand, many women with hot flushes at the time of menopause require lower doses of estrogen.[125] Initiation of therapy with low doses of estrogen often will minimize adverse effects, such as breast tenderness and unscheduled bleeding. Transdermal estradiol is less likely than oral estrogen to cause nausea and headache. In many cases changing from one estrogen regimen to another can alleviate certain adverse effects.

Prior to initiating pharmacologic therapy, a complete medical history and physical examination should be performed. Medical history should include a personal and family history of cardiovascular disease and thrombotic problems. The physical examination should include a complete cardiovascular examination, clinical assessment of thyroid status, and breast and pelvic examinations. Papanicolaou cervical cytologic examination and screening mammography negative for malignancy are required before initiating MHT. Thyroid function tests and lipoprotein lipid profile also are performed at the discretion of the clinician. Oral estrogen should be avoided in women with hypertriglyceridemia, liver disease, and gallbladder disease. For these women, transdermal administration is a safer approach. Sequential estrogen/progestogen therapy results in scheduled vaginal withdrawal bleeding but often is scant or completely absent in older women. For many women, scheduled withdrawal bleeding is one of the main reasons for avoiding or discontinuing MHT. Because there is no physiologic need for bleeding, new MHT regimens that reduce monthly bleeding (eg, continuous long-cycle regimens) or prevent monthly bleeding (eg, continuous combined and intermittent combined regimens) were developed. Continuous combined estrogen–progestogen administration results in endometrial atrophy and the absence of vaginal bleeding. Initially, it causes unpredictable spotting or bleeding, which usually resolves within 6 to 12 months. Decreasing the estrogen dose or increasing the progestogen dose usually decreases or stops the spotting. Occasionally, a drug-free period of 1 or 2 weeks is useful to stop the bleeding. Women who recently have undergone menopause have a higher risk for excessive, unpredictable bleeding while receiving continuous therapy; thus, this regimen is best reserved for women who are at least 2 years postmenopause.

If MHT is to be initiated, the selection of the drug should also take into account the potential for drug interactions, including those involving the cytochrome P450 (CYP450) microsomal enzyme system. Estrogen is metabolized partly by the CYP 450 isoenzymes 1A2 and 3A4, and the progestin

medroxyprogesterone is metabolized by CYP450 3A4. Inducers or inhibitors of these enzymes may either decrease or increase, respectively, the therapeutic effects or result in side effects. Similarly, selection of nonhormonal drug therapy options should take into account the potential for interactions with other prescription and nonprescription medications the patient may be taking. Selective serotonin reuptake inhibitors and serotonin norepinephrine reuptake inhibitors can have major interactions with other drugs also affecting CYP450 2D6 and 3A4 (Chapter 68). Patients using vaginal estrogen creams or nonestrogen vaginal moisturizers should be warned that products with oil-based lubricants or vehicles can weaken latex condoms, which can decrease protection against sexually transmitted infections. Pharmacodynamic drug interactions (eg, additive side effects) should also be considered.

Evaluation of Therapeutic Outcomes

The relief of moderate and severe hot flushes is the primary goal of MHT. In order to adequately assess treatment effect, women should be encouraged to continue their MHT regimen for at least 1 month. The main reasons for discontinuing MHT are side effects such as bleeding, breast tenderness, bloating, and "premenstrual-like symptoms." Reducing the dose or changing the regimen or the route of administration can minimize these effects. Alternatively, if vasomotor symptoms are not controlled adequately with a lower-dose regimen, increasing the estrogen dose may be a reasonable option. Therefore, after the menopausal woman begins MHT, a brief follow-up visit 6 weeks later may be useful to discuss patient concerns about MHT and to evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding. Women receiving MHT should be seen by the clinician for annual monitoring (**Table 82-8**).

TABLE 82-8 Management of Patients Taking Hormone Therapy Regimens

Initiation of Hormone Therapy

Hormone therapy should be used only as long as vasomotor symptom control is necessary (usually 2-3 years)

6-Week Follow-up Visit

- To discuss patient concerns about hormone therapy
- To evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding (if continuous sequential hormone therapy is given)

Drug	Adverse Drug Reaction	Monitoring Parameter	Suggested Change
Estrogen		Persistence of hot flushes	Increase estrogen dose
Estrogen	Breast tenderness		Reduce estrogen dose; switch to a transdermal regimen
Progestogen	Bloating Premenstrual-like		Switch to another progestogen

	symptoms

Annual Follow-up Visit

Annual monitoring: medical history, physical examination (including pelvic examination), blood pressure measurement, and routine endometrial cancer surveillance (as indicated). Additional follow-up is determined based on the patient's initial response to therapy and the need for any modification of the regimen

Breast examinations: annual mammograms (scheduled based on patient's age and risk factors)

Osteoporosis prevention: BMD should be measured in women 65 years and older and in women younger than 65 years with risk factors for osteoporosis. Repeat testing should be performed as clinically indicated.

In women taking sequential hormone therapy	Transvaginal ultrasound, and where indicated an endometrial biopsy should be performed if vaginal bleeding occurs at any time other than the expected time of withdrawal bleeding or when heavier or more prolonged withdrawal bleeding occurs (if endometrial pathology cannot be excluded by endovaginal ultrasonography, further evaluation may be required, such as hysteroscopy)
In women taking continuous combined hormone therapy	Endometrial evaluation should be considered when irregular bleeding persists for more than 6 months after initiating therapy

BMD, bone mineral density.

The main indication for MHT is relief of menopausal symptoms. If combined estrogen/progestogen treatment is stopped within 5 years, no evidence of increased risk of breast cancer is observed.[13] Estrogen-alone treatment is not associated with an increased risk of breast cancer.[35]

Many women have no difficulty abruptly stopping MHT; others develop vasomotor symptoms after discontinuation. Although these symptoms may be mild and resolve over a few months, in some women the symptoms are severe and intolerable. There is no evidence that gradual discontinuation of MHT reduces the recurrence of hot flushes compared with sudden discontinuation.[126]

CONCLUSION

Menopause is a natural life event—not a disease. Therefore, the decision to use MHT must be individualized based on the severity of menopausal symptoms and the risk for cardiovascular disease, breast cancer, thromboembolism, and osteoporotic fracture (**Table 82-9**).

TABLE 82-9 Evidence-Based Hormone Therapy Guidelines for Menopausal Symptom Management

Recommendation	Recommendation Grade[a]
In the absence of contraindications, estrogen-based postmenopausal hormone therapy should be used for treatment of moderate to severe vasomotor	A1

Recommendation	Recommendation Grade[a]
symptoms	
Systemic or vaginal estrogen therapy should be used for treatment of urogenital symptoms and vaginal atrophy	A1
Postmenopausal women taking estrogen-based therapy should be followed up every year, taking into account findings from new clinical trials	A1
Postmenopausal women taking estrogen-based therapy should be informed about potential risks	A1
Safety and tolerability may vary substantially with the type and regimen of hormone therapy	B2
Breast cancer risk increases after use of continuous combined hormone therapy for longer than 5 years	A1
Breast cancer risk does not increase after long-term estrogen-only therapy (6.8 years) in postmenopausal women with hysterectomy	A1
Hormone therapy should not be used for primary or secondary prevention of coronary heart disease	A1
Oral hormone therapy increases risk of venous thromboembolism	A1
Non-oral hormone therapy may be safer for postmenopausal women at risk for venous thromboembolism who choose to take hormone therapy	B2
Oral hormone therapy increases risk of ischemic stroke	A1
Although hormone therapy decreases risk of osteoporotic fractures, it cannot be recommended as a first-line therapy for the treatment of osteoporosis	A1
Potential harm (cardiovascular disease, breast cancer, and thromboembolism) from long-term hormone therapy (use greater than 5 years) outweighs potential benefits	A1
Young women with primary ovarian insufficiency have severe menopausal symptoms and increased risk for osteoporosis and cardiovascular disease. Decisions on whether and how these young women must be treated should not be based on studies of hormone therapy in women older than 50 years	B3

Quality of evidence: 1, evidence from more than one properly randomized controlled trial; 2, evidence from more than one well-designed clinical trial with randomization from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert communities.

[a]*Strength of recommendations:* A, good evidence to support recommendation; B, moderate evidence to support recommendation; C, poor evidence to support recommendation.

The WHI trial reported increased risk of cardiovascular disease, breast cancer, stroke, and thromboembolic disease among women using continuous combined therapy with CEE plus MPA

compared with placebo. In the estrogen-alone arm of the study, CEE had no effect on cardiovascular disease or breast cancer risk compared to placebo, but an increased risk of stroke and thromboembolic disease was noted in those who received estrogen. The WHI trial also demonstrated that quality of life and cognition were no better in the group receiving MHT than in the placebo group, and that MHT increases dementia risk in women 65 years or older. Recent studies suggest dose, duration, and timing (early or late menopause) of therapy may alter the benefit-risk profile and should be considered for individual patients.

In the absence of contraindications, MHT is the most effective treatment for managing postmenopausal symptoms, such as hot flushes, night sweats, and vaginal dryness. For many women, the benefits of short-term use of MHT for the relief of menopausal symptoms, far outweighs any risks. For symptoms of genital atrophy alone, the use of local, nonsystemic estrogen, nonhormonal lubricants and moisturizers, or ospemifene should be considered.

Long-term use of MHT cannot be recommended routinely for osteoporosis prevention given the availability of alternative therapies, such as bisphosphonates and raloxifene. For long-term MHT use, the potential harm (cardiovascular disease, breast cancer, and thromboembolism) outweighs the potential benefits. MHT should not be used for prevention of CHD. Women with cardiovascular risk factors (eg, hypertension and lipid abnormalities) can benefit from reduction of these risk factors through interventions such as weight loss, lipid-lowering therapy, use of aspirin, and physical activity.

PRIMARY OVARIAN INSUFFICIENCY AND PREMENOPAUSAL HORMONE REPLACEMENT THERAPY

Primary ovarian insufficiency (POI) is a condition characterized by sex-steroid deficiency, amenorrhea, and infertility in women younger than 40 years.[127] POI was once considered irreversible and was described as "premature menopause," and the condition is still referred to as *premature ovarian failure*. However, POI is not an early, natural menopause. Normal menopause results from ovarian follicle depletion, whereas POI is characterized by intermittent ovarian function in half of affected women.[127] These women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. Pregnancies have occurred in 5% to 10% of women after the diagnosis of POI, even in women with no follicles observed on ovarian biopsy.

Epidemiology

The prevalence of POI increases with increasing age, reaching approximately 1% of women by age 40 years.[128]

Etiology

A number of physiologic or metabolic abnormalities can lead to POI (**Table 82-10**). In most cases, the etiology cannot be identified.

TABLE 82-10 Etiology of Primary Ovarian Insufficiency

Idiopathic or karyotypically normal spontaneous primary ovarian insufficiency

Autoimmunity:

(A) Isolated autoimmune primary ovarian insufficiency

(B) As a component of an autoimmune polyglandular syndrome in association with Addison's disease, hypothyroidism, hypoparathyroidism, or mucocutaneous candidiasis (*AIRE* gene mutations; 21q22.3)

Ovarian insufficiency due to chemotherapy, radiation, and extensive ovarian surgery

Chromosomal abnormalities:

(A) X-chromosome defects (X-monosomy; X-mosaicism; X-chromosome translocations or partial deletions; *FMR1* gene permutations, Xq27,3; *FMR2* gene permutations, Xq28; *BMP15* gene mutation, Xp11.2)

(B) Autosomal chromosome abnormalities

Gonadotropin-receptor abnormalities affecting ovarian function (FSH-receptor gene mutations, 2p21-p16; LH-receptor gene mutations, 2p21)

Enzyme deficiencies affecting ovarian function

(A) Cholesterol desmolase deficiency

(B) 17α-hydroxylase deficiency

(C) 17-20 desmolase deficiency

Galactosemia (galactose-1-phosphate uridyl transferase, *GALT* gene mutations, 9p13)

Blepharophimosis, ptosis, and epicanthus in versus syndrome type 1 (autosomal dominant syndrome, in which primary ovarian insufficiency is the predominant syndrome)

Perrault's syndrome (familial autosomal recessive primary ovarian insufficiency in association with deafness)

Pathophysiology

Primary ovarian insufficiency may occur as a result of ovarian follicle dysfunction or ovarian follicle depletion and may present as either primary amenorrhea (absence of menses in a girl who has reached age 16 years) or secondary amenorrhea (cessation of menses in a woman previously menstruating for at least 6 months). Approximately 50% of women with POI have documented ovarian follicle function.[127]

Clinical Presentation

No characteristic menstrual pattern or history precedes POI. Approximately 50% of patients with this condition have a history of oligomenorrhea or DUB (prodromal POI), and approximately 25% develop amenorrhea acutely. Some patients develop amenorrhea postpartum, whereas others experience amenorrhea after discontinuing oral contraceptives. Primary amenorrhea is not associated with symptoms of estrogen deficiency. In cases of secondary amenorrhea, symptoms may include hot flushes, night sweats, fatigue, and mood changes. Prodromal POI may present with hot flushes even in women who menstruate regularly. Incomplete development of secondary sex characteristics may occur in women with primary amenorrhea, whereas these characteristics typically are normal in women with secondary amenorrhea. In general, women with POI have normal fertility before the disorder develops.

Primary ovarian insufficiency is defined by the presence of at least 4 months of amenorrhea and at least two serum FSH concentrations measuring greater than 40 IU/L (obtained at least 1 month apart) in women younger than 40 years. A complete history should be taken, considering other factors that can affect ovarian function such as prior ovarian surgery, chemotherapy, radiation, and autoimmune disorders. In patients with primary amenorrhea, particular attention should be paid to breast and pubic hair development according to Tanner stages. Short stature, stigmata of Turner syndrome, and other dysmorphic features of gonadal dysgenesis should be considered. Ideally, a pelvic examination is performed but is not always clinically appropriate. Alternatively, transabdominal ultrasonography can be performed in patients with primary amenorrhea to confirm the presence of normal anatomic structures. In the majority of cases, physical examination is completely normal. A karyotype should be performed in all patients experiencing POI. Women with ovarian insufficiency and a karyotype containing a Y chromosome should undergo bilateral gonadectomy because of substantial risk for gonadal germ cell neoplasia.[127] Ovarian biopsy and antiovarian antibody testing are investigational procedures with no proven clinical benefit in POI. As clinically indicated, the workup should include tests for the diagnosis of other possible associated autoimmune disorders, such as hypothyroidism, diabetes mellitus, and Addison's disease.

In the majority of patients, ovarian insufficiency develops after the establishment of regular menses. Young women with POI who develop ovarian dysfunction before they achieve peak adult bone mass sustain sex steroid deficiency for more years than do naturally menopausal women. This deficiency can result in a significantly higher risk for osteoporosis[129] and cardiovascular disease.[130,131] Importantly, a survey of more than 19,000 women between the ages of 25 and 100 years suggests that ovarian insufficiency occurring before age 40 years is associated with significantly increased mortality, with an age-adjusted odds ratio for all-cause mortality of 2.14 (95% CI: 1.15-3.99).[132]

Young women find the diagnosis of POI particularly traumatic and frequently need extensive emotional and psychological support. Although most of these women will, in fact, be infertile, it is important to emphasize that POI can be transient and that spontaneous pregnancies have occurred even years after diagnosis.

Treatment: Primary Ovarian Insufficiency

Women with POI require hormone replacement, and long-term follow-up is necessary. Optimal

hormone therapy depends on whether the patient has primary or secondary amenorrhea. Young women with primary amenorrhea in whom secondary sex characteristics have failed to develop initially should be given very low doses of estrogen in an attempt to mimic the gradual pubertal maturation process. A typical regimen is 0.3 mg CEE unopposed (ie, no progestogen) daily for 6 months, with incremental dose increases at 6-month intervals until the required maintenance dose is achieved. Gradual dose escalation often results in optimal breast development and allows time for the young woman to adjust psychologically to her physical maturation. Cyclic progestogen therapy, given 12 to 14 days per month, should be instituted toward the end of the second year of treatment.

Women with secondary amenorrhea who have been estrogen deficient for 12 months or longer also should be given low-dose estrogen replacement initially to avoid adverse effects such as mastalgia and nausea. However, the dose can be titrated up to maintenance levels over a 6-month period, and progestogen therapy can be instituted with the initiation of estrogen therapy. Women with a brief history of secondary amenorrhea are less likely to experience undesired effects from hormone therapy if they are given a reduced dose for the first month of therapy, followed by a full dose from the second month onward.

An estrogen dose equivalent to at least 1.25 mg CEE (or 100 mcg transdermal estradiol) is needed to achieve adequate estrogen replacement in young women. A progestogen should be given for 12 to 14 days per calendar month to prevent endometrial hyperplasia (**Table 82-11**). Estrogens given in usual replacement doses do not suppress spontaneous follicular activity or ovulation. Because women with POI can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns (ie, only cyclic regimens should be used). Patients who miss an expected menses should be tested for pregnancy and should discontinue hormone therapy if the result is positive. Because most young women negatively associate MHT with menopause in older women, some clinicians prefer to prescribe oral contraceptives for hormone replacement in premenopausal women with hypogonadism. However, oral contraceptives may not inhibit ovulation or effectively prevent pregnancy in young women with elevated gonadotropin levels.

TABLE 82-11 Premenopausal Hormone Replacement Therapy in Primary Ovarian Insufficiency *(Continuous Sequential Therapy)*

Regimen[a]	Brand Name	Dosage
Estrogen Therapy		
Conjugated equine estrogens	Premarin	1.25 mg (oral; daily)
Estropipate (piperazine estrone sulfate)	Ogen Ortho-Est	2.5 mg (oral; daily)
Micronized 17β-estradiol	Estrace	4 mg (oral; daily)
Transdermal estrogen system (estradiol)	Alora	0.1 mg, apply patch twice weekly
	Climara	0.1 mg, apply patch twice weekly
	Vivelle, Vivelle Dot	0.1 mg, apply patch twice weekly

Regimen[a]	Brand Name	Dosage
Progestogen Therapy		
Dydrogesterone[b]	Duphaston	10-20 mg/day for 12-14 days per calendar month (oral dosage form available as 10 mg tablets)
Medroxyprogesterone acetate	Provera	5-10 mg/day for 12-14 days per calendar month (oral dosage form available as 2.5, 5, 10 mg tablets)
	Generic MPA	
Micronized progesterone	Prometrium	200 mg/day for 12-14 days per calendar month (oral dosage form available as 100 and 200 mg tablets)
Norethindrone acetate	Norethindrone acetate	5 mg/day for 12-14 days per calendar month (oral dosage form available as 5 mg tablets)
	Aygestin	5 mg/day for 12-14 days per calendar month (oral dosage form available as 2.5, 5 mg tablets)

[a]Off-label indication in the United States.

[b]Not available in the United States.

Women with POI have testosterone deficiency.[133] In these young women, testosterone replacement, in addition to estrogen, was considered potentially important.[104,133] However, a prospective, randomized, placebo-controlled study conducted at the National Institutes of Health showed that long-term "physiologic" testosterone supplementation (150 mcg/day), in addition to standard hormone replacement, did not significantly improve BMD and sexual function in these young women.[134,135] More importantly, however, this study provided evidence that treatment with a physiological dose of estradiol (delivered via a transdermal patch) combined with oral medroxyprogesterone not only reduced the decline in lower hip and spine BMD in women with POI but actually restored it to normal levels.[134]

CLINICAL PRESENTATION Primary Ovarian Insufficiency Symptoms

- Primary amenorrhea: no symptoms of estrogen deficiency.
- Secondary amenorrhea: vasomotor symptoms (hot flushes and night sweats), sleep disturbances, mood changes, sexual dysfunction, problems with concentration and memory, vaginal dryness, and dyspareunia.

Signs

- Primary amenorrhea: incomplete development of secondary sex characteristics.
- Secondary amenorrhea: normal development of secondary sex characteristics, signs of urogenital atrophy.

Laboratory Tests

- FSH greater than 40 IU/L.
- Other relevant diagnostic tests (eg, bone mineral density, ultrasound of the ovaries).
- Thyroid function tests, fasting glucose level, and adrenocorticotropic hormone stimulation test.

Desired Outcome

The goal of therapy in young women with POI is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normally functioning ovary.

General Approach to Treatment

9 Premenopausal hormone therapy in young women with POI differs markedly from MHT, and results of randomized trials conducted in menopausal women, including the WHI trial, cannot be extrapolated to premenopausal women with ovarian dysfunction. In POI, hormone replacement therapy with estrogen and a progestogen is aimed at mimicking the normal age-specific physiology and should generally be continued until the average age of natural menopause. Unlike postmenopausal women who have a natural decline in estrogen with aging and in whom MHT prolongs exposure to estrogen well beyond completion of the normal span of reproductive life, those with POI require exogenous sex steroids to compensate for an abnormal decrease in production by their ovaries. The observation that nearly half of young women with POI have significantly reduced BMD within 1.5 years of their diagnosis despite taking "standard" hormone therapy,[129] emphasizes the importance of providing optimal hormone therapy using dosing regimens that provide true physiologic replacement.[134]

Personalized Pharmacotherapy

Despite the heterogeneous nature of POI, efforts are ongoing to identify genetic factors that may influence the development and manifestation of this condition. However, the use of personalized pharmacotherapy to treat POI has not been described, and recommendations regarding how currently available therapies can be individualized to maximize benefit or reduce risk are not yet available.

Evaluation of Therapeutic Outcomes

Similar to the treatment of menopause, an assessment of the efficacy of hormone therapy, and its accompanying risks, should be performed on a regular basis. Young women with POI should be monitored annually for their response to treatment, and their adherence with hormone therapy should be assessed regularly. Patients should be evaluated continuously for the presence of signs and symptoms of associated autoimmune endocrine disorders, such as hypothyroidism, adrenal insufficiency, and diabetes mellitus. Baseline BMD testing should be performed in all women with POI. Mammography should be performed annually after age 45 years in accordance with accepted

guidelines. Additional mammography screening in premenopausal women younger than 45 years who are receiving physiologic hormone therapy is not warranted. Other tests should be performed as clinically indicated.

CONCLUSION

Approximately 1% of women spontaneously develop ovarian insufficiency before age 40 years. POI is not an early natural menopause. Most affected women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. However, these women sustain sex steroid deficiency for more years than do naturally menopausal women, resulting in a significantly higher risk for osteoporosis and cardiovascular disease.

Women with POI need exogenous sex steroids to compensate for the decreased production by their ovaries. Thus, premenopausal hormone therapy is required at least until these women reach the age of natural menopause.

The goal of therapy is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normally functioning ovary.[131] This usually requires the administration of estrogen at a higher dose than the standard dose given to older women experiencing natural menopause.[131]

Because women with POI can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns. Patients who miss an expected menses should be tested for pregnancy and, if positive, the hormone therapy should be promptly discontinued.

Annual follow-up should include assessment of adherence with the prescribed hormone therapy regimen and evaluation for signs and symptoms of associated endocrine disorders.

Chapter 83: Erectile Dysfunction

Mary Lee; Roohollah Sharifi

INTRODUCTION

KEY CONCEPTS

- 1 The incidence of erectile dysfunction is low in men younger than 40 years of age. The incidence increases as men age likely as a result of concurrent medical conditions that impair the vascular, neurologic, psychogenic, and hormonal systems necessary for a normal penile erection.
- 2 Many commonly used drugs have sympatholytic, anticholinergic, sedative, or antiandrogenic effects that may exacerbate or contribute to the development of erectile dysfunction. Clinicians should be familiar with these agents and be prepared to make adjustments in drug regimens to minimize adverse effects of these drugs on a patient's erectile function.
- 3 The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse the underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, and chronic ethanol abuse, should be addressed and minimized.
- 4 Specific treatments for erectile dysfunction include vacuum erection devices (VEDs), pharmacologic treatments, psychotherapy, and surgery. Of these, phosphodiesterase type 5 inhibitors are the medications of first choice.
- 5 The ideal treatment of erectile dysfunction should have a fast onset, be effective, be convenient to administer, be cost effective, have a low incidence of serious adverse effects, and be free of serious drug interactions.
- 6 Specific treatment is first initiated with the least invasive forms of treatment, including VEDs or oral phosphodiesterase type 5 inhibitors, followed by intracavernosal injections or intraurethral inserts, and finally by surgical insertion of a penile prosthesis.
- 7 Vacuum erection devices can have a slow onset of action (up to 20 minutes) during initial use and are not discreet; therefore, they are most effective for a couple in a stable relationship.
- 8 Although phosphodiesterase type 5 inhibitors are convenient and effective regardless of the etiology of erectile dysfunction, they fail in 30% to 40% of patients. Also, phosphodiesterase type 5

inhibitors are contraindicated in patients taking any dosage formulation of nitrate.

- 9 Testosterone supplementation should be reserved for patients with primary, secondary, or mixed hypogonadism who have erectile dysfunction as a consequence of a decreased libido. Testosterone supplementation should not be used by patients with erectile dysfunction who have normal serum testosterone levels.

- 10 Although intracavernosal injections and intraurethral pellets of alprostadil are effective independent of the etiology of erectile dysfunction, they fail in up to one third of patients. To self-administer medication by these routes, patients require training to minimize administration-related adverse effects.

The National Institutes of Health Consensus Development Panel on Impotence defines erectile dysfunction as the persistent failure to achieve a penile erection to allow for satisfactory sexual intercourse.[1] A persistent failure refers to erectile dysfunction for a minimum of3 months.[2] Patients may refer to it as impotence.

Erectile dysfunction must be distinguished from disorders of libido or ejaculation, and infertility, which are caused by different pathophysiologic mechanisms and are treated with alternative agents (**Table 83-1**). A patient may suffer from one or more disorders of sexual dysfunction. For example, an elderly man with primary hypogonadism may suffer from decreased libido and erectile dysfunction. Diagnosis of the type of sexual disorder that a patient has is key to initiating the most appropriate treatment.

TABLE 83-1 Types of Sexual Dysfunction in Men

Type of Dysfunction	Definition
Decreased libido	Decreased sexual drive or desire
Increased libido	Inappropriate and excessive sexual drive or desire
Erectile dysfunction (impotence)	Failure to achieve a penile erection suitable for satisfactory sexual intercourse
Delayed ejaculation	Commonly referred to as “dry sex”; ejaculation is delayed or absent
Retrograde ejaculation	Ejaculate passes retrograde into the bladder, instead of toward the anterior urethra (antegrade) and out of the penis
Infertility	Sperm are insufficient in number, have abnormal morphology, or have inadequate motility, and fail to fertilize the ovum

EPIDEMIOLOGY

1 The incidence of erectile dysfunction is low in men younger than 40 years of age but increases as men age. The Massachusetts Male Aging Study, a cross-sectional survey of a random sample of 1,290 men in the Boston area, was conducted during the period from 1987 to 1989. The study reported an overall prevalence of 52% for any degree of erectile dysfunction in men aged 40 to 70 years, with an age-related increase in incidence ranging from 12.4% in men aged 40 to 49 years, up to 46.4% in men aged 60 to 69 years.[3] In men older than 70 years, the prevalence of erectile dysfunction increases and has been reported to be as high as 80%, depending on the population studied.[4] In the more recent Health Professional

Follow-Up Study of more than 31,000 male health professionals aged 53 to 90 years, the prevalence of erectile dysfunction was 33%.[5] Interestingly, although the prevalence of erectile dysfunction increases with patient age, many patients fail to seek medical treatment.[6,7]

Erectile dysfunction is sometimes assumed to be a symptom of the aging process in men. However, more likely it results from concurrent medical conditions of the patient (eg, hypertension, arteriosclerosis, hyperlipidemia, diabetes mellitus, metabolic syndrome, or psychiatric disorders) or from medications that patients may be taking for these diseases.[8] For example, up to 50% of patients with diabetes mellitus develop erectile dysfunction, and medications such as diuretics are associated with a high incidence of erectile dysfunction.

PHYSIOLOGY OF A NORMAL PENILE ERECTION

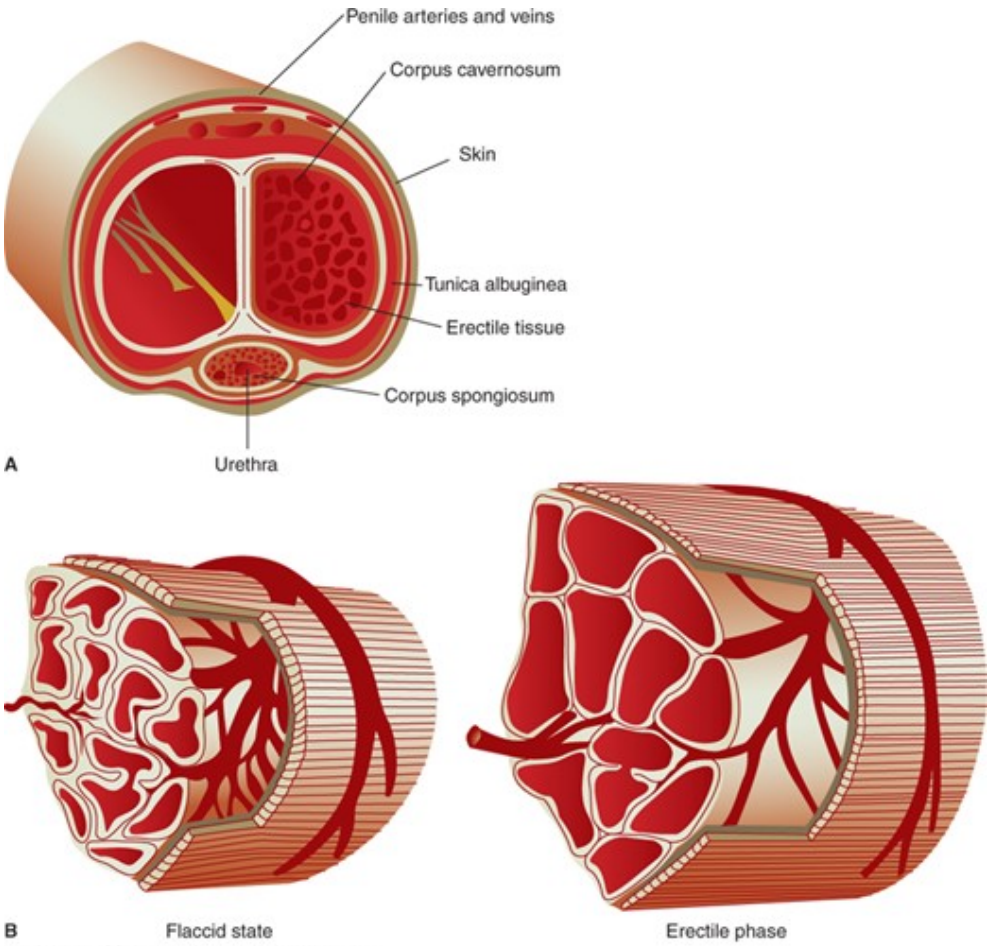
A normal penile erection requires full functioning of several physiologic systems: vascular, nervous, and hormonal. The patient also must be psychologically receptive to sexual stimuli.[9,10]

Vascular System

The penis comprises two corpora cavernosa on the dorsal side and one corpus spongiosum on the ventral side. The corpus spongiosum surrounds the urethra and forms the glans penis. The corpora are composed of multiple interconnected sinuses, which can fill with blood to produce an erection. The corpora cavernosa are encased by the tunica albuginea, a fibrous tissue membrane, which has limited distensibility. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, which causes penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules against the tunica albuginea by the swollen corpora (**Fig. 83-1**).

FIGURE 83-1

Microanatomy of and vascular changes in the penis in flaccid and erect states. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, causing penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules by the swollen corpora. *(Reprinted with permission from Walsh PC, ed. Campbell's Urology, 8th ed. Philadelphia, PA: WB Saunders; 2002:1595, 1697. Copyright © 2002 with permission from Elsevier.)*



Arterial flow into the corpora is enhanced by acetylcholine-mediated vasodilation. Acetylcholine indirectly enhances arterial flow to the corpora and increases sinusoidal filling of the corporal tissue. That is, acetylcholine is a co-neurotransmitter, which works along with other nonpeptidergic intracellular neurotransmitters—including cyclic guanosine monophosphate (cGMP), cyclic adenosine monophosphate (cAMP), or vasoactive intestinal polypeptide—to produce vasodilation. In effect, cGMP and cAMP are secondary messengers that direct desired effects in target tissues.

Specifically, acetylcholine produces an erection probably through two different pathways. Through one pathway, in the presence of sexual stimulation to genital tissue, acetylcholine enhances the production of nitric oxide by endothelial cells and nonadrenergic–noncholinergic neurons. Nitric oxide enhances the activity of guanylate cyclase, which increases the conversion of cyclic guanosine triphosphate to cGMP. cGMP activates a cGMP-dependent kinase, which decreases intracellular calcium concentrations in smooth muscle cells of penile arteries and cavernosal sinuses. As a result, smooth muscle relaxation occurs, which enhances arterial blood flow to and blood filling of the corpora.[10] An erection results.

In an alternative pathway, acetylcholine or prostaglandin E enhances the activity of adenyl cyclase, which increases the conversion of cyclic adenosine triphosphate to cAMP, a potent muscle relaxant. Similar to cGMP, cAMP decreases intracellular calcium concentrations to produce smooth muscle relaxation in cells of the arteries and cavernosal sinuses. Arterial blood flow to and blood filling of the corpora are enhanced, and a penile erection results.[10]

Nervous System and Psychogenic Stimuli

Some erections are mediated by a sacral nerve reflex arc (eg, erections can occur while the patient is sleeping). However, in the conscious patient, sensory sexual stimulation mediates erections via the CNS. That is, when a patient sees an attractive partner, hears sweet words, smells a particular scent, or tastes or touches a pleasant object, these situations can result in an erection. In this case, the patient's brain processes this information and the nervous impulse is carried down the spinal cord to peripheral cholinergic nerves that innervate the vascular supply to the corpora, resulting in an erection.

The medial preoptic area of the hypothalamus is thought to be that portion of the brain responsible for integrating external stimuli. Here dopamine exerts a proerectogenic effect, whereas, α_2-adrenergic stimulation causes the penis to become and/or remain flaccid. After moving down the spinal cord, stimulatory nerve impulses travel to the penis by efferent peripheral nerves, including inhibitory sympathetic neurons (T11-L2), proerectogenic parasympathetic neurons (S2-S4), and proerectogenic somatic neurons (S2-S4).

In summary, acetylcholine produces an erection by working along with other coneurotransmitters, including cGMP and cAMP. Thus, an erection is mediated neurologically, maintained by arterial blood filling of the corpora, and sustained by occlusion of venous outflow from the corpora.

Detumescence, or the progression of an erect penis to a flaccid state, results from the actions of norepinephrine, which contracts vascular smooth muscle to decrease arterial inflow to the corpora and contracts sinusoidal tissue in the corpora. As a result, venous outflow from the corpora increases.

Hormonal System

Testosterone is principally produced by the testes at a daily rate of 4 to 8 mg and a normal physiologic serum concentration is 300 to 1,100 ng/dL (10.4-38.2 nmol/L). Production follows a circadian pattern with highest blood levels in the morning and lowest levels in the evening. Physiologically active (free) testosterone comprises only 2% of circulating blood levels. About 44% of testosterone in the bloodstream is tightly bound to sex hormone-binding globulin and is inactive. Approximately 50% is reversibly bound to albumin and 4% is reversibly bound to corticosteroid-binding globulin; both of these portions of testosterone are in equilibrium with the 2% of testosterone that is free. Thus, the bioavailable portion of testosterone is normally 56% and comprises that which is bound to albumin and corticosteroid-binding globulin, and that which is free.[11] However, the bioavailable percentage of testosterone can vary considerably with changes in sex hormone-binding globulin. Sex hormone-binding globulin increases with aging, hyperthyroidism, human immunodeficiency virus disease, and hepatic cirrhosis; and decreases with obesity, diabetes mellitus, hypothyroidism, nephrotic syndrome, and corticosteroid use.[11]

Testosterone stimulates libido (sexual drive) and increases muscle mass in males. In addition, androgen receptors have been identified in the penile arterial endothelium and are thought to increase cavernosal levels of nitric oxide and cGMP, thereby enhancing vascular processes essential for a penile erection.[10,12] In some target cells with 5-α reductase, testosterone is activated to dihydrotestosterone. Dihydrotestosterone, which is more potent than testosterone, stimulates prostate gland growth, increases facial and body hair, induces baldness, and causes acne. In adipose tissue, a small portion of testosterone is converted to estradiol which can lead to gynecomastia.

Beginning at age 40 years, men experience a gradual decrease in testicular production of testosterone, with an associated decrease in muscle mass and sexual function.[10] The Massachusetts Male Aging Study reported that 6% to 12% of elderly males had symptoms of hypogonadism.[3] The European Male Aging Study described three cardinal symptoms of low serum testosterone levels: decreased libido, erectile dysfunction, and loss of spontaneous morning erections.[11] Other symptoms include fatigue, malaise, depressed mood, decreased bone density, increased fat:muscle ratio, gynecomastia, anemia, and insulin resistance.[12]

Within the normal physiologic serum total testosterone concentration, sexual drive is usually normal. However, because of variability in circulating levels of sex hormone-binding globulin and the lack of precision of available assays,[13,14] a patient's serum concentration of testosterone should always be interpreted in the context of the patient's symptoms and physical exam findings. To confirm hypogonadism when the serum total testosterone concentration is equivocal, the clinician should repeat the serum level measurement or obtain a serum-free (bioavailable) testosterone level.[15,16]

The relationship between erectile dysfunction and serum testosterone levels is complicated. Patients with normal serum testosterone levels may have erectile dysfunction, and patients with subnormal serum testosterone levels may have normal sexual function.[15] When a patient has hypogonadism and libido is decreased, a patient may not develop erections. In this case, erectile dysfunction is considered secondary to a decreased libido.

As a result, although the Food and Drug Administration defines hypogonadism as when the serum testosterone concentration is less than 300 ng/dL (10.4 nmol/L) in an adult man, treatment is indicated only in patients who are symptomatic or have signs of hypogonadism. Similarly, the European Association of Urology and the American Society of Andrology guidelines state that a serum testosterone greater than 350 ng/dL (12.2 nmol/L) requires no treatment, a serum testosterone of 230 to 350 ng/dL (8.0-12.2 nmol/L) requires treatment if the patient is symptomatic, and a serum testosterone below 230 ng/dL (8.0 nmol/L) generally should be treated.[13]

PATHOPHYSIOLOGY

Erectile dysfunction can result from any single abnormality or combination of abnormalities of the four systems necessary for a normal penile erection. Vascular, neurologic, or hormonal etiologies of erectile dysfunction are collectively referred to as *organic erectile dysfunction*. Approximately 80% of patients with erectile dysfunction have the organic type. Patients who do not respond to psychogenic stimuli and have no organic cause for dysfunction have *psychogenic erectile dysfunction*.[8,15,16]

Diseases that compromise vascular flow to the corpora cavernosum (eg, peripheral vascular disease, arteriosclerosis, and essential hypertension) are associated with an increased incidence of erectile dysfunction. Diseases that impair nerve conduction to the brain (eg, spinal cord injury or stroke) or conditions that impair peripheral nerve conduction to the penile vasculature (eg, diabetes mellitus) can result in erectile dysfunction.[17]

Diseases associated with hypogonadism, primary, secondary, or mixed, result in subphysiologic levels of testosterone, which cause diminished sexual drive (decreased libido) and secondary erectile dysfunction.

Primary hypogonadism occurs with surgical removal of the testes for treatment of prostate or testicular cancer, or with testicular injury or disease. Secondary hypogonadism may result from hypothalamic or pituitary disorders of luteinizing hormone–releasing hormone or luteinizing hormone, respectively; or elevated prolactin levels, which can be associated with pituitary tumors or can occur in patients with chronic renal failure. In aging males, the etiology of hypogonadism is mixed. In addition to decreased Leydig cell function in the testes, the release of gonadotropin from the hypothalamus is reduced, the circadian pattern of luteinizing hormone release from the pituitary gland is impaired, and sex hormone-binding globulin production increases.[14]

Patients must be in the proper mental frame of mind to be receptive to sexual stimuli. Patients who suffer from malaise, have reactive depression or performance anxiety, are sedated, or have Alzheimer disease, hypothyroidism, or mental disorders commonly complain of erectile dysfunction. In most studies, patients with psychogenic erectile dysfunction generally exhibit a higher response rate to various interventions than do patients with organic erectile dysfunction because the former have less severe disease.

Social habits of patients have been linked to erectile dysfunction. The vasoconstrictor effect of cigarette smoking may compromise blood flow to the corpora and decrease cavernosal filling. Excessive ethanol intake may lead to androgen deficiency, peripheral neuropathy, or chronic liver disease, all of which can contribute to erectile dysfunction.

2 Medications may cause erectile dysfunction through similar pathophysiologic mechanisms (**Table 83-2**).[18,19,20] Medications are responsible for approximately 10% to 25% of cases of erectile dysfunction.

TABLE 83-2 Medication Classes That Can Cause Erectile Dysfunction

Drug Class	Proposed Mechanism by Which Drug Causes Erectile Dysfunction	Special Notes
Anticholinergic agents (antihistamines, antiparkinsonian agents, tricyclic antidepressants, phenothiazines)	Anticholinergic activity	• Second-generation nonsedating antihistamines (eg, loratadine, fexofenadine, or cetirizine) are associated with less erectile dysfunction than first-generation agents • Selective serotonin reuptake inhibitor (SSRI) and multiple receptor reuptake inhibitor antidepressants cause less erectile dysfunction than tricyclic antidepressants. Of the SSRIs, paroxetine, sertraline, fluvoxamine, and fluoxetine cause erectile dysfunction more commonly than venlafaxine, nefazodone, trazodone, bupropion, duloxetine, mirtazapine, escitalopram, or vilazodone • Phenothiazines with less anticholinergic

Drug Class	Proposed Mechanism by Which Drug Causes Erectile Dysfunction	Special Notes
		effect (eg, chlorpromazine) can be substituted in some patients if erectile dysfunction is a problem
Dopamine antagonists (eg, metoclopramide, phenothiazines)	Inhibit prolactin inhibitory factor, thereby increasing prolactin levels	• Increased prolactin levels inhibit testicular testosterone production; depressed libido results
Estrogens or drugs with antiandrogenic effects (eg, luteinizing hormone-releasing hormone superagonists, digoxin, spironolactone, ketoconazole, cimetidine)	Suppress testosterone-mediated stimulation of libido	• In the face of a decreased libido, a secondary erectile dysfunction develops because of diminished sexual drive
CNS depressants (eg, barbiturates, narcotics, benzodiazepines, short-term use of large doses of alcohol, anticonvulsants)	Suppress perception of psychogenic stimuli	
Agents that decrease penile blood flow (eg, diuretics, peripheral β-adrenergic antagonists, or central sympatholytics [methyldopa, clonidine, guanethidine])	Reduce arteriolar flow to corpora	• Any diuretic that produces a significant decrease in intravascular volume can decrease penile arteriolar flow • Safer antihypertensives include angiotensin-converting enzyme inhibitors, postsynaptic α_1-adrenergic antagonists (terazosin, doxazosin), calcium channel blockers, and angiotensin II receptor antagonists[9]
Miscellaneous • Finasteride, dutasteride • Lithium carbonate • Gemfibrozil • Interferon • Clofibrate	Unknown mechanism	

Drug Class	Proposed Mechanism by Which Drug Causes Erectile Dysfunction	Special Notes
• Monoamine oxidase inhibitors (eg, phenelzine, isocarboxazid, tranylcypromine) • Opiates

DIAGNOSIS

With the availability in the late 1990s of effective medications for erectile dysfunction independent of the etiology, diagnostic evaluation of erectile dysfunction became streamlined. Key assessments include a description of the severity of erectile dysfunction, complete medical, psychosocial, and surgical histories, review of concurrent medications, physical examination, and selected clinical laboratory tests.[9,21]

To assess the severity of erectile dysfunction, the patient should be asked about the quality of sexual intercourse for the past 4 weeks to 6 months. A self-administered standardized questionnaire, such as the International Index of Erectile Function (IIEF), is often used. It is administered before initiation of any treatment and repeated at regular intervals during treatment. It includes 15 questions about the quality of sexual function and satisfactoriness of sexual intercourse.[22] Questions include the following: How often were you able to maintain an erection? How difficult was it to sustain an erection? How satisfied are you with your sexual life? The physician should carefully assess the expectations for erectile function of the patient and the partner to ensure that expectations are reasonable. Shorter versions of the IIEF and other self-reporting questionnaires are also used in clinical practice. For example, the IIEF-EF comprises the six questions from the IIEF that focus on erectile function. The patient responds to each question, each response is scored on a range of 1 to 5. A score of 26 to 30 is considered normal function, 22 to 25 is mild erectile dysfunction, 17 to 21 is mild-to-moderate erectile dysfunction, 11 to 16 is moderate erectile dysfunction, and 10 or less is severe erectile dysfunction.

A medical history should be obtained to identify concurrent medical illnesses (eg, hypertension, atherosclerosis, hyperlipidemia, diabetes mellitus, and depression) or surgical procedures (eg, perineal or pelvic) that are risk factors for or are associated with organic or psychogenic erectile dysfunction. Underlying diseases that do not optimally respond to treatment should be addressed before specific treatment for erectile dysfunction is initiated. If the patient smokes cigarettes, drinks excessive amounts of ethanol, or uses recreational drugs, these social habits should be discontinued before specific treatment for erectile dysfunction is started.

A complete listing of the patient's prescription and nonprescription medications and dietary supplements should be reviewed by the clinician, who should identify drugs that may be contributing to erectile

dysfunction. If possible, causative agents should be discontinued or the dose should be reduced.

A physical examination of the patient should include a check for hypogonadism (ie, signs of gynecomastia, small testicles, and decreased beard or body hair). The penis should be evaluated for diseases associated with abnormal penile curvature (eg, Peyronie's disease), which are associated with erectile dysfunction. Femoral and lower extremity pulses should be assessed to provide an indication of vascular supply to the genital area. Anal sphincter tone and other genital reflexes should be checked for the integrity of the nerve supply to the penis. A digital rectal examination in patients 50 years or older is needed to rule out benign prostatic hyperplasia, which may contribute to erectile dysfunction.

Selected laboratory tests should be obtained to identify the presence of underlying diseases that could cause erectile dysfunction. They include a fasting serum blood glucose and lipid profile. Serum testosterone levels should be checked in patients older than 50 years and in younger patients who complain of decreased libido and erectile dysfunction. At least two early morning serum testosterone levels on different days are needed to confirm the presence of hypogonadism.[23]

CLINICAL PRESENTATION Erectile Dysfunction General

- Men are affected emotionally in many different ways
- Depression
- Performance anxiety
- Marital difficulties and avoidance of sexual intimacy (patients are often brought to a physician by their partners).
- Nonadherence to medications patient believes are causing erectile dysfunction.

Symptoms

- Erectile dysfunction or inability to have sexual intercourse, which may or may not be associated with decreased libido and ejaculatory disorders.

Signs

- If completing an IIEF survey, results are consistent with low satisfaction with the quality of erectile function.
- Medical history may identify concurrent medical illnesses or past surgical procedures that interfere with good vascular flow to the penis, damaged nerve function to the corpora, or mental disorders associated with decreased reception of sexual stimuli.
- Medication history may reveal prescription or nonprescription medications that could cause or contribute to erectile dysfunction.
- Physical examination may reveal signs of hypogonadism (eg, gynecomastia, small testicles, decreased body hair or beard, and decreased muscle mass), which may contribute to erectile dysfunction. The patient may have an abnormally curved penis when erect, decreased pulses in the pelvic region (suggesting impaired vascular flow to the penis), or decreased anal sphincter tone

(suggesting impaired nerve function to the corpora). Men older than 50 years should undergo a digital rectal examination to determine whether an enlarged prostate is contributing to the patient's erectile dysfunction.

Laboratory Tests

- If the patient has signs of hypogonadism and complains of decreased libido, a serum testosterone concentration may be below the normal range, which would be consistent with a hormonal cause of erectile dysfunction. A low serum testosterone level should always be confirmed with a repeat blood level.
- If the patient has an enlarged prostate noted on digital rectal examination, a blood sample for prostate-specific antigen should be obtained. If elevated, the patient should be evaluated for a prostate disorder, which could contribute to erectile dysfunction.

Finally, erectile dysfunction is a potential marker for arteriosclerosis. Therefore, older patients and those at intermediate and high risk for cardiovascular disease should undergo a cardiovascular risk assessment before starting on drug treatment for erectile dysfunction. By doing so, patients will be categorized into low-, intermediate-, or high-risk groups for cardiovascular morbidity related to sexual intercourse. Patients in the intermediate-risk group should undergo additional testing to reclassify them into the low- or high-risk group. The high-risk group should defer sexual activity and drug treatment for erectile dysfunction. Patients in the low-risk group may start specific treatment for erectile dysfunction.[9,24,25,26] The risk assessment is described in **Table 83-3** and detailed in the Third Princeton Consensus Panel recommendations.[26]

TABLE 83-3 Recommendations of the Third Princeton Consensus Conference for Cardiovascular Risk Stratifi cation of Patients Being Considered for Phosphodiesterase Inhibitor Therapy

Risk Category	Description of Patient's Condition	Management Approach
Low risk	Has asymptomatic cardiovascular disease with <3 risk factors for cardiovascular disease Has well-controlled hypertension Has mild congestive heart failure (NYHA class I or II) Has mild valvular heart disease Had a myocardial infarction >8 weeks ago	Patient can be started on phosphodiesterase inhibitor
Intermediate risk	Has ≥3 risk factors for cardiovascular disease	Patient should undergo complete cardiovascular workup and treadmill stress test to determine tolerance to

Risk Category	Description of Patient's Condition	Management Approach
	Has mild or moderate, stable angina	
	Had a recent myocardial infarction or stroke within the past 2-8 weeks	increased myocardial energy consumption associated with increased sexual activity. Reclassify in low or high risk category
	Has moderate congestive heart failure (NYHA class III)	
	History of stroke, transient ischemic attack, or peripheral artery disease	
	Has unstable or refractory angina, despite treatment	
	Has uncontrolled hypertension	
	Has severe congestive heart failure (NYHA class IV)	
High risk	Had a recent myocardial infarction or stroke within past 2 weeks	Phosphodiesterase inhibitor is contraindicated; sexual intercourse should be deferred
	Has moderate or severe valvular heart disease	
	Has high-risk cardiac arrhythmias	
	Has obstructive hypertrophic cardiomyopathy	

NYHA, New York Heart Association.

TREATMENT

Erectile Dysfunction

Desired Outcomes

The goal of treatment is improvement in the quantity and quality of penile erections suitable for intercourse and considered satisfactory by the patient and his partner. Simple as this may sound,

healthcare providers must ensure that patients and their partners have reasonable expectations for any therapies that are initiated. Furthermore, only patients with erectile dysfunction should be treated. Patients who have normal sexual function should not seek—or be encouraged to seek—treatment in an effort to enhance sexual function or enable increased activity. In addition, treatment should be well tolerated and be of reasonable cost.

General Approach to Treatment

3 The Third Princeton Consensus Conference recommendations are a widely accepted multidisciplinary approach to managing erectile dysfunction that maps out a stepwise treatment plan.[26] This approach is based on the knowledge that erectile dysfunction and cardiovascular disease and its risk factors co-exist in many patients, and that sexual intercourse can precipitate serious cardiovascular consequences in high-risk patients. The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse underlying causes. Risk factors for erectile dysfunction, including hypertension, coronary artery disease, dyslipidemia, diabetes mellitus, smoking, or chronic ethanol abuse, should be addressed and minimized. Patients should follow a heart-healthy lifestyle, which includes physical fitness, weight loss to achieve a normal body mass index, low cholesterol diet, no excessive ethanol intake, and no smoking.[27] In some cases, these types of interventions are sufficient to restore erectile function.[28,29] However, if erectile dysfunction does not respond to these measures, specific treatment is indicated.

For patients with psychogenic erectile dysfunction, psychotherapy can be used as monotherapy or as an adjunct to specific treatments for the disorder. To enhance the relevance of psychotherapy, both the patient and the partner should be included in the counseling sessions. Treatment should be individualized and should address immediate factors that may be causing performance anxiety or depression. The effectiveness of psychotherapy is generally low, and long-term psychotherapy is often necessary.

4 5 6 Specific treatments of erectile dysfunction include vacuum erection devices (VEDs), pharmacologic treatments, and surgery. The ideal treatment of this disorder should have a fast onset, be effective, be convenient to administer, be cost-effective, have a low incidence of serious adverse effects, and be free of serious drug interactions (**Table 83-4**). Generally, when choosing from among treatment approaches, those that are least invasive are selected first; more invasive therapies are reserved for patients who do not respond to first-line agents.

TABLE 83-4 Dosing Regimens for Selected Drug Treatments for Erectile Dysfunction

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Phosphodiesterase Inhibitor					
Sildenafil	Viagra	50 mg orally 1 hour before intercourse	25-100 mg 1 hour before intercourse. Limit to one dose per day	In patients age 65 years and older, start with 25 mg dose. In patients with creatinine clearance less	Titrate dose so that erection lasts no more than 1 hour. Food decreases absorption by 1 hour.

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
				than 30 mL/min (0.5 mL/s) or severe hepatic impairment, limit starting dose to 25 mg. In patients taking potent P450 CYP3A4 inhibitors, limit starting dose to 25 mg every 48 hours.	Contraindicated with nitrates by any route of administration.
Vardenafil	Levitra	5-10 mg orally 1 hour before intercourse	5-20 mg 1 hour before intercourse. Limit to one dose per day	In patients age 65 years and older, start with 5 mg Levitra. No dosage adjustment is required in patients with decreased creatinine clearance. In patients with moderate hepatic impairment, start with 5 mg Levitra. In patients taking potent P450 CYP3A4 inhibitors, limit starting dose to 2.5-5 mg every 24-72 hours. Not recommended in patients with congenital prolonged QT	Titrate dose so that erection lasts no more than 1 hour. Food decreases absorption by 1 hour. Contraindicated with nitrates by any route of administration.

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
				interval or in patients taking Type 1A or Type 3 antiarrhythmics.	
	Staxyn	10 mg tablet to dissolve on the tongue 1 hour before intercourse	10 mg tablet to dissolve on the tongue 1 hour before intercourse. Limit to one dose per day.	Dose of Staxyn requires no adjustment in patients 65 years or older or in patients with creatinine clearance less than 30 mL/min (0.5 mL/s). Do not use in patients with moderate or severe hepatic impairment or those taking moderately or highly potent P450 CYP3A4 inhibitors. Do not initiate Staxyn in patients taking α-adrenergic antagonists.	Staxyn should be taken without any liquid or food. The tablet should be placed on the tongue where it will dissolve. No up-titration of dose is recommended. Do not substitute Staxyn for Levitra, or vice versa.
Tadalafil	Cialis	5-10 mg orally at least 30 minutes before intercourse OR 2.5-5 mg orally once daily	10-20 mg at least 30 minutes before intercourse. Limit to one dose per day; the drug improves erectile function for up to 36	Dose of tadalafil requires no dosage adjustment in patients 65 years or older. In patients with creatinine clearance of 30-50 mL/min (0.5-0.83 mL/s),	Titrate dose so that erection lasts not more than 1 hour. Food does not affect rate or extent of drug absorption. Contraindicated with nitrates by any route of administration.

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
				limit starting dose to 10 mg every 48 hours; if less than 30 mL/min (0.5 mL/s), limit starting dose to 5 mg every 72 hours. In patients with mild-moderate hepatic impairment, limit starting dose to 10 mg every 24 hours. Do not use in patients with severe hepatic impairment. In patients taking potent P450 CYP3A4 inhibitors, limit starting dose to 10 mg every 72 hours (if using it on demand) or 2.5 mg daily (if using a continuous daily regimen).	When taken with large amounts of ethanol, tadalafil may cause orthostatic hypotension.
Avanafil	Stendra	100 mg orally 15-30 minutes before intercourse	50-200 mg orally 15-30 minutes before intercourse	In patients with creatinine clearance of 30-89 mL/min (0.5-1.49 mL/s), no dosage adjustment is needed. Do not use if creatinine clearance is less	May be taken with food. When taken with large amounts of ethanol, avanafil may cause orthostatic hypotension.

hours

2.5-5 mg once daily. Limit to one dose per day

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
				than 30 mL/min (0.5 mL/s), if the patient has severe hepatic disease, or if the patient is taking P450 CYP3A4 inhibitors.	
Prostaglandin E1					
Alprostadil intracavernosal injection	Caverject, Edex	2.5 mcg intracavernosally 5-10 minutes before intercourse	10-20 mcg 5-10 minutes before intercourse. Maximum recommended dose is 60 mcg. Limit to not more than one injection per day and not more than three injections per week with a 24 hour interval between doses.	None	Titrate dose to achieve an erection that lasts 1 hour Patient will require training on aseptic intracavernosal injection technique. Avoid intracavernosal injections in patients with sickle cell anemia, multiple myeloma, leukemia, severe coagulopathy, schizophrenia, poor manual dexterity, severe venous incompetence, severe cardiovascular disease, or Peyronie's disease.

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Alprostadil intraurethral pellet	Muse	125-250 mcg intraurethrally 5-10 minutes before intercourse	250-1,000 mcg just before intercourse. Limit to not more than two doses per day	None	Patient will require training on proper intraurethral administration techniques. Use applicator provided to administer medications to avoid urethral injury.
Testosterone Supplements					
Methyltestosterone	Android, Testred, Methitest	10 mg once daily	10-50 mg once daily	Will likely cause fluid retention in patients with renal or hepatic disease	Not recommended for use due to extensive first-pass hepatic catabolism and because it is associated with hepatotoxicity.
Fluoxymesterone	Androxy	5 mg once daily	5-20 mg once daily	Contraindicated in patients with severe renal or hepatic impairment	Not recommended because it is associated with hepatotoxicity. This is a 17α-alkylated androgen.
Testosterone buccal system	Striant	30 mg every 12 hours, morning and evening	30 mg every 12 hours, morning and evening		Time the dose so that buccal system is removed before every morning and evening toothbrushing. Place buccal system just above incisor

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
					tooth on both sides of the mouth, and hold in place for 30 seconds to adhere. To remove, slide buccal system down toward the tooth. Buccal tablet may become detached during eating. If this occurs, discard and replace with new buccal system. Do not chew or swallow buccal system.
Testosterone cypionate intramuscular injection	Depo-Testosterone	200-400 mg every 2-4 weeks	200-400 mg every 2-4 weeks (up to 6 weeks)	Contraindicated in patients with severe hepatic or renal impairment	During the dosing interval, supraphysiologic serum concentrations of testosterone are produced during a portion of the dosing interval. This has been linked to mood swings.
Testosterone enanthate intramuscular injection	Delatestryl	200-400 mg every 2-4 weeks	200-400 mg every 2-4 weeks (up to 6 weeks)	Although not so labeled, it should probably not be used in patients with severe hepatic or renal impairment	During the dosing interval, supraphysiologic serum concentrations of testosterone are produced during a portion of the dosing interval. This has

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
					been linked to mood swings.
Testosterone undecanoate intramuscular injection	Aveed	750 mg as a single dose	750 mg as a single dose on day 0, week 4, and then 750 mg every 10 weeks		Only available in facilities certified through a Risk Evaluation and Mitigation Strategy Program.
Testosterone transdermal patch	Androderm	4 mg as a single dose at bedtime	2-6 mg as a single dose at bedtime	Safety in patients with hepatic or renal dysfunction has not been evaluated	When administered at bedtime, serum concentrations of testosterone in the usual circadian pattern are produced. Apply to those sites recommended in the package labeling: upper arm, back, abdomen, and thigh. Rotate application sites every 7 days. May have to apply multiple patches at one time to achieve appropriate serum testosterone level. Avoid swimming, showering, or washing administration site for 3 hours after patch application.

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Testosterone gel	Androgel 1%, Testim 1%	5-10 g of gel (equivalent to 50-100 mg testosterone, respectively) as a single dose in the morning	5-10 g of gel (equivalent to 50-100 mg testosterone, respectively) as a single dose in the morning. Titrate dose up at 14-day intervals	None	Cover application site to avoid inadvertent transfer to others. Avoid swimming, showering, or washing administration site for 2 hours after gel application. Apply to those sites recommended in the product labeling: shoulders, upper arms, or abdomen. Children and women should avoid contact with unclothed or unwashed application sites. Patients should wash hands with soap and water after administration of transdermal testosterone product. For patients who have difficulty measuring the appropriate dose using tubes of gel, it is also available in

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
					premeasured dose packets or from a pump dispenser.
	Androgel 1.6%	2 pumps (equivalent to 40.5 mg testosterone) as a single dose in the morning	2-4 pumps (equivalent to 40.5-81 mg) as a single dose in the morning		Apply to shoulders and upper arms. Avoid swimming, showering, or washing administration site for 2 hours after application. Titrate dose 14-28 days after starting treatment.
Testosterone transdermal spray	Fortesta	Four sprays (equivalent to 40 mg testosterone) once daily	Four to seven sprays (equivalent to 40-70 mg testosterone) once daily. Titrate dose up at 14- to 35-day intervals.		Cover application site to avoid inadvertent transfer to others. Avoid swimming, showering, or washing administration site for 2 hours after spray application. Apply to those sites recommended in the product labeling: front and inner thighs. Children and women should avoid contact with unclothed or unwashed

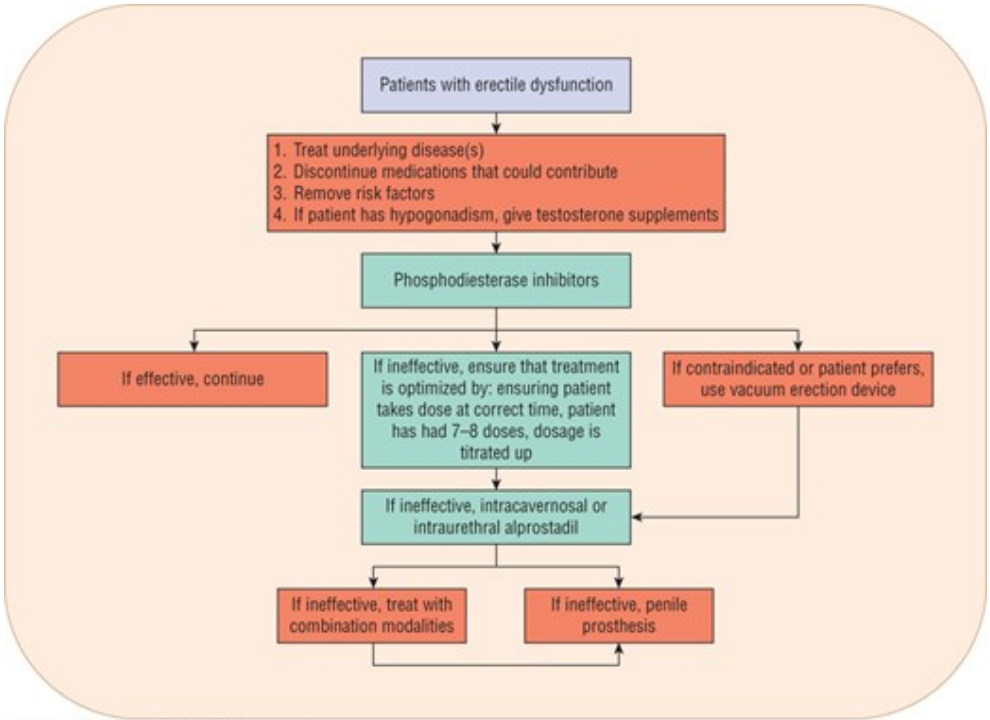
Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
					application sites. Patients should wash hands with soap and water after administration of transdermal testosterone product.
Testosterone transdermal solution	Axiron	Two pump sprays (equivalent to 60 mg testosterone) to left or right axilla daily	One to four pump sprays (equivalent to 30-120 mg testosterone, respectively) to left or right axilla daily. Titrate dose up at 14- to 35-day intervals		Limit application to axilla. Apply antiperspirant or deodorant before Axiron. Avoid swimming, showering, or washing administration site for 2 hours after application.
Testosterone subcutaneous implant pellet	Testopel	150-450 (equivalent to 2-6 pellets) mg as a single dose every 3-6 months. Administration of the dose requires a forearm incision and subcutaneous dose implant under local anesthesia	150-450 mg as a single dose every 3-6 months		Trained health professional is required to administer the dose. Should use sterile implanter kit. Clinical onset is delayed for 3-4 months after initial dose. Generic formulations are available in higher strengths: 100 mg or 200 mg per pellet.

The American Urological Association Guideline on the Management of Erectile Dysfunction,[21] the 2009 International Consultation of Sexual Medicine,[30] the 2010 European Urology Association guideline,[31] and the American College of Physicians[2] clearly identify oral phosphodiesterase type 5 inhibitors for first-line

treatment. VEDs, intracavernosal injection of erectogenic agents, or intraurethral prostaglandin inserts are second-line treatments. Prescribing of a particular agent for a patient should be individualized. Surgical intervention should be reserved for patients who fail to respond to first- and second-line treatments. A sample algorithm that guides selection of treatment is shown in **Fig. 83-2**.

FIGURE 83-2

Algorithm for selecting treatment for erectile dysfunction.



Vacuum Erection Device

A VED is a noninvasive medical device with few contraindications to use. A patient makes a one-time purchase and the device can be used repeatedly.

A VED has two parts: a pump, which generates a negative vacuum pressure; and a cylinder, which is closed at one end and into which the penis is inserted. The patient inserts his penis into the open end of the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. Then the patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient can use constriction bands or tension rings, which are placed at the base of the penis, to keep the arteriolar blood in and reduce venous outflow from the penis. With the assistance of loading cones to protect the glans, these bands or rings can be rolled over the glans penis and up the erect penile shaft. Alternatively, they can be first threaded onto the plastic cylinder before the penis is inserted. Once the penis is erect, the band or ring can be rolled off the cylinder onto the base of the penis (**Fig. 83-3**). However, some patients prefer to apply the band or ring before the penis is erect.[32,33]

FIGURE 83-3

Technique for using a vacuum erection device. *(From Osbon Erec Aid Esteem Vacuum Therapy System User Guide. Eden Prairie, MN: TIMM Medical Technologies.)*

Assemble your system according to the two-step procedure.

Step 1

Apply Osbon Personal Lubricant™ to the following:

1. two inches inside the open end of the cylinder;
2. the rim of the cylinder that meets the body to form the vacuum seal; and
3. the entire head of the penis.

Applying lubricant properly will help you achieve the best erection possible.

Tip: Trimming the pubic hair around the base of the penis with a pair of scissors may also prove helpful in creating an airtight seal.

Step 2

It is recommended that you stand for this step (the system can also be used when you are sitting or lying down).

Place the lubricated penis inside the cylinder with the label on the cylinder facing up. With one hand, hold the cylinder at a downward 45° angle with the open end snugly against the body.

Tip: Rotate cylinder slightly back and forth to make an airtight seal against the body, make sure the testicles are not drawn into the cylinder.

7 The onset of action of the VED is 3 to 20 minutes; a faster onset of 2 to 3 minutes is associated with continued, more experienced use.[32] VEDs are not discreet. That is, a patient's use of a VED is evident to the partner. For this reason, VEDs appear to work best in older patients who are married or who have stable sexual relationships. In this group, VEDs could be considered first-line therapy, and the overall satisfaction rate can be as high as 60% to 80% (range, 27%-94%).[32,33] VEDs may be used as second-line therapy in patients who do not respond to oral phosphodiesterase type 5 inhibitors, which includes patients who have had radical prostatectomy[34] or those who do not respond to injectable drug treatments for erectile dysfunction. The combination of a VED with intracavernosal or intraurethral alprostadil[32] or a phosphodiesterase type 5 inhibitor[34] is associated with a higher efficacy rate than use of the VED alone. As a result, combination therapy sometimes is attempted before penile prosthesis surgery

is considered in the patient who fails to respond to a VED alone.

Patients may discontinue using VEDs because they are inconvenient and not discreet. It has been reported that the dropout rate is as high as 56% during the first year of use.[32,33] Also, 6% to 11% of partners complain that the penis is cool to the touch or is discolored (bluish) in appearance, particularly when constriction bands are used.

Vacuum erection devices are available with battery-operated pumps, which offer convenience, particularly in patients with arthritis of the hands. The American Urological Association recommends the use of commercially available VEDs by prescription only. These have safety mechanisms that minimize the likelihood of excessively high vacuum pressures which can cause penile discomfort and injury.[21]

Penile pain, bruising, or injury from VEDs most often is caused by the constriction bands used to sustain an erection. Because these rings trap blood in the corpora and reduce arteriolar flow into the penis, the penile shaft may feel cold and numb. If the constriction bands are applied for longer than 30 minutes, the penile shaft may turn blue and hurt. Patients may complain that a hinge-like erection is produced in that the penis pivots on the rubber ring or tension band. Patients sometimes fail to ejaculate.

Vacuum erection devices are contraindicated in patients with sickle cell disease or patients with a history of prolonged erections. These patients are prone to priapism, which can be exacerbated by the use of constriction bands with VEDs. The devices also should be used cautiously by patients taking oral anticoagulants because warfarin, through a poorly understood and idiosyncratic mechanism, can cause priapism. Finally, VEDs are contraindicated in patients with severe penile curvature.

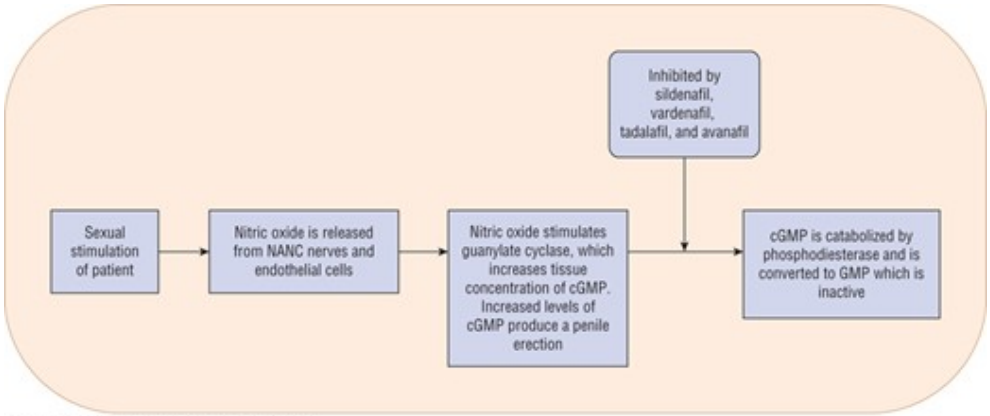
Phosphodiesterase Type 5 Inhibitors

Mechanism

In the presence of sexual stimulation, nitric oxide is released by neurons and endothelial cells in cavernosal tissue, thereby enhancing the activity of guanylate cyclase, the enzyme responsible for conversion of guanylate triphosphate to cGMP (**Fig. 83-4**).[35] cGMP is a vasodilatory secondary messenger that upregulates the response to nitric oxide by activating protein kinase G. This decreases intracellular calcium levels, resulting in smooth muscle relaxation, enhanced arterial flow to the corpora cavernosa, and enhanced blood filling of cavernosal sinuses.[35] Catabolism of cGMP in cavernosal tissue is mediated by phosphodiesterase isoenzyme type 5.

FIGURE 83-4

Mechanism of action of phosphodiesterase type 5 inhibitors. All inhibit catabolism of cGMP, a vasodilatory secondary messenger. (cGMP, cyclic guanosine monophosphate; NANC, nonadrenergic noncholinergic.)



Four competitive, reversible inhibitors of the phosphodiesterase isoenzyme type 5 found in genital tissue are marketed for erectile dysfunction in the United States (**Table 83-5**). Chemically, they are nonhydrolyzable analogs of cGMP and they act by decreasing catabolism of cGMP. However, phosphodiesterase isoenzyme type 5 is also found in peripheral vascular tissue, tracheal smooth muscle, and platelets. Inhibition of phosphodiesterase in these nongenital tissues can produce unwanted effects.[35]

TABLE 83-5 Pharmacodynamics and Pharmacokinetics of Phosphodiesterase Inhibitors

	Sildenafil (Viagra)	Vardenafil (Levitra/Staxyn)	Tadalafil (Cialis)	Avanafil (Stendra)
Inhibits PDE-5	Yes	Yes	Yes	Yes
Inhibits PDE-6	Yes	Minimally	No	Minimally
Inhibits PDE-11	No	No	Yes	Minimally

The four marketed phosphodiesterase type 5 inhibitors differ in their degree of selectivity in inhibiting phosphodiesterase isoenzyme type 5 and other phosphodiesterase isoenzymes, pharmacokinetic profiles, drug–food interactions, and adverse effects (see Table 83-4).

Efficacy

Because of their apparent effectiveness, convenient route of administration, and comparatively low incidence of serious adverse effects, phosphodiesterase type 5 inhibitors are considered first-line therapy for erectile dysfunction, particularly in younger patients. They allow for discreet use. Although not based on direct comparison trials, all four commercially available phosphodiesterase type 5 inhibitors are considered to be equally effective.[35,36] Patient preference studies show that some patients may prefer one agent over another based on the preferences of the patient or partner; or the onset, duration, or cost of treatment.[37] Usual starting and maintenance dose regimens are included in Table 83-4.

In the presence of sexual stimulation and in doses of 25 to 100 mg, sildenafil produces satisfactory erections in 56% to 82% of patients, independent of the etiology of erectile dysfunction. Similar results are documented in the product labeling for the other agents in this class (65%-80% for vardenafil, 62%-77% for tadalafil, and 50%-55% for avanafil). Response rates in the lower range for phosphodiesterase type 5 inhibitors have been documented in patients with diabetes mellitus or after radical prostatectomy, or those with severe vascular disease, probably due to neuropathy, or surgery-related nerve damage.[21,38] The effectiveness of the drugs appears to be dose related.

8 Approximately 30% to 40% of patients do not respond to phosphodiesterase type 5 inhibitors.[21] At least half of nonresponders can benefit from education on proper use of the drugs.[39] Therefore, follow-up is always recommended after a phosphodiesterase type 5 inhibitor is initiated. Education of patients should include the following points: (a) patients must engage in sexual stimulation (foreplay) for the best response; (b) sildenafil and vardenafil should be taken on an empty stomach, at least 2 hours before meals, for the fastest response, but tadalafil and avanafil can be taken without regard to meals; (c) patients who do not respond to the first dose should continue with the phosphodiesterase type 5 inhibitor for at least five to eight doses before failure is declared, as increasing success rates are reported with sequential dose administration; (d) some patients require dosage titration up to 100 mg sildenafil, 20 mg vardenafil, 20 mg tadalafil, or 200 mg avanafil for a response; (e) patients should avoid excessive alcohol intake, which can cause drowsiness and hypotension and worsen erectile dysfunction; (f) involvement of the sexual partner can help improve the patient's response to treatment; (g) treatment of concomitant medical illnesses which contribute to erectile dysfunction (eg, diabetes mellitus, hypertension, and hypogonadism) should be optimized (if the patient has depression because of divorce or loss of a sexual partner, or has performance anxiety, psychologic counseling may be helpful); (h) if applicable, the patient should stop smoking and reduce weight if obese.[28,29]

The phosphodiesterase type 5 inhibitors should not be used by patients with normal erectile function.

Also, according to FDA-approved labeling, the drugs should not be used in combination with other forms of therapy for erectile dysfunction because prolonged erections (which may lead to priapism) may result.[21,40] Also, phosphodiesterase type 5 inhibitors should be avoided in patients predisposed to developing priapism, including men with sickle cell anemia, leukemia, or multiple myeloma.

Long-term use of phosphodiesterase type 5 inhibitors for up to 10 consecutive years continues to be effective and is not associated with tachyphylaxis.[4,40,41,42] The voluntary discontinuation rate among patients who respond to phosphodiesterase type 5 inhibitors is less than 2% per year in controlled clinical trials;[40,41] however, the actual voluntary discontinuation rate is probably closer to 35% to 47% after 6 to 24 months of treatment, despite a positive treatment response.[36] This phenomenon is likely due to the high out-of-pocket costs of phosphodiesterase type 5 inhibitors, the inconvenient process of obtaining the medication, adverse drug effects, the patient's loss of interest in sexual intercourse, or the efficacy of the medication being below the patient's expectations.[43]

Clinical Controversy...

Whether tachyphylaxis—a rapid decrease in drug response—develops with long-term use of phosphodiesterase type 5 inhibitors is unclear. Some patients continue to respond to the medication even after many years of regular use, although they may require increasing doses over time. Other patients eventually become nonresponsive to treatment. This change in response could be due to upregulation of phosphodiesterase type 5 enzymes.[42]

Despite the initial effectiveness of phosphodiesterase type 5 inhibitors and the measures to salvage patients with re-education, some patients with severe vascular or neurologic disease will show minimal or no response to maximum doses of a phosphodiesterase type 5 inhibitor. Various strategies have been attempted in this subgroup of patients, including the following:

1. The effectiveness of switching from one phosphodiesterase type 5 inhibitor to another when the patient does not respond to an initial agent is controversial. In one study, vardenafil was beneficial in 12% of patients who did not respond to sildenafil.[44] Controlled clinical trials in larger patient groups are needed before this strategy is used as routine treatment.

2. Switching the patient from an as-needed to an everyday regimen of tadalafil may be reasonable in a patient who has difficulty coordinating the timing of tadalafil before meals or sexual intercourse.

3. High-dose phosphodiesterase type 5 inhibitor treatment (eg, sildenafil 200 mg) has been used anecdotally. However, such doses are also associated with a higher frequency of adverse effects.[45]

4. In older patients (age greater than or equal to 65 years) with late-onset hypogonadism and erectile dysfunction, correcting the former with testosterone supplementation improves the response to a phosphodiesterase type 5 inhibitor.[46]

5. Phosphodiesterase type 5 inhibitors have been combined with intracavernosal or intraurethral alprostadil in selected patients.[4,47,48]

Clinical Controversy...

For patients who fail to respond to a particular phosphodiesterase type 5 inhibitor, a common strategy employed is to increase the dose of the medication above the FDA-labeled dosage range. The maximum effective and safe dosage is not known.

Selectivity of Other Phosphodiesterase Isoenzymes

More than 25 different phosphodiesterase isoenzymes have been identified; however, the physiologic effects of stimulation and inhibition of some of these isoenzymes remain to be elucidated. Of note, phosphodiesterase isoenzyme type 6 is localized to the rods and cones of the eye. Inhibition of this isoenzyme has been associated with blurred vision and cyanopsia. Sildenafil is the most potent inhibitor of phosphodiesterase isoenzyme type 6, vardenafil and avanafil are intermediate inhibitors, and tadalafil is the least potent inhibitor.[35] Likewise, phosphodiesterase isoenzyme type 11 is localized to striated muscle. Inhibition of this isoenzyme has been associated with myalgia and muscle pain. Tadalafil exerts the greatest inhibitory activity against phosphodiesterase type 11.[35]

Pharmacokinetics and Drug–Food Interactions

Pharmacokinetic parameters of the phosphodiesterase type 5 inhibitors are listed in Table 83-4.[49]

Sildenafil and the conventional oral formulation of vardenafil have similar pharmacokinetic profiles. Both drugs have a 1-hour onset of action and short duration of action. Oral absorption is significantly delayed by 1 hour when either drug is taken within 2 hours of a fatty meal. In contrast, tadalafil has a slower onset of action of 2 hours, has a prolonged duration of action up to 36 hours, and food does not affect its rate of absorption. Thus, tadalafil offers greater spontaneity for patients, as one dose can last through an entire weekend and allows for multiple acts of sexual intercourse over multiple days with a single dose.[36] An oral disintegrating tablet formulation of vardenafil, which dissolves on the tongue, has 1.2- to 1.4-fold higher bioavailability than the conventional oral tablet; however its clinical efficacy appears comparable to the conventional tablet. The oral disintegrating tablet formulation is not susceptible to the drug–food interaction of the conventional oral tablet, which is an advantage for some patients.[50] Avanafil has a slightly faster onset than, but similar duration to, sildenafil and vardenafil. Food does not significantly affect the rate or extent of absorption of avanafil.

The onset of action of these agents has undergone reexamination to assess how soon after drug administration patients can expect to have an erection suitable for intercourse. Although up to 50% of patients may develop an erection within 20 to 30 minutes of sildenafil 100 mg, vardenafil 20 mg, tadalafil 20 mg, or avanafil 200 mg, the rest of the patients may require a full hour to achieve an adequate erectile response.[51] Therefore, patients should be instructed to allow adequate time for the drug to work. In addition, sildenafil and vardenafil have been reported to be effective in some patients up to 12 hours after dosing, which is long after plasma concentrations have declined. It has been hypothesized that this may be due to the continued intracellular action of the phosphodiesterase type 5 inhibitor.[52]

Concomitant ingestion of ethanol with phosphodiesterase type 5 inhibitors can result in orthostatic hypotension and drowsiness. Therefore, the manufacturer recommends that patients avoid ethanol when taking these medications.

All four phosphodiesterase type 5 inhibitors are hepatically catabolized principally by the cytochrome

P450 3A4 microsomal isoenzyme, and other P450 isoenzymes (minor routes) and/or other hepatic enzymes (see Table 83-5). Sildenafil has an active metabolite, which is excreted primarily in the urine. Tadalafil has a clinically insignificant active metabolite; however, 36% of the parent drug is renally eliminated. Thus, both sildenafil and tadalafil doses should be reduced in patients with significant renal impairment. Vardenafil and avanafil have active metabolites that are largely excreted in feces. No specific dosage reduction of these medications is recommended in patients with reduced renal function because of the intermittent nature of the dosing schedule. Avanafil is not recommended when the creatinine clearance is less than 30 mL/min (0.5 mL/s) (see Table 83-4).

Dosing

The usual oral doses of the phosphodiesterase type 5 inhibitors are listed in Table 83-4. Sildenafil, vardenafil, and avanafil should be taken on demand at least 30 to 60 minutes before sexual intercourse. Tadalafil should be taken at least 2 hours before sexual intercourse. The durations of action for sildenafil, vardenafil, and avanafil are 4 to 5 hours, whereas the effects of tadalafil last for 36 hours. The agents vary as to whether doses must be adjusted for patients 65 years and older and those with compromised hepatic or renal function. Patients should be advised to take not more than the amount prescribed and not more than one dose per day. Doses higher than those recommended have been described in the published literature (eg, sildenafil 200 mg[45]); however, such dosing regimens have not consistently produced improved erectile responses.

For patients who do not respond to an adequate course of on-demand phosphodiesterase type 5 inhibitors for erectile dysfunction, daily low dosing of tadalafil may improve endothelial function in cavernosal tissue. That is, regular use of phosphodiesterase type 5 inhibitors may activate endothelial nitric oxide synthase, increase local concentrations of cGMP, which may lead to increased oxygen tension, improved blood flow, and reduced endothelial damage and cavernosal fibrosis.[53] A preliminary clinical trial of daily dosing of tadalafil 5 mg showed a 86% frequency of successful sexual intercourse compared with conventional on-demand use of tadalafil 20 mg, which produced 95% global efficacy.[54,55] Other potential advantages of daily low dosing regimens include a lower potential for dose-related adverse effects and increased spontaneity of sexual intercourse.[52] However, disadvantages of the daily low-dose regimen are the high cost of treatment and patients with more severe erectile dysfunction, who may require higher doses of a phosphodiesterase type 5 inhibitor, may not respond.[52] Although clinical trials of daily dosing of tadalafil 10 and 20 mg,[54,55] and sildenafil 50 and 100 mg[56,57] have been published, the only FDA-approved labeling is for daily dosing of tadalafil 2.5 or 5 mg.

Clinical Controversy…

It is not known if short-term phosphodiesterase type 5 inhibitor use can cure erectile dysfunction. Some have theorized that such a regimen can permanently increase cavernosal tissue levels of cGMP.[58]

Adverse Effects

Most adverse effects of the phosphodiesterase type 5 inhibitors are mild or moderate and are self-limited, and patients often become tolerant to them with continued use.[59,60] The rates of drug discontinuation caused by adverse effects are low, ranging from 2.1% to 25%, and are similar for all four agents. In usual doses, the most common adverse effects are headache (11%), facial flushing (12%),

dyspepsia (5%), nasal congestion (3.4%), and dizziness (3%),[61] all of which are dose-related and result from vasodilation or smooth muscle relaxation secondary to inhibition of phosphodiesterase isoenzyme type 5 in extragenital tissues.

Sildenafil and vardenafil produce an 8- to 10-mm Hg decrease in systolic and a 5- to 6-mm Hg decrease in diastolic blood pressure starting approximately 1 hour after a dose is taken and lasting for 4 hours. Most patients are asymptomatic as a result of these blood pressure changes, but some patients, particularly those taking multiple antihypertensives or nitrates or those with baseline hypotension, may develop clinical symptoms as a consequence of these peripheral vascular effects. Avanafil can produce similar decreases in blood pressure, especially when used along with other antihypertensives or α-adrenergic antagonists. Tadalafil does not produce decreases in blood pressure but must be used with caution in patients with cardiovascular disease because of the cardiac risk inherent to sexual activity. The management approach for such patients, developed based on an analysis of deaths in men who were using sildenafil and commonly referred to as the recommendations of the Princeton Consensus Guideline Conference III,[26] should be applied to all the phosphodiesterase type 5 inhibitors (see Table 83-3).

Sildenafil, vardenafil, and avanafil cause increased sensitivity to light, blurred vision, or loss of blue–green color discrimination in 2% to 3% of patients. The adverse effect is dose-related with the incidence increasing to 40% to 50% in patients taking sildenafil 200 mg.[62] These effects result from inhibition of phosphodiesterase type 6 in the photoreceptor cells of retinal rods and cones. Visual adverse effects commonly occur at the time of peak serum concentrations. Although visual adverse effects are mild and reversible, caution regarding use is recommended for airplane pilots, who rely on seeing green and blue lights for landing planes. Avanafil has moderate and tadalafil has minimal to no inhibitory activity against phosphodiesterase type 6, and a lower incidence of visual adverse effects (less than 1%) has been reported.[63] Nevertheless, according to current product labeling, all phosphodiesterase type 5 inhibitors should be used cautiously in patients at risk for retinitis pigmentosa, a genetic disease associated with retinal phosphodiesterase deficiency.

Nonarteritic anterior ischemic optic neuropathy (NAION) is a sudden, unilateral, painless blindness, which may be irreversible. Isolated cases of NAION have been associated with phosphodiesterase type 5 inhibitor use.[62] NAION has developed at variable and unpredictable times after starting a phosphodiesterase type 5 inhibitor, ranging from 6 hours to months or years after the first dose.[62] Although a cause-and-effect relationship has not been established,[64] the blood pressure-lowering effects of these medications may decrease blood flow to the optic nerve and lead to a sudden unilateral decrease in vision. Because NAION may lead to permanent vision loss, the FDA has required inclusion of warnings on the product labeling of phosphodiesterase type 5 inhibitors. Specifically, before receiving these agents, patients at risk for NAION should be evaluated by an ophthalmologist, risk factors for NAION should be addressed, and the patient should be cautioned against using a phosphodiesterase type 5 inhibitor.

Patients at risk of NAION include a wide variety of patients: those with glaucoma, macular degeneration, diabetic retinopathy, dyslipidemia, or hypertension, those who have undergone eye surgery or have experienced eye trauma, patients who are age 50 years or more, or smokers. A patient who experiences sudden vision loss in one eye while taking a phosphodiesterase type 5 inhibitor should be evaluated for NAION before continuing treatment. If NAION is present, the phosphodiesterase type 5 inhibitor should be discontinued as there is a 15% to 25% risk of developing NAION in the other eye in the ensuing 5 to

10 years.[62]

Tadalafil produces lower back and limb muscle pain, which occurs in a dose-related fashion in 7% to 30% of patients treated with doses of 10 to 100 mg.[35] The mechanism for this is not known. It may be linked to inhibition of type 11 phosphodiesterase, a unique characteristic of tadalafil.

Acute unilateral hearing loss has also been reported after use of a phosphodiesterase type 5 inhibitor. A cause–effect relationship has not been established. In the cases reported, the hearing loss occurred within 1 day of starting treatment; it was variably accompanied by tinnitus or vertigo, and often resulted in residual hearing loss despite discontinuation of the phosphodiesterase type 5 inhibitor.[65,66] The product labeling now includes a warning that a phosphodiesterase type 5 inhibitor should be immediately stopped and the patient should see a physician if sudden hearing loss develops.

Priapism is a rare adverse effect of phosphodiesterase type 5 inhibitors, particularly sildenafil and vardenafil, which have shorter plasma half-lives than tadalafil. Priapism has been associated with excessive doses of the phosphodiesterase type 5 inhibitor or concomitant use with other erectogenic drugs.

Recently, sildenafil use has been associated with an increased risk of melanoma. The proposed mechanism theorized is that phosphodiesterase type 5 inhibition activates *BRAF*, a human gene that produces a protein that causes proliferation of melanoma cells. However, a cause-effect relationship has not been established.[67,68]

Recommendations for adverse effect monitoring are included in **Table 83-6**.

TABLE 83-6 Drug Monitoring Table

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Phosphodiesterase Inhibitor			
Sildenafil	Headache Flushing Gastroesophageal reflux Nasal congestion Cyanopsia NAION Hypotension Priapism Hearing loss	Clinical symptoms Visual complaints, loss of vision Blood pressure Pulse	Discontinue sildenafil if the patient has any visual or hearing loss and refer the patient to a physician If the patient is taking any antihypertensives, stabilize the blood pressure before starting sildenafil If the patient develops priapism, he should proceed to the emergency department

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Vardenafil	Headache Flushing Gastroesophageal reflux Nasal congestion Cyanopsia NAION Hypotension QT interval prolongation on EKG Priapism Hearing loss	Clinical symptoms Visual complaints, loss of vision Blood pressure Pulse Palpitations or dizziness	Discontinue vardenafil if the patient has any visual or hearing loss and refer the patient to a physician If the patient is taking any antihypertensives, stabilize their blood pressure before starting vardenafil If the patient has palpitations or dizziness, check EKG. If QT prolongation is present, refer the patient for appropriate medical care If the patient develops priapism, he should proceed to the emergency department
Tadalafil	Headache Flushing Gastroesophageal reflux Nasal congestion Cyanopsia Hearing loss NAION Hypotension Low back or muscle pain Priapism	Clinical symptoms Visual complaints, loss of vision Blood pressure Pulse Palpitations or dizziness Hearing loss	Discontinue tadalafil if the patient has any visual or hearing loss and refer the patient to a physician If the patient is taking any antihypertensives, stabilize their blood pressure before starting tadalafil If the patient develops priapism, he should proceed to the emergency department
Avanafil	Headache Flushing Gastroesophageal	Clinical symptoms Visual complaints, loss	Discontinue avanafil if the patient has any visual or hearing loss and refer the patient to a physician If the patient is taking any antihypertensives,

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
	reflux		
	Nasal congestion	of vision	
	Cyanopsia	Blood pressure	stabilize their blood pressure before starting avanafil
	Hearing loss	Pulse	
	NAION	Palpitations or dizziness	If the patient develops priapism, he should proceed to the emergency department
	Hypotension	Hearing loss	
	Low back or muscle pain		
	Priapism		
Prostaglandin E_1			
	Penile pain		Penile pain responds to acetaminophen
	Hematoma at injection site	Clinical symptoms	To avoid hematoma, apply pressure to injection site for 510 minutes after injection
	Priapism	Presence of hematoma or fibrotic nodules	If the patient develops priapism, he should proceed to the emergency department
Alprostadil, intracavernosal	Hypotension	Blood pressure	Fibrotic nodules are rare but may occur after repeated injections. These may cause curvature of the penis during an erection and this requires assessment by a urologist
	Fibrotic nodules along penile shaft	Pulse	Hypotension and dizziness are uncommon and are associated with inadvertent venous injection of the drug
	Decreased blood pressure		Burning pain usually resolves spontaneously. If urethral injury is suspected, this requires assessment by a urologist. Pain experienced by the female partner is due to leakage of medication from male urethra into vagina. Pain will usually resolve spontaneously
	Dizziness		If the patient develops priapism, he should proceed to the emergency department
	Aching pain in penis, testicles, legs, and perineum	Clinical symptoms	Hypotension and dizziness are uncommon, occurring in only 3% of patients, and are associated with systemic absorption of the
	Urethral burning, bleeding, or tearing	Urethral injury as evidenced by pain, bleeding, or tissue damage	
Alprostadil, intraurethral	Decreased blood pressure	Blood pressure	
	Dizziness	Pulse	
	Female partner may experience vaginal

Testosterone Supplements			
Methyltestosterone	Sodium and water retention Hyperlipidemia Increased hematocrit Gynecomastia Sleep apnea Increased libido Mood swings Oligospermia Hepatotoxicity Prostate enlargement	Physical exam for edema Blood pressure Serum lipids, hematocrit, hepatic transaminases, prostate specific antigen	Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55%, methyltestosterone should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer
Fluoxymesterone	Sodium and water retention Hyperlipidemia Increased hematocrit Gynecomastia Sleep apnea Increased libido Mood swings Oligospermia Hepatotoxicity	Physical exam for edema Blood pressure Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen	Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55%, fluoxymesterone should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Testosterone buccal system	Prostate enlargement Sodium and water retention Hyperlipidemia Increased hematocrit Gynecomastia Sleep apnea Increased libido Mood swings Oligospermia Hepatotoxicity Gum irritation and pain Bitter taste	Physical exam for edema Blood pressure Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen	Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55%, testosterone buccal system should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer
Testosterone cypionate or enanthate	Prostate enlargement Sodium and water retention Hyperlipidemia Increased hematocrit Gynecomastia Sleep apnea Increased libido Oligospermia Mood swings Hepatotoxicity	Clinical symptoms Physical exam for edema Blood pressure Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen	Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55%, testosterone supplement should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. These formulations produce supraphysiologic serum concentrations of testosterone. Mood swings have been reported with these agents

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Testosterone undecanoate	Prostate enlargement Acne Injection site pain Pulmonary oil microembolism (POME) Anaphylactic reactions Prostate enlargement Sodium and water retention Increased hematocrit Gynecomastia	Clinical symptoms Physical exam for edema Blood pressure Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen	Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55%, testosterone supplement should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. These formulations produce supraphysiologic serum concentrations of testosterone. Mood swings have been reported with these agents. Signs of POME include cough, dyspnea, chest pain, and syncope. This medication should only be administered by a health care provider or setting which is certified through a Risk Evaluation and Mitigaton Strategy program
Testosterone patch	Sodium and water retention Hyperlipidemia Gynecomastia Sleep apnea Increased libido Contact dermatitis Erythema Pruritus Prostate enlargement	Clinical symptoms Physical exam for edema Blood pressure Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen	Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. Contact dermatitis has been associated with the alcohol-based agent used to enhance transdermal drug absorption. It responds to topical corticosteroids. Of significance, hepatotoxicity has not been reported with transdermal patches
Testosterone gel/spray/axillary solution	Sodium and water retention Hyperlipidemia	Clinical symptoms Physical exam for edema	Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer

	Gynecomastia Sleep apnea Increased libido Dermatitis Erythema Pruritis Prostate enlargement Sodium and water retention Hyperlipidemia Increased hematocrit	Blood pressure Serum lipids, hematocrit, hepatic transaminases, prostate specific antigen	
Testosterone subcutaneous implant	Gynecomastia Sleep apnea Increased libido Mood swings Oligospermia Hepatotoxicity Prostate enlargement Pain and infection at the implant site	Clinical symptoms Physical exam for edema Blood pressure Serum lipids	Subcutaneous implant pellet may be extruded with loss of the dose. Androgen-related adverse effects may persist for a long time after drug administration unless the implant is removed. If hematocrit exceeds 55%, testosterone supplement should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer

LUTS, lower urinary tract symptoms.

Drug Interactions

Approximately 8% of patients taking organic nitrates may develop sudden, severe hypotension if these agents are taken with phosphodiesterase type 5 inhibitors as a result of two major factors: (a) organic nitrates on their own produce hypotension, and (b) organic nitrates are nitric oxide donors, which can stimulate the activity of guanylate cyclase and increase tissue levels of cGMP.[49] For this reason, use of

phosphodiesterase type 5 inhibitors is contraindicated in patients taking nitrates given by any route at scheduled times or intermittently.[26,69] Furthermore, nitrates should be withheld for24 hours after sildenafil or vardenafil administration and for 48 hours after tadalafil administration.[26,69] Finally, if a patient who has taken a phosphodiesterase type 5 inhibitor requires medical treatment of angina, non-nitrate-containing agents (eg, calcium channel blocker, β-adrenergic antagonist, and morphine) should be used.

If severe hypotension occurs after exposure to nitrates and a phosphodiesterase type 5 inhibitor, the patient should be placed in a Trendelenburg position and aggressive fluid administration initiated. If severe hypotension continues, parenteral β-adrenergic agonists (eg, dopamine) should be administered cautiously.

Interestingly, dietary sources of nitrates, nitrites, or L-arginine (a precursor for nitrates) do not interact with phosphodiesterase type 5 inhibitors. This is because dietary sources do not increase circulating levels of nitric oxide in humans.

The phosphodiesterase type 5 inhibitors have a low potential to interact with antihypertensive medications.[70] In a retrospective analysis of patients taking sildenafil in combination with α-adrenergic antagonists, β-adrenergic antagonists, diuretics, angiotensin—converting enzyme inhibitors, angiotensin receptor blockers, or calcium channel blockers, the incidence of hypotension was similar to that reported in patients taking sildenafil alone.[71] This finding was confirmed by a retrospective analysis of pooled data on more than 4,800 patients in 35 clinical trials.[70]

Small decreases in blood pressure with clinically symptomatic orthostatic hypotension have been described in some patients taking phosphodiesterase type 5 inhibitors and α-adrenergic antagonists. The degree of hypotension that develops is dependent on several factors: (a) stability of patient's blood pressure prior to taking both drugs; (b) dose of the α-adrenergic antagonist used; (c) particular α-adrenergic antagonist used; (d) particular phosphodiesterase type 5 inhibitor used; and (e) timing of administration of both drugs. The drug interaction produces less hypotension when the patient has stable blood pressure prior to taking both drugs; a low dose of α-adrenergic antagonist is taken; a uroselective (eg, tamsulosin or silodosin) or extended-release formulation of an α-adrenergic antagonist (eg, alfuzosin, or modified-release doxazosin) is used; tadalafil is preferentially prescribed over sildenafil, vardenafil, or avanafil; and when there is an interval of 4 to 6 hours between the dosing of the α-adrenergic antagonist and phosphodiesterase type 5 inhibitor.[70,72,73,74,75]

Hepatic metabolism of all three phosphodiesterase type 5 inhibitors can be inhibited by enzyme inhibitors of CYP 3A4, including fluvoxamine, fluoxetine, nefazodone, verapamil, diltiazem, cimetidine, erythromycin, clarithromycin, ketoconazole, fluconazole itraconazole, ritonavir, saquinavir, and grapefruit juice.[70] Potent CYP 3A4 inhibitors may increase plasma levels of phosphodiesterase type 5 inhibitors by 3-fold or more.[4,75] Lower starting doses of the phosphodiesterase type 5 inhibitor should be used in these patients to minimize dose-related adverse effects, including cyanopsia, hypotension, flushing, nasal congestion, and priapism (see Table 83-4). Similarly CYP 3A4 inducers, including carbamazepine, phenytoin, and phenobarbital, can decrease plasma levels of phosphodiesterase type 5 inhibitors.

If used with type 1A antiarrhythmics (eg, quinidine or procainamide) or type 3 antiarrhythmics (eg, sotalol, amiodarone), vardenafil can prolong the QT interval. This is a unique drug interaction of vardenafil and

not a pharmacologic class effect.

Testosterone Replacement Regimens

Mechanism

Testosterone replacement regimens supply exogenous testosterone and restore serum testosterone levels to the normal range (300-1,100 ng/dL; 10.4-38.2 nmol/L). In so doing, testosterone replacement regimens correct symptoms of hypogonadism, which include malaise, loss of muscle strength, depressed mood, and decreased libido. Testosterone can directly stimulate androgen receptors in the CNS and is thought to be responsible for maintaining normal sexual drive. In addition, testosterone may stimulate nitric oxide synthase, thereby increasing cavernosal concentrations of nitric oxide, and enhancing the effects of phosphodiesterase type 5 in cavernosal tissue.[76]

Indications

Testosterone replacement regimens are indicated in symptomatic patients with primary, secondary, or mixed hypogonadism, as confirmed by both the presence of a decreased libido and low serum concentrations of testosterone.[2] Mixed hypogonadism is characteristic of aging men who undergo andropause, in which the Leydig cells of the testes slowly and progressively decrease testosterone production, and hypothalamic and pituitary production of gonadotropin and luteinizing hormone, respectively, are altered.[77] Serum testosterone levels decrease starting at age 40 years by approximately 10% per decade of life. This is often referred to as late-onset hypogonadism, symptomatic late-onset hypogonadism andropause, or the male menopause. Symptoms include decreased libido, erectile dysfunction, gynecomastia, small testes, reduced growth of body hair and beard, decreased muscle mass, and increased body fat. If left untreated, patients develop anemia and osteoporosis.

Serum testosterone concentrations typically are measured in the early morning (approximately 8 am) because the secretion pattern of this hormone follows a circadian pattern, with highest serum concentrations in the morning hours and the lowest level at night (approximately 10 pm). A low measured serum testosterone level is confirmed with a repeat measurement on a separate day. Confirmation of a low serum testosterone level is essential because of an approximate 10% intra-individual variation of measured levels and variable performance characteristics of various testosterone assays.[77] Simultaneous serum luteinizing hormone levels help to distinguish patients with primary hypogonadism, who have elevated luteinizing hormone levels, from those with secondary hypogonadism, who have decreased luteinizing hormone levels.[2,78]

Testosterone replacement regimens should never be administered to men with normal serum testosterone levels, patients who are asymptomatic with hypogonadism, or in patients with isolated erectile dysfunction as the only sign of hypogonadism.[2,76,78]

Efficacy

Testosterone replacement regimens restore muscle strength and sexual drive and improve mood in patients with hypogonadism. Improvements are generally observed within days or weeks of the start of testosterone replacement. Administration of testosterone will correct the serum testosterone level to the

normal range. No additional benefit has been demonstrated for large doses of testosterone, which increase the serum testosterone level from the low end to the upper end of the normal range or to the above-normal range.[79] Testosterone replacement regimens do not directly correct erectile dysfunction; instead, they improve libido, thereby correcting secondary erectile dysfunction.[79]

Testosterone replacement regimens can be administered parenterally, orally, buccally, or transdermally (see Tables 83-4). Intramuscular injections of testosterone enanthate and cypionate are the preferred treatment for symptomatic patients with primary or secondary hypogonadism because they are effective, inexpensive, and not associated with the bioavailability problems or hepatotoxic adverse effects of oral androgens.[2,77,78] Patients generally require dosing every 2 to 4 weeks. A longer-acting depot intramuscular formulation of testosterone undecanoate, which can be dosed every 10 weeks, offers greater convenience but is more expensive than testosterone enanthate or cypionate. A subcutaneous implant of testosterone pellets lasts 3 to 6 months, but it requires a surgical incision in the forearm and is expensive. Although convenient for the patient, testosterone patches, gels, and sprays are much more expensive than testosterone enanthate or cypionate; therefore, they should be reserved for patients who refuse injectable testosterone. Oral formulations are associated with hepatotoxicity and are not recommended; and the buccal formulation must be dosed twice a day and is expensive.

In the ideal testosterone replacement regimen, the medication would mimic the normal circadian pattern of serum testosterone concentrations such that peak and trough concentrations occur in the early morning and late afternoon, respectively; produce serum concentrations in the normal range; produce serum concentrations of dihydrotestosterone and estradiol, which are (metabolites of testosterone) that mimic the normal physiologic pattern; and produce minimal adverse effects.[79] The ideal replacement regimen should be inexpensive and be convenient for the patient to use. **Table 83-4** compares commercially available testosterone replacement regimens for these characteristics and shows that an ideal regimen has yet to be identified.

Pharmacokinetics

Natural testosterone has poor oral bioavailability because of extensive first-pass hepatic metabolism; therefore, large doses must be taken. To improve oral bioavailability, alkylated derivatives were formulated. Of these derivatives, methyltestosterone and fluoxymesterone are more resistant to hepatic catabolism and can be taken in smaller daily doses, which are theoretically safer. However, oral alkylated derivatives of testosterone are not metabolized to dihydrotestosterone or estradiol, are associated with a higher incidence of serious hepatotoxicity, and therefore are not preferred for management of hypogonadism.

An alternative to oral administration is the testosterone buccal system (Striant), which is applied to the gum above the upper incisor teeth twice per day. Over time it forms a gel from which testosterone is absorbed. One advantage of this route of administration is that the drug bypasses first-pass hepatic catabolism, which allows for increased bioavailability of testosterone. Serum testosterone levels are maintained in the normal range for approximately 80% of the day.[80]

Several testosterone esters have been formulated for intramuscular injection, with different durations of action (see Table 83-4). The shorter-acting testosterone propionate, which requires dosing three times per week, has been replaced with testosterone cypionate or enanthate, which can be dosed every 2, 4, or 6

weeks in most patients. These testosterone formulations produce supraphysiologic serum testosterone levels 2 to 4 days after each dose; these have been linked to mood swings and polycythemia in some patients. After the first and second dose, which are given 4 weeks apart, intramuscular injections of testosterone undecanoate generally last 10 weeks. Although this can be convenient for the patient, testosterone undecanoate has been associated with pulmonary oil microembolism or anaphylactic reactions that can necessitate hospitalization. For this reason, testosterone undecanoate is restricted to settings certified through a Risk Evaluation and Mitigation Strategy Program.[81] An even longer-acting parenteral testosterone is available as a subcutaneous implant for dosing every 3 to 6 months. Although this schedule minimizes repeat visits to the clinician's office for dosing, the implant must be administered by a physician, and the implanted pellet may be extruded after administration. Extrusion has been reported in up to 8.5% of treated patients and results in loss of drug effect.

Transdermal testosterone replacement regimens can be delivered as once-daily patches or gel. For convenience, the gel is available in premeasured dose packets or in a pump dispenser. Testosterone patches increase serum testosterone levels into the normal range in 2 to 6 hours. Serum testosterone levels return to baseline 24 hours after patch or gel administration. However, unlike oral or injectable supplements, transdermal testosterone patches applied at bedtime or testosterone gel applied each morning produce physiologic patterns of serum testosterone levels throughout the day. Although these formulations are often described as producing more "natural" hormone levels, the clinical importance of this biochemical effect is unknown.[76]

The original Testoderm brand patch was formulated for scrotal application. Scrotal skin is thinner and has a richer vascular supply than does the skin on the arms or thighs. Therefore, application of Testoderm patches produced excellent absorption of the hormone. However, the patch could detach when the scrotum became damp or moist, when the patient exercised, or if the scrotum was excessively hairy.[81] Due to its inconvenient site of application, the scrotal patch is no longer commercially available in the United States.

For improved convenience, Androderm patches were formulated for application to the upper arms, back, abdomen, or thighs. The addition of absorption enhancers and adhesives has been linked to a higher incidence of contact dermatitis with Androderm patches compared with the original Testoderm scrotal patch or to gel formulations.[77]

Testosterone gel 1% formulation (AndroGel) is applied in much larger doses (5 or 10 g each day) to the skin of the shoulders, upper arms, or abdomen. The hormone is absorbed quickly, within 30 minutes, but several hours may be required for complete absorption of the dose. For this reason, the patient should be reminded to wait at least 2 hours after application before showering. To prevent inadvertent transfer of testosterone gel to others, the patient should thoroughly wash his hands with soap and water after administration of a dose, allow the application site to dry undisturbed for several minutes before dressing or covering it, and ensure that there is no contact with clothing contaminated with the gel by children and female members of the household.

A high-strength testosterone gel (1.6%) formulation is also available. It allows administration of a daily dose with a smaller amount of gel. It should be applied to the shoulder or upper arms.

Dosing

Table 83-4 lists the usual doses for testosterone replacement regimens. Three months is considered as an adequate treatment trial with a particular dose.[11,77,78] Thus, a dose should not be increased until the patient has used one particular dose for at least this time period. The serum testosterone level should return to the normal range and symptoms of androgen deficiency should be relieved with appropriate dosing. Repeated serum testosterone levels that exceed the normal range require a dosage reduction or increased interval between drug doses. **Table 83-7** provides guidance on the timeline for monitoring serum testosterone levels based on the particular testosterone replacement regimen. After starting treatment, patients should be reassessed in 1 to 3 months. The patient's libido, mood, and quality of life may improve in 3 to 4 weeks, erectile function may improve in 6 months, but other symptoms of hypogonadism (eg, bone density) may take longer to resolve. If the patient is responding to treatment and serum testosterone levels have returned to normal, the patient can be followed up annually. At each visit, the use of a validated self-assessment tool (eg, Androgen Deficiency in Aging Men Questionnaire) can assist the physician in gauging the patient's response to treatment.[82]

TABLE 83-7 Timing of Serum Testosterone Level Monitoring in Patients on Testosterone Replacement Regimens

When to Monitor Serum Testosterone Levels	
Oral testosterone tablets/capsules	2-3 hours after dose
Intramuscular testosterone cypionate or enanthate	Midpoint of dosing interval
Intramuscular testosterone undecanoate	Right before the 4th dose
Transdermal gel	Anytime after the first 1-2 weeks of continuous use
Transdermal patch	3-12 hours after patch application
Testosterone subcutaneous implant	1-4 months after implantation
Buccal system	Before a dose

Before initiating any testosterone replacement regimen in patients 40 years and older, patients should be screened for breast cancer, benign prostatic hyperplasia, and prostate cancer. All are testosterone-dependent conditions and theoretically could be worsened by exogenous administration of testosterone. However, no confirmed cases of prostate cancer caused by testosterone supplementation in a hypogonadal patient have been documented.[83,84,85] Nevertheless, untreated prostate cancer is a contraindication to androgen supplementation. To screen for prostate disorders, a prostate-specific antigen serum concentration should be obtained and a digital rectal examination of the prostate performed. These tests are generally repeated at 1-year intervals after treatment is started. Other baseline tests that are recommended include hematocrit and liver function tests. These should be repeated 3 and 6 months after the start of a testosterone replacement regimen. If normal, these tests can be repeated annually thereafter. If the hematocrit exceeds 55% (0.55), the testosterone replacement regimen should be withheld to avoid polycythemia and its consequences.

The dropout rate with testosterone supplementation is high. Approximately 30% and 85% of patients stop testosterone replacement after 6 and 12 months, respectively. The reasons for this include the cost of the medication, slow onset of response, and inadequate perceived benefit.[86]

Adverse Effects

Testosterone replacement regimens can cause sodium retention, which can lead to weight gain, or

exacerbate hypertension, congestive heart failure, and edema (Table 83-6). Although serum lipoprotein perturbations may occur, testosterone replacement regimens have a neutral effect in that they decrease both total cholesterol and high-density lipoprotein cholesterol levels. Two recent retrospective studies have associated testosterone supplementation with an increased risk of myocardial infarction and stroke.[87,88] However, these studies did not prove a cause-effect relationship and are considered inconclusive. Nevertheless, the Food and Drug Administration has posted a warning that testosterone supplementation may lead to cardiovascular disease and physicians should discuss this potential risk with patients before initiating treatment. This was prompted by the significant increase in testosterone use in the United States, inadequate monitoring of serum testosterone levels prior to and during testosterone supplementation, and the potential hazards of using testosterone supplementation in elderly patients with cardiovascular risk factors.[89]

Gynecomastia can occur as a result of conversion of testosterone to estrogen in peripheral tissues. This has been reported most often in patients with liver cirrhosis or those who are obese.

Oral alkylated testosterone replacement regimens have caused hepatotoxicity, ranging from mild elevations of hepatic transaminases to serious liver diseases, including peliosis hepatis (hemorrhagic liver cysts), hepatocellular and intrahepatic cholestasis, and benign or malignant tumors. For this reason, parenteral testosterone replacement regimens are preferred.

Transdermal testosterone patches may cause contact dermatitis, which responds well to topical corticosteroids. This adverse effect has been associated with the presence of permeation enhancers, which are added to patch formulations. If the dermatitis becomes problematic, an alternative is testosterone gel formulations, which are associated with a lower incidence of contact dermatitis compared with patches.

Polycythemia occurs most often in patients receiving parenteral testosterone formulations. If this occurs, testosterone injections should be stopped and can be replaced with a transdermal testosterone product.[78]

Alprostadil

Mechanism

Alprostadil, also known as prostaglandin E_1, stimulates adenyl cyclase, resulting in increased production of cAMP, a secondary messenger that decreases the intracellular calcium concentration and causes smooth muscle relaxation of the arterial blood vessels and sinusoidal tissues in the corpora. This results in enhanced blood flow to and blood filling of the corpora. Because it does not require nitric oxide to produce its clinical effects, patients with erectile dysfunction due to diseases that are associated with an impaired nitric oxide pathway (eg, diabetes mellitus, postradical prostatectomy, and who have failed phosphodiesterase type 5 treatment) may respond to alprostadil.[90] In one study, 88% of men who failed to respond to sildenafil responded to intracavernosal alprostadil.[91]

Alprostadil is commercially available as an intracavernosal injection (Caverject and Edex) and as an intraurethral insert (medicated urethral system for erection [MUSE]).

Indications

Both commercially available formulations of alprostadil are FDA approved as monotherapy for management of erectile dysfunction. Alprostadil is more effective by the intracavernosal route than the intraurethral route.

The enhanced efficacy of the intracavernosal injection may be related to the excellent bioavailability of the drug when injected directly into the corpora cavernosum. In contrast, intraurethral alprostadil doses generally are several hundred times larger than intracavernosal doses. This is because intraurethral alprostadil must be absorbed from the urethra, through the corpus spongiosum, and into the corpus cavernosum, where it exerts its full proerectogenic effect.

Although several other agents, including papaverine and phentolamine, have been used off-label for intracavernosal therapy, alprostadil is preferentially prescribed. This is because intracavernosal alprostadil has been FDA approved for erectile dysfunction, it does not require extemporaneous compounding, and it has a low potential for causing prolonged erections and priapism.

Both formulations of alprostadil are considered more invasive than VEDs or phosphodiesterase type 5 inhibitors. For this reason, intracavernosal alprostadil is generally prescribed after patients do not respond to or cannot use less invasive interventions. Intracavernosal alprostadil is preferred over intraurethral alprostadil because of its greater effectiveness. Intracavernosal alprostadil may be preferred in patients with diabetes mellitus, who are accustomed to injectable drug therapy and may have peripheral neuropathies, which decrease the patient's perception of pain upon injection. Intraurethral alprostadil is generally reserved as a treatment of last resort for patients who do not respond to other less invasive and more effective forms of therapy, and who refuse surgery.

Intracavernosal Alprostadil

Efficacy

The overall efficacy of intracavernosal alprostadil is 70% to 90%.[92] Three characteristics of intracavernosal alprostadil include the following:

1. The effectiveness of alprostadil is dose related. The mean duration of erection is directly related to the dose of alprostadil administered and ranges from 12 to 44 minutes.
2. A higher percentage of patients with psychogenic and neurogenic erectile dysfunction respond to alprostadil at a lower dose compared to patients with vasculogenic erectile dysfunction.
3. Tolerance does not appear to develop with continued use of intracavernosal alprostadil at home.

10 Although 70% to 75% of patients respond to intracavernosal alprostadil, a high proportion of patients elect to discontinue its use over time. Depending on the study and the length of observation, 30% to 50% of patients voluntarily discontinue therapy, usually during the first 6 to 12 months, and this increases to 54% and 67% after 2 to 4 years, respectively.[4] Common reasons for discontinuation include lack of perceived effectiveness; inconvenience of administration; an unnatural, nonspontaneous erection; needle phobia; loss of interest; or cost of therapy.[92]

Approximately one third of patients do not respond to usual doses of intracavernosal alprostadil. In these

patients, intracavernosal alprostadil has been used successfully along with VEDs. Such combination therapy can be attempted by patients before transitioning to more invasive surgical procedures.[32,76] Alternatively, intracavernosal injections of synergistic combinations of vasoactive agents that act by different mechanisms have been used. Intracavernosal drug combinations typically produce an erection that lasts longer than an erection produced by any one of the agents in the mixture. In addition, because of the low dosage of each agent in the combination, fewer systemic and local fibrotic adverse effects develop compared with high-dose monotherapy. For example, when used in low-dose combination regimens, papaverine is less likely to induce hypotension and liver dysfunction, and phentolamine is less likely to induce tachycardia and hypotension.[4,92,93] However, as previously mentioned, such intracavernosal drug combinations are not commercially available and must be extemporaneously compounded.

Pharmacokinetics

Intracavernosal injection should be administered into only one corpus cavernosum. From this injection site, the drug will reach the other corpus cavernosum through vascular communications between the two corpora. Alprostadil acts rapidly, with an onset of 5 to 15 minutes. The duration is directly related to the dose. Within the usual dosage range of 2.5 to 20 mcg, the duration of erection is not more than 1 hour. Higher doses are expected to exhibit a longer duration of action. Local 15-hydroxy dehydrogenase in the corpora cavernosum quickly converts alprostadil to inactive metabolites. Any alprostadil that escapes into the systemic circulation is deactivated on first pass through the lungs. Hence, the plasma half-life of alprostadil is approximately 5-10 minutes, and the potential for systemic adverse effects is negligible. Dose modification is not necessary in patients with renal or hepatic disease.

Dosing
