The quality of cardiac chest pain is often described as squeezing, crushing, a heaviness, or tightness in the chest. It can also be more vague and described as a numbness or burning in the chest. Chest pain that is described as sharp in origin, pain that increases with inspiration or expiration, or a reproducible pain with palpation is usually not cardiac pain. The region of the pain is substernal and may radiate to the right or left shoulder, right or left arm (left more commonly than right), neck, back, or abdomen. Cardiac chest pain rarely radiates above the mandible or below the umbilicus. The severity of cardiac chest pain can be difficult to quantify since pain is a subjective measure, but the pain is usually considered severe and ranked a five or higher on a ten-point scale. The temporal pattern or duration of the chest pain in patients with SIHD is less than 20 minutes, but is usually around 5 to 10 minutes. Other symptoms that may also be present during times of ischemia include diaphoresis, nausea, vomiting, and dyspnea.

It is helpful to connect the pathophysiology with the clinical presentation. [1] In SIHD, ischemia is produced by an increase in MVO_2 in the setting of a fixed decrease in supply. [3] Exertion beyond the point in which autoregulation and coronary flow reserve are exhausted, the patient experiences chest pain. The patient then rest, or uses a SL NTG, and the MVO_2 comes down to a point in which myocardial supply and demand are back in balance, about 5 to 10 minutes, and the pain goes away and the patient feels better. [This sentence is covers concepts presented earlier and can be deleted] Relief of chest pain with the use of SL NTG can be a useful diagnostic tool for determining the origin of a patient's chest pain. However, esophageal pain also responds well to SL NTG. Esophageal pain is also relieved by food, antacids, milk, and occasionally warm liquids, while ischemic chest pain is not. The major differences between the pain with SIHD and the pain with an ACS would be the precipitating factors and the duration of the chest pain. The patient with an ACS typically has chest pain at rest that lasts longer than 20 minutes. The pathophysiology in a patient with an ACS is an

abrupt decrease in myocardial oxygen supply from a plaque rupture, while increases in MVO_2 precipitate chest pain in patients with SIHD.

The severity of the angina and the impact of the disease on daily activity are often evaluated using the Canadian Cardiovascular Society (CCS) classification system (**Table 16-3**).[26] This system is a modification of the New York Heart Association functional classification used in patients with heart failure. Instead of determining the level of activity needed to produce dyspnea in patients with heart failure, the CSS system evaluates the level of activity needed to produce angina. There is also a scale developed by Goldman and associates that evaluates the metabolic cost to specific activities, and therefore, more specifically assesses the amount of MVO_2 a patient can achieve before producing angina.[27] Califf and associates developed an angina score that includes the tempo of angina along with ST and T wave changes on the electrocardiograph (ECG).[28] All of the current severity scores are limited by the subjective nature of a patient's pain as well as the reliability and reproducibility of patient observations.

TABLE 16-3 Grading of Angina Pectoris by the Canadian Cardiovascular Society Classification System[26]

Class	Description of Stage
Class I	Ordinary physical activity does not cause angina such as walking and climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation
Class II	Slight limitation or ordinary activity. Angina occurs on walking or climbing stairs rapidly, on walking uphill, on walking or stair climbing after meals, in cold, in wind, under emotional stress, or only during the few hours after wakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal condition
Class III	Marked limitations of ordinary physical activity. Angina occurs on walking one to two blocks on the level and climbing one flight of stairs in normal conditions and at a normal pace
Class IV	Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest

Not all patients have a typical chest pain presentation.[1] "Typical" angina is comprised of three components: (1) substernal chest discomfort with a characteristic quality and duration that is (2) provoked by exertion or emotional stress and (3) relieved by rest or NTG. Patients with "atypical" angina meet two of the three criteria for typical angina. Patients meeting one or none of the typical angina characteristics are described as having noncardiac chest pain. Patient groups more likely to present with atypical angina include women and the elderly. Patients with DM may also have decreased sensation of pain due to complications of neuropathy.[29] Features of atypical angina or angina equivalents include symptoms such as midepigastric discomfort, effort intolerance, dyspnea, and excessive fatigue. To demonstrate the frequency of some of these symptoms, one study suggests that 65% of women with ischemia present with atypical symptoms.[30]

After a description of the chest pain has been obtained, a review of the patient's CAD risk factors should be performed. Non-modifiable risk factors include the patient's age and sex, and a family history of atherosclerotic disease in first-degree relatives (male onset before age 55 or female before age 65). The existence of the modifiable risk factors of HTN, DM, dyslipidemia, and cigarette smoking should also be evaluated. In addition to considering traditional risk factors, markers of inflammation, such as high sensitive C-reactive protein, have been investigated as risk factors for atherosclerosis. The value of C-reactive protein for primary prevention is growing, while the value for secondary prevention is less certain. Due to the systemic nature of atherosclerotic disease, patients with a history of cerebrovascular or peripheral arterial disease are also at high-risk for CAD. It is likely that patients having atherosclerosis in cerebral or peripheral arteries also have atherosclerosis in their coronary arteries even if it has not yet led to episodes of angina.

The physical examination of a patient with SIDH usually produces general and nonspecific findings. At the time of an ischemic episode, patients may present with tachycardia, diaphoresis, shortness of breath, and nausea. Other physical findings are related to the discovery of risk factors that may have led to the development of angina including an increased BP or a fourth heart sound reflecting long-standing HTN. Other positive findings may include pulmonary rales, displaced point of maximal impulse, or a third heart sound in patients with heart failure.

Diagnostic and Prognostic Testing

A number of noninvasive, as well as coronary angiography (invasive) testing can be done to assist in the diagnosis and evaluation of patients with SIHD. The most appropriate test based on available information and the clinical scenario for diagnosis is outlined in **Figs. 16-3** and the use of testing for risk stratification is outlined in **Fig. 16-4**.[1] More information of how each test is preformed is available in Chapter 12.

FIGURE 16-3

Diagnosis of patients with suspected ischemic heart disease. The algorithms do not represent a comprehensive list of recommendations (see ACC/AHA stable ischemic heart disease guidelines for all recommendations).

[a]See Table 16-2 in the ACC/AHA stable ischemic heart disease guidelines.

[b]CCTA is reasonable only for patients with intermediate probability of IHD.

(CCTA, computed coronary tomography angiography; CMR, cardiac magnetic resonance; ECG, electrocardiogram; Echo, echocardiography; IHD, ischemic heart disease; MI, myocardial infarction; MPI, myocardial perfusion imaging; Pharm, pharmacological; NSTE ACS, non-ST-segment elevation acute coronary syndrome; UA, unstable angina).

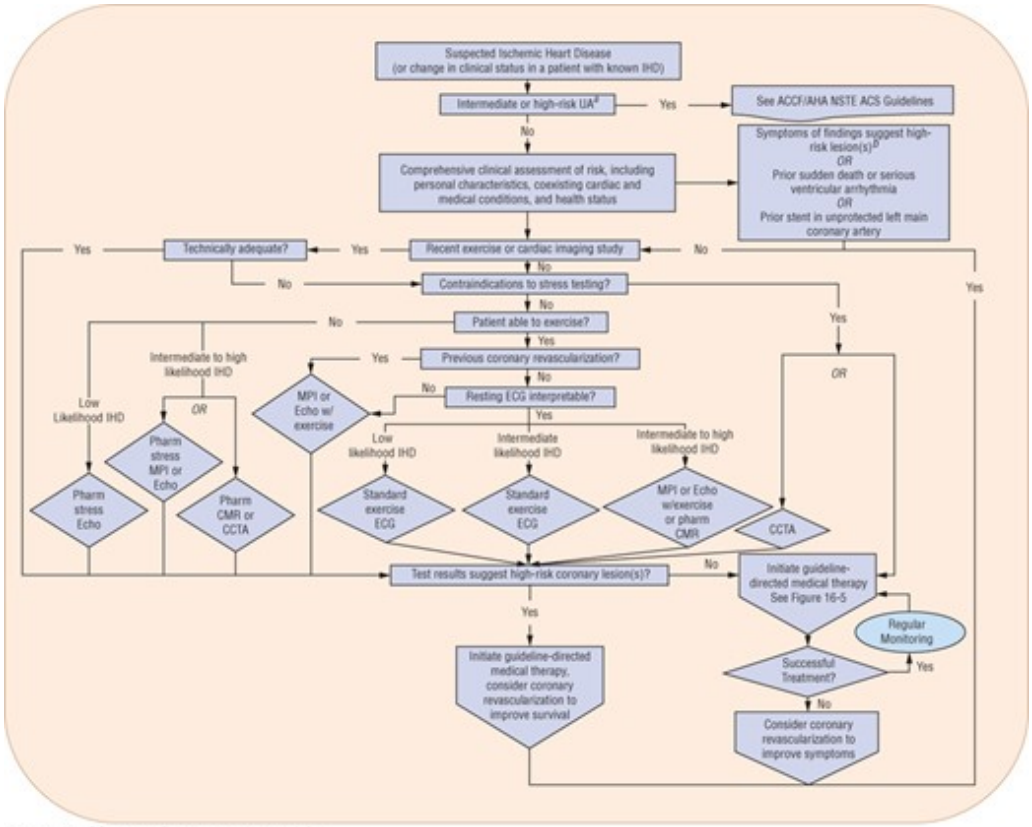

FIGURE 16-4

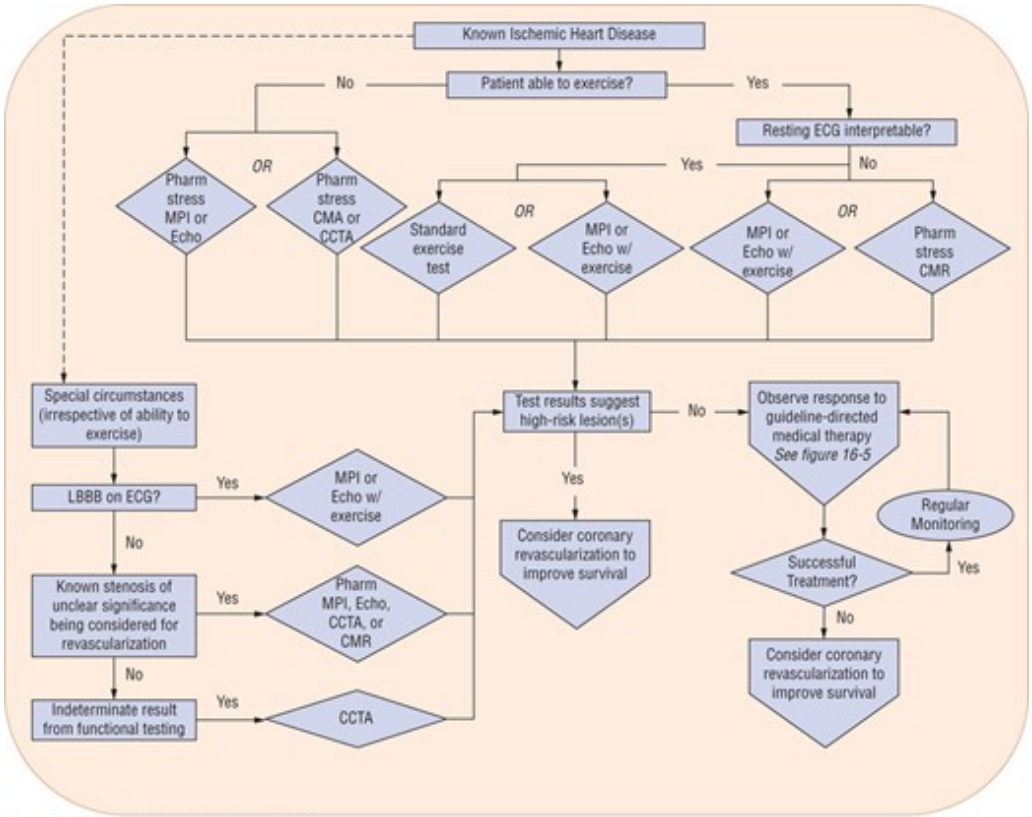
Algorithm for risk assessment of patients with stable ischemic heart disease. The algorithm does not represent a comprehensive list of recommendations. (CCTA, coronary computed tomography angiography; CMR, cardiac magnetic resonance; ECG, electrocardiogram; Echo, echocardiography; LBBB, left bundle branch block; MPI, myocardial perfusion imaging; Pharm, pharmacological.)



Several tests can also provide prognostic information, which may help in determining the aggressiveness of pharmacotherapy and need for revascularization. All patients with symptoms suggestive of angina should receive a 12-lead ECG. In the resting state, the ECG will be normal in more than or equal to 50% of patients with SIHD. In patients with SIHD having a normal ECG at rest, about 50% will develop ischemic ST-T wave changes during an episode of angina. These changes can be observed on the ECG conducted during an exercise stress test. Exercise stress testing is a relatively easy and inexpensive method for detecting CAD. Since about 40% of patients who need a stress test cannot physically endure the test, the myocardium can also be stressed pharmacologically with adenosine, dipyridamole, or dobutamine. Stress testing can provide important diagnostic and prognostic information, especially when conducted with a nuclear imaging study to evaluate myocardial perfusion.

Coronary angiography is the most accurate test for the diagnosis and assessment of patients with CAD and is commonly considered the "gold standard." Unfortunately, coronary angiography is an invasive technique that requires arterial access. Findings in patients with SIHD routinely reveal that approximately 25% of patients have single-vessel disease, 25% have double-vessel disease, and 25% have triple-vessel disease, with 5% to 10% presenting with left main coronary disease and another 15% with no detectable critical vessel obstruction.

Coronary angiography is also useful in determining the fractional flow reserve (FFR) in patients with obstructive coronary stenosis. FFR is an indirect index determined by measuring the driving pressure of microcirculatory flow distal to the stenosis relative to the coronary driving pressure available in the absence of stenosis.[31] Although derived, the measurements are conceptually similar to those of

relative coronary flow reserve because they only rely on minimum mean coronary pressure measurements during intracoronary vasodilation and compare regions supplied by vessels with stenosis with region supplied by vessels without atherosclerotic obstructions under similar hemodynamic conditions. The FFR is attractive for clinical use in that it can immediately assess the physiologic significance of an intermediate stenosis to help guide decisions regarding coronary intervention and are unaffected by alterations in resting flow. Data currently suggest that patients with an FFR of less than 0.80 may do better with revascularization compared to medical therapy, but investigation continues to determine the best use of this measurement.[31,32]

Biomarkers

B-type natriuretic peptide (BNP) and the N-terminal fragment (NT-proBNP) have been a useful biomarker in the diagnosis and prognosis of patients with heart failure and ACS for many years. Data on the prognostic implications of elevated natriuretic peptides in patients with SIHD have also been evaluated. BNP is a cardiac hormone that is mainly synthesized in the LV in response to increased ventricular volume and/or pressure creating ventricular wall stress.[33] The production of BNP begins as a prohormone (pro-BNP) that is enzymatically cleaved into the active hormone BNP and the NT-proBNP of the prohormone. There are a number of potential explanations for elevations in these biomarkers in patients with SIHD including a cumulative effect, increased LV filling pressure during ischemic episodes, or potential increased expression of the BNP gene.[33]

A number of cohort trials of patients with SIHD have assessed BNP or NT-proBNP plasma concentrations and evaluated adverse CV outcomes several years later. One trial followed demonstrated that patients with initial BNP concentrations more than or equal to 87 pg/mL had a significant increase in all-cause mortality as compared to patients with lower BNP concentrations.[34] An additional trial followed patients for 2.5 years and found that patients in the highest quartile of BNP (>100 pg/mL) had over a 4-fold increased risk of CV death and MI compared to patients in the lowest quartile (<12 pg/mL).[35] Based on these data, elevated plasma concentrations of BNP or NT-proBNP may be considered an emerging risk factor for SIHD.

Cardiac troponin concentrations are released when there is myocyte death (infarction), and hence are not typically elevated in patients with SIHD. In one study of patients undergoing percutaneous coronary intervention (PCI) for treatment of SIHD found that 6% of patients had an elevated troponin before PCI.[36] After adjusting for demographic, clinical, angiographic, and procedural factors, patients with an elevated pre-procedure troponin had a significant increase of inhospital death or MI compared to patients without an elevated troponin (13.4% vs 5.6%). The difference in these outcomes was still significant 1 year later.[36] Due to the fact there were multiple study sites, and therefore multiple reference ranges, no specific cut-off troponin value designating increased risk could be determined. The mechanism of the increase in troponin is not completely understood, but may be due to increased cardiac cell membrane permeability with repeated ischemia.

TREATMENT

Desired Outcomes

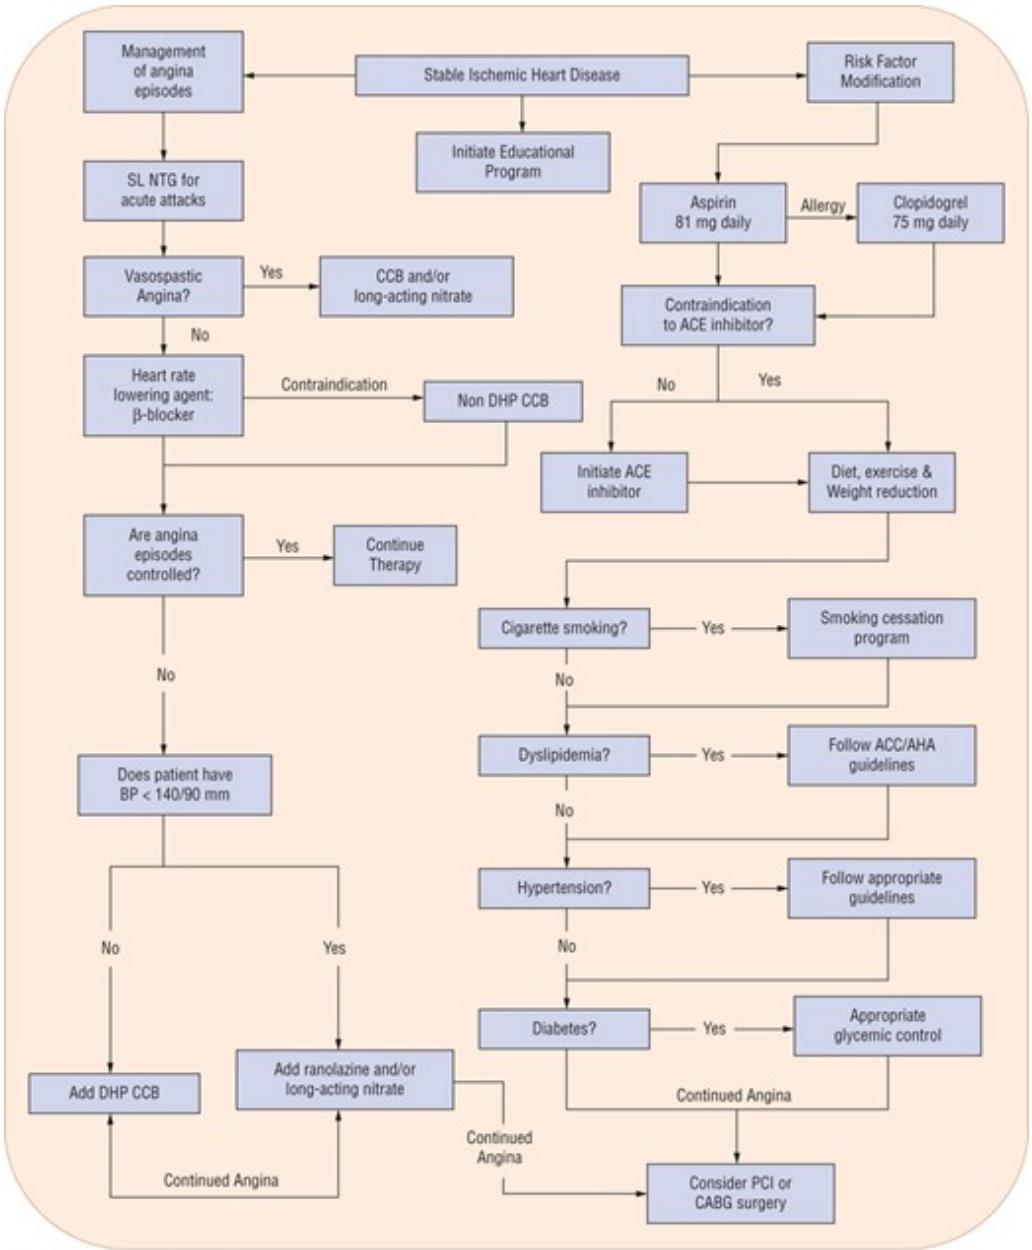
The management of patients with SIHD is typically divided into two parts (**Fig. 16-5**) that aim to improve the quantity and quality of life for the patient.[1] The first is directed toward slowing the progression of atherosclerosis and preventing complications of such as MI, heart failure, stroke, as well as death (either sudden cardiac death, or death secondary to progression of underlying CV conditions). Therapy in this approach generally is targeted at risk factor modification and other vasculoprotective therapies. While these therapies have demonstrated the ability to reduce mortality, and therefore, the quantity of life for the patient with SIHD, they typically have minimal impact on improving symptoms and limitations of angina, or the quality of life. The other approach targets reducing the number of ischemic episodes as well as increasing the amount of exertion or exercise a patient can accomplish before inducing an ischemic episode. Therapies used in this approach rarely have demonstrated an improvement in improving the quantity of life, but do improve the quality of life through a reduction in symptoms. The ACC/AHA SIHD guidelines state that a goal of therapy should be the complete, or nearly complete, elimination of angina chest pain and return to normal activities and a functional capacity of CCS class I angina.[1] Recommendations from the ACC/AHA are organized in to a Class of Recommendation, which is an estimate of the size of the treatment effect, balancing efficacy and safety. Each recommendation is also based on a Level of Evidence (LOE), which describes the level of certainty or precision of the treatment effect and is based on the amount of evidence to support a recommendation. **Table 16-4** describes the different classes of recommendation and the levels of evidence used to classify the ACC/AHA recommmendations.[1]

TABLE 16-4 The American College of Cardiology and American Heart Association Evidence Grading System[1]

Recommendation Class	Level of Evidence
I Conditions for which there is evidence or general agreement that a given procedure or treatment is useful and effective	
II Conditions for which there is conflicting evidence or a divergence of opinion that the usefulness/efficacy of a given procedure or treatment is useful and effective	A. Data derived from multiple randomized clinical trials with large numbers of patients
IIa Weight of evidence/opinion is in favor or usefulness/efficacy	B. Data derived from a limited number of randomized trials with small numbers of patients, careful analyses of nonrandomized studies, or observational registries
IIb Usefulness/efficacy is less well established by evidence/opinion	C. Expert consensus was the primary basis for the recommendation
III Conditions for which there is evidence or general agreement that a given procedure or treatment is not useful/effective and in some cases may be harmful	

FIGURE 16-5

Algorithm for treatment of stable ischemic heart disease (Guideline-directed medical therapy).



Guideline-Directed Medical Therapy

The primary method in which to improve mortality in patients with SIHD is providing guideline-directed medical therapy (GDMT), also referred to as optimal medical therapy.[1] [5] [6] Besides certain settings of disease severity (**Table 16-5**), GDMT provides similar rates of death and MI compared to revascularization therapy. These are therapies that have demonstrated a reduction in mortality, and consequently improving the quantity of life for patients with SIHD. These therapies mainly include risk factor modifications (**Table 16-6**), but additionally medications such as aspirin and angiotensin converting enzyme (ACE) inhibition.

TABLE 16-5 Revascularization to Improve Survival: ACC/AHA Recommendations[1]

Left Main CAD Revascularization

Class I

1. CABG to improve survival is recommended for patients with significant (≥50% diameter stenosis) left main coronary artery stenosis. (LOE B)

Class IIa

1. PCI to improve survival is reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: (1) anatomic conditions associated with a low risk of PCI procedural complications and a high likelihood of good long-term (eg, a low SYNTAX score [≤22], ostial or trunk left main CAD); and (2) clinical characteristics that predict a significantly increased risk of adverse surgical outcomes (eg, STS-predicted risk of operative mortality ≥5%). (LOE B)

2. PCI to improve survival is reasonable in patients with UA/NSTEMI when an unprotected left main coronary artery is the culprit lesion and the patient is not a candidate for CABG. (LOE B)

3. PCI to improve survival is reasonable in patients with acute STEMI when an unprotected left main coronary artery is the culprit lesion, distal coronary flow is less than TIMI (Thrombolysis in Myocardial Infarction) grade 3, and PCI can be performed more rapidly and safely than CABG. (LOE C)

Class IIb

1. PCI to improve survival may be reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: (a) anatomic conditions associated with a low to intermediate risk of PCI procedural complications and an intermediate to high likelihood of good long-term outcome (eg, low-intermediate SYNTAX score of <33, bifurcation left main CAD); and (b) clinical characteristics that predict an increased risk of adverse surgical outcomes (eg, moderate-severe chronic obstructive pulmonary disease, disability from previous stroke, or previous cardiac surgery; STS-predicted risk of operative mortality >2%). (LOE B)

Class III: Harm

1. PCI to improve survival should not be performed in stable patients with significant (≥50% diameter stenosis) unprotected left main CAD who have unfavorable anatomy for PCI and who are good candidates for CABG. (LOE B)

Non-Left Main CAD Revascularization

Class I

1. CABG to improve survival in beneficial in patients with significant (≥70% diameter) stenosis in

3 major coronary arteries with or without involvement of the proximal LAD artery or in the proximal LAD artery plus 1 other major coronary artery. (LOE B)

2. CABG or PCI to improve survival is beneficial in survivors of sudden cardiac death with presumed ischemia-mediated ventricular tachycardia caused by significant (≥70% diameter) stenosis in a major coronary artery. (LOE C)

Class IIa

1. CABG to improve survival is reasonable in patients with significant (≥70% diameter) stenosis in 2 major coronary arteries with severe or extensive myocardial ischemia (eg, high-risk criteria on stress testing, abnormal intracoronary hemodynamic evaluation, or >20% perfusion defect by myocardial perfusion stress imaging) or target vessels supplying a large area of viable myocardium. (LOE B)

2. CABG to improve survival is reasonable in patients with mid-moderate LV systolic dysfunction (EF 35%-50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal LAD coronary artery stenosis, when viable myocardium is present in the region of intended revascularization. (LOE B)

3. CABG with a left internal mammary artery (LIMA) graft to improve survival is reasonable in patients with significant (≥70% diameter) stenosis in the proximal LAD artery and evidence of extensive ischemia. (LOE B)

4. It is reasonable to choose CABG over PCI to improve survival in patients with complex 3-vessel CAD (eg, SYNTAX score >22), with or without involvement of the proximal LAD artery who are good candidates for CABG. (LOE B)

5. CABG is probably recommended in preference to PCI to improve survival in patients with multivessel CAD and diabetes mellitus, particularly if a LIMA graft can be anastomosed to the LAD artery. (LOE B)

Class IIb

1. The usefulness of CABG to improve survival is uncertain in patients with significant (70% diameter) stenoses in two major coronary arteries not involving the proximal LAD artery and without extensive ischemia. (LOE C)

2. The usefulness of PCI to improve survival is uncertain in patients with 2- or 3-vessel CAD (with or without involvement of the proximal LAD artery or 1-vessel proximal LAD disease. (LOE B)

3. CABG might be considered with the primary or sole intent of improving survival in patients with SIHD with severe LV systolic dysfunction (EF <35%) whether or not viable myocardium is present. (LOE B)

4. The usefulness of CABG or PCI to improve survival is uncertain in patient with CABG and

extensive anterior wall ischemia on noninvasive testing. (LOE B)

Class III: Harm

1. CABG or PCI should not be performed with the primary or sole intent to improve survival in patients with SIHD with 1 or more coronary stenoses that are not anatomically or functionally significant (<70% diameter non-left main coronary artery stenosis, FFR >0.80, no or only mild ischemia on noninvasive testing), involve only the left circumflex or right coronary artery, or subtend only a small area of viable myocardium. (LOE B)

TABLE 16-6 Risk Factor Modification: ACC/AHA Recommendations[1]

Lipid Management

Class I

1. Lifestyle modifications, including daily physical activity and weight management, are strongly recommended for all patients with SIHD. (LOE B)
2. Dietary therapy for all patients should include reduced intake of saturated fats (to <7% of total calories), *trans* fatty acids (to <1% of total calories), and cholesterol (to <200 mg/day). (LOE B)
3. In addition to therapeutic lifestyle changes, a moderate or high dose of a statin therapy should be prescribed, in the absence of contraindications or documented adverse effects. (LOE A)

Class IIa

1. For patients who do not tolerate statins, LDL cholesterol-lowering therapy with bile acid sequestrates, niacin, or both is reasonable. (LOE B)

Blood Pressure Management

Class I

1. All patients should be counseled about the need for lifestyle modification: weight control; increased physical activity; alcohol moderation; sodium reduction; and emphasis on increased consumption of fresh fruits, vegetables, and low-fat dairy products. (LOE B)
2. In patients with SIHD with BP 140/90 mm Hg or higher, antihypertensive drug therapy should be instituted in addition to or after a trial of lifestyle modifications. (LOE A)
3. The specific medications used for treatment of high BP should be based on specific patient characteristics and may include ACE inhibitors and/or beta blockers, with addition of other drugs, such as thiazide diuretics or calcium channel blockers, if needed to achieve a goal BP of <140/90 mm Hg. (LOE B)

Diabetes Management

Class IIa

1. For selected individual patients, such as those with a short duration of diabetes mellitus and a long life expectancy, a goal HbA1c of 7% or less is reasonable. (LOE B)

2. A goal HbA1c between 7% and 9% is reasonable for certain patients according to age, history of hypoglycemia, presence of microvascular or macrovascular complications, or presence of coexisting medical conditions. (LOE C)

Class IIb

1. Initiation of pharmacotherapy interventions to achieve target HgA1c might be reasonable. (LOE A)

Class III: Harm

1. Therapy with rosiglitazone should not be initiated in patients with SIHD. (LOE C)

Physical Activity

Class I

1. For all patients, the clinician should encourage 30 to 60 minutes of moderate-intensity aerobic activity, such as brisk walking, at least 5 days and preferably 7 days per week, supplemented by an increase in daily lifestyle activities (eg, walking breaks at work, gardening, and household work) to improve cardiorespiratory fitness and move patients out of the least-fit, least-active, high-risk cohort (bottom 20%). (LOE B)

2. For all patients, risk assessment with a physical activity history and/or an exercise test is recommended to guide prognosis and prescription. (LOE B)

3. Medically supervised programs (cardiac rehabilitation) and physician-directed, home-based programs are recommended for at risk patients at first diagnosis. (LOE A)

Class IIa

1. It is reasonable for the clinician to recommend complementary resistance training at least 2 days per week. (LOE C)

Weight Management

Class I

1. BMI and/or waist circumference should be assessed at every visit, and the clinician should consistently encourage weight maintenance or reduction through an appropriate balance of lifestyle physical activity, structured exercise, caloric intake, and formal behavioral programs when indicated to maintain or achieve a BMI between 18.5 and 24.9 kg/m^2 and a waist circumference less than 102 cm (40 inches) in men and less than 88 cm (35 inches) in women

(less for certain racial groups). (LOE B)

2. The initial goal of weight loss therapy should be to reduce body weight by approximately 5% to 10% from baseline. With success, further weight loss can be attempted if indicate. (LOE C)

Smoking Cessation Counseling

Class I

1. Smoking cessation and avoidance of exposure to environmental tobacco smoke at work and home should be encouraged for all patients with SIHD. Follow-up, referral to special programs, and pharmacotherapy are recommended, as is a stepwise strategy for smoking cessation (Ask, Advise, Assess, Assist, Arrange, Avoid). (LOE B)

Management of Psychological Factors

Class IIa

1. It is reasonable to consider screening SIHD patients for depression and to refer or treat when indicated. (LOE B)

Class IIb

1. Treatment of depression has not been shown to improve cardiovascular disease outcomes but might be reasonable for its other clinical benefits. (LOE C)

Alcohol Consumption

Class IIb

1. In patients with SIHD who use alcohol, it might be reasonable for nonpregnant women to have 1 drink (4 ounces of wine, 12 ounces of beer, or 1 ounce of spirits) a day and for men to have 1 or 2 drinks per day, unless alcohol is contraindicated (such as in patients with a history of alcohol abuse or dependence or with liver disease. (LOE C)

Avoiding Exposure to Air Pollution

Class IIa

1. It is reasonable for patients with SIHD to avoid exposure to increased air pollution to reduce the risk of cardiovascular events. (LOE C)

Antiplatelet Therapy

Aspirin provides its antiplatelet effect by providing nearly complete blockade of cyclooxygenase-1 (COX-1) activity (~ 95%) and subsequent thromboxane A_2 production. The reduction in thromboxane A_2 leads to reduced platelet activation and aggregation for the life of the platelet. Aspirin doses as small as 30 mg used chronically have been shown to provide the needed

level of COX-1 inhibition. Therefore, further increases in aspirin doses above 75 to 100 mg would be expected to provide little additional antiplatelet potency of aspirin.[37] Aspirin is also thought to provide benefits through some nonplatelet mediated effects. Compared to higher doses of aspirin (≥325 mg daily), low-dose aspirin has demonstrated a lack of significant impairment of endothelial secretion of prostacyclin, which is a natural vasodilator. Even though there may be some inhibition of prostacyclin with the use of aspirin, the effects on the endothelium are reversible, compared to the effect on platelets.[38] After unbound aspirin has been removed from the circulation (half-life is about 30 minutes), prostacyclin secretion and its vasodilation effects are restored. Aspirin may also attenuate the synthesis of cytokines such as interleukin-2, interleukin-6, and interferon in leukocytes.[39] Aspirin may also prevent leukocyte rolling and macrophage-induced endothelial activation.[39,40]

Clinical evidence describing the effectiveness of aspirin in patients with SIHD first came from a subgroup analysis of the Physicians Health Study.[41] The original trial was a double-blind evaluation of the efficacy of low-dose aspirin (325 mg every other day) compared to placebo in the primary prevention of MI, stroke, or CV death. Of the 22,071 patients enrolled in the trial, 333 had a history of SIHD. After the 5-year follow-up period, the patients with SIHD had an 87% significant reduction in risk for first MI.[41] Similar to the overall trial results, this benefit came with a significant increase in hemorrhagic stroke, although none of the strokes were fatal. There was no difference in total or CV mortality, but there were too few patients with SIHD to provide a meaningful analysis of these endpoints.

These beneficial effects of aspirin were confirmed in the more robust SAPAT (Swedish Angina Pectoris Aspirin Trial).[42] The SAPAT trial randomized 2,035 patients with controlled angina on sotalol to 75 mg of aspirin daily or matching placebo. At the end of the 50 month follow-up, patients receiving aspirin had a 34% relative reduction in first MI or sudden death. There was no difference in major bleeding or stroke between the groups. These results support the ACC/AHA recommendation for the use of aspirin in patients with SIHD.[1]

Concern has been raised over the past decade about patients being nonresponsive to the antiplatelet effects of aspirin, and therefore, not receiving the clinical benefit. A recent meta-analysis reported the average rate of aspirin nonresponsiveness to be 24%, but the range of reported nonresponsiveness is wide (0%-57%).[43] If only studies that used light transmission aggregometry (the gold standard test) induced with arachidonic acid and/or measurement of serum thromboxane B_2 are used, the rate of aspirin nonresponsiveness is only 6%.[43] These results are similar to the findings of the ASPECT (Aspirin-Induced Platelet Effects) trial, in which aspirin nonresponsiveness defined by COX-1-nonspecific methods was 27%, compared to only 6% when COX-1-specific methods were used.[44] The ASPECT investigators also reported no difference in aspirin nonresponsiveness between patients receiving 81 mg, 162 mg, or 325 mg daily.[44] A lack of dose response to clinical outcomes is consistent with the findings of the Antithrombotic Trialists' Collaboration meta-analysis which found a similar protection against vascular events regardless if patients were receiving low dose (75-150 mg daily), moderate dose (160-325 mg daily), or high dose (500-1,500 mg daily) aspirin.[37]

Pharmacodynamic aspirin nonresponsiveness may occur because of changes to the COX-1 enzyme, such as changes to the enzyme structure, or the transient inaccessibility of the enzyme due to the blockade of the active site. Of particular concern is the potential for nonsteroidal anti-inflammatory drug therapy to inhibit the effect of aspirin on the COX-1 enzyme. Naproxen and ibuprofen have shown to interfere with aspirin's antiplatelet effect when coadministered due to competition for access to the site of action in the COX-1 enzyme.[45] Timing of coadministration appears to be an important factor in the extent of competition. The effect of aspirin on platelet aggregation is impaired when ibuprofen is given 2 hours before aspirin, but when aspirin is given first there is no effect on the ability of aspirin to inhibit platelet aggregation.

A number of clinical trials have found a relationship between aspirin nonresponsiveness and increased risk of ischemic events. One commonly referenced trial of 325 patients with SIHD identified a lack of aspirin response in 5.2% of patients.[46] The incidence of death, MI, or stroke was significantly higher for nonresponders compared to responders (24% vs 10%).[46] Another trial of 468 patients with SIHD also found a 3-fold increase in risk of ischemic events associated with aspirin nonresponsiveness compared to responsive patients (15.6% vs 5.3%).[47] While aspirin nonresponsiveness does exist, the incidence is probably not as high as once thought. Even though patients with aspirin nonresponsiveness have demonstrated a higher rate of ischemic events, there are no recommendations for screening. Also, since increasing the dose of aspirin is unlikely to impact the incidence of nonresponsiveness or clinical outcomes, the only management strategy would be to change or add additional antiplatelet therapy.

In patients unable to take aspirin due to allergy or intolerance, clopidogrel represents a suitable alternative antiplatelet agent to prevent MI and death in patients with CAD.[1] While clopidogrel significantly reduced the incidence of stroke, MI, or vascular death in patients with atherosclerotic vascular disease (previous MI, stroke, or peripheral arterial disease) compared to aspirin in the CAPRIE (The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) trial (5.32% vs 5.83%; p = 0.043), the absolute difference in the primary outcome between the two strategies was quite small (0.5%, number need to treat = 200).[48] Only 22% of the patients in the CAPRIE trial had documented SIHD and no specific subgroup analysis is available for those patients. Given the small magnitude of benefit along with significantly higher cost, clopidogrel has remained a second line choice behind aspirin in patients with CAD. When used in patients with SIHD, clopidogrel should be administered at a dose of 75 mg per day.

The role of dual antiplatelet therapy (DAPT) with aspirin and a $P2Y_{12}$ inhibitor, such as clopidogrel, has mainly been evaluated in patients receiving PCI with stents and in the post-ACS setting, and not in patients with SIHD. In a patient population similar to the CAPPRIE trial, the CHARISMA trial (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance) evaluated aspirin compared to aspirin plus clopidogrel in patients (n=15,603) with documented vascular disease (CAD, cerebrovascular disease, peripheral arterial disease), or with no documented vascular disease but with multiple CV risk factors.[49]

The combination of aspirin plus clopidogrel for 28 months did not reduce the risk of death, MI, stroke, or coronary revascularization as compared to aspirin alone in the entire study population,

although there was a significant reduction in the risk of death, MI and stroke in those patients receiving aspirin plus clopidogrel compared to aspirin alone (7.3% vs 8.8%, p = 0.01) in patients with established vascular disease at study entry (n = 12,319).[49,50] There was a significant increase in the risk of bleeding with the use of DAPT compared to aspirin alone. Therefore, there are limited data to support the use of DAPT in patients with SIHD who have not received PCI with stent placement or a recent ACS event.

A number of trials have demonstrated that there is extensive variability in patient response to clopidogrel, but for the most part, the antiplatelet activity follows a bell-shaped curve.[51] Due to the variety of tests evaluating clopidogrel activity, and the different definition of nonresponsiveness used, estimates reported in these trials range from 5% to 44%.[52,53] A number of different definitions have been evaluated for clopidogrel nonresponsiveness, and trials have correlated these definitions with clinical response.

There is currently significant confusion about what to do if a patient is found to have a lack of appropriate response to clopidogrel therapy. The most common cause of nonresponsiveness is noncompliance. If patients are even partially noncompliant with their clopidogrel therapy, the tests to evaluate clopidogrel therapy will demonstrate a lack of response. Data from the PREMIER (Prospective Registry Evaluating Myocardial Infarction: Events and Recovery) registry provides evidence that noncompliance is associated with increased ischemic events, as well as important insight into patient predictors of noncompliance.[54]

Conversion of clopidogrel to its active compound requires a two-step conversion process. While numerous cytochrome P450 (CYP) enzymes may play a role in conversion, the CYP2C19 enzyme seems to be the major contributor in both steps. This has led some to suggest a role for CYP2C19 genetic testing in patients receiving clopidogrel as a method to identify potential nonresponders to clopidogrel therapy.[55] Genetic polymorphisms to CYP2C19 may contribute to a lack of response to clopidogrel therapy, but do not fully explain a lack of response in most patients. Trials have demonstrated that identification of CYP2C19 status only explains 12% to 15% of the variability in clopidogrel response.[56,57] Therefore, many patients with “wild-type” CYP2C19 will still not achieve adequate antiplatelet response to clopidogrel. At this time genetic testing is not the answer to explaining poor antiplatelet response to clopidogrel therapy.

Another consideration when patients are found to have a lack of adequate response to clopidogrel is drug-drug interactions involving CYP 2C19. All proton pump inhibitors (PPIs) are metabolized by CYP 2C19 to varying degrees. These are the most widely prescribed medications worldwide and a number of trials evaluating the impact of PPIs on clopidogrel activity have been conducted. A number of pharmacodynamic and observational cohort trials have suggested that patients receiving a PPI (mainly omeprazole) and clopidogrel have reduced antiplatelet activity and more ischemic outcomes.[58,59] Other prospective data do not support that this drug interaction has significant clinical implications.[60]

Recommendations from the ACC/AHA for the use of antiplatelet agents in the management of SIHD include a Class I recommendation for the use of aspirin 75 to 162 mg daily, continued indefinitely in

the absence of contraindications (LOE A).[1] Clopidogrel is considered a reasonable alternative when aspirin in contraindicated (LOE B). The guidelines state that treatment with aspirin (75-162 mg daily) and clopidogrel 75 mg daily might be reasonable in certain high-risk patients with SIHD as a Class IIb (LOE B) recommendation. The use of dipyridamole is a Class III recommendation (LOE B).

Angiotensin-Converting Enzyme Inhibitors

7 The use of ACE inhibitors has been shown to provide significant mortality benefit in patients with systolic heart failure or recent MI with reduced ejection fraction. They have also been shown to reduce the progression of nephropathy in patients with or without HTN. In the setting of atherosclerotic disease and SIHD, ACE inhibitors have demonstrated the ability to stabilize coronary plaque, provide restoration or improvement in endothelial function, inhibition of vascular smooth muscle cell growth, decreased macrophage migration, and possibly possess some antioxidant activities. They may also possess some antithrombotic properties through inhibition of platelet aggregation and augmentation of the endogenous fibrinolytic system. However, despite a reduction in silent ischemia on ambulatory ECG monitoring in a small number of trials, ACE inhibitors have not been shown to improve symptomatic ischemia.[61,62]

The role of ACE inhibitors in patients at high risk for CV events was evaluated in the HOPE (Heart Outcomes Prevention Evaluation) trial.[63] The HOPE trial investigators randomized patients to placebo or ramipril 10 mg daily. The HOPE trial evaluated patients with atherosclerotic disease (history of CAD, stroke, peripheral arterial disease, or DM with at least one additional risk factor), with approximately 80% of the patients having a history of CAD and approximately 55% had a history of SIHD.

After the 5-year follow-up period, ramipril patients had a significant reduction in the primary endpoint (CV death, MI, or stroke).[63] These impressive benefits were seen despite the minimal reduction in BP observed with the use of ramipril at 1 month (4/2 mm Hg), 2 years (3/2 mm Hg), and at the end of the 5-year period of the study (3/1 mm Hg). Benefits were consistent across all groups of patients enrolled, regardless of the location of atherosclerotic disease.

The results of the HOPE trial were confirmed in the EUROPA (European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease) trial.[64] The EUROPA trial evaluated only patients with SIHD, and not atherosclerotic disease in other vascular beds. In the EUROPA trial, perindopril 8 mg daily significantly reduced the incidence of CV death, MI, or cardiac arrest compared to placebo.[64] Data from the PEACE (Prevention of Events with Angiotensin Converting Enzyme Inhibitors) trial did not confirm the earlier results seen in the HOPE and EUROPA trials. In the PEACE trial, the addition of trandolapril 4 mg daily to standard therapy in patients with documented CAD did not significantly reduce the incidence of CV death, MI, or coronary revascularization.[65]

One possible explanation for the conflicting results in these three major trials may be related to the different agents and their relative dosing evaluated in the trials. Another explanation is the different patient populations and baseline therapy provided in the trials, with the patients enrolled in the PEACE trial appearing to be lower risk of ischemic event, and receiving better background therapy,

such as statins and PCI, compared to the HOPE and EUROPA trials.

Regardless of whether there is a reasonable explanation for the discordant results of these trials, the PEACE trial does raise the issue of whether ACE inhibitors should be added to the pharmacotherapy regimen of all patients with SIHD. Based on existing well established benefits, it is appropriate to consider ACE inhibitors for patients with SIHD who have concomitant HTN, DM, HF, or who are post-MI.[1] Use of ACE inhibitors in all patients with SIHD would also be supported by a meta-analysis of seven trials with 33,960 patients that suggest a 14% significant reduction in morality ($p < 0.001$) when used in patients with CAD.[66]

Trials evaluating the role of angiotensin receptor blockers (ARBs) to determine if they provide a similar benefit as ACE inhibitors in the setting of CAD, and if the combination is better than either agent alone. In ONTARGET (ONgoing Telmisartan Alone and in combination with Ramipril Global Endpoint Trial), patients with existing CV disease and DM had similar benefit between the ACE inhibitor ramipril 10 mg daily and the ARB telmisartan 80 mg daily.[67] There was no added benefit of combination of the two agents, but there were significantly more adverse effects of hypotension, syncope, and renal dysfunction. In a second trial, there was no significant benefit of telmisartan over placebo in patients who were intolerant to ACE inhibitors.[68] Based on these conflicting data, an ARB would be used if the patient cannot tolerate ACE inhibitor therapy, and combination therapy is not justified.

Recommendations from the ACC/AHA for the use of ACE inhibition include a Class I recommendation for the use of ACE inhibitors in all patients with SIHD who also have HTN, DM, LV dysfunction, or chronic kidney disease, unless contraindicated (LOE A).[1] ARBs are recommended for the same patient populations if they are intolerant to ACE inhibitors (LOE A). It is a Class IIa recommendation to use ACE inhibitors in patients with both SIHD and other vascular diseases (LOE B), and ARBs in these patients if intolerant to ACE inhibitors (LOE B).

Risk Factor Modification

Lipid Management

8 Multiple studies have demonstrated a continuous, graded increase in coronary events with increasing low-density lipoprotein cholesterol (LDL-C) in men and women with or without initial SIHD. Multiple controlled clinical trials have demonstrated the ability of statin therapy to lower LDL-C and reduce CV events. The Cholesterol Treatment Trialist Collaborators published a meta-analysis of 26 trials of statin therapy, which demonstrated a 10% reduction in all-cause mortality for every 40 mg/dL reduction in LDL-C.[69] This same reduction in LDL-C was also associated with a 20% reduction in coronary mortality, with corresponding reductions in MI, stroke, and need for coronary revascularization. When comparing a higher dose to a lower dose statin regimen, there was a mean reduction of 20 mg/dL LDL-C more with the higher dose regimen. This resulted in a 15% lower rate of major vascular events, reflected by a 13% lower risk of MI, 16% lower risk of stroke, and a 19% lower risk of needing coronary revascularization, will a higher compared with a lower dose statin regimen.[69]

Until 2013, guidelines for the treatment of patients with dyslipidemia was centered around achieving particular LDL-C goals based on a patient's risk of CHD. Patients with existing CHD had a goal LDL-C of less than 100 mg/dL, and a goal of less than 70 mg/dL in patients considered to be at very high risk of coronary events. Unfortunately, the data to date do not support using statin therapy to achieve a specific target LDL-C to minimize CV events. The positive benefits demonstrated in most actively controlled trials support the use of a high dose or higher-intensity statin regimen. Therefore, the 2013 guidelines now recommend that all patients with known atherosclerotic CVD, such as SIHD, should receive high-intensity statin therapy.[70] Patients over the age of 75 years, or those who cannot tolerate high-intensity statin therapy, should receive moderate-intensity statin therapy. High-intensity statin options include atorvastatin 40 or 80 mg daily or rosuvastatin 20 or 40 mg daily. It should be noted that atorvastatin 80 mg is considered the preferred dose, and that the 40 mg dose was only used in one trial in patients who could not tolerate the 80 mg dose.[71] Also, rosuvastatin 20 mg daily is the preferred regimen based on the evidence, with the 40 mg daily dose being mentioned because it is also an approved dose. Moderate-intensity statin regimens include once daily atorvastatin 10 to 20 mg, rosuvastatin 5 to 10 mg, simvastatin 20 to 40 mg, pravastatin 40 mg, lovastatin 40 mg, pitavastatin 2 to 4 mg, and twice daily fluvastatin 40 mg.[70]

Other mechanisms for control of a patient's lipid profile, such as physical activity, weight management, management of psychological factors should also be implemented. Dietary approaches to lowering LDL-C include replacing saturated and *trans* fatty acids with dietary carbohydrates or unsaturated fatty acids and reducing dietary cholesterol. Although the response to dietary interventions is variable, a diet low in saturated fat and cholesterol typically lowers LDL-C by 10% to 15%. Other beneficial dietary interventions can include addition of plant stanols/sterols (2 g/day), which trials suggest lower LDL-C by 5% to 15%, and addition of viscous fiber (>10 g/day), which reduces LDL-C by 3% to 5%. A 10 lb weight loss reduces LDL-C by 5% to 8%. Regular physical exercise is key to therapeutic lifestyle modifications, but does not reliably lower LDL-C but facilitates weight loss and other beneficial effects on the lipid profile.

Blood Pressure Management

A number of observational trials have demonstrated a continuous and graded relationship between BP and risk of CV events. The risk of vascular death increases linearly over the BP range of 115/75 mm Hg to 185/115 mm Hg, with a doubling of risk for every 20 mm Hg increase in systolic BP or 10 mm Hg increase in diastolic BP.[72] Despite an abundance of trials evaluating when to initiate therapy and the target BP goal for patients with SIHD, the specific BP remains elusive. Current recommendations are to initiate pharmacotherapy, and treat to a BP goal of less than 140/90 mm Hg.[1,2,73] While observational trials suggest that patients with vascular disease might benefit from a lower target BP, other trials do not support this assumption. In the ACCORD (Action to Control Cardiovascular Risk in Diabetes) BP trial, patients with type 2 DM at high risk of CV events were randomized to a goal systolic BP of 120 mm Hg or 140 mm Hg.[74] There was no significant reduction in the incidence of CV death, MI, or stroke in patients randomized to a target systolic BP of 120 mm Hg compared to those treated to a target systolic BP of 140 mm Hg. Therefore, there was no benefit of a more aggressive BP reduction.

In contrast to the ACCORD trial, the SPRINT (Systolic Blood Pressure Intervention Trial) study found that patients with an initial baseline BP of 140/78 mm Hg treated to a target systolic BP of less than 120 mm Hg demonstrated a significant 25% reduction in CV events compared to those treated to a systolic BP of less than 140 mm Hg over a 3.26 year follow-up.[75] There was also a significant 27% reduction in all-cause mortality in patients in the more intense BP management group compared to the standard management group.[75] Some differences between the trials was the inclusion of patients with DM in the ACCORD trial and their exclusion in SPRINT, as well as the older patients being enrolled in SPRINT compared to the ACCORD trial (mean age 68 years vs 62 years). The most probable reason for the difference in the results is based on the size of the trials. While the ACCORD trial evaluates 4,733 patients, SPRINT had stronger statistical power by evaluating 9,361 patients. Based on the results of SPRINT, future guideline recommendations will likely be changing. Therefore, it seems reasonable to treat to a lower BP goal as long as adverse effects, such as hypotension, syncope, renal dysfunction, and electrolyte abnormalities, can be prevented or managed. Since approximately 30% of the patients in SPRINT were older than age 75, and they demonstrated a similar magnitude of benefit compared to younger patients, the current guideline recommendation to treat a goal systolic BP of less than 150 mm Hg in older patients needs to be reconsidered.[73]

Reduction of BP should consist of life style modifications as well as pharmacotherapy. This includes a diet rich in fruits, vegetables, and low-fat dairy products, regular physical exercise, a reduction in dietary sodium, and limited alcohol consumption. Many of these contribute to weight loss, where a 10-kg weight loss has contributed to a reduction in systolic BP of 5 to 20 mm Hg.

Several agents used to treat HTN have demonstrated the ability to reduce CV events. Drug selection in patients with SIHD includes a number of agents typically used to treat other aspects of the disease. Since β-blockers are usually the first agents selected for control of angina symptoms, they will also assist with lowering of BP. Patients may also be on ACE inhibitors based on the results of the HOPE trial or due to other comorbidities benefiting from ACE inhibitor therapy. Therefore, most patients with SIHD will typically get these two classes of agents for initial treatment of existing HTN. If additional therapy is needed, calcium channel blockers (CCBs) would be a good option since they could be used for the HTN, as well as help reduce angina episodes. Thiazide diuretics could also be an option based on their benefits in other populations and they would not be detrimental in patients with SIHD.

Smoking Cessation

Numerous observational studies have demonstrated that smoking significantly increases a patient's risk of having CV events.[76,77] Smoking increases risk by promoting atherosclerotic disease through a number of mechanism such as increasing platelet adhesion, increasing fibrinogen levels, causing endothelial dysfunction, decreasing high-density lipoprotein cholesterol (HDL-C) levels, and inducing vasoconstriction. While there have not been studies specifically in patients with SIHD, observational studies consistently demonstrate that smoking cessation is associated with a reduction in coronary events. A meta-analysis of 20 prospective cohort trials demonstrated a 30% relative risk reduction in mortality and MI for those who quit smoking compared to those who did not.[78] These benefits can occur within 2 to 3 years from initiation of smoking cessation.

One of the most important impacts of getting a patient to quit smoking is advice from their clinician recommending and discussing the importance of smoking cessation. Clinicians should approach smoking cessation by using the 6 A's framework:[1]

- Ask each patient about tobacco use at every visit;
- Advise each smoker to quit;
- Assess each smoker's wiliness to make a quit attempt;
- Assist each smoker in making a quit attempt by offering medication and referral for counseling;
- Arrange for follow-up; and
- Avoid exposure to environmental tobacco smoke.

Nonpharmacologic methods for smoking cessation are just as important as pharmacotherapy. Self-help programs, telephone counseling, behavioral therapy, and even exercise have had a beneficial effect at getting patients to quit smoking. Nicotine replacement therapy had demonstrated a nearly doubling of the rate of smoking cessation success.[79] There are a number of dosage forms available to fit the patient's lifestyle, such as patches, tablets, gum, lozenges, and a nasal spray. Sustained-release bupropion has also demonstrated a 2-fold increase in smoking cessation rates.[80] The partial agonist of the $\alpha_4\beta_2$ nicotinic receptor, varenicline, has demonstrated efficacy similar to that of buproprion.[81]

Diabetes Management

Diabetes mellitus is a significant risk factor of the development of CV disease in patients with type 1 and type 2 DM. Patients with type 1 DM have a 10-fold increase in risk of having a CV event compared to those without DM. Patients with type 2 DM have a 2- to 6-fold risk of CV death compared to those without DM. In fact, 80% of all deaths in patients with DM are associated with atherosclerotic disease.

The optimal goal HbA1c for patients with DM has not been determined. Studies have demonstrated that getting patients to an HbA1c of less than 7% is able to reduce microvascular complications of DM such as retinopathy, nephropathy, and neuropathy.[82] While subgroup analysis of larger trials have suggest a potential benefit, there have not been data from prospective trials to support reductions in macrovascular complications of DM, such as MI, stroke, and CV death.[83] In a trial that attempted to reduce these macrovascular complications by treating to a lower HbA1c (<6%), there was a failure to demonstrate any reductions in MI, stroke, or CV death, but did produce a 22% increase in all-cause mortality.[84]

Date from the EMPA-REG OUTCOME (Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients) trial seems to be a breakthrough in the ability of glucose lowering agents to have a positive impact on CV events.[85] Patients with type 2 DM, with an HbA1c between 7% and

9% on glucose lowering therapy (up to 10% if treatment naïve) with established CV disease received 10 mg or 25 mg of empagliflozin once daily or placebo. Empagliflozin inhibits the sodium-glucose cotransporter 2, consequently inhibiting renal glucose resorption and thereby lowering plasma glucose levels. After approximately 3 years of follow-up patients receiving empagliflozin (n=4,687) had a significant relative reduction of 14% in CV events compared to placebo (10.5% vs 12.1%; p=0.04).[85] Interestingly, the 38% significantly lower rate of CV death was not due to lower rates of MI or stroke. There was a significant 35% relative reduction in hospitalizations for heart failure with the use of empagliflozin. There was no difference between the two doses of empagliflozin. It is unlikely the mechanism of the benefit of empagliflozin is due the magnitude of glucose lowering since there was only an approximate 0.5% reduction in HbA1c compared to placebo. Empagliflozin was more likely to cause genital infections compared to placebo, but otherwise adverse effects were similar between the groups. Based on these results, it would seem prudent that empagliflozin be part of the medication regimen for patients with DM and CVD. While studies are currently ongoing, it is unknown at this time of the other available sodium-glucose cotransporter inhibitors, canagliflozin or dapagliflozin, provide a similar benefit in patients with DM and CVD.

Metformin is typically the initial agent used in the treatment of DM in patients with SIHD. While sulfonylurea agents provide a similar reduction in HbA1c, their potentials to induce hypoglycemia and weight gain make metformin a more attractive option. Rosiglitazone should not be used in patients with SIHD due to an increase in CV events demonstrated with this agent. Pioglitazone has not been reported to carry this same risk of CV events, but is should not be used in patients with NYHA class III or IV heart failure due to risk of fluid retention.

Medical Therapy for Relief of Symptoms Recommendations[1]

Class I

1. β-blockers should be prescribed as initial therapy for relief of symptoms in patients with SIHD (LOE B).
2. Calcium channel blockers or long-acting nitrates should be prescribed for relief of symptoms when β-blockers are contraindicated or cause unacceptable side effects in patients with SIHD (LOE B).
3. Calcium channel blockers or long-acting nitrates, in combination with β-blockers, should be prescribed for relief of symptoms when initial treatment with β-blockers is unsuccessful in patients with SIHD (LOE B).
4. Sublingual nitroglycerin or nitroglycerin spray is recommended for immediate relief of angina in patients with SIHD (LOE B).

Class IIa

1. Treatment with a long-acting nondihydropyridine CCB (verapamil or diltiazem) instead of a β-blocker as initial therapy for relief of symptoms is reasonable in patients with SIHD (LOE B).

2. Ranolazine can be useful when prescribed as a substitute for β-blockers for relief of symptoms in patients with SIHD if initial treatment with β-blockers leads to unacceptable side effects or is ineffective or if initial treatment with β-blockers is contraindicated (LOE B).

3. Ranolazine in combination with β-blockers can be useful when prescribed for relief of symptoms when initial treatment with β-blockers is not successful in patients with SIHD (LOE A).

β-blockers

9 β-adrenergic blocking agents are commonly used in the management of patients with SIHD and are effective in reducing both symptomatic and silent episodes of myocardial ischemia. β-adrenergic blocking agents cause competitive inhibition of the effects of neuronally released and circulating catecholamines on β-adrenoceptors. The predominant adrenergic receptor type in the heart is the β_1-receptor, and competitive blockade minimizes the influence of endogenous catecholamines on the chronotropic and inotropic state of the myocardium. β-blockers also produce a moderate reduction in BP through competitive inhibition of β_1-receptors found in the kidney, leading to a reduction in renin release. By reducing HR, myocardial contractility, and intramyocardial wall tension (through BP reduction), β-blockers impact all of the major contributing factors of MVO_2.[86] HR reduction may also improve myocardial oxygen delivery by prolonging diastole filling time and increasing myocardial perfusion. Overall, β-blockers are effective agents for patients with effort-induced angina through their reduction in MVO_2.

β_1-selectivity does not influence the efficacy of β-blockers in the treatment of SIHD and all agents appear equally effective. β_1-selective agents would be preferred in patients with chronic obstructive pulmonary disease, peripheral arterial disease, DM, dyslipidemias, and sexual dysfunction, where blockage of the β_2-adrenergic receptor may be problematic. It should be noted that even β_1-selective agents lose their selectivity and provide additional β_2-blockage at higher doses. β-blockers with combined α_1 and β-blockade are also effective in the management of patients with angina. β-blockers with intrinsic sympathomimetic activity cause a slight to moderate activation of the β-receptor, in addition to preventing the binding of natural catecholamines. Due to this unique pharmacologic property, they provide little to no reduction in resting HR. There is a reduction in exercise HR when catecholamine concentrations are increased. While agents with intrinsic sympathomimetic activity can be useful for patients with peripheral arterial disease and dyslipidemia, they are not preferred in patients with CAD. In general, selection of a β-blocker in patients with SIHD usually depends on the presence of comorbid disease states, preferred dosing frequency, and cost.

Most side effects experienced with the use of β-blockers are typically an extension of their pharmacologic activity. Patients receiving β-blockers may experience bradycardia, hypotension, heart block, impaired glucose metabolism, and altered serum lipids. Changes in a patient's lipid profile are demonstrated as in increase in triglycerides, decrease in HDL-C, and no change in LDL-C. These change in a patient's lipid profile are more extensive with non-selective β-blockers and are usually transient. Central nervous system adverse effects, such as fatigue, depression, insomnia, and overall malaise, are somewhat less severe, but account for a significant number of β-blocker discontinuations. Impotence has been reported in approximately 1% of patients receiving β-blockers

and inability to maintain an adequate erection has been reported in up to 25% of patients in some series. Patients with a history of airway disease may suffer from bronchospasm, and patients with LV systolic dysfunction may suffer from fluid overload. Patients without these preexisting disease states usually do not suffer from these adverse effects and it is important to note that even patients at risk for adverse effects receive significant benefit from the use of β-blockers. β-blockers are absolutely contraindicated in patients with existing bradycardia, hypotension, 2nd or 3rd degree atrioventricular (AV) block, a history of reactive airway disease (asthma), severe peripheral arterial disease, LV dysfunction with unstable fluid status, and difficult to control patients with DM who frequently have episodes of hypoglycemia. The highest risk post-MI patients should all receive β-blockers unless there is an absolute contraindication. A patient with SIHD who has never had an ACS, especially acute MI, with moderate chronic obstructive pulmonary disease could be treated adequately with an appropriate CCB or a β-blocker.

If β-blocker therapy needs to be discontinued, doses need to be tapered over 2 to 3 weeks to prevent abrupt withdrawal. During β-blocker therapy, there is a known up regulation of β-receptors on the myocardium. With abrupt withdrawal, these new receptors, along with all of the blocked receptors, are now exposed to be stimulated by endogenous catecholamines. This can produce a significant increase in MVO_2, induce ischemia, and even MI. If for some reason β-blockers cannot be tapered, patient should be instructed to avoid exertion as much as possible and manage angina episodes with SL NTG. Substitution with a non-dihydropyridine (DHP) CCB would be preferred if possible.

Calcium Channel Blockers

10 Calcium channel blockers are also effective agents in reducing angina episodes in patients with SIHD. All types of CCBs reduce MVO_2, as well as provide some increase in supply by inducing coronary vasodilation and preventing vasospasm. These effects are the result of CCB ability to modulate calcium entry into the myocardium and vascular smooth muscle, as well as a number of other tissues. This leads to a reduction in the cytosolic concentration of calcium responsible for activation of the actin-myosin complex leading to contraction of vascular smooth muscle and myocardium.

Calcium channel blockers should be considered as two separate classes of drugs. While they all inhibit influx of calcium ions, the location of the inhibition differs based on the chemical structure of the agents. The DHP CCBs, such as nifedipine, amlodipine, isradipine, and felodipine, provide their calcium channel blockade mainly in vascular smooth muscle cells, such as arterioles, with minimal effect on the myocardium. In contrast, the phenylalkylamine (verapamil) and benzothiazepine (diltiazem) agents, commonly referred to as non-DHP CCB, block calcium ion entry in mostly in the myocardium, with minimal effect on vascular smooth muscle. Verapamil is considered to have the most impact on myocardial calcium channels, with diltiazem having an effect intermediate between verapamil and a DHP CCB.

All CCBs reduce MVO_2 due to reduction in wall tension secondary to reduced arterial pressure and, to a minor extent, depressed contractility. While this is the main mechanism of benefit of DHP CCBs in

patients with SIHD, non-DHPs are able to reduce all components of MVO2.

Like β-blockers, non-DHP CCBs also reduce HR and contractility through blockade of myocardial calcium channels. The DHP CCBs do produce a minimal reduction in contractility, and produce either a neural or increase in HR due to reflex tachycardia from direct arterial dilation. The effect on contractility and reflex tachycardia are not uniform across the class of DHP CCBs. Agents such as nifedipine produce more impairment of LV function than newer agents such as amlodipine and felopidine. Due to their propensity to cause reflex tachycardia, short acting DHP CCBs should not be used in the treatment of SIHD, as well as the treatment of chronic HTN, hypertensive crisis, or during an ACS event. If reflex tachycardia occurs with the use of longer acting DHP CCBs, it is typically less significant as than that seen with nitrate therapy, and can be prevented with β-blocker therapy.

Common side effects of CCBs vary between the classes. Patients taking non-DHP CCBs may experience bradycardia, hypotension, AV block, and symptoms of LV depression. Non-DHP CCBs should not be used in patients who have contraindications or cannot tolerate β-blockers associated with these same effects. Non-DHP CCBs should be avoided in patients with concomitant systolic heart failure due to their negative inotropic effects, but can provide benefit to patients in atrial fibrillation with rapid ventricular response to due to their negative dromotropic effects. Verapamil also been reported to cause significant constipation in up 8% of patients. Patients taking DHP CCBs may experience reflex tachycardia, hypotension, headache, gingival hyperplasia, and peripheral edema. While most DHP CCBs are contraindicated in patients with systolic heart failure, amlodipine and felodipine are considered safe options in patients with systolic heart failure and concomitant SIHD and/or HTN.

Calcium channel blockers undergo hepatic oxidative biotransformation via the P450 isoenzyme 3A4 and other isoenzymes. Verapamil and diltiazem inhibit clearance of other substrates that utilize the 3A4 isoenzyme such as carbamazepine, cyclosporine, lovastatin, simvastatin, and benzodiazepines. The DHP CCBs generally do not have this same impact on these medications. Verapamil, and to a lesser extent diltiazem, also inhibit P-glycoprotein mediated drug transport. This interaction is partially responsible for increases in serum concentrations of agents such as digoxin and cyclosporine. Verapamil also decreases the clearance of digoxin, requiring close monitoring if these agents are used together. Agents that induce the P450 3A4 isoenzyme can reduce the effectiveness of all CCBs. Pharmacodynamic interactions also need to be monitored for in patients taking CCBs. Patients receiving verapamil or diltiazem concomitantly with other agents that reduce HR and AV nodal conduction (β-blockers, digoxin, and amiodarone) should be monitored for the development of bradycardia or heart block. Patients with LV dysfunction should not receive verapamil or diltiazem, especially if patients are treated with β-blockers.

Nitrates

10 Organic nitrates were found to have antianginal properties over 100 years ago when Murrell first reported in 1879 the ability of a 1% nitroglycerin solution administered orally relieved and prevented angina attacks. Organic nitrates are generally regarded as prodrugs that require biotransformation into the active compounds. This process leads to denitration of the nitrate and the release of nitric oxide, also known as EDRF. The EDRF works on the vascular endothelium to increase concentrations

of cyclic guanosine monophosphate leading to a reduction in cytoplasmic calcium and vasodilation. Most of this vasodilation occurs on the venous side of the vascular system, leading to a reduction in preload, and subsequently a reduction in myocardial wall tension and MVO_2. As doses are increased, arterial vasodilation also occurs. This direct arterial vasodilatory effect can produce reflex tachycardia that can counter some of the antiangina benefits. Patients on adequate doses of β-blockers will not have reflex tachycardia, making this an effect combination for controlling a patient's angina symptoms.

Nitrates also provide vasodilation of stenotic vessels as well as the intracoronary collateral circulation. Due to the exponential reduction in flow with increasing stenosis, even small increases in vasodilation in these narrowed vessels can produce a significant increase in myocardial oxygen supply to ischemic portions of the myocardium. Nitrate-induced coronary vasodilation occurs predominately in epicardial vessels, with minimal effect on the coronary microcirculation. This explains why nitrates do not induce coronary steal similar to agents such as dipyridamole or sodium nitroprusside. Possible explanations for this lack of microcirculatory vasodilation include autoregulatory influences from the adjacent myocardium that counteract the vasodilatory effects of NTG, an absence of guanylate cyclase in these vessels, or an inability of the nitrate to undergo denitration in these vessels. Nitrates have been reported to have an antiaggregate effect on platelets, but the clinical relevance of this effect has not been documented.

Common side effects of nitrate therapy include headache, flushing, nausea, postural hypotension, and syncope. The hypotension is usually not severe but in volume depleted patients who rapidly try to stand, the hypotension can be accompanied with a paradoxical bradycardia. Headache will usually resolve after about 2 weeks of continued therapy. However, it is important to note that this does not necessarily represent tolerance or loss of antianginal effectiveness of the nitrate therapy. Acetaminophen has proven to be effective in managing nitrate-induced headache during the initial weeks of therapy. Patients utilizing transdermal nitroglycerin may experience skin erythema and inflammation. Initiating therapy with smaller doses and/or rotating the application site can manage adverse effects of transdermal NTG.

Several different formulations of nitrates are available for acute and chronic use (**Table 16-7**). [11] All patients with CAD should have access to SL NTG tables or spray for treatment of acute episodes of angina. Thorough patient education is critical for optimal benefit from SL NTG tablets and spray (**Table 16-8**). The SL route of administration is important to avoid the delay of gastrointestinal absorption and hepatic first pass metabolism. By going directly into the blood stream, SL NTG typically provides relief of angina within 5 minutes of administration. Despite the small tablet size of SL NTG, a dose of 300 to 400 mcg is substantial. Patients experience relief of symptoms due to the coronary artery vasodilation provided by this dose. This dose is also able to provide benefit, regardless if patients are already taking chronic long-acting nitrates. The side effects of flushing, headache, and postural hypotension can appear rapidly and the patient should be aware of this potential. Sublingual NTG can also be used for prophylaxis of acute episodes of angina. When patients want to involve themselves in a particular activity which they know leads to angina after a certain amount of exertion, they can take a SL NTG about 2 to 5 minutes before the activity. This prophylactic dose can provide up to 30 minutes of protection and allows the patient to take part in

activities that they may otherwise be unable to because of angina episodes. Due to its longer half-life, sublingual isosorbide dinitrate could provide protection for up to 1 hour.

TABLE 16-7 Nitrate Products

Product	Onset (minutes)	Duration	Initial Dose
Nitroglycerin			
IV	1-2	3-5 minutes	5 mcg/min
Sublingual/lingual	1-3	30-60 minutes	0.3 mg
Oral	40	3-6 hours	2.5-9 mg three times a day
Ointment	20-60	2-8 hours	0.5-1 in
Patch	40-60	>8 hours	1 patch
Erythritol tetranitrate	5-30	4-6 hours	5-10 mg three times a day
Pentaerythritol tetranitrate	30	4-8 hours	10-20 mg three times a day
Isosorbide dinitrate			
Sublingual/chewable	2-5	1-2 hours	2.5-5 mg three times a day
Oral	20-40	4-6 hours	5-20 mg three times a day
Isosorbide mononitrate	30-60	6-8 hours	20 mg daily, twice a day[a]

[a]Product dependent.

TABLE 16-8 Education for Clinicians and Patients on Use of Sublingual Nitroglycerin

Education Point	Purpose
Keep in original dark glass container	SL NTG is degraded by sunlight and can lose potency.
Do not dump into a regular prescription bottle	SL NTG will interact with plastic and can lose potency. This is why it is packaged in a glass container.
Do not dispense in a larger plastic vial with safety cap	During an episode of angina you do not want the patient struggling to figure out how to open the safety cap.
Do not store in the bathroom	SL NTG will degrade in moisture and tablets will lose their integrity and potency.
Keep with them at all times, and may need multiple vials	SL NTG does not do the patient any good if they do not have it with them at the time of an episode of angina. Patient should consider having one at home, at work, in garage, etc.
Patient should be sitting down and resting with taking tablet	While the SL NTG tablets are small, the dose is not. It is likely the patient will have some flushing, may get a headache, and even become a little light headed. They need to know this can happen.
Describe how to use a SL tablet	The quick onset of a SL NTG is based on avoiding GI transite time and first-pass metabolism of the nitroglycerin. Therefore, the patient needs to know how to keep the tablet under the tongue until devolved and to try to attempt from swallowing the tablet.

Education Point	Purpose
Tablets need to be refilled every 6 months and spray every 3 years	Due to the instability of SL NTG tablets, they are typically only good for 6 months after they are opened.[a] Shelf-life of the spray is longer. Patients need to be advised to refill SL NTG even if they are not all gone once opened.
Remove cotton plug from the bottle	Larger quantity bottles commonly have a cotton plug. During an episode of angina you do not want the patient to be struggling with trying to get the cotton plug out of the bottle.
How to use prophylactically	SL NTG can be used to prevent episodes of angina if taken before partaking in an exertional event known to precipitate angina.
Contact 911 if first SL NTG does not relieve angina[b]	Most episodes of angina are relieved within 5 to10 minutes of rest and a single SL NTG. If pain persists, the episode may be an acute coronary syndrome, and not stable ischemic heart disease. This requires rapid medical attention.

SL NTG, sublingual nitroglycerin.

[a]product specific.

[b]may be patient specific base on their known experience with SL NTG and angina episodes.

The use of chronic long-acting nitrate therapy for SIHD has been limited due to the phenomenon of nitrate tolerance. Several trials have shown that continuous nitrate therapy for more than 24 hours leads to a reduction or loss of the hemodynamic and antianginal effects of nitrates. In a trial of 562 patients receiving 24 hours of transdermal NTG, almost all of the patients lost control of their angina symptoms that could not be overcome with higher doses.

Nitrate tolerance is not necessarily an “all or none” phenomenon. Some patients may experience a reduction in the efficacy, while others may experience a total loss of efficacy. It is known that despite continued use of nitrates and a loss of antianginal effect, plasma volume remains expanded and some hemodynamic effects are maintained. Since the impact of continuous nitrate utilization varies from patient to patient and is unpredictable, the appropriate clinical strategy is to prescribe nitrates with a nitrate-free interval. Chronic administration of nitrates produces a state of oxidative stress leading to dysfunction of mitochondrial aldehyde dehydrogenase, the enzyme responsible for converting nitrates to the active agent NO.[87,88]

The mechanism of nitrate tolerance remains unknown, which has led to several pharmacologic approaches for its management and prevention. One thought is that tolerance is due to an exhausting of sulfhydryl groups needed for utilization of organic nitrates.[87] Based on this hypothesis, acetylcysteine has been investigated as a potential strategy for preventing nitrate tolerance because it supplies sulfhydryl groups. ACE inhibitors have also been investigated with mixed results. Agents such as captopril can supply sulfhydryl groups, but ACE inhibitors may prevent nitrate tolerance through other mechanisms. The inhibition of angiotensin II production can reduce superoxide anion production, leading to reduced nitrate degradation, as well as a reduction in protein kinase C and

endothelin leading to a reduction in vasoconstriction. Unfortunately, none of these approaches have shown to be effective in maintaining the antianginal effects of continuous nitrate therapy despite their ability to maintain the hemodynamic effects of nitrates.

Despite multiple hypotheses for the mechanism of nitrate tolerance, the preferred management of nitrate tolerance for patients with CAD remains a 10- to 14-hour nitrate-free interval daily. This approach has been shown to maintain antianginal efficacy with the use of chronic nitrates. The rationale for this approach is based on the observation that although nitrate tolerance develops rapidly, it also is reversed rapidly. Unfortunately, this approach does not provide the patient anti-ischemic coverage during the nitrate-free interval and places the patient at risk for angina episodes. Usually the nitrate-free interval is provided during the nighttime hours when the patient is sleeping, and should have a reduced MVO_2. Several trials have utilized a nitrate-free interval and have demonstrated an increase in exercise time, a reduction in exercise induced ischemic events, and a reduction in the need for SL NTG. Despite these benefits, a nitrate-free interval would not provide protection to the 20% to 30% of patients with SIHD that also experience occasional nocturnal episodes of angina. The greatest concern with the use of chronic nitrates as the only antianginal therapy relates to the circadian timing of MI and other ischemic episodes. It is well documented that angina episodes and MI commonly occur in the morning hours, either right before or after awakening. Patients utilizing chronic nitrate therapy would generally not have taken or applied their nitrate therapy for the day during this critical time period. Nitrates should not be routinely used as monotherapy for SIHD because of the lack of coverage during the nitrate-free interval, lack of protection against circadian rhythm ischemic events, and potential for reflex tachycardia from vasodilatory properties. Trials have shown that patients taking intermittent transdermal NTG did not generally have rebound ischemia during the nitrate-free interval when concomitant β-blockers or diltiazem were also being administered.

10 While there are number of potential nitrate preparations that can be used for chronic long-term prevention of angina episodes, transdermal patches and isosorbide mononitrate (ISMN) are most commonly prescribed. Despite the fact that isosorbide dinitrate had proven to be effective, the three times a day dosing regimen would require that patients take a dose every 4 to 5 hours in order to provide an adequate nitrate-free interval. Two of the ISMN preparations are dosed twice daily. It is critical to be specific on the times of doses so patients do not take the dose 12 hours apart, and eliminate the nitrate-free interval. Dosing for these preparations should be dosed 7 hours apart, such as 7 am and 2 pm. One preparation is dosed once daily, which is designed as an extended-release preparation that provides 12 hours of nitrate exposure followed by a 12 hour nitrate-free interval. Transdermal NTG patches are typically prescribed as “on in the am and off in the pm.” It would be best if instructions were clear to provide specific times for application and remove. Finally, third shift workers need to have the timing of their nitrate therapy altered to correlate with when they are active and resting during a day.

Ranolazine

12 Unlike other agents used for the management of episodes of angina, ranolazine does not provide its benefit by impacting hemodynamics such as HR, BP, the inotropic state, or increase coronary

blood flow. Animal studies have demonstrated that ranolazine has little affinity for α_1, β_1, or β_2 adrenoreceptors and has minimal calcium channel blocking activity, but with no clinical significance. Ranolazine reduces ischemic episodes by selective inhibition of late sodium current (I_{Na}). Total sodium entry during an action potential in comprised of an early (fast) and late (slow) component. Under normal conditions, late I_{Na} constitutes only 1% of peak I_{Na}, or total I_{Na}. A number of preclinical studies have observed an increase in late I_{Na} that exceeds the duration of a typical action potential in ischemic and failing hearts.[89] It is not fully appreciated if this increase in late I_{Na} is due to an increase in density, or a dysfunction of these late Na^+ channels. The increase in intracellular Na^+ triggers an increase in the influx of Ca^{2+} through the reverse mode of the Na^+/Ca^{2+} exchanger, resulting in intracellular Ca^{2+} overload and eventually myocardial stunning.[90] It has also been demonstrated that intracellular Na^+ accumulation during ischemia is the substrate for reperfusion injury and that the Na^+ concentration kinetics during reperfusion, which is coupled with Ca^{2+} influx, also determines the degree of injury. Therefore, it is not the intracellular Na^+ concentration that produces ischemic damage, but its recognized role in Ca^{2+} accumulation via Na^+/Ca^{2+} exchange.[91] The rise in intracellular Ca^{2+} then directly contributes to lethal ischemic cell injury.[91] Increased intracellular Ca^{2+} also results in increased LV diastolic tension, increased myocardial oxygen consumption, depletion of adenosine triphosphate stores, and the potential for compression of the vascular space and further reduction of nutrient coronary blood flow to the ischemic territory. Through the mechanism of inhibiting late I_{Na}, ranolazine produces an overall reduction in intracellular Na^+. The reduction in intracellular Na^+ contributes to a reduction in the magnitude of ischemia-induced Ca^{2+} overload, and improves myocardial function as well as myocardial perfusion.[92]

Ranolazine is available as a sustained-release preparation with a half-life of approximately 7 hours and achieves steady state within 3 days of twice daily dosing. Ranolazine doses of 500 mg, 1,000 mg, and 1,500 mg, all twice daily, significantly increased total exercise duration, time to onset of angina, and time to 1 mm ST-segment depression compared to placebo.[93] While 1,000 mg twice daily was better than 500 mg twice daily, the difference between the 1,000 mg twice daily dose and the 1,500 mg twice daily dose was minimal. Due to the escalation of adverse events demonstrated with the 1,500 mg twice daily dose the 1,000 mg twice daily dose in the preferred regimen. When ranolazine 1,000 mg twice daily was added to existing therapy of atenolol (50 mg daily), diltiazem (180 mg daily), or amlodipine (5 mg daily), there was an increase in exercise duration, time to angina, time to 1 mm ST-depression, and a decrease in the number of angina episodes per week and number or SL NTG tablets used per week compared to the addition of placebo.[108] Ranolazine also demonstrated a significant reduction in weekly episodes of angina and SL NTG use when added to amlodipine 10 mg daily.[95]

In these trials, the average magnitude of increase in exercise duration over placebo was 29 to 50 seconds at peak and 24 to 34 seconds at trough. While these increases in exercise duration may seem of little clinical significance, this type of increase during an exercise tolerance test corresponds to a meaningful improvement in the ability of patients to carry on activities of daily living and take part in more minor types of exertion as compared to what is induced during testing. In one study, this magnitude of increase in exercise duration during testing was associated with a 25% reduction in the

weekly number of angina episodes and SL NTG use over placebo and almost a 50% reduction from baseline.[94] These increases in exercise duration demonstrated with ranolazine is consistent with results produced in similar patients with β-blockers, CCBs, and chronic nitrates.[96,97]

Patients should be initiated on ranolazine 500 mg twice daily, with the dose increased to 1,000 mg twice daily within the next 1 to 2 weeks as long as there are not significant side effects. Clearance of ranolazine is reduced by renal insufficiency and moderate hepatic impairment. Ranolazine is primarily cleared by the liver metabolic enzyme cytochrome P450 (CYP) 3A4 (70%-85%) and CYP 2D6 (10%-15%), as well as being a substrate of P-glycoprotein. Ranolazine is contraindicated in patients with liver cirrhosis.

Due to the extensive hepatic metabolism of ranolazine there are a number of significant drug interactions to be considered. Potent inhibitors of CYP3A4 and P-glycoprotein (ketoconazole, itraconazole, protease inhibitors, clarithromycin and nefazodone) or potent inducers of CYP3A4 and P-glycoprotein (phenytoin, phenobarbital, carbamazepine, rifampin, rifabutin, rifapentine, or St. John's wort) are contraindicated with use with ranolazine due to significant increases and decreases in ranolazine drug concentrations, respectively. Moderate inhibitors of CYP3A4, such as diltiazem, verapamil, erythromycin, and fluconazole, can be used with ranolazine, but the maximum dose should not exceed 500 mg twice daily in these patients. Due to a weak inhibition of CYP3A4 by ranolazine, doses of simvastatin should not exceed 20 mg daily if coadministered. Ranolazine increases digoxin concentrations 1.4- to 1.6-fold at trough and approximately 2-fold at peak plasma concentrations, most likely through competition for intestinal and renal P-glycoprotein. Agents that are potent inhibitors of P-glycoprotein, such as cyclosporine, my increase ranolazine concentrations leading to increased side effects and a dose reduction of ranolazine.

Ranolazine and metformin compete for renal clearance through the organic cation transporter 2, which has to potential to increase metformin drug concentrations and increase the risk of lactic acidosis. The impact on metformin concentrations in only thought to be clinically meaningful when both full does ranolazine (1,000 mg twice daily) and full dose metformin (1,000 mg twice daily) are used together at the same time. In this setting, the metformin dose should be reduced to 850 mg twice daily. There is not expected to be any change in blood glucose control, as the metformin dose of 850 mg twice daily with ranolazine 1,000 mg twice daily produces similar metformin concentrations as 1,000 mg twice daily without the use of ranolazine. Patients on ranolazine 500 mg twice daily do not need to alter their metformin doses.

Clinical trials have identified adverse effects with ranolazine that range in incidence from 4% to 6% including constipation, nausea, dizziness, and headache. Ranolazine also has a linear relationship between QTc interval and ranolazine plasma concentration, with a 2.6 msec increase in QTc per 1,000 ng/mL. Clinical studies have reported QTc prolongation of 15 msec or less at therapeutic doses. However, an analysis of the electrophysiological data obtained from the MERLIN-TIMI 36 (Metabolic Efficiency With Ranolazine for Less Ischemia in Non ST-Elevation Acute Coronary Syndrome Thrombolysis in Myocardial Infarction 36) trial demonstrated that ranolazine was associated with a reduction in arrhythmias compared to placebo.[98] Patients should not receive doses of more than 1,000 mg twice daily and caution should be used in patients receiving concomitant QTc-prolonging agents. Ranolazine has also demonstrated the ability to produce reductions in HgA1C. One study

found a statistically significant reduction in HgA1C of 0.70±0.18% with ranolazine 1,000 mg twice daily at 12 weeks.[94] Similarly, the MERLIN-TIMI 36 trial found a reduction in HgA1C of 0.64% from baseline.[98] These findings occurred in patients with or without diabetes. While ranolazine is not a treatment for DM, clinicians may find this property useful when targeting risk reduction goals.

While ranolazine has demonstrated efficacy and safety as monotherapy for patients with SIHD for treating angina episodes, it would only be an option in patient who cannot tolerate any of the traditional agents due to hemodynamic or other adverse effects. The number of patients fitting into this category would be expected to be relatively few. Ranolazine is recommended as add-on therapy to traditional anti-angina agents. Due to the lack of clinically meaningful impact on HR and BP, opportunities for ranolazine would be patients who achieve goal HR and BP and still have exertional angina symptoms, patients who cannot achieve these hemodynamic goals due to adverse effects, and patients who reach maximum dose of traditional agents, but still have angina symptoms.

NON-PHARMACOLOGIC THERAPY (REVASCULARIZATION)

Surgical revascularization plays an important and growing role in the treatment of SIHD. Revascularization options usually consist of coronary artery bypass grafting (CABG) surgery or PCI with or without stent placement. According to the AHA, approximately 492,000 PCI procedures are done in the United States annually, with about half being for management of SIHD.[3] Stents are used in over 90% of all patients undergoing PCI, with drug-eluting stents (DESs) accounting for 75% of all stent use compared to bare metal stent (BMS) use (25%). Approximately 219,000 patients undergo 397,000 CABG surgeries annually.[3] Other revascularization options are available and under development, but are less established.

The primary goal with revascularization is to prolong life, with the secondary goal being to eliminate or reduce symptoms. 5 Recommendations for revascularization over medical therapy as initial management to reduce mortality are described in Table 16-5, and recommendations for improvement in symptoms are described in **Table 16-9**.[1] 1 Whereas most of the pharmacologic approaches reduce MVO_2, revascularization increases myocardial oxygen supply in vessels with significant stenosis. This is accomplished by opening the vessel via PCI with or without stent placement, or using alternative transplanted vessels to bypass a critical stenosis in the setting of CABG surgery. While both of these therapies provide significant improvement in the care of patients with SIHD, and have advantages in certain groups of patients over a pharmacologic approach, both revascularization approaches have limitations.

TABLE 16-9 Revascularization to Improve Symptoms: ACC/AHA Recommendations[1]

Class I

1. CABG or PCI to improve symptoms is beneficial in patients with 1 or more significant (≥70% diameter) coronary artery stenoses amenable to revascularization and unacceptable angina despite GDMT. (LOE A)

Class IIa

1. CABG or PCI to improve symptoms is reasonable in patients with 1 or more significant (≥70% diameter) coronary artery stenoses and unacceptable angina for whom GDMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences. (LOE C)

2. PCI to improve symptoms is reasonable in patients with previous CAGB, 1 or more significant (≥70% diameter) coronary artery stenoses associated with ischemia, and unacceptable angina despite GDMT. (LOE C)

3. It is reasonable to choose CABG over PCI to improve symptoms in patients with complex 3-vessel CAD (eg, SYNTAX score >22), with or without involvement of the proximal LAD artery, who are good candidates for CABG. (LOE B)

Class IIb

1. CABG to improve symptoms might be reasonable for patients with previous CABG, 1 or more significant (≥70% diameter) coronary artery stenoses not amenable to PCI, and unacceptable angina despite GDMT. (LOE C)

2. TMR performed as an adjunct to CABG to improve symptoms may be reasonable in patients with viable ischemic myocardium that is perfused by arteries that are not amenable to grafting. (LOE B)

Class III: Harm

1. CABG or PCI to improve symptoms should not be performed in patients who do not meet anatomic (≥50% diameter left main or ≥70% non-left main stenosis diameter) or physiological (eg, abnormal FFR) criteria for revascularization. (LOE C)

Percutaneous Coronary Intervention

While the first use of balloon angioplasty was conducted on a femoral arterial stenosis by Dotter and Judkins in 1964, the first coronary balloon angioplasty was performed by Grüentizig in 1977. Initially, the procedure was done in a limited number of patients with symptomatic CAD who had single focal atherosclerotic plaque in a proximal coronary vessel. Since that time the use and techniques of the procedure have advanced several fold and is now performed in patients with multivessel CAD, total occlusions, diseased saphenous vein grafts (SVGs), and in patients with ST-elevation MI. The two major limitations of balloon angioplasty are abrupt vessel closure of the treated vessel, which occurred in 5% to 8% of cases and required emergency CABG surgery in 3% to 5%. The other main limitation is restenosis, which presents as recurrent symptoms and the need for repeat revascularization in approximately 30% to 50% of patients within the following year.[99] Today these complications have been dramatically reduced with the use of appropriate antithrombotic therapy and intracoronary stents, respectively. The term PCI encompasses the use of balloon angioplasty with

stent placement, as well as other less commonly used intracoronary procedures such as rotational atherectomy and aspiration thrombectomy.

The PCI procedure requires arterial access. While the femoral approach is most commonly used, a brachial or radial artery approach is gaining in acceptance due to lower rates of bleeding compared to a femoral approach. A sheath is placed in the artery to maintain access during the procedure. A guide catheter is then introduced through the sheath and advanced to the ostium of the coronary arteries. A guide wire is then advanced through the guide catheter and across the stenosis in the coronary vessel. The deflated balloon is then slid along the guide wire and to the site of the coronary stenosis. The balloon is then inflated. The inflated balloon expands the coronary lumen by stretching and tearing the atherosclerotic plaque. Due to physical disruption of the plaque during this process, antithrombotic therapy is necessary to prevent acute thrombosis and abrupt vessel closure. After the balloon is deflated, elastic recoil of the stretched vessel wall generally leaves a 30% to 35% residual diameter stenosis. The balloon, guide wire, guide catheter, and sheath are then removed, with pressure and possibly a closure device used to prevent bleeding at the site of arterial access. Most elective PCI procedures are completed in 30 to 60 minutes, depending of the complexity of the patient's CAD.

Stents provide a stainless steel scaffold within coronary arterials that can treat acute vessels closure, but mainly reduce restenosis. The stent is placed over the deflated balloon and advanced to the area of coronary stenosis. When the balloon is inflated, the stent expands into the coronary vascular wall. The balloon is then deflated, leaving the expanded stent permanently in the diseased coronary vessel. While stents have had a dramatic effect of reducing restenosis, and therefore repeat revascularizations, they have not demonstrated an ability to prevent death or MI compared to stand alone balloon angioplasty. Currently, more than 90% of PCI procedures include the use of a stent.[3]

Restenosis is a phenomenon characterized by the loss of more than or equal to 50% diameter of the lumen at the site of prior successful intervention, and almost occurs within the first 3 to 6 months. The pathophysiology of restenosis involves a complex cascade of the effects of various growth factors and cytokines, as each contributes to the progressive loss of luminal diameter via smooth muscle cell proliferation.[100] Restenosis typically occurs by one of the following mechanisms: early vessel recoil, late constrictive ("negative") remodeling, or neointimal proliferation.[100]

Elastic recoil is a nearly instantaneous phenomenon, occurring during the first hour after successful dilation of the vessel. As the vessel is stretched during balloon angioplasty, the endothelium lining the vessel becomes damaged. In response to the balloon induced stretching of the elastic fibers, these fibers begin to recoil back to their previous size.[100] Late constrictive remodeling, also referred to as negative remodeling, is mediated by myofibroblasts of the adventitia layer of the coronary vessel. Balloon-induced injury often results in exposure of the adventitia to the lumen. Cell proliferation begins as activated fibroblasts contribute to the enlargement of the adventitia. In time, these activated fibroblasts differentiate into myofibroblasts that are involved in the profibrotic and remodeling effects of the vessel.[101] As the adventitia becomes thick and fibrotic, a decrease in arterial cross-sectional area results, contributing to the process of restenosis.

The scaffold-like properties of a BMS are effective at preventing restenosis by controlling elastic

recoil and negative remodeling. Use of this technology has reduced restenosis rates from 30% to 50% with balloon angioplasty, to 15% to 30% with the use of BMS. However, stent-induced vessel injury and inflammatory reactions around stent struts trigger a set of events that ultimately lead to increased neointimal hyperplasia.[101] Neointimal proliferation, a normal response to vascular damage, is the target of the anti-proliferative effects of DES. Currently, DES are coated with sirolimus, paclitaxel, zotarolimus, or everolimus. These agents interrupt the cell cycle and prevent neointimal proliferation and reduce restenosis rates to approximately 5% to 10%.[102] This reduced need for repeat revascularization, along with the effectiveness of risk factor modification and better understanding of the patients who benefits from revascularization, has contributed to a slowing in the growth of the use of PCI over the last several years.

Despite the benefits in reducing restenosis demonstrated by the use of stents, the disadvantage is the risk of stent thrombosis due to exposed stent struts to circulating blood. Stent thrombosis is generally driven by the implantation of the stent into an atherosclerotic plaque, exposing platelet adhering proteins to the foreign stent surface. Patients are considered to be at risk of developing stent thrombosis until a thin layer of endothelial tissue can grow around the stent struts and prevent the exposure of the stent to the circulation. This process is called reendothelialization and typically occurs within 2 and 4 weeks after BMS deployment, with most adverse events occurring within the first 2 weeks after stent deployment. The process of reendotheliazation is significantly prolonged with the use of DES. The drugs used on these stents do not differentiate between a smooth muscle, neointimal, and an endothelial cell. Therefore, the mechanism of the benefit of reducing neointimal proliferation and restenosis also increases the duration of risk of stent thrombosis.

Stent thrombosis is a rare event (<5% of cases), but when it occurs it is usually catastrophic, with two-thirds of events associated with a large MI or death. The mortality rate alone from stent thrombosis ranges from 20% to 45%. Prevention of stent thrombosis is provided by the use of DAPT with aspirin and clopidogrel.

PCI vs Medical Therapy

6 Despite advancements in the technique of PCI and technology of stents, no study to date has demonstrated that PCI in patients with SIHD improves survival. This is most likely due the advancements in medical therapy and improved use of GDMT. A number of earlier studies demonstrated less recurrent angina in patients randomized to PCI compared to medical therapy, but PCI in these trials rarely included the use of stents, and medical therapy did not include the use of high-intensity statins or ACE inhibitors.[103]

The role of contemporary PCI and GDMT has been evaluated in two more recent clinical trials. In the COURAGE (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) trial, patients (n=2,287) with SIHD, and without elevated troponin or symptoms of heart failure, were randomized to GDMT alone or PCI with GDMT.[104] The components of GDMT in the COURAGE trial are defined in **Table 16-10**. Medication compliance was exceptional with more than 90% of patients being adherent to aspirin, β-blocker, and ACE inhibitor therapies. The LDL-C, systolic BP, and HgA1C goals were achieved in 70%, 65%, and 45% of patients, respectively. The primary outcome of death

and MI was not different between the groups after a median follow-up of 4.6 years (19.0% in PCI group vs 18.5% in GDMT group). While more patients were angina-free in the PCI group compared to the GDMT group at 1 year (66% vs 58%), there was no difference at the 5-year follow-up time point (74% vs 72%). There was a reduction in the need for revascularization after 5 years for patients randomized to PCI with GDMT compared to GDMT alone (21.1% vs 32.6%; <0.001). This trial confirms that even in modern day practice, PCI with GDMT does not offer a reduction in death and MI compared to GDMT alone, and PCI should be reserved for management of medication refractory angina in patients with SIHD. A 12-year follow-up of 53% of the originally randomized patients from the COURGAE trial did not demonstrate any difference in mortality between these groups (25% vs 24%; p=0.76).[105] These data underscore the importance of aggressive, goal-oriented, pharmacotherapy use in patients with SIHD. Two limitations to consider when evaluating the COURAGE trial include the low use of DES (<1%) and the number of patients in the GDMT group who crossed over and received PCI (33%). Since DES placement reduces rates of restenosis, and not death or MI, there was unlikely an impact on the primary outcome of the COURAGE trial, but there would have probably been a larger difference in the need for revascularization. While one-third of patients in the GDMT group did need to receive PCI over the course of 5 years, two-thirds did not. Therefore, supporting the lack of a need for all patients with SIHD to be treated with PCI as an initial management strategy.

TABLE 16-10 Guideline-directed Medical Therapy in the COURAGE Trial[104]

Medication Class	Drug	Indication
Antiplatelet agents	Aspirin (clopidogrel if patients intolerant to aspirin)	Aspirin for all subjects; clopidogrel as part of dual antiplatelet therapy for at least 1 month after PCI with a BMS
ACE inhibitors	Lisinopril	Hypertension, heart failure, LVEF <40%; encouraged for all patients
Angiotensin receptor blocker	Losartan	Consider in individuals with hypertension, clinical evidence of heart failure, or LVEF <40% who are intolerant to ACE inhibitors
Beta-blockers	Long-acting metoprolol	Hypertension, angina, or postmyocardial infarction
Thiazide diuretic	Any	Hypertension
Statin	Simvastatin	All patients
Calcium channel blocker	Amlodipine	Hypertension or angina
Long-acting nitrates	Isosorbide mononitrate	Angina
Niacin	Extended-release niacin	LDL-C >85 mg/dL, HDL-C <40 mg/dL, or triglycerides >150 mg/dL despite statin
Cholesterol absorption inhibitor	Ezetimibe	LDL-C >85 mg/dL despite statin
Fibrate	Fenofibrate	Triglycerides >150 mgdL despite statin

Medication Class	Drug	Indication
Omega-3 fatty acids	Various formulations	Triglycerides >150 mg/dL despite statin
Risk factor	Goal	
Smoking	Cessation	
Total dietary fat/saturated fat	<30%/<7% of calories	
Dietary cholesterol	<200 mg/day	
Physical activity	30-45 minutes, moderate intensity 5 times per week	
Body weight by BMI	Initial BMI: 25-27.5 kg/m^2 Goal: <25 kg/m^2	
	Initial BMI: >27.5 kg/m^2 Goal: 10% relative weight loss	
Blood pressure	<130/85 mm Hg (<130/80 mm Hg if diabetes or renal disease present)	
LDL-C	60-85 mg/dL (goal became <70 mg/dL during the study)	
HDL-C	>40 mg/dL	
Triglycerides	<150 mg/dL	
Diabetes	HbAc <7.0%	

PCI, percutaneous coronary intervention; BMS, body mass index; ACE, angiotensin converting enzyme; LVEF, left ventricular ejection fraction; LDL-C, low-density lipoprotein cholesterol; HDL-C, high-density lipoprotein cholesterol; BMI, body mass index.

The BARI 2D trial (Bypass Angioplasty Revascularization Investigation 2 Diabetes) trial randomized patients similar to those in COURGE, but they all had to have type 2 DM.[106] Patients in the BARI 2D trial (n=2,368) were randomized to GDMT alone or GDMT and revascularization with PCI or CABG surgery. The primary endpoint of freedom from death, MI, or stroke was not different between the groups after 5 years of follow-up (77.2% revascularization group vs 75.0% GDMT group; p=0.70). While patients receiving CABG surgery did have a lower rate of the primary endpoint compared to GDMT alone, there was no difference between patients receiving PCI compared to GDMT therapy. Approximately 35% of patients undergoing PCI in the BARI 2D trial received a DES.

While the COURAGE and BARI 2D trials suggest that PCI in SIHD should be reserved for treatment of medication refractory disease instead of an initial treatment approach, the results remain controversial with strong opinions of both sides. The ISCHEMIA trial (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches) is currently ongoing in an attempt to bring a final answer to this question. In an attempt to address limitation to the current data, the investigators will: (1) enroll patients before catheterization, so that anatomically high-risk patients are not excluded; (2) enrolling a higher-risk group with at least moderate ischemia; (3) minimizing crossovers; (4) using contemporary DES and physiologically guided decision making (FFR) to achieve complete ischemic (rather than anatomic) revascularization; and (5) being adequately powered to demonstrate whether routine revascularization reduces CV death or MI in patients with SIHD and at least moderate ischemia. An important secondary outcome will be a quality of life

assessment and evaluation of angina. An estimated 8,000 patients will be followed for an average of 4 years with enrollment projected to end in 2017.

Clinical Controversy...

Timing of PCI remains an issue of debate. One approach is to perform PCI once the diagnosis of SIHD is made. This approach has not demonstrated a reduction in hard outcomes such as death or MI. The most current data also do not support a reduction in episodes of angina. The ongoing ISHCEMIA trial should assist in settling this debate, but results are not due for several years.

Pharmacotherapy with PCI

The physical damage imposed on the atherosclerotic plaque during PCI with stent placement induces platelet recruitment and activation, leading to the potential for thrombus formation. Therefore, antithrombotic therapy with antiplatelet and anticoagulant therapy are necessary to produce a successful outcome. Antiplatelet therapy is also used after the procedure to reduce the risk of stent thrombosis.

All patients without a contraindication should receive aspirin before PCI and continued for life. Patients already on chronic aspirin therapy should take an additional 75 to 325 mg before PCI. Aspirin-naive patients should be given a dose of 325 mg at least 2 hours, and preferably 24 hours before PCI. Patients also receiving a stent (>90%) should also receive a $P2Y_{12}$ inhibitor before PCI.

A number of trials conducted in the 1990s demonstrated the benefit of glycoprotein (GP) IIb/IIIa inhibitors in patients undergoing elective PCI with stent placement. Abciximab demonstrated significant reduction in death and MI compared to placebo in the EPISTENT trial (Evaluation of Platelet IIb/IIIa Inhibition in Stenting).[107] There was also significant reduction in mortality with the use of abciximab at 1 year in the EPISTENT trial (1.0% vs 2.4%; p=0.037). In the ESPRIT trial (Enhanced Suppression of the Platelet IIb/IIIa Receptor with Integrilin Therapy) eptifibatide demonstrated a significant reduction in death and MI compared to placebo in patients undergoing PCI with stent placement.[108] The only head-to-head trial in these type of patients was TARGET (Do Tirofiban and ReoPro Give Similar Efficacy Trial), in which abciximab demonstrated a significant reduction in death, MI, or urgent revascularization compared to tirofiban (6.0% vs 7.6%; p=0.038).[109]

Despite the benefits demonstrated with GP IIb/IIIa inhibitors in patients undergoing PCI with stenting for SIHD, it is important to consider that these trials were conducted before pretreatment loading doses of clopidogrel 600 mg became part of standard of care. In the ISAR-REACT (Intracoronary Stenting and Antithrombotic Regimen-Rapid Early Action for Coronary Treatment) trial (n=2,159), patients received a clopidogrel 600 mg pretreatment dose at least 2 hours prior to elective PCI with stenting and were randomized to abciximab or placebo.[110] The incidence for the primary endpoints of death, MI, or revascularization between the abciximab and placebo groups at 30 days was similar (4% each). The ISAR-SWEET (Intracoronary Stenting and Antithrombotic Regimen: Is Abciximab a Superior Way to Eliminate Elevated Thrombotic Risk in Diabetics) trial (n=701) had a similar design as the ISAR-REACT trial, but included elective PCI patients with DM (excluded from ISAR-REACT).[111] The incidence of death and MI were similar between patients receiving abciximab and those not receiving

abciximab (8.3% vs 8.6%). These data suggest that the addition of a GP IIb/IIIa inhibitor to patients undergoing elective PCI for refractory stable angina pretreated with clopidogrel 600 mg does not confer additional benefit in the prevention of adverse cardiovascular events. While prasugrel and ticagrelor are oral $P2Y_{12}$ inhibitors that provide faster and more potent antiplatelet effect compared to clopidogrel, they have not been prospectively evaluated in the setting of elective PCI. There use should be reserved to patients with ACS, where their benefits over clopidogrel have been clearly demonstrated.

After elective PCI, DAPT needs to be continued to reduce the risk of stent thrombosis. In patients receiving a BMS, 4 to 6 weeks of DAPT is needed. In patients at high risk of bleeding, a minimum of 2 weeks can be given, as most reendothelialization of the stent surface should have occurred. Patients receiving a DES should receive at least a year of DAPT due to the delay, and somewhat unknown duration of the reendothelialization process in this setting. A Class III (harm) recommendation from the ACC/AHA for patients to receive a stent if it is thought that they will not tolerate or comply with the recommended duration of DAPT.[1] While some evidence suggest that the second generation DES (everolimus and zotarolimus) may not need a full year of DAPT, these studies are limited by small sample size, low event rates, and poor patient enrollment. The theory for a shorter duration of DAPT is based mainly on stent design. Second generation DES have thinner and less stent struts compared to first generation stents, which exposes less “stent” to the blood, and theoretically should lower the risk of stent thrombosis. The trade-off is a slightly lower reduction in restenosis compared to first generation DES. The results of the DAPT trial not only suggest that there is not a difference between the type of DES received, but also that a longer duration of DAPT (up to 30 months) provides a better reduction in CV adverse events compared to 12 months.[112] Therefore, the optimal duration of DAPT is being debated, but at least 6 to 12 months of DAPT in patients receiving any DES seems prudent.

Clinical Controversy…

The duration of DAPT after DES placement has not been determined. A number of relatively poorly conducted trials suggest less than 1 year may be adequate, while the highest quality trial suggest more than a year is optimal.

Anticoagulant therapy during PCI has traditionally been provided with unfractionated heparin (UFH) 70 to 100 units/kg with additional bolus doses (2,000-5,000 units) sufficient to maintain the activated clotting time between 250 to 300 seconds with the HemoTec device and 300 to 350 seconds with the Hemochron device. When using UFH with a GP IIb/IIIa inhibitor, bolus doses of 50 to 70 units/kg should be used to maintain an activated clotting time between 200 and 300 seconds (regardless of the device) to reduce the risk of major bleeding.

Enoxaparin has been evaluated in the setting of elective PCI in the STEEPLE (SafeTy and Efficacy of Enoxaparin in PCI patients, an internationaL randomized Evaluation) trial. Immediately before PCI, patients (n=3,528) received either a single intravenous dose of 0.5 mg/kg enoxaparin, 0.75 mg/kg enoxaparin, or appropriately dosed UFH.[113] The primary endpoint of non-coronary artery bypass graft-related bleeding in the first 48 hours was significantly reduced with enoxaparin 0.5 mg/kg compared to UFH (5.9% vs 8.5%), but not with enoxaparin 0.75 mg/kg compared to UFH (6.5% vs 8.5%). Ischemic endpoints of death, MI, and revascularization were not different between the groups.

Before the end of the trial, there was a significantly higher incidence of death in the patients receiving enoxaparin 0.5 mg/kg, and therefore, this arm of the trial was discontinued. At the end of the trial, and at the 1 year follow-up, this difference was not significant. It appears that either of these doses of enoxaparin are a possible alternative to UFH.

The direct thrombin inhibitor bivalirudin was evaluated in patients undergoing elective PCI in the REPLACE 2 (Randomized Evaluation in PCI Linking Angiomax to Reduced Clinical Events) trial.[114] Patients (n=6,010) in the REPLACE 2 trial were randomly assigned to receive bivalirudin with provisional GP IIb/IIIa inhibitor or UFH with planned GP IIb/IIIa inhibitor. The patient population involved both elective (about 75% of patients) and urgent PCI (about 25% of patients). Bivalirudin was administered as a 0.75 mg/kg bolus followed by a 1.75 mg/kg/h infusion for the duration of the procedure. The results of the REPLACE 2 trial demonstrated a significantly lower rate of bleeding with the use of bivalirudin compared to a GP IIb/IIIa inhibitor, with no significant difference in thrombotic events. Since GP IIb/IIIa inhibitors are typically reserved for high-risk patients with ACS, and rarely used in modern practice for patients undergoing PCI for SIHD, the utility of the REPLACE 2 data is difficult to determine.

Coronary Artery Bypass Graft Surgery

5 The majority of the data investigating the impact of CABG surgery on relieving angina symptoms and improving survival compared to initial medical therapy comes from three large multicenter randomized trials. These trials, the Veterans Administration Cooperative Study, the European Coronary Surgery Study and CASS (Coronary Artery Surgery Study), were initiated between 1972 and 1975.[115,116,117] All were powered to evaluate mortality benefit from CABG surgery compared to medical treatment. These trials have reported both short- and long-term outcomes and have provided the cardiology community valuable data on the role of CABG surgery in the treatment of SIHD.

There are several limitations to applying these data to current practice. As mentioned above, these trials were conducted three decades ago. Since that time cardiothoracic surgeons have gained significant experience in performing CABG surgery while newer techniques, such as off-pump and minimally invasive surgeries, have been utilized. Additionally, utilization of arterial grafts was limited to one trial in which only 14% of the patients received one vessel. These trials are also limited by the narrow spectrum of patients selected for enrollment. These trials primarily enrolled patients less than or equal to 65 years of age (>90%), very few women (<5%), and low to moderate risk patients who were clinically stable. Finally, the medical treatment in the comparative arm was clearly suboptimal by today's standard. Aspirin was not widely used, lipid lowering therapy and ACE inhibitors were not yet considered standard of care, and β-blockers were used in only about one-half of the patients.

5 Despite these issues, these trials along with a meta-analysis have provided us with valuable information about the role of an initial strategy of CABG surgery compared to medical management. Utilization of CABG surgery provides a mortality benefit in patients over medical management at 5 years (10.2% vs 15.8%; p=0.0001), 7 years (15.8% vs 21.7%; p<0.001) and at 10 years (26.4% vs 30.5%; p=0.03).[118]

5 Despite the survival benefit seen in the entire patient cohort, there were several subgroups of patients for which the survival benefit was even more profound. These patients included those at high risk of death without surgery (see Table 16-4). Patients with significant (>50% stenosis) left main CAD have a median survival of 13.3 years with CABG surgery compared to 6.6 years with medical treatment. Patients with left main equivalent disease (≥70% stenosis in both the proximal left anterior descending and proximal circumflex arteries) experience a similar survival advantage to CABG surgery. Patients with three-vessel disease with reduced LV function, or two- or three-vessel disease with more than 75% stenosis in the proximal left anterior descending also have pronounced benefit from CABG surgery compared to medical therapy. Female and older patients have a higher risk of short-term mortality, but have a similar long-term prognosis compared to the general population.

There is an increase in the event rate in patients randomized to CABG surgery in the long-term follow-up period. This is related to the progressive atherosclerotic disease in native vessels as well as graft disease over time. Atherosclerotic obstruction of a native coronary vessel, leading to ischemic complications, usually takes five or more decades to accumulate, but the life span of a saphenous vein graft (SVG) is significantly shorter. Studies have shown occlusion rates of SVGs to be 20% to 25% at 5 years and almost 40% at 10 years, with one-half of all the remaining patent vessels showing atherosclerotic changes. This is due to the inability of SVG endothelium to withstand the increased BP seen on the arterial side compared to venous pressures. The endothelial damage and incorporation of LDL-C accelerates the atherosclerotic process significantly. The use of arterial grafts has provided promise in reducing occlusion of the coronary artery bypass grafts. The most commonly used arterial graft is the internal mammary artery (IMA), which has shown graft patency to be greater than 90% at 10 years. Due to similar endothelial and smooth muscle cell function, arterial grafts are better designed to accommodate arterial BP compared to SVGs. Limitations to the use of arterial grafts include vasospasm and long surgical times for harvest. Due to the increased time needed, arterial grafts are not ideal in the setting of emergency CABG surgery. There may also be an increase in wound infections in diabetic or obese patients receiving bilateral IMA grafts.

Despite the advancements in technique and patient care, CABG surgery still has some significant complications. One of the most feared and most common (~ 6%) complications is postoperative neurological impairment, which may be attributed to hypoxia, emboli, hemorrhage, or a metabolic abnormality during or shortly after the surgery. Neurological complications are divided into type 1 and type 2 deficits. A type 1 deficit is associated with major, focal neurological deficits, stupor, or coma. In a type 2 deficit, a reduction in intellectual function and memory is present. The incidence of neurologic deficits is equal between the two types, while mortality may be as high as 21% and 10% respectively. Many deficits are not clinically significant and resolve with time. Patients with advanced age and/or a history of HTN are at increased risk of a neurological complication after CABG surgery.

Other non-cardiac complications of CABG surgery include renal dysfunction and mediastinitis. Postoperative serum creatinine levels more than 2.0 mg/dL or an increase in baseline creatinine level of more than 0.7 mg/dL occurs in as many as 8% of CABG surgery patients. While most patients recover without problems, the mortality rate in these patients is 19%, and increases to almost 65% in the 1.5% of CABG surgery patients that require dialysis. Patients with advanced age, a history of heart failure, prior CABG surgery, DM type 1, and preexisiting renal impairment are at an increased risk of

developing postoperative renal dysfunction. Patients with preoperative renal dysfunction (serum creatinine >2.5 mg/dL) are at an exceptionally high risk of needing postoperative hemodialysis (40%-50%). Despite the infrequent occurrence of mediastinitis (1%-4%), the mortality rate can be as high as 25%. Patients with obesity, reoperation, use of both IMAs, longer surgeries with increased complexity, and DM are at increased risk of developing postsurgical mediastinitis.

New approaches to CABG surgery have been developed in an attempt to minimize the morbidity related to the operation. One of these approaches is the off-pump bypass coronary surgery that is performed on a beating heart. This type of surgery currently accounts for about 20% of all CABG surgeries performed in the United States. Patients undergoing off-pump bypass experience the same relief from angina, vessel patency, and mortality benefit (evaluated out to 1 year) as traditional CABG surgery. Patients utilizing off-pump bypass with sternotomy can undergo multivessel bypass, but data on patients with left main disease and impaired LV function are limited. By reducing the need for cardiopulmonary bypass and preventing the need for clamping of the aorta, there is a significant reduction in adverse neurologic events, length of hospitalization, and cost. The cardiac motion is reduced by a number of pharmacological and mechanical devices. These include slowing the HR with β-blockers and non-DHP CCBs, creating a temporary cardiac arrest with adenosine, or vagal simulation.

The use of minimally invasive direct CABG is conducted without median sternotomy and without the use of cardiopulmonary bypass. In addition to the benefits of avoiding cardiopulmonary bypass, the prevention of sternotomy reduces the incidence of wound infections as well as patient recovery time. Due to the small incision and technical difficulty of the surgery, it is limited to patients with single vessel disease of either the LAD or right coronary artery. Both of these newer types of procedures are limited by the needed learning curve of the surgeon and lack of long-term follow-up for patency and mortality compared to standard CABG surgery.

Pharmacotherapy after CABG surgery includes aspirin and lipid-lowering therapy (ACC/AHA Class I recommendations). Aspirin in doses between 100 mg a day to 325 mg three times daily have been shown to be effective in reducing vein graft closure during the first year after the surgery. It is recommended that the first dose of aspirin be given within the first 24 hours of surgery. The efficacy of aspirin is lost if initiation is delayed more than 48 hours postoperatively. Aspirin is usually continued indefinitely due to its benefit in primary and secondary prevention of acute MI. If patients are truly aspirin allergic, clopidogrel is an acceptable alternative. Due to the accelerated atherosclerotic process in patients with SVGs, lipid-lowering therapy should be used aggressively to a target LDL-C of less than 100 mg/dL. The Cholesterol Lowering Atherosclerotic Study and the Post Coronary Artery Bypass Graft Trial have both shown angiographic evidence of significant reductions in SVG atherosclerosis. The need for long-term anti-angina therapy is significantly reduced with the use of CABG surgery. Only 30% of patients undergoing CABG surgery required chronic nitrate or β-blocker therapy compared with over 70% of medically treated patients. It would be reasonable to include a β-blocker and/or CCB for the treatment of preexisting HTN after surgery. Patients need to continue to have access to SL NTG after surgery. Smoking cessation (ACC/AHA Class 1 recommendation) and cardiac rehabilitation are also critical to successful postoperative outcomes.

CABG Surgery vs PCI

The decision to undergo PCI or CABG surgery as initial treatment is based on the severity of coronary stenoses, number of diseased vessels, location of stenosed vessels, as well as LV function. Several randomized clinical trials have compared revascularization strategies. Unfortunately, there are significant limitations to many of these trials. A number of the older trials compared CABG surgery with balloon angioplasty. Since less than 10% of patients who undergo PCI receive only balloon angioplasty without a stent, data from these trials are not reflective of modern practice. Most of the other trials compared CAGB surgery to PCI with a BMS, and only three trials comparing CABG surgery with PCI with a DES. Since 75% of stent use in modern practice is a DES, the seemingly large number of comparison trials does not offer as much information as would be expected. Even the more contemporary trials have limitations. Since CABG surgery was utilized for almost a decade before PCI, patient groups who had already demonstrated benefit from CABG surgery compared to medical treatment were not heavily included in these trials. Recruitment of patients in these trials proved to be difficult since patients with three-vessel disease seemed to be referred to CABG surgery, and patients with one- or two-vessel disease seemed to be referred to PCI prior to enrollment. Less than 10% of patients enrolled in these trials had an ejection fraction less than 50%. These trials enrolled patients with stable and unstable CAD, but the results did not appear to vary between the two types of patients.

One of the largest comparison study was the BARI trial, which randomized 1,792 patients to either PCI or CABG surgery to evaluate the primary endpoint of mortality at 5 years.[119] Most patients had normal LV function and had one- or two-vessel disease with a low utilization of stents. Survival at 5.4 years and freedom from MI was not different between the groups. There was a higher incidence of inhospital MI in patients receiving CABG surgery, but there was a significant increase in rehospitalization and need for repeat revascularization over the follow-up period for those randomized to PCI. Despite the initial increase in cost of CABG surgery, the cost of the two revascularization approaches became almost neutral, due to the higher need for repeat procedures in PCI patients. Despite the longer follow-up and larger number of patients compared to other trials, BARI is still limited due to the narrow scope of patients enrolled and the high crossover rate of PCI patient that received CABG surgery (31%).

The largest randomized clinical trial comparing CABG surgery to PCI with DES was the SYNTAX trial (Synergy between PCI with TAXUS and Cardiac Surgery).[120] In this trial 1,800 patients with left main or three-vessel disease were randomized to revascularization with PCI with DES or CABG surgery. At 3 years, the composite primary endpoint of death, stroke, MI, or repeat revascularization occurs significantly less often in the patients receiving CABG surgery compared to PCI with DES (20.2% vs 28.0%; $p<0.001$). While the rates of death and stroke were not different between the groups, the rates of MI (3.6% vs 7.1%) and repeat revascularizations (10.7% vs 19.7%) were higher with the use of PCI with DES compared to CABG surgery.

In the SYNTAX trial, the extent of CAD was assessed using the SYNTAX score. This scoring system is based on the location, severity, and extent of coronary stenoses, with a lower score indicating less complicated anatomic CAD. In a post-hoc analysis of the SYTNAX trial, a low score was defines as less than or equal to 22, an intermediate score was 23 to 32, and a high score was more than or equal to 33. The incidence of the primary endpoint correlated with the SYNTAX score for patients receiving PCI

with DES, but not with those receiving CABG surgery. At 12 months, patients with a low SYNTAX score had a similar outcome regardless of the type of revascularization received, although those with intermediate or high scores did better if they received CABG surgery compared to PCI with DES. At the 3-year follow-up, the difference in the primary endpoint increased between PCI with DES and CABG surgery as the SYNTAX score increased. Therefore, patients with relatively uncomplicated and less extensive CAD could receive either revascularization approach, but those with more complex and diffuse disease would seem to benefit from CABG surgery.

MANAGEMENT OF EPISODES OF FIXED THRESHOLD ANGINA

Medical management of improving patient's quality of life through control of angina episodes follows a stepwise approach (see Fig. 16-5). [11] All patients should have access to SL NTG for treatment of a current episode of angina. Patients need to be sure to be adequately educated on appropriate use and storage, as well as being sure they have consistent access to the tablets or spray. This may require patients to have multiple vials or canisters that are in areas that they spend time (eg, home, work, car, and garage). While some patients may only need SL NTG for infrequent attacks, many patients will require chronic treatment for prevention of angina episodes. [4] Patients experiencing frequent angina episodes, or in whom angina is impacting quality of life, should receive chronic therapy. The goal of chronic therapy to provide complete or nearly complete elimination of angina episodes while having the patient take part in normal activities. The mechanism of chronic therapy is typically to prevent increases in MVO_2 that surpass the reduction in myocardial oxygen supply.

[9] An initial goal in the reduction in MVO_2 is to lower the patient's resting HR to 50 to 60 beats per minute and an exercise HR of less than 100 beats per minutes. It should be noted that not all patients, especially elderly patients can tolerate an HR in this range, and therefore the goal HR would be as low as the patient can tolerate above 60 beats per minute. Reductions in HR also alter the cardiac cycle to increase diastolic filling time and an improvement in myocardial perfusion. Hence, initial chronic management of angina episodes to achieve this goal HR is either a β-blocker or a non-DHP CCB (verapamil or diltiazem). These agents not only reduce HR, but also contractility and myocardial wall tension (through BP reduction). Both agents are effective for increasing exercise duration and reducing the number of weekly angina episodes. While there have been a number of studies comparing β-blockers and CCBs in patients with SIHD, many of these trials demonstrating an advantage of β-blocker therapy were compared to DHP CCBs, and not HR lowering non-DHP CCBs. The APSIS trial (Angina Prognosis Study in Stockholm) did compare sustained-release metoprolol to sustained-release verapamil in patients with SIHD.[121] After the mean follow-up of 3.4 years, there was no significant difference in the occurrence of CV events (30.8% vs 29.3%) or mortality (5.4% vs 6.2%) between metoprolol and verapamil. These findings suggest that CV outcomes and mortality are similar regardless of whether a β-blocker or a non-DHP CCB is used as initial therapy in patients with SIHD.

[9] β-blockers are currently recommended over CCBs as initial therapy for control of angina episodes in patients with SIHD.[1] This recommendation is mainly based on the improved survival demonstrated

with the use of β-blockers in patients after MI. After the acute episode, these patients are often treated as those with SIHD. The mortality benefit in patients with LV dysfunction is also a contributing factor to this recommendation. It should be noted that only carvedilol, SR metoprolol, and bisoprolol should be used in patients with LV systolic dysfunction, starting with low doses and titrating up in a slow and set regimen. None of the non-DHP CCBs have demonstrated similar benefits in patients with MI or LV dysfunction. Patients with contraindications or intolerable side effects to β-blocker therapy, not related to HR lowering, should use verapamil or diltiazem as initial therapy. In patients without a history of MI or HF, the use of β-blocker therapy does not provide a survival advantage and is used purely for control of ischemic episodes and symptoms of angina.

If angina symptoms are controlled once the goal HR is achieved, then no further chronic therapy is necessary and patients are monitored for continued efficacy and side effects. Regardless of whether a β-blocker or non-DHP CCB are selected as initial therapy, many patients will require combination therapy to attain adequate control of their symptoms. [10] If additional therapy is required, control of BP helps decide the next step in therapy. Patients who continue to have a BP above the goal of 140/90 mm Hg should be prescribed a DHP CCB as their next agent. Since long-acting nitrates and ranolazine are not used to treat HTN, and DHP CCBs are effective agents for reducing MVO_2 and BP, they are a logical selection for use in these patients. The addition of a DHP CCP to a β-blocker has demonstrated efficacy in improving exercise duration and reducing weekly angina episodes.[122,123] While the addition of a DHP CCB to a non-DHP CCB is not often used, the different targets of calcium channel blockade do make this a rational regimen, so long as appropriate consideration is paid to the potential additive hemodynamic effects that may manifest in an individual patient.

[10] [12] Patients with continued angina episodes after achieving the goal HR, and having controlled BP, should receive a long-acting nitrate or ranolazine added to their regimen. Both agents have demonstrated efficacy when used in combination therapy. While long-acting nitrates are not optimal agents as monotherapy due to their ability to cause reflex tachycardia, this is avoided in patients who have already achieved HR control with a β-blocker or non-DHP CCB. The inability of ranolazine to reduce HR or BP make it an option in these patients who have already achieved their HR and BP goals, but still have exertional angina. The selection of one agent over the other is mainly based on patient preferences and tolerability. Long-acting nitrates do not provide 24-hour angina protection, but this may not be an issue for all patients. Ranolazine provides 24-hour protection, but is a more expensive agent compared to generic nitrates. Ranolazine has a more attractive side effect profile compared to long-acting nitrates, but the severity of these effects will be patient specific.

Clinical Controversy…

When to initiate ranolazine continues to be a point of controversy. While ranolazine has proven to be an effective and well tolerated agent for the management of episodes of angina, it is much more expensive. All other agents used for control of symptoms of angina are available in generic formulations, with many be only $4 a months.

Similar to the treatment of HTN, it is reasonable for patients to eventually end up on multiple agents in the attempt to achieve full control of angina symptoms and have patients fully participate in the

activities that bring them joy in life. Patients who are unable to achieve this goal are defined as having refractory angina. Patients with refractory angina are those who continue to have symptoms, despite maximally tolerated therapy. Due to contraindications or intolerance to higher doses of medications, patients may end up with refractory angina with a smaller medication list than others, and not on full doses of anti-angina agents. Patients with refractory angina should be referred for revascularization therapy.

Management of Variable Threshold Angina and Prinzmetal's Angina

2 Patients with variable-threshold angina require pharmacotherapy that assists in management of vasospasm. While β-blockers are typically the agents of first choice in patients with fixed-threshold angina, they are not appropriate agents for patients with vasospasm. Although not all studies report increased painful episodes of angina with the addition of β-blockers in patients with vasospasm, they may induce coronary vasoconstriction and prolong ischemia, as documented by continuous ECG monitoring. The mechanism of worsening angina is most likely due to unopposed α^1-adrenergic receptor stimulation during β-blockade.

Both nitrates and CCBs are effective agents for reducing vasospasm. Most patients respond well to SL NTG for acute attacks. While long-acting nitrates can be used in the treatment of vasospasm, the high doses typically needed for adequate symptom control are not well tolerated. Therefore, nitrates are often given with CCBs. There is no preference to which agent is selected first, but CCBs are given less times a day and may allow for a single agent to be used to manage symptoms. Nifedipine, verapamil, and diltiazem are all equally effective as single agents for the initial management of coronary vasospasm. Dose titration is important to maximize the response with CCBs. Comparative trials are few in number and do not reveal significant differences among these three drugs for vasospasm. Patients unresponsive to calcium antagonists alone may have nitrates added.

EVALUATION OF THERAPEUTIC OUTCOMES

The two main therapeutic outcomes in the management of patients with SIHD are to prolong life and reduce symptoms of angina. Both of these should be accomplished while minimizing adverse effects to medications and improving the patient's quality of life. While "improved mortality" does not have a defined monitoring parameter, focus on surrogate endpoints, such as BP goal, use of high-intensity statin, HbA1c goal, smoking cessation, and weight loss from appropriate diet and exercise regimens, are targets that patients and clinicians can work on accomplishing. Patients may need to be evaluated every 1 to 2 months until goals are achieved. Follow-up then every 6 to 12 months would be appropriate.

4 Improvement in symptoms of angina should include reducing the number of angina episodes and weekly SL NTG use, as well as increasing their exercise capacity, or duration of exertion needed to induce angina. This should be accomplished while the patient is able to do the things in life that they want to do. It is not uncommon for patients to report reduced or no episodes of angina because they have given up on doing things that bring on angina. Once patients have been optimized on medical therapy, symptoms should improve over 2 to 4 weeks and remain stable until their disease

progresses. There are several instruments such as the Seattle Angina Questionnaire and CCS, which can be used to improve the reproducibility of symptom assessment. If the patient is doing well, then no other assessment may be necessary. While objective assessment of control of ischemic episodes can be obtained by performing follow-up ETT with or without cardiac imaging, due to their expense they are rarely used unless patients are not responding to treatment. Patients receiving revascularization still require assessment of symptoms of angina at least every 6 to 12 months since a return of angina is not uncommon.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACC	American College of Cardiology
ACE	angiotensin converting enzyme
ACS	acute coronary syndrome
AHA	American Heart Association
ARB	angiotensin receptor blocker
ASPECT	aspirin-induced platelet effects
AV	atrioventricular
BARI	Bypass Angioplasty Revascularization Investigation
BMS	bare metal stent
BNP	B-type natriuretic peptide
BP	blood pressure
CAPRIE	The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events
CABG	coronary artery bypass grafting
CAD	coronary artery disease
CCS	Canadian Cardiovascular Society
CCB	calcium channel blocker
CHARISMA	Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance
CHD	coronary heart disease
COX	cyclooxygenase
CVD	cardiovascular disease
DAPT	dual antiplatelet therapy
DES	drug eluting stent
DHP	dihydropyridine
DM	diabetes mellitus
ECG	electrocardiogram
EDRF	endothelium-derived relaxing factor
FFR	fractional flow reserve

GDMT	guideline-directed medical therapy
GP	glycoprotein
HDL-C	high-density lipoprotein cholesterol
HR	heart rate
HTN	hypertension
IMA	internal mammary artery
ISMN	isosorbide mononitrate
LDL-C	low-density lipoprotein cholesterol
LOE	Level of Evidence
LV	left ventricular
MI	myocardial infarction
MVO_2	myocardial oxygen demand
NT-proBNP	N-terminal pro B-type natriuretic peptide
PCI	percutaneous coronary intervention
PPI	proton pump inhibitor
PREMIER	Prospective Registry Evaluating Myocardial Infarction: Events and Recovery
SIHD	stable ischemic heart disease
SL NTG	sublingual nitroglycerin
SVG	saphenous vein graft
UFH	unfractionated heparin

Chapter 17: Acute Coronary Syndromes

Kelly C. Rogers; Simon de Denus; Shannon W. Finks; Sarah A. Spinler

INTRODUCTION

KEY CONCEPTS

- 1 The cause of an acute coronary syndrome (ACS) is the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, and aggregation, and the activation of the clotting cascade. Ultimately, a clot forms composed of fibrin and platelets.
- 2 National guidelines exist for ACS patient care for ST-segment elevation (STE) myocardial infarction (MI) and non–ST-segment elevation (NSTE) ACS, including guidelines for patients undergoing percutaneous coronary intervention (PCI).
- 3 Patients with ischemic chest discomfort and suspected ACS are risk-stratified based on a 12-lead electrocardiogram (ECG), clinical presentation, past medical history, and results of the troponin assays. The diagnosis of MI is confirmed based on the results of the troponin biochemical marker tests.
- 4 Early reperfusion therapy with primary PCI of the infarct artery is recommended for patients presenting with STEMI within 12 hours of symptom onset.
- 5 The most recent PCI practice guidelines recommend coronary angiography with either PCI or coronary artery bypass graft (CABG) surgery revascularization as an early treatment (early invasive strategy) for patients with NSTE-ACS at an elevated risk for death or MI, including those with a high risk score or patients with refractory angina, acute heart failure, other symptoms of cardiogenic shock, or arrhythmias.
- 6 In addition to reperfusion therapy, other early pharmacotherapy that all patients with STEMI and without contraindications should receive within the first day of hospitalization, and preferably in the emergency department (ED), are intranasal oxygen (if oxygen saturation is low), sublingual (SL) nitroglycerin (NTG), aspirin, a $P2Y_{12}$ inhibitor (clopidogrel, prasugrel, or ticagrelor depending on reperfusion strategy), and anticoagulation with bivalirudin, unfractionated heparin (UFH), enoxaparin, or fondaparinux (Agent dependent on reperfusion strategy). A glycoprotein IIb/IIIa inhibitor (GPI) may be considered if UFH is selected as the anticoagulant for patients undergoing primary PCI. A high-intensity statin should be administered prior to PCI. Intravenous (IV) β-blockers

and IV NTG should be administered cautiously in selected patients. Oral β-blockers should be initiated within the first day in patients without contraindications.

- 7 In the absence of contraindications, all patients with NSTE-ACS should be treated in the ED with intranasal oxygen (if oxygen saturation is low), SL NTG, aspirin, and an anticoagulant (UFH, enoxaparin, fondaparinux, or bivalirudin). High-risk patients should proceed to early angiography, and may receive a GPI. A $P2Y_{12}$ inhibitor (selection of agent and timing of indication dependent on interventional (PCI versus CABG surgery) versus conservative approach (medical managment/also referred to as "ischemia-guided approach")) and should be administered to all patients. A high-intensity statin should be administered prior to PCI. IV β-blockers and IV NTG should be administered cautiously in selected patients. Oral β-blockers should be initiated within the first day in patients without contraindications.

- 8 Secondary prevention guidelines suggest that following MI from either STEMI or NSTE-ACS, all patients, in the absence of contraindications, should receive indefinite treatment with aspirin, a β-blocker, a moderate to high-intensity statin, and an angiotensin-converting enzyme (ACE) inhibitor for secondary prevention of death, stroke, or recurrent infarction. A $P2Y_{12}$ inhibitor should be continued for at least 12 months for patients undergoing PCI and for patients treated medically (without PCI or thrombolytics). Clopidogrel should be continued for at least 14 days, and ideally 1 year, in patients with STEMI treated with fibrinolytics. An angiotensin II receptor blocker and an aldosterone antagonist should be given to selected patients. For all patients with ACS, treatment and control of modifiable risk factors such as hypertension (HTN), dyslipidemia, obesity, smoking, and diabetes mellitus (DM) are essential.

- 9 To determine the efficacy of nonpharmacologic treatments and pharmacotherapy, monitor patients for relief of ischemic discomfort, return of ECG changes to baseline, and absence or resolution of heart failure signs and symptoms. Patients should be monitored for adverse drug reactions that can be induced from pharmacotherapy of ACS.

Cardiovascular disease (CVD) is the leading cause of death in the United States and one of the major causes of death worldwide. *Acute coronary syndrome* (ACS), including unstable angina (UA) and *myocardial infarction* (MI), is a form of coronary heart disease (CHD) that comprises the most common cause of CVD death.[1] 1 The cause of an ACS is primarily the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, and aggregation, and the activation of the clotting cascade. Ultimately, a clot forms composed of fibrin and platelets. 2 National guidelines recommend strategies for ACS patient care for *ST-segment elevation* (STE), *non–ST-segment elevation* (NSTE) ACS, and for *percutaneous coronary intervention* (PCI), including PCI in the setting of ACS.[2,3,4] These practice guidelines are based on a review of available clinical evidence, have graded recommendations based on evidence and expert opinion, and are updated periodically. These guidelines form the cornerstone for quality care of the ACS patient.

EPIDEMIOLOGY

One in seven deaths are secondary to CHD in America. It is estimated that every 42 seconds, an

American will experience an MI.[1] Each year, more than 1.1 million persons are discharged from the hospital with a diagnosis of an ACS with 813,000 diagnosed with MI. Annually, approximately 660,000 Americans will have a new "coronary event" (a first hospitalization for an MI or CHD death), while 305,000 will have a recurrent event. It is estimated that 116,800 Americans die of an MI each year.[1] Moreover an estimated additional 160,000 Americans will have a "silent MI", which means that approximately more than 21% of individuals who experience a coronary event will not experience any, or only minimum symptoms. This nevertheless places these individuals at high-risk of subsequent additional events and death. Although the overall death rates from CHD has declined by 38% from 2003 to 2013, the estimated annual mortality in the first year following a new coronary event and MI remain high at 34% and 15%, respectively necessitating careful attention to secondary prevention measures.[1] Hospitals are required to report mortality rates and 30-day readmission rates following MI to the Centers for Medicare and Medicaid Services. These data are publically available and reported as better than, no different than, or worse than the national rate.[5]

Of patients presenting with suspected ACS, approximately 31% have STEMI, 32% NSTEMI, 26% UA, 8% another cardiac diagnosis, and 4% a noncardiac final diagnosis. The mean length of hospital stay is 3 days. An analysis of hospitalizations from the Healthcare Cost and Utilization Project's Nationwide Inpatient Sample reported unadjusted in-hospital mortality rates for STEMI of 3.52% in patients undergoing PCI and 14.91% for patients receiving no revascularization during hospitalization.[6] Analogous in-hospital mortality rates for NSTEMI were lower at 1.45% and 6.26%, respectively in 2011.[6] Nevertheless, data from Worcester, MA, indicate that at 1 year post-discharge mortality rates may be higher for NSTEMI than STEMI, with rates of 18.7% and 8.4%, respectively.[1] This suggests that more energy should be put in using disease-modifying therapies following hospital discharge in patients with NSTEMI. Other than persistent ST-segment changes and troponin, other predictors of in-hospital mortality include older age, elevated serum creatinine (SCr)/renal dysfunction, tachycardia, and heart failure (HF).

The cost of heart disease is high, with estimated direct and indirect costs of more than $207.3 billion in the United States.[1] These costs include MI and CHD, which at $11.5 and $10.4 billion respectively, represented 2 of the 10 most expensive hospital principal discharge diagnoses in 2011. The reported cost of hospitalization for STEMI or NSTEMI in the United States in 2011 was reported to be $19,000.[6]

ETIOLOGY

Endothelial dysfunction, inflammation, and the formation of fatty streaks contribute to the formation of atherosclerotic coronary artery plaques, the underlying cause of coronary artery disease (CAD).[7] 1 The predominant cause of ACS in more than 90% of patients is atheromatous plaque rupture, fissuring, or erosion of an unstable atherosclerotic plaque. This is called an MI type 1, which generally occurs in coronary arteries where the stenosis occludes less than 50% of the lumen prior to the event; rather than a more stable 70% to 90% stenosis of the coronary artery.[3,9,10]. MI type 2 is related to a reduction in myocardial oxygen supply or an increase in myocardial demand in the absence of a coronary artery process. MI type 3 is defined as MI resulting in death without the possibility of measuring biomarkers, while MI types 4 and 5 occur during revascularization procedures.[10] Stable plaques are characteristic of stable angina.

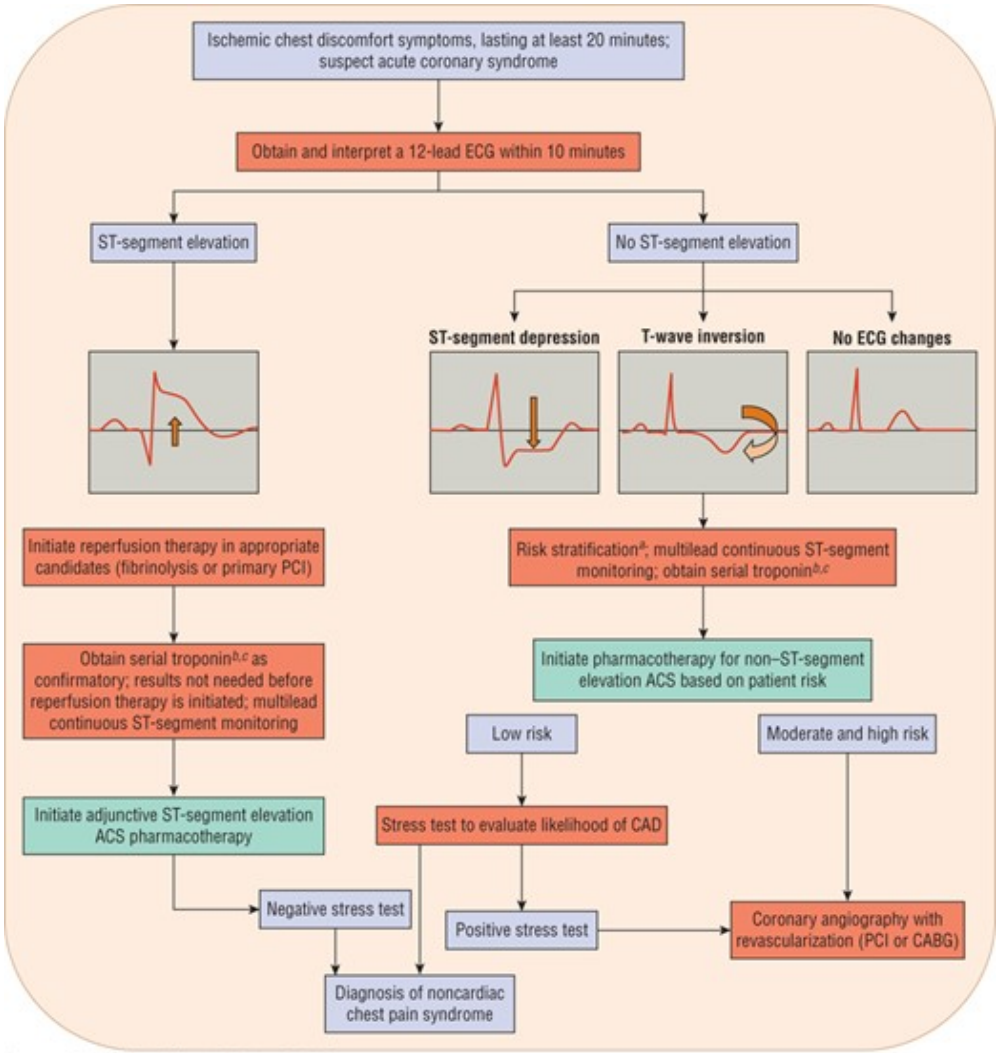
PATHOPHYSIOLOGY

Spectrum of ACS

Acute coronary syndrome includes all clinical syndromes compatible with acute MI resulting from an imbalance between myocardial oxygen demand and supply. In contrast to stable angina, an ACS results primarily from diminished myocardial blood flow secondary to an occlusive or partially occlusive coronary artery thrombus. ACS is classified according to electrocardiogram (ECG) changes into STEMI or NSTE-ACS (NSTEMI and UA) (**Fig. 17-1**).[3] A STEMI occurs when symptoms of myocardial ischemia occur in conjunction with new STE with subsequent release of biomarkers of myocardial necrosis, mainly *troponins T* or *I*.[2] A STEMI typically results in an injury that transects the thickness of the myocardial wall. Following a STEMI, pathologic Q waves are frequently seen on the ECG, indicating transmural MI, whereas such an ECG manifestation is seen less commonly in patients with NSTEMI.[3] NSTEMI is limited to the subendocardial myocardium and is not as extensive as STEMI. NSTEMI differs from UA in that ischemia is severe enough to produce myocardial necrosis resulting in the release of a detectable amount of *troponins T* or *I*, from the necrotic myocytes in the bloodstream. The clinical significance of serum markers will be discussed in greater detail in later sections of this chapter.

FIGURE 17-1

Evaluation of the acute coronary syndrome patient. [a]*As described in Table 17-1*. [b]"Positive": Above the myocardial infarction decision limit. [c]"Negative": Below the myocardial infarction decision limit. (ACS, acute coronary syndrome; CABG, coronary artery bypass graft; CAD, coronary artery disease; ECG, electrocardiogram; PCI, percutaneous coronary intervention.) *(Used with permission from Spinler SA. Evolution of antithrombotic therapy used in acute coronary syndromes. In: Richardson MM, Chant C, Cheng JWM, et al., eds. Pharmacotherapy Self-Assessment Program. Book 1: Cardiology, 7th ed. Lenexa, KS: American College of Clinical Pharmacy, 2010.)*



Plaque Rupture and Clot Formation

Following plaque rupture, a clot (a partially or completely occlusive thrombus) forms on top of the ruptured plaque. The thrombogenic contents of the plaque are exposed to blood elements. Exposure of collagen and tissue factor induces platelet adhesion and activation, which promote the release of platelet-derived vasoactive substances including adenosine diphosphate (ADP) and thromboxane A_2 (TXA_2).[7] These produce vasoconstriction and potentiate platelet activation. Furthermore, during platelet activation, a change in the conformation in the glycoprotein (GP) IIb/IIIa surface receptors of platelets occurs that cross-links platelets to each other through fibrinogen bridges. This is considered the final common pathway of platelet aggregation. Inclusion of platelets gives the clot a white appearance. Simultaneously, the extrinsic coagulation cascade pathway is activated as a result of exposure of blood components to the thrombogenic lipid core and disrupted endothelium, which are rich in tissue factor. This leads to the production of thrombin (factor IIa), which converts fibrinogen to fibrin through enzymatic activity. Fibrin stabilizes the clot and traps red blood cells, which gives the clot a red appearance. Therefore, the clot is composed of cross-linked platelets and fibrin strands.[8]

Ventricular Remodeling Following an Acute MI

Ventricular remodeling is a process that occurs in several cardiovascular (CV) conditions including HF and following MI. It is characterized by left ventricular (LV) dilation and reduced pumping function of the LV, leading to HF.[11] Because HF represents one of the principal causes of morbidity and mortality following an MI, preventing ventricular remodeling is an important therapeutic goal.

Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), β-blockers, and aldosterone antagonists are all agents that slow down or reverse ventricular remodeling through inhibition of the renin–angiotensin–aldosterone system and/or through improvement in hemodynamics (decreasing preload, afterload or neurohormonal activation).[11] These agents also improve survival and will be discussed in more detail in subsequent sections of this chapter.

Complications

This chapter focuses on management of the uncomplicated ACS patient. However, it is important for clinicians to recognize complications of MI, because MI is associated with increased mortality. The most serious complication of MI is cardiogenic shock, occurring in approximately 5% to 10% of hospitalized patients presenting with STEMI.[12] Mortality of cardiogenic shock complicated by MI has been decreasing secondary to guideline-implemented therapies, yet remains high at approximately 34%.[12] Other complications that may result from MI are HF, valvular dysfunction, bradycardia, heart block, pericarditis, stroke secondary to LV thrombus embolization, venous thromboembolism, LV free wall or ventricular septal rupture, LV aneurysm formation, and ventricular and atrial tachyarrhythmias.[2]

CLINICAL PRESENTATION Diagnosis of ACS General

- The patient is typically in acute distress and may develop or present with acute HF, cardiogenic shock, or cardiac arrest.

Symptoms

- The classic symptom of ACS is midline anterior chest discomfort. Accompanying symptoms may include arm, back, or jaw pain, nausea, vomiting, or shortness of breath.
- Patients less likely to present with classic symptoms include elderly patients, diabetic patients, and women.

Signs

- No signs are classic for ACS.
- Patients with ACS may present with signs of acute decompensated HF including jugular venous distention and an S_3 sound on auscultation.
- Patients may also present with arrhythmias, and therefore may have tachycardia, bradycardia, or heart block.

Laboratory Tests

- Troponin I or T are measured at the time of first assessment and repeated at least once, 3 to 6

hours later to ascertain heart muscle damage, confirmatory for the diagnosis of infarction. Additional troponin levels should be obtained beyond 6 hours after symptom onset in patients with normal troponin levels in patients for who an intermediate to high suspicion of ACS is present.

For patients with NSTE-ACS, an elevated troponin is diagnostic for MI, defining a NSTEMI. Patients presenting with suspected NSTE-ACS who do not have an MI undergo further diagnostic testing to determine whether or not they have UA or ACS.

- Blood chemistry tests are performed with particular attention given to potassium and magnesium, which may affect heart rhythm.
- SCr is measured and creatinine clearance (CrCl) is used to identify patients who may need dosing adjustments for some medications as well as those who are at high risk of morbidity and mortality.
- Baseline complete blood count (CBC) and coagulation tests (aPTT and INR) should be obtained, as most patients will receive antithrombotic therapy that increases the risk for bleeding.
- Fasting lipid panel (optional).

Other Diagnostic Tests

- The 12-lead ECG is the first step in management. Patients are risk-stratified into two groups: STEMI and suspected NSTE-ACS.
- High-risk ACS patients and those with recurrent chest discomfort will undergo coronary angiography via a left heart catheterization and injection of contrast dye into the coronary arteries to determine the presence and extent of coronary artery stenosis.
- During hospitalization, a measurement of LV function, such as an echocardiogram, is performed to identify patients with low LV ejection fractions (EF) (≤40%) who are at high risk of death following hospital discharge.
- Selected low-risk patients may undergo early stress testing.

Symptoms and Physical Examination Findings

The classic symptom of ACS is midline anterior anginal chest pain often described as crushing, burning, or a heavy pressure. It most often occurs when an individual is at rest, as a severe new onset, or as increasing angina that is at least 20 minutes in duration. The chest discomfort may radiate to the shoulder, down the left arm, and to the back or to the jaw. Associated symptoms that may accompany the chest discomfort include nausea, vomiting, diaphoresis, or shortness of breath. Although similar to stable angina, the duration may be longer and the intensity greater. All healthcare professionals should review these warning symptoms with patients at high risk for CHD. On physical examination, no specific features are indicative of ACS.[13]

Twelve-Lead ECG

There are key features of a 12-lead ECG that identify and risk-stratify a patient with an ACS. Within 10

minutes of presentation to an ED with symptoms of ischemic chest discomfort, a 12-lead ECG should be obtained and interpreted. When possible, a 12-lead ECG should be performed by emergency medical system (EMS) providers in order to reduce the delay until myocardial reperfusion can be achieved. If available, a prior 12-lead ECG should be reviewed to identify whether or not the findings on the current ECG are new or old, with new findings being more indicative of ACS. Key findings on review of a 12-lead ECG that indicate myocardial ischemia or infarction are STE, ST-segment depression, and T-wave inversion (see Fig. 17-1).[2,13] ST-segment and/or T-wave changes in certain groupings of leads help to identify the location of the coronary artery that is the cause of the ischemia or infarction. In addition, the appearance of a new left bundle-branch block accompanied by chest discomfort is highly specific for acute MI. About one half of patients diagnosed with MI present with STE on their ECG, with the remainder having ST-segment depression, T-wave inversion, or, in some instances, no ECG changes. Some parts of the heart are more "electrically silent" than others, and myocardial ischemia may not be detected on a surface ECG. Therefore, it is important to review findings from the ECG in conjunction with biochemical markers of myocardial necrosis, such as troponin I or T, and other risk factors for CHD to determine the patient's risk for experiencing a new MI or having other complications.

Biochemical Markers/Cardiac Enzymes

Biochemical markers of myocardial cell death are important for confirming the diagnosis of MI. The diagnosis of acute MI is confirmed when the following conditions are met in a clinical setting consistent with myocardial ischemia: "Detection of a rise and/or fall of cardiac biomarkers with at least one value above the 99th percentile of the upper reference limit with at least one of the following: (a) symptoms of ischemia; (b) new or presumed new significant ST-segment–T wave changes or new left bundle-branch block; (c) development of pathologic Q waves; or (d) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality."[10] Typically, a blood sample is obtained once in the ED, and then 3 to 6 hours after symptoms unset, and in patients at a high suspicion of MI but in whom previous measurements did not reveal elevations in biomarkers, further measurement can be performed beyond 6 hours after the onset of symptoms. A single measurement of troponin is not adequate to exclude a diagnosis of MI, as up to 15% of values that were initially below the level of detection (a "negative" test) rise to the level of detection (a "positive" test) in subsequent hours. Troponins appear in the blood within 6 hours of infarction and stay elevated for up to 10 days.[10]

Risk Stratification

Patient symptoms, past medical history, ECG, and biomarkers are utilized to stratify patients into low, medium, or high risk of death, MI, or likelihood of failing pharmacotherapy and needing urgent coronary angiography and PCI (**Table 17-1**).[3,4] Initial treatment according to risk stratification is depicted in Fig. 17-1.[2,3,4] Patients with STEMI are at the highest risk of death. Initial treatment of STEMI should proceed without evaluation of the troponins because these patients have a greater than 97% chance of having an MI subsequently diagnosed with biochemical markers. A target time to initiate reperfusion treatment within 30 minutes of hospital presentation for fibrinolytics (eg, streptokinase, alteplase, reteplase, and tenecteplase) and within 90 minutes or less from first medical contact for primary PCI is recommended.[2,4] The sooner the infarct-related coronary artery is opened for these patients, the lower their mortality and the greater the amount of myocardium that is preserved.[2] Although all patients

should be evaluated for reperfusion therapy, not all patients may be eligible. Indications and contraindications for fibrinolytic therapy are described in the Treatment section of this chapter. Approximately 34% of hospitals in the United States are equipped to perform primary PCI.[14] Pharmacotherapy for STEMI patients should be initiated in the ED and the patient transferred to a coronary intensive care unit.[2]

TABLE 17-1 Risk Stratification for Acute Coronary Syndromes[3]

TIMI Risk Score for NSTE-ACS

One point is assigned for each of the seven medical history and clinical presentation findings. The point total is calculated, and the patient is assigned a risk for experiencing the composite endpoint of death, MI, or urgent need for revascularization as follows:

- Age 65 years or older
- Three or more CHD risk factors: smoking, hypercholesterolemia, hypertension, diabetes mellitus, family history of premature CHD death/events
- Known CAD (50% or greater stenosis of at least one major coronary artery on coronary angiogram)
- Aspirin use within the past 7 days
- Two or more episodes of chest discomfort within the past 24 hours
- ST-segment depression 0.5 mm or greater
- Positive biochemical marker for infarction

High-Risk	Medium-Risk	Low-Risk
TIMI Risk Score 5-7 points	TIMI Risk Score 3-4 points	TIMI Risk Score 0-2 points

TIMI Risk Score	Mortality, MI, or Severe Recurrent Ischemia Requiring Urgent Revascularization Through 14 Days
0/1	4.7%
2	8.3%
3	13.2%
4	19.9%
5	26.2%
6/7	40.9%

GRACE Risk Factors for Increased Mortality and the Composite of Death or MI in ACS

Signs and symptoms of heart failure

Low systolic blood pressure

Elevated heart rate

Older age

Elevated serum creatinine

Baseline risk factors on clinical evaluation: cardiac arrest at admission, ST-segment deviation, elevated troponin

A high-risk patient is defined as a GRACE Risk Score more than 140 points

ACS, acute coronary syndromes; CAD, coronary artery disease; CHD, coronary heart disease; GRACE, Global Registry of Acute Coronary Events; MI, myocardial infarction; NSTE, non-ST-segment elevation; TIMI, Thrombolysis in Myocardial Infarction.

An online calculator for the GRACE Risk Model is available at: http://www.outcomes-umassmed.org/GRACE/acs_risk/acs_risk_content.html. (Accessed January 25, 2016)

Because NSTE-ACS is heterogeneous, risk stratification is more complex as patients with UA have a lower short-term mortality risk compared to NSTEMI. In-hospital outcomes for this group of patients vary with reported rates of death of 0% to 12%, reinfarction rates of 0% to 3%, and recurrent severe ischemia rates of 5% to 20%.[15,16] Not all patients presenting with suspected NSTE-ACS will even have CAD. Some will eventually be diagnosed with nonischemic chest discomfort. In general, among NSTE-ACS patients, those with ST-segment depression (see Fig. 17-1) and/or elevated biomarkers are at higher risk of death or recurrent infarction.[16]

TREATMENT

Desired Outcomes

Short-term desired outcomes in a patient with ACS are: (a) early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in UA); (b) prevention of death and other MI complications; (c) prevention of coronary artery reocclusion; and as evidence of restoration of coronary artery blood flow; (d) relief of ischemic chest discomfort; and (e) resolution of ST-segment and T-wave changes on the ECG.

Long-term desired outcomes are control of CV risk factors, prevention of additional CV events, including reinfarction, stroke, and HF, and improvement in quality of life.

General Approach to Treatment

Selecting evidence-based therapies for patients without contraindications results in lower mortality.[17,18] General treatment measures for all STEMI and high- and intermediate-risk NSTE-ACS patients include admission to hospital, oxygen administration (if oxygen saturation is low, less than 90%), continuous multi-lead ST-segment monitoring for arrhythmias and ischemia, frequent measurement of vital signs, bed rest for 12 hours in hemodynamically stable patients, avoidance of the Valsalva maneuver (prescribe stool softeners routinely), and pain relief (**Figs. 17-2 and 17-3**).[2,3]

FIGURE 17-2

Initial pharmacotherapy for ST-segment elevation myocardial infarction. [a]Options after coronary angiography also include medical management alone or CABG surgery. [b]Clopidogrel preferred $P2Y_{12}$ inhibitor when fibrinolytic therapy is utilized. No loading dose recommended if age older than 75 years. [c]Given for up to 48 hours or until revascularization. [d]Given for the duration of hospitalization, up to 8 days or until revascularization. [e]If pretreated with UFH, stop UFH infusion for 30 minutes prior to administration of bivalirudin (bolus plus infusion). [f]In patients with STEMI receiving a fibrinolytic or who do not receive reperfusion therapy, administer clopidogrel for at least 14 days and ideally up to 1 year. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ASA, aspirin; CI, contraindication; FMC, first medical contact; GPI, glycoprotein IIb/IIIa inhibitor; IV, intravenous; MI, myocardial infarction; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.) *(Reproduced with permission from Rogers KC, de Denus S, Finks SW. Chapter 8. Acute Coronary Syndromes. In: Chisholm-Burns MA, Schwinghammer TL Wells BG, et al, eds. Pharmacotherapy: Principles and Practice. 4th ed. New York: McGraw-Hill Companies; 2016.)*

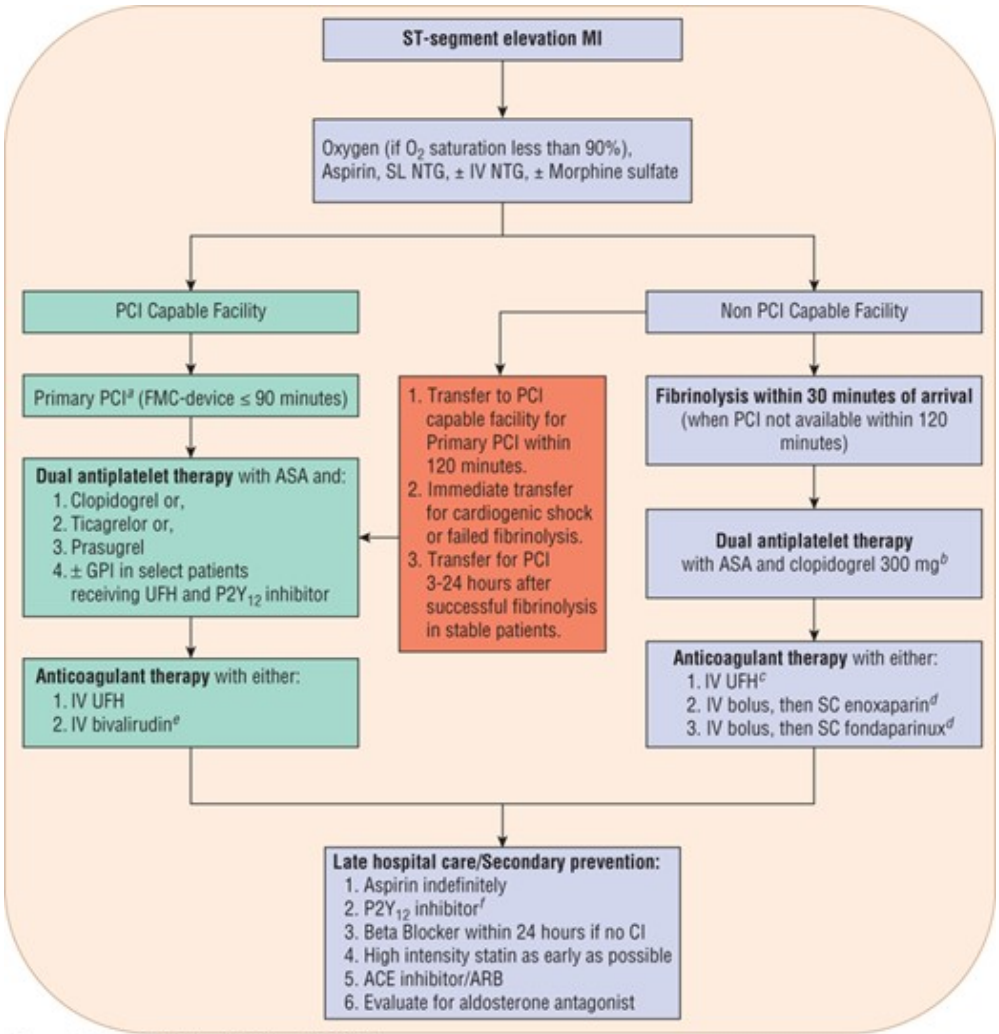


FIGURE 17-3

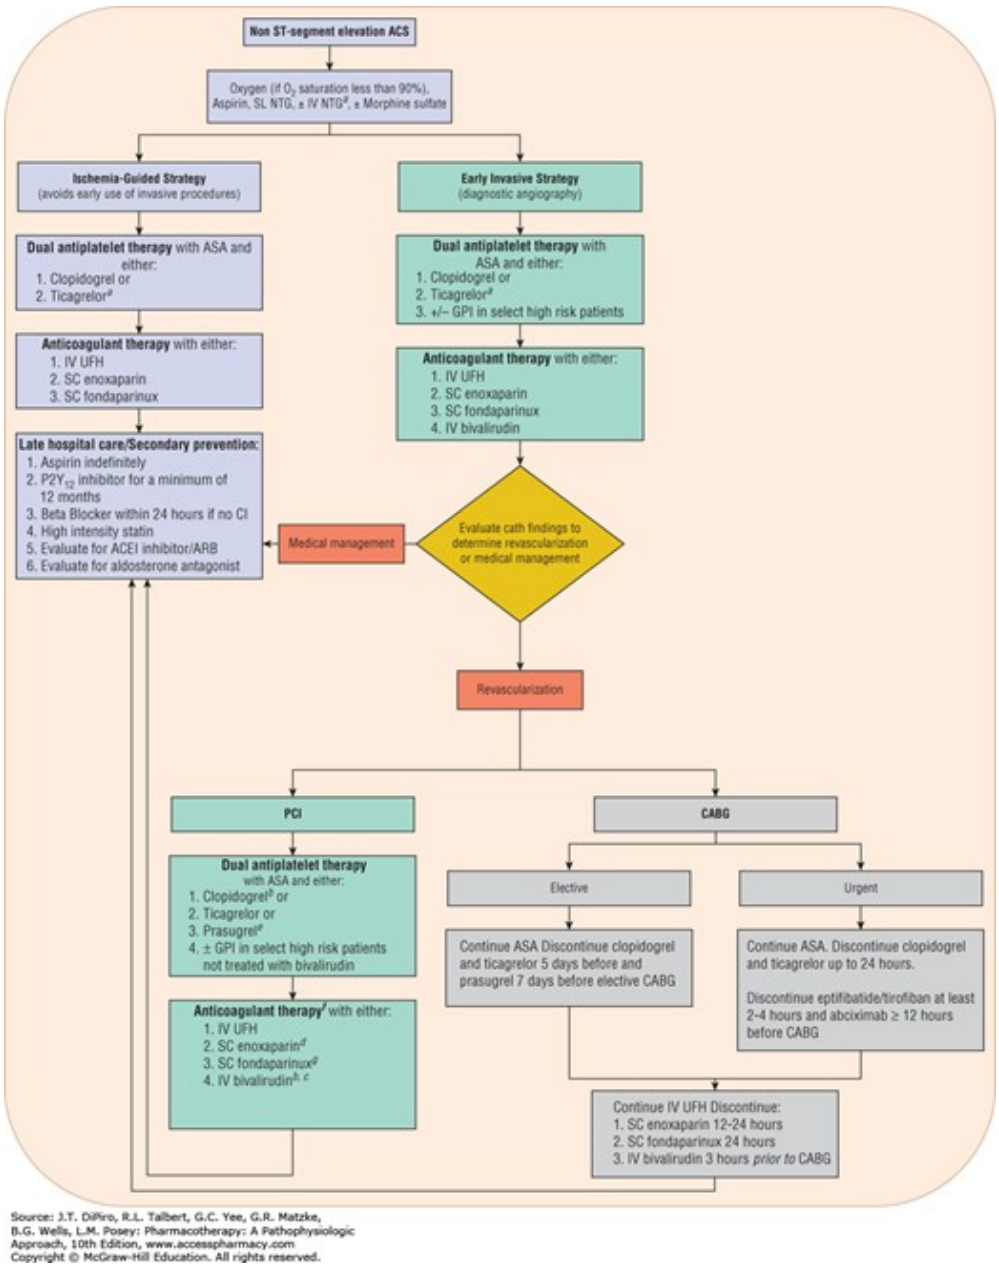
Initial pharmacotherapy for non–ST-segment elevation ACS. [a]For selected patients, see Table 17-2. [b]Preferred in patients at high risk for bleeding. [c]If pretreated with UFH, stop UFH infusion for 30 minutes

prior to administration of bivalirudin bolus plus infusion. [d]May require IV supplemental dose of enoxaparin; see Table 17-2. [e]Do not use if prior history of stroke/transient ischemic attack (TIA), age older than 75 years, or body weight less than or equal to 60 kg. [f]Subcut enoxaparin or UFH can be continued at a lower dose for venous thromboembolism prophylaxis following PCI. [g]Requires an IV supplemental dose of UFH; see Table 17-2. (ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; ARB, angiotensin receptor blocker; CABG, coronary artery bypass graft; CAD, coronary artery disease; CHD, coronary heart disease; GP, glycoprotein; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.) *(Reproduced with permission from Spinler SA, de Denus S. Acute coronary syndromes. In: Chisholm-Burns M, Wells BG, Schwinghammer TL, Malone PM, Kolesar JM, DiPiro JT, eds. Pharmacotherapy Principles and Practice. 3rd ed. New York: McGraw-Hill; 2013.)*



Because risk varies and resources are limited, it is important to triage and treat patients according to their risk category. Initial approaches to treatment of STEMI and NSTE-ACS patients are outlined in Figs.

17-2 and 17-3. Patients with STEMI are at high risk of death, and efforts to reestablish coronary perfusion, as well as adjunctive pharmacotherapy, should be initiated immediately.

Features identifying low-, moderate-, and high-risk NSTE-ACS patients are described in Table 17-1.[3,19,20]

Nonpharmacologic Therapy

Primary PCI for STEMIs

Early reperfusion therapy with primary PCI of the infarct artery within 90 minutes of first medical contact is the reperfusion treatment of choice for patients presenting with STEMI who present within 12 hours of symptom onset[2] (see Fig. 17-2). EMS may be activated for a patient complaining of ischemic symptoms well in advance of hospital arrival. Paramedics can electronically transmit a 12-lead ECG where a physician can review and notify the cardiac catheterization medical team to alert them that a patient with STEMI is en route to the hospital for reperfusion. For primary PCI, the patient is taken from the ED to the cardiac catheterization laboratory and undergoes coronary angiography with either balloon angioplasty or placement of a bare metal or drug-eluting intracoronary stent in the artery associated with the infarct. In order to meet the quality of care metric of less than 90 minutes from first medical contact to primary PCI, many transitions of care occur and care coordination between paramedics, ED staff, and cardiac catheterization is vital. Every minute delay results in additional myocardial cell damage that may be irreversible.

About 80% of patients with STEMI are treated with primary PCI; 11% are treated with fibrinolytics.[14,21] Results from a meta-analysis of trials comparing fibrinolysis with primary PCI indicate a lower mortality rate with primary PCI.[22] One reason for the superiority of primary PCI compared with fibrinolysis is that more than 90% of occluded infarct-related coronary arteries are opened with primary PCI compared with fewer than 60% of coronary arteries opened with currently available fibrinolytics.[2] In addition, intracranial hemorrhage (ICH) and major bleeding risks from primary PCI are lower than the risks of severe bleeding events following fibrinolysis. An invasive strategy of primary PCI is generally preferred in patients presenting to institutions with skilled interventional cardiologists and a catheterization laboratory immediately available, patients in cardiogenic shock, those with contraindications to fibrinolytics, and those with continuing symptoms 12 to 24 hours after symptom onset.[2]

Myocardial infarction performance measures are developed from practice guidelines and intended to permit the quality of patient care to be assessed, compared between institutions and ultimately, over time, improve the care of patients with the care of MI. Important quality organizations that have developed standards for the care of patients with MI are the Joint Commission, Centers for Medicare and Medicaid Services (Hospital Compare and Million Hearts), and the AHA (Mission: Lifeline). For STEMI, one important measure is the time from first medical contact to the time the occluded artery is opened with PCI. This first medical contact-to-primary PCI time should be equal to or less than 90 minutes.[2] In 2011, the median door-to-primary PCI time (meaning the time from hospital arrival to primary PCI) was 63 minutes, decreasing from a median of 96 minutes in 2005.[23] In 2005, 44% of patients treated with primary PCI had door-to-primary PCI times of less than 90 minutes, while in 2010 this percentage had increased to 94%.[23] Unfortunately, most hospitals do not have interventional cardiology services capable of performing primary PCI 24 hours a day. Patients presenting to facilities that do not have interventional

cardiology services can be transferred to such facilities when a transfer protocol that minimizes transfer delays has been established between the institutions and if primary PCI can be performed within the first 120 minutes of medical contact.[2]

Percutaneous coronary intervention during hospitalization for STEMI may also be appropriate in other patients following STEMI, such as those in whom fibrinolysis is not successful, those presenting later in cardiogenic shock, those with life-threatening ventricular arrhythmias, and those with persistent rest ischemia or signs of ischemia on stress testing following MI.[2]

PCI in NSTE-ACS

The most recent practice guidelines recommend an early invasive (within 24 hours) strategy with interventions, including left heart catheterization, coronary angiography and revascularization with either PCI or *coronary artery bypass graft* (CABG) *surgery* for patients with NSTE-ACS at an elevated risk for death or MI, including those with a high risk score (see Table 17-1) or patients with refractory angina, acute HF, other symptoms of cardiogenic shock, or arrhythmias (see Fig. 17-3).[3,4] Several clinical trials support an early invasive strategy with early angiography and PCI or CABG versus a more conservative or "ischemia guided" strategy in low-risk patients (those have a low TIMI Risk Score or the absence of high-risk features), whereby coronary angiography with revascularization is reserved for patients with symptoms refractory to pharmacotherapy and patients with signs of ischemia on stress testing.[4,24] An early invasive approach results in a lower rate of refractory angina over the first year as well as MI between 30 days and 5 years. A recent trial comparing immediate invasive strategy versus delayed invasive strategy in patients with NSTEMI reported lower rates of death, reinfarction, or MI.[24,25] Whether an early invasive strategy reduces the risk of CV or total mortality remains to be established.

Antiplatelet Therapy Pharmacotherapy in PCI and STEMI and NSTE-ACS

All patients undergoing PCI with ACS should receive an initial dose of 162- or 325-mg of aspirin followed by a daily aspirin dose of 81 mg/day indefinitely (unless aspirin is part of triple antithrombotic therapy [TT]—see Clinical Controversy 1) (**Table 17-2**).[2,4] A $P2Y_{12}$ inhibitor antiplatelet (clopidogrel, prasugrel, ticagrelor, or IV cangrelor) should be administered as early as possible concomitantly with aspirin and then an oral $P2Y_{12}$ agent should ideally be continued for at least 12 months following PCI (see Table 17-2).[2,4] Earlier discontinuation of the $P2Y^{12}$ inhibitor can be reasonable in patients at a high bleeding risk or with overt bleeding".[2,4,26] Either ticagrelor or prasugrel are preferred over clopidogrel secondary to improved efficacy with a reduction in the frequency of the composite endpoint of CV death, MI, or stroke.[3]

TABLE 17-2 Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction and Non-ST-Segment Elevation Acute Coronary Syndrome[2,3,4,26]

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
Aspirin	STEMI, class I recommendation for	Hypersensitivity, active bleeding,	160-325 mg orally once on hospital day 1.

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
	all patients. NSTE-ACS, class I recommendation for all patients.	severe bleeding risk	81-162 mg once daily orally starting hospital day 2 and continued indefinitely in all patients. In STEMI, doses of up to 325 mg included in the guidelines, but a dose of 81 mg is preferred. In patients dual receiving dual antiplatelet therapy, a daily dose of 81 mg is recommended (Class I recommendation) Limit dose to <100 mg if using ticagrelor.
Clopidogrel	NSTE-ACS, class I recommendation added to aspirin. STEMI, class I recommendation added to aspirin. PCI in STE and NSTE-ACS, class I recommendation. In patients with aspirin allergy, class I recommendation.	Hypersensitivity, active bleeding, severe bleeding risk	300 mg-600 mg oral loading dose on hospital day 1 followed by a maintenance dose of 75 mg once daily starting on hospital day 2 in patients with NSTE-ACS. 300 mg oral loading dose followed by 75 mg orally daily in patients receiving a fibrinolytic or who do not receive reperfusion therapy with a STEMI, avoid loading dose in patients 75 years or older. 600 mg (class I recommendation) loading dose before or when PCI performed (unless within 24 hours of fibrinolytic therapy, a dose of 300 mg should be given). Discontinue at least 5 days before CABG surgery if bleeding risk outweighs benefit (class I recommendation). Administer indefinitely in patients with aspirin allergy (class I recommendation). Continue for at least 12 months (class I recommendation) and possibly beyond 12 months (class IIb recommendation) in patients with ACS managed with PCI/stent. In patients with NSTE-ACS treated medically, administer for up to 1 year (class I recommendation). In patients receiving a fibrinolytic or who do not receive reperfusion therapy, administer for at least 14 days (class I recommendation) and

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
			up to 1 year. In patients not at high-risk of bleeding and who have not add a bleeding complication, continuing dual antiplatelet therapy may be reasonable (class IIb recommendation). Genetic testing might be considered to identify patients at high risk of poor response (class IIb recommendation). In these patients, an alternative $P2Y_{12}$ inhibitor might be considered (class IIb recommendation). The routine use of genetic testing is not recommended (class III recommendation). Initiate in patients with known coronary artery anatomy only (so as to avoid use in patients needing CABG surgery; class I recommendation). Give no later than 1 hour after PCI. Patients who have history of prior stroke or TIA or are 75 years of age or more or weigh <60 kg (132 lb) have higher risk of bleeding and no added benefit compared with clopidogrel.
Prasugrel	PCI in STE and NSTE-ACS, added to aspirin, class I recommendation.	Active bleeding, prior stroke or TIA	60 mg oral loading dose followed by 10 mg once daily for patients weighing 60 kg (132 lb) or more. Consider 5 mg once daily in patients weighing <60 kg (132 lb) (based on limited data). Discontinue at least 7 days prior to CABG surgery if bleeding risk outweighs benefit (class I recommendation). Continue for at least 12 months (class I recommendation) and possibly beyond 12 months (class IIb recommendation or treated with only medical therapy) in patients with ACS managed with PCI/stent.
Ticagrelor	PCI in STEMI and NSTE-ACS, added to aspirin, class I recommendation.	Active bleeding	180 mg (class I recommendation) oral loading dose in patients undergoing PCI or ischemia-guided management, followed by 90 mg twice daily for at least 12 months (class I

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
	Class IIa as preference over clopidogrel. Medically treated patients (without fibrinolytics or revascularization) STEMI and NSTE ACS added to aspirin, class I recommendation.		recommendation) and possibly beyond 12 months (class IIb recommendation) in patients with ACS managed with PCI/stent. After 1 year, administer 60 mg twice daily. Current data are too limited to recommend use in patients with STEMI receiving fibrinolytics. Discontinue at least 5 days prior to CABG surgery if bleeding risk outweighs benefit (class I recommendation).
Cangrelor	PCI—adjunct in patients, not treated with oral $P2Y_{12}$ inhibitors or GPI. Newly FDA approved agent without guideline recommendations.	Active bleeding	30 mcg/kg IV bolus initiated prior to PCI followed by 4 mcg/kg/min IV infusion for duration of PCI or 2 hours, whichever is longer. To maintain platelet inhibition after infusion, initiate oral $P2Y_{12}$ agent as follows: ticagrelor 180 mg at any time during or immediately after infusion; clopidogrel 600 mg or prasugrel 60 mg immediately after discontinuation of infusion. Do not administer clopidogrel or prasugrel during infusion of cangrelor.
Unfractionated heparin	STEMI, class I recommendation in patients undergoing PCI and for those patients treated with fibrinolytics; NSTE-ACS, class I recommendation in combination with antiplatelet therapy for ischemia-guided or early invasive approach PCI, class I recommendation (NSTE-ACS and STEMI).	Active bleeding, history of heparin-induced thrombocytopenia, severe bleeding risk, recent stroke	For STEMI with fibrinolytics, administer 60 Units/kg IV bolus (maximum 4,000 Units) heparin followed by a constant IV infusion at 12 Units/kg/h (maximum 1000 Units/h). For STEMI primary PCI, administer 50-70 Units/kg IV bolus if a GP IIb/IIIa inhibitor planned; 70-100 Units/kg IV bolus if no GP IIb/IIIa inhibitor planned and supplement with IV bolus doses to maintain target ACT. For NSTE-ACS, administer 60 Units/kg IV bolus (maximum 4,000 Units) followed by a constant IV infusion at 12 Units/kg/h (maximum 1,000 Units/h). Titrated to maintain an aPTT of 1.5-2.0 times control (approximately 50-70 seconds) for STEMI with fibrinolytics and for NSTE-ACS. Titrated to ACT of 250-350 seconds for primary

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
			PCI without a GP IIb/IIIa inhibitor and 200-250 seconds in patients given a concomitant GP IIb/IIIa inhibitor. The first aPTT should be measured at 4-6 hours for NSTE-ACS and STE ACS in patients not treated with fibrinolytics or undergoing primary PCI. The first aPTT should be measured at 3 hours in patients with STE ACS who are treated with fibrinolytics. Continue for 48 hours or until the end of PCI.
Enoxaparin	STEMI class I recommendation in patients receiving fibrinolytics and class IIa for patients not undergoing reperfusion therapy. NSTE-ACS, class I recommendation in combination with aspirin for conservative or invasive approach. For PCI, class IIa recommendation as an alternative to UFH in patients with NSTE-ACS. For primary PCI in STEMI, class IIb recommendation as an alternative to UFH.	Active bleeding, history of heparin-induced thrombocytopenia, severe bleeding risk, recent stroke, avoid enoxaparin if CrCl <15 mL/min (<0.25 mL/s), avoid if CABG surgery planned	Enoxaparin 1 mg/kg SC every 12 hours for patients with NSTE-ACS (CrCl ≥ to 30 mL/min [≥ to 0.50 mL/s]). Enoxaparin 1 mg/kg SC every 24 hours (CrCl 15-29 mL/min [0.25-0.49 mL/s]) for NSTE or STEMI. For all patients undergoing PCI following initiation of SC enoxaparin for NSTE-ACS, a supplemental 0.3 mg/kg IV dose of enoxaparin should be administered at the time of PCI if the last dose of SC enoxaparin was given 8-12 hours prior to PCI or who received less than two therapeutic SC doses. For patients with STEMI receiving fibrinolytics: • Age <75 years: Administer enoxaparin 30 mg IV bolus followed immediately by 1 mg/kg. • SC every 12 hours (first two doses administer maximum of 100 mg for patients weighing more than 100 kg). • Age ≥75 years: Administer enoxaparin 0.75 mg/kg SC every 12 hours (first two doses administer maximum of 75 mg for patients weighing more than 75 kg).

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
			Continue throughout hospitalization or up to 8 days for STEMI. Continue for 24-48 hours for NSTE-ACS or until the end of PCI for NSTEMI. Stop at least 12-24 hours after CABG surgery.
Bivalirudin	NSTE-ACS class I recommendation for invasive strategy. PCI in STEMI (class I recommendation).	Active bleeding, severe bleeding risk	For NSTE-ACS, administer 0.1 mg/kg IV bolus followed by 0.25 mg/kg/h infusion. For PCI in NSTE-ACS, administer a second bolus of 0.5 mg/kg IV and increase infusion rate to 1.75 mg/kg/h. For PCI in STEMI, administer 0.75 mg/kg IV bolus followed by 1.75 mg/kg/h infusion. If prior UFH given, discontinue UFH and wait 30 minutes before initiating bivalirudin. Dosage adjustment for severe renal failure and HD. Discontinue at end of PCI or continue at 0.25 mg/kg/h if prolonged anticoagulation necessary. Lower bleeding rates are mitigated when administered with a GPI inhibitor. Clopidogrel should be administered at least 6 hours before if a GPI inhibitor is not used. Discontinue at least 3 hours prior to CABG surgery.
Fondaparinux	STEMI class I recommendation receiving fibrinolytics and IIa for patients not undergoing reperfusion therapy. NSTE-ACS class I recommendation for	Active bleeding, severe bleeding risk, SCr ≥3.0 mg/dL (≥265 µmol/L) or CrCl <30 mL/min (<0.50 mL/s)	For STEMI, 2.5 mg IV bolus followed by 2.5 mg SC once daily starting on hospital day 2. For NSTE-ACS, 2.5 mg SC once daily. Continue until hospital discharge or up to 8 days. For PCI, give additional 85 Units/kg IV UFH without and 60 Units/kg IV with GP IIb/IIIa inhibitor.

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
	invasive or conservative approach. Class III as sole agent in PCI.		Discontinue at least 24 hours prior to CABG surgery.
Fibrinolytic therapy	STEMI, class I recommendation for patients presenting within 12 hours following the onset of symptoms, class IIa in patients presenting between 12 and 24 hours following the onset of symptoms with continuing signs of ischemia. NSTE-ACS, class III recommendation.	Any prior intracranial hemorrhage, known structural cerebrovascular lesions, such as an arterial venous malformation, known intracranial malignant neoplasm, ischemic stroke within 3 months, active bleeding (excluding menses), significant closed head or facial trauma within 3 months	Streptokinase: 1.5 MU IV over 60 minutes. Alteplase: 15 mg IV bolus followed by 0.75 mg/kg IV over 30 minutes (maximum 50 mg) followed by 0.5 mg/kg (maximum 35 mg) over 60 minutes (maximum dose 100 mg). Reteplase: 10 Units IV × 2, 30 minutes apart. Tenecteplase: • <60 kg (<132 lb), 30 mg IV bolus • 60-69.9 kg (132-153 lb), 35 mg IV bolus • 70-80 kg (154-176 lb), 40 mg IV bolus
Glycoprotein IIb/IIIa receptor inhibitors (GPI)	NSTE-ACS PCI, class I recommendation for abciximab, high-bolus dose tirofiban or double-bolus eptifibatide at the time of PCI in high-risk patients already receiving aspirin and not adequately pretreated with a $P2Y_{12}$ inhibitor and not receiving bivalirudin as the anticoagulant; class IIa at the time of PCI	Active bleeding, thrombocytopenia, prior stroke, renal dialysis (eptifibatide)	**Drug** / **Dose** / **Dosing adjustment for CKD** Abciximab / 0.25 mg/kg IV bolus followed by 0.125 mcg/kg /min(maximum 10 mcg/min) for 12 hours / None Eptifibatide / 180 mcg/kg IV bolus × 2, 10 minutes apart / Reduce maintenance infusion to 1

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy		
	for high-risk patients already receiving aspirin and pretreated with a $P2Y_{12}$ inhibitor; class IIb for upstream use in high-risk patients already receiving aspirin and pretreated with a $P2Y_{12}$ inhibitor and not receiving bivalirudin as the anticoagulant; class I for upstream use in addition to aspirin without $P2Y_{12}$ inhibitor pretreatment for moderate- to high-risk patients. NSTE-ACS for patients not undergoing PCI (ischemia guided management), class IIb recommendation (eptifibatide or tirofiban). STEMI primary PCI, class IIa recommendation for abciximab, high-bolus dose tirofiban or double-bolus eptifibatide.		Tirofiban	with an infusion of 2 mcg/kg/min for 18-24 hours after PCI	mcg/kg/min for CrCl < 50 mL/min (<0.83 mL/s); contraindicated if patient dependent on dialysis. Patients weighing 121 kg (266 lb) or more should receive a maximum infusion rate of 22.6 mg per bolus and a maximum rate of 15 mg/h
				25mcg/kg IV bolus followed by an infusion of 0.15 mcg/kg/min for up to 18 hours	Reduce maintenance infusion to 0.075 mcg/kg/min for patients with CrCl ≤ 60 mL/min (<0.05 mL/s)
Nitroglycerin	STEMI and NSTE-ACS, class I recommendation in	Hypotension, sildenafil or vardenafil within 24	0.4 mg SL, repeated every 5 minutes × 3 doses then assess need for IV infusion.		

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
	patients with ongoing ischemic discomfort, control of hypertension or management of HF.	hours or tadalafil within 48 hours	5-10 mcg/min IV infusion titrated up to 75-100 mcg/min until relief of symptoms or limiting side effects (headache) with a systolic blood pressure <90 mm Hg or more than 30% below starting mean arterial pressure levels if significant hypertension is present. Topical patches or oral nitrates are acceptable alternatives for patients without ongoing or refractory symptoms. Discontinue IV infusion after 24-48 hours.
β-Blockers[c]	STEMI and NSTE-ACS, class I recommendation for oral β-blockers in all patients without contraindications in the first 24 hours, class IIa for IV β-blockers STEMI patients with hypertension or those with ongoing ischemia. Class III for IV β-blockers in patients with risk factors for shock.	PR interval >0.24 seconds, second-degree or third-degree atrioventricular heart block, heart rate <60 beats/min, systolic blood pressure <90 mm Hg, shock, left ventricular failure with decompensated HF, severe reactive airway disease	Metoprolol 5 mg slow IV push (over 1-2 minutes), repeated every 5 minutes for a total of 15 mg followed in 1-2 hours by 25-50 mg orally every 6 hours; if a very conservative regimen is desired, initial doses can be reduced to 1-2 mg. Propranolol 0.5-1 mg IV dose followed in 1-2 hours by 40-80 mg orally every 6-8 hours. Atenolol 5 mg IV dose followed in 5 minutes by a second 5 mg IV dose for a total of 10 mg followed in 1-2 hours by 50-100 mg orally once daily. Alternatively, initial IV therapy can be omitted and treatment started with oral dosing. For dosing of carvedilol, metoprolol succinate and bisoprolol in patients with systolic HF, please refer to Chapter X. Continue oral β-blocker for 3 years and possibly indefinitely.
Calcium channel blockers	NSTE-ACS class I recommendation for patients with ongoing ischemia who are already taking adequate doses of nitrates	Pulmonary edema, evidence of left ventricular dysfunction, systolic blood pressure < 100 mm Hg, PR segment to	Diltiazem 120-360 mg sustained release orally once daily. Verapamil 180-480 mg sustained release orally once daily. Amlodipine 5-10 mg orally once daily.

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy		
	and β-blockers or in patients with contraindications to or intolerance to β-blockers (diltiazem or verapamil preferred calcium channel blockers during initial presentation if EF > 40%). NSTE-ACS, class IIb recommendation for diltiazem for patients with AMI.	>0.24 seconds second- or third-degree atrioventricular heart block for verapamil or diltiazem, pulse rate <60 beats/min for diltiazem or verapamil	Continue as indicated to manage angina, hypertension, or arrhythmias.		
ACE inhibitors	NSTE-ACS and STEMI, class I recommendation for patients with HF left ventricular dysfunction and EF <40%, type 2 diabetes mellitus or CKD in the absence of contraindications. Consider in all patients with CAD (class I recommendation, class IIa in low-risk patients). Indicated indefinitely for all patients with EF <40% (class I recommendation).	Systolic blood pressure <100 mm Hg, history of intolerance to an ACE inhibitor, bilateral renal artery stenosis, serum potassium more than 5.5 mEq/L (>5.5 mmol/L), acute renal failure, pregnancy	**Drug**	**Initial Dose (mg)**	**Target Dose (mg)**
			Captopril	6.25-12.5	50 twice daily orally to 50 three times daily
			Enalapril	2.5-5.0	10 twice daily orally
			Lisinopril	2.5-5.0	10-20 once daily orally
			Ramipril	1.25-2.5	5 twice daily or 10 once daily orally
			Trandolapril	1.0	4 once daily orally
Angiotensin receptor blockers	NSTEMI and STEMI, class I recommendation in	Systolic blood pressure <100 mm Hg, bilateral renal	**Drug**	**Initial Dose (mg)**	**Target Dose (mg)**

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy		
	patients with HF or left ventricular EF <40% and intolerant of an ACE inhibitor, class IIa recommendation in patients with clinical signs of HF or EF <40% and no documentation of ACE inhibitor intolerance. Class I in other ACE inhibitor–intolerant patients with hypertension.	artery stenosis, serum potassium more than 5.5 mEq/L (>5.5 mmol/L), acute renal failure, pregnancy	Candesartan	4-8	32 once daily orally
			Valsartan	40	160 twice daily orally
			Losartan	12.5-25	150 daily
			Continue indefinitely		
Aldosterone antagonists	NSTEMI and STEMI class I recommendation in patients with EF <40% and either diabetes mellitus or HF who are already receiving an ACE inhibitor and β-blocker.	Hypotension, hyperkalemia, serum potassium >5.0 mEq/L (>5 mmol/L), SCr >2.5 mg/dL (221 µmol/L) for men and >2.0 mg/dL (177 µmol/L) for women and/or CrCl <30 mL/min (<0.50 mL/s)	**Drug**	**Initial Dose (mg)**	**Target Dose (mg)**
			Eplerenone	25	50 once daily orally
			Spironolactone	12.5	25-50 once daily orally
			Continue indefinitely		
Morphine sulfate	STEMI and NSTE-ACS (class IIb) recommendation for patients whose chest pain persists despite treatment with maximally tolerated anti-anginal drugs.	Hypotension, respiratory depression, confusion, obtundation	1-5 mg IV bolus dose May be repeated every 5-30 minutes as needed to relieve symptoms and maintain patient comfort		
Statins	NSTE-ACS and STEMI class I recommendation to initiate or continue	Caution with use of fibrate and statin-specific drug interactions	High Intensity: Atorvastatin 40-80 mg daily; Rosuvastatin 20-40 mg daily Moderate Intensity: Atorvastatin 10-20 mg		

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
	high-intensity statin therapy during early hospital care. Consider moderate-intensity statin for patients >75.		daily; Fluvastatin 80mg daily, Lovastatin 40 mg daily, Pitavastatin 2-4 mg daily, Pravastatin 40-80 mg daily, Rosuvastatin 5-10 mg daily, Simvastatin 20-40 mg daily.

[a]Class I recommendations are conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.

Class II recommendations are those conditions for which there is conflicting evidence and/or divergence of opinion about the usefulness/efficacy of a procedure or treatment. For Class IIa recommendations, the weight of the evidence/opinion is in favor of usefulness/efficacy. Class IIb recommendations are those for which usefulness/efficacy is less well established by evidence/opinion. Class III recommendations are those where the procedure or treatment is not useful and may be harmful.

[b]Allergy or prior intolerance contraindication for all categories of drugs listed in this chart.

[c]Choice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance due to existing pulmonary disease, especially asthma, selection should favor a short-acting agent, such as metoprolol or the ultrashort-acting agent, esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (eg, 2.5 mg IV metoprolol, 12.5 mg oral metoprolol, or 25 mcg/kg/min esmolol as initial doses) rather than complete avoidance of β-blocker therapy.

ACE, angiotensin-converting enzyme inhibitor; ACS, acute coronary syndrome; ACT, activated clotting time; AMI, acute myocardial infarction; aPTT, activated partial thromboplastin time; CABG, coronary artery bypass graft; CAD, coronary artery disease; CKD, chronic kidney disease; CrCl, Creatinine clearance; ECG, electrocardiogram; EF, ejection fraction; GPI, glycoprotein IIb/IIIa inhibitor; HD, hemodialysis; HF, heart failure; IV, intravenous; MI, myocardial infarction; NSTEMI, non-ST-segment elevation myocardial infarction; PCI, percutaneous coronary intervention; SC, subcutaneous, SCAI, Society for Cardiac Angiography and Interventions; SCr, serum creatinine; SL, sublingual; STEMI, ST-segment elevation myocardial infarction; TIA, transient ischemic attack; UFH, unfractionated heparin.

Stents are small, metal mesh tubes, which are inserted and expanded in the artery to prevent vessel closure during or following the angioplasty to keep the vessel open. There are currently two types of coronary stents that are used during PCI, a drug-eluting stent (DES) and a bare metal stent (BMS). Compared to BMS, DES reduce the rate of smooth muscle cell growth and thus stent restenosis, a gradual process whereby the stent lumen is reduced, necessitating repeat procedures for angina or MI. However, with DES there is a delay in endothelial cell regrowth at the site of the stent that places the patient at higher risk of long-term thrombotic events, particularly stent thrombosis, following PCI due to continued contact of the metal stent with blood leading to coagulation activation. Older generation DES coated with paclitaxel or sirolimus pose a higher risk of stent thrombosis than do newer generations

stents such as those coated with zotarolimus, everolimus, biodegradable polymer biolimus or bioabsorbable everolimus. Therefore, dual antiplatelet therapy (DAPT—aspirin plus a $P2Y_{12}$ inhibitor) is indicated for a longer period of time following PCI with a DES.[26] Trials evaluating the need for an extended duration in patients with or without ACS undergoing PCI (greater than 12 months) of DAPT therapy following PCI demonstrate a reduction in stent thrombosis and ischemia endpoints with increased bleeding for patients continued on DAPT beyond 12 months.[27] Further, the risk of stent thrombosis is greater on cessation of DAPT.[27] However, continued DAPT beyond 1 year is not associated with a reduction in either CV or total mortality.[28,29] A longer duration of $P2Y_{12}$ inhibitor therapy is an individualized approach based upon the patient's risk for ischemic and bleeding risks.[29] Despite arising trials suggesting a shorter duration of DAPT for patients receiving newer generation stents, at present, the preferred duration of $P2Y_{12}$ therapy is at least 1 year regardless of whether or not a patient with STEMI or NSTE-ACS receives a stent.[2,4,26,30,31,32]

Additional Testing and Risk Stratification

For patients with NSTE-ACS, an initial ischemia guided strategy is recommended for patients with a low risk score, normal 12-lead ECG, and negative troponins (below the cut-off threshold for the diagnosis of MI) who are without recurrence of chest discomfort (see Fig. 17-3).[3]

Within the first 3 days of hospital admission patients with MI should have their LV function evaluated for risk stratification.[2] The most common way LV function is measured is using an echocardiogram to calculate the patient's left ventricular ejection fraction (LVEF). LV function is the single best predictor of mortality following MI. Patients with LVEFs less than or equal to 40% (0.40) are at highest risk of death. Patients with ventricular fibrillation or sustained ventricular tachycardia occurring more than 2 days following MI and those with LVEF less than or equal to 30% (0.30, measured at least 40 days after MI and have a New York Heart Association functional class I) or who have nonsustained ventricular tachycardia secondary to a prior MI and an LVEF of less than or equal to 40% (0.40) with inducible ventricular fibrillation or ventricular tachycardia at electrophysiology study benefit from placement of an implantable cardioverter-defibrillator (ICD) for sudden cardiac death prevention.[33]

Prior to discharge from the hospital, stress testing (see Fig. 17-3) is indicated in patients with NSTE-ACS where an initial ischemia guided strategy is selected and for patients with STEMI where coronary angiography was not performed and there has been no recurrent ischemia.[2,3] Following the stress test, patients deemed at higher risk should undergo left heart catheterization with coronary angiography and revascularization as indicated by the results.[3]

Early Pharmacotherapy for STEMI

Pharmacotherapy for early treatment of ACS is outlined in Fig. 17-2 and Table 17-2.[2,3,4] 6 According to the STEMI practice guidelines, in addition to reperfusion therapy, other early pharmacotherapy that all patients with STEMI and without contraindications should receive within the first day of hospitalization, and preferably in the ED, are intranasal oxygen (if oxygen saturation is low), sublingual (SL) nitroglycerin (NTG), aspirin, a $P2Y_{12}$ inhibitor (clopidogrel, prasugrel, or ticagrelor depending on reperfusion strategy), and anticoagulation with bivalirudin, unfractionated heparin (UFH), enoxaparin, or fondaparinux (agent

dependent on reperfusion strategy; see Table 17-2). A GPI may be administered with UFH for patients undergoing primary PCI. Intravenous (IV) NTG should be given in selected patients (see Table 17-2). The use of IV β-blockers is reasonable at the time of presentation for patients with hypertension (HTN) and ongoing ischemia. Oral β-blockers are preferred to IV and should be initiated within the first day in patients without cardiogenic shock or other contraindications.[2,3,4] Morphine is administered to patients with refractory angina as an analgesic and a venodilator that lowers preload. However, morphine has been shown to slow the absorption of oral antiplatelet agents due to decreased gastric motility and its role in the contemporary management of ACS and contemporary trials suggest limiting morphine administration where possible.[34,35] These anti-ischemic agents are administered early while the patient is still in the ED. An ACE inhibitor is recommended to be administered within the first 24 hours in patients with STEMI who have either an anterior wall MI or an LVEF less than or equal to 40% (0.40) and no contraindications. Dosing and contraindications for SL and IV NTG, aspirin, clopidogrel, β-blockers, ACE inhibitors, anticoagulants, and fibrinolytics are described in Table 17-2.[2,3,4]

Fibrinolytic Therapy

Administration of a fibrinolytic agent is indicated in patients with STEMI who present within 12 hours of the onset of chest discomfort to a hospital not capable of primary PCI, have at least a 1 mm STE in two or more contiguous ECG leads, have no absolute contraindications to fibrinolytic therapy **(Table 17-3)** and are not able to be transferred and undergo primary PCI within 120 minutes of medical contact.[2] The mortality benefit of fibrinolysis is highest with early administration and diminishes after 12 hours.[2] The use of fibrinolytics between 12 and 24 hours after symptom onset should be limited to patients with ongoing ischemia. Fibrinolytic therapy is preferred over primary PCI where there is no cardiac catheterization laboratory or there would be a delay in "door-to-primary PCI" of more than 90 minutes (of first medical contact) within the institution or 120 minutes (of first medical contact) if the patient is transferred. Indications and contraindications for fibrinolysis are listed in Table 17-3.[2] It is not necessary to obtain the troponin result before initiating fibrinolytic therapy. Because administration of fibrinolytics results in clot lysis, patients or those who are at high risk of major bleeding (including a history of ICH) presenting with an absolute contraindication should not receive fibrinolytic therapy, and should be transferred to a hospital capable of performing PCI. In patients who have a contraindication to fibrinolytics and PCI, or who do not have access to a facility that can perform PCI, treatment with an anticoagulant (other than UFH) for up to 8 days can be administered.

TABLE 17-3 Indications and Contraindications to Fibrinolytic Therapy for Management of ST-Segment Elevation Myocardial Infarction[2]

Indications

1. Ischemic chest discomfort at least 20 minutes in duration but 12 hours or less since symptom onset

   and

   ST-segment elevation of at least two contiguous leads of ≥2 mm in men and ≥1.5 mm in women in leads V_2-V_3 and/or of ≥1 mm in other leads, or new or presumed new left bundle-branch block

2. Ongoing ischemic chest discomfort at least 20 minutes in duration 12-24 hours since symptom

onset

and

ST-segment elevation of at least 1 mm in height in two or more contiguous leads

Absolute Contraindications

- Active internal bleeding (not including menses)
- Previous intracranial hemorrhage at any time; ischemic stroke within 3 months (except acute ischemic stroke within 4.5 hours)
- Known intracranial neoplasm
- Known structural cerebral vascular lesion (eg, arteriovenous malformation)
- Suspected aortic dissection
- Significant closed head or facial trauma within 3 months
- Intracranial or intraspinal surgery within 2 months
- Severe uncontrolled hypertension (unresponsive to emergency therapy)
- For streptokinase, prior treatment within the previous 6 months

The percentage of eligible patients who receive reperfusion therapy fibrinolytic therapy is a quality performance measure of care in patients with MI.[36] The primary reason for lack of reperfusion therapy is that most patients present more than 12 hours after the time of symptom onset. The door-to-needle time, the time from hospital presentation to start of fibrinolytic therapy, is another quality performance measure of timely and effective care. The guidelines recommend a door-to-needle time of less than 30 minutes from the time of hospital presentation until start of fibrinolytic therapy.[2] The median administration time in the United States in 2006 was 29 minutes, with only 50% of patients meeting the quality performance target of less than 30 minutes.[37] In the past 10 years, there has been little improvement in this quality measure with only 59% of patients receiving fibrinolytic reperfusion therapy having a door-to-needle time of less than 30 minutes in 2015. All hospitals should have protocols addressing fibrinolysis eligibility, dosing, and monitoring.[36]

A fibrin-specific agent, such as alteplase, reteplase, or tenecteplase, is preferred over a non–fibrin-specific agent such as streptokinase.[2] Fibrin-specific fibrinolytics open a greater percentage of infarcted arteries. Two trials compared alteplase with reteplase and alteplase with tenecteplase and found similar mortality between agents.[38,39] Therefore, alteplase, reteplase, and tenecteplase are acceptable as first-line agents. ICH and major bleeding are the most serious side effects of fibrinolytic agents. The risk of ICH is higher with fibrin-specific agents than with streptokinase.[2] However, the risk of systemic bleeding other than ICH is higher with streptokinase than with other more fibrin-specific agents and was higher with alteplase versus tenecteplase in one study.[2,38,39,40]

Aspirin

Aspirin is the preferred antiplatelet agent in the treatment of choice in all subsets of ACS.[2,3,4] Aspirin administration within 24 hours before or after hospital arrival to all patients without contraindications is recommended. The antiplatelet effects of aspirin are mediated by inhibiting the synthesis of TXA_2 through an irreversible inhibition of platelet cyclooxygenase-1. In patients undergoing PCI, aspirin prevents acute thrombotic occlusion during the procedure. In patients receiving fibrinolytics, aspirin reduces mortality, and its effects are additive to fibrinolysis alone.[2,4] Additionally, in patients undergoing PCI, aspirin, in addition to a $P2Y_{12}$ inhibitor, reduces the risk of stent thrombosis.[4]

In patients experiencing an ACS, an initial dose equal to or greater than 160 mg non-enteric aspirin is necessary to achieve a rapid platelet inhibition.[3] Current guidelines for STEMI recommend an initial aspirin dose of 162 to 325 mg (see Table 17-2).[2] This first dose can be chewed in order to achieve high blood concentrations and platelet inhibition rapidly. Preferably, patients undergoing PCI not previously taking aspirin should receive 325 mg non–enteric-coated aspirin.[4] Current data suggest that although an initial dose of 162 to 325 mg is required, long-term therapy with doses of 75 to 150 mg daily is as effective as higher doses, and therefore a daily maintenance dose of 75 to 162 mg is recommended in most patients to inhibit the 10% of the total platelet pool that is regenerated daily.[41] Most recent guidelines recommend a dose of 81 mg in patients receiving dual antiplatelet therapy.[26] In a large (*n* = 25,086) randomized trial, high-dose aspirin, 300 to 325 mg daily, had similar frequency of CV death, MI, or stroke as well as major bleeding compared with low-dose aspirin in the first 30 days following ACS presentation.[42,43] Minor bleeding and GI bleeding were less frequent with low-dose aspirin. In this trial, patients undergoing PCI during hospitalization had a lower frequency of death, MI, or stroke, but major bleeding was increased with high-dose aspirin.[44] Post-hoc analysis from the Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction (HORIZONS-AMI) trial compared outcomes in patients treated with aspirin doses of less than or equal to 200 mg with doses of greater than 200 mg daily and found that higher doses were a predictor of major bleeding but demonstrated similar 3-year risk of CV events.[45] In the Study of Platelet Inhibition and Patient Outcomes (PLATO), a randomized, double-blind clinical trial comparing ticagrelor with clopidogrel in patients receiving aspirin, a post-hoc analysis suggested that maintenance doses of aspirin above 100 mg daily reduced the effectiveness of ticagrelor.[44] Because of increased bleeding risk in patients receiving aspirin plus a $P2Y_{12}$ inhibitor compared with aspirin alone, low-dose aspirin (81 mg daily) is preferred following PCI.[4,46] Low-dose aspirin should be continued indefinitely.[46]

Nonsteroidal anti-inflammatory agents other than aspirin, as well as cyclooxygenase-2 (COX-2) selective anti-inflammatory agents are contraindicated in STEMI and should be discontinued at the time of STEMI secondary to increased risk of death, reinfarction, HF, and myocardial rupture.[2]

The most frequent side effects of aspirin are dyspepsia and nausea. Patients should be counseled about the risk of bleeding, especially GI bleeding, with aspirin.

Platelet $P2Y_{12}$ Inhibitors

Clopidogrel, prasugrel, and ticagrelor are oral agents that block a subtype of the ADP receptor, the

$P2Y_{12}$ receptor, on platelets, preventing the binding of ADP to the receptor and subsequent expression of platelet GP IIb/IIIa receptors, reducing platelet activation and aggregation. Both clopidogrel and prasugrel are thienopyridines and prodrugs that are converted to an active metabolite by a variety of cytochrome P450 (CYP) isoenzymes (**Table 17-4**).[47]

TABLE 17-4 Clinical Considerations When Choosing a $P2Y_{12}$ Receptor Inhibitor[2,3,4,26,64,66,67,69]

	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Pharmacologic class	Thienopyridine	Thienopyridine	Cyclopentyl triazolopyrimidine	Stabilized ATP analog
ADP receptor binding	Irreversible	Irreversible	Reversible	Reversible
Pharmacokinetics	Prodrug Converted twice to active metabolite primarily through CYP2C19	Prodrug Converted to active metabolite through CYP 3A4 and 2B6	Active moiety Converted to active metabolite through CYP 3A4/5	Active drug Independent of hepatic function; rapidly dephosphorylzed to inactive metabolite
	Elimination half-life of active metabolite is approximately 30 minutes after a 75-mg dose	Median elimination half-life of the active metabolite approximately 7.4 hours	Median elimination half-life of the parent compound is approximately 7 hours and active metabolite approximately 9 hours	Plasma half-life of 5-10 minutes; elimination half-life of 3-6 minutes
	Excretion is 50% urinary and 46% fecal	Excretion is primarily urinary (approximately 70%); fecal excretion <30%	Excretion is primarily metabolism (84%); fecal excretion 58%, urinary excretion (26%)	Excretion is 58% renal and 35% fecal (presumed biliary)
	No dose adjustment necessary in CKD	Not recommended when eGFR <15 mL/min/1.73 m^2	Not recommended when eGFR < 15 mL/min/1.73 m^2	No dose adjustment necessary in CKD
Dosing	300-600 mg Loading dose; 75 mg daily	60 mg loading dose; 10 mg daily	180 mg loading dose; 90 mg twice daily for 1 year, 60 mg twice daily thereafter	30 mcg/kg bolus; 4 mcg/kg/min IV infusion continued for at least 2 hours or the duration of PCI, whichever is longer

	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Onset of loading dose effect	Peak platelet inhibition occurs within 2 hours after 600 mg load and 6 hours after oral 300 mg load	Peak platelet inhibition reached within 1-1.5 hours after oral 60 mg load	Peak platelet inhibition within 1 hour after oral 180 mg load	Peak platelet inhibition within 2 minutes after 30 mcg/kg bolus
Duration of effect	3-10 days	7-10 days	3-5 days	1-2 hours
Drug and Disease considerations	Genetic polymorphisms may influence efficacy; Enhanced bleeding with NSAIDs; avoid use Enhanced bleeding with warfarin; monitor carefully for bleeding; target INR to 2.0-2.5 for most indications Avoid use with moderate or strong CYP2C19 inhibitors (omeprazole, esomeprazole, chloramphenicol, cimetidine, efavirenz, etravirine felbamate, fluoxetine, fluconazole, fluvoxamine, isoniazid, oxcarbazepine, ketoconazole, voriconazole); select alternative non-interacting $P2Y_{12}$ inhibitor or alternative non-interacting drug	Enhanced bleeding with warfarin and NSAIDs, avoid use	Enhanced bleeding with warfarin and NSAIDs Use aspirin doses <100 mg daily Avoid use with strong CYP3A inhibitors (atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, ketoconazole, ritonavir, saquinavir, telithromycin, voriconazole) Avoid use with potent CYP3A inducers (carbamazepine, dexamethasone, phenobarbital, phenytoin, rifampin) Avoid simvastatin and lovastatin doses more than 40 mg daily (ticagrelor inhibits CYP3A4 and increases statin concentration) Monitor digoxin	Do not administer clopidogrel or prasugrel prior to the discontinuation of cangrelor infusion Ticagrelor may be given at any time during cangrelor infusion or immediately after the discontinuation of cangrelor infusion

	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
			serum concentrations with any change in ticagrelor dose (ticagrelor inhibits P-glycoprotein) Unique side-effects including dyspnea and bradycardia	
Contraindications	Any active pathological bleeding	Any active pathological bleeding; any history of TIA/stroke	Any active pathological bleeding; ICH or severe hepatic disease	Significant active bleeding or hypersensitivity
Surgery hold time	5 days for elective surgery; 24 hours for urgent	7 days	5 days for elective surgery; 24 hours for urgent	1 hour
NSTE-ACS indication	May be used regardless of treatment strategy; additional non-ACS indications	Reasonable over clopidogrel in patients treated with PCI who are not at high risk for bleeding	Preferable to clopidogrel for NSTE ACS patients treated with early or invasive or ischemia-guided approach	No US guideline recommendation; May be considered in $P2Y_{12}$ inhibitor—naïve patients undergoing PCI
STEMI indication	Preferred when fibrinolytics used	Superior to clopidogrel in STEMI or in other high-risk patients like DM; Not studied in patients receiving fibrinolytic therapy	Superior to clopidogrel; Not studied in patients receiving fibrinolytic therapy	No US guideline recommendation; May be considered in $P2Y_{12}$ inhibitor—naïve patients undergoing PCI
Risk benefit considerations	Gold standard for reducing CV death and stent thrombosis compared to placebo Consider alternative if documented clopidogrel ineffectiveness (ie, poor metabolism, stent thrombosis	Superior to clopidogrel with a significant increase in bleeding risk (driven mainly by reductions in MI and stent thrombosis); No clinical benefit when age ≥75 or	Superior to clopidogrel with modest increase in major non-CABG related bleeding; Associated with an all-cause mortality reduction; Consider compliance with twice daily dosing	Demonstrated better efficacy than post PCI clopidogrel with minor increases in bleeding Has potential use as a bridge to CABG surgery in high-risk patients

	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
	during clopidogrel therapy)	weight <60 kg; Net harm in patients with history of TIA or stroke		

ADP, adenosine diphosphate; CABG, coronary artery bypass grafting; CV, cardiovascular; CYP, cytochrome P450; DM, diabetes mellitus; ICH, intracranial hemorrhage; INR, international normalized ratio; NSAIDs, non-steroidal anti-inflammatory drugs; NSTE-ACS, Non-ST-segment elevation acute coronary syndrome; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; TIA, transient ischemic attack.

Both of these agents bind irreversibly to $P2Y_{12}$ receptor. Ticagrelor, which is not a thienopyridine, is a reversible, noncompetitive $P2Y_{12}$ receptor inhibitor. Ticagrelor's parent compound has antiplatelet effects and is also metabolized primarily by CYP3A to an active metabolite producing its antiplatelet effects.

A newer agent, cangrelor is an intravenous $P2Y_{12}$ inhibitor recently approved as an adjunct to PCI in patients not receiving prior oral $P2Y_{12}$ inhibitors or planned GPIs. Cangrelor is indicated to reduce periprocedural MI, repeat revascularization and stent thrombosis in patients undergoing PCI. In a randomized, double-blind study comparing cangrelor to clopidogrel in patients undergoing PCI (42% of patients with ACS), cangrelor reduced the rate of periprocedural complications of PCI without a statistically significant difference in risk of major bleeding.[48] At this time, there are no US guideline recommendations describing the role of cangrelor in ACS.

Both prasugrel and ticagrelor are more potent ADP inhibitors than clopidogrel. Prasugrel has the fewest significant drug–drug interactions of the oral $P2Y_{12}$ inhibitors. The production of clopidogrel's active metabolite and consequently its antiplatelet effect is reduced by moderate and strong inhibitors of CYP2C19, while ticagrelor's concentration is reduced by strong inhibitors of CYP3A. Labeled drug interactions are described in Table 17-4. A more detailed discussion of the interaction between clopidogrel and proton pump inhibitors may be found in Chapter 16. Both clopidogrel and prasugrel interact with cangrelor and cannot be administered until the end of the infusion as the patient would not have any antiplatelet effect of the oral agent until after the next administered dose. This does not appear to be the case with ticagrelor and it can be administered at any time during the active infusion of cangrelor.

Genetic variations in the gene coding for *CYP2C19* significantly modulate the antiplatelet effects of clopidogrel. Specifically, carriers of reduced-function allele (ie, *2 or *3) are not able to convert clopidogrel to its active metabolite in comparison to carriers of the wild-type allele (*1). This results in decreased antiplatelet effects, as well as higher rates of CV events, especially stent thrombosis and MI around the time of PCI.[49,50] Prasugrel and ticagrelor efficacy are not associated with *CYP2C19* genotype.[51] Hence, either ticagrelor or prasugrel are preferred in either intermediate metabolizers (*1/*2, *1/*3, *2/*17) or poor metabolizers (*2/*2, *2/*3, *3/*3) of *CYP2C19* reduced-function alleles if there is no contraindication.[52] Nevertheless, in the absence of a large randomized trial demonstrating

the benefit of such genotype-based approach, the most recent practice guidelines have not endorsed routine genotyping to guide the prescription of $P2Y_{12}$ inhibitors.[2,3,4] Ongoing clinical trials should clarify the benefits of a genotype-guided use of these agents.

Administration of a $P2Y_{12}$ receptor inhibitor, in addition to aspirin, is recommended for all patients with STEMI.[2,26] For patients undergoing primary PCI, clopidogrel, prasugrel, ticagrelor, or IV cangrelor in addition to aspirin, should be administered to prevent subacute stent thrombosis and longer-term CV events (see Table 17-2).[2,4] Although not FDA approved, a clopidogrel loading dose of 600 mg is recommended over administration of 300 mg for patients undergoing PCI.[4] A systematic review and meta-analysis of randomized and nonrandomized trials in more than 25,000 patients demonstrated a reduction in CV ischemic events with a loading dose of 600 mg compared with 300 mg in patients undergoing PCI.[53] Although a modest benefit of using a 7-day course of clopidogrel 150 mg compared to 75 mg daily has been suggested, it is also associated with a higher risk of major bleeding. Thus, routine use of such dosing is not recommended in current practice guidelines.[2,3,4]

In the most recent PCI practice guidelines, no preference is given for one oral agent over the other.[4] Nevertheless, clinical trials comparing these agents have highlighted distinct clinical differences between these antiplatelet agents. Based on these evidences, the most recent NSTE-ACS guidelines nonetheless favor ticagrelor or prasugrel in selected patients and this will be discussed in a later section.[3]

A large randomized, double-blind study demonstrated that, compared with clopidogrel, the addition of prasugrel to aspirin for patients undergoing PCI in the setting of STEMI or NSTE-ACS significantly reduced risk of CV death or MI by 19% (9.9% vs 12.1%), as well as MI and stent thrombosis, but increased the risk of major bleeding (not ICH) by 32% (2.4% vs 1.8%).[54] Patients with a history of prior stroke or transient ischemic attack (TIA) had an increased risk of ICH and no net clinical benefit from prasugrel, therefore stroke or TIA is a contraindication to prasugrel.[54] Patients older than 75 years and those weighing less than 60 kg (132 lb) are at increased risk of bleeding with prasugrel compared with clopidogrel.[47] Two subgroups of patients do not have an increased bleeding risk with prasugrel compared with clopidogrel and have even greater benefit, namely, patients undergoing primary PCI for STEMI and patients with a history of diabetes mellitus (DM).[55,56]

Platelet Inhibition and Patient Outcomes compared ticagrelor with clopidogrel in patients receiving aspirin and presenting with either STEMI or NSTE-ACS and undergoing an intended interventional management strategy with PCI or conservative noninterventional management strategy with medical therapy alone. In this trial, ticagrelor significantly reduced the rate of the CV death, MI, stroke, and stent thrombosis compared with clopidogrel.[57] Although no increase in study-defined major bleeding was noted with ticagrelor, the frequency of non-CABG major bleeding was increased compared with clopidogrel. As with the prasugrel trial described, several subgroups of patients enrolled in this trial had particular benefit with ticagrelor, including those with an intended invasive approach, those with an intended noninvasive approach, patients with STEMI primary PCI, and patients with DM.[58,59,60,61] Therefore, both of the more potent $P2Y_{12}$ inhibitors are more efficacious than clopidogrel but may also be associated with an increased risk of bleeding. No large randomized trial has directly compared ticagrelor and prasugrel.[62]

The recommended duration of $P2Y_{12}$ inhibitors for a patient undergoing PCI for ACS, either STEMI or NSTE-ACS, is at least 12 months for patients receiving either a BMS or DES.[2,4,26] The consequence of prolonging treatment beyond 12 months had been uncertain until recently.[2,4] Indeed, given the risk of late stent thrombosis, in particular with DES, it had been suggested that long-term use of DAPT could be beneficial, but the uncertainty related to the potential increased risk of bleeding associated with this approach translated in the need for clinical trials with long-term follow-up to properly assess the risk: benefit of such an approach. Many previous trials had suggested that indeed this approach was associated with a reduction in the risk of stent thrombosis with a higher risk of bleeding, and uncertain impact on mortality. The most definitive data comes from the PEGASUS-TIMI (Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin -Thrombolysis in Myocardial Infarction) 54 trial, which was published after the latest guidelines. In this trial, 21,162 patients who had a history of MI within the previous 1 to 3 years were randomly assigned in a double-blind fashion to receive, in addition to low-dose, aspirin: (1) ticagrelor (90 mg twice daily), (2) ticagrelor (60 mg twice daily), or (3) placebo. Eighty-three percent had a previous PCI. After a median follow-up of 33 months, both ticagrelor doses reduced the risk of the primary efficacy endpoint, which was a composite of CV death, MI, or stroke compared with placebo (ticagrelor 90 mg: 7.85%; ticagrelor 60 mg: 7.77%; placebo: 9.04%; $p < 0.01$ for each ticagrelor dose vs placebo). This benefit was at the expense of an increased risk of major bleeding (ticagrelor 90 mg: 2.60%; ticagrelor 60 mg: 2.30%; placebo: 1.06%); $p < 0.001$ for each dose vs placebo). CV mortality and all-cause mortality were not significantly reduced in any of the ticagrelor group compared to placebo. These results highlight a very fragile benefit: risk ratio of prolonging DAPT beyond 12 months and the necessity to carefully assess the CV and bleeding risk of a patient when contemplating the prolongation of DAPT beyond 12 months.[63] While there was no statistical comparison between doses reported in the PEGASUS-TIMI 54 publication, only the 60 mg dose is currently approved by the FDA for use beyond 1 year after an ACS.[64] The rates of dyspnea and bleeding were numerically lower with the 60 mg dose.[63]

Nonadherence to $P2Y_{12}$ inhibitors is a major risk factor for stent thrombosis, and hence the likelihood of adherence to DAPT (aspirin and a $P2Y_{12}$ inhibitor) should be assessed prior to angiography. The use of a BMS over a DES should be considered in patients who are anticipated to be nonadherent to 12 months of DAPT.[4]

To minimize the risk of CV events, elective noncardiac surgery should be delayed to more than 4 to 6 weeks after angioplasty or BMS implantation, or 12 months after DES implantation if the discontinuation of the $P2Y_{12}$ inhibitor is required. If CABG surgery is planned, clopidogrel and ticagrelor should be withheld preferably for 5 days, and prasugrel at least 7 days, to reduce the risk of postoperative bleeding, and restarted postoperatively, unless the need for immediate revascularization outweighs the bleeding risk. Low-dose aspirin should be continued.[2,4]

Although a variety of blood tests can assess functional platelet aggregation inhibition to $P2Y_{12}$ inhibitors, especially clopidogrel, there is no one gold standard test. Moreover, despite using a higher maintenance dose of clopidogrel (150 mg daily) in patients with a high level of on-treatment platelet aggregation (low platelet aggregation inhibition) that resulted in improved platelet aggregation inhibition, dosing of clopidogrel via platelet aggregation testing does not result in improved clinical outcomes.[65] Therefore, current practice guidelines do not recommend routine platelet aggregation testing to determine $P2Y_{12}$ inhibitor strategy.[2,3,4]

The most frequent side effects of clopidogrel and prasugrel are nausea, vomiting, and diarrhea, which occur in approximately 2% to 5% of patients.[66,67] Rarely, thrombotic thrombocytopenic purpura (TTP) has been reported with clopidogrel.[67] Clopidogrel hypersensitivity, most commonly presenting as rash develops in up to 6% of patients.[68] In addition to nausea (4%) and diarrhea (3%), use of ticagrelor is associated with dyspnea (up to 19% resulting in drug discontinuation in up to 7% of patients) and, rarely, ventricular pauses and bradyarrhythmias.[63] Patients at risk of bradycardia were excluded from PLATO and PEGASUS-TIMI 54.[57,63] Small non-clinically significant increases in SCr and serum uric acid have also been reported with ticagrelor.[64] A greater incidence of bleeding, hypersensitivity reactions, dyspnea, and worsening renal function has occurred with cangrelor compared to control.[69]

In STEMI patients receiving fibrinolysis, early therapy with clopidogrel 75 mg once daily administered during hospitalization and up to 28 days (mean: 14 days) reduced mortality and reinfarction without increasing the risk of major bleeding.[2,70,71] In adult patients younger than 75 years of age receiving fibrinolytics, the first dose of clopidogrel can be a 300 mg loading dose.[2,71] Although prasugrel and ticagrelor have been studied in the setting of PCI, no studies have evaluated their use when added to both aspirin and a fibrinolytic.

Clopidogrel added to aspirin should be continued for at least 14 days (and up to 1 year) for patients presenting with STEMI who do not undergo reperfusion therapy with either primary PCI or fibrinolysis.[2,70] However, recent subgroup analysis from PLATO suggests that ticagrelor may also be an option in medically managed patients with ACS not receiving fibrinolysis because the frequency of CV death, MI, or stroke as well as mortality was lower in ticagrelor-treated patients compared with those receiving clopidogrel **(Fig. 17-4)**. Ticagrelor use was not associated with a higher bleeding rate compared with clopidogrel.[58]

FIGURE 17-4

Proposed use of $P2Y_{12}$ inhibitors. [a]Do not use clopidogrel in patients with active pathologic bleeding; consider alternative $P2Y_{12}$ receptor inhibitor if documented clopidogrel ineffectiveness (eg, poor metabolism, stent thrombosis during clopidogrel therapy) or drug–drug interactions (eg, avoid moderate and strong CYP2C19 inhibitors); clopidogrel should be held for at least 5 days before CABG surgery, if the surgery can be delayed. [b]Do not use prasugrel in patients with active pathologic bleeding or a history of transient ischemic attack or stroke; if a patient subsequently goes on to receive CABG surgery, the drug should be held for at least 7 days if the surgery can be delayed. [c]Do not use ticagrelor in patients with active pathologic bleeding or a history of intracranial hemorrhage, or in patients planned to undergo urgent CABG surgery; concomitant maintenance aspirin dose above 100 mg should be avoided; dose of ticagrelor should be held for 5 days before CABG surgery, if the surgery can be delayed; when selecting this agent, consider patient compliance (dosed twice daily), unique adverse effects (e.g., dyspnea), and potential drug–drug interactions (e.g., avoid strong CYP3A inhibitors/inducers). [d]Prior to diagnostic angiography, it is difficult to determine the likelihood that an individual patient will receive CABG surgery; notable variables that predict this occurrence include previous CABG, male gender, previous heart failure, presence of diabetes, and previous percutaneous coronary intervention, among others. [e]Recommendation based on subgroup analysis. [f]At this time, there are insufficient data to support ticagrelor or prasugrel in the "fibrinolytic or nonprimary PCI" patient group. (ACS, acute

coronary syndrome; CABG, coronary artery bypass graft; MI, myocardial infarction; NSTE, non–ST-segment elevation; PCI, percutaneous coronary intervention; STE, ST-segment elevation; TIA, transient ischemic attack.) Clinical Controversy… PERSONALIZED MEDICINE OF $P2Y_{12}$ INHIBITORS

In the last decade, a significant amount of information has been published with regard to the association of genetic factors with the antiplatelet response to clopidogrel.[47,50,72]

Specifically, a great amount of evidence indicates that patients carrying a reduced or loss-of-function allele of the gene coding for *CYP2C19*, one of the isoenzymes implicated in the conversion of clopidogrel to its active metabolite, have a higher risk of CV events following an ACS, particularly those undergoing PCI. These data do not extend to other populations of patients receiving clopidogrel. Nevertheless, despite these extensive data, the most recent guidelines do not endorse routine genotyping in patients receiving an ADP $P2Y_{12}$ inhibitor, but favor a case-by-case approach in selected individuals.[2,3] On the other hand, guidelines from the Clinical Pharmacogenetics Implementation Consortium (CPIC) recommend the use of genetic information when it is available in patients with an ACS undergoing PCI for whom clopidogrel is being prescribed to personalize treatment.[73] The guidelines indicate that prasugrel or ticagrelor are preferred over clopidogrel in intermediate or poor metabolizers (for example, those carrying one or two *CYP2C19*2* alleles), when not contraindicated. These inconsistencies between two professional organizations reflect differences in their level of evidence to evaluate the data. The guidelines are primarily based on results from large, randomized controlled trials demonstrating a superiority of an approach before it can be strongly endorsed, whereas CPIC focused more on consistent results from well-designed clinical studies to give strong recommendations. Moreover, CPIC recommendations focus on "how to use" genetic information, rather than "when to genotype" patients.

Glycoprotein IIb/IIIa Receptor Inhibitors

GP IIb/IIIa receptor inhibitors (GPIs) block the final common pathway of platelet aggregation, namely, cross-linking of platelets by fibrinogen bridges between the GP IIb and IIIa receptors on the platelet surface. In patients with STEMI undergoing primary PCI who are treated with UFH, abciximab (IV or

intracoronary administration), eptifibatide, or tirofiban may be administered.[2,4] Routine use of a GPI is not recommended in patients who have received fibrinolytics or in those receiving bivalirudin secondary to increased bleeding risk. GPIs should not be administered for medical management of the patient with STEMI who will not be undergoing PCI.[2] A meta-analysis of STEMI primary PCI trials demonstrated no reduction in mortality or 30-day reinfarction but increased risk of major bleeding with GPIs compared with control.[74] Although there are more clinical trial data with abciximab for primary PCI compared with the small-molecule GPIs eptifibatide and tirofiban, the small-molecule agents are used more commonly in clinical practice. A meta-analysis found no difference in efficacy and safety between abciximab and the small-molecule GPIs.[75]

Dosing and contraindications for GPIs are described in Table 17-2. Bleeding is the most significant adverse effect associated with administration of GPIs. GPIs should not be administered to patients with a prior history of hemorrhagic stroke or recent (less than 30 days) ischemic stroke. The risk of bleeding is increased in patients with chronic kidney disease.[76] The recommended dosing for tirofiban (high bolus dose) referenced in the STEMI guidelines is not an FDA-approved regimen but one that has been studied in more contemporary clinical trials.[77,78] This regimen is FDA-approved for patients with NSTE ACS. The dose of tirofiban should be halved in patients with CrCl less than 30 mL/min (0.50 mL/s).[79] No dosage adjustment for renal function is necessary for abciximab. An immune-mediated thrombocytopenia associated with both bleeding as well as thrombosis (when therapy is stopped) occurs in approximately 5% of patients with abciximab and less than 2% of patients receiving eptifibatide or tirofiban.[76,79,80]

Anticoagulants

Options for anticoagulant therapy for patients with STEMI are outlined in Fig. 17-2 and Table 17-2.[2,4] For patients undergoing primary PCI, either UFH or bivalirudin is preferred, whereas for fibrinolysis, UFH, enoxaparin, or fondaparinux may be administered. For patients undergoing PCI, anticoagulation is discontinued immediately following the PCI procedures. In patients receiving an anticoagulant plus a fibrinolytic, UFH is continued for a minimum of 48 hours and if either enoxaparin or fondaparinux is selected, those agents are continued for the duration of hospitalization, up to 8 days. In patients who do not undergo reperfusion therapy, it is reasonable to administer anticoagulant therapy for up to 48 hours for UFH or for the duration of hospitalization for enoxaparin or fondaparinux.[2,4]

Unfractionated heparin has been the traditional anticoagulant administered to patients with STEMI to prevent reocclusion of an infarct artery for more than 50 years. The results of a meta-analysis of more than 7,500 patients suggest that low-molecular-weight heparins (LMWHs) reduce both mortality and reinfarction compared with placebo in patients treated with fibrinolytics and aspirin.[81] Earlier trials favored bivalirudin, a direct thrombin inhibitor, over UFH plus a GPI (abciximab, eptifibatide, or tirofiban) due to bivalirudin's similar or greater efficacy but less bleeding compared with UFH.[82,83] Clinical practice patterns have evolved since time of these trials including a lower use of GPIs and greater PCI through the radial artery instead of the femoral artery which both reduce bleeding risk. Yet contemporary management also includes more frequent use of more potent $P2Y_{12}$ inhibitors than clopidogrel, which may increase bleeding risk. The superiority of either UFH or bivalirudin in primary PCI has been subject of recent trials, which demonstrate conflicting results (see Clinical Controversy).

While UFH or bivalirudin is preferred in primary PCI, enoxaparin, administered for a median of 7 days,

has shown a reduction in the risk of death or nonfatal MI but increased bleeding risk compared with UFH (administered for a median of 2 days) in a large randomized clinical trial of patients treated with fibrinolytics.[84] Enoxaparin dosing is adjusted for body weight (mg/kg) and renal function, and when administered in combination with fibrinolysis, it has special dosing requirements for older patients and those weighing more than 100 kg (see Table 17-2).

Besides bleeding, the most serious adverse effect of UFH and enoxaparin is *heparin-induced thrombocytopenia*. ACS registry data indicate, however, that the frequency of heparin-induced thrombocytopenia is rare (less than 0.5%).[85] Bivalirudin would be a preferred anticoagulant for patients with a history of heparin-induced thrombocytopenia undergoing PCI.[2,4]

Clinical Controversy… UFH or Bivalirudin in Primary PCI

Antiplatelet and anticoagulant regimens are used concomitantly during primary PCI to combat the physiological process of platelet aggregation and thrombin formation during STEMI as well as to reduce periprocedural complications. Both UFH and bivalirudin are recommended anticoagulants for patients with STEMI who are undergoing primary PCI.[2] Until recently, bivalirudin was preferred by practice guidelines to UFH as anticoagulant therapy in patients at high risk for bleeding because of data suggesting similar or greater efficacy but less bleeding compared with UFH plus GPI (abciximab, eptifibatide, or tirofiban).[82,83] Recently, data supporting the use of bivalirudin in preference to UFH have been criticized and the optimal anticoagulant for use in primary PCI has been debated. Earlier trials demonstrated reduced mortality and major bleeding favoring bivalirudin, a direct thrombin inhibitor, over UFH but the majority of data comparing the two anticoagulants in this setting is confounded by a high coadministration of GPIs with UFH but not with bivalirudin. Since then, clinical practice patterns have evolved including a more limited and selective use of GPIs, increased utilization of more potent $P2Y_{12}$ inhibitors, and percutaneous access through the radial instead of the femoral artery; all of which may influence safety and efficacy outcomes.

With current evidence, it is difficult to distinguish superiority of one agent over the other in terms of efficacy or safety because contemporary comparisons of UFH and bivalirudin during primary PCI have yielded differing results. Study design, definitions for primary and secondary endpoints including net or major adverse cardiac events, bleeding definitions, and clinical practice patterns (GPI use, $P2Y_{12}$ utilization, and access technique) have varied between the published studies. All trials to date have been open-label, for which potential bias cannot be ruled out. Very few trials have been powered to detect mortality differences.

Bleeding definitions were not standardized across the trials and thus differences between the anticoagulants cannot be easily compared. Studies with more liberal definitions of bleeding demonstrated results favoring bivalirudin.[83,86] Recent studies with more conservative definitions have mixed results overall and do not demonstrate the overwhelming benefit of bivalirudin over UFH in terms of bleeding outcomes.[87,88] Yet other variances such as concomitant antiplatelet use and access site of procedure can influence bleeding results, which have made comparisons of safety between the two anticoagulants difficult. Radial access, which is increasingly used in the United States for coronary angiography, reduces bleeding complications compared to femoral access.[89]

Importantly, recent concerns have been raised over increased risk for acute stent thrombosis with

bivalirudin.[86,87] A post-intervention infusion of bivalirudin has been theorized to reduce the risk of stent thrombosis during the immediate post-procedure timeframe. Immediately after PCI, there may be a delay in the onset of full antiplatelet effect with a $P2Y_{12}$ inhibitor during the time that bivalirudin's anticoagulant effect is waning secondary to its short half-life and rapid clearance. Post-hoc and meta-analysis findings support the association between a full-dose post-PCI bivalirudin infusion and decreased stent thrombosis risk yet one prospective trial has not.[90]

At this point, there is no clearly superior agent and both UFH and bivalirudin remain as viable options for use in this setting, each with its own set of advantages and disadvantages when considering ischemic and bleeding complications as well as cost.

β-Blockers

In ACS, the benefit of β-blockers results mainly from the competitive blockade of β_1-adrenergic receptors located on the myocardium. β_1-Blockade produces a reduction in heart rate (HR), myocardial contractility, and blood pressure (BP), decreasing myocardial oxygen demand. In addition, the reduction in HR increases diastolic time, thus improving ventricular filling and coronary artery perfusion. As a result of these effects, β-blockers reduce the risk for recurrent ischemia, infarct size, risk of reinfarction, and occurrence of ventricular arrhythmias in the hours and days following MI.

Landmark clinical trials have established the role of early β-blocker therapy in reducing MI mortality. Most of these trials were performed in the 1970s and 1980s before routine use of early reperfusion therapy. However, data regarding the acute benefit of β-blockers in MI in the reperfusion era are derived mainly from a single large clinical trial that suggests that although initiating IV followed by oral β-blockers early in the course of STEMI was associated with a lower risk of reinfarction or ventricular fibrillation, there may be an early risk of cardiogenic shock, especially in patients presenting with pulmonary congestion or systolic BP less than 120 mm Hg.[91] Oral beta blockers are preferred over IV in the contemporary management of ACS. Initiation of β-blockers, particularly when administered IV, should be limited to patients who present with HTN and/or have ongoing signs of myocardial ischemia and do not demonstrate any signs or symptoms of acute HF.[2] Careful assessment for signs of hypotension and HF should be performed following β-blocker initiation and prior to any dose titration. Patients already taking β-blockers can continue taking them.[2]

The most serious side effects of β-blocker administration early in ACS are hypotension, acute HF, bradycardia, and heart block. Although initial acute administration of β-blockers is not appropriate for patients who present with acute HF, initiation of β-blockers may be attempted before hospital discharge in most patients following treatment of acute HF. β-Blockers should be continued for at least 3 years in patients with normal LV function and indefinitely in patients with LV systolic dysfunction and an LVEF less than or equal to 40% (0.40).[46]

Statins

A high-intensity statin (either atorvastatin 80 mg or rosuvastatin 40 mg) should be administered to all patients without contraindications prior to PCI (regardless of prior lipid-lowering therapy) to reduce the frequency of periprocedural MI (a Type IVa MI) following PCI.[4,10]

Nitrates

One SL NTG tablet should be administered every 5 minutes for up to three doses in order to relieve myocardial ischemia. If patients have been previously prescribed SL NTG and ischemic chest discomfort persists for more than 5 minutes after the first dose, the patient should be instructed to contact EMS before self-administering subsequent doses to activate EMS sooner. IV NTG should then be initiated in all patients with an ACS who have persistent ischemia, HF, or uncontrolled high BP in the absence of contraindications.[2] IV NTG should be continued for approximately 24 hours after ischemia is relieved (see Table 17-2). Nitrates promote the release of nitric oxide from the endothelium, which results in venous and arterial vasodilation. Venodilation lowers preload and myocardial oxygen demand. Arterial vasodilation may lower BP, thus reducing myocardial oxygen demand. Arterial vasodilation also relieves coronary artery vasospasm, dilating coronary arteries to improve myocardial blood flow and oxygenation. Although used to treat ACS, nitrates have been suggested to play a limited role in the treatment of ACS patients because randomized clinical trials failed to show a mortality benefit for IV nitrate therapy followed by oral nitrate therapy in acute MI. The most significant adverse effects of nitrates are tachycardia, flushing, headache, and hypotension. Nitrate administration is contraindicated in patients who have received oral phosphodiesterase-5 inhibitors, such as sildenafil and vardenafil, within the last 24 hours, and tadalafil within the last 48 hours.[2]

Calcium Channel Blockers

Calcium channel blockers in the setting of STEMI are used for relief of ischemic symptoms in patients who have certain contraindications to β-blockers. Current data suggest little benefit on clinical outcomes beyond symptom relief for calcium channel blockers in the setting of ACS.[2] Therefore, calcium channel blockers should be avoided in the acute management of all ACS unless there is a clear symptomatic need or a contraindication to β-blockers. Agent selection is based on presenting HR and LVF. Administration of an agent that lowers HR, either diltiazem or verapamil, is preferred unless the patient has LV systolic dysfunction, bradycardia, or heart block, and then either amlodipine or felodipine is preferred.[2] Nifedipine should be avoided because it has demonstrated reflex sympathetic activation, tachycardia, and worsened myocardial ischemia.[2] Dosing and contraindications are described in Table 17-2.

Early Pharmacotherapy for NSTE-ACS

In general, early pharmacotherapy of NSTE-ACS (see Fig. 17-3) is similar to that of STEMI. In the absence of contraindications, all patients with NSTE-ACS should be treated in the ED with intranasal oxygen (if oxygen saturation is low), SL NTG, aspirin, and an anticoagulant: UFH, enoxaparin, fondaparinux, or bivalirudin. High-risk patients should proceed to early angiography and may receive a GPI (optional with either UFH or enoxaparin but should be avoided with bivalirudin).[3] A $P2Y_{12}$ inhibitor (choice of agent and timing of initiation dependent on selection of an interventional approach involving an early invasive strategy with either PCI or CABG surgery versus an ischemia-guided strategy with medical management alone) should be administered to all patients. IV β-blockers and IV NTG should be given in selected patients. Oral β-blockers should be initiated within the first 24 hours in patients without cardiogenic shock.[3] Morphine is also administered to patients with refractory angina as described previously. These agents should be administered early while the patient is still in the ED. Fibrinolytic therapy is never

administered. Dosing and contraindications for SL and IV NTG (for selected patients), aspirin, $P2Y_{12}$ inhibitors, β-blockers, and anticoagulants are listed in Table 17-2.

Fibrinolytic Therapy

Fibrinolytic therapy is not indicated in any patient with NSTE-ACS because increased mortality has been reported with fibrinolytics compared with controls in clinical trials in which fibrinolytics have been administered to patients with NSTE-ACS (patients with normal or ST-segment depression ECGs).[3]

Aspirin

Aspirin reduces the risk of death or developing MI by about 50% (compared with no antiplatelet therapy) in patients with NSTE-ACS. Therefore, aspirin remains the cornerstone of early treatment for all patients with ACS. Dosing of aspirin for NSTE-ACS is the same as that for STEMI (see Table 17-2). Low-dose aspirin is continued indefinitely.[3,46]

Anticoagulants

The choice of anticoagulant for a patient with NSTE-ACS is guided by risk stratification and initial treatment strategy, either an early invasive approach with early coronary angiography and PCI or an early ischemic-guided with angiography in selected patients guided by relief of symptoms and stress testing (see Fig. 17-3). For patients treated by an early invasive strategy, UFH, enoxaparin, fondaparinux, or bivalirudin should be administered.[3,4] In a large open-label randomized clinical trial evaluating bivalirudin versus UFH or enoxaparin plus a GPI (abciximab, eptifibatide, or tirofiban) in moderate- and high-risk patients with NSTE-ACS undergoing an early invasive strategy, bivalirudin demonstrated similar efficacy in preventing CV ischemic events but a lower bleeding rate.[92] Similarly, in a smaller randomized trial specifically comparing abciximab plus UFH with bivalirudin for patients with NSTEMI undergoing PCI, bivalirudin demonstrated no differences in clinical outcomes but a lower bleeding risk.[93]

In patients in whom an initial ischemia-guided strategy is planned (ie, they are not anticipated to receive coronary angiography and revascularization), enoxaparin, UFH, or low-dose fondaparinux is recommended.[3] UFH and LMWH when added to aspirin reduce the frequency of death or MI in patients presenting with NSTE-ACS compared with control/placebo in patients primarily managed with a conservative strategy.[94,95] Compared with enoxaparin, fondaparinux showed similar ischemic outcomes with a lower bleeding rate in a large randomized trial of patients with NSTE-ACS primarily managed with a conservative strategy.[96] If fondaparinux is chosen for a patient initially receiving a conservative strategy who subsequently undergoes angiography and PCI, it should be administered in combination with UFH (and not as the sole anticoagulant) because the dose of fondaparinux studied appears too low to prevent thrombotic events during PCI.[4] Neither fondaparinux nor bivalirudin is FDA approved for NSTE-ACS despite being recommended by the NSTE-ACS guidelines. Bivalirudin has not been studied for initial therapy in patients intended to receive a conservative management strategy. Guideline-recommended dosing and contraindications are described in Table 17-2.

Therapy should be continued for up to at least 48 hours for UFH, until the patient is discharged from the hospital (or 8 days, whichever is shorter) for either enoxaparin or fondaparinux, or until the end of PCI or

angiography procedure (or up to 72 hours following PCI for bivalirudin).[3,4] For patients undergoing CABG during the same hospitalization, UFH can be continued until a few hours before CABG and LMWH should be stopped 12 hours prior to the surgery.[97] Because enoxaparin is eliminated renally and patients with renal insufficiency generally have been excluded from clinical trials, some practice protocols recommend UFH for patients with CrCl rates of less than 30 mL/min (0.50 mL/s) based on total patient body weight using the Cockroft-Gault equation.[3] Although recommendations for dosing adjustment of enoxaparin in patients with CrCl between 10 and 30 mL/min (0.27 and 0.50 mL/s) are listed in the product manufacturer's label, the safety and efficacy of enoxaparin in this patient population remain vastly understudied.[98] Administration of enoxaparin should be avoided in dialysis patients with ACS. It is unclear whether or not bivalirudin requires dose adjustment for patients with significant renal dysfunction. Although bivalirudin is eliminated renally, the duration of infusion in recent trials has been short (several hours only), and therefore the actual need for dosing adjustment is unlikely. Practice guidelines recommend manufacturer's suggested dosing adjustment for patients with chronic kidney disease.[4] Patients with SCr greater than 3 mg/dL (265 µmol/L) were excluded from ACS trials with fondaparinux, and the product label states that fondaparinux is contraindicated in patients with CrCl less than 30 mL/min (0.50 mL/s) and in patients weighing less than 50 kg (110 lb).

Unfractionated heparin is monitored and the dose adjusted to a target activated partial thromboplastin time (aPTT) or anti-factor Xa levels, whereas enoxaparin is administered by a fixed actual body weight-based dose without routine monitoring of anti-factor Xa levels. Some experts recommend anti-factor Xa monitoring for LMWHs in patients with renal impairment during prolonged courses of administration of more than several days. No monitoring of coagulation is recommended for bivalirudin and fondaparinux.

$P2Y_{12}$ Inhibitors

Administration of $P2Y_{12}$ receptor inhibitors are recommended in addition to aspirin for most patients presenting with and following NSTE-ACS. Due to their effectiveness and potency following oral loading and maintenance therapy, the need for IV antiplatelets such as GPIs has diminished.

For patients with NSTE-ACS with an initial ischemia-guided approach, either clopidogrel (a 300 or 600-mg loading dose followed by 75 mg daily) or ticagrelor can be used in addition to low-dose aspirin. Ticagrelor is preferred by practice guidelines due to greater efficacy in this setting. If an invasive management strategy is selected, either clopidogrel or ticagrelor can be used either prehospital or in the ED. Following PCI, in patients not already treated with a $P2Y_{12}$ inhibitor, either clopidogrel, prasugrel or ticagrelor can be used (ticagrelor and prasugrel are preferred in patients not at high-risk of bleeding) and should be initiated at the time of or within 1 hour following PCI.[3,54] Specific dosing and contraindications of the $P2Y_{12}$ inhibitors are described in Table 17-2.

In a subgroup of patients undergoing PCI enrolled in a large clinical trial evaluating clopidogrel versus placebo added to aspirin in patients with NSTE-ACS, clopidogrel reduced the frequency of death or MI by 30%.[99] In the large pivotal trials of prasugrel versus clopidogrel (TRITON TIMI 38) and ticagrelor versus clopidogrel (PLATO), no added benefit of the newer $P2Y_{12}$ inhibitors was observed in the subgroup of patients with NSTE-ACS undergoing PCI.[54,57] Following PCI in ACS, for patients receiving either a BMS or a DES, oral DAPT (with aspirin plus clopidogrel, ticagrelor, or prasugrel) is continued for

at least 12 months.[3] For patients receiving an initial ischemia-guided treatment strategy, either clopidogrel or ticagrelor in addition to aspirin should be given for up to 12 months.[3] After an NSTEMI, ticagrelor at a reduced dose of 60 mg/day may be continued beyond 12 months based on the results of the PEGASUS-TIMI 54 trial (results discussed previously).[63]

Glycoprotein IIb/IIIa Receptor Inhibitors

The role of GPIs in NSTE-ACS is diminishing as $P2Y_{12}$ inhibitors are used earlier in therapy, and bivalirudin is selected more commonly as the anticoagulant in patients receiving an early intervention approach. See $P2Y_{12}$ Inhibitors above, which includes the selection and timing of GPIs in patients with NSTE-ACS undergoing PCI.[3] Routine administration of eptifibatide (added to aspirin and clopidogrel) prior to angiography and PCI (ie, "upstream" use) in NSTE-ACS does not reduce ischemic events and increases bleeding risk compared to placebo.[100] Therefore, the two antiplatelet initial therapy options, described in the previous section, are preferred.[3,4]

For low-risk patients where a conservative management strategy is selected, there is no role for routine GPIs as the bleeding risk exceeds the benefit. For patients in whom an initial conservative strategy was selected but who experience recurrent ischemia (chest discomfort and ECG changes), HF, or arrhythmias after initial medical therapy necessitating a change in strategy to angiography and revascularization, a GPI may be added to aspirin and clopidogrel prior to the angiogram.[3]

Doses and contraindications to GPIs are described in Table 17-2.

Nitrates

Sublingual nitroglycerin followed by IV NTG should be administered to patients with NSTE-ACS and ongoing ischemia, HF, or uncontrolled high BP (see Table 17-2). The mechanism of action, dosing, contraindications, and adverse effects are the same as those described in Early Pharmacotherapy for STEMIs above. IV NTG is typically continued for approximately 24 hours following ischemia relief.

β-Blockers

The use of β-blockers in NSTE-ACS is similar to that in STEMI in that oral β-blockers should be initiated within 24 hours of hospital admission to all patients in the absence of contraindications. Benefits of β-blockers in this patient group are assumed to be similar to those seen in patients with STEMI. β-Blockers are continued indefinitely in patients with LVEF less than or equal to 40% (0.40) and for at least 3 years in patients with normal LV function.[3]

Calcium Channel Blockers

As described in the previous section, calcium channel blockers should not be administered to most patients with ACS. Their role is a second-line treatment for patients with certain contraindications to β-blockers and those with continued ischemia despite β-blocker and nitrate therapy. Agent selection for NSTE-ACS is identical to that for STEMI with either diltiazem or verapamil preferred unless the patient has LV systolic dysfunction, bradycardia, or heart block, and then either amlodipine or felodipine is

preferred. Immediate-release nifedipine is contraindicated, especially in the absence of a β-blocker.[3]

Secondary Prevention Following MI

The long-term goals following MI are to (a) control modifiable CHD risk factors; (b) prevent the development of systolic HF; (c) prevent recurrent MI and stroke; (d) prevent death, including sudden cardiac death; and (e) prevent stent thrombosis following PCI. Pharmacotherapy, which has been proven to decrease mortality, HF, reinfarction or stroke, and stent thrombosis, should be initiated prior to hospital discharge for secondary prevention. Secondary prevention guidelines suggest that following an ACS all patients, in the absence of contraindications, should receive indefinite treatment with aspirin, an ACE inhibitor, and a "high-intensity" statin for secondary prevention of death, stroke, or recurrent infarction.[46,101] A β-blocker should be continued for at least 3 years in patients with normal LV function and indefinitely in patients with LVEF of less than or equal to 40% (0.40) or HF symptoms.[46] It may be reasonable to continue a β-blocker indefinitely in patients without contraindications and with normal LVEF.[3] A $P2Y_{12}$ inhibitor should be continued for at least 12 months for patients undergoing PCI and for patients with NSTE-ACS receiving an ischemia-guided strategy of treatment.[3] Clopidogrel should be continued for at least 14 days in patients with STEMI not undergoing PCI.[2] An ARB and aldosterone antagonist should be given to selected patients as discussed in greater detail later in the chapter.[2,3,46] For all patients with ACS, treatment and control of modifiable risk factors, such as HTN, dyslipidemia, obesity, smoking, and DM, are essential.[46] Dosing and contraindications are described in detail in Table 17-2. Benefits and adverse effects of long-term treatment with these medications are discussed in more detail later. Use of ICDs for the prevention of sudden cardiac death following MI in patients with diminished LVF and nonsustained ventricular arrhythmias is discussed in more detail in Chapter 18.

Aspirin

Aspirin decreases the risk of death, recurrent infarction, and stroke following MI. All patients should receive aspirin indefinitely; those patients with a contraindication to aspirin should receive clopidogrel.[46] The risk of major bleeding from chronic aspirin therapy is approximately 2% and is dose related. Higher doses of aspirin, 160 to 325 mg, are not more effective than aspirin doses of 75 to 81 mg but have higher rates of bleeding.[102] Even in the setting of PCI, low-dose aspirin (75-100 mg daily) was found to be equally safe and efficacious compared with higher doses of aspirin (300-325 mg daily) in a prespecified subgroup analysis of 30-day outcomes in a large randomized, double-blind clinical trial of patients with ACS who underwent PCI.[45] Therefore, chronic doses of aspirin should not exceed 81 mg.[2,3,46]

$P2Y_{12}$ Inhibitors

For patients with either STEMI or NSTE-ACS, clopidogrel decreases the risk of CV events and stent thrombosis compared with placebo. Compared with clopidogrel, either prasugrel or ticagrelor lowers the risk of CV death, MI, or stroke by an additional 20% to 30% depending on the patient population studied. The frequency of stent thrombosis following PCI is also lower with prasugrel or ticagrelor compared with clopidogrel. However, the rate of non-CABG surgery-associated bleeding is higher with both prasugrel and ticagrelor compared with clopidogrel. For most patients with STEMI or NSTE-ACS, a

$P2Y_{12}$ inhibitor should be continued for at least 1 year.[2,3,4,27,63] For patients with STEMI managed with fibrinolytics, clopidogrel should be continued for at least 14 days and ideally 1 year. For patients STEMI and NSTE-ACS patients who were medically treated, who received fibrinolytics or who had a PCI who are not at high-risk of bleeding and who have not had overt bleeding, new guidelines indicate it is reasonable to continue dual antiplatelet therapy after 12 months.

The combination of clopidogrel and aspirin increases the risk of major bleeding by approximately 50% and minor bleeding by approximately 40% but not fatal bleeding compared with single agent alone.[103] Compared with clopidogrel, ticagrelor increased the risk of major bleeding not related to CABG surgery by 18% in a large randomized comparative trial of patients presenting with ACS and undergoing either PCI or medical management while prasugrel increased major bleeding by 33% compared with clopidogrel in a pivotal trial of patients with ACS undergoing PCI.[54,57] Oral antiplatelet agents are the third leading cause of adverse drug reaction-associated hospital admissions after ED visits among senior citizens.[104] Therefore, patients should be counseled on the risks and sites of potential bleeding and should be told to seek medical care immediately if significant bleeding is noticed. Lower-weight patients (less than or equal to 60 kg) and elderly patients are at higher risk of bleeding with prasugrel or ticagrelor compared with clopidogrel.[105,106] Prasugrel is contraindicated in patients with a prior history of stroke as the risk of ICH is increased with prasugrel compared with clopidogrel.[54,66]

Clinical Controversy… TRIPLE ORAL ANTITHROMBOTIC THERAPY

Patients with ACS undergoing PCI and intracoronary stent placement with either a BMS or a DES are managed with DAPT that reduces stent thrombosis risk and reinfarction risk.[4] But what antithrombotic therapy is best for patients with a chronic or new indication for longer-term anticoagulant therapy following hospital discharge such as atrial fibrillation, the presence of a mechanical heart valve, venous thromboembolism, or LV thrombus?

Which combination of antithrombotic agents is best to maximize efficacy while decreasing bleeding risk? Meta-analyses including mostly observational studies suggest a significant reduction in all-cause mortality at a cost of increased major bleeding with triple antithrombotic therapy (TT), such as aspirin, clopidogrel, and an oral vitamin K antagonist, compared with DAPT alone (aspirin plus clopidogrel).[107,108] Current practice guidelines recommend TT (warfarin, low-dose aspirin, and clopidogrel) for 1 to 6 months for patients following PCI with a BMS placement and between 6 and 12 months for patients following PCI with a DES placement, depending on bleeding risk. Thereafter, a single antiplatelet agent, either clopidogrel or low-dose aspirin, is recommended in addition to warfarin.[109]

Only one randomized trial, the *W*hat is the *O*ptimal Antiplat*e*let and Anticoagulant Therapy in Patients with Oral Anticoagulation and Coronary *S*tent*i*ng (WOEST) trial, has been published.[110] In this open-label study, patients undergoing PCI who were chronically treated with an oral vitamin K antagonist were randomized to receive clopidogrel alone or clopidogrel plus low-dose aspirin 80 to 100 mg/day. The target international normalized ratio (INR) of anticoagulation was that recommended based on the indication. At 1-year follow-up, the primary endpoint, any bleeding episode was increased more than twofold in patients randomized to TT compared with clopidogrel plus anticoagulation (44.4% vs 19.4%, $P < 0.0001$). GI bleeding was the most common type of bleeding and was increased threefold by aspirin (2.9% in patients receiving anticoagulation plus clopidogrel vs 8.8% in patients receiving triple therapy).

In addition, there was no difference in the secondary endpoint of thromboembolic events. Therefore, consideration should be given to stopping aspirin in patients receiving TT as is an option in the practice guidelines recommended above.

The manufacturers of prasugrel and ticagrelor recommend against combining those $P2Y_{12}$ inhibitors with an oral anticoagulant due to a lack of data as well as clinical experience.[64,66] Therefore, when TT is needed, clopidogrel should be selected as the $P2Y_{12}$ inhibitor. Also, both rivaroxaban and apixaban have increased bleeding risk, including increased ICH risk when combined with aspirin plus clopidogrel in patients with ACS, and there is no information on long-term treatment with dabigatran, aspirin, and clopidogrel, and therefore warfarin should be selected as the anticoagulant of choice when TT is needed.[111,112] While guidelines suggest a tighter warfarin INR range goal of 2 to 2.5 in patients receiving TT, no clinical trial has prospectively tested this more stringent goal.[2,109,113]

In summary, TT, when needed, should consist of warfarin (INR target 2-2.5), low-dose aspirin 81 mg orally daily, and clopidogrel 75 mg orally daily. The anticoagulant should be discontinued if possible (such as in 3-6 months post-MI in patients at risk of LV thrombus but without actual thrombi present), and then either clopidogrel or preferably aspirin, discontinued after at least 1 month in a patient with a BMS and after at least 6 months in a patient with a DES. Concomitant use of a proton pump inhibitor is recommended in patients receiving TT undergoing PCI.[4,26,113]

β-Blockers, Nitrates, and Calcium Channel Blockers

Current treatment guidelines recommend that following an ACS, patients should receive a *β*-blocker for at least 3 years following MI in the absence of LV dysfunction and regardless of whether they have residual symptoms of angina or not. Patients with or without HF and LVEF less than or equal to 40% should receive a *β*-blocker indefinitely. Overwhelming data support the use of *β*-blockers in patients with a previous MI.[114] Currently, there are no data to support the superiority of one *β*-blocker over another in the absence of HF.

Although *β*-blockers should be avoided in patients with decompensated HF from LV systolic dysfunction complicating an MI, clinical trial data suggest it is safe to initiate *β*-blockers prior to hospital discharge in these patients once HF symptoms have resolved.[115] These patients may actually benefit more than those without LV dysfunction.[116] In patients who cannot tolerate or have a contraindication to a *β*-blocker, a calcium channel blocker can be used to prevent anginal symptoms but should not be used routinely in the absence of such symptoms.[2,3,117]

Finally, all patients should be prescribed short-acting, SL NTG or lingual NTG spray to relieve any anginal symptoms when necessary and instructed on its use.[117] Chronic long-acting nitrate therapy has not been shown to reduce CHD events following MI. Therefore, IV NTG is not routinely followed by chronic, long-acting oral nitrate therapy in ACS patients who have undergone revascularization, unless the patient has stable ischemic heart disease or significant coronary stenoses that were not revascularized.[117]

ACE Inhibitors and ARBs

Angiotensin-converting enzyme inhibitors should be initiated in all patients following MI to reduce mortality, decrease reinfarction, and prevent the development of HF.[2,4,46,118] The benefit of ACE inhibitors in patients with MI most likely comes from their ability to prevent cardiac remodeling. The largest reduction in mortality is observed in patients with LV dysfunction (low LVEF) or HF symptoms. Early initiation (within 24 hours) of an *oral* ACE inhibitor appears to be crucial during an acute MI because 40% of the 30-day survival benefit is observed during the first day, 45% from days 2 to 7, and approximately 15% from days 8 to 30.[119] However, current data do not support the early administration of IV ACE inhibitors in patients experiencing an MI because mortality may be increased.[120] Administration of ACE inhibitors should be continued indefinitely. Hypotension should be avoided because coronary artery filling may be compromised. Additional trials suggest that most patients with CAD, not just ACS or HF patients, benefit from ACE inhibitors. Therefore, ACE inhibitors should be considered in all patients following an ACS in the absence of a contraindication.

Many patients cannot tolerate chronic ACE inhibitor therapy secondary to adverse effects. The ARBs, candesartan, valsartan, and losartan, have been documented in trials to improve clinical outcomes in patients with HF.[121,122] Therefore, either an ACE inhibitor or candesartan, valsartan, or losartan is an acceptable choice for chronic therapy for patients who have a low LVEF and HF following MI. Besides hypotension, the most frequent adverse reaction to an ACE inhibitor is cough, which may occur in up to 30% of patients. Patients with an ACE inhibitor cough and either clinical signs of HF or LVEF less than or equal to 40% (0.40) may be prescribed an ARB.[46] Other, less common but more serious adverse effects to ACE inhibitors and ARBs include acute renal failure, hyperkalemia, and angioedema.

Aldosterone Antagonists

To reduce mortality, administration of an aldosterone antagonist, either eplerenone or spironolactone, should be considered within the first 7 days following MI in all patients who are already receiving an ACE inhibitor (or ARB) and a β-blocker and have an LVEF of less than or equal to 40% (0.40) and either HF symptoms or DM.[2,3,46] Aldosterone plays an important role in HF and in MI because it promotes vascular and myocardial fibrosis, endothelial dysfunction, HTN, LV hypertrophy, sodium retention, potassium and magnesium loss, and arrhythmias. Aldosterone antagonists have been shown in experimental and human studies to attenuate these adverse effects.[123] Spironolactone decreases all-cause mortality in patients with stable, severe HF.[124]

Eplerenone, like spironolactone, is an aldosterone antagonist that blocks the mineralocorticoid receptor. In contrast to spironolactone, eplerenone has no effect on the progesterone or androgen receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities. In a large clinical trial, eplerenone significantly reduced mortality as well as hospitalization for HF in post-MI patients with an LVEF less than or equal to 40% (0.40) and symptoms of HF at any time during hospitalization.[125] Eplerenone has also been demonstrated to reduce mortality in patients with mild systolic HF.[126] The risk of hyperkalemia, however, was increased in both of these studies. Therefore, patients with serum potassium concentrations greater than 5 mmol/L (5 mEq/L) should not receive an aldosterone antagonist. Additional contraindications for spironolactone include a SCr greater than 2.5 mg/dL (221 µmol/L) for men, 2 mg/dL (177 µmol/L) for women, or CrCl less than 30 mL/min (0.5 mL/s). Specific contraindications for eplerenone include a SCr greater than or equal to 2 mg/dL (177 µmol/L) for men or 1.8 mg/dL (159 µmol/L) for women, or CrCl less than or equal to 50 mL/min (0.83 mL/s).

Currently, there are no data to support that the more selective, more expensive eplerenone is superior to, or should be preferred to, the less expensive generic spironolactone unless a patient has experienced gynecomastia, breast pain, or impotence while receiving spironolactone.

Lipid-Lowering Agents

Following MI, statins reduce total mortality, CV mortality, and stroke. Results from landmark clinical trials have unequivocally demonstrated the value of statins in secondary prevention following MI. A meta-analysis of randomized controlled clinical trials in almost 18,000 patients with recent ACS (less than 14 days) found that statin therapy reduces mortality by 19%, with benefits observed after approximately 4 months of treatment.[127] In the 2013 ACC/AHA guidelines on managment of lipids, patients with clinical atherosclerotic vascular disease, such as MI, are one of the four groups of patients that benefit from moderate- or high-dose statins.[101] Therefore, all patients, regardless of low-density lipoprotein cholesterol level, should ideally be prescribed a high-intensity statin. Patients aged greater than 75 years may be prescribed a moderate-intensity statin as initial therapy because they are at higher risk of adverse drug effects and the data using high-dose statins in this patient subgroup are less robust. See Chapter 21 for a more detailed discussion. Use of other agents such as ezetimibe and proprotein convertase subtilisin kexin type 9 (PCSK9) inhibitors in patients already receiving statins for secondary prevention is supported by current guidelines with preference given to ezetimibe due to the benefit of ezetimibe-statin combination after ACS.[128]

Results of the Improved Reduction of Outcomes: Vytorin Efficacy International Trial Efficacy International Trial (IMPROVE-IT) study where ezetimibe added to moderate-dose simvastatin in patients with recent (within 10 days) ACS and an LDL level 50 mg/dL to 100 mg/dL reduced the frequency of a composite endpoint of CV events or stroke over a median follow-up of 6 years compared to simvastatin alone.[129] Patients on combined ezetimibe/simvastatin had a median LDL cholesterol level of 54 compared to 70 mg/dL in patients on simvastatin alone. Event rates were lower in patients with lower LDL cholesterols suggesting a direct relationship between LDL and benefit. Data with newer injectable PCSK9 inhibitors, such as alirocumab and evolocumab, added to high-intensity statins in patients with CHD or who are at high-risk for CHD are promising. However, current analyses indicate that they may not be cost-effective.[130] The results of ongoing clinical trials with prospective CV mortality endpoints are necessary before a more widespread use of PCSK9 inhibitors is employed.[128,131,132,133,134]

Other Modifiable Risk Factors

Smoking cessation, managing HTN, weight loss, exercise, and tight glucose control for patients with DM, in addition to treatment of dyslipidemia, are important treatments for secondary prevention of CHD events. Referral to a comprehensive CV risk reduction program for cardiac rehabilitation is recommended.[46] Behavioral therapy aided with nicotine replacement alone or combined with bupropion or varenicline, for smoking cessation should be absolutely considered in appropriate patients.[2,3,46] HTN should be strictly controlled according to published guidelines.[135] Patients who are overweight should be educated on the importance of regular exercise, healthy eating habits, and reaching and maintaining an ideal weight. Moderate-intensity aerobic exercise for at least 30 minutes, 7 days/wk (minimum 5 days/wk) is recommended.[46] The goal body mass index is less than 25 kg/m^2. Finally, because patients with DM have up to a fourfold increased mortality risk compared with patients without DM, the

importance of blood glucose control, as well as other CHD risk factor modifications, cannot be overstated.[46]

OUTCOME EVALUATION

To determine the efficacy of nonpharmacologic therapy and pharmacotherapy for both STE and NSTE-ACS, monitor patients for: (a) relief of ischemic discomfort; (b) return of ECG changes to baseline; and (c) absence or resolution of HF signs and symptoms.

Monitoring parameters for recognition and prevention of adverse effects from ACS pharmacotherapy are described in **Table 17-5**. 9 In general, the most common adverse reactions from ACS therapies are hypotension and bleeding. To treat for bleeding and hypotension, discontinue the offending agent(s) until symptoms resolve. Severe bleeding resulting in hypotension secondary to hypovolemia may require blood transfusion.

TABLE 17-5 Therapeutic Drug Monitoring of Pharmacotherapy for Acute Coronary Syndromes

Drug	Adverse Effects	Monitoring
Aspirin	Dyspepsia, bleeding, gastritis	Clinical signs of bleeding[a]; GI upset; baseline and every 6 months: Hgb, HCT, platelet count
Clopidogrel and prasugrel	Bleeding, diarrhea, rash, TTP (rare)	Clinical signs of bleeding[a]; baseline and every 6 months: Hgb, HCT, platelet count
Ticagrelor	Bleeding, dyspnea, diarrhea, rash, elevated SCr, elevated serum uric acid	Clinical signs of bleeding[a]; baseline and every 6 months: Hgb, HCT, platelet count
Unfractionated heparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding[a]; baseline aPTT, INR, Hgb, HCT, and platelet count; aPTT every 6 hours until target then every 24 hours; daily Hgb, HCT, and platelet
Enoxaparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, Hgb, HCT, and platelet count; daily SCr, Hgb, HCT, and platelet count
Fondaparinux	Bleeding	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, Hgb, HCT, and platelet count; daily SCr, Hgb, HCT, and platelet count
Bivalirudin	Bleeding	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, Hgb, HCT, and platelet count
Fibrinolytics	Bleeding, especially intracranial hemorrhage	Clinical signs of bleeding[a]; baseline aPTT, INR, Hgb, HCT, and platelet count; mental status every 2 hours for signs of intracranial hemorrhage; daily Hgb, HCT, and platelet count
GPIs	Bleeding, acute profound thrombocytopenia	Clinical signs of bleeding[a]; baseline SCr (for eptifibatide and tirofiban), Hgb, HCT, and platelet count; platelet count at 4 hours after initiation; daily Hgb, HCT, and

Drug	Adverse Effects	Monitoring
		platelet count(and SCr for eptifibatide and tirofiban)
IV nitrates	Hypotension, flushing, headache, tachycardia	BP and HR every 2 hours
β-Blockers	Hypotension, bradycardia, heart block, bronchospasm, acute HF, fatigue, depression, sexual dysfunction	BP, RR, HR, 12-lead ECG, and clinical signs of HF every 5 minutes with bolus IV dosing; BP, RR, HR, and clinical signs of HF every shift with oral therapy, then BP and HR every 6 months following hospital discharge
Diltiazem and verapamil	Hypotension, bradycardia, heart block, HF, gingival hyperplasia	BP and HR every shift with oral therapy, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
Amlodipine	Hypotension, dependent peripheral edema, gingival hyperplasia	BP every shift with oral therapy, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
ACE inhibitors and ARBs	Hypotension, cough (with ACE inhibitors), hyperkalemia, prerenal azotemia, acute renal failure, angioedema (ACE inhibitors more so than ARBs)	BP every 4 hours × 3 for first dose, then every shift with oral therapy, then once every 6 months following hospital discharge; baseline SCr and potassium; daily SCr and potassium while hospitalized, then every 6 months (or 1–2 weeks after each outpatient dose titration); closer monitoring required in patients receiving spironolactone or eplerenone or if renal insufficiency; counsel patient on throat, tongue, and facial swelling
Aldosterone antagonists	Hypotension, hyperkalemia, increased SCr	BP and HR every shift with oral therapy, then once every 6 months; baseline SCr and serum potassium concentration then at 48 hours, at 7 days, monthly for 3 months, then every 3 months thereafter
Morphine	Hypotension, respiratory depression	BP and RR 5 minutes after each bolus dose
Statins	GI upset, myopathy, hepatotoxicity	Liver function tests at baseline. CK if indicated. Only repeat if patients present with sign/symptoms of liver failure or muscle symptoms; counsel patient on myalgia; baseline LDL cholesterol prior to treatment and at 4-6 weeks following initiation to determine adequate response and consideration of additional guideline-recommended lipid-lowering therapy

[a]Clinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites.

ACE, angiotensin-converting enzyme; aPTT, activated partial thromboplastin time; ARB, angiotensin receptor blocker; BP, blood pressure; CK, creatine kinase; ECG, electrocardiogram; GI, gastrointestinal; GPI, glycoprotein IIb/IIIa inhibitor; Hgb, hemoglobin; HCT, hematocrit; HF, heart failure; HR, heart rate; INR, international normalized ratio; LDL, low-density lipoprotein RR, respiratory rate; SCr, serum

creatinine, TTP, thrombotic thrombocytopenic purpura.

Because poor medication adherence of secondary prevention medications following MI leads to worsened CV outcomes, patients should receive medication counseling (including counseling prior to hospital discharge) and be monitored for medication persistence.[2,3,136] Counseling should include assessment of health literacy level, assessment of barriers to adherence, assessment of access to medications, written and verbal instructions about the purpose of each medication, changes to previous medication regimen, optimal time to take each medication, new allergies or medication intolerances, need for timely prescription fill after discharge, anticipated duration of therapy, consequences of nonadherence, common and/or serious adverse reactions that may develop, drug–drug and drug–food interactions, and an assessment of instruction understanding.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACE	angiotensin-converting enzyme
ACS	acute coronary syndrome
ADP	adenosine diphosphate
AMI	acute myocardial infarction
aPTT	activated partial thromboplastin time
ARB	angiotensin receptor blocker
BMS	bare metal stent
BP	blood pressure
CABG	coronary artery bypass graft
CAD	coronary artery disease
CBC	complete blood count
CHD	coronary heart disease
CPIC	clinical pharmacogenetics implementation consortium
CrCl	creatinine clearance
CV	cardiovascular
CVD	cardiovascular disease
CYP	cytochrome P450
DAPT	dual antiplatelet therapy
DES	drug-eluting stent
DM	diabetes mellitus
ECG	electrocardiogram
ED	emergency department
EF	ejection fraction
EMS	emergency medical system
GPI	glycoprotein IIb/IIIa inhibitor

HDL	high-density lipoprotein
HF	heart failure
HORIZONS-AMI	Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction
HR	heart rate
HTN	hypertension
ICD	implantable cardioverter-defibrillator
ICH	intracranial hemorrhage
IMPROVE-IT	Improved Reduction of Outcomes: Vytorin Efficacy International Trial
INR	international normalized ratio
IV	intravenous
LDL	low-density lipoprotein
LMWH	low-molecular-weight heparin
LV	left ventricular
LVEF	left ventricular ejection fraction
MI	myocardial infarction
NSTEMI	non–ST-segment elevation myocardial infarction
NTG	nitroglycerin
PCI	percutaneous coronary intervention
PCSK9	proprotein convertase subtilisin kexin 9
PLATO	Platelet Inhibition and Patient Outcomes
SCr	serum creatinine
SL	Sublingual
STE	ST-segment elevation
STEMI	ST-segment elevation myocardial infarction
TIA	transient ischemic attack
TTP	thrombotic thrombocytopenic purpura
TXA_2	thromboxane A_2
UA	unstable angina
UFH	unfractionated heparin

Chapter 18: The Arrhythmias

Cynthia A. Sanoski; Jerry L. Bauman

INTRODUCTION

KEY CONCEPTS

- 1 The use of antiarrhythmic drugs (AADs) in the United States has declined because of major trials that show increased mortality with their use in several clinical situations, the realization of proarrhythmia as a significant side effect, and the advancing technology of nonpharmacologic therapies such as ablation and the implantable cardioverter-defibrillator (ICD).

- 2 AADs frequently cause side effects and are complex in their pharmacokinetic characteristics. Close monitoring is required of all of these drugs to assess for adverse effects as well as potential drug interactions.

- 3 The most commonly prescribed AAD is now amiodarone. This drug is effective in terminating and preventing a wide variety of symptomatic supraventricular and ventricular arrhythmias. However, because this AAD is plagued by frequent side effects, it requires close monitoring. The most concerning toxicity is pulmonary fibrosis; side effect profiles of the intravenous (IV) (acute, short-term) and oral (chronic, long-term) forms of amiodarone differ substantially.

- 4 In patients with atrial fibrillation (AF), therapy is traditionally aimed at controlling ventricular rate (digoxin, nondihydropyridine (non-DHP) calcium channel blockers (CCBs), β-blockers), preventing thromboembolic (TE) complications (warfarin, aspirin), and restoring and maintaining sinus rhythm (SR) (AADs, direct current cardioversion). Studies show there is no need to aggressively pursue strategies to maintain SR (ie, long-term AAD therapy); rate control alone (leaving the patient in AF) is often sufficient in patients who can tolerate it. Nonetheless, chronic AAD therapy may still be needed in patients who continue to have symptoms despite adequate ventricular rate control.

- 5 Paroxysmal supraventricular tachycardia (PSVT) is usually a result of reentry in or proximal to the atrioventricular (AV) node or AV reentry incorporating an extranodal pathway; common tachycardias can be terminated acutely with AV nodal blocking drugs such as adenosine, and recurrences can be prevented by ablation with radiofrequency current.

- 6 Patients with Wolff-Parkinson-White (WPW) syndrome may have several different tachycardias that are acutely treated by different strategies: orthodromic reentry (adenosine), antidromic reentry (adenosine or procainamide), and AF (procainamide or amiodarone). AV nodal blocking drugs are contraindicated in patients with WPW syndrome and AF.

- 7 Because of the results of the Cardiac Arrhythmia Suppression Trial (CAST) and other trials, AADs (with the exception of β-blockers) should not be routinely used in patients with prior myocardial infarction (MI) or left ventricular (LV) dysfunction and minor ventricular rhythm disturbances (eg, premature ventricular complexes [PVCs]).

- 8 Patients with hemodynamically significant ventricular tachycardia (VT) or ventricular fibrillation not associated with an acute MI who are successfully resuscitated (with electrical cardioversion, epinephrine, amiodarone) are at high risk for sudden cardiac death (SCD) and should receive an ICD ("secondary prevention").

- 9 Implantation of an ICD should be considered for the primary prevention of SCD in certain high-risk patient populations. High-risk patients include those with a history of MI and LV dysfunction (regardless of whether they have inducible sustained ventricular arrhythmias), as well as those with New York Heart Association (NYHA) class II or III heart failure (HF) as a result of either ischemic or nonischemic causes.

- 10 Life-threatening ventricular proarrhythmia generally takes two forms: sinusoidal or incessant monomorphic VT (class Ic AADs) and torsade de pointes (TdP) (class Ia or III AADs and many other noncardiac drugs).

The heart has two basic properties, namely, an electrical property and a mechanical property. The synchronous interaction between these two properties is complex, precise, and relatively enduring. The study of the electrical properties of the heart has grown at a steady rate, interrupted by periodic salvos of scientific breakthroughs. Einthoven's pioneering work allowed graphic electrical tracings of cardiac rhythm and probably represents the first of these breakthroughs. This discovery of the surface electrocardiogram (ECG) has remained the cornerstone of diagnostic tools for cardiac rhythm disturbances. Since then, intracardiac recordings and programmed cardiac stimulation have advanced our understanding of arrhythmias, and microelectrode, voltage clamping, and patch clamping techniques have allowed considerable insight into the electrophysiologic actions and mechanisms of AADs. Certainly, the new era of molecular biology and mapping of the human genome promises even greater insights into mechanisms (and potential therapies) of arrhythmias. Noteworthy in this regard is the discovery of genetic abnormalities in the ion channels that control electrical repolarization (heritable long QT syndrome) or depolarization (Brugada syndrome).

The clinical use of drug therapy started with the use of digitalis and then quinidine. A surge of new agents followed somewhat later in the 1980s. A theme of drug discovery during this decade was initially to find orally absorbed lidocaine congeners (such as mexiletine and tocainide); later, the emphasis was on drugs with extremely potent effects on conduction (ie, flecainide-like agents). The most recent focus of investigational AADs is the potassium channel blockers, with dronedarone being the most recently approved AAD in the United States in nearly a decade. Previously, there was some

expectation that advances in AAD discovery would lead to a highly effective and nontoxic agent that would be effective for a majority of patients (ie, the so-called magic bullet). Instead, significant problems with drug toxicity and proarrhythmia have resulted in a decline in the overall volume of AAD usage in the United States since 1989. [1] The other phenomenon that has significantly contributed to the decline in AAD utilization is the development of extremely effective nonpharmacologic therapies. Technical advances have made it possible to permanently interrupt reentry circuits with radiofrequency ablation, which renders long-term AAD use unnecessary in certain arrhythmias. Furthermore, the impressive survival data associated with the use of ICDs for the primary and secondary prevention of SCD have led most clinicians to choose "device" therapy as the first-line treatment for patients who are at high risk for life-threatening ventricular arrhythmias. Both of these nonpharmacologic therapies have become increasingly popular for the management of arrhythmias so that the potential proarrhythmic effects and organ toxicities associated with AADs can be avoided.

This chapter reviews the principles involved in both normal and abnormal cardiac conduction and addresses the pathophysiology and treatment of the more commonly encountered arrhythmias. Certainly, many volumes of complete text could be (and have been) devoted to basic and clinical electrophysiology. Consequently, this chapter briefly addresses those principles necessary for clinicians.

ARRHYTHMOGENESIS

Normal Conduction

Electrical activity is initiated by the sinoatrial (SA) node and moves through cardiac tissue by a tree-like conduction network. The SA node initiates cardiac rhythm under normal circumstances because this tissue possesses the highest degree of automaticity or rate of spontaneous impulse generation. The degree of automaticity of the SA node is largely influenced by the autonomic nervous system in that both cholinergic and sympathetic innervations control the sinus rate. Most tissues within the conduction system also possess varying degrees of inherent automatic properties. However, the rates of spontaneous impulse generation of these tissues are less than that of the SA node. Thus, these latent automatic pacemakers are continuously overdriven by impulses arising from the SA node (primary pacemaker) and do not become clinically apparent.

From the SA node, electrical activity moves in a wave front through an atrial specialized conducting system and eventually gains entrance to the ventricle via the AV node and a large bundle of conducting tissue referred to as the bundle of His. The conducting tissues bridging the atria and ventricles are referred to as the junctional areas. Again, this area of tissue (junction) is largely influenced by autonomic input and possesses a relatively high degree of inherent automaticity (about 40 beats/min which is less than that of the SA node). From the bundle of His, the cardiac conduction system bifurcates into several (usually three) bundle branches: one right bundle and two left bundles. These bundle branches further arborize into a conduction network referred to as the Purkinje system. The conduction system as a whole innervates the mechanical myocardium and serves to initiate excitation-contraction coupling and the contractile process. After a cell or group of cells within the heart is electrically stimulated, a brief period of time follows in which those cells cannot again be excited. This time period is referred to as the refractory period. As the electrical wave front moves down the conduction system, the impulse eventually encounters tissue refractory to stimulation (recently excited)

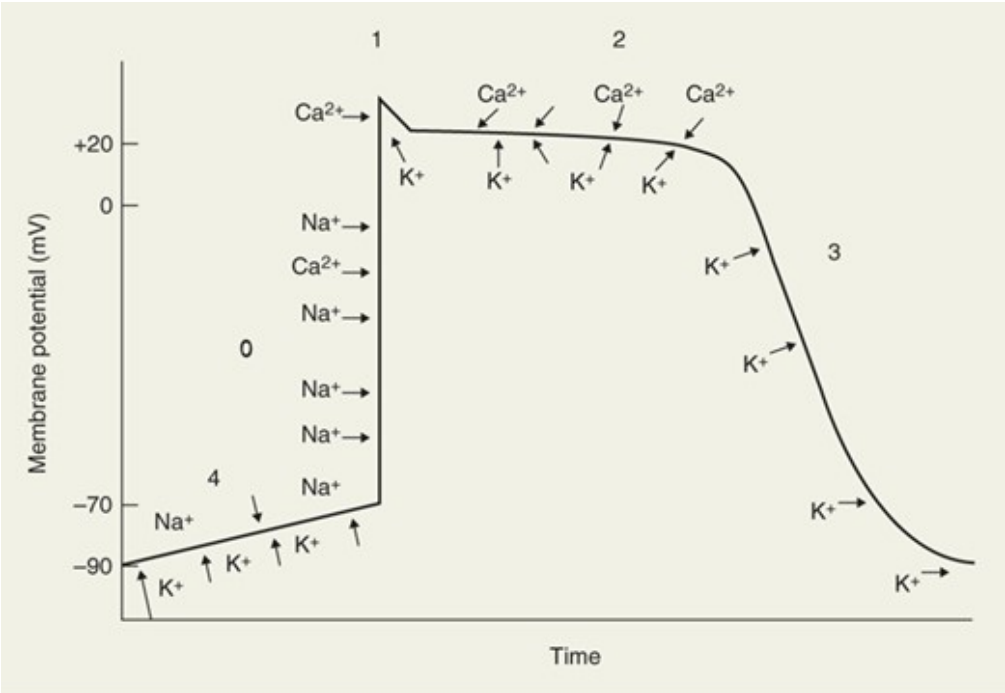
and subsequently dies out. The SA node subsequently recovers, fires spontaneously, and begins the process again.

Prior to cellular excitation, an electrical gradient exists between the inside and the outside of the cardiac cell membrane. At this time, the cell is polarized. In atrial and ventricular conducting tissues, the intracellular space is approximately -80 to -90 mV with respect to the extracellular environment. The electrical gradient just prior to excitation is referred to as the resting membrane potential (RMP) and is the result of differences in ion concentrations between the inside and the outside of the cell. At RMP, the cell is polarized primarily by the action of active membrane ion pumps, the most notable of these being the sodium-potassium pump. For example, this specific pump (in addition to other systems) attempts to maintain the intracellular sodium concentration at 5 to 15 mEq/L and the extracellular sodium concentration at 135 to 142 mEq/L, as well as the intracellular potassium concentration at 135 to 140 mEq/L and the extracellular potassium concentration at 3 to 5 mEq/L.

Electrical stimulation (or depolarization) of the cell will result in changes in membrane potential over time or a characteristic action potential curve (**Fig. 18-1**). The action potential curve results from the transmembrane movement of specific ions and is divided into different phases. Phase 0 or initial, rapid depolarization of atrial and ventricular tissues is caused by an abrupt increase in the permeability of the membrane to sodium influx. This rapid depolarization more than equilibrates (overshoots) the electrical potential, resulting in a brief initial repolarization or phase 1. Phase 1 (initial repolarization) is caused by a transient and active potassium efflux (ie, the I_{Kto} current). Calcium begins to move into the intracellular space at about –60 mV (during phase 0), causing a slower depolarization. Calcium influx continues throughout phase 2 of the action potential (plateau phase) and is balanced to some degree by potassium efflux. Calcium entrance (only through L channels in myocardial tissue) distinguishes cardiac conducting cells from nerve tissue and provides the critical ionic link to excitation-contraction coupling and the mechanical properties of the heart as a pump. The membrane remains permeable to potassium efflux during phase 3, resulting in cellular repolarization. Phase 4 of the action potential is the gradual depolarization of the cell and is related to a constant sodium leak into the intracellular space balanced by a decreasing (over time) efflux of potassium. The slope of phase 4 depolarization determines, in large part, the automatic properties of the cell. As the cell is slowly depolarized during phase 4, an abrupt increase in sodium permeability occurs, allowing the rapid cellular depolarization of phase 0. The juncture of phase 4 and phase 0 where rapid sodium influx is initiated is referred to as the threshold potential of the cell. The level of threshold potential also regulates the degree of cellular automaticity.

FIGURE 18-1

Purkinje fiber action potential showing specific ion flux responsible for the change in membrane potential. Ions outside of the line (eg, sodium) move from the extracellular space to the intracellular space and ions on the inside of the line (eg, potassium) move from the inside of the cell to the outside.



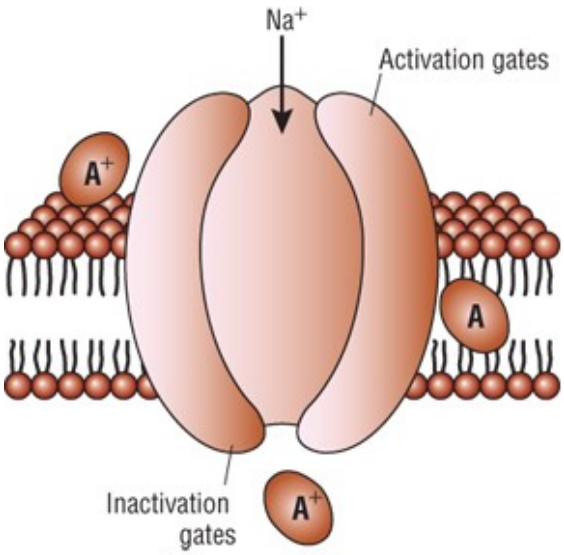
Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Not all cells in the cardiac conduction system rely on sodium influx for initial depolarization. Some tissues depolarize in response to a slower inward ionic current caused by calcium influx. These "calcium-dependent" tissues are found primarily in the SA and AV nodes (both L and T channels) and possess distinct conduction properties in comparison to "sodium-dependent" fibers. Calcium-dependent cells generally have a less negative RMP (–40 to –60 mV) and a slower conduction velocity. Furthermore, in calcium-dependent tissues, recovery of excitability outlasts full repolarization, whereas in sodium-dependent tissues, recovery is prompt after repolarization. These two types of electrical tissues also differ dramatically in how drugs modify their conduction properties.

Ion conductance across the lipid bilayer of the cell membrane occurs via the formation of membrane pores or "channels" (**Fig. 18-2**). Selective ion channels probably form in response to specific electrical potential differences between the inside and the outside of the cell (voltage dependence). The membrane itself is composed of both organized and disorganized lipids and phospholipids in a dynamic sol-gel matrix. During ion flux and electrical excitation, changes in this sol-gel equilibrium occur and permit the formation of activated ion channels. Besides channel formation and membrane composition, intrachannel proteins or phospholipids, referred to as gates, also regulate the transmembrane movement of ions. These gates are thought to be positioned strategically within the channel to modulate ion flow. Each ion channel conceptually has two types of gates: an activation gate and an inactivation gate (see Fig. 18-2). The activation gate opens during depolarization to allow the ion current to enter or exit from the cell, and the inactivation gate later closes to stop ion movement. When the cell is in a rested state, the activation gates are closed and the inactivation gates are open. The activation gates then open to allow ion movement through the channel, and the inactivation gates later close to stop ion conductance. Thus, the cell cycles between three states: resting, activated or open, and inactivated or closed. Activation of SA and AV nodal tissue is dependent on a slow depolarizing current through calcium channels and gates, whereas the activation of atrial and ventricular tissues is dependent on a rapid depolarizing current through sodium channels and gates.

FIGURE 18-2

Lipid bilayer, sodium channel, and possible sites of action of the class I AADs (*A*). Class I AADs may theoretically inhibit sodium influx at an extracellular, intramembrane, or intracellular receptor site. However, all approved agents appear to block sodium conductance at a single receptor site by gaining entrance to the interior of the channel from an intracellular route. Active ionized drugs block the channel predominantly during the activated or inactivated state and bind and unbind with specific time constants (described as fast on-off, slow on-off, and intermediate). (AADs, antiarrhythmic drugs.)



Abnormal Conduction

The mechanisms of tachyarrhythmias have been classically divided into two general categories: those resulting from an abnormality in impulse generation or "automatic" tachycardias and those resulting from an abnormality in impulse conduction or "reentrant" tachycardias.

Automatic tachycardias depend on spontaneous impulse generation in latent pacemakers and may be a result of several different mechanisms. Drugs, such as digoxin or catecholamines, and conditions, such as hypoxia, electrolyte abnormalities (eg, hypokalemia), and fiber stretch (cardiac dilation), may lead to an increased slope of phase 4 depolarization in cardiac tissues other than the SA node. These factors that experimentally lead to abnormal automaticity are also known to be arrhythmogenic in clinical situations. The increased slope of phase 4 causes heightened automaticity of these tissues and competition with the SA node for dominance of cardiac rhythm. If the rate of spontaneous impulse generation of the abnormally automatic tissue exceeds that of the SA node, then an automatic tachycardia may result. Automatic tachycardias have the following characteristics: (a) the onset of the tachycardia is unrelated to an initiating event such as a premature beat; (b) the initiating beat is usually identical to subsequent beats of the tachycardia; (c) the tachycardia cannot be initiated by programmed cardiac stimulation; and (d) the onset of the tachycardia is usually preceded by a gradual acceleration in rate and termination is usually preceded by a gradual deceleration in rate. Clinical tachycardias resulting from the classic forms of enhanced automaticity already described are not as common as

once thought. Examples are sinus tachycardia and junctional tachycardia.

Triggered automaticity is also a possible mechanism for abnormal impulse generation. Briefly, triggered automaticity refers to transient membrane depolarizations that occur during repolarization (early afterdepolarizations [EADs]) or after repolarization (late afterdepolarizations [LADs]) but prior to phase 4 of the action potential. Afterdepolarizations may be related to abnormal calcium and sodium influx during or just after full cellular repolarization. Experimentally, EADs may be precipitated by hypokalemia, class Ia AADs, or slow stimulation rates—any factor that blocks the ion channels (eg, potassium) responsible for cellular repolarization. EADs provoked by drugs that block potassium conductance and delay repolarization are the underlying cause of TdP. LADs may be precipitated by digoxin or catecholamines and suppressed by CCBs, and have been suggested as the mechanism for multifocal atrial tachycardia, digoxin-induced tachycardias, and exercise-provoked VT. Triggered automatic rhythms possess some of the characteristics of automatic tachycardias and some of the characteristics of reentrant tachycardias (description follows).

Reentry is a concept that involves indefinite propagation of the impulse and continued activation of previously refractory tissue. There are three conduction requirements for the formation of a viable reentrant focus: (1) two pathways for impulse conduction, (2) an area of unidirectional block (prolonged refractoriness) in one of these pathways, and (3) slow conduction in the other pathway (**Fig. 18-3**). Usually, a critically timed premature beat initiates reentry. This premature impulse enters both conduction pathways but encounters refractory tissue in one of the pathways at the area of unidirectional block. The impulse dies out because the tissue is still refractory from the previous (sinus) impulse. Although it fails to propagate in one pathway, the impulse may still proceed in a forward direction (antegrade) through the other pathway because of this pathway's relatively shorter refractory period. The impulse may then proceed through a loop of tissue and "reenter" the area of unidirectional block in a backward direction (retrograde). Because the antegrade pathway has slow conduction characteristics, the area of unidirectional block has time to recover its excitability. The impulse can proceed in a retrograde fashion through this previously refractory tissue and continue around the loop of tissue in a circular fashion. Thus, the key to the formation of a reentrant focus is crucial conduction discrepancies in the electrophysiologic characteristics of the two pathways. The reentrant focus may excite surrounding tissue at a rate greater than that of the SA node, leading to formation of a clinical tachycardia. The above model is anatomically determined in that there is only one pathway for impulse conduction with a fixed circuit length. Another model of reentry, referred to as a functional reentrant loop or leading circle model, may also occur (**Fig. 18-4**).[1] In a functional reentrant focus, the length of the circuit may vary depending on the conduction velocity and recovery characteristics of the impulse. The area in the middle of the loop is continually kept refractory by the inwardly moving impulse. The length of the circuit is not fixed but is the smallest circle possible, such that the leading edge of the wave front is continuously exciting tissue just as it recovers. It differs from the anatomic model in that the leading edge of the impulse is not preceded by an excitable gap of tissue, and it does not have an obstacle in the middle or a fixed anatomic circuit. Clinically, many reentrant foci probably have both anatomic and functional characteristics. In the figure 8 model, a zone of unidirectional block is present, allowing for two impulse loops that join and reenter the area of block in a retrograde fashion to form a pretzel-shaped reentrant circuit. This model combines functional characteristics with an excitable gap. All of these theoretical models require a critical balance of refractoriness and conduction velocity within the circuit and as such have helped to explain the effects of drugs on terminating, modifying, and

causing cardiac rhythm disturbances.

FIGURE 18-3

Conduction system of the heart. The magnified portion shows a bifurcation of a Purkinje fiber traditionally explained as the etiology of reentrant VT. A premature impulse travels to the fiber which is damaged by heart disease or ischemia. It encounters a zone of prolonged refractoriness (area of unidirectional block; *cross-hatched area*) but fails to propagate because the fiber remains refractory to stimulation from the previous impulse. However, the impulse may slowly travel (*squiggly line*) through the other portion of the Purkinje twig and will "reenter" the cross-hatched area if the refractory period is concluded and the fiber is now excitable. Thus, the premature impulse never meets refractory tissue; circus movement ensues. If this site stimulates the surrounding ventricle repetitively, clinical reentrant VT results. (VT, ventricular tachycardia.)

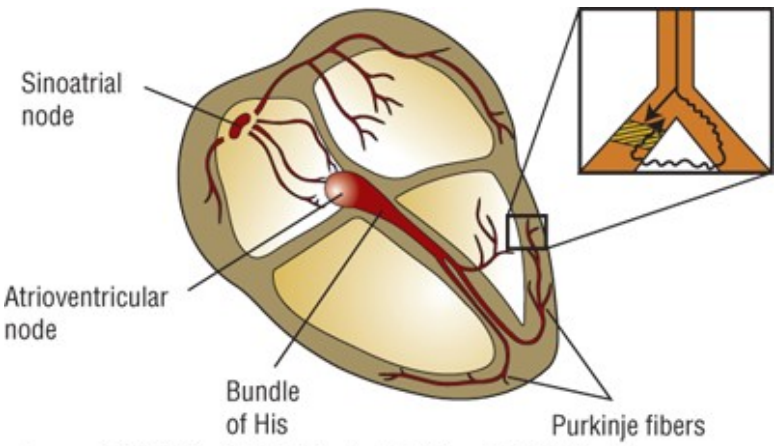


FIGURE 18-4

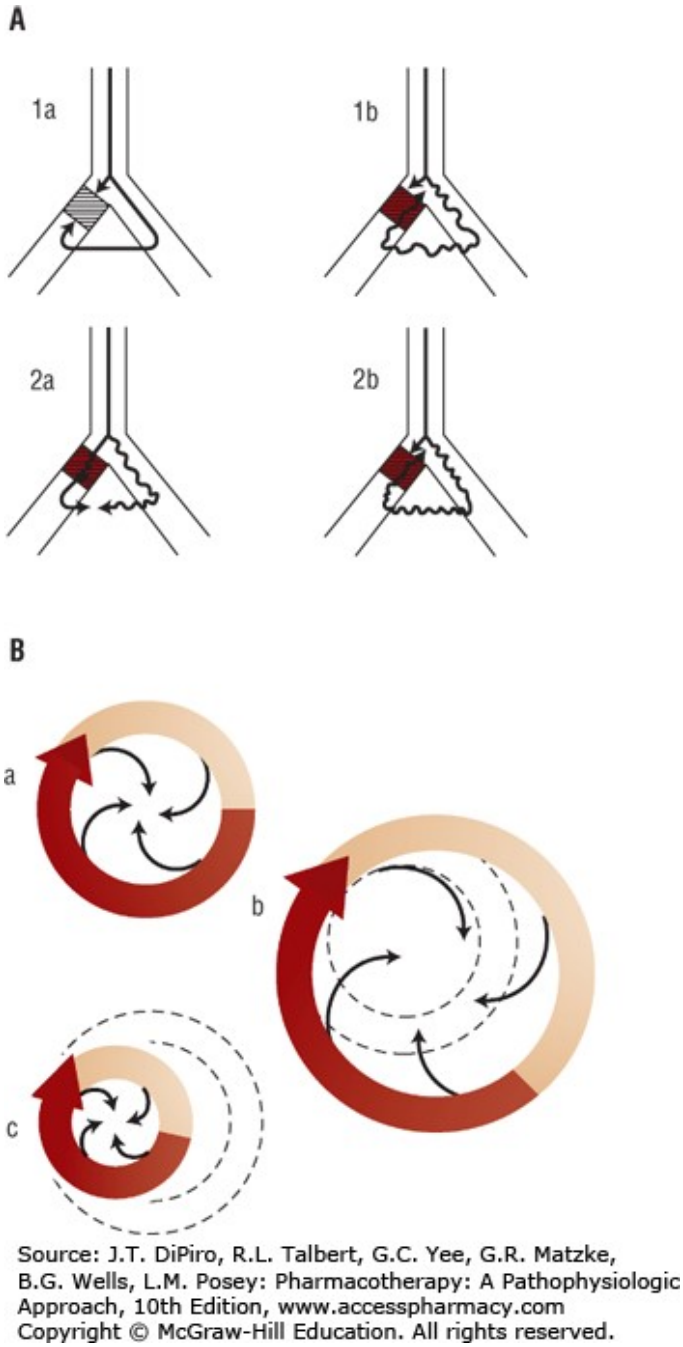
A. Possible mechanism of proarrhythmia in the anatomic model of reentry. *1a.* Nonviable reentrant loop due to bidirectional block (*shaded area*). *1b.* Instance where a drug slows conduction velocity without significantly prolonging the refractory period. The impulse is now able to reenter the area of unidirectional block (*shaded area*) because slowed conduction through the antegrade pathway allows recovery of the block. A new reentrant tachycardia may result. *2a.* Nonviable reentrant loop due to a lack of a unidirectional block. *2b.* Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The impulse moving antegrade meets refractory tissue (*shaded area*) allowing for unidirectional block. A new reentrant tachycardia may result. *B.* Mechanism of reentry and proarrhythmia. *a.* Functionally determined (*leading circle*) reentrant circuit. This model should be contrasted with anatomic reentry; here the circuit is not fixed (it does not necessarily move around an anatomic obstacle) and there is no excitable gap. All tissue inside is held continuously refractory. *b.* Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The tachycardia may terminate or slow in rate as shown as a consequence of a greater circuit length. The *dashed lines* represent the original reentrant circuit prior to drug treatment. *c.* Instance where a drug slows conduction velocity without significantly prolonging the refractory period

(ie, class Ic *antiarrhythmic drugs*) and accelerates the tachycardia. The tachycardia rate may increase (proarrhythmia) as shown as a consequence of a shorter circuit length. The dashed lines represent the original reentrant circuit prior to drug treatment. *(Reproduced with permission from McCollam PL, Parker RB, Beckman KJ, et al. Proarrhythmia: A paradoxic response to antiarrhythmic agents.* Pharmacotherapy *1989;9:146.)*



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

What causes reentry to become clinically manifest? Reentrant foci may occur at any level of the conduction system: within the branches of the specialized atrial conduction system, within the Purkinje network, and even within portions of the SA and AV nodes. The anatomy of the Purkinje system appears to provide a suitable substrate for the formation of microreentrant loops and is often used as a model to facilitate the understanding of reentry concepts. Of course, because reentry does not usually occur in normal, healthy conduction tissue, various forms of heart disease or conduction abnormalities must usually be present before reentry becomes manifest. In other words, the various forms of heart

disease (eg, coronary artery disease [CAD], LV dysfunction) can result in changes in conduction in the pathways of a suitable reentrant substrate. An often-used example is reentry occurring as a consequence of ischemic or hypoxic damage; with inadequate cellular oxygen, cardiac tissue resorts to anaerobic glycolysis for adenosine triphosphate production. As high-energy phosphate concentrations diminish, the activity of the transmembrane ion pumps declines and RMP rises. This rise in RMP causes inactivation in the voltage-dependent sodium channel, and the tissue begins to assume slow conduction characteristics. If changes in conduction parameters occur in a discordant manner due to varying degrees of ischemia or hypoxia, then a reentry circuit may become manifest. Furthermore, an ischemic, dying cell liberates intracellular potassium, which also causes a rise in RMP. In other cases, reentry may occur as a consequence of anatomic or functional variants in the normal conduction system. For instance, patients may possess two (instead of one) conduction pathways near or within the AV node, or have an anomalous extranodal AV pathway that possesses different electrophysiologic characteristics from the normal AV nodal pathway. Reentry in these cases may occur within the AV node or encompass both atrial and ventricular tissues. Reentrant tachycardias have the following characteristics: (a) the onset of the tachycardia is usually related to an initiating event (ie, premature beat); (b) the initiating beat is usually different in morphology from subsequent beats of the tachycardia; (c) the initiation of the tachycardia can usually be incited with programmed cardiac stimulation; and (d) the initiation and termination of the tachycardia is usually abrupt without an acceleration or deceleration phase. There are many examples of reentrant tachycardias, including AF, atrial flutter (AFl), AV nodal or AV reentrant tachycardia, and recurrent VT.

ANTIARRHYTHMIC DRUGS

In a theoretical sense, drugs may have antiarrhythmic activity by directly altering conduction in several ways. First, a drug may depress the automatic properties of abnormal pacemaker cells. A drug may do this by decreasing the slope of phase 4 depolarization and/or by elevating threshold potential. If the rate of spontaneous impulse generation of the abnormally automatic foci becomes less than that of the SA node, normal cardiac rhythm can be restored. Second, drugs may alter the conduction characteristics of the pathways of a reentrant loop.[1,2] A drug may facilitate conduction (shorten refractoriness) in the area of unidirectional block, allowing antegrade conduction to proceed. On the other hand, a drug may further depress conduction (prolong refractoriness) either in the area of unidirectional block or in the pathway with slowed conduction and a relatively shorter refractory period. If refractoriness is prolonged in the area of unidirectional block, retrograde propagation of the impulse is not permitted, causing a “bidirectional” block. In the anatomic model, if refractoriness is prolonged in the pathway with slow conduction, antegrade conduction of the impulse is not permitted. In either case, drugs that reduce the discordance and cause uniformity in conduction properties of the two pathways may suppress the reentrant substrate. In the functionally determined model, if refractoriness is prolonged without significantly slowing conduction velocity, the tachycardia may terminate or slow in rate as a consequence of a greater circuit length (see Fig. 18-4). There are other theoretical ways to stop reentry: (a) a drug may eliminate the critically timed premature impulse that triggers reentry; (b) a drug may slow conduction velocity to such an extent that conduction is extinguished; or (c) a drug may reverse the underlying form of heart disease that was responsible for the conduction abnormalities that led to the arrhythmia (ie, “reverse remodeling”).

AADs have specific electrophysiologic actions that alter cardiac conduction in patients with or without

heart disease. These actions form the basis of grouping AADs into specific categories based on their electrophysiologic actions in vitro. Vaughan Williams proposed the most frequently used classification system (**Table 18-1**).[2] This classification has been criticized for the following reasons: (a) it is incomplete and does not allow for the classification of drugs such as digoxin or adenosine; (b) it is not pure, and many agents have properties of more than one class of drugs; (c) it does not incorporate drug characteristics such as mechanisms of tachycardia termination/prevention, clinical indications, or side effects; and (d) drugs become "labeled" within a class, although they may be distinct in many regards.[3] These criticisms formed the basis for an attempt to reclassify AADs based on a variety of basic and clinical characteristics (called the Sicilian Gambit[3]). Nonetheless, the Vaughan Williams classification remains the most frequently used despite many proposed modifications and alternative systems.

TABLE 18-1 Classification of Antiarrhythmic Drugs

Class	Drug	Conduction Velocity[a]	Refractory Period	Automaticity	Ion Block
Ia	Quinidine Procainamide Disopyramide	↓	↑	↓	Sodium (intermediate) Potassium
Ib	Lidocaine Mexiletine	0/↓	↓	↓	Sodium (fast on–off)
Ic	Flecainide Propafenone[b]	↓↓	0	↓	Sodium (slow on–off)
II[c]	β-Blockers Amiodarone[d] Dofetilide	↓	↑	↓	Calcium (indirect)
III	Dronedarone[d] Sotalol[b] Ibutilide	0	↑↑	0	Potassium
IV[c]	Verapamil Diltiazem	↓	↑	↓	Calcium

[a]Variables for normal tissue models in ventricular tissue.

[b]Also has β-blocking actions.

[c]Variables for sinoatrial (SA) and atrioventricular (AV) nodal tissue only.

[d]Also has sodium, calcium, and β-blocking actions; see Table 18-2 (for amiodarone).

The class Ia AADs, quinidine, procainamide, and disopyramide, slow conduction velocity, prolong refractoriness, and decrease the automatic properties of sodium-dependent (normal and diseased) conduction tissue. Although class Ia AADs are primarily considered sodium channel blockers, their electrophysiologic actions can also be attributed to blockade of potassium channels. In reentrant tachycardias, these drugs generally depress conduction and prolong refractoriness, theoretically transforming the area of unidirectional block into a bidirectional block. Clinically, class Ia drugs are broad-spectrum AADs that are effective for both supraventricular and ventricular arrhythmias. Procainamide is only available in the IV formulation as all of its oral formulations have been discontinued. These AADs tend not to be used frequently in clinical practice for the management of either supraventricular or ventricular arrhythmias primarily because of their limited efficacy and significant toxicities.

The class Ib AADs, lidocaine, mexiletine, and phenytoin, were historically categorized separately from quinidine-like drugs. This was a result of early work demonstrating that lidocaine had distinctly different electrophysiologic actions. In normal tissue models, lidocaine generally facilitates actions on cardiac conduction by shortening refractoriness and having little effect on conduction velocity. Thus, it was postulated that these agents could improve antegrade conduction, eliminating the area of unidirectional block. Of course, arrhythmias do not usually arise from normal tissue, leading investigators to study the actions of lidocaine and phenytoin in ischemic and hypoxic tissue models. Interestingly, studies have shown these drugs to possess class Ia quinidine-like properties in diseased tissues. Therefore, it is probable that lidocaine acts in a similar fashion to the class Ia AADs (ie, prolongs refractoriness in diseased ischemic tissues leading to bidirectional block in a reentrant circuit). Lidocaine and similar agents have accentuated effects in ischemic tissue caused by the local acidosis and potassium shifts that occur during cellular hypoxia. Changes in pH alter the time that local anesthetics occupy the sodium channel receptor, thereby affecting the agent's electrophysiologic actions. In addition, the intracellular acidosis that ensues as a consequence of ischemia could cause lidocaine to become "trapped" within the cell, allowing increased access to the receptor. The class Ib AADs are considerably more effective in ventricular arrhythmias than supraventricular arrhythmias. As a group, these drugs are relatively weak sodium channel blockers (at normal stimulation rates).

The class Ic AADs, propafenone and flecainide, are extremely potent sodium channel blockers, profoundly slowing conduction velocity while leaving refractoriness relatively unaltered. The class Ic AADs theoretically eliminate reentry by slowing conduction to a point where the impulse is extinguished and cannot propagate further. Although the class Ic AADs are effective for both ventricular and supraventricular arrhythmias, their use for ventricular arrhythmias has been limited by the risk of proarrhythmia.

Class I AADs are grouped together because of their common action in blocking sodium conductance. The receptor site for these AADs is probably inside the sodium channel so that, in effect, the drug plugs the pore. The AAD may gain access to the receptor either via the intracellular space through the membrane lipid bilayer or directly through the channel. Several principles are inherent in antiarrhythmic sodium channel receptor theories[4]:

1. Class I AADs have predominant affinity for a particular state of the channel (eg, during activation or inactivation). For example, lidocaine and flecainide block sodium current primarily when the cell is in the inactivated state, whereas quinidine is predominantly an open (or activated)-channel

blocker.

2. Class I AADs have specific binding and unbinding characteristics to the receptor. For example, lidocaine binds to and dissociates from the channel receptor quickly ("fast on-off") but flecainide has very "slow on-off" properties. This explains why flecainide has such potent effects on slowing ventricular conduction, whereas lidocaine has little effect on normal tissue (at normal heart rates). In general, the class Ic AADs are "slow on-off," the class Ib AADs are "fast on-off," and the class Ia AADs are intermediate in their binding kinetics.

3. Class I AADs possess rate dependence (ie, sodium channel blockade and slowed conduction are greatest at fast heart rates and least during bradycardia). For "slow on-off" drugs, sodium channel blockade is evident at normal rates (60-100 beats/min), but for "fast on-off" agents, slowed conduction is only apparent at fast heart rates.

4. Class I AADs (except phenytoin) are weak bases with a pK_a greater than 7 and block the sodium channel in their ionized form. Consequently, pH will alter these actions: acidosis accentuates and alkalosis diminishes sodium channel blockade.

5. Class I AADs appear to share a single receptor site in the sodium channel. It should be noted, however, that a number of class I AADs have other electrophysiologic properties. For instance, quinidine has potent potassium channel blocking activity (manifests predominantly at low concentrations) as does *N*-acetylprocainamide (manifests predominantly at high concentrations), the primary metabolite of procainamide. Additionally propafenone has β-blocking actions.

These principles are important in understanding additive drug combinations (eg, quinidine and mexiletine), antagonistic combinations (eg, flecainide and lidocaine), and potential antidotes to excess sodium channel blockade (sodium bicarbonate). They also explain a number of clinical observations, such as why lidocaine-like drugs are relatively ineffective for supraventricular arrhythmias. The class Ib AADs are "fast on-off," inactivated sodium channel blockers; atrial cells, however, have a very brief inactivated phase relative to ventricular tissue.

The β-blockers are classified as class II AADs. For the most part, the clinically relevant acute antiarrhythmic mechanisms of the β-blockers result from their antiadrenergic actions. Because the SA and AV nodes are heavily influenced by adrenergic innervation, β-blockers would be most useful in tachycardias in which these nodal tissues are abnormally automatic or are a portion of a reentrant loop. These drugs are also helpful in slowing ventricular response in atrial arrhythmias (eg, AF) by their effects on the AV node. Furthermore, some tachycardias are exercise-related or precipitated by states of high sympathetic tone (perhaps through triggered activity), and β-blockers may be useful in these instances. β-Adrenergic stimulation results in increased conduction velocity, shortened refractoriness, and increased automaticity of the nodal tissues; β-blockers will antagonize these effects. In the nodal tissues, β-blockers interfere with calcium entry into the cell by altering catecholamine-dependent channel integrity and gating kinetics. In sodium-dependent atrial and ventricular tissues, β-blockers shorten repolarization somewhat but otherwise have little direct effect. The antiarrhythmic properties of β-blockers observed with long-term, chronic therapy in patients with heart disease are less well understood. Although it is clear that β-blockers decrease the likelihood of SCD (presumably arrhythmic death) after MI, the mechanism for this benefit remains unclear but may relate to the complex interplay

of changes in sympathetic tone, damaged myocardium, and ventricular conduction. In patients with HF, drugs such as β-blockers, angiotensin-converting enzyme inhibitors, and angiotensin II receptor blockers may prevent arrhythmias such as AF by attenuating the structural and/or electrical remodeling process in the myocardium.[5,6]

The class III AADs include those agents that specifically prolong refractoriness in atrial and ventricular tissues. This class includes amiodarone, dronedarone, sotalol, ibutilide, and dofetilide; these drugs share the common effect of delaying repolarization by blocking potassium channels. Amiodarone and sotalol are effective in most supraventricular and ventricular arrhythmias. Amiodarone displays electrophysiologic characteristics of all four Vaughan Williams classes; it is a sodium channel blocker with relatively "fast on-off" kinetics, has nonselective β-blocking actions, blocks potassium channels, and also has a small degree of calcium channel blocking activity (**Table 18-2**). At normal heart rates and with chronic use, its predominant effect is to prolong repolarization. With IV administration, its onset is relatively quick (unlike the oral form) and β-blockade predominates initially. Theoretically, amiodarone, like class I AADs, may interrupt the reentrant substrate by transforming an area of unidirectional block into an area of bidirectional block. However, electrophysiologic studies using programmed cardiac stimulation imply that amiodarone may leave the reentrant loop intact. The impressive effectiveness of amiodarone coupled with its low proarrhythmic potential has challenged the notion that selective ion channel blockade by AADs is preferable. Sotalol is a potent inhibitor of outward potassium movement during repolarization and also possesses nonselective β-blocking actions. Unlike amiodarone and sotalol, dronedarone, ibutilide, and dofetilide are only approved for the treatment of supraventricular arrhythmias. Both ibutilide (only available IV) and dofetilide (only available orally) can be used for the acute conversion of AF or AFl to SR. Dofetilide can also be used to maintain SR in patients with AF or AFl of longer than 1 week's duration who have been converted to SR. Dronedarone is approved to reduce the risk of cardiovascular (CV) hospitalization in patients with a history of paroxysmal or persistent AF who are currently in SR. Although structurally related to amiodarone, dronedarone's structure has been modified through the addition of a methylsulfonyl group and the removal of iodine. Dronedarone is also similar to amiodarone in exhibiting electrophysiologic characteristics of all four Vaughan Williams classes (sodium channel blocker with relatively "fast on-off" kinetics, nonselective β-blocker, potassium channel blocker, and calcium channel antagonist).

TABLE 18-2 Time Course and Electrophysiologic Effects of Amiodarone

Class	Mechanism	EP	ECG	IV		Oral	
				Minutes–Hours	Hours–Days	Days–Weeks	Weeks–Months
Class I	Na^+ block	↑HV	↑QRS	0	+	+	++
Class II	β-block	↑AH	↑PR ↓HR	++	++	++	++
Class III	K^+ block	↑VERP ↑AERP	↑QT	0	+	++	++++
Class IV	Ca^{2+} block[a]	↑AH	↑PR ↓HR	+	+	+	+

AERP, atrial effective refractory period; AH, atria–His interval; ECG, electrocardiographic effects; EP, electrophysiologic actions; HR, heart rate; HV, His–ventricle interval; IV, intravenous; VERP, ventricular effective refractory period.

[a]Rate-dependent.

There are a number of different potassium channels that function during normal conduction; all approved class III AADs inhibit the delayed rectifier current (I_K) responsible for phase 2 and phase 3 repolarization. Subcurrents make up I_K: an ultrarapid component (I_{Kur}), a rapid component (I_{Kr}), and the slow component (I_{Ks}). Sotalol, ibutilide, and dofetilide selectively block I_{Kr}, whereas amiodarone and dronedarone block both I_{Kr} and I_{Ks}. New drugs that selectively block I_{Kur} (found predominantly in the atrium but not ventricle) are being investigated for supraventricular arrhythmias. The clinical relevance of selectively blocking components of the delayed rectifier current remains to be determined. Potassium channel blockers (particularly those with selective I_{Kr} blocking properties) display "reverse use dependence" (ie, their effects on repolarization are greatest at low heart rates). Sotalol and drugs like it also appear to be much more effective in preventing VF (in dog models) than the traditional sodium channel blockers. They also decrease defibrillation threshold in contrast to class I AADs which tend to increase this parameter. This feature could be important in patients with ICDs, as concurrent therapy with class I AADs may require more energy for successful cardioversion or may render the ICD ineffective in terminating the ventricular arrhythmia. The Achilles' heel of all class III AADs is an extension of their underlying ionic mechanism; that is, by blocking potassium channels and delaying repolarization, these medications may also cause proarrhythmia in the form of TdP by provoking EADs.

The non-DHP CCBs, verapamil and diltiazem, are categorized as class IV AADs. At least two types of calcium channels are operative in SA and AV nodal tissues: an L-type channel and a T-type channel. Both L-type channel blockers (verapamil and diltiazem) and selective T-type channel blockers (mibefradil was previously approved but withdrawn from the market) will slow conduction, prolong refractoriness, and decrease automaticity (eg, due to EADs or LADs) of the calcium-dependent tissue in the SA and AV nodes. Therefore, these agents are effective in automatic or reentrant tachycardias which arise from or use the SA or AV nodes. In supraventricular arrhythmias (eg, AF or AFl), these drugs can slow ventricular response by slowing AV nodal conduction. Furthermore, because calcium entry seems to be integral to exercise-related tachycardias and/or tachycardias caused by some forms of triggered automaticity, these agents may be effective in the treatment of these types of arrhythmias. The DHP CCBs (eg, nifedipine) do not have significant antiarrhythmic activity as they do not affect AV nodal conduction.

All AADs currently available have an impressive side effect profile (**Table 18-3**). A considerable percentage of patients cannot tolerate long-term therapy with these drugs and will have to discontinue therapy because of side effects. 2 Flecainide, propafenone, quinidine, procainamide, disopyramide, sotalol, and dronedarone may precipitate worsening HF in a significant number of patients with underlying LV systolic dysfunction; consequently, these drugs should be avoided in patients with heart failure with reduced ejection fraction (HF*r*EF). The class Ib AAD, mexiletine, causes neurologic and/or gastrointestinal toxicity in a high percentage of patients. One of the most frightening side effects related to AADs is the aggravation of underlying ventricular arrhythmias or the precipitation of new (and life-threatening) ventricular arrhythmias.[7]

TABLE 18-3 Side Effects of Antiarrhythmic Drugs

Disopyramide	Anticholinergic symptoms (dry mouth, urinary retention, constipation, blurred vision), nausea, anorexia, TdP, HF, conduction disturbances, ventricular arrhythmias
Procainamide[a]	Hypotension, TdP, worsening HF, conduction disturbances, ventricular arrhythmias
Quinidine	Cinchonism, diarrhea, abdominal cramps, nausea, vomiting, hypotension, TdP, worsening HF, conduction disturbances, ventricular arrhythmias, fever
Lidocaine	Dizziness, sedation, slurred speech, blurred vision, paresthesia, muscle twitching, confusion, nausea, vomiting, seizures, psychosis, sinus arrest, conduction disturbances
Mexiletine	Dizziness, sedation, anxiety, confusion, paresthesia, tremor, ataxia, blurred vision, nausea, vomiting, anorexia, conduction disturbances, ventricular arrhythmias
Flecainide	Blurred vision, dizziness, dyspnea, headache, tremor, nausea, worsening HF, conduction disturbances, ventricular arrhythmias
Propafenone	Dizziness, fatigue, blurred vision, bronchospasm, headache, taste disturbances, nausea, vomiting, bradycardia or AV block, worsening HF, ventricular arrhythmias
Amiodarone	Tremor, ataxia, paresthesia, insomnia, corneal microdeposits, optic neuropathy/neuritis, nausea, vomiting, anorexia, constipation, TdP (<1%), bradycardia or AV block (IV and oral use), pulmonary fi brosis, liver function test abnormalities, hypothyroidism, hyperthyroidism, photosensitivity, blue-gray skin discoloration, hypotension (IV use), phlebitis (IV use)
Dofetilide	Headache, dizziness, TdP
Dronedarone	Nausea, vomiting, diarrhea, serum creatinine elevations, bradycardia, worsening HF, hepatotoxicity, pulmonary fibrosis, acute renal failure, TdP (<1%)
Ibutilide	Headache, TdP, bradycardia or AV block, hypotension
Sotalol	Dizziness, weakness, fatigue, nausea, vomiting, diarrhea, bradycardia or AV block, TdP, bronchospasm, worsening HF

AV, atrioventricular; HF, heart failure; IV, intravenous; TdP, torsade de pointes.

[a]Side effects listed are for the IV formulation only; oral formulations are no longer available.

Amiodarone has assumed a prominent place in the treatment of both acute and chronic supraventricular and ventricular arrhythmias and is now the most commonly prescribed AAD.[8] Once considered a drug of last resort, it is now the first AAD considered for the treatment of many arrhythmias. Yet amiodarone is a peculiar and complex drug, displaying unusual pharmacologic effects, pharmacokinetics, dosing regimens, and multiorgan side effects. Amiodarone has an extremely long elimination half-life (approximately 60 days) and large volume of distribution; consequently, its onset of action with the oral form is delayed (days to weeks) despite the use of a loading regimen, and its effects persist for a long period (months) after discontinuation. Amiodarone is a substrate of the cytochrome P450 (CYP) 3A4 isoenzyme, a moderate inhibitor of many CYP isoenzymes (eg, CYP2C9, CYP2D6, CYP3A4), and a P-glycoprotein (P-gp) inhibitor, all of which can result in the potential for numerous drug interactions. Amiodarone interacts with digoxin and warfarin and can significantly increase plasma concentrations of both drugs. By inhibiting P-gp, amiodarone can increase digoxin concentrations by approximately 2-fold; therefore, the digoxin dose should be empirically reduced by

50% when amiodarone is initiated. By inhibiting CYP2C9 and CYP3A4, amiodarone can increase warfarin concentrations and the international normalized ratio (INR). Consequently, when amiodarone and warfarin are initiated concurrently, warfarin should be started at a dose of 2.5 mg daily. When amiodarone is initiated in a patient already receiving warfarin, the warfarin dose should be reduced by approximately 30%.[9] Through inhibition of P-gp, amiodarone can also increase concentrations of dabigatran, especially in patients with severe renal impairment (creatinine clearance [CrCl] 15-30 mL/min); consequently, the use of dabigatran should be avoided in these patients who are receiving amiodarone. Acute administration of amiodarone is usually well tolerated by patients; however, severe organ toxicities may result with chronic use. Severe bradycardia (sometimes requiring pacing to allow the patient to remain on amiodarone), hyperthyroidism, hypothyroidism, peripheral neuropathy, gastrointestinal discomfort, photosensitivity, and a blue-gray skin discoloration on exposed areas are common. Fulminant hepatitis (uncommon) and pulmonary fibrosis (5%-10% of patients) have caused death.[10,11] Although amiodarone can cause corneal microdeposits (usually do not affect vision) in virtually every patient, it has also been associated with the development of optic neuropathy/neuritis which can lead to blindness. Even though amiodarone markedly prolongs the QT interval, the risk of proarrhythmia (ie, TdP) is rare. All of these side effects mandate close and continued monitoring (liver enzymes, thyroid function tests, eye examinations, chest radiographs, pulmonary function tests) and have led to a proliferation of "amiodarone clinics" designed just for patients receiving this drug on a chronic basis (**Table 18-4**). [12,13]

TABLE 18-4 Amiodarone Monitoring

Side Effect	Monitoring Recommendations	Management of Side Effect
	Chest radiograph (baseline, and then every 12 months)	
Pulmonary fibrosis	Pulmonary function tests (baseline, and then if symptoms develop)	Discontinue amiodarone immediately; may consider corticosteroid therapy
	High-resolution CT (if symptoms develop)	
Hypothyroidism	TFTs (baseline, and then every 6 months)	Thyroid hormone supplementation (eg, levothyroxine)
Hyperthyroidism	TFTs (baseline, and then every 6 months)	Antithyroid drugs (eg, methimazole, propylthiouracil) or corticosteroids; may need to discontinue amiodarone)
Optic neuritis/neuropathy	Ophthalmologic examination (baseline [only if visual impairment present], and then if symptoms develop)	Discontinue amiodarone immediately
Corneal microdeposits	Slit-lamp examination (routine monitoring not necessary)	No treatment necessary

Side Effect	Monitoring Recommendations	Management of Side Effect
Hepatotoxicity	LFTs (baseline, and then every 6 months)	Lower the dose or discontinue amiodarone if LFTs >2× the upper limit of normal
Bradycardia/heart block	ECG (baseline, and then every 3-6 months)	Lower the dose, if possible, or discontinue amiodarone if severe (or continue amiodarone and implant permanent pacemaker)
Tremor, ataxia, peripheral neuropathy	History/physical examination (each office visit)	Lower the dose, if possible, or discontinue amiodarone if severe
Photosensitivity/blue-gray skin discoloration	History/physical examination (each office visit)	Lower the dose; advise patients to wear sunblock while outdoors

ECG, electrocardiogram; LFTs, liver function tests, TFTs, thyroid function tests.

With the addition of a methylsulfonyl group and the deletion of the iodine moiety, dronedarone is less lipophilic than amiodarone; consequently, dronedarone is supposed to be less likely to accumulate in tissues and cause various organ toxicities. Dronedarone also has a considerably shorter half-life (approximately 24 hours) when compared with amiodarone, which allows for steady state to be achieved in 5 to 7 days without the need for loading doses. Like amiodarone, dronedarone is a substrate of the CYP3A4 isoenzyme and a moderate inhibitor of the CYP2D6 and CYP3A4 isoenzymes. Its use with potent CYP3A4 inhibitors or inducers should be avoided. Dronedarone may increase plasma concentrations of (*S*)-warfarin; therefore, the INR should be closely monitored with concurrent use of these drugs. Dronedarone also inhibits P-gp and can increase digoxin concentrations by about 2.5-fold. Consequently, when concomitantly using dronedarone and digoxin, the digoxin dose should be empirically reduced by 50%. Additionally, dronedarone can increase dabigatran and rivaroxaban concentrations in patients with renal impairment. To minimize the risk of bleeding when concomitantly using dronedarone and dabigatran in this patient population, the dose of dabigatran should be reduced to 75 mg twice daily in those with moderate renal impairment (CrCl 30-50 mL/min). The concomitant use of dronedarone and dabigatran should be avoided in patients with severe renal impairment (CrCl 15-30 mL/min). Rivaroxaban should only be used if the benefit outweighs the risk in patients receiving dronedarone who have a CrCl of 15 to 80 mL/min. While it was initially believed that dronedarone would cause fewer organ toxicities with the deletion of the iodine moiety, several postmarketing reports have suggested that this AAD may be associated with several significant organ toxicities, including severe hepatic injury, interstitial lung disease (ie, pulmonary fibrosis), and acute kidney injury.[14,15,16]

Table 18-5 summarizes the pharmacokinetics of the AADs and **Table 18-6** lists recommended dosages of the oral dosage forms of the AADs. **Table 18-7** lists the dosing recommendations for the IV forms of various AADs.

TABLE 18-5 Pharmacokinetics of Antiarrhythmic Drugs

Drug	Oral Bioavailability	Primary Route of	Substrate[b]	Inhibitor[b]	V_{Dss} (L/kg)	Protein Binding	$t_{1/2}$[c]	Therapeutic Range

	(%)	Elimination[a]				(%)		(mg/L)
Disopyramide	70-95	H/R	CYP3A4 (M)	—	0.8-2	50-80	4-8 hours	2-6 (6-18 µmol/L)
Procainamide	—	H/R	NAT CYP2D6 (M)	—	1.5-3	10-20	5-6 hours (SAs) 2-3 hours (FAs)	4-15 (17-64 µmol/L)
Quinidine	70-80	H	CYP3A4 (M) CYP2C9	CYP2D6 (S) CYP3A4 (S) CYP2C9 P-gp	2-3.5	80-90	5-9 hours	2-6 (6-18 µmol/L)

[a]H, hepatic; R, renal.

[b]CYP, cytochrome P450 isoenzyme; M, major; NAT, N -acetyltransferase; P-gp, P-glycoprotein; S, strong.

[c]EMs, extensive metabolizers; FAs, fast acetylators; PMs, poor metabolizers; SAs, slow acetylators.

[d]Variables for parent compound (not 5-OH-propafenone).

TABLE 18-6 Typical Maintenance Doses of Oral Antiarrhythmic Drugs

Drug	Dose	Dose Adjusted
Disopyramide	100-150 mg q 6 hours 200-300 mg q 12 hours (SR form)	HEP, REN
Quinidine	200-300 mg sulfate salt q 6 hours 324-648 gluconate salt q 8-12 hours	HEP
Mexiletine	200-300 mg q 8 hours	HEP
Flecainide	50-200 mg q 12 hours	HEP, REN
Propafenone	150-300 mg q 8 hours 225-425 mg q 12 hours (SR form)	HEP
Amiodarone	400 mg two to three times daily until 10 g total, and then 200-400 mg daily[a]	
Dofetilide	500 mcg q 12 hours	REN[b]
Dronedarone	400 mg twice daily (with meals)[c]	
Sotalol	80-160 mg q 12 hours	REN[d]

HEP, hepatic disease; REN, renal impairment; SR, sustained release.

[a] Usual maintenance dose for atrial fibrillation is 200 mg/day (may further decrease dose to 100 mg/day with long-term use if patient clinically stable in order to decrease risk of toxicity); usual maintenance dose for ventricular arrhythmias is 300-400 mg/day.

[b]Dose should be based on creatinine clearance; should not be used when creatinine clearance <20 mL/min.

[c]Should not be used in severe hepatic impairment.

[d]Should not be used for atrial fibrillation when creatinine clearance <40 mL/min.

TABLE 18-7 IV Antiarrhythmic Dosing

Drug	Clinical Situation	Dose
Amiodarone	Pulseless VT/VF	300 mg IV/IO push (can give additional 150 mg IV/IO push if persistent VT/VF or if VT/VF recurs), followed by infusion of 1 mg/min for 6 hours, and then 0.5 mg/min
	Stable VT (with a pulse)	150 mg IV over 10 minutes, followed by infusion of 1 mg/min for 6 hours, and then 0.5 mg/min
	AF (termination)	5 mg/kg IV over 30 minutes, followed by infusion of 1 mg/min for 6 hours, and then 0.5 mg/min
Diltiazem	PSVT; AF (rate control)	0.25 mg/kg IV over 2 minutes (may repeat with 0.35 mg/kg IV over 2 minutes), followed by infusion of 5-15 mg/h

Drug	Clinical Situation	Dose
Ibutilide	AF (termination)	1 mg IV over 10 minutes (may repeat if needed)
Lidocaine	Pulseless VT/VF	1-1.5 mg/kg IV/IO push (can give additional 0.5-0.75 mg/kg IV/IO push every 5-10 minutes if persistent VT/VF [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1-4 mg/min (1-2 mg/min if liver disease or HF)
	Stable VT (with a pulse)	1-1.5 mg/kg IV push (can give additional 0.5-0.75 mg/kg IV push every 5-10 minutes if persistent VT [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1-4 mg/min (1-2 mg/min if liver disease or HF)
Procainamide	AF (termination); stable VT (with a pulse)	15-18 mg/kg IV over 60 minutes, followed by infusion of 1-4 mg/min
Verapamil	PSVT; AF (rate control)	2.5-5 mg IV over 2 minutes (may repeat up to maximum cumulative dose of 20 mg); can follow with infusion of 2.5-10 mg/h

AF, atrial fibrillation; HF, heart failure; IO, intraosseous; IV, intravenous; PSVT, paroxysmal supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

SUPRAVENTRICULAR ARRHYTHMIAS

The common supraventricular tachycardias that often require drug treatment are: (a) AF or AFl, (b) PSVT, and (c) automatic atrial tachycardias. Other common supraventricular arrhythmias that usually do not require drug therapy include premature atrial complexes, wandering atrial pacemaker, sinus arrhythmia, and sinus tachycardia. As an example, premature atrial complexes rarely cause symptoms and never cause hemodynamic compromise; therefore, drug therapy is usually not indicated. Likewise, sinus tachycardia is usually the result of underlying metabolic or hemodynamic disorders (eg, infection, dehydration, hypotension), and therapy should be directed at the underlying cause, not the tachycardia per se. Of course, there are exceptions to these suggestions. For example, sinus tachycardia may be deleterious in patients after cardiac surgery or MI. Therefore, AADs, such as β-blockers, may be indicated in these situations. Stated in another way, although many arrhythmias generally do not require therapy, clinical judgment and patient-specific variables play an important role in this decision. AF, AFl, and PSVT tend to be the most common supraventricular arrhythmias seen in clinical practice; therefore, this discussion will focus only on these arrhythmias.

Atrial Fibrillation and Atrial Flutter

Mechanisms and Background

AF continues to be the most common sustained arrhythmia encountered in clinical practice, affecting between 2.7 and 6.1 million Americans.[17] In the general population, the overall prevalence of AF is 0.4% to 1%, and this increases with age (eg, approximately an 8% prevalence in patients greater than 80 years old).[18,19] The prevalence of AF also appears to increase as patients develop more severe HF,

increasing from 4% in asymptomatic NYHA class I patients to 50% in patients with NYHA class IV HF.[20] With the aging population, improved survival in patients with HF, CAD, and hypertension, and the increased frequency of surgical procedures being performed, it is expected that the prevalence of AF will dramatically increase to an estimated 12 to 15 million by the year 2050.[20] Based on data derived from the Framingham study cohort, the general lifetime risk for AF in men and women at least 40 years of age is estimated to be 1 in 4.[21]

AF and AFl may present as a chronic, established tachycardia, an acute tachycardia, or a self-terminating, paroxysmal form. The following semantics and definitions are sometimes used specifically for AF: acute AF (onset within 48 hours), paroxysmal AF (terminates spontaneously in less than 7 days), recurrent AF (two or more episodes), persistent AF (duration longer than 7 days and does not terminate spontaneously), and permanent AF (does not terminate with attempts at pharmacologic or electrical cardioversion).[22] AF is characterized by extremely rapid (atrial rate of 400 to 600 beats/min) and disorganized atrial activation. With this disorganized atrial activity, there is a loss of the contribution of synchronized atrial contraction (atrial kick) to forward cardiac output. Supraventricular impulses penetrate the AV conduction system in variable degrees resulting in an irregular activation of the ventricles and an irregularly irregular pulse. The AV junction will not conduct most of the supraventricular impulses, causing the ventricular response to be considerably slower (120 to 180 beats/min) than the atrial rate. It is sometimes stated that "AF begets AF," that is, the arrhythmia tends to perpetuate itself. Long episodes are more difficult to terminate perhaps because of tachycardia-induced changes in atrial function (mechanical and/or electrical "remodeling").

CLINICAL PRESENTATION Supraventricular Tachycardias Atrial Fibrillation/Flutter General

- These arrhythmias are usually not directly life-threatening and do not generally cause hemodynamic collapse or syncope; 1:1 AFl (ventricular response approximately 300 beats/min) is an exception. Also, patients with underlying forms of heart disease who are heavily reliant on atrial contraction to maintain adequate cardiac output (eg, mitral stenosis, obstructive cardiomyopathy) display more severe symptoms of AF or AFl.

Symptoms

- Most often, patients complain of rapid heart rate/palpitations and/or worsening symptoms of HF (dyspnea, fatigue). Medical emergencies are severe HF (ie, pulmonary edema, hypotension) or AF occurring in the setting of acute MI.

Diagnostic Tests/Signs (ECG)

- AF is an irregularly irregular supraventricular rhythm with no discernible, consistent atrial activity (P waves). Ventricular rate is usually 120 to 180 beats/min and the pulse is irregular. AFl is (usually) a regular supraventricular rhythm with characteristic flutter waves (or sawtooth pattern) reflecting more organized atrial activity. Commonly, the ventricular rate is in factors of 300 beats/min (eg, 150, 100, or 75 beats/min).

Paroxysmal Supraventricular Tachycardia Caused by Reentry General

- This arrhythmia can be transient, resulting in little, if any, symptoms.

Symptoms

- Patients frequently complain of intermittent episodes of rapid heart rate/palpitations that abruptly start and stop, usually without provocation (but occasionally as a result of exercise). Severe symptoms include syncope. Often (in particular, those with AV nodal reentry), patients complain of a chest pressure or neck sensation. This is caused by simultaneous AV contraction with the right atrium contracting against a closed tricuspid valve. Life-threatening symptoms (syncope, hemodynamic collapse) are associated with an extremely rapid heart rate (eg, greater than 200 beats/min) and AF associated with an accessory AV pathway.

Diagnostic Tests/Signs (ECG)

- Most commonly, PSVT is a rapid, narrow QRS tachycardia (regular in rhythm) that starts and stops abruptly. Atrial activity, although present, is difficult to ascertain on surface ECG because P waves are "buried" in the QRS complex or T wave.

AFl occurs less frequently than AF but is similar in its precipitating factors, consequences, and drug therapy approach. This arrhythmia is characterized by rapid (atrial rate of 270 to 330 beats/min) but regular atrial activation. The slower and regular electrical activity results in a regular ventricular response that is in approximate factors of 300 beats/min (ie, 1:1 AV conduction = ventricular rate of 300 beats/min; 2:1 AV conduction = ventricular rate of 150 beats/min; 3:1 AV conduction = ventricular rate of 100 beats/min). AFl may occur in two distinct forms (type I and type II). Type I flutter is the more common classic form with atrial rates of approximately 300 beats/min and the typical "sawtooth" pattern of atrial activation as shown by the surface ECG. Type II flutter tends to be faster, being somewhat of a hybrid between classic AFl and AF. Although the ventricular response usually has a regular pattern with this arrhythmia, AFl with varying degrees of AV block or that occur with episodes of AF ("fib-flutter") can cause an irregular ventricular rate.

It is generally accepted that the predominant mechanism of AF and AFl is reentry. AF appears to result from multiple atrial reentrant loops (or wavelets), whereas AFl is caused by a single, dominant, reentrant substrate (counterclockwise circus movement in the right atrium around the tricuspid annulus). AF or AFl usually occurs in association with various forms of structural heart disease (SHD) that cause left atrial distension, including myocardial ischemia or infarction, hypertensive heart disease, valvular disorders such as mitral stenosis or mitral insufficiency, congenital abnormalities such as septal defects, dilated or hypertrophic cardiomyopathy, and obesity. Disorders that cause right atrial stretch and are associated with AF or AFl include acute pulmonary embolism and chronic lung disease resulting in pulmonary hypertension and cor pulmonale. AF may also occur in association with states of high adrenergic tone such as thyrotoxicosis, surgery, alcohol withdrawal, sepsis, and excessive physical exertion. AF that develops in the absence of clinical, electrocardiographic, radiographic, and echocardiographic evidence of SHD is defined as lone AF. Other states in which patients are predisposed to episodes of AF are the presence of an anomalous AV pathway (ie, Kent's bundle) and sinus node dysfunction (ie, sick sinus syndrome).

Patients with AF or AFl may experience the entire range of symptoms associated with other supraventricular tachycardias, although syncope as a presenting symptom is uncommon. Because left atrial kick is lost with the onset of AF, patients with HF*r*EF or HF with preserved ejection fraction (HF*p*EF)

may develop worsening signs and symptoms of HF as they often depend on the contribution of their atrial kick to maintain an adequate cardiac output. TE events, resulting from atrial stasis and poorly adherent mural thrombi, are an additional complication of AF. Of course, the most devastating complication in this regard is the occurrence of an embolic stroke. The average rate of ischemic stroke in patients with AF who are not receiving antithrombotic therapy is approximately 5% per year.[23] Stroke can precede the onset of documented AF, probably as a result of undetected paroxysms prior to the onset of established AF. The risk of stroke significantly increases with age, with the annual attributable risk increasing from 1.5% in individuals 50 to 59 years of age to almost 24% in those 80 to 89 years of age.[24] The risk of stroke in patients with only AFl has been traditionally believed to be low, prompting some to recommend only aspirin for prevention of thromboembolism in this particular patient population. However, because patients with AFl may also intermittently have episodes of AF, this patient population may also be at risk for a TE event. Although the role of antithrombotic therapy in patients with AFl has not been adequately studied in clinical trials, the most recent guidelines suggest that the same risk stratification scheme and antithrombotic recommendations used in patients with AF should also be applied to those with AFl.[22]

Management

The traditional approach to the treatment of AF can be organized into several sequential goals. First, evaluate the need for acute treatment (usually administering drugs that slow ventricular rate). Next, contemplate methods to restore SR, taking into consideration the risks (eg, thromboembolism). Lastly, consider ways to prevent the long-term complications of AF such as arrhythmia recurrence and thromboembolism. 4 One of the biggest controversies in the management of AF is whether restoring and maintaining SR is a desirable goal for all patients. A review of the management of AF and AFl, including a discussion of this controversy follows, organized according to the goals already outlined. **Figure 18-5** shows an algorithm for the management of AF and AFl. In addition, **Table 18-8** summarizes the recommendations for pharmacologically controlling ventricular rate and restoring and maintaining SR from the most recent AF guidelines developed by the American Heart Association (AHA)/American College of Cardiology (ACC)/Heart Rhythm Society (HRS).[22]

FIGURE 18-5

Algorithm for the treatment of AF and AFl. [a]If AF is less than 48 hours in duration, anticoagulation prior to cardioversion is unnecessary; initiate anticoagulation with unfractionated heparin, a low-molecular-weight heparin, apixaban, dabigatran, or rivaroxaban as soon as possible either before or after cardioversion for patients at high risk for stroke (this anticoagulant regimen or no antithrombotic therapy may be considered in low-risk patients). [b]Ablation may be considered for patients who fail or do not tolerate at least 1 AAD or as first-line therapy (before AAD therapy) for select patients with recurrent symptomatic paroxysmal AF. [c]Chronic antithrombotic therapy should be considered in all patients with AF and risk factors for stroke regardless of whether or not they remain in sinus rhythm. (AAD, antiarrhythmic drug; AF, atrial fibrillation; AFl, atrial flutter; BB, β-blocker; CCB, calcium channel blocker [ie, verapamil or diltiazem]; DCC, direct current cardioversion; TEE, transesophageal echocardiogram.)

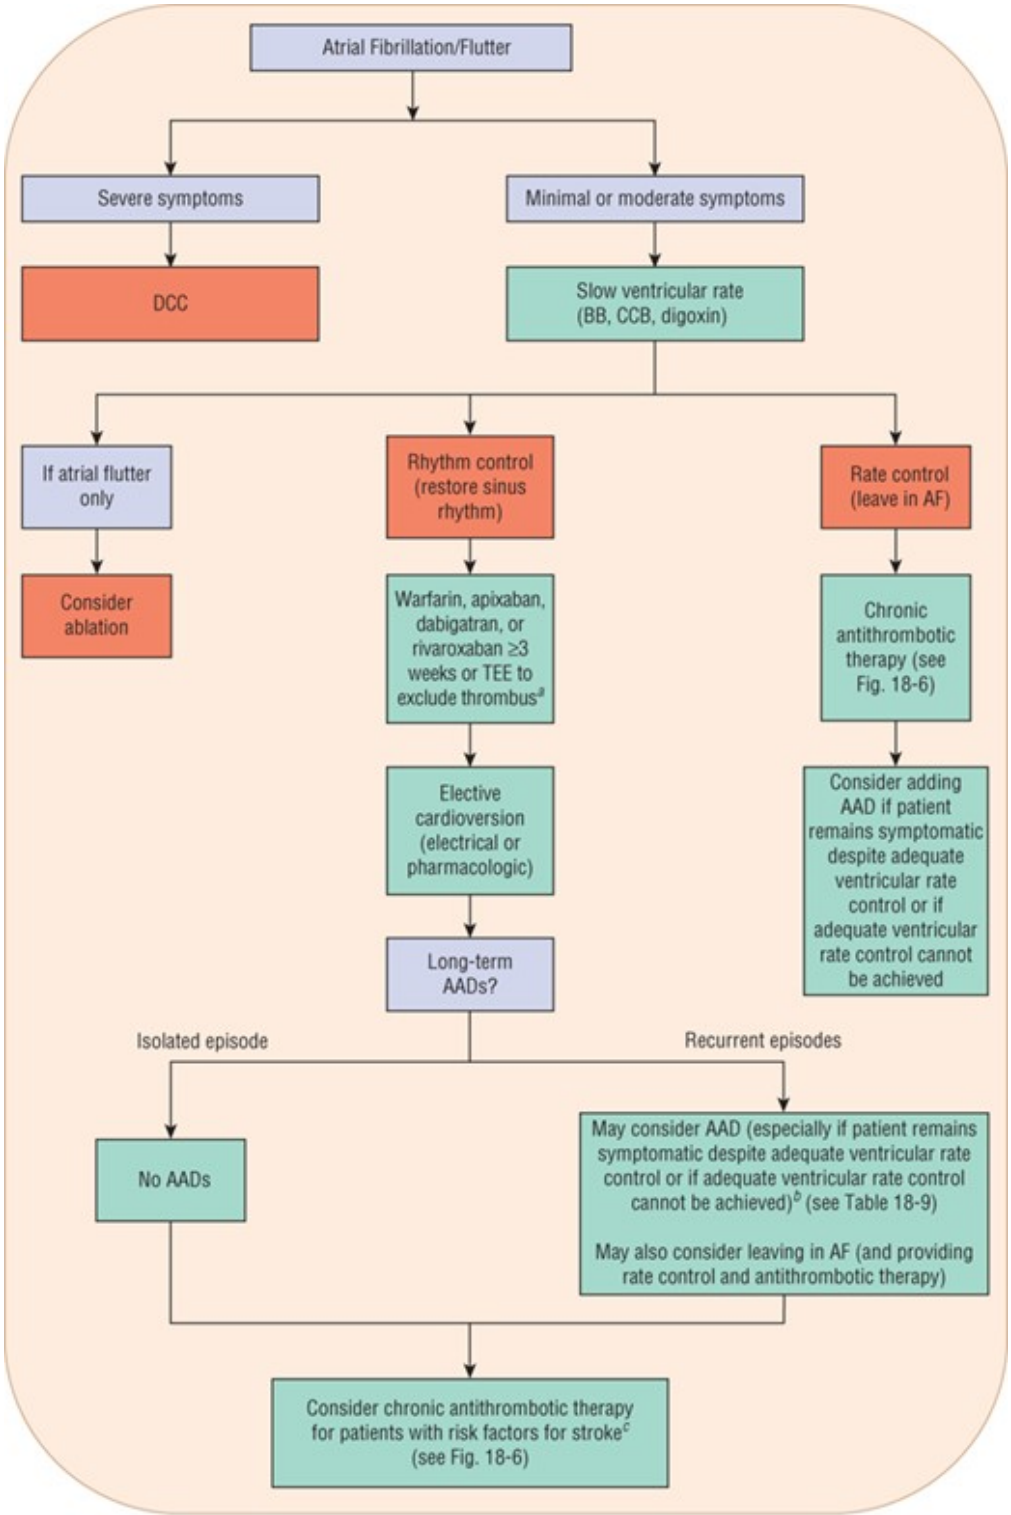

TABLE 18-8 Evidence-Based Pharmacologic Treatment Recommendations for Controlling Ventricular Rate, Restoring Sinus Rhythm, and Maintaining Sinus Rhythm in Patients with Atrial Fibrillation

Treatment Recommendations	ACC/AHA/ESC Guideline Recommendation
Ventricular rate control (acute setting)	

Treatment Recommendations	ACC/AHA/ESC Guideline Recommendation
In the absence of an accessory pathway, an IV β-blocker or IV non-DHP CCB is recommended for patients without HF.	Class I
In the absence of an accessory pathway, IV digoxin or IV amiodarone is recommended to control the ventricular rate in patients with HF.	Class I
In the absence of an accessory pathway, an IV β-blocker is recommended to control the ventricular rate in patients with stable HF*r*EF.	Class I
In the absence of an accessory pathway, in IV non-DHP CCB is recommended to control the ventricular rate in patients with stable HF*p*EF.	Class I
In the absence of an accessory pathway, IV amiodarone is recommended to control the ventricular rate in critically ill patients.	Class IIa
IV amiodarone can be useful to control the ventricular rate when other measures are unsuccessful or contraindicated.	Class IIa
Digoxin, non-DHP CCBs, or IV amiodarone should not be used in patients with an accessory pathway.	Class III
IV β-blockers or IV non-DHP CCBs are not recommended in patients with decompensated HF.	Class III
Ventricular rate control (chronic setting)	
An oral β-blocker or non-DHP CCB is recommended to control the ventricular rate in patients with paroxysmal, persistent, or permanent AF.	Class I
An oral β-blocker or non-DHP CCB is recommended to control the ventricular rate in patients with persistent or permanent AF and compensated HF*p*EF.	Class I
Digoxin is effective for controlling resting heart rate in patients with HF*r*EF.	Class I
A combination of digoxin and a β-blocker is reasonable to control resting and exercise heart rate in patients with HF*r*EF.	Class IIa
A combination of digoxin and a non-DHP CCB is reasonable to control resting and exercise heart rate in patients with HF*p*EF.	Class IIa
Oral amiodarone can be used when the ventricular rate cannot be adequately controlled at rest and during exercise with an oral β-blocker, non-DHP CCB, and/or digoxin.	Class IIb
Oral non-DHP CCBs and dronedarone are not recommended to control the ventricular rate in patients with decompensated HF.	Class III
Dronedarone should not be used to control the ventricular rate in patients with permanent AF.	Class III
Restoration of SR	
In the absence of contraindications, flecainide, dofetilide, propafenone, or ibutilide is recommended for pharmacologic cardioversion of AF.	Class I

Treatment Recommendations	ACC/AHA/ESC Guideline Recommendation
Oral amiodarone is a reasonable option for pharmacologic cardioversion of AF.	Class IIa
The "pill-in-the-pocket" approach with flecainide or propafenone can be used to terminate persistent AF on an outpatient basis once the treatment has been used safely in the hospital, in patients without sinus or AV node dysfunction, bundle-branch block, QT interval prolongation, Brugada syndrome, or SHD (*Note*: AV node must be adequately blocked with *β*-blocker or non-DHP CCB therapy before initiating this therapy).	Class IIa
Dofetilide should not be initiated on an outpatient basis.	Class III
Maintenance of SR	
The following AADs are recommended for maintaining SR, depending on underlying SHD and other comorbidities: amiodarone, dofetilide, dronedarone, flecainide, propafenone, and sotalol.	Class I
Because of its potential toxicities, amiodarone should only be used after consideration of its risks and when other agents have failed or are contraindicated.	Class I
The risk of the AAD, including proarrhythmia, should be considered before initiating treatment with that drug.	Class I
Antiarrhythmic therapy can be useful for maintaining SR for the treatment of tachycardia-induced cardiomyopathy.	Class IIa
It may be reasonable to continue current AAD therapy in the setting of infrequent, well-tolerated recurrences of AF when the drug has reduced the frequency or symptoms of AF.	Class IIb
An AAD should not be continued when the AF becomes permanent.	Class III
Dronedarone should not be used in patients with class III or IV HF or patients who have had an episode of decompensated HF in the last 4 weeks)	Class III

AAD, antiarrhythmic drug; ACC, American College of Cardiology; AF, atrial fibrillation; AHA, American Heart Association; AV, atrioventricular; CCB, calcium channel blocker; DCC, direct current cardioversion; DHP, dihydropyridine; HF, heart failure; HF*p*EF, heart failure with preserved ejection fraction; HF*r*EF, heart failure with reduced ejection fraction; HRS, Heart Rhythm Society; IV, intravenous; SHD, structural heart disease; SR, sinus rhythm.

Data from Fuster et al.[16] and Wann et al.

Acute Treatment

First, consider the patient with new-onset, symptomatic AF or AFl. Although uncommon, patients may present with signs and/or symptoms of hemodynamic instability (eg, severe hypotension, angina, or pulmonary edema), which qualifies as a medical emergency. In these situations, direct current

cardioversion (DCC) is indicated as first-line therapy in an attempt to immediately restore SR (without regard to the risk of thromboembolism). AFl often requires relatively low energy levels of countershock (ie, 50 joules [J]), whereas AF often requires higher energy levels (ie, greater than 200 J).

If patients are hemodynamically stable, there is no emergent need to restore SR. Instead, the focus should be directed toward controlling the patient's ventricular rate. Achieving adequate ventricular rate control should be a treatment goal for all patients with AF. To achieve this goal, drugs that slow conduction and increase refractoriness in the AV node (eg, β-blockers, non-DHP CCBs, or digoxin) should be used as initial therapy. Although loading doses of digoxin have been historically recommended as first-line treatment to slow ventricular rate, use of this drug for this purpose, especially in patients with normal LV systolic function (left ventricular ejection fraction [LVEF] greater than 40%), has declined.[8] Potential reasons for the declining use of digoxin in this patient population are its relatively slow onset and its inability to control the ventricular rate during exercise. Although an initial decrease in the ventricular rate can sometimes be observed within 1 hour of IV administration of digoxin, full control (heart rate less than 80 beats/min at rest and less than 100 beats/min during exercise) is usually not achieved for 24 to 48 hours. Digoxin also tends to be ineffective for controlling ventricular rate under conditions of increased sympathetic tone (ie, surgery, thyrotoxicosis) because it slows AV nodal conduction primarily through vagotonic mechanisms. Additionally, in several recent analyses, the use of digoxin in patients with AF has been associated with a significant increase in the risk of mortality.[25,26] In contrast, IV β-blockers and non-DHP CCBs have a relatively quick onset and can effectively control the ventricular rate at rest and during exercise. β-Blockers are also effective for controlling ventricular rate under conditions of increased sympathetic tone.

Based on the most recent AHA/ACC/HRS guidelines for the treatment of AF, the selection of a drug to control ventricular rate in the acute setting should be primarily based on the patient's LV function.[22] In patients with normal LV function (LVEF greater than 40%), an IV β-blocker (propranolol, metoprolol, esmolol) or non-DHP CCB (diltiazem or verapamil) is recommended as first-line therapy to control ventricular rate.[22] All of these drugs have proven efficacy in controlling the ventricular rate in patients with AF. Propranolol and metoprolol can be administered as intermittent IV boluses, whereas esmolol (because of its very short half-life of 5 to 10 minutes) must be administered as a series of loading doses followed by a continuous infusion. Likewise, because control of ventricular rate can be transient with a single bolus, verapamil or diltiazem can be given as an initial IV bolus followed by a continuous infusion.[27] These continuous infusions can be adjusted in monitored settings to the desired ventricular response (eg, acutely less than 100 beats/min). In situations where AF or AFl is precipitated by states of increased sympathetic tone (ie, surgery, thyrotoxicosis), IV β-blockers can be highly effective and should be considered as first-line therapy.

In patients with HF*r*EF (LVEF less than or equal to 40%), both IV diltiazem and verapamil should be avoided because of their potent negative inotropic effects.[22] IV β-blockers should be used with caution in this patient population and should be avoided if patients are in the midst of an episode of decompensated HF. In those patients who are having an exacerbation of HF symptoms, IV administration of either digoxin or amiodarone should be used as first-line therapy to achieve ventricular rate control. IV amiodarone can also be used in patients who are refractory to or have contraindications to β-blockers, non-DHP CCBs, and digoxin. However, clinicians should be aware that the use of amiodarone for controlling ventricular rate may also stimulate the conversion of AF to SR

and place the patient at risk for a TE event, especially if the AF has persisted for at least 48 hours or is of unknown duration. In patients with stable HF*p*EF, either IV diltiazem or verapamil is recommended to acutely control ventricular rate; however, these agents should be avoided in these patients if they are experiencing decompensated HF.

Patients may present with a slow ventricular response (in the absence of AV nodal blocking drugs) and thus do not require therapy with *β*-blockers, non-DHP CCBs, or digoxin. This type of presentation should alert the clinician to the possibility of preexisting SA or AV nodal conduction disease such as sick sinus syndrome. In these patients, DCC should not be attempted without a temporary pacemaker in place.

Restoration of Sinus Rhythm

After treatment with AV nodal blocking drugs and a subsequent decrease in the ventricular rate, the patient should be evaluated for the possibility of restoring SR if AF persists. Within the context of this evaluation, several factors should be considered. First, many patients spontaneously convert to SR without intervention, obviating the need for therapy to achieve this goal. For instance, AF occurs frequently as a complication of cardiac surgery and often spontaneously reverts to SR without therapy. Second, restoring SR is not a necessary or realistic goal in some patients. The results of six landmark clinical trials (Pharmacological Intervention in Atrial Fibrillation [PIAF], Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation [RACE], Atrial Fibrillation Follow-Up Investigation of Rhythm Management [AFFIRM], Strategies of Treatment of Atrial Fibrillation [STAF], How to Treat Chronic Atrial Fibrillation [HOT-CAFE], and Atrial Fibrillation and Congestive Heart Failure [AF-CHF]) have shed significant light on the comparative efficacy of rate-control (controlling ventricular rate; patient remains in AF) and rhythm-control (restoring and maintaining SR) treatment strategies in patients with AF.[28,29,30,31,32,33] The AFFIRM trial is the largest rate-control versus rhythm-control study to be conducted to date in patients with AF.[30] In this trial, patients with AF and at least one risk factor for stroke were randomized to either a rate-control or a rhythm-control group. Rate-control treatment involved AV nodal blocking drugs (digoxin, *β*-blockers, and/or non-DHP CCBs) first, and then nonpharmacologic treatment (AV nodal ablation with pacemaker implantation), if necessary. All patients in this group were anticoagulated with warfarin to achieve an INR of 2 to 3. In the rhythm-control group, class I or III AADs were used to maintain SR. The choice of AAD therapy was left up to each patient's physician; however, by the end of the trial, more than 60% of patients had received at least one trial of amiodarone and approximately 40% of patients had received at least one trial of sotalol. In this group, anticoagulation was encouraged but could be discontinued if SR had been maintained for at least 4 weeks. After a mean follow-up period of 3.5 years, overall mortality was not statistically different between the two strategies but tended ($P = 0.08$) to be higher in the rhythm-control group. The results of the PIAF, RACE, STAF, and HOT-CAFE trials were consistent with those of the AFFIRM trial.[28,29,31,32] In addition, a meta-analysis of the data from all of these trials demonstrated no significant difference in overall mortality between rate-control and rhythm-control strategies, which persisted even when the results from the AFFIRM trial were excluded from this analysis.[34]

Even though the results of the PIAF, RACE, STAF, HOT-CAFE, and AFFIRM trials collectively demonstrate that a rate-control strategy is a viable alternative to a rhythm-control strategy in patients with persistent AF, a significant limitation of these results is that they cannot be applied to patients with HF

because only a small proportion of patients enrolled in these trials had LV systolic dysfunction. The AF-CHF trial was conducted to specifically evaluate the safety and efficacy of rate-control and rhythm-control strategies in patients with HF*r*EF.[33] In this trial, patients with an LVEF less than or equal to 35%, a history of HF (defined as NYHA class II to IV HF within the last 6 months, NYHA class I HF with a hospitalization for HF during the previous 6 months, or an LVEF less than or equal to 25%), and a history of AF were randomized to either a rate-control or a rhythm-control group. Rate-control treatment involved concomitant therapy with a β-blocker and digoxin first, and then nonpharmacologic treatment (AV nodal ablation with pacemaker implantation), if necessary. In the rhythm-control group, amiodarone was the preferred AAD, whereas sotalol and dofetilide were considered alternatives (most of the patients ultimately received amiodarone). If patients in this group did not convert to SR within 6 weeks, electrical cardioversion was performed. Anticoagulation was recommended for all patients in both treatment groups. After a mean follow-up period of 37 months, no significant difference was observed between the treatment groups with regard to the primary end point of death from CV causes. Patients in the rhythm-control group tended to have more hospitalizations, primarily due to repeated cardioversions and adjustment of AAD therapy, compared with patients in the rate-control group; however, this difference was not statistically significant (P = 0.06). It is important to note that the results of this trial should not be applied to patients with HF*p*EF. Nevertheless, the results of this trial are generally consistent with those of the PIAF, RACE, AFFIRM, STAF, and HOT-CAFE trials and suggest that a rhythm-control strategy does not confer any advantage over a rate-control strategy in patients with AF and HF*r*EF.

Clearly, these important findings temper the old approach of aggressively attempting to maintain SR. Because a rhythm-control strategy does not offer any significant advantage over a rate-control strategy in the management of patients with persistent or recurrent AF (including those with concomitant HF*r*EF), it is acceptable to allow patients to remain in AF, while being chronically treated not only with AV nodal blocking drugs to achieve adequate ventricular rate control but also with appropriate antithrombotic therapy to prevent TE complications. 4 The important question with this rate-control approach is: What defines “adequate” ventricular rate control? While adequate ventricular rate control was previously considered to be achieving a heart rate less than 80 beats/min at rest and less than 100 beats/min during exercise, evidence from the RACE II trial has suggested that selecting a more lenient rate-control strategy (resting heart rate less than 110 beats/min) may be a reasonable approach for certain patients with AF.[35] In this trial, a lenient rate-control strategy (resting heart rate less than 110 beats/min) was considered to be noninferior to a strict heart rate-control strategy (resting heart rate less than 80 beats/min and heart rate during moderate exercise less than 110 beats/min) with regard to the primary end point of CV death, hospitalization for HF, stroke, systemic embolism, bleeding, and life-threatening arrhythmic events. According to the most recent AHA/ACC/HRS guidelines for AF, this lenient rate-control strategy is recommended for those patients with persistent AF provided that patients are asymptomatic and have preserved LV systolic function (LVEF >40%).[22] In patients who are symptomatic or have LV systolic dysfunction (LVEF less than or equal to 40%), a stricter rate-control approach (resting heart rate less than 80 beats/min) should be considered..

As in the acute setting, the selection of an AV nodal blocking drug to control ventricular rate in the chronic setting should be primarily based on the patient’s LV function.[22] In patients with normal LV function (LVEF >40%) or in patients with stable HF*p*EF, an oral β-blocker or non-DHP CCB (diltiazem or verapamil) is preferred over digoxin because of their relatively quick onset and maintained efficacy

during exercise. When adequate ventricular rate control cannot be achieved with one of these drugs, the addition of digoxin may result in an additive lowering of the heart rate. Verapamil and diltiazem should not be used in patients with HF*r*EF (LVEF ≤40%). Instead, *β*-blockers (ie, metoprolol succinate, carvedilol, or bisoprolol) and digoxin are preferred in these patients, as these drugs are also concomitantly used to treat chronic HF*r*EF. Specifically, in patients with NYHA class II or III HF, *β*-blockers should be considered over digoxin because of their survival benefits in patients with HF*r*EF. If patients are having an episode of decompensated HF (NYHA class IV), digoxin is preferred as first-line therapy to achieve ventricular rate control because of the potential for worsening HF symptoms with the initiation and subsequent titration of *β*-blocker therapy. If adequate ventricular rate control during rest and exercise cannot be achieved with *β*-blockers, non-DHP CCBs, and/or digoxin in patients with normal or depressed LV function, oral amiodarone can be used as alternative therapy to control the heart rate.

Because a rate-control strategy is now considered a reasonable initial approach for the chronic management of AF, the question that remains to be answered is, "In which patients should restoration of SR be considered?" Electrical or pharmacologic cardioversion should be considered for those patients with AF who remain symptomatic despite having adequate ventricular rate control or for those patients in whom adequate ventricular rate control cannot be achieved.[22] A rhythm-control strategy may also be considered in patients who are experiencing their first episode of AF if they are likely to convert to and remain in SR. Other factors that may lend themselves the use of a rhythm-control strategy include younger age, presence of tachycardia-induced cardiomyopathy, AF precipitated by acute illness, and patient preference.

In those patients in whom it is decided to restore SR, one must consider that this very act (regardless of whether an electrical or pharmacologic method is chosen) places the patient at risk for a TE event. The reason for this heightened risk is that the return of SR restores effective contraction in the atria, which may dislodge poorly adherent thrombi. Administering antithrombotic therapy prior to cardioversion not only prevents clot growth and the formation of new thrombi but also allows existing thrombi to become organized and well adherent to the atrial wall. It is a generally accepted principle that the risk of thrombus formation and a subsequent embolic event increases if the duration of the AF exceeds 48 hours. Therefore, it is vital for clinicians to estimate the duration of the patient's AF so that appropriate antithrombotic therapy can be administered prior to cardioversion if needed.

According to the most recent AHA/ACC/HRS guidelines for the treatment of AF, in patients undergoing elective cardioversion (electrical or pharmacologic) for AF lasting at least 48 hours or for an unknown duration, therapeutic anticoagulation with warfarin (INR target range 2 to 3), apixaban, dabigatran, or rivaroxaban should be given for at least 3 weeks before cardioversion is performed.[22] If 3 weeks of therapeutic oral anticoagulant therapy is not feasible in these patients, there is an alternative regimen whereby the patient can undergo a transesophageal echocardiogram (TEE) prior to cardioversion. If no thrombus is observed on TEE, the patient can undergo cardioversion. In these patients, anticoagulant therapy with either IV unfractionated heparin (UFH) (target activated partial thromboplastin time 60 seconds; acceptable range 50 to 70 seconds) or a low-molecular-weight heparin (LMWH) (subcutaneously at treatment doses) should be initiated at the time the TEE will be performed.[36] Cardioversion should then be performed within 24 hours of the TEE. Alternatively, warfarin therapy (INR target range 2 to 3) may be used for at least 5 days prior to the TEE and cardioversion. If cardioversion

is successful, therapeutic anticoagulation with warfarin (INR target range 2 to 3), apixaban, dabigatran, or rivaroxaban should be continued for at least 4 weeks, regardless of the patient's baseline risk of stroke.[22] The reason for continuing anticoagulation for this additional 4-week time period is that after restoration of SR, full atrial contraction does not occur immediately. Rather, it returns gradually to a maximum contractile force over a 3- to 4-week period. Decisions regarding long-term antithrombotic therapy after this 4-week time period should be primarily based on the patient's risk for stroke and not on whether he/she is in SR.[22] If a thrombus is seen on TEE, cardioversion should not be performed and the patient should be anticoagulated indefinitely. If cardioversion is considered in these patients at a later time, a TEE should again be performed. Overall, the use of a TEE-guided approach to cardioversion in patients with AF has been compared with the conventional 3 weeks of anticoagulation before cardioversion in a large, multicenter, randomized trial.[37] In this trial, the incidence of TE events was not different between the two strategies, but bleeding episodes were higher in the group that received 3 weeks of warfarin therapy before cardioversion. Patients in the TEE strategy group had a higher success rate of achieving SR, probably because it is more difficult to terminate AF the longer a patient remains in this arrhythmia.

In patients with AF that is less than 48 hours in duration, anticoagulation prior to cardioversion is unnecessary because there has not been sufficient time to form atrial thrombi.[22] In those patients who are at high risk for stroke, IV UFH (target activated partial thromboplastin time 60 seconds; acceptable range 50 to 70 seconds), a LMWH (subcutaneously at treatment doses), apixaban, dabigatran, or rivaroxaban should be initiated as soon as possible either before or after cardioversion. If cardioversion is successful in these high-risk patients, therapeutic anticoagulation with warfarin (INR target range 2 to 3), apixaban, dabigatran, or rivaroxaban should be continued for at least 4 weeks. While the above anticoagulants can also be initiated immediately before or after cardioversion in patients at low risk for stroke, it is also reasonable to not initiate antithrombotic therapy in these patients. Decisions regarding long-term antithrombotic therapy in this low-risk population should be primarily based on the patient's risk for stroke and not on whether he/she is in SR.

After prior anticoagulation or TEE, the process of restoring SR can be considered. There are two methods of restoring SR in patients with AF or AFl: pharmacologic cardioversion and DCC. The decision to use either of these methods is generally a matter of clinical preference. The disadvantages of pharmacologic cardioversion are the risk of significant side effects (eg, drug-induced TdP), the potential for drug-drug interactions (eg, digoxin-amiodarone), and the lower efficacy of AADs when compared with DCC. The advantages of DCC are that it is quick and more often successful (80% to 90% success rate) compared to pharmacologic cardioversion. The disadvantages of DCC are the need for prior sedation/anesthesia and a risk (albeit small) of serious complications such as sinus arrest or ventricular arrhythmias.

Nonetheless, despite the relatively high success rate associated with DCC, clinicians often elect to use AADs first, and then resort to DCC in the event that these drugs fail. Pharmacologic cardioversion appears to be most effective when initiated within 7 days after the onset of AF.[22] According to the most recent treatment guidelines for AF, there is relatively strong evidence for efficacy of the class III pure I_K blockers (ibutilide and dofetilide), the class Ic AADs (flecainide and propafenone), and amiodarone (oral or IV) for cardioversion of AF.[22] Class Ia AADs have limited efficacy or have not been adequately studied in this setting. Sotalol is not effective for cardioversion of paroxysmal or persistent AF. Single,

oral loading doses of propafenone (600 mg) and flecainide (300 mg) are effective compared with placebo for conversion of recent-onset AF and have been incorporated into the "pill-in-the-pocket" approach endorsed by the treatment guidelines.[22,38] With this method, outpatient, patient-controlled self-administration of a single, oral loading dose of either flecainide or propafenone can be a relatively safe and effective approach for the termination of recent-onset AF in a selected patient population that does not have sinus or AV node dysfunction, bundle-branch block, QT interval prolongation, Brugada syndrome, or SHD.[38] This treatment regimen should only be considered in patients who have previously been successfully cardioverted with these drugs on an inpatient basis.

Overall, when considering pharmacologic cardioversion, the selection of an AAD should be based on whether the patient has SHD (eg, LV dysfunction, CAD, valvular heart disease, LV hypertrophy).[22] In the absence of any type of SHD, the use of a single, oral loading dose of flecainide or propafenone is a reasonable approach for cardioversion. Ibutilide can also be used as an alternative in this patient population; however, use of this agent is restricted to a monitored setting in the hospital because it requires QT interval monitoring. In patients with underlying SHD, flecainide, propafenone, and ibutilide should be avoided because of the increased risk of proarrhythmia; amiodarone or dofetilide should be used instead. Although amiodarone can be administered safely on an outpatient basis because of its low proarrhythmic potential, dofetilide therapy can only be initiated in the hospital (for QT interval monitoring and assessment of renal function). Additionally, it should be remembered that a patient's ventricular rate should be adequately controlled with AV nodal blocking drugs prior to administering a class Ic AAD for cardioversion. The class Ic AADs may paradoxically increase ventricular response. The most likely mechanism for this effect is that by slowing atrial conduction, the class Ic AADs decrease the number of impulses reaching the AV node. Consequently, the AV node paradoxically allows more impulses to gain entrance to the ventricular conduction system, thereby increasing ventricular rate.

Long-Term Complications

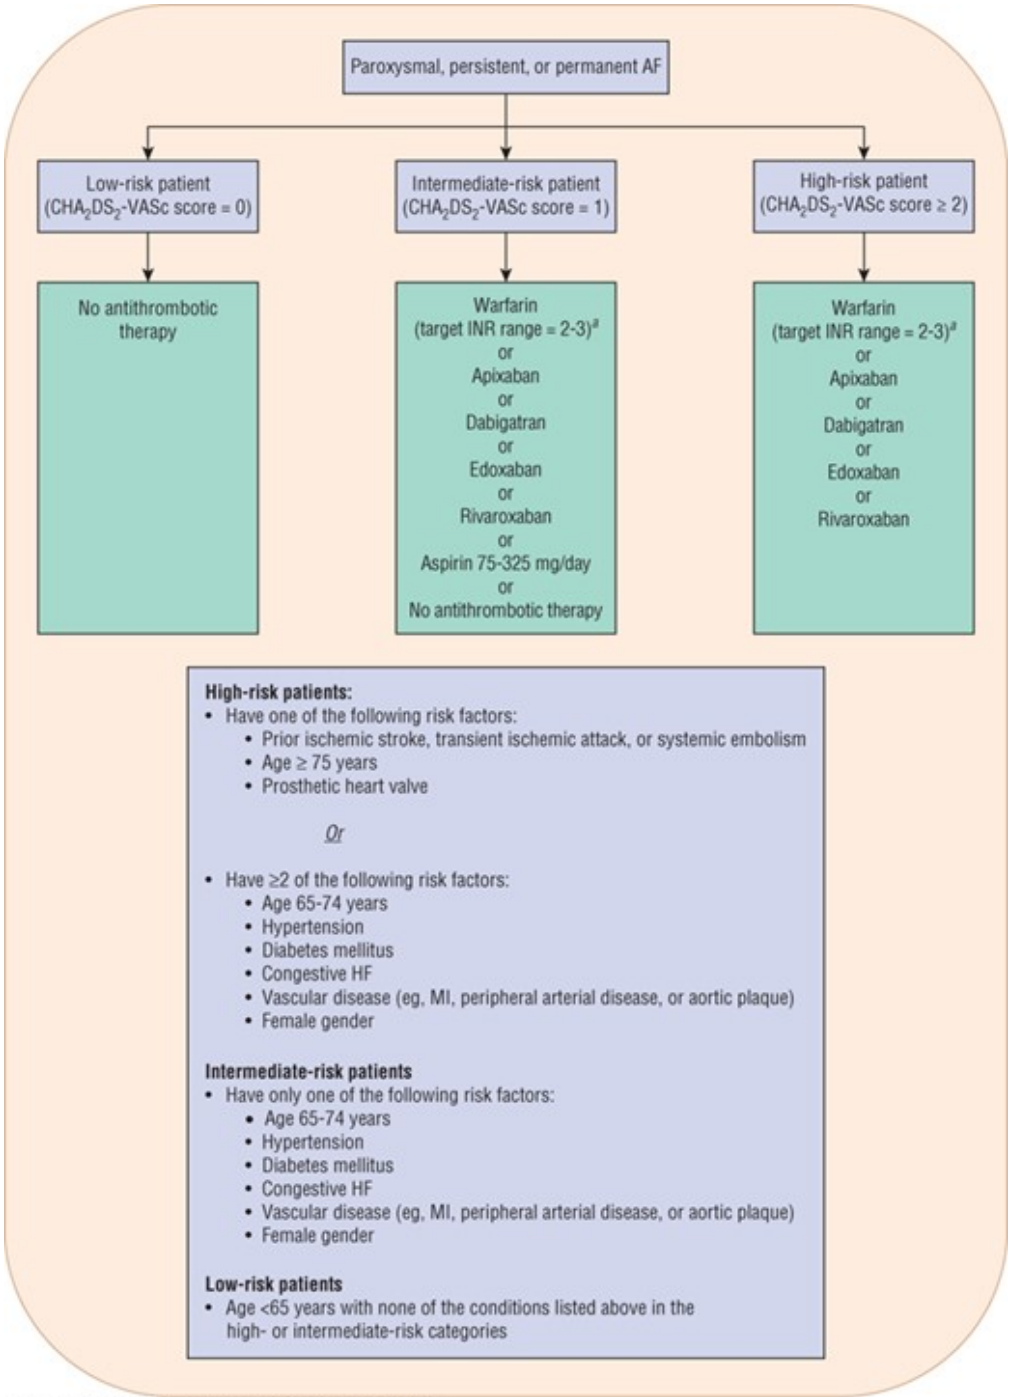
There are two forms of therapy that the clinician must consider in each patient with AF: long-term antithrombotic therapy to prevent stroke and long-term AADs to prevent recurrences of AF. Consider the issue of antithrombotic therapy first. Historically, warfarin has been the standard of care for stroke prevention in patients considered to be moderate or high risk for stroke. However, while warfarin is undoubtedly effective in preventing strokes in patients with AF, its use can be associated with a number of potential limitations, including a narrow therapeutic window, requirement for INR monitoring, food and drug interactions, and pharmacogenetic influences. Therefore, researchers have long been searching for an antithrombotic therapy that could be used as an alternative or even as a replacement for warfarin in patients with AF. Over the past few years, several oral antithrombotic therapies have been approved by the Food and Drug Administration for stroke prevention in patients with AF. These oral anticoagulant drugs, commonly referred to as target specific oral anticoagulants (TSOACs), include the direct thrombin inhibitor, dabigatran, and the factor Xa inhibitors, apixaban, edoxaban, and rivaroxaban.

When initiating chronic antithrombotic therapy in patients with AF, assessing the patient's risk for stroke becomes important for selecting the most appropriate regimen. Based on the most recent AHA/ACC/HRS guidelines for the treatment of AF, the CHA_2DS_2-VASc risk scoring system has been recommended for stroke risk stratification in patients with AF.[22] With this risk index, patients with AF

are given 2 points each if they have a history of a previous stroke, transient ischemic attack, or thromboembolism, or if they are at least 75 years old. Patients are given one point each for being 65 to 74 years old, having hypertension, having diabetes, having congestive HF, having vascular disease (eg, MI, peripheral arterial disease, or aortic plaque), or being female. CHA_2DS_2-VASc is an acronym for each of these risk factors. The points are added up, and the total score is then used to determine the most appropriate antithrombotic therapy for the patient (**Fig. 18-6**). Patients with a CHA_2DS_2-VASc score of 2 or higher are considered to be at high risk for stroke. In these patients, oral anticoagulant therapy with warfarin (INR target range 2 to 3), apixaban, dabigatran, edoxaban, or rivaroxaban is preferred over aspirin. Patients with a CHA_2DS_2-VASc score of 1 are considered to be at intermediate risk for stroke. In these patients, oral anticoagulant therapy (warfarin [INR target range 2 to 3], apixaban, dabigatran, edoxaban, or rivaroxaban), aspirin 75 to 325 mg/day, or no antithrombotic therapy can be selected. Patients with a CHA_2DS_2-VASc score of 0 are considered to be at low risk for stroke. The guidelines state that it is reasonable to not give any antithrombotic therapy to this particular patient population.

FIGURE 18-6

Algorithm for the prevention of thromboembolism in paroxysmal, persistent, or permanent AF. [a]The target INR for patients with prosthetic heart valves should be based on the type of valve that is present. (AF, atrial fibrillation; HF, heart failure; INR, international normalized ratio; MI, myocardial infarction.)



The efficacy and safety of dabigatran were compared with those of warfarin in patients with AF in the Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY) trial.[39] In this study, patients were randomized to receive dabigatran 110 mg twice daily, dabigatran 150 mg twice daily or adjusted-dose warfarin. The median follow-up period was 2 years. For the primary end point of stroke or systemic embolism, both dabigatran groups were shown to be noninferior to warfarin. However, superiority was also assessed and the dabigatran 150-mg group was shown to be superior to warfarin in reducing this end point. The rate of major bleeding was similar between the dabigatran 150-mg and warfarin groups, while the rate of major bleeding was significantly lower in the dabigatran 110-mg group than in the warfarin group. The rate of intracranial hemorrhage was significantly lower in both

dabigatran groups than in the warfarin group. Even though the 110- and 150-mg dosing regimens of dabigatran were evaluated in this trial, only the 150-mg dose was approved by the Food and Drug Administration for AF. A lower 75-mg dose was also approved for patients with a CrCl of 15 to 30 mL/min, even though this dose has not been evaluated in a randomized, prospective clinical trial in patients with AF; this dose has only pharmacokinetic data to support its use.[40] It is important to note that the RE-LY trial excluded patients with a CrCl less than 30 mL/min. Dabigatran is contraindicated in patients with mechanical heart valves because its use in this population has been associated with an increased risk of TE complications and bleeding.[41] The use of dabigatran is also not recommended in patients with bioprosthetic heart valves since the safety and efficacy of this antithrombotic have not been evaluated in this population. Patients with hemodynamically significant valvular disease or advanced liver disease are also not appropriate candidates for dabigatran therapy.

The efficacy and safety of rivaroxaban were compared with those of warfarin in patients with AF in the Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation.[42] In this study, patients were randomized to receive rivaroxaban 20 mg daily or adjusted-dose warfarin. The median follow-up period was 1.9 years. For the primary end point of stroke or systemic embolism, rivaroxaban was shown to be noninferior to warfarin. The rate of major and nonmajor clinically relevant bleeding was similar between the rivaroxaban and warfarin groups. Significantly fewer intracranial hemorrhages occurred in the rivaroxaban group compared with the warfarin group. The use of rivaroxaban is not recommended in patients with prosthetic heart valves since its safety and efficacy have not been evaluated in this population.

The efficacy and safety of apixaban were compared with those of aspirin in patients with AF in the Apixaban versus Acetylsalicylic Acid to Prevent Stroke in Atrial Fibrillation Patients Who Have Failed or Are Unsuitable for Vitamin K Antagonist Treatment trial.[43] This particular trial enrolled patients who failed or were considered unsuitable candidates for vitamin K antagonist therapy. This study was stopped prematurely when a significant benefit with regard to the primary efficacy outcome of stroke and systemic embolism was observed in the apixaban group. The efficacy and safety of apixaban were compared with those of warfarin in patients with AF in the Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation trial.[44] Overall, apixaban was shown to be noninferior and superior to warfarin with regard to the primary end point of stroke or systemic embolism. The rate of major bleeding in this trial was significantly lower in the apixaban group than in the warfarin group. Additionally, significantly fewer intracranial hemorrhages occurred in the apixaban group compared with the warfarin group. The use of apixaban is not recommended in patients with prosthetic heart valves since the safety and efficacy of this anticoagulant have not been evaluated in this population.

The efficacy and safety of edoxaban were compared with those of warfarin in patients with AF in the Effective Anticoagulation with Factor Xa Next Generation in Atrial Fibrillation-Thrombolysis in Myocardial Infarction 48 trial.[45] In this study, patients were randomized to receive edoxaban 60 mg daily, edoxaban 30 mg daily or adjusted-dose warfarin. Overall, both doses of edoxaban were shown to be noninferior to warfarin with regard to the primary end point of stroke or systemic embolism. However, the edoxaban 60-mg dosing regimen was also shown to be superior to warfarin with regard to this primary end point. The rate of major bleeding and the risk of intracranial bleeding were significantly lower in both edoxaban groups than in the warfarin group. However, the risk of major

gastrointestinal bleeding was significantly higher in the edoxaban 60-mg group but significantly lower in the edoxaban 30-mg group when compared to the warfarin group. The use of edoxaban is not recommended in patients with mechanical heart valves or moderate-to-severe mitral stenosis since the safety and efficacy of this anticoagulant have not been evaluated in this population.

The most recent AHA/ACC/HRS guidelines for the treatment of AF provide recommendations regarding the use of various anticoagulant agents for stroke prevention in patients with nonvalvular AF.[22] These recommendations state that warfarin, dabigatran, rivaroxaban and apixaban are all indicated for the prevention of initial and recurrent strokes in patients with nonvalvular AF. These guidelines were published prior to the Food and Drug Administration's approval of edoxaban, and consequently do not provide recommendations regarding the role of this oral anticoagulant for stroke prevention in patients with AF. Anticoagulant therapy should be individualized for each patient, with consideration given to stroke risk factors, drug cost, tolerability, patient preference and drug interaction potential. Additionally, if a patient has previously taken warfarin, the time that his/her INR has been within the therapeutic range should also be considered before making the decision to switch the patient to a TSOAC. If a patient is unable to maintain a therapeutic INR while on warfarin, therapy with a TSOAC is recommended. Strict compliance with the TSOACs is important because missing a single dose could result in an increased risk of TE events.[46] If treatment with warfarin or a TSOAC must be temporarily interrupted for the patient to undergo a medical procedure, coverage with a parenteral anticoagulant (eg, UFH, LMWH) should be considered. In these patients, the risks of stroke and bleeding must be evaluated to determine if bridging therapy is warranted. In patients with mechanical heart valves, warfarin is the anticoagulant of choice and the INR should be based on the type and location of the valve placed. Dabigatran, edoxaban, and rivaroxaban should be avoided in patients with a CrCl less than 15 mL/min. In this particular population, warfarin is the anticoagulant of choice. Edoxaban should also be avoided in patients with a CrCl greater than 95 mL/min because of the potential for reduced efficacy.

Although it was previously an acceptable practice to continue antithrombotic therapy for only 4 weeks after successful cardioversion (with the belief that a patient's risk for thromboembolism had abated since he/she was in SR), data from the RACE and AFFIRM trials, in particular, strongly suggest that patients with AF and other risk factors for stroke continue to be at risk for stroke even when maintained in SR.[29,30] It is possible that these patients may be having undetected episodes of paroxysmal AF, placing them at risk for stroke. Consequently, the most recent AHA/ACC/HRS guidelines recommend that decisions regarding chronic antithrombotic therapy should be based on a patient's risk for stroke using the CHA_2DS_2-VASc scoring system.[22]

The second form of chronic therapy to be considered is AADs to prevent recurrences of AF. Historically, many clinicians have aggressively attempted to maintain SR by prescribing oral AADs (usually quinidine) to prevent AF recurrences despite the fact that only small studies with conflicting results existed evaluating this approach. To evaluate the efficacy of quinidine in preventing AF, a well-known meta-analysis of the existing literature was completed.[47] This meta-analysis demonstrated that indeed more patients remain in SR with quinidine therapy (compared with placebo); however, approximately 50% of patients have recurrences of AF within a year despite the use of quinidine. This reported effectiveness was at the cost of an associated increase in mortality (presumably due, in part, to proarrhythmia) in the quinidine-treated patients. These disturbing results (published soon after the

CAST[48]) became widely quoted and highly visible, making clinicians question the wisdom of long-term prevention of recurrences of AF with AADs. These results coupled with the findings of the PIAF, RACE, AFFIRM, STAF, HOT-CAFE, and AF-CHF trials question the need to use AADs to prevent AF recurrences.[28,29,30,31,32,33] In fact, based on the results of these landmark trials, the use of AADs to maintain SR may be more reasonable to consider in patients who remain symptomatic despite having adequate ventricular rate control or for those patients in whom adequate ventricular rate control cannot be achieved.

According to the most recent AHA/ACC/HRS treatment guidelines for AF, the class Ic or III AADs are reasonable to consider to maintain patients in SR (**Table 18-9**).[22] The role of the class Ia AADs for maintenance of SR has been deemphasized throughout these guidelines as they are considered less effective or incompletely studied compared with the class Ic and III AADs. Interestingly, a systematic review of AADs for the maintenance of SR after cardioversion in patients with AF demonstrated that AF recurrences were significantly reduced with the use of class Ia, Ic, and III AADs; however, mortality was significantly increased with the class Ia drugs, in particular.[49]

TABLE 18-9 Guidelines for Selecting Antiarrhythmic Drug Therapy for Maintenance of Sinus Rhythm in Patients with Recurrent Paroxysmal or Recurrent Persistent Atrial Fibrillation

No structural heart disease[a] (absence of heart failure, coronary artery disease, signifi cant LVH, and valvular disease)

First line:[b] dofetilide, dronedarone, flecainide, propafenone, or sotalol

Second line:[c] amiodarone

Heart failure[a]

First line:[b] amiodarone or dofetilide

Second line: catheter ablation

Coronary artery disease[a]

First line:[b] dofetilide, dronedarone,[d] or sotalol[d]

Second line:[c] amiodarone

Hypertension[a]

Presence of signifi cant LVH:

First line:[b] amiodarone or dronedarone

Second line: catheter ablation

Absence of signifi cant LVH:

First line:[b] dofetilide, dronedarone, flecainide, propafenone, or sotalol

Second line:[c] amiodarone

LVH, left ventricular hypertrophy.

[a]Drugs are listed alphabetically and not in order of suggested use.

[b]Catheter ablation may also be considered first-line therapy in select patients with paroxysmal atrial fibrillation.

[c]Catheter ablation may also be considered when patients are refractory or intolerant to at least 1 antiarrhythmic drug.

[d]Should only be used in this situation if the patient has normal left ventricular systolic function.

The class Ic AADs, flecainide and propafenone, are effective for maintaining SR. However, because of the increased risk for proarrhythmia, these drugs should be avoided in patients with SHD.

Although all of the oral class III AADs have demonstrated efficacy in preventing AF recurrences, amiodarone is clearly the most effective agent and is now the most frequently used AAD despite its potential for causing significant organ toxicity.[8] The superiority of amiodarone over other AADs for maintaining patients in SR has been demonstrated in a number of clinical trials. In the Canadian Trial of Atrial Fibrillation, amiodarone was significantly more effective than sotalol or propafenone in maintaining SR in patients with persistent or paroxysmal AF.[50] Furthermore, in a substudy of the AFFIRM trial, amiodarone appeared to be the most effective AAD in maintaining SR of those used in the study.[51] In the Sotalol Amiodarone Atrial Fibrillation Efficacy Trial, amiodarone and sotalol were equally effective at converting AF to SR.[52] However, amiodarone was significantly more effective than sotalol at maintaining SR in all patient subgroups, except for those with CAD where the efficacy of these two drugs was comparable.

Although sotalol is not effective for conversion of AF, it is an effective drug for maintaining SR. Sotalol appears to be at least as effective as quinidine or propafenone in preventing recurrences of AF.[50,53] However, treatment with either quinidine or sotalol is associated with a similar incidence of TdP. Because this form of proarrhythmia primarily occurs with higher doses of sotalol (quinidine usually causes TdP at low or therapeutic concentrations), it may be more easily predicted and therefore avoided. Nonetheless, sotalol may be similar to quinidine in increasing mortality in patients with AF; however, this finding requires further study.[54]

Dofetilide is effective in preventing recurrences of AF but has not been directly compared with either amiodarone or sotalol. In a large, multicenter trial, dofetilide was more effective than placebo in maintaining SR (approximately 35%-50% at 1 year).[55] The efficacy of dofetilide for the maintenance of SR has also specifically been demonstrated in patients with HF*r*EF.[56] Like sotalol and quinidine, dofetilide also has significant potential to cause TdP (in a dose-related fashion).

The safety and efficacy of dronedarone for the treatment of AF and AFl have been evaluated in several clinical trials. In the European Trial in Atrial Fibrillation or Flutter Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm and the American-Australian-African Trial with Dronedarone in Atrial

Fibrillation or Flutter Patients for the Maintenance of Sinus Rhythm, which were similar in design, dronedarone was more effective than placebo in maintaining SR in patients with paroxysmal or persistent AF or AFl.[57] In another trial, the use of dronedarone in patients with persistent or paroxysmal AF or AFl was associated with significantly fewer hospitalizations due to CV events or death when compared with placebo.[58] The safety and efficacy of dronedarone were also evaluated in a trial that included patients with NYHA class III or IV HF and an LVEF of 35% or less.[59] This trial was prematurely terminated because all-cause mortality (primarily due to worsening HF) was significantly higher in the dronedarone group when compared with the placebo group. Consequently, based on these findings, dronedarone is contraindicated in and has received a black box warning for patients with advanced HF (NYHA class IV or NYHA class II or III with a recent hospitalization for decompensated HF). The efficacy and safety of dronedarone in patients with AF have been compared with those of amiodarone.[60] In this trial, dronedarone was shown to be significantly less effective than amiodarone in reducing AF recurrences; however, tolerability was significantly better in the dronedarone group than in the amiodarone group as evidenced by higher rates of premature drug discontinuation and adverse events in the amiodarone group. Most recently, a trial that enrolled patients with permanent AF and risk factors for major vascular events was terminated prematurely after significantly more patients in the dronedarone group died (primarily from CV causes), were hospitalized for HF, and suffered a stroke when compared wi.th the placebo group.[61] Based on the results of this trial, dronedarone is contraindicated in and has received a black box warning for patients with permanent AF.

Overall, the selection of an AAD to maintain SR should be primarily based on whether the patient has SHD.[22] However, other factors, including renal and hepatic function, concomitant disease states and drugs, and the AAD's side effect profile, also need to be considered. Based on the most recent AHA/ACC/HRS treatment guidelines for AF, dofetilide, dronedarone, flecainide, propafenone, or sotalol should be considered initially for those patients with no underlying SHD because these drugs have the most optimal long-term safety profile in this setting.[22] However, amiodarone could be used as alternative therapy if the patient fails or does not tolerate one of these initial AADs. In the presence of SHD, flecainide and propafenone should be avoided because of the risk of proarrhythmia. For those patients with HF*r*EF (LVEF ≤40%), amiodarone or dofetilide should be considered the AADs of choice. At this time, only amiodarone and dofetilide have been shown to be mortality-neutral in patients with AF and HF*r*EF. Both dronedarone and sotalol should be avoided in patients with HF*r*EF because of the risk for increased mortality (dronedarone) or worsening HF (dronedarone and sotalol). In patients with CAD, dofetilide, dronedarone, or sotalol can be used initially. Again, dronedarone and sotalol should not be used if patients have concomitant HF*r*EF. Amiodarone could be used as an alternative therapy if the patient fails or does not tolerate one of these initial AADs. The presence of LV hypertrophy may predispose the myocardium to proarrhythmic events. Because of their low proarrhythmic potential, amiodarone or dronedarone should be considered first-line AAD therapy in these patients.

Nonpharmacologic forms of therapy, designed to maintain SR, are becoming increasingly popular treatment options for patients with AF or AFl. For patients who have "pure" (ie, not associated with concurrent AF) type I AFl, ablation of the reentrant substrate with radiofrequency current is highly effective (approximately 90%) and can be considered first-line treatment of AFl to prevent recurrences.[62,63] Catheter ablation for patients with AF is much more technically difficult for a variety of reasons, including the lack of a single, identifiable, and ablatable reentrant focus (as in AFl).

Nonetheless, progress has been made in this area. Patients with AF have been found to have arrhythmogenic foci that occur in atrial tissue near and within the pulmonary veins. During the ablation procedure, radiofrequency energy can be delivered to these areas in an attempt to abolish the foci. Historically, this procedure was often considered last-line therapy for patients who had failed all AADs, including amiodarone. However, in some of the recent trials, the use of catheter ablation in patients with AF has been associated with a significant reduction in recurrent episodes of AF and an improvement in quality of life when compared with AAD therapy.[64,65,66] There is also evidence to suggest that this procedure may be superior to AADs as first-line therapy of symptomatic AF.[67,68] According to the most recent AHA/ACC/HRS guidelines for AF, for those patients with symptomatic episodes of AF who fail or do not tolerate at least one class I or III AAD, catheter ablation is recommended for those with paroxysmal AF, reasonable for those with persistent AF, and may be considered for those with long-standing (more than 12 months) persistent AF.[22] For those patients with symptomatic episodes of AF who have not yet received treatment with a class I or III AAD, catheter ablation is reasonable for those with recurrent, paroxysmal AF and may be considered for persistent AF. This procedure is not without its risks, as major complications, such as pulmonary vein stenosis, TE events, cardiac tamponade, and new AFl, have been reported in 4.5% of patients.[69]

Paroxysmal Supraventricular Tachycardia Caused By Reentry

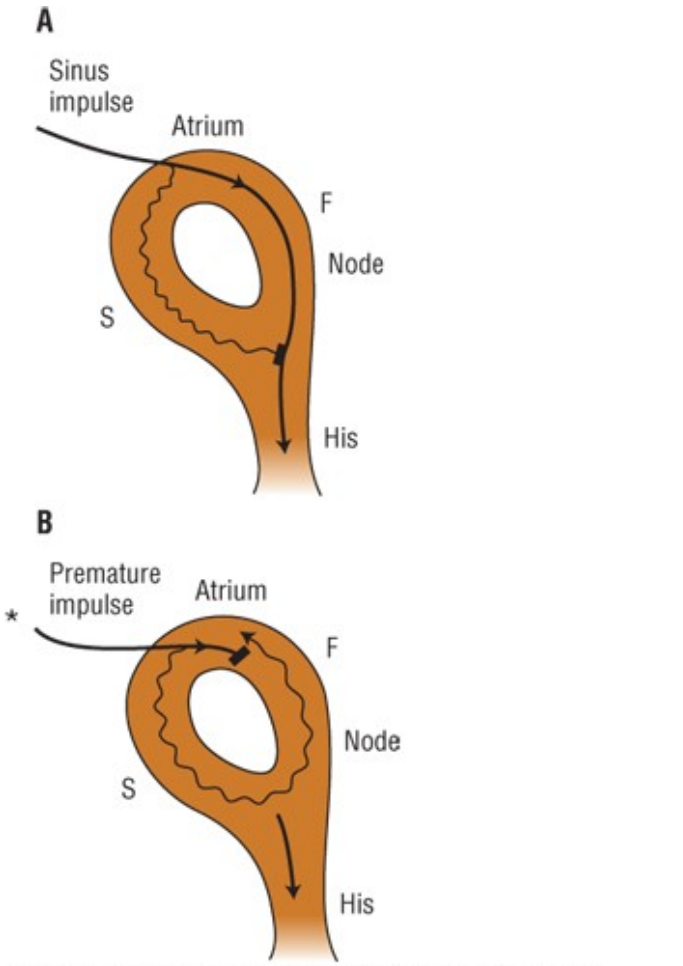
PSVT arising by reentrant mechanisms includes those arrhythmias caused by AV nodal reentry, AV reentry incorporating an anomalous AV pathway, SA nodal reentry, and intraatrial reentry. AV nodal reentry and AV reentry are by far the most common of these tachycardias.

Mechanisms

The underlying substrate of AV nodal reentry is the functional division of the AV node into two (or more) longitudinal conduction pathways or "dual" AV nodal pathways.[70] It is now clear that there are not two distinct anatomic pathways inside the AV node itself; rather, it is likely that a fan-like network of perinodal fibers inserts into the AV node and represents the second pathway. The pathways possess key differences in conduction characteristics: one is a fast-conducting pathway with a relatively long refractory period (fast pathway) and the other is a slower-conducting pathway with a shorter refractory period (slow pathway). The presence of dual pathways does not necessarily imply that the patient will have clinical PSVT. In fact, it is estimated that between 10% and 50% of patients have discernible dual pathways, but the incidence of PSVT is considerably lower.[70] Sustenance of the tachycardia depends on the critical electrophysiologic discrepancies and the ability of one pathway (usually the slow) to allow repetitive antegrade conduction, and the ability of the other pathway (usually the fast) to allow repetitive retrograde conduction. During SR, a patient with dual pathways conducts supraventricular impulses antegrade through both pathways. Electrical activity reaches the distal common pathway at the level of or above the His bundle and continues to depolarize the ventricles in an antegrade direction. Conduction proceeds via the two pathways but reaches the distal common pathway first through the fast AV nodal route (**Fig. 18-7**). For this reason, a short PR interval is sometimes observed during SR.

FIGURE 18-7

Reentry mechanism of dual AV nodal pathway PSVT. *A*. Sinus rhythm: the impulse travels from the atrium through the fast pathway (F) and then to the His-Purkinje system (His). The impulse also travels through the slow pathway (S) but is stopped when refractory tissue is encountered. *B*. Dual AV nodal reentry: a critically timed premature impulse (*) is stopped in the fast pathway (F) (because of prolonged refractoriness) but is able to travel antegrade down the slow pathway (S) and retrograde through the fast pathway. (AV, atrioventricular; PSVT, paroxysmal supraventricular tachycardia.)



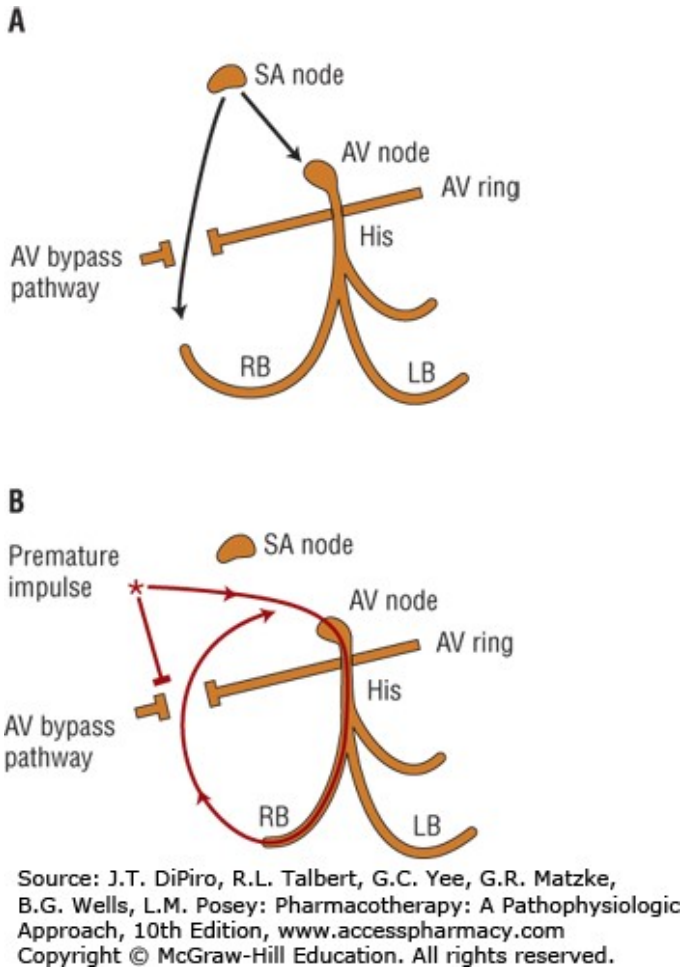
PSVT caused by AV nodal reentry may occur by the following sequence of events. The occurrence of an appropriately timed premature impulse penetrates the AV node but is blocked in the fast pathway that is still refractory from the previous beat. However, the slow pathway, which has a shorter refractory period, permits antegrade conduction of the premature impulse. By the time the impulse has reached the distal common pathway, the fast pathway has recovered its excitability and now will permit retrograde conduction. The impulse reaches the common proximal pathway, preceded by an excitable gap of tissue, and reenters the slow pathway. A reentrant circuit that does not require atrial or ventricular tissue is completed within the AV node, and a tachycardia is thereby initiated. The common form of this tachycardia uses the slow pathway for antegrade conduction and the fast pathway for retrograde conduction; an uncommon form exists in which the reentrant impulse travels in the opposite direction.

AV reentrant tachycardia depends on the presence of an anomalous, or accessory, extranodal pathway

that bypasses the normal AV conduction pathway. Several different types of accessory pathways have been described, depending on the specific anatomic areas they connect (eg, AV bundles or nodoventricular tracts); some are also referred to as eponyms, such as the Kent's bundle. A Kent's bundle is an extranodal AV connection that is associated with WPW syndrome. During SR (**Fig. 18-8**), patients with WPW syndrome depolarize the ventricles simultaneously through both AV pathways (AV nodal pathway and the Kent's bundle), creating a fusion pattern on the early portion of the QRS complex (delta wave). The degree of ventricular "preexcitation" depends on the contribution of antegrade ventricular activation through the accessory pathway. Patients may have an accessory pathway that is not evident on ECG, which is referred to as a "concealed" Kent's bundle. These concealed accessory pathways are often incapable of antegrade conduction and can only accept electrical stimulation in a retrograde fashion. The electrocardiographic expression of preexcitation (delta wave) depends on the location of the accessory pathway, the distance from the wave front of sinus activation, and the conduction characteristics of the various structures involved. It should be noted that (similar to patients with dual AV nodal pathways) not all patients with preexcitation with an accessory AV pathway are capable of having clinical PSVT.

FIGURE 18-8

Reentry mechanism for AV accessory pathway PSVT in Wolff-Parkinson-White syndrome. *A.* Sinus rhythm: the impulse travels from the atrium to the ventricle by two pathways—the AV node and an accessory bypass pathway. *B.* AV reentry: a critically timed premature impulse (*) is stopped in the Kent's bundle (because of prolonged refractoriness) but travels antegrade through the AV node and retrograde through the Kent's bundle. (AV, atrioventricular; His, His-Purkinje system; LB, left bundle branch; PSVT, paroxysmal supraventricular tachycardia; RB, right bundle branch; SA, sinoatrial.)



Patients with an accessory AV pathway may have three forms of supraventricular tachycardia: (a) orthodromic reentry; (b) antidromic reentry; and/or (c) AF or AFl. AV reentrant PSVT usually occurs by the following sequence of events. Analogous to AV nodal reentry, two pathways (the normal AV nodal pathway and the accessory AV pathway) exist that have different electrophysiologic characteristics. The AV nodal pathway usually has a relatively slower conduction velocity and shorter refractory period, and the accessory pathway has a faster conduction velocity and a longer refractory period. A critically timed premature impulse may be blocked in the accessory pathway because this area is still refractory from the previous sinus beat. However, the AV nodal pathway, with a relatively shorter refractory period, may accept antegrade conduction of the premature impulse. Meanwhile, the accessory pathway may recover its excitability and now allow retrograde conduction. A macroreentrant tachycardia is thereby initiated in which the antegrade pathway is the AV nodal pathway, the distal common pathway is the ventricle, the retrograde pathway is the accessory pathway, and the proximal common pathway is the atrium (see Fig. 18-8). This sequence of events (down the AV node, up the Kent's bundle), termed *orthodromic PSVT*, is the common variety of reentry in patients with an accessory AV pathway, resulting in a narrow QRS tachycardia. In the uncommon variety, conduction proceeds in the opposite direction (down the Kent's bundle, up the AV node), resulting in a wide QRS tachycardia, which is termed *antidromic PSVT*. Patients with WPW syndrome can have a third type of tachycardia, namely, AF. The occurrence of AF in the setting of an accessory AV pathway (ie, WPW syndrome) can be extremely serious. As AF is an extremely rapid atrial tachycardia, conduction can proceed down the accessory AV pathway, resulting in a very fast ventricular response or even VF. Unlike the AV nodal pathway, the refractory period of the accessory bundle shortens in response to rapid stimulation rates.

Sinus node reentry and intraatrial reentry occur less commonly and are not as well described as AV nodal reentry and AV reentry. Aside from a characteristic abrupt onset and termination, coupled with subtle changes in P-wave morphology, these tachycardias can be difficult to diagnose. Electrophysiologic studies may be necessary to determine the ultimate mechanism of the PSVT.

Management

Both pharmacologic and nonpharmacologic methods have been used to treat patients with PSVT. Drugs used in the treatment of PSVT can be divided into three broad categories: (a) those that directly or indirectly increase vagal tone to the AV node (eg, digoxin); (b) those that depress conduction through slow, calcium-dependent tissue (eg, adenosine, β-blockers, and non-DHP CCBs); and (c) those that depress conduction through fast, sodium-dependent tissue (eg, quinidine, procainamide, disopyramide, and flecainide). Drugs within these categories alter the electrophysiologic characteristics of the reentrant substrate so that PSVT cannot be sustained. In PSVT caused by AV nodal reentry, class I AADs, such as flecainide, act primarily on the retrograde fast pathway. Digoxin and β-blockers may work on either the retrograde fast or the antegrade slow pathway. Verapamil, diltiazem, and adenosine prolong conduction time and increase refractoriness, primarily in the slow antegrade pathway of the reentrant loop. In PSVT caused by AV reentry incorporating an extranodal pathway, class I AADs increase refractoriness in the fast accessory pathway or within the His-Purkinje system. β-Blockers, digoxin, adenosine, and verapamil all act by their effects on the AV nodal (antegrade, slow) portion of the reentrant circuit. Regardless of the mechanism, treatment measures are directed first at terminating an acute episode of PSVT and then at preventing symptomatic recurrences of the arrhythmia.

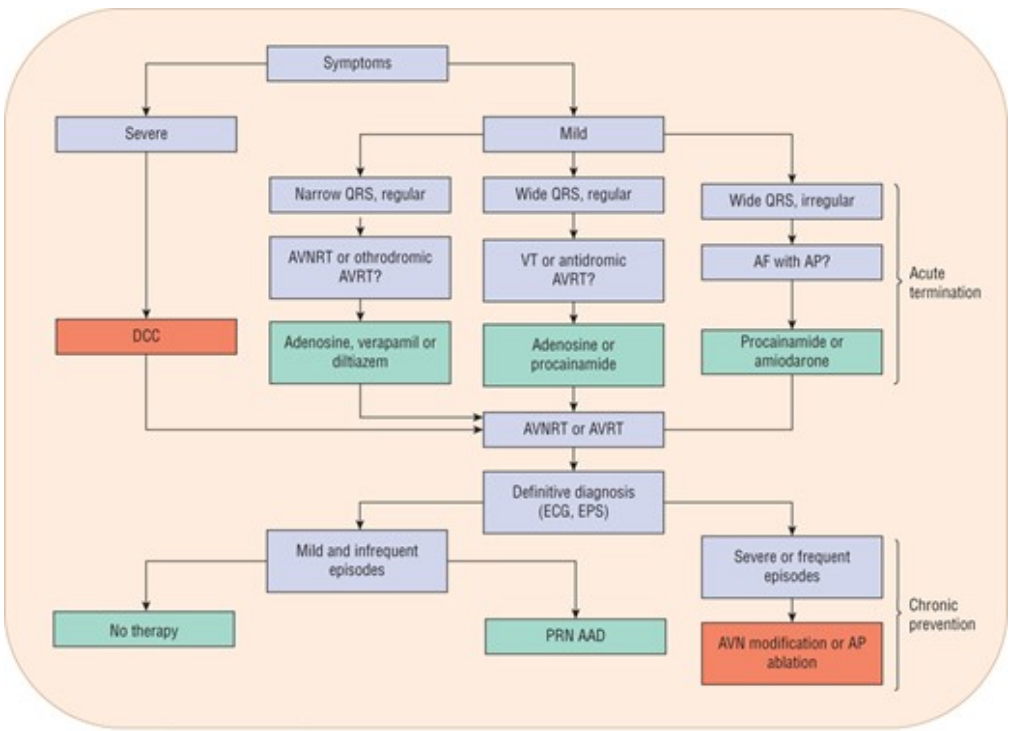
For those patients with PSVT who present with severe symptoms (ie, syncope, near syncope, angina, or severe HF), synchronized DCC is the treatment of choice. Even at low energy levels (such as 25 J), DCC is almost always effective in quickly restoring SR and correcting symptomatic hypotension. Patients with only mild-to-moderate symptoms usually do not require DCC, and nonpharmacologic measures that increase vagal tone to the AV node can be used initially. Vagal techniques, such as unilateral carotid sinus massage, Valsalva maneuver, ice water facial immersion, or induced retching, are often successful in terminating PSVT, although carotid massage and Valsalva maneuver are the simplest, least obtrusive, and most frequently used of these techniques.

In the event that vagal maneuvers fail (approximately 80% of acute episodes) in those patients with tolerable symptoms, drug therapy is the next option. **Figure 18-9** shows a therapeutic approach to the acute treatment of the different forms of reentrant PSVT. 6 This approach is based on analysis of the electrocardiographic characteristics of the rhythm because PSVT is not always discernible from other arrhythmias, and some forms of PSVT require different treatment. In patients with a narrow QRS, regular arrhythmia (AV nodal reentry or orthodromic AV reentry), IV verapamil (5-10 mg), IV diltiazem (15-25 mg), and adenosine (6-12 mg) are all equally efficacious. Approximately 80% to 90% of PSVT episodes will revert to SR within 5 minutes of these drug therapies.[71] The 2010 Guidelines for Cardiopulmonary Resuscitation (CPR) and Emergency Cardiovascular Care (ECC) from the AHA (no updated recommendations regarding treatment of PSVT in 2015 Guidelines Update for CPR and ECC), and the 2003 guidelines from the ACC/AHA/European Society of Cardiology,[63,72,73] promote adenosine as the drug of first choice in patients with PSVT. 5 These recommendations are particularly important when treating a patient who presents with a wide QRS, regular tachycardia that may be VT or PSVT

(antidromic AV reentry or as a result of aberrancy). Because of its ultrashort duration of action (seconds), adenosine will not cause the severe and prolonged hemodynamic compromise seen in patients with VT who were mistakenly treated with verapamil and suffered from its negative inotropic effects and vasodilator properties.[74] If, in fact, the arrhythmia is PSVT, adenosine will likely terminate it. An alternative treatment for this type of patient is IV procainamide, which works on the fast, sodium-dependent extranodal pathway and is also effective for VT. Likewise, IV procainamide, or perhaps IV amiodarone (particularly in patients with LV dysfunction) should be used for the patient who presents with a wide QRS, irregular arrhythmia that is hemodynamically stable.[72] This rhythm could represent AF with rapid ventricular activation occurring primarily through an extranodal pathway. Administration of IV verapamil, diltiazem, digoxin, or adenosine to these patients may result in a paradoxical increase in ventricular response, causing severe symptoms requiring cardioversion. Consequently, these drugs are considered contraindicated in this specific setting.

FIGURE 18-9

Algorithm for the treatment of acute (*top portion*) PSVT and chronic prevention of recurrences (*bottom portion*). *Note*: For empiric bridge therapy prior to ablation procedures, CCBs (or other AV nodal blockers) should not be used if the patient has AV reentry with an accessory pathway. (AAD, antiarrhythmic drug; AF, atrial fibrillation; AP, accessory pathway; AV, atrioventricular; AVN, atrioventricular nodal; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; CCBs, calcium channel blockers; DCC, direct current cardioversion; ECG, electrocardiogram; EPS, electrophysiologic studies; PRN, as needed; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia.)



Once the acute episode of PSVT is terminated, a decision on long-term preventive therapy must follow. Most patients require long-term therapy; preventive treatment is indicated if (a) frequent episodes

occur that necessitate therapeutic intervention (ie, emergency department visits or interference with the patient's lifestyle) or (b) infrequent but severely symptomatic symptoms occur. For those patients in whom a preventive treatment is deemed necessary, two methods of management have been used: preventive drug therapy and catheter ablation.

AADs are no longer the treatment of choice to prevent recurrences of reentrant PSVT for the following reasons: (a) lifelong treatment is necessary in these generally young, but otherwise healthy, individuals; (b) there are few, if any, large controlled or comparative trials to assist the clinician in rationally choosing effective agents; and (c) most importantly, other nonpharmacologic treatments are clearly more effective. Nevertheless, drug therapy may occasionally be necessary in some patients, particularly those with mild symptoms and infrequent recurrences. A trial-and-error approach may be used, complemented by the use of ambulatory electrocardiographic recordings (Holter) or telephonic transmissions of cardiac rhythm (event monitors) to objectively document the efficacy or failure of the chosen drug regimen. Drugs known to be effective in preventing recurrences of PSVT are the AV nodal blocking drugs (digoxin, β-blockers, non-DHP CCBs, and combinations of these agents) and the class Ic AADs (flecainide, propafenone). Drugs such as quinidine, disopyramide, and amiodarone, although effective in some patients, should be discouraged because of the risk of toxicity with long-term treatment.

Catheter ablation using radiofrequency current on the PSVT substrate has dramatically altered the traditional treatment of these patients (**Fig. 18-10**). Radiofrequency energy delivered through a transvenous or arterial catheter causes small, discrete lesions through thermal energy. During invasive electrophysiologic studies, portions of the reentrant circuit can be located (or mapped) by the use of a number of catheters. Once this is completed, radiofrequency energy is applied, creating thermal injury in the tissue necessary for reentry. In this way, the substrate for reentry is destroyed, "curing" the patient of recurrent episodes of PSVT and obviating the need for chronic drug therapy. Complications, although unusual, include cardiac tamponade, pericarditis, valvular insufficiency, and AV block. Radiofrequency ablation is highly effective, preventing the recurrences of PSVT in more than 90% of patients.[75,76] The procedure was originally used in patients with WPW syndrome.[75] In these patients, the extranodal pathway is most often located at the left lateral free wall of the left ventricle (see Fig. 18-10). After the pathway is located, the catheter is put as close to the site as possible, and radiofrequency current is applied to make small burns in the tissue. Ablation of the extranodal connection occurs promptly, and evidence of preexcitation (delta waves) disappears. Thereafter, a similar approach was developed for patients with AV nodal reentry, placing the catheter in the coronary sinus, proximal to the AV node.[76] The preferred method in these individuals is to apply small amounts of radiofrequency current to the slow pathway of the reentrant circuit in order to modify its properties enough so that PSVT cannot recur.

FIGURE 18-10

Drawing showing catheter placement for radiofrequency ablation of a left lateral free wall accessory pathway. Here, a venous (atrial) transseptal puncture to gain access to the Kent's bundle is shown; a retrograde arterial approach has also been used. *(Data from Lerman BB, Basson CT. Catheter ablation is now the preferred treatment strategy (over AADs) for patients with symptomatic PSVT because the procedure is highly effective and curative, rarely results in complications, and obviates the need for chronic AAD therapy.[63] Catheter ablation is also a cost-effective approach (in the long term) because, if effective, the costs of drugs and repeated hospital visits are avoided. In one cost-effectiveness analysis, radiofrequency ablation improved quality of life and reduced lifetime medical expenditures by nearly $30,000 compared with chronic drug treatment.[77]

VENTRICULAR ARRHYTHMIAS

The common ventricular arrhythmias include (a) PVCs, (b) VT, and (c) VF. These arrhythmias may result in a wide variety of symptoms. PVCs often cause no symptoms or only mild palpitations. VT may be a life-threatening situation associated with hemodynamic collapse or may be totally asymptomatic. VF, by definition, is an acute medical emergency necessitating CPR.

Premature Ventricular Complexes and Prevention of Sudden Cardiac Death

PVCs are very common ventricular rhythm disturbances that occur in patients with or without SHD. Experimental models show that PVCs may be elicited by abnormal automaticity, triggered activity, or reentrant mechanisms. It is well known that PVCs are commonly observed in apparently healthy individuals; in these patients, the PVCs seem to have little, if any, prognostic significance. PVCs occur more frequently and in more complex forms in patients with SHD than in healthy individuals. The prognostic meaning of PVCs has been well studied in patients with MI (acute or remote) with several consistent themes. Patients with some forms of PVCs are at higher risk for SCD than if they did not have these minor rhythm disturbances. SCD can be defined as unexpected death (without an obvious noncardiac cause) occurring in a patient within 1 hour of experiencing symptoms (witnessed episodes) or within 24 hours of last being observed in normal health (unwitnessed episodes).[78] Studies of patients who experienced SCD (and happened to be wearing an electrocardiographic monitor at the time) often demonstrate the cause to be VF preceded by a short run of VT and frequent PVCs.[79]

Significance

Historically, investigators promoted the concept that patients in the acute phase of MI may have types of PVCs that are predictive of VF and SCD. These types of PVCs were referred to as “warning arrhythmias” and included frequent ventricular ectopy (more than 5 beats/min), multiform configuration (different morphology), couplets (two in a row), and R-on-T phenomenon (PVCs occurring during the repolarization phase of the preceding sinus beat in the vulnerable period of ventricular recovery). However, as a result of using continuous electrocardiographic monitoring techniques, it has become apparent that almost all patients have warning arrhythmias in the acute MI setting. In those patients who experience VF, warning arrhythmias are no more common than in those without VF. Consequently, warning arrhythmias observed during acute MI are neither sensitive nor specific for determining which patients will have VF. Thus, there is little need to direct drug therapy specifically at PVC suppression in these particular patients. Studies show that effective prevention of VF in the acute MI setting may be achieved without the abolition of PVCs.

CLINICAL PRESENTATION Ventricular Arrhythmias PVCs

- PVCs are non-life-threatening and usually asymptomatic. Occasionally, patients will complain of palpitations or uncomfortable heartbeats. Since the PVC, by definition, occurs early and the ventricle contracts when it is incompletely filled, patients do not feel the PVC. Rather, the next beat (after the PVC and a compensatory pause) is usually responsible for the patient's symptoms.

VT

- The symptoms of VT (monomorphic VT or TdP), if prolonged (ie, sustained), can vary from nearly completely asymptomatic to pulseless, hemodynamic collapse. Fast heart rates and underlying poor LV function will result in more severe symptoms. Symptoms of nonsustained, self-terminating VT also correlate with duration of episodes (eg, patients with 15-second episodes will be more symptomatic than those with three-beat episodes).

VF

- By definition, VF results in hemodynamic collapse, syncope, and cardiac arrest. Cardiac output and blood pressure are not recordable.

Conversely, data strongly imply that PVCs documented in the convalescence period of MI do carry important long-term prognostic significance.[80] PVCs occurring after an MI seem to be a risk factor for patient death that is independent of the degree of LV dysfunction or the extent of coronary atherosclerosis. Ruberman et al. employed a simple classification of PVCs: simple or benign (infrequent and monomorphic) versus "complex" (≥5 PVCs/min, couplets, R-on-T beats, and multiform).[80] These investigators found that the presence of complex (but not simple) ventricular ectopy in the setting of CAD was associated with a higher incidence of overall mortality and cardiac death.

Because PVCs without associated SHD, in apparently healthy individuals, carry little or no risk, drug therapy is unnecessary. However, because of the prognostic significance of complex PVCs in patients with SHD, the use of AAD therapy to suppress them has been controversial. Historically, many supported the aggressive use of AAD therapy to suppress PVCs, based on the underlying premise of eliminating a risk factor for SCD in patients with CAD (namely, the presence of complex PVCs). However, others favored a more conservative approach and disregarded the use of AAD therapy in the absence of significant symptoms. An important study, the CAST, abruptly put an end to this debate in noteworthy fashion; its results are reviewed in the following section because of its great historical significance and lingering impact.[48]

The Cardiac Arrhythmia Suppression Trial

The CAST[48,81] was initiated by the National Institutes of Health in 1987 to determine if suppression of ventricular ectopy with encainide, flecainide, or moricizine could decrease the incidence of death from arrhythmia in patients who had suffered an MI. Entrance criteria included documented MI between 6 days and 2 years prior to enrollment, and at least 6 PVCs/h (associated with no or minimal symptoms) without runs of VT greater than 15 beats in length. Also, patients were required to have an LVEF less than or equal to 55% if recruited within 90 days of the MI or an LVEF less than or equal to 40% if

recruited at least 90 days after the MI. Patients with an LVEF less than 30% were randomized only to encainide or moricizine. Patients were randomized to receive AAD therapy or placebo after demonstrating PVC suppression with one of the agents.

In April 1989, a routine, preliminary review of the study by the Safety and Monitoring Board revealed alarming results, and the study was interrupted.[48] The results showed that when compared with placebo, treatment with encainide or flecainide was associated with a significantly higher rate of total mortality and death due to arrhythmia, presumably caused by proarrhythmia. Analysis of the moricizine arm indicated neither harm nor benefit from this therapy; therefore, only this portion of the study was allowed to continue as CAST II.[82] However, in July 1991, CAST II was also prematurely discontinued because there was a trend toward an increase in mortality in moricizine-treated patients. This increase in mortality was primarily observed during the initiation of moricizine (dose titration phase) but not during the chronic treatment phase. The overall results of the two CASTs conclusively prove that the use of AAD therapy (beyond the general use of β-blockers) to suppress PVCs in patients after an MI does not improve survival and is most likely detrimental.

Even though the CAST was conducted more than 2 decades ago, it is considered one of the most important trials ever undertaken and has had a tremendous influence on the overall approach to the treatment of arrhythmias, as well as a far-reaching impact on AAD development. The results of the CAST have clearly had a negative influence on the long-term use of all AADs, causing a broad skepticism in the risk-versus-benefit analysis of this class of drugs. Consequently, pharmaceutical companies have shifted their drug discovery and investigative efforts away from potent sodium channel blockers. The findings of the CAST have also provided additional fuel for the pursuit of nonpharmacologic therapies for arrhythmias, such as catheter ablation and implantable devices.

Despite the discouraging results of the CAST, post-MI patients with complex ventricular ectopy remain at risk for death. Other drugs, besides the class Ic AADs, have been studied in this patient population, including sotalol. Sotalol is comprised of a racemic mixture of d- and l- isomers: both isomers are class III potassium channel blockers but the l-isomer also has β-blocking actions. Chronic therapy with d-sotalol was studied in patients with a remote MI complicated by complex ectopy in the Survival with Oral d-Sotalol trial.[82] In this trial, d-sotalol treatment was not targeted at PVC suppression (unlike the CAST), yet (like the CAST) the trial was halted prematurely because of excessive mortality in the treatment arm. Again, the presumed reason for this observation was d-sotalol–related proarrhythmia. Currently, only two AADs have been shown *not* to increase mortality in post-MI patients with long-term use: amiodarone and dofetilide. A number of trials have shown amiodarone to decrease the incidence of sudden (or arrhythmic) death, but not total mortality, in post-MI patients with complex ventricular ectopy.[83,84] A meta-analysis of all trials (n = 6,553 patients) demonstrated a 13% reduction in total mortality with long-term amiodarone therapy.[85] It is unclear if these findings can be attributed to one of amiodarone's electrophysiologic properties (eg, β-blocking) or a combination of its complex pharmacologic effects on conduction. It is noteworthy to mention that in two major studies, patients treated with amiodarone and a β-blocker generally did better than when no β-blocker was used.[83,84] Clearly, because of its impressive side effect profile and its inability to improve survival, amiodarone should not routinely be recommended in patients with heart disease such as remote MI and complex PVCs. Two randomized controlled trials have also shown that chronic therapy with dofetilide has no effect on overall mortality in post-MI patients with LV dysfunction.[86,87]

How should the clinician approach the patient with documented asymptomatic PVCs? Clearly, attempts to suppress asymptomatic PVCs should *not* be made with any AAD. Indeed, those patients who are at risk for arrhythmic death (recent MI, LV dysfunction, complex PVCs) should also *not* be routinely given *any* class I or III AAD.[88] If these patients have symptomatic PVCs, chronic drug therapy should be limited to the use of β-blockers. The use of β-blockers in post-MI patients is associated with a reduction in the incidence of total mortality and SCD, especially in the presence of LV dysfunction. β-Blockers can also be used in patients without underlying SHD to suppress symptomatic PVCs.

Ventricular Tachycardia

Mechanisms and Types of VT

VT is a wide QRS tachycardia that may acutely occur as a result of metabolic abnormalities, ischemia, or drug toxicity, or chronically recur as a paroxysmal form. On ECG, VT may appear as repetitive monomorphic or polymorphic ventricular complexes. The definition of VT is three or more consecutive PVCs occurring at a rate greater than 100 beats/min. An acute episode of VT may be precipitated by severe electrolyte abnormalities (hypokalemia or hypomagnesemia), hypoxia, or digoxin toxicity, or (most commonly) may occur in patients presenting with acute MI or myocardial ischemia complicated by HF. In these cases, correction of the underlying precipitating factors will usually prevent further recurrences of VT. As an example, if VT occurs during the first 24 hours of an acute MI, it will probably not reappear on a chronic basis after the infarcted area has been reperfused or healed with scar formation. This form of acute VT may be caused by a transient reentrant mechanism within temporarily ischemic or dying ventricular tissue. In contrast, some patients have a chronic, recurrent form of VT that is almost always associated with some type of underlying SHD. Common examples are paroxysmal VT associated with idiopathic dilated cardiomyopathy or remote MI with an LV aneurysm. In chronic, recurrent VT, microreentry within the distal Purkinje network is presumed to be responsible for the underlying substrate in a large majority of patients (see Fig. 18-3). Theoretically, electrophysiologic discrepancies occur as a result of structural damage and heart disease within the ventricular conducting system. The reentrant circuit may possess both anatomically determined and functional properties coursing through normal tissue, damaged (but not dead) tissue, and islands of necrosed tissue. In a minority of patients, macroreentrant circuits may be responsible for recurrent VT, including reentry incorporating the bundle branches.

Patients with acute VT associated with a precipitating factor often suffer severe symptoms, requiring immediate treatment measures. Chronic, recurrent VT may also cause severe hemodynamic compromise but may also be associated with only mild symptoms that are generally well tolerated. Sustained VT is that which requires therapeutic intervention to restore a stable rhythm or persists for a relatively long time (usually more than 30 seconds). Nonsustained VT is that which self-terminates after a brief duration (usually less than 30 seconds). Patients who experience VT more frequently than SR (ie, VT is the dominant rhythm) are considered to have incessant VT. In monomorphic VT, the QRS complexes are similar in morphologic characteristics from beat to beat. In polymorphic VT, the QRS complexes vary in shape and/or size between beats. A characteristic type of polymorphic VT, in which the QRS complexes appear to undulate around a central axis and that is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves), is referred to as TdP.

Most, but not all forms of recurrent VT occur in patients with extensive SHD. VT occurring in a patient without SHD is sometimes referred to as idiopathic VT and may take several forms, including fascicular VT and ventricular outflow tract VT.[89,90,91] Fascicular VT arises from a fascicle of the left bundle branch (usually posterior) and is usually not associated with severe underlying SHD. In distinct contrast to the common form of recurrent VT associated with extensive SHD, non-DHP CCBs (but not adenosine) are effective in terminating an acute episode of fascicular VT. Ventricular outflow tract VT (usually originating from the right ventricular outflow tract) originates from near the pulmonic valve (or uncommonly the aortic valve or LV outflow tract) and also occurs in patients with normal LV function without discernible SHD.[91] Unlike other forms of VT, right ventricular outflow tract VT often terminates with adenosine and may be prevented with β-blockers and/or non-DHP CCBs.

Some unusual forms of VT are congenital or heritable (**Table 18-10**). TdP can be associated with heritable defects in the flux of ions that govern ventricular repolarization. Although multiple syndromes and genetic mutations have been described, the more common examples are long QT syndrome 1 (depressed I_{Ks}), long QT syndrome 2 (depressed I_{Kr}), and long QT syndrome 3 (enhanced, inward sodium ion flux during repolarization).[92,93] Polymorphic VT (without a long QT interval) or VF may also occur as a result of a heritable defect in the sodium channel. This is the case in Brugada syndrome, which is described as a typical ECG pattern (ST-segment elevation in leads V_1 to V_3) in SR that is associated with SCD, and commonly occurs in males of Asian descent.[94]

TABLE 18-10 Heritable Polymorphic Ventricular Tachycardia

Syndrome	Channel Defect	Mutant Gene	Characteristics	Treatment
$LQTS_1$	$\downarrow I_{Ks}$	KVLQT1	SCD/TdP with exercise	BB/ICD
$LQTS_2$	$\downarrow I_{Kr}$	HERG	SCD/TdP with arousal	BB/ICD
$LQTS_3$	$\uparrow I_{Na}$ during plateau/repolarization	SCN5A	SCD/TdP at rest/sleep	Flecainide/mexiletine/ICD
Brugada	$\downarrow I_{Na}$	SCN5A	SCD/PMVT or VF at rest/sleep in Asian males	ICD/quinidine

BB, β-blocker; ICD, implantable cardioverter-defibrillator; LQTS, long QT syndrome; PMVT, polymorphic ventricular tachycardia; SCD, sudden cardiac death; TdP, torsade de pointes; VF, ventricular fibrillation.

Note: LQTS can be provoked by potassium channel blockers (eg, quinidine, sotalol), and Brugada syndrome can be provoked by potent sodium channel blockers (eg, cocaine, flecainide). $LQTS_3$ and Brugada syndrome may coexist.

Management

Consider the patient with the more common form of sustained monomorphic VT (ie, those with SHD, usually ischemic in nature). Like other rapid tachycardias, the initial management of an acute episode of VT (with a pulse) requires a quick assessment of the patient's signs and symptoms. If severe symptoms are present (ie, severe hypotension, angina, pulmonary edema), synchronized DCC should be delivered immediately to attempt to restore SR. An investigation should be made into possible precipitating

factors, which should be corrected if possible. The diagnosis of acute MI should always be entertained. If the episode of VT is thought to be an isolated electrical event associated with a transient initiating factor (such as acute myocardial ischemia or digoxin toxicity), there is no need for long-term AAD therapy once the precipitating factors are corrected (eg, an MI has been reperfused and healed and the patient is stable). Nevertheless, the patient should be monitored closely for possible recurrences of VT.

Patients presenting with an acute episode of VT (with a pulse) associated with only mild symptoms can be initially treated with AADs. The reader is referred to the 2010 AHA Guidelines for CPR and ECC (no updated recommendations regarding treatment of VT [with a pulse] in 2015 Guidelines Update for CPR and ECC).[72] IV procainamide, amiodarone, or sotalol can be considered in this situation. Lidocaine can be considered as an alternative. In one small study, procainamide was shown to be superior to lidocaine in terminating VT.[95] Synchronized DCC should be delivered if the patient's status deteriorates, VT degenerates to VF (would be unsynchronized in this situation), or drug therapy fails.

Once an acute episode of sustained VT has been successfully terminated by electrical or pharmacologic means and an acute MI has been ruled out, the possibility of a patient having recurrent episodes of VT should be considered. Evidence for the possibility of VT recurrence can often be gleaned from invasive electrophysiologic studies using programmed ventricular stimulation. Because these patients are at extremely high risk for death, trial-and-error attempts to find effective therapy are unwarranted. To gain some objective evidence of a response to a specific AAD regimen, serial testing of these drugs using the following two surrogate end points has been used: (a) inability to induce sustained VT with programmed extrastimuli by invasive electrophysiologic studies and (b) suppression of ventricular ectopic beats by serial 24-hour continuous electrocardiographic (Holter) monitoring. These two strategies have been compared but largely abandoned for several reasons.[96,97] First, the yield for finding an effective AAD is low. For instance, sustained monomorphic VT can be rendered noninducible or nonsustained by programmed stimulation protocols in only 20% to 25% of patients. Therefore, the clinician frequently must search for other therapeutic options or settle for other treatment end points such as slower and more tolerable inducible VT. Second, amiodarone is the most effective (approximately 50% effective after 2 years) AAD in patients with recurrent VT; however, electrophysiologic drug testing does not necessarily predict the clinical efficacy of amiodarone. Patients may have continued inducibility of VT on amiodarone despite long-term success. Indeed, empiric amiodarone has been compared with therapy (with other AADs) guided by electrophysiologic testing in patients at high risk for recurrent VT.[98] In this trial, amiodarone therapy without invasive testing was superior in preventing SCD and recurrences of severe ventricular arrhythmias at all time points. Third, the recurrence rate of life-threatening VT is high (20%-50% per year depending on the AAD chosen), regardless of the method of acute drug testing. Fourth, as referred to previously, there is a substantial side effect profile of the class I and III AADs. Lastly, and perhaps most importantly, is the impressive demonstrated effectiveness of nonpharmacologic approaches to the treatment of recurrent VT/VF.[99] For instance, some forms of recurrent VT are amenable to catheter ablation therapy using radiofrequency current. This approach is highly effective (approximately 90%) in idiopathic VT (right ventricular outflow tract or fascicular VT), but less so in recurrent VT associated with a cardiomyopathic process or remote MI with LV aneurysm. In the latter patients, ablation is usually regarded as second-line therapy after other methods have failed. Additionally, numerous trials have established the ICD as a superior treatment over AAD therapy not only for the prevention of SCD in patients who have been resuscitated from an episode of cardiac arrest or had sustained VT ("secondary prevention") but

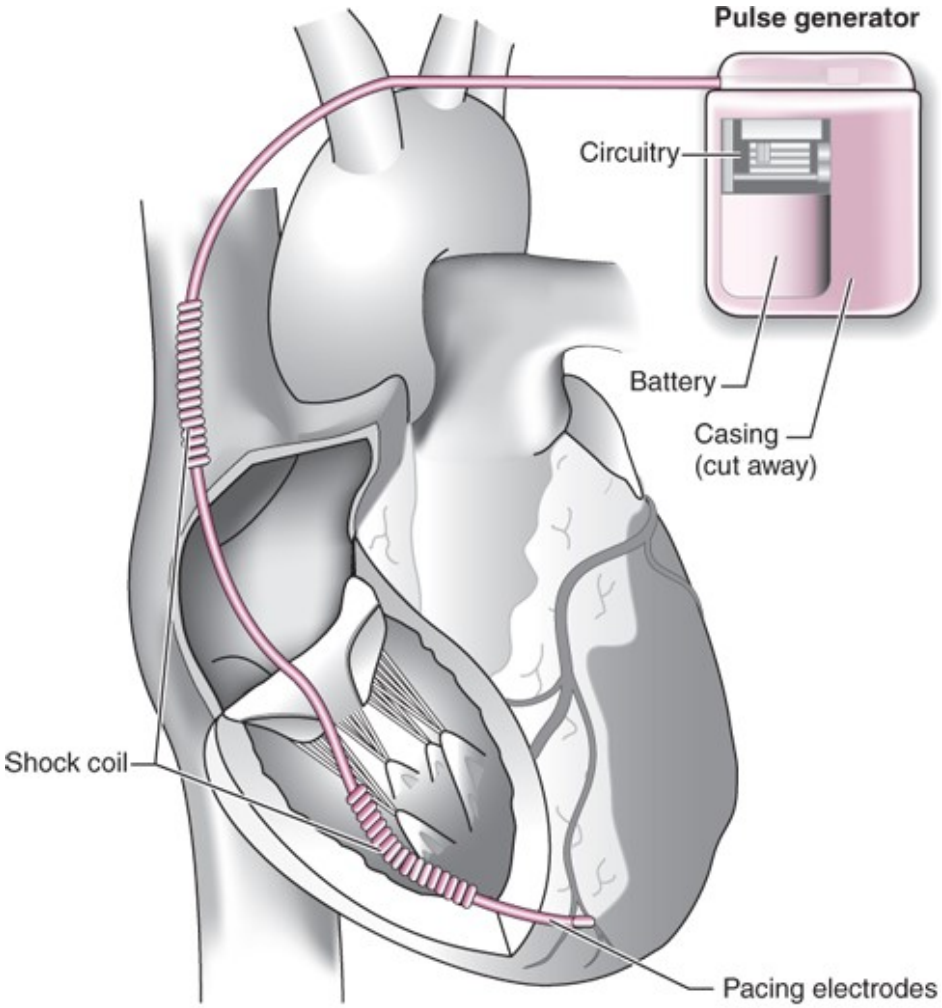
also for the prevention of an initial episode of SCD in certain high-risk patient populations ("primary prevention").

The Implantable Cardioverter-Defibrillator

The introduction of and advances in the ICD (**Fig. 18-11**) have obviated the need to rely solely on the use of AADs to prevent episodes of life-threatening ventricular arrhythmias.[100] Numerous advancements in device technology have allowed the ICD to become smaller, less invasive to implant, and programmable with advanced functions. Early ICDs required a thoracotomy to place the generator in the abdomen, whereas with the newer, smaller models, the leads are implanted transvenously with the generator placed into the pectoral region in a manner similar to cardiac pacemakers. Modern ICDs now employ a "tiered-therapy approach," meaning that overdrive pacing (ie, antitachycardia pacing) can be attempted first to terminate the tachyarrhythmia (no painful shock delivered), followed by low-energy cardioversion, and, finally, by high-energy defibrillation shocks. In addition, backup antibradycardia pacing and extended battery lives have made these newer devices much more attractive. All models store recordings during delivery of pacing shocks, which is extremely important in discerning appropriate shocks (ie, delivers shock for serious ventricular arrhythmia) from inappropriate shocks (ie, delivers shock for AF with rapid ventricular rate) and in documenting true recurrences of the patient's tachycardia.

FIGURE 18-11

Drawing showing implantable cardioverter-defibrillator. *(Reproduced with permission from The Cascade Investigators. Randomized antiarrhythmic drug therapy in survivors of cardiac arrest (the CASCADE Study).* Am J Cardiol *1993;72:280-287.)*



Although the ICD is a highly effective method for preventing SCD due to recurrent VT or VF, several problems remain. First, the device itself, the implantation procedure, electrophysiologic studies, hospitalization, and physician fees are costly. Given that the indications for receiving an ICD have significantly expanded over the past several years, the total cost associated with the implantation of this device is likely to place a great burden on the healthcare system. Second, many patients (as high as 70%) with ICDs end up receiving concomitant AAD therapy (usually amiodarone or sotalol).[101,102] AADs can be initiated in these patients for a number of reasons, including (a) decreasing the frequency of VT/VF episodes to subsequently reduce the frequency of appropriate shocks; (b) reducing the rate of VT so that it can be terminated with antitachycardia pacing; and (c) decreasing episodes of concomitant supraventricular arrhythmias (eg, AF, AFl) that may trigger inappropriate shocks. As a result of these potential benefits, the concomitant use of AADs can minimize patient discomfort and prolong the battery life of the ICD. The decision to initiate concomitant AAD therapy should be individualized, with treatment usually being reserved for those patients with frequent shocks because of VT or AF. If AADs are added to ICD therapy, one should note that many of these drugs alter defibrillation thresholds; consequently, the device may need to be reprogrammed to account for this alteration.[103]

Secondary Prevention of Sudden Cardiac Death

The results of three trials, the Antiarrhythmics versus Implantable Defibrillators (AVID), Cardiac Arrest Study Hamburg (CASH), and Canadian Implantable Defibrillator Study (CIDS), definitively support the ICD as first-line therapy for the secondary prevention of SCD.[104,105,106] Of these, the AVID trial was the largest, randomizing more than 1,000 patients with resuscitated VF, sustained VT with syncope, or hemodynamically significant sustained VT (with LVEF ≤40%) to either an ICD or AADs (approximately 95% received amiodarone at discharge).[104] The trial was stopped early because of a demonstrated superiority of the ICD; patients in the ICD group had a better overall survival when compared with those in the AAD group (75% vs 64%, respectively, at 3 years). Although they were smaller trials, both CASH and CIDS demonstrated the efficacy of an ICD compared with amiodarone in patients with a history of sustained VT or VF, with the ICD reducing overall mortality by 20% to 25%.[105,106] Overall, the results of these three trials provide strong support for the aggressive use of the ICD in patients who are at high risk for recurrent, life-threatening ventricular arrhythmias.

Primary Prevention of Sudden Cardiac Death

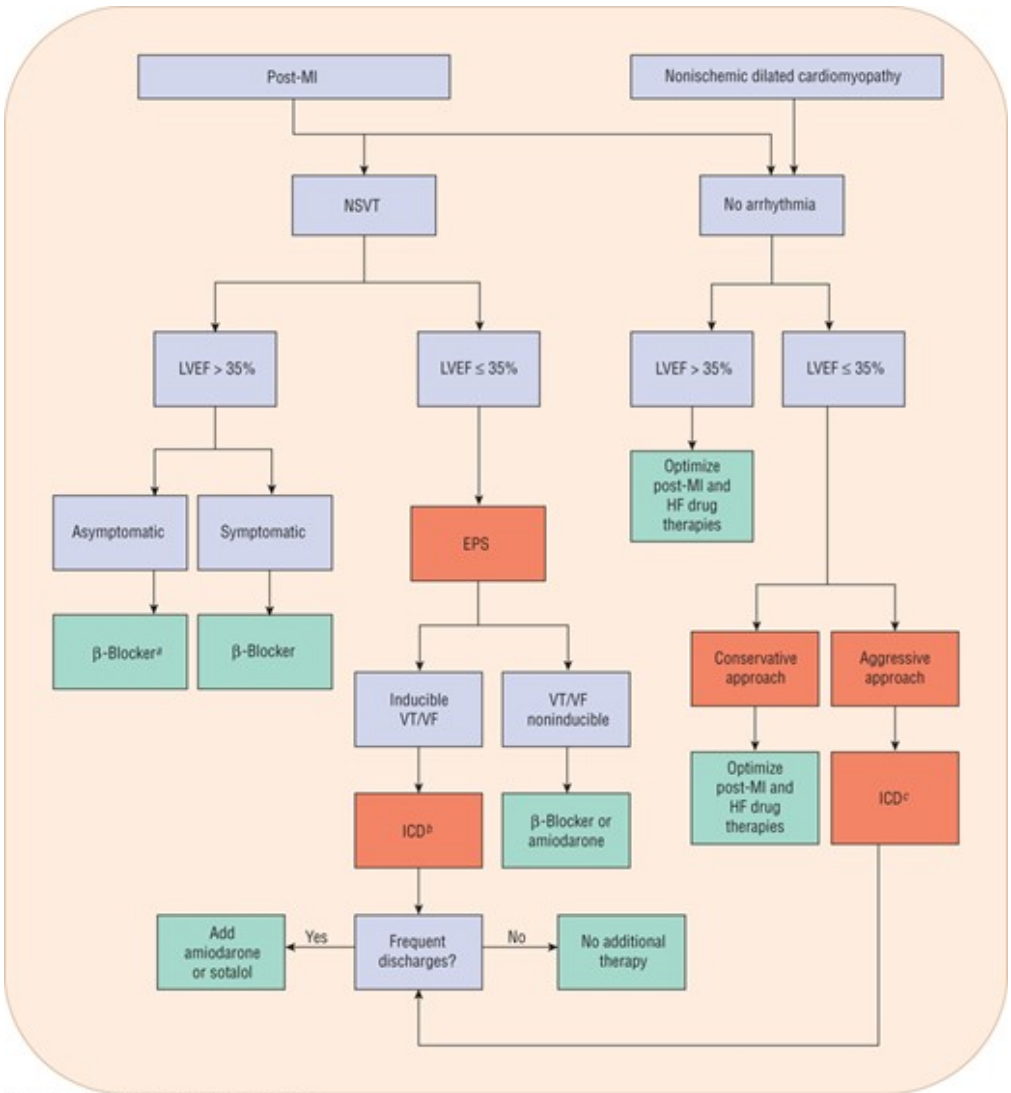
One of the patient populations that appears to be at high risk for a first episode of SCD includes those with a prior MI, LV dysfunction, and nonsustained VT. The use of AADs to prevent SCD in this high-risk group has been significantly limited by the results of the CAST and other similar trials that have collectively demonstrated that these drugs may actually increase the risk of mortality in these patients. As a result of these trials, clinicians have sought a more clearly defined strategy for risk stratification in these patients before initiating drug therapy.

Traditionally, there are three treatment strategies for patients with nonsustained VT: (a) conservative (ie, no AAD treatment beyond β-blockers); (b) empiric amiodarone; and (c) aggressive (ie, electrophysiologic studies with possible insertion of an ICD) (**Fig. 18-12**). 9 A number of early studies suggested that tests such as electrophysiologic studies could be used to determine long-term risk in patients with nonsustained VT.[107,108] For instance, Wilber et al. demonstrated that post-MI patients with nonsustained VT and inducible sustained VT after programmed stimulation were at increased risk for subsequent VT/VF or SCD compared with those in whom sustained VT could not be induced.[107] These data provided the basis for the Multicenter Automatic Defibrillator Implantation Trial (MADIT) and the Multicenter Unsustained Tachycardia Trial (MUSTT).[109,110] The MADIT was the first of these trials to be conducted to evaluate the efficacy of ICD therapy in this high-risk patient population. Specifically, this trial randomized patients with a previous MI, LVEF less than or equal to 35%, asymptomatic nonsustained VT, and inducible VT that was not suppressed with the use of IV procainamide to receive an ICD or conventional medical therapy (74% received amiodarone).[109] This trial was terminated prematurely after a significant survival benefit was detected in the ICD group. The findings of the MADIT were subsequently supported by those of the MUSTT. In the MUSTT, patients with a history of MI, LVEF less than or equal to 40%, asymptomatic nonsustained VT, and inducible sustained VT were randomized to a conservative approach (no AAD therapy beyond β-blockers) or electrophysiologically guided therapy (AADs and/or ICD).[110] The results showed that the conservative approach had a significantly higher event rate (cardiac arrest or death from arrhythmia). However, when the results of the electrophysiologically guided group were further stratified, those receiving only AADs (no ICD) were no different in terms of outcomes than those who received no treatment. In other words, only those treated with an ICD had a significantly lower event rate and greater survival. One problem

with the MUSTT, however, is that, because the trial was initiated in 1989, nearly 50% of patients received class I AADs or drugs that are now known not to improve survival in patients with CAD, LV dysfunction, and ventricular arrhythmias; only 10% of patients received the most effective agent in this setting, amiodarone. Based on the results of the MADIT and MUSTT, it is reasonable for patients with CAD, LV dysfunction, and nonsustained VT to undergo electrophysiologic testing.[111] If these patients do not have inducible sustained VT/VF, chronic AAD therapy is unnecessary; however, if these patients do have inducible sustained VT/VF, implantation of an ICD is warranted.

FIGURE 18-12

Algorithm for the primary prevention of SCD in patients with a history of MI or with a nonischemic dilated cardiomyopathy. [a]In these patients, the β-blocker is being used to reduce post-MI mortality. [b]Patients should be more than 40 days post-MI prior to insertion of the ICD. [c]Patients with an ischemic cardiomyopathy should be more than 40 days post-MI prior to insertion of the ICD. (EPS, electrophysiologic study; HF, heart failure; ICD, implantable cardioverter-defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSVT, nonsustained VT; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia.)



Although the MADIT and MUSTT provide clinicians with important information regarding risk stratification, both of these trials targeted patients who had a history of nonsustained VT. The results of two landmark trials, the MADIT II and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), have provided clinicians with additional information regarding the treatment of other groups of high-risk patients who have no prior history of ventricular arrhythmia (see Fig. 18-12).[112,113] In the MADIT II, patients with a prior MI and LVEF less than or equal to 30% were randomized to receive either an ICD or a conventional therapy (routine post-MI and HF therapy).[112] Neither a history of ventricular arrhythmia nor electrophysiologic testing was required for inclusion in this study. Patients in the ICD group experienced a significant reduction in mortality when compared with the conventional therapy group; the reduction in mortality in the ICD group was primarily due to a reduction in arrhythmic death. Whereas the MADIT, MUSTT, and MADIT II limited enrollment to patients with ischemic cardiomyopathy, the SCD-HeFT is the largest trial, to date, to evaluate the efficacy of an ICD in a nonischemic HF population. In this trial, patients with NYHA class II or III HF (of either ischemic or nonischemic etiology) and LVEF less than or equal to 35% were randomized to receive placebo, amiodarone, or an ICD.[113] All patients were treated with appropriate HF therapies, as indicated. Implantation of an ICD resulted in a significantly lower mortality rate compared with treatment with either placebo or amiodarone (there was no difference between placebo and amiodarone). The survival benefits of the ICD were observed regardless of the etiology of the HF.

Overall, as the ICD trials have evolved over the past decade, the indications for implanting these devices have significantly expanded (**Table 18-11**).[114] Based on the results of the MUSTT, MADIT, MADIT II, and SCD-HeFT, many patients will be eligible for an ICD.

TABLE 18-11 Current Indications for Implantable Cardioverter-Defibrillator Implantation

Indications	ACC/AHA/HRS Guideline Recommendation
Secondary Prevention	
An ICD is *indicated* in the following individuals:	
Patients who survived an episode of cardiac arrest due to VF or have hemodynamically unstable sustained VT, not due to a reversible cause	Class I
Patients with structural heart disease who develop spontaneous sustained VT that is either hemodynamically stable or unstable	Class I
Patients with unexplained syncope who have hemodynamically unstable sustained VT or VF induced by EPS	Class I
An ICD is *considered reasonable* in the following individuals:	
Patients with unexplained syncope who have significant LV dysfunction and nonischemic dilated cardiomyopathy	Class IIa
Patients with sustained VT and normal or near-normal LV function	Class IIa
Primary Prevention	
An ICD is *indicated* in the following individuals:	
Patients with a prior MI (occurring >40 days before ICD implantation) and LVEF ≤30% who are in NYHA FC I	Class I

Indications	ACC/AHA/HRS Guideline Recommendation
Patients with an LVEF ≤35% due to a prior MI (occurring >40 days before ICD implantation) who are in NYHA FC II or III	Class I
Patients with nonsustained VT due to prior MI, an LVEF ≤40%, and inducible, sustained VT or VF at EPS	Class I
Patients with nonischemic dilated cardiomyopathy and an LVEF ≤35% who are in NYHA FC II or III	Class I
An ICD is *considered reasonable* in patients who are not hospitalized and are awaiting cardiac transplantation	Class IIa
An ICD *may be considered* in patients with nonischemic dilated cardiomyopathy and an LVEF ≤35% who are in NYHA FC I	Class IIb

ACC, American College of Cardiology; AHA, American Heart Association; EPS, electrophysiologic study; FC, functional class; HRS, Heart Rhythm Society; ICD, implantable cardioverter-defibrillator; LV, left ventricular; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association; VF, ventricular fibrillation; VT, ventricular tachycardia.

Ventricular Proarrhythmia

All AADs have the potential to aggravate existing arrhythmias or to cause new arrhythmias. It is believed that AADs may cause proarrhythmia in nearly 30% of patients.[7] Many definitions for proarrhythmia have been proposed; however, in the simplest terms, it indicates the development of a significant new arrhythmia (such as VT, VF, or TdP) or worsening of an existing arrhythmia (episodes are longer, faster, or more frequent). As with all arrhythmias, the consequences of proarrhythmia are varied. Some patients who develop proarrhythmia may be totally asymptomatic, others may notice a worsening of symptoms, and some may die suddenly. The development of proarrhythmia results from the same mechanisms that cause arrhythmias in general (eg, quinidine-induced TdP due to EADs) or from an alteration in the underlying substrate due to the AAD (eg, development of an accelerated tachycardia caused by flecainide, which decreases conduction velocity without significantly altering the refractory period).[7] The diagnosis of proarrhythmia is sometimes difficult to make because of the variable nature of the underlying arrhythmias. However, in all cases, the AAD should be discontinued if proarrhythmia is detected or suspected.

Incessant Monomorphic Ventricular Tachycardia

The prototypical form of proarrhythmia caused by the class Ic AADs is a rapid, sustained, monomorphic VT with a characteristic sinusoidal QRS pattern that is often resistant to resuscitation with cardioversion or overdrive pacing. [10] It is sometimes referred to as sinusoidal or incessant VT and is the result of excessive sodium channel blockade and slowed conduction. Sinusoidal VT caused by the class Ic AADs was thought to occur within the first several days of drug initiation; however, the results of the CAST indicate that the risk for this type of proarrhythmia may exist as long as the AAD is continued. Factors that can predispose a patient to this form of proarrhythmia include: (a) the presence of underlying

ventricular arrhythmias; (b) CAD; and (c) LV dysfunction. Provocation of proarrhythmia by the class Ic AADs is sometimes reported during exercise, which is most likely a result of augmented slowed conduction at rapid heart rates (ie, rate-dependent sodium blockade). The incidence of proarrhythmia caused by class Ic AADs is greatest in patients with all three of the above risk factors (approximately 10% to 20%) and extremely uncommon in those without these risk factors, such as patients with supraventricular tachycardias and normal LV function. Other factors that have a less well-defined association with proarrhythmia are elevated AAD serum concentrations and rapid dosage escalation of the AAD. It has been proposed that the presence of underlying ventricular conduction delays may also pose a risk for proarrhythmia. As mentioned earlier, incessant monomorphic VT is often resistant to resuscitation; however, some have had success with lidocaine ("fast on-off" AAD, which successfully competes with a "slow on-off" agent such as flecainide for sodium channel receptor) or sodium bicarbonate (reverses the excessive sodium channel blockade).

Torsade de Pointes

As defined previously, TdP is a rapid form of polymorphic VT (**Fig. 18-13**) that is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves) on ECG. It is important to note that most forms of polymorphic VT occurring in the setting of a normal QT interval are similar to monomorphic VT in terms of etiology and treatment strategies (thus, a long QT interval is crucial to the diagnosis of TdP). Much has been learned about the underlying etiology of TdP. Basic defects (genetic, drugs, or diseases) that delay repolarization by influencing ion movement (usually by blocking potassium efflux) provoke EADs preferentially in cells deep in the heart muscle, which, in turn, trigger reentry and TdP. Drugs that cause TdP usually delay ventricular repolarization in an inhomogeneous way (termed *dispersion of refractoriness*), which facilitates the formation of multiple reentrant loops in the ventricle.[115] TdP may occur in association with hereditary syndromes or as an acquired form (ie, a result of drugs or diseases). The underlying etiology in both cases is delayed ventricular repolarization due to blockade of potassium conductance. It is possible, however, that some individuals have a partially expressed form of these congenital syndromes but never suffer TdP unless some other external factor (eg, drugs, diseases, electrolyte disturbances, abrupt heart rate changes) further delays ventricular repolarization. Specifically, acquired forms of TdP are associated with electrolyte disturbances (hypokalemia or hypomagnesemia), subarachnoid hemorrhage, myocarditis, liquid protein diets, arsenic poisoning, severe hypothyroidism, or, most commonly, drug therapy (notably phenothiazines, antibiotics, antihistamines, antidepressants, and AADs) (**Table 18-12**).

FIGURE 18-13

Torsade de pointes caused by quinidine. Note the presence of a couplet and two triplets following each extra systolic pause. The pause gets progressively longer until it is long enough to result in an episode of sustained torsade de pointes. Also, as the pause lengthens, discernible U waves (labeled ↑) (EADs?) begin to appear. The amplitude of the U wave is somewhat greater with the longest pause. *(Reproduced with permission from Bauman JL. Drug safety: Cardiac arrhythmias. Antihistamine update symposium.* Hosp Med *1995;31:24.)*

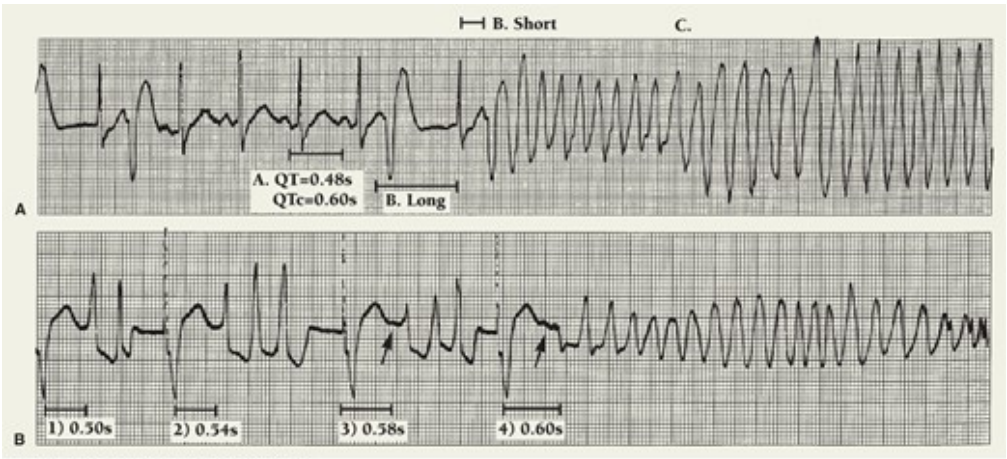


TABLE 18-12 Potential Causes of QT Interval Prolongation and Torsade de Pointes

Conditions

Congenital long QT syndromes

Heart failure

Hypokalemia

Hypomagnesemia

Myocardial ischemia/infarction

Myocarditis

Severe bradycardia (<50 beats/min)

Severe hypothermia

Severe starvation/liquid protein diets

Subarachnoid hemorrhage

Drugs

Antiarrhythmic drugs

Amiodarone (<1%)

Disopyramide

Dofetilide

Dronedarone (<1%)

Ibutilide

- Procainamide (also *N*-acetylprocainamide)
- Quinidine
- Sotalol

Cancer chemotherapy or biologic agents

- Ceritinib
- Crizotinib
- Dasatinib
- Degarelix
- Eribulin
- Lapatinib
- Leuprolide
- Nilotinib
- Oxaliplatin
- Pazopanib
- Sorafenib
- Sunitinib
- Toremifene
- Vandetanib
- Vemurafenib

Psychotropics

- Atypical antipsychotics (eg, quetiapine, ziprasidone)
- Droperidol
- Haloperidol
- Phenothiazines (eg, thioridazine, chlorpromazine)
- Pimozide
- Tricyclic and tetracyclic antidepressants

Toxins

Arsenic

Organophosphate insecticides

Antibiotics

Fluoroquinolones (levofloxacin, moxifloxacin, gemifloxacin)

Macrolides

Pentamidine

Trimethoprim-sulfamethoxazole

Voriconazole

Pain

Methadone

Miscellaneous

Chloroquine

Corticosteroids[a]

Diuretics[a]

Dolasetron

Liquid protein diets[a]

Ondansetron (IV)

Quinine

Tacrolimus

IV, intravenous

[a]More than likely a result of severe electrolyte imbalance.

Note: For a complete list, see *www.crediblemeds.org*.

The class Ia AADs (especially quinidine) and class III I_{Kr} blockers are most notorious for precipitating TdP; the class Ib and Ic AADs rarely, if ever, cause TdP as they do not appreciably delay repolarization. Most AADs with I_{Kr} blocking activity cause TdP in approximately 2% to 4% of patients, with the exceptions being amiodarone and dronedarone (<1%). Risk factors and associated features of

drug-induced TdP have been identified and can be summarized as follow[116]: (a) high dosages or plasma concentrations of the offending drug ("dose-related") (except for quinidine-induced TdP, which tends to occur more frequently at low-to-therapeutic plasma concentrations); (b) concurrent SHD (eg, CAD, HF, and/or LV hypertrophy); (c) evidence of mild delayed repolarization (prolonged QT interval) at baseline; (d) evidence of a prolonged QT interval shortly after initiation of the offending drug; (e) concomitant electrolyte disturbances such as hypokalemia or hypomagnesemia; (f) female gender; and (g) a characteristic long-short initiating sequence (so-called "pause dependence") of the TdP episode (see Fig. 18-13). However, none of these associations are absolute prerequisites to the development of drug-induced TdP. For instance, although TdP is usually documented early in the course of quinidine therapy, patients may develop this arrhythmia anytime during chronic treatment.[117] The reason for quinidine's relatively unique propensity for causing TdP at relatively low dosages and plasma concentrations requires explanation. Quinidine's ability to block I_{Kr} is clinically manifest at low plasma concentrations; at higher plasma concentrations, its sodium channel blocking properties predominate. Other drugs that block I_{Kr} usually do so in a concentration-dependent fashion. The observation that most patients who suffer drug-induced TdP have evidence of mildly delayed repolarization (long QT intervals) even before they are prescribed the offending drug has stimulated a search for a potential genetically linked risk. Indeed, it appears that at least some patients with acquired drug-induced TdP possess mutations of genes that encode for I_{Kr} or I_{Ks}.[116]

The common underlying electrophysiologic cause of TdP is a delay in ventricular repolarization (provoking EADs), which usually results from inhibition (drug-induced or genetic) of the I_K current and manifests as QT interval prolongation on the ECG. Therefore, the extent of QT interval prolongation has been used as a measurement of risk of TdP; however, considerable controversy exists regarding this practice. Amiodarone, for example, commonly causes significant QT prolongation but is a relatively infrequent cause of TdP. Nonetheless, the QT interval should be measured and monitored in all patients prescribed drugs that have a high potential for causing TdP (see Table 18-12). Patients with a baseline QT_c interval (QT interval corrected for heart rate, which can be calculated using Bazett's formula: QT_c = QT measured/ $\sqrt{\text{R}-\text{R Interval})}$) greater than 450 milliseconds should not be given drugs that have a high potential for causing TdP; an increase in the QT_c interval to at least 560 milliseconds after the initiation of the drug is an indication to discontinue the agent or, at least, to reduce its dosage and carefully monitor.

Drug-induced TdP has become an extremely visible hazard plaguing new drugs, sometimes resulting in public health disasters. For instance, several drugs (cisapride, astemizole, levomethadyl, grepafloxacin, sparfloxacin, terfenadine, and high-dose [32 mg] IV ondansetron) have been withdrawn from the market in the United States because of their significant potential for causing TdP. One of the most visible and striking examples of drug withdrawal due to TdP occurred with the popular nonsedating antihistamine, terfenadine. Terfenadine is a potent I_{Kr} blocker but is rapidly metabolized by CYP3A4 to an active moiety (fexofenadine) that is not associated with delayed repolarization. Consequently, in the presence of drugs that block the CYP3A4 isoenzyme (eg, ketoconazole, erythromycin, diltiazem), accumulation of the parent compound, terfenadine, causes clinically significant blockade of I_{Kr} that could result in TdP and even death.[118] Because of experiences like this, all new drug entities under investigation are screened for their ability to block I_K and cause significant QT prolongation.

Acute treatment of TdP is different than treatment for the more common acute monomorphic VT. For an acute episode of TdP, most patients will require and respond to DCC. However, TdP tends to be paroxysmal in nature and often will rapidly recur after DCC. Therefore, after the initial restoration of a stable rhythm, therapy designed to prevent recurrences of TdP should be instituted. AADs that further prolong repolarization such as IV procainamide are absolutely contraindicated. Lidocaine is usually ineffective. Although there are no true efficacy trials, IV magnesium sulfate, by suppressing EADs, is considered the drug of choice in preventing recurrences of TdP.[119] If IV magnesium sulfate is ineffective, treatment strategies designed to increase heart rate, shorten ventricular repolarization, and prevent the pause dependency should be initiated. Either temporary transvenous pacing (105-120 beats/min) or pharmacologic pacing (isoproterenol or epinephrine continuous infusion) can be initiated for this purpose. All drugs that prolong the QT interval should be discontinued, and exacerbating factors (eg, hypokalemia or hypomagnesemia) should be corrected.

Ventricular Fibrillation

Background and Prevention

VF is electrical anarchy of the ventricle resulting in no cardiac output and CV collapse. Death will ensue rapidly if effective treatment measures are not taken. Patients who die abruptly (within 1 hour of initial symptoms) and unexpectedly (ie, "sudden death") usually have VF recorded at the time of death.[120] SCD accounts for about 350,000 deaths per year in the United States.[17] It occurs most commonly in patients with CAD or LV dysfunction; it occurs less commonly in those with WPW syndrome or mitral valve prolapse, and occasionally in those without associated heart disease (eg, Brugada syndrome). Patients who have SCD (not associated with acute MI) but survive because of appropriate CPR and defibrillation (where warranted) often have inducible sustained VT and/or VF during electrophysiologic studies. These individuals are at high risk for the recurrence of VT and/or VF.

In contrast, patients who have VF associated with acute MI (ie, within the first 24 hours after symptoms) usually have little risk of recurrence. Of all patients who die as a result of an acute MI, approximately 50% die suddenly prior to hospitalization. VF associated with acute MI can be subdivided into two types: primary VF and complicated or secondary VF. Primary VF occurs in an uncomplicated MI not associated with HF; secondary VF occurs in an MI complicated by HF. The time course, incidence, mechanisms, treatment, and complications of these two forms of VF are different. For example, approximately 2% to 6% of patients with acute MI suffer primary VF within 24 hours of chest pain, but the risk of VF declines rapidly over time and is nearly zero after the initial 24-hour period. Complicated or secondary VF does not follow such a predictable time course and may occur in the late infarction period. The premise of prophylactic AADs administered to all patients with uncomplicated MI is based on (a) the inability to predict which patients are at risk for primary VF and (b) the predictable time course of primary VF (in contrast to complicated VF). Of the prophylactic therapies used, lidocaine has been the most widely debated and studied. Lie et al. performed the classic study showing the effectiveness of lidocaine in preventing primary VF.[121] Although lidocaine significantly reduced the incidence of VF compared with placebo, there was no significant difference in mortality due to VF between the groups. These results, along with the effectiveness of rapidly instituted defibrillation in modern coronary care units with sophisticated monitoring techniques, have caused most to reject the notion of prophylactic lidocaine administration for all patients with uncomplicated MI. In support of

this, two meta-analyses concluded against the routine use of prophylactic lidocaine because of a possible increase in mortality in lidocaine-treated patients as well as the declining incidence of primary VF documented in recent years (probably a result of the more aggressive and rapid use of β-blockers, thrombolytics, and percutaneous intervention for the treatment of acute coronary syndromes).[122,123]

Acute Management

A patient with pulseless VT or VF should be managed according to the most recent AHA guidelines for CPR and ECC.[72,73] A detailed discussion regarding the acute management of pulseless VT/VF can be found in Chapter 12.

BRADYARRHYTHMIAS

The previous sections reviewed the pathophysiology and treatment of tachyarrhythmias, and this section serves to briefly consider the bradyarrhythmias. For the most part, the symptoms of bradyarrhythmias result from a decline in cardiac output. Because cardiac output decreases as heart rate decreases (to a point), patients with bradyarrhythmias may experience symptoms in association with hypotension, such as dizziness, syncope, fatigue, and confusion. If LV dysfunction exists, patients may experience worsening HF symptoms. Except in the case of recurrent syncope, symptoms associated with bradyarrhythmias are often subtle and nonspecific.

Sinus Bradycardia

Sinus bradyarrhythmias (heart rate <60 beats/min) are a common finding, especially in young, athletically active individuals, and usually are neither symptomatic nor in need of therapeutic intervention. On the other hand, some patients, particularly the elderly, have sinus node dysfunction. This may be the result of underlying SHD and the normal aging process that attenuate SA nodal function over time. Sick sinus syndrome refers to this process resulting in symptomatic sinus bradycardia and/or periods of sinus arrest.[124] Sinus node dysfunction is usually reflective of diffuse conduction disease, and accompanying AV block is relatively common. Furthermore, symptomatic bradyarrhythmias may be accompanied by alternating periods of paroxysmal tachycardias such as AF. In this instance, AF sometimes presents with a rather slow ventricular response (in the absence of AV nodal blocking drugs) because of diffuse conduction disease. The occurrence of alternating bradyarrhythmias and tachyarrhythmias is referred to as the tachy-brady syndrome. The occurrence of paroxysmal AF in a patient with sinus node dysfunction may be a result of underlying SHD with atrial dysfunction or atrial escape in response to reduced sinus node automaticity. In fact, because the rate of impulse generation by the sinus node is generally depressed or may fail altogether, other automatic pacemakers within the conduction system may "rescue" the sinus node. These rescue rhythms often present as paroxysmal atrial rhythms (eg, AF) or as a junctional escape rhythm.

The treatment of sinus node dysfunction involves the elimination of symptomatic bradycardia and potentially managing alternating tachycardias such as AF. In general, the long-term therapy of choice is a permanent ventricular pacemaker. Dual-chamber, rate-adaptive chronic pacing clearly improves symptoms and overall quality of life and decreases the incidence of paroxysmal AF and systemic

embolism.[124] Drugs commonly employed to treat supraventricular tachycardias should be used with caution, if at all, in the absence of a functioning pacemaker. AADs prescribed to prevent AF recurrences may also suppress the escape or rescue rhythms that appear in severe sinus bradycardia or sinus arrest. Consequently, these drugs may transform an asymptomatic patient with bradycardia into a symptomatic one. The addition of class I AADs can also affect pacemaker threshold and result in loss of capture if the pacemaker is not appropriately interrogated and adjusted. Other drugs that depress SA or AV nodal function, such as β-blockers, non-DHP CCBs, and ivabradine, may also significantly exacerbate bradycardia. Even drugs with indirect sympatholytic actions, such as methyldopa and clonidine, may worsen sinus node dysfunction. The use of digoxin in these patients is controversial; however, in most cases, it can be used safely.

Other Causes

Another reason for paroxysmal bradycardia and sinus arrest that is not directly due to sinus node dysfunction is carotid sinus hypersensitivity.[125,126] Again, this syndrome occurs commonly in the elderly with underlying SHD, and may precipitate falls and hip fractures. Symptoms occur when the carotid sinus is stimulated, resulting in an accentuated baroreceptor reflex. Often, however, symptoms are not well correlated with the obvious physical manipulation of the carotid sinus (in the lateral neck region). Patients may experience intermittent episodes of dizziness or syncope because of sinus arrest caused by increased vagal tone and sympathetic withdrawal (the cardioinhibitory type), a drop in systemic blood pressure caused by sympathetic withdrawal (the vasodepressor type), or both (mixed cardioinhibitory and vasodepressor types). The diagnosis can be confirmed by performing carotid sinus massage with ECG and blood pressure monitoring in a controlled setting. Symptomatic carotid sinus hypersensitivity should also be treated with permanent pacemaker therapy.[125] However, some patients, particularly those with a significant vasodepressor component, still experience syncope or dizziness. The choice of definitive drug therapy in this situation is marred by the lack of controlled trials, although α-adrenergic stimulants such as midodrine are often tried in addition to the pacemaker.[126]

Vasovagal syndrome, by causing bradycardia, sinus arrest, and/or hypotension, is the cause of syncope in many patients who present with recurrent fainting of unknown origin.[127] By history, many individuals can recount rare instances of fainting spells at times of duress or fear. These episodes are most often caused by vasovagal syncope. However, some patients have extremely frequent, unexpected syncopal episodes that interfere with the patient's quality of life and cause physical danger (sometimes referred to as neurocardiogenic syncope syndrome or malignant vasovagal syndrome). Vasovagal syncope is presumed to be a neurally mediated, paradoxical reaction involving stimulation of cardiac mechanoreceptors (ie, Bezold-Jarisch reflex). Forceful contraction of the ventricle (eg, as with adrenergic stimulation) coupled with low ventricular volumes (eg, with upright posture or dehydration) provides a powerful stimulus for cardiac mechanoreceptors. Syncope results from the spontaneous development of transient hypotension (sympathetic withdrawal) and bradycardia (vagotonia). However, the true mechanism of vasovagal syncope remains to be definitively determined. For instance, patients with denervated hearts (eg, heart transplant recipients) can still experience this form of syncope. This observation has led some to question the ultimate role of the Bezold-Jarisch reflex in these patients. Regardless, patients believed to have frequent episodes of vasovagal syncope have been evaluated and diagnosed using the upright body-tilt test, a potent stimulus for the development of vasovagal

symptoms.[128] Although commonly used, the sensitivity and reproducibility of this test have been questioned.[129]

Traditionally, β-blockers, such as metoprolol, were frequently chosen as the drugs of choice in preventing episodes of vasovagal syncope. Although these drugs may seem inappropriate to treat a syndrome resulting from vasodilation and bradycardia, the therapeutic approach is designed to block an inappropriate vasovagal reaction (ie, they inhibit the sympathetic surge that causes forceful ventricular contraction and precedes the onset of hypotension and bradycardia). To most clinicians' surprise, most controlled trials of the use of β-blockers in patients with severe vasovagal syncope have shown no effect compared with placebo in preventing syncopal episodes.[130] Some trials have suggested that β-blockers are more effective and should be used in older patients (older than 40 years of age) with vasovagal syncope rather than the relatively young.[131] Other drugs that have been used successfully (with or without β-blockers) include mineralocorticoids as volume expanders (fludrocortisone), anticholinergic drugs (scopolamine patches, disopyramide), α-adrenergic agonists (midodrine), adenosine analogs (theophylline, dipyridamole), and selective serotonin receptor antagonists (sertraline, paroxetine).[132] Permanent pacing has been used with some success but should be reserved for drug-refractory patients.[127] Because of the questionable effectiveness of β-blockers and the paucity of controlled or comparative trials, there is not a true drug of choice for severe vasovagal syncope, and clinicians are left with choosing agents and judging clinical effectiveness in individual patients on a case-by-case basis.

Atrioventricular Block

Conduction delay or block may occur in any area of the AV conduction system: the AV node, the His bundle, or the bundle branches. AV block is usually categorized into three different types based on ECG findings (**Table 18-13**). First-degree AV block is 1:1 AV conduction with a prolonged PR interval. Second-degree AV block is divided into two forms: Mobitz I AV block (Wenckebach periodicity) is less than 1:1 AV conduction with progressively lengthening PR intervals until a ventricular complex is dropped; Mobitz II AV block is intermittently dropped ventricular beats in a random fashion without progressive PR lengthening. Third-degree AV block is complete heart block where AV conduction is totally absent (AV dissociation). First-degree AV block usually represents prolonged conduction in the AV node. Mobitz I, second-degree AV block is also usually caused by prolonged conduction in the AV node. In contrast, Mobitz II, second-degree AV block is usually caused by conduction disease below the AV node (ie, His bundle). Third-degree AV block may be caused by disease at any level of the AV conduction system: complete AV nodal block, His bundle block, or trifascicular block. In this situation, the ventricle beats independently of the atria (AV dissociation), and the rate of ventricular activation and QRS configuration are determined by the site of the AV block. The usual degree of automaticity of ventricular pacemakers progressively declines as the site of impulse generation moves down the ventricular conduction system. Therefore, the ventricular escape rate in cases of trifascicular block will be significantly less than complete AV nodal block. Consequently, trifascicular block is a much more dangerous form of AV block. For instance, complete AV block at the level of the AV node usually results in the ventricular rhythm being controlled by the stable AV junctional pacemaker (rate approximately 40 beats/min). In contrast, in complete AV block due to trifascicular or His bundle block, a much less reliable pacemaker with slower rates below the site of block controls ventricular rhythm.

TABLE 18-13 Forms of Atrioventricular Block

Type	Criteria	Site of Block
First-degree block	Prolonged PR interval (>0.2 second); 1:1 AV conduction	Usually AVN
Second-degree block		
Mobitz I	Progressive PR prolongation until QRS is dropped; <1:1 AV conduction	AVN
Mobitz II	Random nonconducted beats (absence of QRS); <1:1 AV conduction	Below AVN
Third-degree block	AV dissociation; absence of AV conduction	AVN or below

AV, atrioventricular; AVN, atrioventricular node.

AV block may be found in patients without underlying SHD such as trained athletes or during sleep when vagal tone is high. Also, AV block may be transient where the underlying etiology is reversible such as in myocarditis, myocardial ischemia, after CV surgery, or during drug therapy. β-Blockers, digoxin, or non-DHP CCBs may cause AV block, primarily in the AV nodal area. Class I AADs may exacerbate conduction delays below the level of the AV node (sodium-dependent tissue). In other cases, AV block may be irreversible, such as that caused by acute MI, rare degenerative diseases, primary myocardial disease, or congenital heart disease.

If patients with Mobitz II AV block or third-degree AV block develop signs or symptoms of poor perfusion (eg, altered mental status, chest pain, hypotension, shock), IV atropine (0.5 mg given every 3 to 5 minutes, up to 3 mg total dose) should be administered.[72] If these patients do not respond to atropine, transcutaneous pacing can be initiated. Sympathomimetic infusions such as epinephrine (2 to 10 mcg/min) or dopamine (2-10 mcg/kg/min) can also be used in the event of atropine failure and are particularly effective in sinus bradycardia/arrest and AV nodal block. An isoproterenol infusion (2-10 mcg/min) may be considered if the patient does not respond to dopamine or epinephrine; however, this drug should be used with caution because of its vasodilating properties and ability to increase myocardial oxygen consumption (particularly during active MI). As would be expected, these drugs usually do not help when the site of AV block is below the AV node (eg, Mobitz II or trifascicular AV block) because their primary mechanism is to accelerate conduction through the AV node. If patients with bradycardia or AV block present with signs and symptoms of adequate perfusion, no acute therapy other than close observation is recommended.

Patients with chronic symptomatic AV block should be treated with the insertion of a permanent pacemaker. Patients without symptoms can sometimes be followed closely without the need for a pacemaker. The reader is referred for more detail to the national consensus guidelines for pacemaker implantation.[114] Patients with acute MI and evidence of new AV block or conduction disturbances will often require the insertion of a temporary transvenous pacemaker. AV block more commonly occurs as a complication of inferior wall MIs because of high vagal innervation at this site, and the coronary blood flow to the nodal areas usually supplies the inferior wall. However, the AV block may only be

transient, obviating the need for permanent pacing.

EVALUATION OF THERAPEUTIC AND ECONOMIC OUTCOMES

Generally, patients who suffer from tachyarrhythmias can be monitored for one or several possible therapeutic outcomes. Obviously, the presence or recurrence of any arrhythmia can be documented by electrocardiographic means (eg, surface ECG, Holter monitor, or event monitor). Furthermore, patients may experience a decrease in blood pressure that may result in symptoms ranging from light-headedness to abrupt syncope, depending on the rate of the arrhythmia and the status of the underlying heart disease. For some patients, the potential alteration in hemodynamics may result in death if the arrhythmia is not detected and treated immediately. Besides these clinical outcomes, many patients with tachyarrhythmias experience alterations in quality of life as a result of recurrent symptoms of the arrhythmia or from side effects of therapy. And, finally, there are the economic considerations of medical or surgical intervention, continued medical care, and chronic drug or nonpharmacologic treatment.[133,134] Most of the studies are limited to the use of nonpharmacologic therapies such as the ICD or radiofrequency ablation.[77,135] Because that technology is rapidly evolving, what is not very cost-effective now may indeed be cost-effective in the next several years. For example, original cost-effectiveness analysis of the ICD showed it to be highly sensitive to the life of the generator, yet newer-generation devices have made significant advances not only in their size but also in their battery life. More recent data on the effect of the ICD on mortality coupled with the declining costs of an ICD imply that the device is indeed cost-effective in certain subsets of patients, which is similar to well-proven drug therapies used for other disorders.[135] Other nonpharmacologic treatments, such as catheter ablation for PSVT, not only improve quality of life but also save money on medical expenditures compared with chronic drug therapy.[76]

There are some therapeutic outcomes that are unique to certain arrhythmias. For instance, patients with AF or AFl need to be monitored for thromboembolism and for complications of antithrombotic therapy (bleeding, drug interactions). However, the most important monitoring parameters for most patients fall into the following categories: (a) mortality (total and arrhythmic); (b) arrhythmia recurrence (duration, frequency, symptoms); (c) hemodynamic consequences (heart rate, blood pressure, symptoms); and (d) treatment complications (side effects or need for alternative or additional drugs, devices, surgery) (**Table 18-14**). When evaluating the arrhythmia literature, care should be taken to consider real outcomes. For example, total mortality is more meaningful than SCD rates; it is possible an intervention prevents arrhythmic death but patients die from other causes, leaving all-cause mortality unaltered. Likewise, surrogate markers of drug efficacy (eg, noninducible tachycardia, suppression of minor arrhythmias) should be judged with a degree of skepticism. One should ask: Did the treatment make patients live longer (reduce mortality)? Did the treatment make them feel better (improve humanistic outcomes or quality of life)? Was the treatment economically worth it (cost-effective)?

TABLE 18-14 Arrhythmia Outcomes

Mortality
Total, all-cause

- Arrhythmic death (ie, sudden cardiac death)

Recurrences documented by electrocardiogram

- Time to recurrence
- Frequency of recurrences

Tolerance

- Symptoms
- Blood pressure
- Rate of tachycardia

Surrogate markers of efficacy such as:

- Number of premature ventricular complexes per day
- Inducibility of tachycardia with programmed stimulation

Necessity of nondrug interventions (eg, ICD)

ICD shocks

Side effects of drugs/treatment complications

Quality of life

Economics

Outcomes specific to tachycardia (eg, systemic embolism in atrial fibrillation)

ICD, implantable cardioverter-defibrillator.

Chapter 19: Venous Thromboembolism

Daniel M. Witt; Nathan P. Clark; Sara R. Vazquez

INTRODUCTION

KEY CONCEPTS

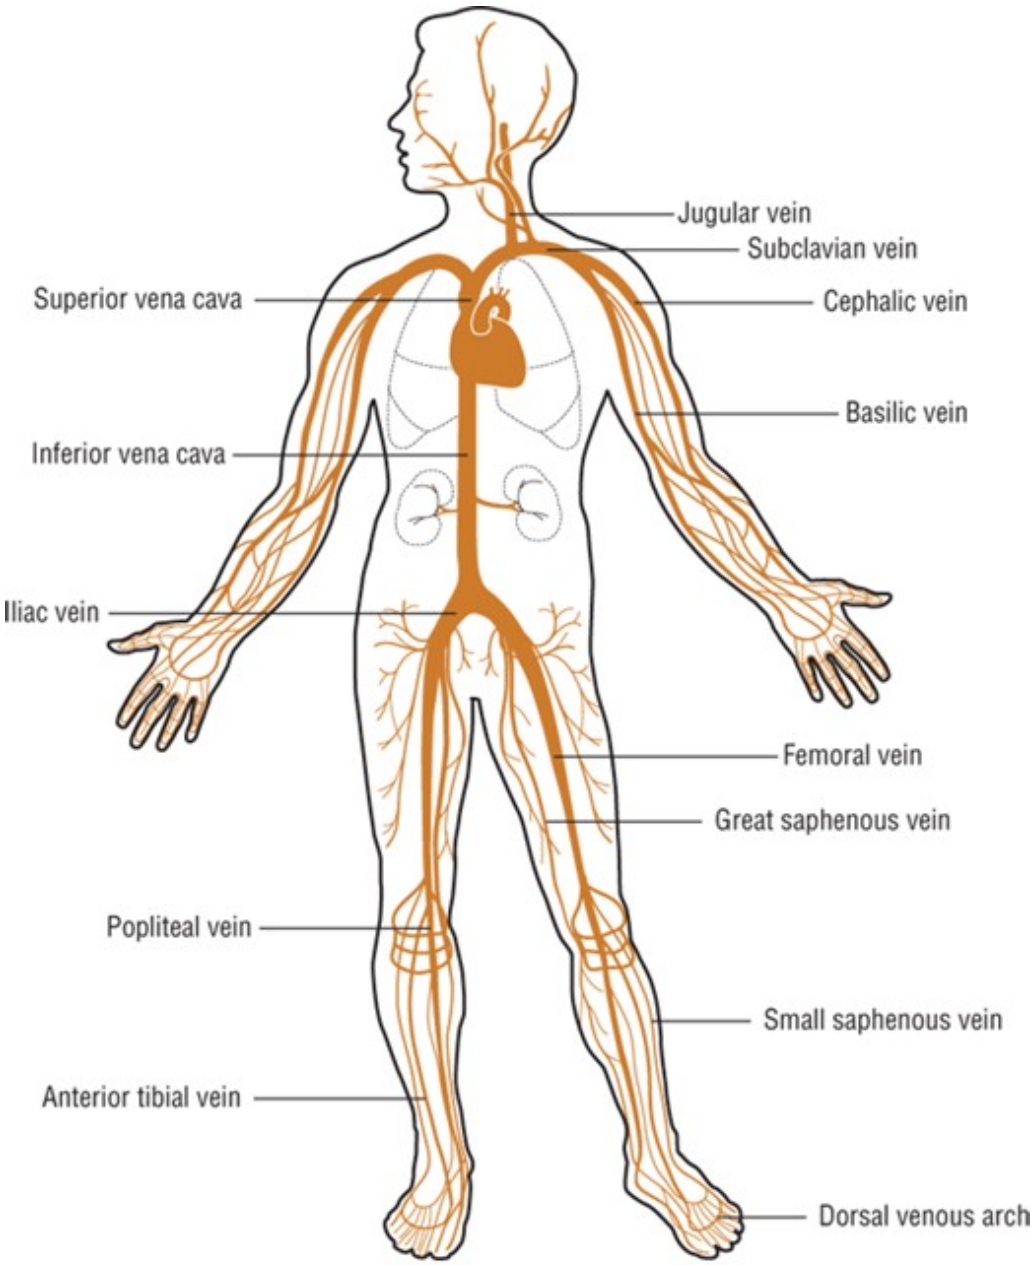
- 1 Venous thromboembolism (VTE) is often associated with identifiable risk factors.
- 2 The diagnosis of VTE should be confirmed by objective testing.
- 3 During hospitalization, patients should receive prophylaxis against VTE corresponding to their degree and duration of risk.
- 4 Initial VTE treatment should include a rapid-acting anticoagulant.
- 5 During warfarin initiation injectable anticoagulants should be overlapped with warfarin for at least 5 days and until the patient's international normalized ratio is more than or equal to 2.0 for at least 24 hours.
- 6 Most patients with uncomplicated deep vein thrombosis (DVT) or pulmonary embolism (PE) can be safely treated as outpatients.
- 7 Most patients with VTE should receive 3 months of anticoagulation therapy; duration of anticoagulation therapy beyond 3 months should be based on risks for VTE recurrence and major bleeding as well as patient preferences.
- 8 Optimal anticoagulant management requires knowledge of pharmacologic and pharmacokinetic characteristics as well as systematic management and ongoing patient education.
- 9 Direct oral anticoagulants (DOACs), such as rivaroxaban, apixaban, dabigatran, and edoxaban, are a significant advancement in VTE treatment.

Venous thromboembolism (VTE) is a potentially fatal disorder and significant health problem in our aging society.[1] VTE results from clot formation within the venous circulation and is manifested as

deep vein thrombosis (DVT) and/or pulmonary embolism (PE) (**Fig. 19-1**).[1] DVT is rarely fatal, but PE can result in death within minutes of symptom onset, before effective treatment can be given. Beyond the symptoms produced by the acute event, VTE complications, such as the postthrombotic syndrome and chronic thromboembolic pulmonary hypertension (CTPH), also cause substantial disability and suffering.[1] Identifying VTE risk factors is important for targeting patients at high risk for VTE to guide prevention strategies.[2,3,4]

FIGURE 19-1

Venous circulation.



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Rapid and accurate diagnosis is critical to making appropriate treatment decisions when VTE is

suspected.[5] Optimal use of anticoagulant drugs for prevention and treatment of VTE requires an in-depth knowledge of their pharmacology and pharmacokinetic properties, and a comprehensive approach to patient management.[6] Bleeding is a common and serious complication of administering anticoagulant drugs.[2,3,4]

EPIDEMIOLOGY

Venous thromboembolism is associated with major global disease burden.[7] The incidence rate of symptomatic first VTE is estimated at 1.32 per 1,000 patient-years and occurs more frequently in women (55.6%).[8] When standardized by age, Asians appear to have the lowest VTE incidence (1.22 per 1,000 patient-years) followed by whites (1.91) and blacks (2.03).[8] The rate of recurrent VTE is highest in the 180 days following the initial event and declines slowly over the next 4 to 10 years to a relatively constant rate. The 10-year cumulative risk of recurrent VTE is approximately 25.0%.[8]

ETIOLOGY

1 A number of identifiable factors increase the risk of developing VTE (**Table 19-1**). Many risk factors fall into categories constituting what is known as Virchow's triad: blood stasis, vascular injury, and hypercoagulability.

TABLE 19-1 Risk Factors for Venous Thromboembolism

Risk Factor	Comments/Examples
Age	Annual incidence increases from 10 per 100,000 in adolescence to 1 per 100 in old age
History of VTE	Potent risk factor for recurrence, risk is highest during the first 180 days after VTE
Blood stasis	Acute medical illness requiring hospitalization
	Surgery (especially general anesthesia >30 minutes)
	Paralysis (eg, status post stroke, spinal cord injury)
	Immobility (eg, plaster casts, status post stroke or spinal cord injury)
	Polycythemia vera
	Obesity
Vascular injury	Major orthopedic surgery (eg, knee or hip replacement)
	Trauma (especially fractures of the pelvis, hip, or leg)
	Indwelling venous catheters
Hypercoagulability	Malignancy, diagnosed or occult

Risk Factor	Comments/Examples
	Factor V Leiden (homozygous >>heterozygous)
	Prothrombin (G20210A) gene mutation
	Protein C deficiency
	Protein S deficiency
	Antithrombin deficiency
	Factor VIII excess (>90th percentile)
	Factor XI excess (>90th percentile)
	Antiphospholipid antibodies
	Lupus anticoagulant
	Anticardiolipin antibodies
	Anti–β_2-glycoprotein I antibodies
	Inflammatory bowel disease
	Nephrotic syndrome
	Paroxysmal nocturnal hemoglobinuria
	Pregnancy/postpartum
	Drug therapy (eg, estrogen-containing contraceptives, estrogen replacement therapy, tamoxifen, raloxifene, cancer therapy, heparin-induced thrombocytopenia)

VTE, venous thromboembolism.

Data from References 2, 3, 4, 12, 15.

Blood Stasis

Blood stasis favors clotting in part through reduced clearance of the elements responsible for blood clot formation.[9] Contraction of the calf and thigh muscles coupled with one-way valves in leg veins facilitate blood flow back to the heart and lungs; thus, damage to venous valves and periods of prolonged immobility result in venous stasis.[10] Blood stasis in the venous system partly explains why numerous medical conditions and surgical procedures are associated with an increased VTE risk (see Table 19-1).

Vascular Injury

Intact vascular endothelial cells separate flowing blood from vessel wall components responsible for preventing blood loss through clot formation (see detailed description in PATHOPHYSIOLOGY section). Vascular injury (eg, surgery and trauma) disrupts this protective barrier and initiates blood clot formation.[11]

Hypercoagulability

Inherited and acquired conditions and certain drugs have been linked to blood hypercoagulability (see Table 19-1). Inherited and acquired hypercoagulability disorders will be covered in detail later. Estrogen-containing contraception, estrogen replacement therapy, and selective estrogen receptor modulators are all linked to VTE risk.[12] Women with inherited hypercoagulability disorders are at particularly high risk of developing VTE during pregnancy and while taking estrogens.[12]

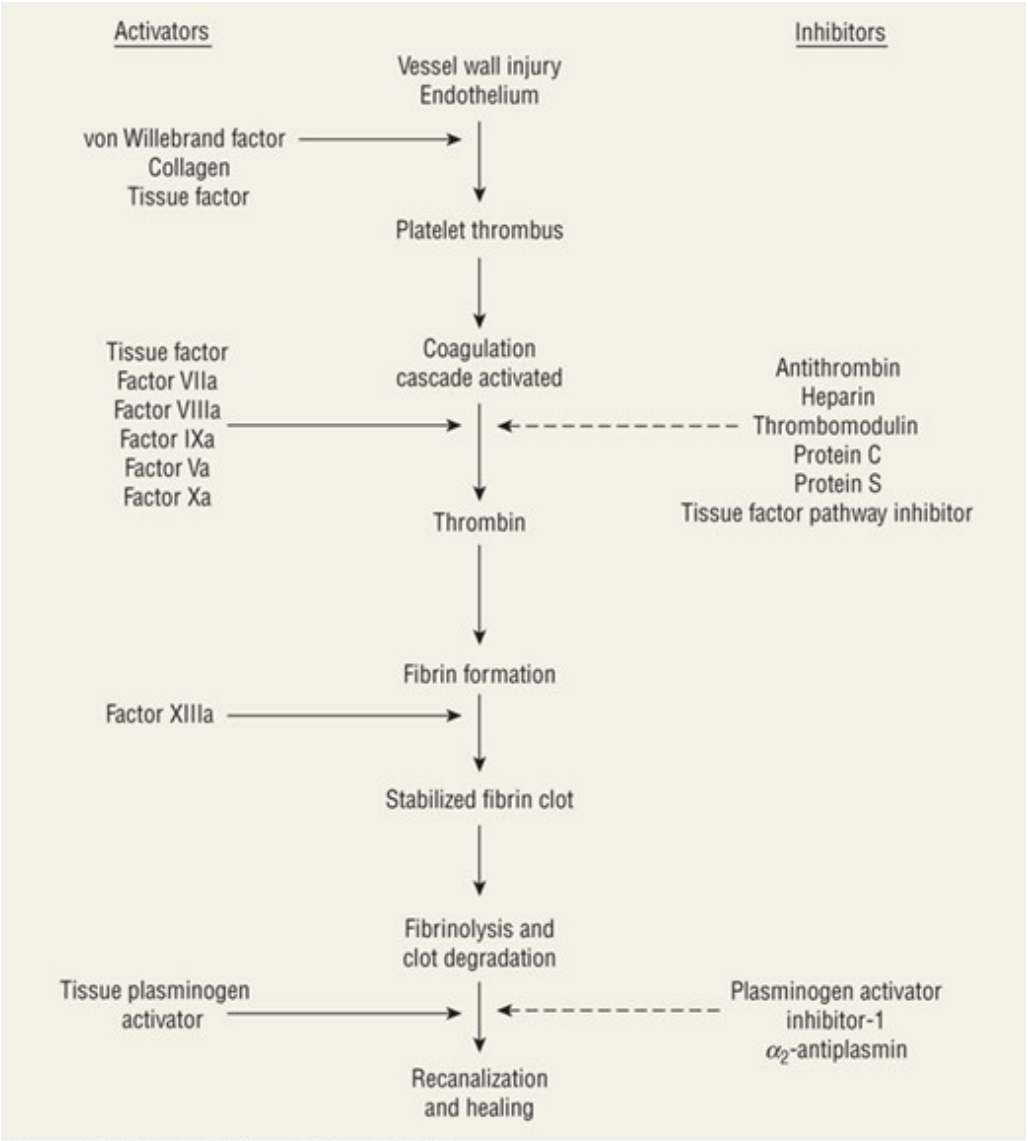
In many cases, VTE is the result of converging combinations of inherited and acquired thrombotic risk factors. Thus, many individuals with congenital hypercoagulable conditions experience VTE only after being placed in high-risk situations such as orthopedic surgery, immobilization, the use of estrogen-containing oral contraceptives, or pregnancy. Approximately 34.0% of VTEs are provoked by identifiable risk factors.[8]

PATHOPHYSIOLOGY

Hemostasis is the process responsible for maintaining the integrity of the circulatory system following blood vessel damage (**Fig. 19-2**).[11] Hemostatic clots remain localized to the vessel wall and do not greatly impair blood flow. In contrast, pathologic clots like those causing VTE result in blood flow impairment and often cause complete vessel occlusion.[11]

FIGURE 19-2

Overview of hemostasis.



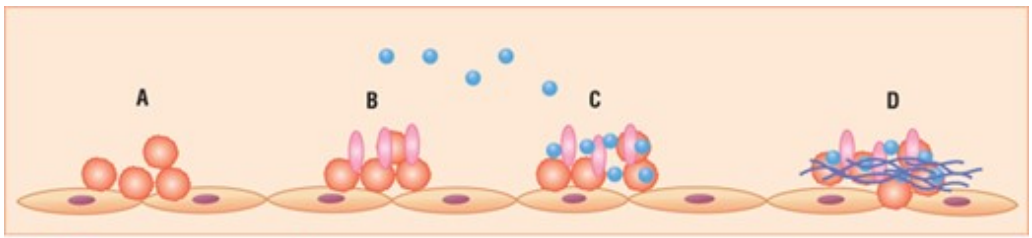
Collagen and tissue factor (TF) form a hemostatic barrier around blood vessels and organs. Under normal circumstances, endothelial cells lining the vessel wall physically separate collagen and TF from circulating platelets and clotting factors (namely, activated factor VII [VIIa]). Vessel injury results in platelet activation and TF-mediated initiation of the clotting factor cascade culminating in the formation of thrombin and ultimately fibrin clot, which seals the breach (see Fig. 19-2).[11] In contrast to physiologic hemostasis, pathologic VTE often occurs in the absence of gross vessel wall damage and may be triggered by TF brought to the clot formation site by circulating microparticles. Venous clots are mainly composed of fibrin with platelets and trapped red blood cells and often occur in areas of disturbed blood flow (eg, valve cusps in the deep leg veins).[11]

The activation of platelets and the coagulation cascade occur nearly simultaneously. Platelets become actively involved in thrombus formation after binding to various adhesion proteins (eg, von Willebrand factor, collagen) when blood is exposed to damaged vessel endothelium.[11] A platelet thrombus develops as activated platelets recruit additional platelets, some of which also become activated while others remain loosely associated without undergoing activation and ultimately break

away from the growing thrombus. Activated platelets change shape and release components critical for sustaining further thrombus formation into the environment surrounding the developing clot.[11] Activated platelets accumulating in the thrombus also express P-selectin, an adhesion molecule that facilitates capture of blood-borne microparticles bearing TF triggering fibrin clot formation via the coagulation cascade (**Fig. 19-3**).[11] As described in the next section, important coagulation cascade reactions take place on the surfaces of activated platelets.[11]

FIGURE 19-3

Model of pathologic thrombus formation: (*A*) activated platelets adhere to vascular endothelium; (*B*) activated platelets express P-selectin; (*C*) pathologic microparticles express active tissue factor and are present at a high concentration in the circulation—these microparticles accumulate, perhaps by binding to activated platelets expressing P-selectin; (*D*) tissue factor can lead to thrombin generation, and thrombin generation leads to fibrin clot formation. *(Adapted from reference 11.)*



The conceptual model for the coagulation cascade has evolved from the classic depiction of extrinsic, intrinsic, and common pathways (**Fig. 19-4**) to a more modern notion whereby highly regulated reactions take place on cell surfaces in three overlapping phases: initiation, amplification, and propagation. The cascade starts on TF-bearing cells, and continues on the surfaces of activated platelets (**Fig. 19-5**).[11]

FIGURE 19-4

Classic depiction of the coagulation cascade.

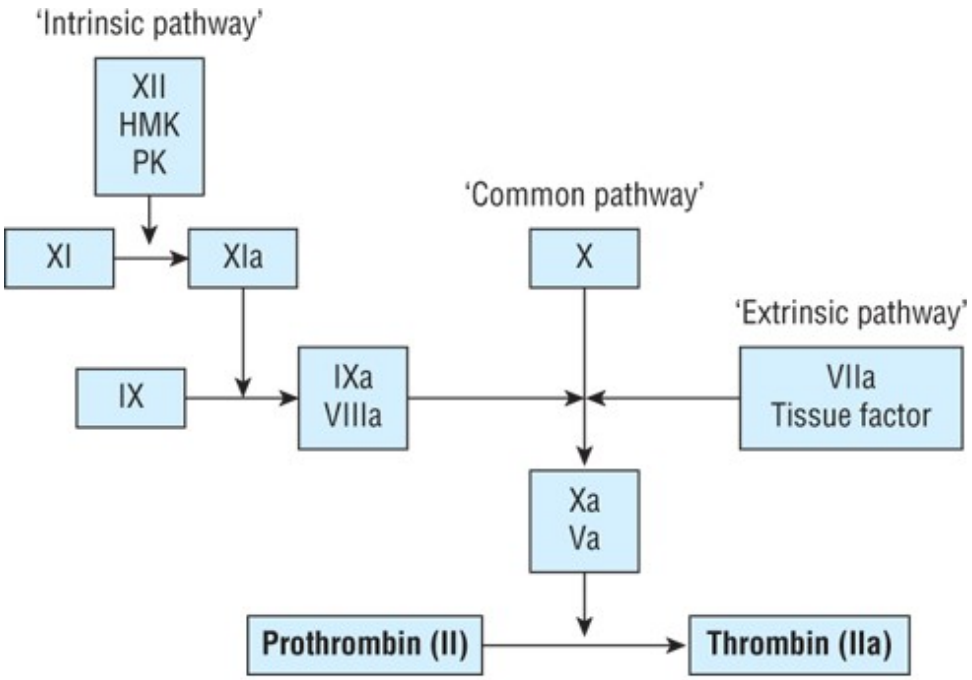


FIGURE 19-5

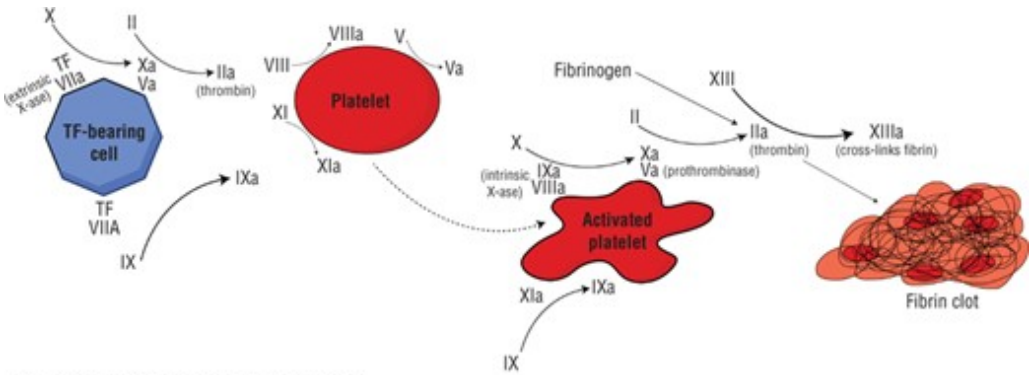
Cellular coagulation cascade model. *(Adapted from reference 11.)*



The initiation phase takes place on TF-bearing cells exposed after vessel injury or captured via P-selectin (see Fig. 19-3). The TF/VIIa complex (known as extrinsic tenase) activates limited amounts of factors IX and X. The resulting factor Xa then associates with factor Va to form the prothrombinase complex, which cleaves prothrombin (factor II) to generate a small (picomolar) amount of thrombin (factor IIa) (see Fig. 19-5). Factor IXa moves from TF-bearing cells to the surface of activated platelets in the growing platelet thrombus. Tissue factor pathway inhibitor (TFPI), an important regulator of TF/FVIIa-induced coagulation, rapidly terminates the initiation phase.[11]

In the amplification phase the small amount of thrombin produced during initiation activates factors V and VIII, which bind to platelet surfaces and support the large-scale thrombin generation occurring during the propagation phase. Platelet-bound factor XI is also activated by thrombin during this

phase.[11]

A burst of thrombin generation occurs during the propagation phase as the VIIIa/IXa (known as "intrinsic tenase") and prothrombinase complexes assemble on the surface of activated platelets and accelerate the generation of factor Xa and thrombin, respectively. Thrombin generation is further supported by factor XIa bound to the platelet surface, which activates factor IX to form additional intrinsic tenase.[11]

Thrombin generated during the propagation phase converts fibrinogen to fibrin monomers that precipitate and polymerize to form fibrin strands. Factor XIIIa, which is also activated by the action of thrombin, covalently bonds these strands to one another (see Fig. 19-5) to form an extensive meshwork that surrounds and encases the aggregated platelet thrombus and red blood cells to form a stabilized fibrin clot.[11] Clot formation is eventually terminated when the expanding meshwork of platelets and fibrin "paves over" the initiation site and additional activated factors are unable to diffuse through the overlying layer of clot.

Normally, a number of tempering mechanisms control coagulation (see Fig. 19-2). Without effective self-regulation, thrombus formation would cause vascular occlusion. Intact endothelium adjacent to the damaged tissue actively secretes several antithrombotic substances.[9] Thrombomodulin modulates thrombin activity by converting protein C to its active form (aPC). When joined with its cofactor protein S, aPC inactivates factors Va and VIIIa regulating the functionality of the prothrombinase and tenase complexes, respectively.[9] aPC and protein S prevent coagulation reactions from spreading to healthy, uninjured vessel walls. Antithrombin is a circulating protein that inhibits thrombin and factor Xa. Heparan sulfate, a heparin-like compound secreted by endothelial cells, exponentially accelerates antithrombin activity.[9] As described previously, TFPI plays an important role by regulating the initiation of the coagulation cascade.[11] When these self-regulatory mechanisms are intact, fibrin clot is limited to the zone of vessel injury. However, disruptions in the system can result in hypercoagulability.[13]

The fibrinolytic system is responsible for blood clot dissolution.[14] Inactive plasminogen is converted by tissue plasminogen activator (tPA) to active plasmin, an enzyme that degrades fibrin mesh into soluble end products collectively known as fibrin degradation products including D-dimer.[14] The fibrinolytic system is also under the control of a series of stimulatory and inhibitory substances (see Fig. 19-2). Plasminogen activator inhibitor-1 inhibits tPA and α_2-antiplasmin inhibits plasmin activity. Impaired functioning of the fibrinolytic system has also been linked to hypercoagulability and thrombotic complications.[14]

Although a thrombus can form in any part of the venous circulation, most begin in the leg(s). Thrombus isolated in calf veins is unlikely to break loose (embolize), but thrombus involving the popliteal and larger veins above it are more likely to embolize and travel through the right side of the heart and lodge in the pulmonary artery or one of its branches, occluding blood flow to the lung and impairing gas exchange. Without treatment, the affected portion of the lung becomes necrotic and oxygen delivery to other vital organs decreases, potentially resulting in fatal circulatory collapse.[1]

Inherited and Acquired Hypercoagulability Disorders

Disturbances in hemostatic regulation processes may result in hypercoagulability. Disorders of hypercoagulability can be inherited or acquired.[13] aPC resistance increases the risk of VTE approximately threefold and is the most common inherited hypercoagulability disorder (prevalence rate in Caucasians 2.0%-7.0%).[13] Most aPC resistance results from a factor V gene mutation that renders it resistant to degradation by aPC. This mutation is known as factor V Leiden, named after the city of Leiden, Holland, where the defect was first described.[13]

The prothrombin G20210A mutation is the second most frequent inherited hypercoagulability disorder, occurring in about 2.0% to 4.0% of Caucasians and imparting about a threefold increased risk of VTE.[13] This mutation increases circulating prothrombin, and enhanced thrombin generation has been observed, but the mechanism whereby this disorder increases VTE risk is not completely understood.[15] Given the prevalence of factor V Leiden and prothrombin G20210A mutation in the general population, some patients inherit multiple genetic defects greatly increasing the lifetime VTE risk.[13]

Although an accurate quantification of the VTE risk associated with inherited protein C, protein S, and antithrombin deficiencies (present in less than 1% of the population) is not known, many experts believe the lifetime risk is high, perhaps sevenfold higher than patients without such disorders. Many patients with protein C, protein S, or antithrombin deficiency will suffer VTE prior to age 60.[15]

Acquired disorders of hypercoagulability may result from malignancy, the presence of antiphospholipid antibodies, or estrogen use. A strong link between cancer and thrombosis has long been recognized.[16] Tumor cells secrete a number of procoagulant substances that activate the coagulation cascade, and patients with cancer often have suppressed levels of protein C, protein S, and antithrombin. Cancer cells may use thrombotic mechanisms to recruit a blood supply, metastasize, and create barriers against host defense mechanisms.[16]

Antiphospholipid antibodies are a heterogeneous group of antibodies targeting proteins that bind phospholipids.[15] These include antibodies that prolong phospholipid-based clotting assays, known as lupus anticoagulants, as well as anticardiolipin and β_2-glycoprotein (β_2-gp) I antibodies. Antiphospholipid antibodies are found in up to 5% of normal healthy populations but are more common in patients with autoimmune disorders such as systemic lupus erythematosus and inflammatory bowel disease. The precise mechanism by which antiphospholipid antibodies provoke thrombosis remains to be definitively determined. Contributing factors include complement activation, inhibition of protein C and fibrinolysis, platelet activation, and increased TF expression.[15]

CLINICAL PRESENTATION (INCLUDING DIAGNOSTIC CONSIDERATIONS)

2 The symptoms of DVT or PE are nonspecific and objective tests are required to confirm or

exclude the diagnosis. Patients with DVT frequently present with unilateral leg pain and swelling. Postthrombotic syndrome, a long-term complication of DVT caused by damage to the venous valves, may also result in chronic lower extremity swelling, pain, tenderness, skin discoloration, and, in the most severe cases, ulceration. PE typically presents with chest pain, shortness of breath, tachypnea, and tachycardia, which in some cases may result in cardiopulmonary collapse.[5,17]

Given that VTE can be debilitating or fatal, it is important to treat quickly and aggressively. Conversely, because major bleeding induced by anticoagulant drugs can be equally harmful, it is important to avoid treatment when the diagnosis is not a reasonable certainty. Assessment of the patient's status should focus on the search for risk factors in the patient's medical history (see Table 19-1). Even in the presence of mild, seemingly inconsequential symptoms, VTE should be strongly suspected in those with multiple risk factors.[17]

Radiographic contrast studies (venography and pulmonary angiography) are the most accurate VTE diagnostic methods, but are expensive invasive procedures technically difficult to perform and evaluate. Severely ill patients are often unable to tolerate these procedures, and many develop hypotension and cardiac arrhythmias. The contrast medium is also nephrotoxic and irritating to vessel walls and may paradoxically precipitate VTE.[18] For these reasons, less invasive tests, such as compression ultrasound (CUS) (either full leg or proximal segments only) and computed tomography pulmonary angiography (CTPA) are most used in clinical practice for the initial evaluation of patients with suspected VTE. In patients with allergy to contrast media, renal impairment, or high radiation exposure risk, the ventilation–perfusion (V/Q) scan is an alternative PE diagnostic test.[19]

D-dimer is a fibrin clot degradation product and levels are significantly elevated in patients with acute thrombosis. Although D-dimer is a very sensitive marker of clot formation, it is not sufficiently specific. A variety of conditions are associated with D-dimer elevations, including recent surgery or trauma, pregnancy, increasing age, and cancer; therefore, a positive D-dimer test is not conclusive evidence of VTE diagnosis. However, a *negative* D-dimer (for most assays defined as less than 500 ng/mL [mcg/L]) can be useful in ruling out the diagnosis of VTE.[19] As advanced age is known to elevate D-dimer levels, utilizing age-adjusted D-dimer cutoffs for ruling out VTE in patients over age 50 is being evaluated. The most promising strategy involves multiplying patient age by 10 to obtain an age-adjusted D-dimer threshold (eg, an 80-year-old patient's D-dimer threshold would be 800 ng/mL [mcg/L]). Appropriate use of D-dimer should include initial risk stratification using a validated clinical assessment tool.[19]

Clinical assessment significantly improves the diagnostic accuracy of noninvasive tests such as CUS, CTPA, and D-dimer. Simple clinical assessment checklists such as the Wells score can be used to determine if a patient is "likely" or "unlikely" to have DVT or PE (**Figs. 19-6 and 19-7**).[18] Patients with likely probability of VTE have more than 60% chance of VTE, compared with less than 10% chance for patient's with unlikely probability.[19] In general, patients with unlikely probability of VTE should first receive D-dimer testing. If the D-dimer result is below the defined cutoff point, VTE is ruled out; if above the cutoff point, the patient should receive appropriate diagnostic imaging (either CUS for suspected DVT or CTPA for suspected PE). All patients with likely probability of DVT should receive either proximal (popliteal, femoral, and iliac veins) or full leg CUS. A normal full leg ultrasound rules

out DVT, whereas a normal proximal ultrasound requires additional testing with D-dimer, full leg ultrasound, or repeat proximal ultrasound surveillance in 1 week. Patients with CUS indicating proximal DVT should receive anticoagulant treatment. Evidence of distal vein DVT (anterior and posterior tibial, peroneal, gastrocnemius veins) after full leg ultrasound may be treated with anticoagulants or have further ultrasound surveillance to assess for propagation into the proximal deep veins of the leg (see Fig. 19-6). Patients with a likely probability of PE should receive imaging with either CTPA or V/Q scan. A negative imaging result rules out PE, whereas a positive imaging result indicates need for anticoagulant treatment (see Fig. 19-7).[5,17,18,19]

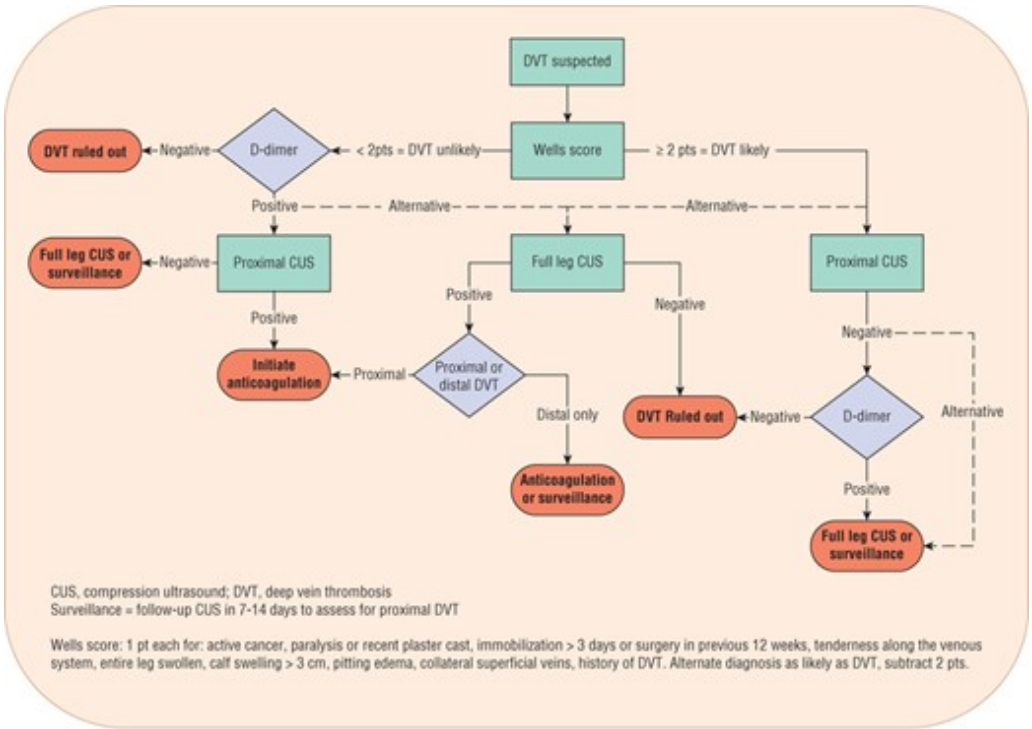

FIGURE 19-7

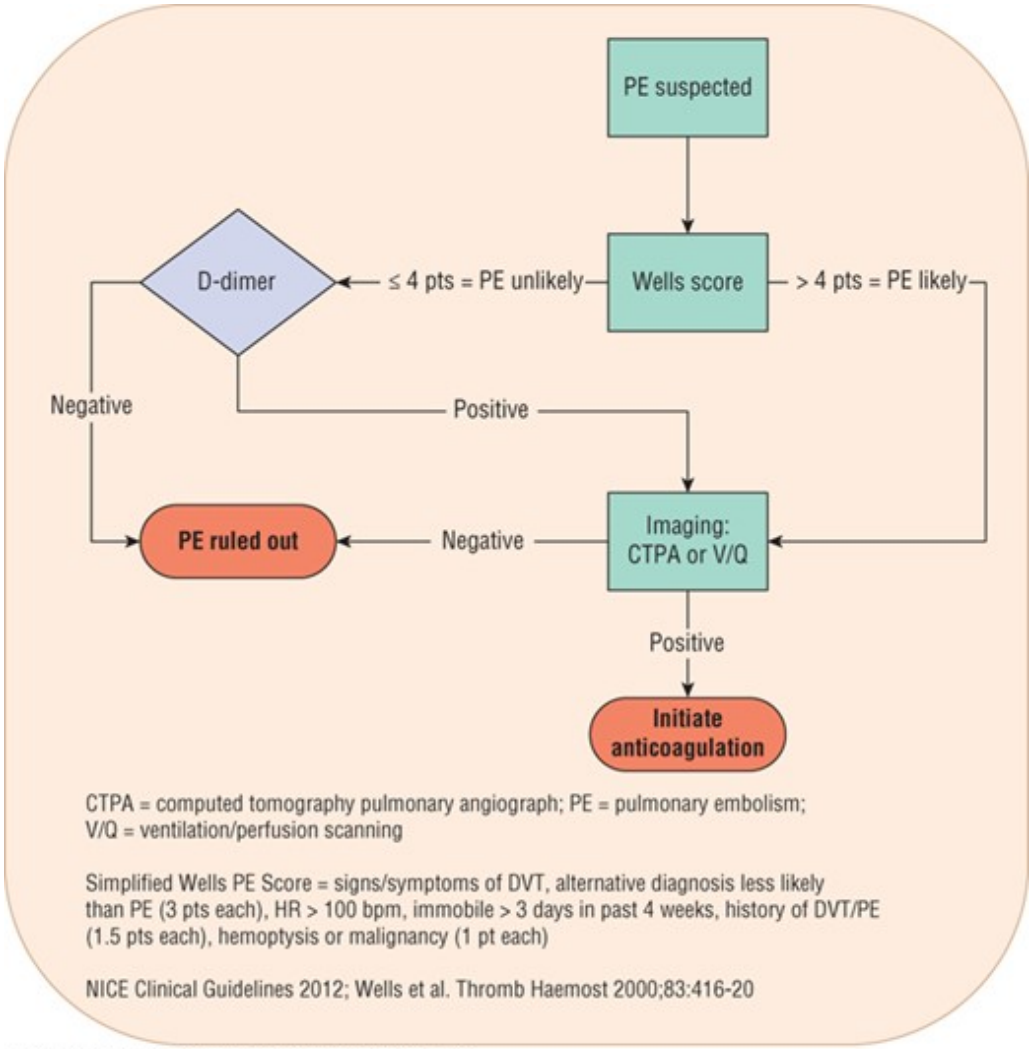
Pulmonary embolism diagnostic algorithm.



PREVENTION AND TREATMENT

Unfortunately, there is little public awareness of the life-threatening nature of DVT and PE. A global survey conducted by the International Society of Thrombosis and Hemostasis suggests that half of patients surveyed have little or no awareness of VTE, and less than half of respondents could identify VTE risk factors.[20] VTE awareness was substantially lower than for other disease states like stroke, heart attack, and breast cancer, each of which have major public awareness campaigns. This underscores the need to increase knowledge of the risks, signs, and symptoms of VTE through increased media visibility.

Desired Outcomes

Prevention strategies in at-risk populations positively impact patient outcomes because VTE is potentially fatal and costly to treat.[21] Treatment of VTE is aimed at preventing thrombus extension and embolization, reducing recurrence risk, and preventing long-term complications such as the postthrombotic syndrome and CTPH. Carefully managed use of anticoagulant drugs is important to

reduce the risk of bleeding associated with these agents.

General Approach to the Prevention of Venous Thromboembolism

Effective prophylaxis can reduce the risk of fatal PE in high-risk surgical and medical populations, whereas early ambulation is often sufficient for those at low risk of VTE.[22] Educational programs and clinical decision support systems have been shown to improve the appropriate use of VTE prevention methods.[23]

3 Despite ongoing efforts to minimize hospital-acquired VTE, up to one-third of hospitalized patients at high VTE risk without contraindications to anticoagulant therapy still do not receive appropriate prophylaxis.[24] The American College of Chest Physicians' *Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: Evidence-Based Clinical Practice Guidelines* (AT9) as well as the United Kingdom's National Institute for Health and Care Excellence (NICE) Guidelines provide evidence-based recommendations for VTE prevention and treatment.[17] A summary of AT9 VTE prophylaxis recommendations can be found in **Table 19-2**. Pharmacologic and mechanical methods are effective for preventing VTE and can be used alone or in combination.[2,3,4]

TABLE 19-2 Guidelines for the Prevention of Venous Thromboembolism

Medical illness

For acutely ill hospitalized medical patients at increased risk of thrombosis, thromboprophylaxis with low-molecular-weight heparin (LMWH), low-dose unfractionated heparin (LDUH) twice or three times daily, or fondaparinux is recommended (Grade 1B)[a]

For acutely ill hospitalized medical patients at low risk of thrombosis, use of pharmacologic prophylaxis or mechanical prophylaxis is not recommended (Grade 1B)

For acutely ill hospitalized medical patients who are bleeding or at high risk for bleeding, anticoagulant thromboprophylaxis is not recommended (Grade 1B)

For acutely ill hospitalized medical patients at increased risk of thrombosis who are bleeding or at high risk for major bleeding, optimal use of mechanical thromboprophylaxis with graduated compression stockings or intermittent pneumatic compression (IPC) is suggested (Grade 2C). When bleeding risk decreases, and if venous thromboembolism (VTE) risk persists, substitution of pharmacologic thromboprophylaxis for mechanical thromboprophylaxis is suggested (Grade 2B)

For critically ill patients, thromboprophylaxis with LMWH or LDUH is suggested over no prophylaxis (Grade 2C)

For critically ill patients who are bleeding, or are at high risk for major bleeding, mechanical thromboprophylaxis with graduated compression stockings or IPC is suggested (Grade 2C). When bleeding risk decreases, substitution of pharmacologic thromboprophylaxis for mechanical thromboprophylaxis is suggested (Grade 2C)

In outpatients with cancer who have no additional risk factors for VTE, routine prophylaxis is not recommended with LMWH or LDUH (Grade 2B) or warfarin (Grade 1B)

Routine thromboprophylaxis is not recommended for chronically immobilized persons residing at home or at a nursing home (Grade 2C)

For long-distance travelers at increased risk of VTE (including previous VTE, recent surgery or trauma, active malignancy, pregnancy, estrogen use, advanced age, limited mobility, severe obesity, or known thrombophilia disorder), frequent ambulation, calf muscle exercise, sitting in an aisle seat or below-the-knee graduated compression stockings providing 15-30 mm Hg (2-4 kPa) pressure at the ankle are suggested (Grade 2C)

In persons with thrombophilia but no previous history of VTE, the long-term daily use of mechanical or pharmacologic thromboprophylaxis to prevent VTE is not recommended (Grade 1C)

Surgical populations excluding orthopedics

For general and abdominal–pelvic surgery patients at very low risk for VTE, no specific pharmacologic (Grade 1B) or mechanical (Grade 2C) prophylaxis other than early ambulation is recommended

For patients at low risk of VTE after abdominal–pelvic surgery or cardiac surgery with an uncomplicated course, mechanical prophylaxis, preferably with IPC, over no prophylaxis is suggested (Grade 2C)

For patients at moderate VTE risk after general, abdominal–pelvic, or thoracic surgery, or cardiac surgery with a prolonged course not at high risk for major bleeding complications, LMWH or LDUH (Grade 2B), or mechanical prophylaxis, preferably with IPC (Grade 2C), is suggested over no prophylaxis

For patients at moderate risk for VTE after general, abdominal–pelvic surgery, thoracic surgery, or cardiac surgery who are at high risk for major bleeding complications or those in whom the consequences of bleeding are thought to be particularly severe, mechanical prophylaxis, preferably with IPC, is suggested over no prophylaxis (Grade 2C)

For patients at high risk for VTE after general, abdominal–pelvic, and thoracic surgery who are not at high risk for major bleeding complications, pharmacologic prophylaxis with LMWH (Grade 1B) or LDUH (Grade 1B) is suggested over no prophylaxis. Combination with graduated compression stockings or IPC is also suggested (Grade 2C)

For high-VTE-risk general, abdominal–pelvic, and thoracic surgery patients who are at high risk for major bleeding complications or those in whom the consequences of bleeding are thought to be particularly severe, the use of mechanical prophylaxis, preferably with IPC, is suggested over no prophylaxis until the risk of bleeding diminishes and pharmacologic prophylaxis may be initiated (Grade 2C)

For high-VTE-risk patients undergoing abdominal or pelvic surgery for cancer who are not

otherwise at high risk for major bleeding complications, extended-duration pharmacologic prophylaxis (4 weeks) with LMWH is recommended over shorter-duration prophylaxis (Grade 1B)

For general and abdominal–pelvic surgery patients at high risk for VTE in whom both LMWH and LDUH are contraindicated or unavailable and who are not at high risk for major bleeding complications, low-dose aspirin (Grade 2C), fondaparinux (Grade 2C), or mechanical prophylaxis, preferably with IPC (Grade 2C), is suggested over no prophylaxis

For general and abdominal–pelvic surgery patients, an inferior vena cava (IVC) filter is not recommended for primary VTE prevention (Grade 2C)

Orthopedic surgery

In patients undergoing total hip arthroplasty (THA) or total knee arthroplasty (TKA), use of one of the following for a minimum of 10-14 days is recommended: LMWH, fondaparinux, apixaban, dabigatran, rivaroxaban, LDUH, adjusted-dose warfarin, aspirin (all Grade 1B), or IPC (Grade 1C)

In patients undergoing hip fracture surgery (HFS), use of one of the following is recommended: antithrombotic prophylaxis for a minimum of 10-14 days, LMWH, fondaparinux, LDUH, adjusted-dose warfarin, aspirin (all Grade 1B), or IPC (Grade 1C)

For patients undergoing major orthopedic surgery (THA, TKA, HFS) and receiving LMWH as thromboprophylaxis, starting either 12 hours or more preoperatively or 12 hours or more postoperatively is recommended over starting within 4 hours or less preoperatively or 4 hours or less postoperatively (Grade 1B)

In patients undergoing THA, TKA, or HFS, irrespective of the concomitant use of IPC or length of treatment, the use of LMWH is suggested over other recommended alternatives, including fondaparinux, apixaban, dabigatran, rivaroxaban, LDUH (all Grade 2B), adjusted-dose warfarin, or aspirin (all Grade 2C)

For patients undergoing major orthopedic surgery, extending thromboprophylaxis in the outpatient period for up to 35 days from the day of surgery is suggested (Grade 2B)

In patients undergoing major orthopedic surgery, dual prophylaxis with an antithrombotic agent and IPC is suggested during the hospital stay (Grade 2C)

In patients undergoing major orthopedic surgery who decline injections or IPC, apixaban or dabigatran (alternatively rivaroxaban or adjusted-dose warfarin) is recommended over alternative forms of prophylaxis (all Grade 1B)

For primary prevention of VTE after major orthopedic surgery, no thromboprophylaxis is suggested over placement of an IVC filter in patients with an increased bleeding risk or contraindications to both pharmacologic and mechanical thromboprophylaxis (Grade 2C)

The use of screening compression ultrasound in asymptomatic patients following major orthopedic surgery is not recommended (Grade 1B)

No prophylaxis is suggested rather than pharmacologic thromboprophylaxis in patients with isolated lower leg injuries requiring leg immobilization (Grade 2C)

For patients undergoing knee arthroscopy without a history of prior VTE, no thromboprophylaxis is suggested (Grade 2B)

[a]Recommendations are graded as strong (Grade 1) or weak (Grade 2) based on high-quality (Grade A), moderate-quality (Grade B), or weak-quality (Grade C) evidence.

Data from references 2, 3 and 4.

Nonpharmacologic Therapy

Compression stockings and intermittent pneumatic compression (IPC) devices prevent VTE by increasing the velocity of venous blood flow through graded pressure application. IPC devices utilize a series of cuffs wrapped around the patient's legs that inflate in continuous 1- to 2-minute cycles from the ankles to the thighs. IPC should be worn at least 18 hours/day for optimal effectiveness.

Graduated compression stockings do not reliably reduce VTE in medically ill patients.[2] However, they reduce the incidence of VTE (including asymptomatic and distal DVT) by approximately 65% when used after orthopedic surgery, cardiac surgery, gynecologic surgery, or neurosurgery.[3] IPC reduces the risk of VTE by more than 60% following general surgery, neurosurgery, and orthopedic surgery.[3] Both modalities can be used in combination with anticoagulation to maximize VTE prevention.[25]

Mechanical methods do not increase bleeding risk, which makes them attractive for postoperative VTE prophylaxis, especially in patients with contraindications to pharmacologic therapies. However, they are not risk-free, as discomfort, skin breakdown, and ulceration can occur.[2]

Inferior vena cava (IVC) filters can provide short-term protection against PE in very-high-risk patients by blocking embolization of thrombus formed below the filter.[27] Percutaneous insertion of an IVC filter is a minimally invasive procedure performed using fluoroscopic imaging to verify placement. Despite widespread IVC filter use, mortality benefit is unproven, and only limited nonrandomized data support effectiveness and long-term safety for VTE prevention. Frequently "retrievable" IVC filters are never retrieved; increasing risk for long-term complications such as DVT, filter migration, IVC occlusion, and insertion site thrombosis. As such, IVC filters should be reserved for patients at highest VTE risk in whom other prophylactic strategies cannot be used. IVC filters should be removed when VTE risk has passed or when anticoagulation is no longer contraindicated.[27]

Pharmacologic Therapy

Pharmacologic options for preventing VTE have been extensively evaluated in randomized clinical trials and significantly reduce the risk of VTE following hip and knee replacement, hip fracture repair, general surgery, myocardial infarction, ischemic stroke, and in selected hospitalized medical patients.[2,3,4] The optimal agent and dose for VTE prevention must be based on assessment of VTE

and bleeding risk, as well as cost and availability.

Medical Patients

Several risk assessment models have been developed to identify hospitalized and critically ill patients at high VTE risk likely to benefit from thromboprophylaxis. The Padua Prediction Score is a prospectively validated VTE risk assessment tool for hospitalized medical patients.[2] Three points each are assigned for active cancer, previous VTE, reduced mobility, and thrombophilia; 2 points are assigned for trauma and/or surgery within the last month; and 1 point each is assigned for age older than or equal to 70 years, heart and/or respiratory failure, acute myocardial infarction or ischemic stroke, acute infection and/or rheumatologic disorder, body mass index more than or equal to 30 kg/m^2, or ongoing hormonal treatment. Among high-risk patients (score more than or equal to 4 points) not receiving prophylaxis, VTE occurred in 11.0% within 90 days compared with just 0.3% of low-risk patients.[2]

Recommendations for preventing VTE during medical illness are summarized in Table 19-2. Compared with placebo, low-dose unfractionated heparin (LDUH), low-molecular-weight heparin (LMWH), and fondaparinux all reduce symptomatic VTE and fatal PE among high-risk medical patients.[2] No direct oral anticoagulant (DOAC) is approved for use in this setting. Hospitalized and acutely ill medical patients at high VTE risk and low bleeding risk should receive pharmacologic prophylaxis with LDUH, LMWH, or fondaparinux during hospitalization or until fully ambulatory. Routine pharmacologic prophylaxis is not warranted in low-VTE-risk medical patients. Mechanical prophylaxis is preferred over anticoagulation therapy in medical patients at high bleeding risk (eg, active gastric or duodenal ulcer, history of bleeding within 90 days, or platelet count less than $50 \times 10^9/L$).[2] Mechanical prophylaxis should also be considered if more than one of the following are present: Age 85 years or more, hepatic failure, renal failure (creatinine clearance [CrCL] less than 30 mL/min [less than 0.5 mL/s]), admission to intensive care or cardiac care units, central venous catheter, rheumatic disease, active cancer, or male sex.[2] Patients with severe hepatic insufficiency are not adequately protected from VTE even if baseline INR is elevated. This population is particularly challenging as they are at risk for VTE without prophylaxis and bleeding with pharmacologic prophylaxis.[29,30]

Surgical Patients

General recommendations for reducing perioperative VTE risk includes stopping estrogen-containing medications 4 weeks prior to surgery and consideration for regional, rather than general anesthesia.[17] The Caprini score can be used to estimate VTE risk after general surgery by awarding 1, 2, 3, or 5 points to patient-specific risk factors (eg, age, body mass index, VTE history) and procedure-related risk factors including minor or major surgery, laparoscopic or open procedures, and elective arthroplasty. Summing risk factor points yields VTE risk categorized as very low (0 to 1 point), low (2 points), moderate (3 to 4 points), or high (more than or equal to 5 points).[3] Estimating surgical bleeding risk is challenging due to the wide variety of surgery types, the effect of surgical technique, and the lack of a validated bleeding predication rule. Table 19-2 summarizes the AT9

recommendation for preventing VTE following nonorthopedic surgery. In general, patients at high VTE risk but low bleeding risk should receive LDUH or LMWH prophylaxis in addition to graduated compression stockings or IPC. Patients at high bleeding risk should receive IPC if VTE risk is moderate or high. Low risk patients able to ambulate early after surgery do not routinely require VTE prophylaxis.[3]

Total joint arthroplasty is associated with very high postoperative VTE risk. Recommended pharmacologic agents for VTE prevention following joint replacement surgery include aspirin, adjusted-dose warfarin, UFH, LMWH, fondaparinux, dabigatran, apixaban, and rivaroxaban for 10 days postsurgery, minimum.[4] Head-to-head trials fail to reliably demonstrate differences in clinically relevant outcomes such as symptomatic VTE, fatal PE, major hemorrhage, and surgical site complications between agents.[4]

CLINICAL PRESENTATION Deep Vein Thrombosis General

- Deep vein thrombosis (DVT) most commonly develops in patients with identifiable risk factors (see Table 19-1) during or following a period of acute illness or hospitalization. Many have asymptomatic disease.

Symptoms

- The patient may complain of leg swelling, pain, or warmth. Symptoms are nonspecific and objective testing must be performed to establish the diagnosis.

Signs

- The patient's superficial veins may be dilated and a "palpable cord" may be felt in the affected leg.
- The patient may experience pain in back of the knee when the examiner dorsiflexes the foot of the affected leg (Homan's sign).

Laboratory tests

- Serum concentration of D-dimer, a by-product of fibrin degradation, is nearly always elevated. D-dimer values less than 500 ng/mL (mcg/L) combined with clinical decision rules are useful in ruling out the diagnosis of DVT.

Diagnostic tests

- Compression ultrasound is the most commonly used test to diagnose DVT. It is a noninvasive test that can visualize clot formation in veins of the legs. It cannot reliably detect small blood clots in calf veins. Coupled with a careful clinical assessment, it can rule in or out the diagnosis in the majority of cases.
- Venography is the gold standard for the diagnosis of DVT. However, it is an invasive test that involves injection of radiopaque contrast dye into a foot vein. It is expensive and can cause

anaphylaxis and nephrotoxicity.

AT9 suggests using LMWHs preferentially over other agents after total joint arthroplasty based on favorable pharmacologic properties and extensive clinical use.[4] LMWH bleeding risk following orthopedic surgery relates closely to thromboprophylaxis initiation timing. LMWH administration within 2 hours preoperatively or postoperatively increases bleeding risk up to fivefold compared with starting 12 hours after surgery.[4]

Clinical Presentation Pulmonary Embolism General

- Pulmonary embolism (PE) most commonly develops in patients with risk factors for venous thromboembolism (see Table 19-1) during or following a hospitalization. Although many patients develop a symptomatic deep vein thrombosis prior to developing a PE, some do not. Patients may die suddenly from cardiogenic shock and circulatory collapse before effective treatment can be initiated.

Symptoms

- The patient may complain of cough, chest pain, chest tightness, shortness of breath, or palpitation. The patient may spit or cough up blood (hemoptysis). When PE is massive, the patient may complain of dizziness or light-headedness. Symptoms may be confused with myocardial infarction, requiring objective testing to establish the diagnosis.

Signs

- The patient may have tachypnea, tachycardia, and appear diaphoretic. The patient's neck veins may be distended. In massive PE, the patient may appear cyanotic and become hypotensive. In such cases, oxygen saturation by pulse oximetry or arterial blood gas will likely indicate that the patient is hypoxic. In the worse cases, the patient may go into cardiogenic shock and die within minutes.

Laboratory tests

- Serum concentration of D-dimer, a by-product of fibrin degradation, is nearly always elevated. D-dimer values less than 500 ng/mL (mcg/L) combined with clinical decision rules are useful in ruling out the diagnosis of PE.

Diagnostic tests

- Computerized tomography pulmonary angiography (CTPA) is the most commonly used test to diagnose PE, but some centers still use the ventilation–perfusion (V/Q) scan. A V/Q scan measures the distribution of blood and airflow in the lungs. When there is a large mismatch between blood and airflow in one area of the lung, there is a high probability that the patient has a PE.

- Pulmonary angiography is the gold standard for the diagnosis of PE. However, it is an invasive test that involves injection of radiopaque contrast dye into the pulmonary artery. The test is

expensive and associated with a significant risk of mortality.

Warfarin remains a commonly prescribed agent for VTE prevention after total joint arthroplasty due to low acquisition cost and oral administration.[31] Warfarin's delayed onset of anticoagulant effect confers both a potential advantage (reduced immediate risk of postoperative bleeding) and disadvantage (increased risk of early VTE). Many orthopedic surgeons prefer low-intensity warfarin (eg, international normalized ratio [INR] 1.5 to 2.5) due to perceived lower postoperative bleeding risk.[31] AT9 now simply recommends "dose-adjusted warfarin" without specific guidance on target INR, and American Academy of Orthopaedic Surgery guidelines also no longer recommend a specific INR target.[4,32] Warfarin use following orthopedic surgery requires a well-coordinated monitoring system and timely INR testing.[33] Arranging INR testing following joint replacement surgery can be challenging due to limited patient mobility and often requires home phlebotomy services or point-of-care INR monitoring devices; this increases complexity and erodes warfarin's cost advantage.

Direct oral anticoagulants offer convenient oral administration and fixed dosing without need for routine coagulation testing. Clinical trials have demonstrated safety and efficacy similar to enoxaparin after total joint replacement, but studies after hip fracture surgery are lacking.[4] AT9 expresses a preference for apixaban, dabigatran, or warfarin in patients unwilling to use LMWH injections.[4]

Duration of Therapy

Optimal VTE prophylaxis duration following surgery is not well established. Prophylaxis should be given throughout the period of increased VTE risk. For general surgical procedures once patients are able to ambulate regularly and other risk factors are no longer present, prophylaxis can be discontinued.[2,3] Because of relatively high VTE incidence in the month following hospital discharge among patients udergoing lower extremity orthopedic procedures, extended prophylaxis appears to be beneficial.[4] Most clinical trials support the use of antithrombotic prophylaxis for 21 to 35 days following total hip replacement and hip fracture repair surgeries.[4]

General Approach to the Treatment of Venous Thromboembolism

4 Anticoagulation therapies remain the mainstay of VTE treatment. DVT and PE are manifestations of the same disease process and are treated similarly (**Figs. 19-8 and 19-9, Table 19-3**). Before prescribing anticoagulation therapy for VTE treatment, establishing an accurate diagnosis is imperative in preventing unnecessary bleeding risk and expense to the patient.[5] Patients with likely VTE probability may need rapid-onset anticoagulation therapy while awaiting diagnostic testing results, whereas patients with unlikely probability but positive D-dimer may need rapid-onset anticoagulation only if diagnostic testing will be delayed more than 4 hours.[17]

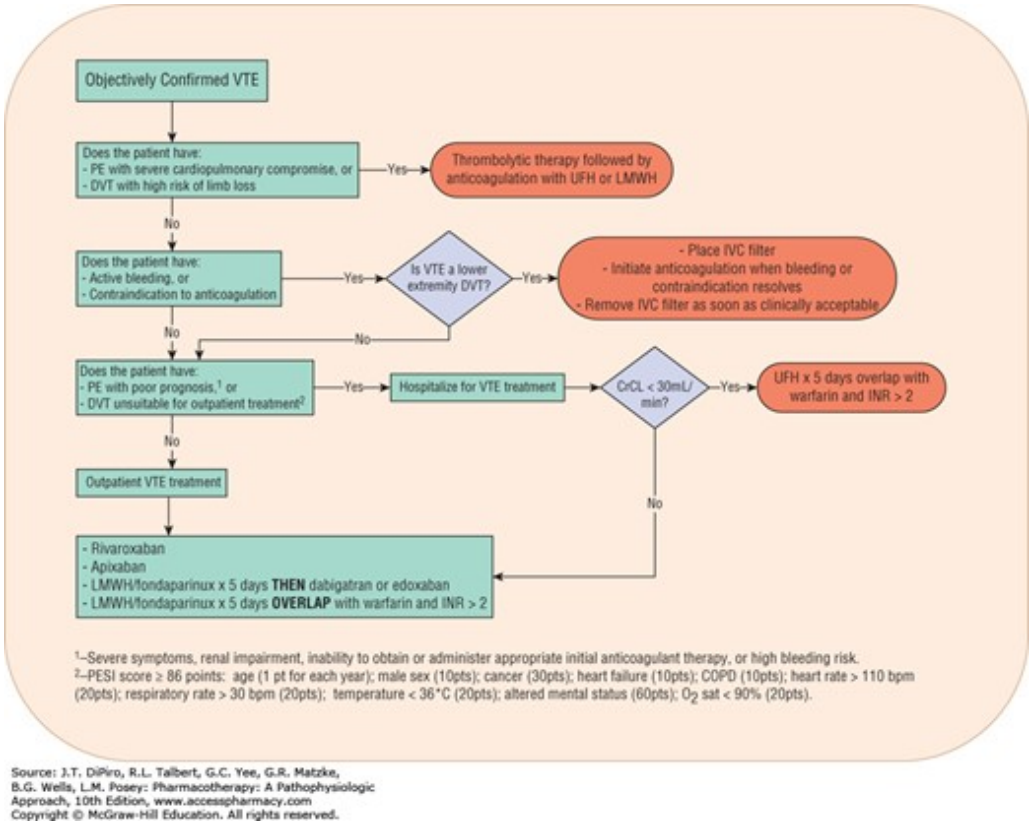

FIGURE 19-9

Overview of VTE treatment strategies.

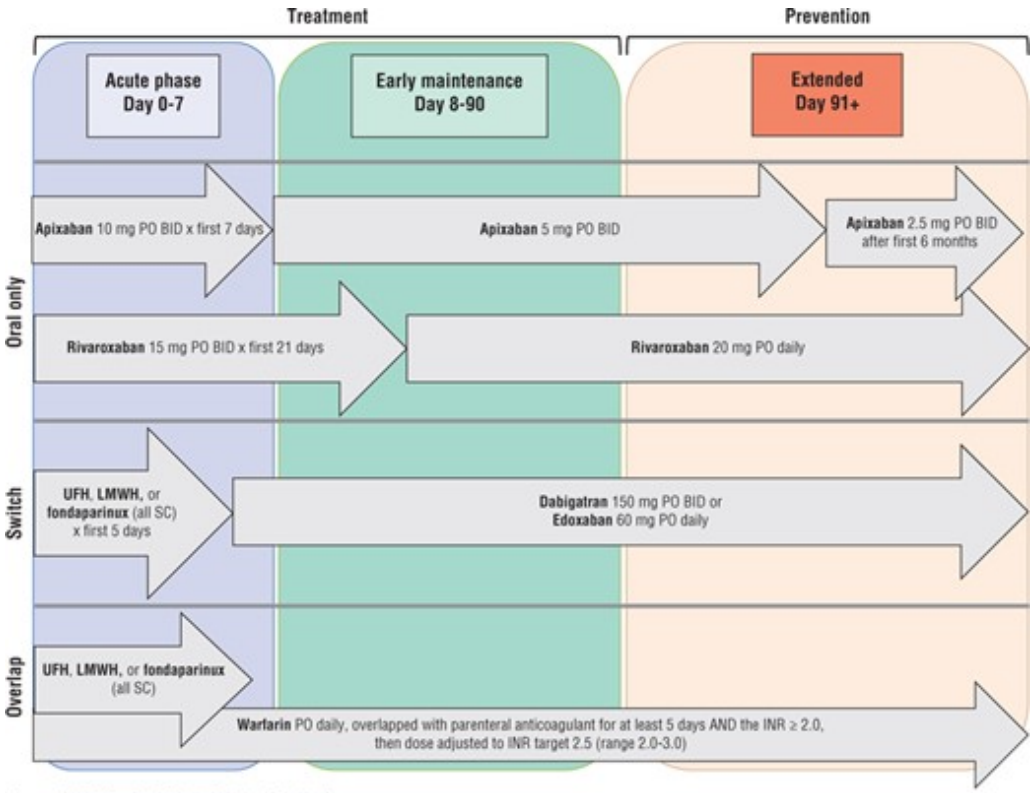

TABLE 19-3 Guidelines for the Treatment of Venous Thromboembolism

Deep vein thrombosis (DVT) and pulmonary embolism (PE)

In patients with acute DVT of the leg or PE, a DOAC (dabigatran, rivaroxaban, apixaban, or edoxaban) is suggested over warfarin therapy (Grade 2B)[a]

In patients with acute DVT of the leg or PE treated with warfarin therapy, initial treatment with LMWH, fondaparinux, IV UFH, or SC UFH is recommended (Grade 1B)

In patients with acute DVT of the leg or PE, early initiation of warfarin (eg, same day as parenteral therapy is started) over delayed initiation, and continuation of parenteral anticoagulation for a minimum of 5 days and until the international normalized ratio (INR) is 2 or above for at least 24 hours are recommended (Grade 1B)

In patients with acute DVT of the leg or PE, LMWH or fondaparinux is suggested over IV UFH (Grade 2C [2B for fondaparinux in PE]) and over SC UFH (Grade 2B for LMWH; Grade 2C for fondaparinux)

In patients with proximal DVT of the leg or PE provoked by surgery, treatment with anticoagulation for 3 months is recommended over treatment of a shorter period (Grade 1B), treatment of a longer time-limited period (eg, 6 or 12 months) (Grade 1B), or extended therapy (Grade 1B regardless of bleeding risk)

In patients with proximal DVT of the leg or PE provoked by a nonsurgical transient risk factor, treatment with anticoagulation for 3 months is recommended over treatment of a shorter period (Grade 1B), treatment of a longer time-limited period (eg, 6 or 12 months) (Grade 1B), and extended

therapy if there is a high bleeding risk (Grade 1B); anticoagulation for 3 months is suggested over extended therapy if there is a low or moderate bleeding risk (Grade 2B)

In patients with a first unprovoked DVT of the leg or PE, treatment with anticoagulation for at least 3 months is recommended over treatment of a shorter duration (Grade 1B); after 3 months of treatment, the risk-to-benefit ratio of extended therapy should be evaluated; for patients with low or moderate bleeding risk, extended anticoagulant therapy is suggested over 3 months of therapy (Grade 2B); for patients with high bleeding risk, 3 months of anticoagulant therapy is recommended over extended therapy (Grade 1B)

In patients with recurrent unprovoked VTE, extended anticoagulant therapy is recommended over 3 months of therapy in those with low bleeding risk (Grade 1B), and suggested in those with moderate bleeding risk (Grade 2B); in patients with high bleeding risk, 3 months of therapy is suggested over extended therapy (Grade 2B)

In all patients who receive extended anticoagulant therapy, the continuing use of treatment should be reassessed at periodic intervals (eg, annually)

In patients with DVT of the leg or PE who are treated with warfarin, a therapeutic INR range of 2-3 (target INR of 2.5) is recommended for all treatment durations (Grade 1B)

In patients with DVT of the leg or PE and no cancer and not treated with a DOAC, warfarin therapy is suggested over LMWH for long-term therapy (Grade 2C)

In patients with DVT of the leg or PE and cancer, LMWH is suggested over warfarin therapy or a DOAC (Grade 2C for all); in patients with DVT or PE and cancer who are not treated with LMWH, either warfarin or a DOAC may be used

In patients with DVT of the leg or PE who receive extended therapy, there is no need to change the choice of anticoagulant after the first 3 months unless patient circumstances dictate a change in therapy (Grade 2C)

In patients with acute DVT of the leg or PE, the use of an inferior vena cava (IVC) filter in addition to anticoagulants is not recommended (Grade 1B) unless anticoagulation therapy is contraindicated (Grade 1B); a conventional course of anticoagulant therapy is suggested if the risk of bleeding resolves (Grade 2B)

In patients who are incidentally found to have asymptomatic DVT of the leg or PE, the same initial and long-term anticoagulation as for comparable patients with symptomatic DVT of PE is suggested (Grade 2B)

In patients with unprovoked proximal DVT of the leg or PE who are stopping anticoagulant therapy and do not have a contraindication to aspirin, aspirin is suggested over no aspirin to prevent recurrent VTE (Grade 2C)

In patients with subsegmental PE (no involvement of more proximal pulmonary arteries) and no proximal DVT in the legs who have a low risk for recurrent VTE, clinical surveillance is suggested over

anticoagulation (Grade 2C); if high risk for recurrent VTE anticoagulation is suggested over clinical surveillance (Grade 2C)

In patients with recurrent VTE while on warfarin therapy (in the therapeutic range) or on DOAC (and believed to be compliant), switching to treatment with LMWH at least temporarily is suggested (Grade 2C)

In patients who have recurrent VTE while on long-term LMWH (and are believed to be compliant), increasing the LMWH dose by about one-quarter to one-third is suggested (Grade 2C)

DVT specific

In patients with acute DVT of the leg and whose home circumstances are adequate, initial treatment at home is recommended over treatment in hospital (Grade 1B)

In patients with acute DVT of the leg, early ambulation is suggested over initial bedrest (Grade 2C)

In patients with acute proximal DVT of the leg, anticoagulant therapy alone is suggested over catheter-directed thrombolysis (Grade 2C)

In patients with acute symptomatic DVT of the leg, suggest against the routine use of graduated compression stockings for the purpose of preventing postthrombotic syndrome (Grade 2B)

PE specific

In patients with low-risk PE and whose home circumstances are adequate, treatment at home or early discharge is suggested over standard discharge (eg, after first 5 days of treatment) (Grade 2B)

In patients with acute PE associated with hypotension (eg, systolic BP <90 mm Hg) who do not have a high bleeding risk, systemically administered thrombolytic therapy is suggested (Grade 2B)

In most patients with acute PE not associated with hypotension, systemically administered thrombolytic therapy is not recommended (Grade 1B)

In selected patients with acute PE who deteriorate after starting anticoagulant therapy but have yet to develop hypotension and who have a low bleeding risk, systemically administered thrombolytic t herapy is suggested over no therapy (Grade 2C)

In patients with acute PE who are treated with a thrombolytic agent, systemically administered thrombolytic therapy is suggested over catheter directed thrombolysis (Grade 2C) In patients with acute PE, when a thrombolytic agent is used, short infusion times (eg, a 2-hour infusion) are suggested over prolonged infusion times (eg, a 24-hour infusion) (Grade 2C); thrombolytic administration through a peripheral vein is suggested over a pulmonary artery catheter (Grade 2C)

In patients with acute PE associated with hypotension and who have high bleeding risk, failed systemic thrombolysis, or shock that is likely to cause death before systemic thrombolysis can take effect (eg, within hours), catheter-assisted thrombus removal is suggested over no such intervention if appropriate expertise and resources are available (Grade 2C); In patients with chronic thromboembolic pulmonary hypertension (CTPH), extended anticoagulation is recommended over stopping therapy (Grade 1B); in selected patients with CTPH who are identified by an experienced

thromboendarterectomy team, pulmonary thromboendarterectomy is suggested (Grade 2C)

Upper extremity DVT

In patients with acute upper extremity DVT (UEDVT) involving the axillary or more proximal veins, acute treatment with parenteral anticoagulation (LMWH, fondaparinux, IV UFH, or SC UFH) is recommended over no such acute treatment (Grade 1B); LMWH or fondaparinux is suggested over IV UFH (Grade 2C) and over SC UFH (Grade 2B); anticoagulant therapy alone is suggested over thrombolysis (Grade 2C)

In patients with UEDVT who undergo thrombolysis, the same intensity and duration of anticoagulant therapy as in similar patients who do not undergo thrombolysis is recommended (Grade 1B)

In most patients with UEDVT associated with a central venous catheter, not removing the catheter is suggested if it is functional and there is an ongoing need for the catheter (Grade 2C)

In patients with UEDVT involving the axillary or more proximal veins, a minimum duration of anticoagulation of 3 months is suggested over a shorter period (Grade 2B); in patients who have UEDVT that is not associated with a central venous catheter or with cancer, 3 months of anticoagulation is recommended over a longer duration of therapy (Grade 1B); in patients who have UEDVT that is associated with a central venous catheter that is not removed, anticoagulation that continues as long as the central venous catheter remains is recommended over stopping after 3 months of treatment in patients with cancer (Grade 1C), and is suggested in patients with no cancer (Grade 2C)

[a]Recommendations are graded as strong (Grade 1) or weak (Grade 2) based on high-quality (Grade A), moderate-quality (Grade B), or weak-quality (Grade C) evidence.

Data from references 5 and 28.

Strict bedrest was traditionally recommended following acute DVT based on the assumption that leg movement would dislodge the clot, resulting in PE. However, ambulation in conjunction with graduated compression stockings results in faster reduction in pain and swelling with no apparent increase in embolization rate. Patients should be encouraged to ambulate as much as symptoms permit. If ambulation increases pain and swelling, the patient should be instructed to lie down and elevate the affected leg until symptoms subside.

Inferior vena cava filters also have a limited role in the management of acute VTE, and should only be used when anticoagulants are contraindicated due to active bleeding.[28] As soon as the bleeding risk resolves, patients should receive a conventional course of anticoagulant therapy and have the filter removed within 90 to 120 days of implantation.[5,17,27] In life- or limb-threatening circumstances, elimination of the obstructing thrombus may be warranted and the use of thrombolysis or thrombectomy considered.[5,34] Removable IVC filter insertion is an option in patients with contraindications to anticoagulation therapy or when anticoagulant therapy has failed.[5,34]

Once the diagnosis of VTE has been objectively confirmed (see Clinical Presentation and Diagnosis discussed earlier), anticoagulant therapy with a rapid-acting anticoagulant should be instituted as

soon as possible (see Fig. 19-8). 6 Available anticoagulants can be administered in the outpatient setting in most patients with DVT and in carefully selected hemodynamically stable patients with PE. The decision to initiate outpatient therapy should be based on institutional resources and patient-specific variables (**Table 19-4**).[34,35]

TABLE 19-4 Outpatient Treatment Suggestions for Deep Venous Thrombosis and Pulmonary Embolism

Inclusion	Patients with objectively diagnosed VTE
Relative exclusion	Patients who are hemodynamically unstable
Exclusion	Arterial thromboembolism or patients who are currently receiving dialysis, actively bleeding, have had recent (within 2 weeks) major surgery/trauma, or have other severe uncompensated comorbid conditions

Suggested procedure: may vary depending on the patient's clinical condition

Confirm diagnosis of VTE by objective testing

Day 1

Baseline laboratory evaluation

- International normalized ratio (INR)—if use of warfarin anticipated
- Serum creatinine (Scr)
- Complete blood count (CBC) with platelets

Medication—see Fig. 19-7

Patient education

- Clinical pharmacy/nursing
    - Educate patient regarding the importance of proper monitoring of anticoagulation therapy (if applicable) and warning signs that should prompt additional medical evaluation; document activities in the medical record
    - If applicable, teach patient how to self-administer LMWH/fondaparinux (if patient or family member unwilling or unable to self-administer injection, visiting nurse services should be arranged or consider single oral anticoagulant approach); initial injection should be administered in the medical office or hospital
    - Instruct patient regarding local therapy: elevation of affected extremity, localized heat, antiembolic exercises (flexion–extension of ankle for lower extremity VTE, or hand squeezing–relaxation for upper extremity VTE)

- Pharmacy operations
    - Reinforce patient education regarding indication, use, monitoring, side effects, and drug interactions with antithrombotic therapy
    - Screen patient's pharmacy profile for potential drug–drug interactions with anticoagulation therapy
    - Dispense anticoagulant therapy
    - Anticoagulation service enrollment

Days 3-4

Laboratory evaluation if on warfarin: check INR

Assess for symptoms of pulmonary embolism

Medications: continue anticoagulant medication(s) as directed

Anticoagulation service

- If on warfarin interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5
- Patient activity: continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated
- Document activities in medical record

Day 5

Laboratory evaluation if on warfarin: check INR

Assess for symptoms of pulmonary embolism

Medications: continue anticoagulant medication(s) as directed

Anticoagulation service

- If on warfarin interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5 (stop LMWH if INR ≥2.0)
- Patient activity: no restriction; if pain increases, contact primary care provider
- Document activities in medical record

Day 6 (Dabigatran or Edoxaban)

Medications: transition from parenteral to oral medication

Assess for symptoms of pulmonary embolism

Anticoagulation service

- Verify adherence, affordability, and tolerability of oral medication
- Patient activity: no restriction; if pain increases, contact primary care provider
- Review key education points (eg, keep in original container [dabigatran])
- Document activities in medical record

Day 7 (Apixaban)

Medications: Decrease apixaban dose

Anticoagulation service

- Patient activity: no restrictions; if pain increases contact primary care provider
- Verify adherence, affordability, and tolerability of oral medication
- Document activities in medical record

Day 21 (Rivaroxaban)

Medications: Decrease riaroxaban dose

Anticoagulation service

- Verify adherence, affordability, and tolerability of oral medication
- Patient activity: no restriction; if pain increases, contact primary care provider
- Review key education points (eg, take with food [rivaroxaban])
- Document activities in medical record

7 The appropriate initial duration of anticoagulation therapy to effectively treat an acute first episode of VTE for all patients is 3 months, as this reduces recurrent VTE risk to as low as can be achieved by a time-limited therapy duration.[28] To prevent new VTE episodes not directly related to the preceding episode, continuing anticoagulation therapy is required.[1] Individually tailoring anticoagulation therapy duration therapy past 3 months requires careful consideration of the circumstances surrounding the initial thromboembolic event, the presence of ongoing thromboembolic risk factors, bleeding risk, and patient preference.[28]

The most important considerations in determining recurrent VTE risk are whether the initial thrombotic event was associated with a major transient or reversible risk factor (eg, surgery, plaster

cast leg immobilization, or hospitalization in the month prior to VTE) and the presence of active cancer.[28] The estimated cumulative risk of recurrent VTE after stopping anticoagulant therapy for VTE provoked by surgery is 1% after 1 year and 3% after 5 years, and that for VTE provoked by a nonsurgical reversible risk factor is 5% after 1 year and 15% after 5 years. Three months of anticoagulation therapy is recommended in these situations.[5] Patients with a first unprovoked (idiopathic) VTE have approximately 10% recurrence risk in the first year and approximately 30% and 50% over 5 and 10 years, respectively. These patients should be considered for extended anticoagulation therapy when feasible.[28] Extended therapy refers to continuing anticoagulation beyond 3 months without a scheduled stop date, but stopping therapy if there is a subsequent increase in bleeding risk or change in patient preference for anticoagulation.[28] For patients with a second idiopathic VTE episode, extended anticoagulation is recommended.[28] Anticoagulation is rarely stopped in patients with VTE and active cancer because of high recurrence risk.[28] Factors that may lead to the decision to stop warfarin therapy after 3 months include noncompliance with therapy, initial clot isolated in calf veins (even if idiopathic), or moderate to high bleeding risk.[28]

Clinically important bleeding risk factors include age more than 75 years, previous noncardioembolic stroke, history of gastrointestinal bleeding, renal or hepatic impairment, anemia, thrombocytopenia, concurrent antiplatelet use (avoid if possible), noncompliance, poor anticoagulant control (for patients on warfarin), serious acute or chronic illness, and the presence of structural lesions (eg, tumor, recent surgery) that could bleed. One to two bleeding risk factors suggest moderate bleeding risk while three or more suggest high bleeding risk.[5]

Various secondary strategies aimed at identifying patients with very low recurrence risk after a first idiopathic VTE have evaluated whether safe withdrawal of anticoagulation therapy may be possible if reliable identification of these patients proves possible. Some factors that may predict lower recurrence risk include female gender, low D-dimer levels 1 month after stopping anticoagulation therapy, absence of residual clot on ultrasound, absence of hereditary and acquired thrombophilia, and absence of the postthrombotic syndrome. Risk assessment derived from combining several independent recurrence risk factors has also been investigated.[5] Further validation is needed before any one factor or prediction rule using a combination of factors can justify stopping anticoagulation. The decision to continue extended warfarin therapy should be reassessed periodically. Patients should be involved in any decision to continue anticoagulation therapy with consideration given to long-term prognosis, risk of bleeding, ability to adhere to anticoagulation therapy instructions, financial resources, lifestyle, and quality of life.[5] When anticoagulation therapy is stopped, there is a similar risk of recurrence whether patients have been treated for 3 months or longer.[28]

Patients with VTE are often tested for hereditary and acquired hypercoagulable states (thrombophilia). The available evidence does not support a strong association between genetically transmitted thrombophilia (especially factor V Leiden and prothrombin G20210A) and higher recurrent VTE rates.[15] Routine testing for thrombophilia is not recommended.[17]

For patients with proximal DVT, wearing graduated compression stockings does not reduce the risk of developing the postthrombotic syndrome.[26] However, for patients with persistent leg pain and

swelling, graduated compression stockings can be suggested for symptomatic relief.

Pharmacologic Therapy

The anticoagulant drugs used to treat VTE are the same as those used for VTE prevention; however, there are important differences in the approach to VTE treatment in terms of the doses used and duration of therapy.

Direct Oral Anticoagulants

9 Clinical trials have demonstrated that single-drug therapy with rivaroxaban or apixaban is noninferior to warfarin overlapped with enoxaparin at initiation (traditional therapy) for both acute DVT and PE with similar rates of recurrent VTE.[36,37,38] Major bleeding was lower with rivaroxaban in the PE trial,[37] but not in the DVT trial.[38] Apixaban caused significantly less major bleeding than traditional therapy.[36] Both drugs are initiated with a higher dose with eventual transition to maintenance dosing (see Fig. 19-9). Neither drug requires routine coagulation monitoring. Patients with CrCL less than 25-30 mL/min (less than 0.42-0.5 mL/s), active cancer, and those requiring thrombolytic therapy were excluded from clinical trials.[36,37,38] Until further data are available, traditional anticoagulation therapy should be utilized in these patient populations. Replacing the effective but cumbersome combination of injectable anticoagulants and warfarin with a single-drug regimen simplifies VTE treatment; however, the higher acquisition cost of rivaroxaban and apixaban and lack of an effective reversal agent is concerning to some patients and clinicians.

Clinical Controversy…

Even though the treatment of acute VTE using apixaban and rivaroxaban is less complex than traditional therapy with warfarin overlapped with LMWH, most patients do not receive therapy with these agents. Clinical inertia may be the primary reason why clinicians continue to use traditional therapy in light of the relative simplicity of apixaban or rivaroxaban therapy compared to daily injections of LMWH coupled with the need for frequent INR monitoring. Therapy with apixaban or rivaroxaban should be the default anticoagulant for acute VTE treatment with other therapies reserved for those situations where DOAC therapy is less desirable (eg, renal dysfunction, cancer-associated VTE, VTE associated with antiphospholipid antibody syndrome).

PREVENTION OF VTE

- Conduct an accurate assessment of VTE and bleeding risks to weigh the competing hazards of symptomatic VTE and bleeding and appropriately target prevention strategies.
- An effective VTE prophylaxis program should not only quantify patients' risks, but also assist providers in selecting prophylaxis regimens that optimally balance these risks in a cost-effective manner.

TREATMENT OF VTE

- Establish an accurate diagnosis of VTE.
- Prevent thrombus extension and embolization with rapidly acting anticoagulants (acute phase of VTE treatment [~7 days]).
- Reduce the risk of long-term sequelae such as the postthrombotic syndrome and CTPH by allowing formed clot to be slowly dissolved by endogenous thrombolytic processes (early maintenance phase [7 days to 3 months]).
- Prevent recurrent VTE (long-term anticoagulation therapy extending beyond 3 months).

Oral dabigatran 150 mg twice daily and oral edoxaban 60 mg once daily have each been compared with traditional therapy in randomized, double-blind, noninferiority trials involving patients with acute VTE.[39,40] In these trials, all patients were initially given at least 5 days of parenteral anticoagulation therapy (unfractionated heparin [UFH] or LMWH) and then randomized to study treatment. Both dabigatran and edoxaban were noninferior to warfarin following the parenteral anticoagulant lead-in for the outcome of recurrent VTE. Dabigatran caused similar major bleeding[39] and edoxaban significantly less bleeding than warfarin.[40] Similar to the other DOACs, patients with hemodynamically unstable PE or at high bleeding risk were excluded and should not receive treatment with dabigatran or edoxaban until further data are available. Patients with CrCL less than 30 mL/min (less than 0.5 mL/s) should not receive dabigatran, but for patients with a CrCL 15-50 mL/min (0.25-0.83 mL/s), edoxaban with dose reduced from 60 mg once daily to 30 mg once daily can be prescribed.[40] The requirement for parenteral anticoagulation prior to initiation of dabigatran or edoxaban therapy is a disadvantage compared with single-drug approaches to VTE treatment (see Fig. 19-9). DOACs are preferred over conventional anticoagulation for management of VTE in the American College of Chest Physician 10th edition guidelines.[28]

Low-Molecular-Weight Heparin

Low-molecular-weight heparin has largely replaced UFH for initial VTE treatment due to improved pharmacokinetic and pharmacodynamic profiles and ease of use. LMWH given subcutaneously in fixed, weight-based doses (**Table 19-5**) is at least as effective as UFH given intravenously for the treatment of VTE.[6] Given the predictable response and reduced need for laboratory monitoring with LMWH, stable patients with DVT or PE who have normal vital signs, low bleeding risk, and no other uncontrolled comorbid conditions requiring hospitalization can be discharged early or treated entirely on an outpatient basis (see Table 19-4).[28] Not all patients are appropriate candidates for outpatient VTE treatment. At a minimum, patients must be reliable or have adequate caregiver support and be willing and active participants in outpatient VTE management. Important patient education aspects for outpatient VTE treatment are summarized in **Table 19-6**. Hemodynamically unstable patients with PE should generally be admitted for anticoagulation therapy initiation. Rapidly reversible UFH is preferred if thrombolytic therapy or embolectomy is anticipated.[41] In patients without cancer, acute treatment with LMWH is generally transitioned to long-term warfarin therapy after about 5 to 10 days.

TABLE 19-5 FDA-Approved Venous Thromboembolism Indications and Doses for Low-Molecular-Weight Heparins

Indications	Enoxaparin	Dalteparin
Hip replacement surgery (prophylaxis)	30 mg SC q 12 h initiated 12-24 hours after surgery *Or* 40 mg SC q 24 h initiated 12 hours prior to surgery Extended prophylaxis may be given for up to 3 weeks	Postoperative start: 2,500 units SC given 4-8 hours after surgery, and then 5,000 units SC q 24 h *Or* Preoperative start (evening before surgery): 5,000 units SC 10-14 hours before surgery, then 5,000 units given 4-8 hours after surgery, and then 5,000 units SC q 24 h *Or* Preoperative start (day of surgery): 2,500 units SC within 2 hours of surgery, then 2,500 units given 4-8 hours after surgery, and then 5,000 units SC q 24 h
Knee replacement surgery (prophylaxis)	30 mg SC q 12 h initiated 12-24 hours after surgery	2,500 units SC q 24 h initiated 1-2 hours prior to surgery
Abdominal surgery (prophylaxis)	40 mg SC q 24 h initiated 2 hours prior to surgery	Patients with malignancy: 5,000 units SC the evening prior to surgery, and then 5,000 units SC q 24 h *Or* 2,500 units SC 1-2 hours prior to surgery, and then 2,500 units 12 hours after surgery followed by 5,000 units SC q 24 h
Acute medical illness (prophylaxis)	40 mg SC q 24 h	5,000 units SC q 24 h
Deep vein thrombosis treatment (with or without pulmonary embolism)	1 mg/kg SC q 12 h *Or* 1.5 mg/kg SC q 24 h	
Venous thromboembolism treatment in patients with cancer		200 units/kg SC q 24 h for 30 days, followed by 150 units SC q 24 h (total daily dose should not exceed 18,000 units)

TABLE 19-6 Patient Education for Outpatient Venous Thromboembolism Therapy

General information regarding VTE and the goals of treatment

- Anticoagulant medications (injections and warfarin tablets, injections and dabigatran or edoxaban, or rivaroxaban or apixaban) have been prescribed to prevent your blood clot from growing larger so that the body can begin to dissolve the clot
- Your body may be able to completely dissolve the clot, but in some cases the clot never goes completely away; even with adequate anticoagulation therapy, some people will have chronic pain and swelling in the affected limb; people who have had one clot are at increased risk of having future clots
- Warfarin tablets take several days to begin to work, so at first LMWH or fondaparinux injections and warfarin tablets are used together
- When the warfarin has become effective, you will be able to stop the LMWH or fondaparinux injections; you will continue to take warfarin tablets for 3 months or longer to prevent blood clots from returning
- It is important for you to administer your LMWH or fondaparinux and warfarin exactly as directed
- It is important not to use LMWH at the same time as dabigatran or edoxaban—first use LMWH then switch to dabigatran or edoxaban

Subcutaneous injection technique (if needed)

- You must learn to give yourself an injection of LMWH or fondaparinux under the skin; alternatively, you may have a family member or visiting nurse give it to you
- If your LMWH or fondaparinux syringes were filled by the manufacturer, they can be stored at room temperature; if your syringes were filled by the pharmacy, they should be stored in the refrigerator; if you were instructed to fill your own syringes, you should prepare the syringe immediately prior to injecting its contents
- If you see a bubble in the syringe, do not try to get it out; you may accidentally squirt out part of your dose
- Choose an injection site on your abdomen; clean the area with alcohol, and then position an uncapped syringe at a 90° angle; pinch the skin, stick the needle in as far as it will go, and gently but firmly push the plunger down; this will inject the medicine into the skin; when all the medication has been injected, remove the needle and dispose of it in an appropriate container
- You will likely experience a burning sensation when the medication is injected; this will go away after a few minutes
- Rotate injection sites from side to side; do not inject into the same site more than once; avoid

the area around your navel; do not inject into any bruises

Blood test monitoring

- If you are taking warfarin, regular blood tests are required to make sure your medication is working properly
- The prothrombin time tells how quickly your blood forms a clot; it is used to tell how well warfarin is working
- The INR is a way to standardize the prothrombin time between laboratories; your goal INR range is between 2 and 3; if your INR is < 2, you are at higher risk for clotting; if your INR is > 3, you are at higher risk for bleeding; your dose of warfarin will be adjusted based on the results of this test
- You need to have a complete blood count test before you begin therapy
- If you are taking LMWH, fondaparinux, dabigatran, edoxaban, rivaroxaban, or apixaban you need to have a blood test to determine how well your kidneys are working

Warfarin information

- Each strength of warfarin has a unique color; each time you refill your prescription, make sure your new tablets are the same color as the ones you have been taking; if not, ask your pharmacist why
- Warfarin should be taken at approximately the same time each day
- The most common and serious side effect of warfarin is bleeding; you should be careful to avoid situations or activities that increase your risk of injury; apply direct pressure to control bleeding from superficial cuts
- Warfarin has many drug interactions; always check with your provider before taking any new medications (including nonprescription medications and dietary supplements)
- Foods rich in vitamin K (green leafy vegetables, etc.) may interfere with warfarin; do not avoid foods rich in vitamin K, but try to maintain consistent dietary habits
- Alcohol can increase your risk for bleeding and interfere with warfarin therapy; drink alcohol in moderation (one to two drinks per day); avoid binge drinking

Dabigatran, edoxaban, rivaroxaban, apixaban information

- Take rivaroxaban 15- or 20-mg doses with food to make sure the medication is well absorbed from your stomach
- It is very important that you take each dose of your medication. These medications leave your

body in a few hours; so missing a dose of medication may place you at a higher risk of blood clots

- If you need to have a surgery or procedure, talk to your provider to make a plan for how to take your medication before and after the procedure. Do not stop taking your medication without first talking to your provider
- There are a few drug interactions with dabigatran, edoxaban, rivaroxaban, and apixaban; always check with your provider before taking any new medications (including nonprescription medications and dietary supplements)

Contact your provider if you experience

- Persistent bleeding from a cut or scrape
- Blood in your urine
- Blood in your stool
- Persistent nose bleeding
- Increased swelling or pain in your affected extremity

Go to the emergency department if you experience

- Shortness of breath
- Chest pain
- Coughing up blood
- Black tarry-appearing stool
- Severe headache of sudden onset
- Slurred speech

INR, international normalized ratio; LMWH, low-molecular-weight heparin.

Clinical Controversy…

Despite recommendations from AT9, the American Society of Clinical Oncology, and the National Comprehensive Cancer Network that patients with cancer should be given LMWH monotherapy for the long-term treatment of VTE, most patients with cancer-related VTE continue to receive warfarin-based therapy. Moreover, a survey of clinicians indicated that 82% of respondents indicated LMWH was their first choice for treating VTE in patients with cancer.[89,90] Possible explanations for this observation might be patient preference for oral therapy over daily injections, and/or the higher

cost of LMWH. In addition, pooled analysis of clinical trials demonstrates no survival advantage of LMWH monotherapy compared with traditional therapy with warfarin.[5]

Fondaparinux

Fondaparinux has been shown to be a safe and effective alternative to LMWH for acute VTE treatment.[5] It is dosed once daily via weight-based SC injection as follows: 5 mg if less than 50 kg, 7.5 mg if 50 to 100 kg, and 10 mg if more than 100 kg.[42] Compared with weight-based LMWH dosing, this flexible dosing scheme may be particularly useful with obese patients. Careful attention should be paid to renal function as fondaparinux is contraindicated if CrCL is less than 30 mL/min (less than 0.5 mL/s).[42]

Unfractionated Heparin

Unfractionated heparin may be administered subcutaneously or by continuous intravenous infusion (**Table 19-7**). Because the anticoagulant response to UFH is highly variable, it is standard practice to adjust the dose based on coagulation test results. The activated partial thromboplastin time (aPTT) is generally used to monitor UFH anticoagulant effect. The therapeutic aPTT range at each institution should be adapted to the responsiveness of the reagent and instrument used.[6] Either weight-based (see Table 19-7) or fixed UFH dosing (eg, 5,000 unit bolus followed by 1,000 units/h continuous infusion) produces similar clinical outcomes.[33] However, failure to give a sufficient intravenous UFH dose has been shown to increase VTE recurrence risk during initial treatment and long-term therapy.[6] Intravenous UFH requires hospitalization with frequent aPTT monitoring and dose adjustment and some patients still fail to achieve an adequate response to UFH therapy.[6] Consequently, traditional intravenous UFH in the acute treatment of VTE has largely been replaced by LMWH or fondaparinux. However, as clearance of LMWH, fondaparinux, and DOACs is dependent in some degree on renal function, UFH will continue to have a role for acute VTE treatment in patients with CrCL less than 30 mL/min (less than 0.5 mL/s).[5,28,43]

TABLE 19-7 Weight-Based[a] Dosing for Unfractionated Heparin Administered by Continuous IV Infusion

Indication	Initial Loading Dose	Initial Infusion Rate
Deep venous thrombosis/pulmonary embolism	80-100 units/kg Maximum = 10,000 units	17-20 units/kg/h Maximum = 2,300 units/h
Activated Partial Thromboplastin Time (seconds)	**Maintenance Infusion Rate** ***Dose Adjustment***	
<37 (or anti–factor Xa <0.20 unit/mL [kU/L])	80 units/kg bolus, and then increase infusion by 4 units/kg/h	
37-47 (or anti–factor Xa 0.20-0.29 unit/mL [kU/L])	40 units/kg bolus, and then increase infusion by 2 units/kg/h	

Indication	Initial Loading Dose	Initial Infusion Rate
48-71 (or anti–factor Xa 0.30-0.70 unit/mL [kU/L])	No change	
72-93 (or anti–factor Xa 0.71-1 unit/mL [kU/L])	Decrease infusion by 1-2 units/kg/h	
>93 (or anti–factor Xa >1 unit/mL [kU/L])	Hold infusion for 1 hour, and then decrease by 3 units/kg/h	

[a]Use actual body weight for all calculations. Adjusted body weight may be used for obese patients (>130% of ideal body weight).

Data from reference 6.

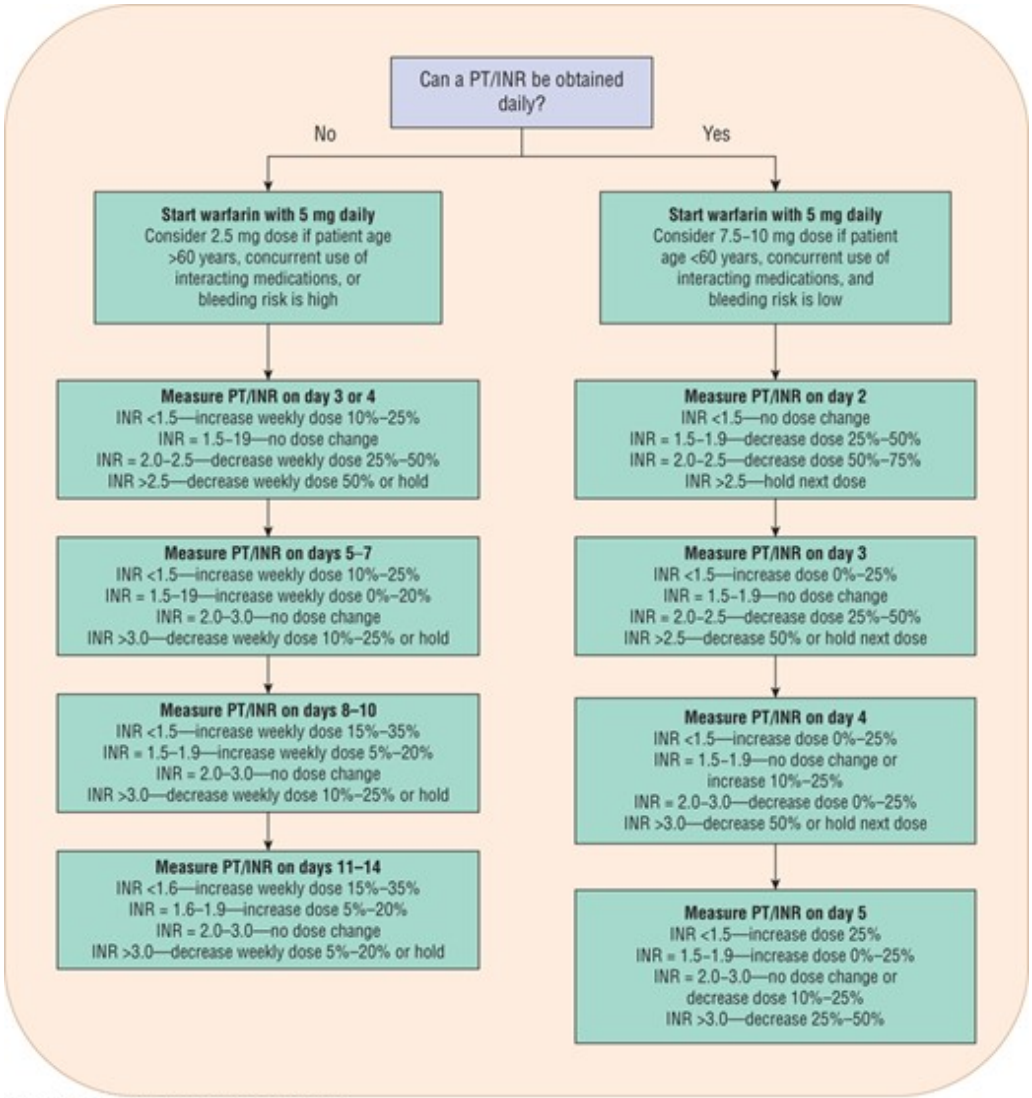
If a sufficient dose of UFH is administered subcutaneously (initial dose 333 units/kg followed by 250 units/kg twice daily), aPTT-guided dose titration may be unnecessary.[6] UFH administered in this manner might be a less costly option for treatment of acute VTE in appropriately selected patients. For patients weighing more than 80 kg, injection volume may be problematic.

Warfarin

Warfarin monotherapy is unacceptable for acute VTE treatment because the slow onset of effect is associated with high incidence of recurrent thromboembolism. However, warfarin is effective in the long-term VTE management provided it is started concurrently with rapid-acting injectable anticoagulant therapy.[5] Injectable anticoagulation should overlap with warfarin therapy for at least 5 days and until an INR more than or equal to 2 has been achieved for at least 24 hours.[5] The initial dose of warfarin should be 5 to 10 mg for most patients and periodically adjusted to achieve and maintain an INR between 2 and 3 (**Fig. 19-10**).

FIGURE 19-10

Initiation of warfarin therapy. INR, international normalized ratio; PT, prothrombin time.



Alternative Treatment

Most VTE cases require only anticoagulation therapy. In rare cases removing the occluding thrombus by pharmacologic or surgical means may be warranted. Consensus panel recommendations regarding thrombolysis or thrombectomy in VTE management are based on low-quality evidence, and more study is needed to clarify their precise role.[5,44]

Thrombolytic agents are proteolytic enzymes that enhance conversion of plasminogen to plasmin.[5] Thrombolytic therapy for DVT improves early venous patency, but this does not necessarily translate into improved long-term outcomes.[28] If thrombolytic therapy is pursued, systemic administration via peripheral vein is preferred to catheter-directed thrombolysis.[28] Patients with extensive proximal DVT presenting within 14 days of symptom onset, with good functional status, low bleeding risk, and a life expectancy of a year or more are thrombolysis candidates (**Table 19-8**). Catheter-directed DVT thrombolysis is preferred provided appropriate expertise and resources are available. Catheter-based thrombus fragmentation, with or without thrombus fragment aspiration, can be combined with catheter-directed thrombolysis and is associated with shorter treatment times and reduced cost. The

same anticoagulation therapy duration and intensity is recommended as for patients with DVT not receiving thrombolysis.[5] Patients with DVT involving the iliac and common femoral veins are at highest risk for postthrombotic syndrome and may have the greatest potential to benefit from thrombus removal strategies. In patients with impending venous gangrene despite optimal anticoagulant therapy, thrombus removal is indicated; for all other patients with acute DVT, AT9 suggests anticoagulation therapy alone over either catheter-directed or systemic thrombolysis.[5]

TABLE 19-8 Thrombolysis for the Treatment of Venous Thromboembolism

- The majority of patients with VTE do not require thrombolytic therapy
- Thrombolytic therapy for DVT should be reserved for patients who present with extensive proximal DVT (eg, ileofemoral) within 14 days of symptom onset, have good functional status, and are at low risk of bleeding
- Thrombolytic therapy should be administered to patients with massive PE with evidence of hemodynamic compromise (hypotension or shock) unless contraindicated by bleeding risk
- Thrombolytic therapy should be considered for selected high-risk patients without hypotension provided the risk of bleeding is acceptable
- Factors associated with high risk for adverse PE outcomes include:
    - Ill-appearing patients with marked dyspnea, anxiety, and low oxygen saturation
    - Elevated troponin levels
    - Right ventricular dysfunction on echocardiography
    - Right ventricular enlargement on chest CT
- Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (ie, recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke or intracranial hemorrhage)
- Baseline labs should include CBC and blood typing in case transfusion is needed
- Alteplase 100 mg infused via peripheral vein over 2 hours is the most commonly used thrombolytic for patients with PE
- Before thrombolytic therapy for PE, IV UFH should be administered in full therapeutic doses
- During thrombolytic therapy it is acceptable to either continue or suspend IV UFH (suspending UFH is the most common practice in the United States)
- aPTT should be measured following the completion of thrombolytic therapy
    - If aPTT is <80 seconds, UFH infusion should be started and adjusted to maintain aPTT in

therapeutic range

    - If aPTT is >80 seconds, measure every 2-4 hours and start UFH infusion when aPTT is <80 seconds

- Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding

aPTT, activated partial thromboplastin time; CBC, complete blood cell count; DVT, deep vein thrombosis; PE, pulmonary embolism; UFH, unfractionated heparin.

Data from references 1 and 28.

In acute PE management successful clot dissolution with thrombolytic therapy reduces elevated pulmonary artery pressure and normalizes right ventricular dysfunction. However, the risk of death from PE should outweigh the risk of serious bleeding associated with thrombolytic therapy. Patients being considered for thrombolytic therapy should be screened carefully for contraindications relating to bleeding risk (see Table 19-8).[5,45] Thrombolytic therapy is considered necessary in addition to aggressive interventions such as volume expansion, vasopressor therapy, intubation, and mechanical ventilation for patients with massive PE accompanied by shock and cardiovascular collapse (about 5% of patients with PE).[5,45] Thrombolytic therapy in these patients should be administered without delay to reduce risk of progression to multisystem organ failure and death. While lifesaving in the acute phase of massive PE with hypotension, the hemodynamic benefit of thrombolysis is comparable to that of UFH after a few days.[46]

The benefit of thrombolytic therapy in patients with PE without hemodynamic compromise is less clear and rapid risk stratification is required to determine whether patients may benefit from thrombolysis or embolectomy in addition to anticoagulation therapy.[41] Risk stratification helps inform the initial treatment intensity, low-risk patients being discharged early or managed as outpatients and high-risk patients receiving surveillance in the intensive care unit and/or advanced therapies such as thrombolysis.[47] Key components of risk stratification are clinical evaluation, determination of cardiac biomarker levels such as troponin, and assessment of right ventricular size and function.[5] The Pulmonary Embolism Severity Index (PESI) is a prognostic tool utilizing 11 routinely available clinical parameters: demographics (age and gender), comorbid illnesses (cancer, heart failure, and chronic lung disease), and clinical findings (pulse, systolic blood pressure, respiratory rate, temperature, mental status, and arterial oxygen saturation). PESI stratifies patients into five risk classes with classes I and II considered low risk.[47] AT9 suggests that patients with acute PE presenting without hypotension be risk stratified predominantly by signs that indicate clinical instability including decrease in systolic blood pressure but still more than 90 mm Hg, tachycardia, elevated jugular venous pressure, clinical evidence of poor tissue perfusion, hypoxemia, and failure to improve on anticoagulant therapy.[5] Patients with one or more of these clinical features are at high risk for PE-related morbidity and mortality and may benefit from thrombolytic therapy, provided bleeding risk is acceptable, even in the absence of hemodynamic compromise (see Table 19-8).[5] The

optimal role of thrombolysis in the management of PE requires further study.

In rare circumstances surgical thrombectomy for extensive ileofemoral DVT may be necessary, but catheter-directed thrombolysis is preferred if bleeding risk is acceptable.[28] For acute PE treatment, catheter-based embolectomy might be suitable in settings where expertise and resources are available for patients who have contraindications to thrombolytic therapy, have failed thrombolytic therapy, or in whom death is likely before thrombolytic onset.[28] In the absence of contraindications, catheter-based PE embolectomy is usually combined with thrombolytic therapy unless bleeding risk is high.[5] Surgical embolectomy is reserved for massive PE and hemodynamic instability when thrombolysis is contraindicated, and for when thrombolysis has failed clinically or will not have sufficient time to take effect.[5] In chronic PE cases—where persistent emboli produce CTPH, hypoxemia, and right-sided heart failure—surgical pulmonary thromboendarterectomy offers greater benefit than anticoagulants and may be the treatment of choice if performed by an experienced surgical team. A permanent IVC filter is usually inserted before or during the procedure and long-term warfarin therapy targeted to an INR of 2 to 3 is needed.[5]

Special Populations

Some patient populations with VTE require special consideration due to increased risk for recurrence, adverse events, or altered anticoagulant pharmacokinetics.

Pregnancy

Anticoagulation therapy is commonly used for the prevention and treatment of VTE during pregnancy.[12] UFH and LMWH do not cross the placenta and are preferred during pregnancy (**Table 19-9**).[12] Warfarin crosses the placenta and can result in fetal bleeding, central nervous system abnormalities, and embryopathy and should not be used for VTE treatment during pregnancy.[12] Women of childbearing age taking warfarin must be counseled regarding fetal risks and need for effective contraception. DOACs should be avoided in pregnancy until more information regarding safety is available.[48,49,50,51] Fondaparinux has not been extensively studied in pregnancy and may cross the placenta.[42] However, fondaparinux may be a viable option in pregnant patients intolerant to LMWH or those with a history of heparin-induced thrombocytopenia (HIT).[52]

TABLE 19-9 Unfractionated and Low-Molecular-Weight Heparin Use During Pregnancy

Acute treatment[a]	LMWH • Enoxaparin 1 mg/kg SC q 12 h or 1.5 mg/kg q 24 h *Or* • Dalteparin 100 units/kg SC q 12 h *Or*

Long-term treatment[c]	UFH • Initiate using weight-based IV therapy and adjust dose to achieve therapeutic anti-Xa level for at least 5 days • Transition to SC adjusted-dose UFH administered q 8-12 h with mid-interval anti-Xa activity in the therapeutic range[b] LMWH Maintain initial LMWH dose regimen throughout pregnancy *Or* Alter LMWH dose in proportion to any weight change (usually gain) *Or* Obtain monthly anti-Xa level measurements 4-6 hours after morning dose and adjust LMWH dose based on anti-Xa level (target = 0.5-1.2 units/mL [kU/L] if twice-daily dosing; 1-2 units/mL [kU/L] if once-daily dosing) *Or* UFH Obtain anti-Xa level at the midpoint of the dosing interval and adjust UFH dose to achieve an anti-Xa level of 0.3-0.7 unit/mL [kU/L]
Issues at time of delivery	Elective induction of labor • Discontinue UFH or LMWH 24 hours prior to induction • Initiate therapeutic doses of UFH by IV infusion and discontinue 4-6 hours prior to expected time of delivery if risk of recurrent VTE is deemed high Spontaneous labor • For LMWH, if there is a reasonable expectation that significant anticoagulant effect will be present at time of delivery: (a) epidural should be avoided and (b) reversal with protamine sulfate may be considered • For UFH, monitor the aPTT and reverse with protamine sulfate if aPTT is prolonged near the time of delivery Postpartum • Commence UFH or LMWH as soon as safely possible (usually 12 hours following delivery)

- Concurrently initiate warfarin therapy and discontinue UFH or LMWH when the INR is 2 or greater
- Continue anticoagulants for at least 6 weeks following delivery
- Warfarin can be safely used by women who are breast-feeding

aPTT, activated partial thromboplastin time; INR, international normalized ratio; LMWH, low-molecular-weight heparin; SC, subcutaneously; UFH, unfractionated heparin; VTE, venous thromboembolism.

[a]Twice-daily LMWH preferred during pregnancy due to increased clearance.

[b]Anti-Xa monitoring preferred as the relationship between aPTT and heparin levels differs in pregnant compared with nonpregnant patients.

[c]As pregnancy progresses the volume of distribution of LMWH changes, glomerular filtration rate increases, and most women gain weight.

Data from reference 12.

Pregnant women with a history of VTE should receive VTE prophylaxis for 6 to 12 weeks after delivery.[53] Antenatal prophylaxis may also be indicated depending on other risk factors, such as history of multiple VTE, VTE associated with pregnancy or estrogen therapy, or known thrombophilia. Anticoagulation for acute VTE during pregnancy should continue for at least 6 weeks postpartum and a minimum total duration of 3 months.[12] Warfarin, UFH, and LMWH are safe during breast-feeding.[6,54] It is not known if DOACs are excreted in human milk and breast-feeding is not recommended.[48,49,50,51]

Pediatric Patients

Venous thromboembolism in pediatric patients is increasing secondary to prematurity, cancer, trauma, surgery, congenital heart disease, and systemic lupus erythematosus. Pediatric patients rarely experience unprovoked VTE, but often develop DVTs associated with indwelling central venous catheters.[55] Recommendations for anticoagulant therapy in pediatric patients are largely extrapolated from adults; however, there are important pharmacokinetic and pharmacodynamic differences that should be taken into consideration. The majority of literature supporting pediatric recommendations is derived from uncontrolled studies, case reports, or in vitro experiments. When possible, a pediatric hematologist with experience managing VTE should manage pediatric patients.[55]

Anticoagulation with UFH and warfarin remains the most frequently used approach for VTE treatment in pediatric patients and the recommended target aPTT and INR ranges as well as the duration of therapy are extrapolated from adults.[55] The recommended initial bolus dose of UFH is 75 to 100 units/kg given intravenously over 10 minutes followed by a maintenance infusion of 28 units/kg/h for

infants 2 to 12 months of age and 20 units/kg/h for children aged 1 year or older.[55] Subsequent infusion rate adjustments should be made every 4 to 6 hours to maintain the aPTT within the institution-specific therapeutic range. The usual warfarin starting dose is 0.2 mg/kg with a maximum of 10 mg. Infants require higher warfarin doses per kilogram to maintain a target INR of 2 to 3 compared with teenagers and adults (mean dose 0.33 mg/kg, 0.09 mg/g, and 0.04 to 0.08 mg/kg, respectively).[55] The INR target range for VTE treatment in children is 2.0 to 3.0. Frequent INR monitoring and warfarin dose adjustments are typically required. When compared with adults, only 10% to 20% of pediatric patients can be safely monitored with once monthly INRs.[55] Obtaining blood for coagulation monitoring tests in pediatric patients is problematic because many have poor venous access; many clinicians recommend using finger-stick blood samples with portable point-of-care INR monitors.[55] Despite need for daily injections, LMWH is an attractive alternative for pediatric patients due to low drug interaction potential and less frequent laboratory testing. Most experts recommend anti-Xa activity monitoring with goal anti–factor Xa levels between 0.5 and 1.0 unit/mL (kU/L) 4 to 6 hours following subcutaneous injection. Compared with adults, children younger than 3 months or weighing less than 5 kg have higher per-kilogram dose requirements to achieve a "therapeutic" anti-Xa response. The LMWH dose for older children is generally similar to weight-adjusted doses used in adults.[55] Warfarin can be initiated concurrently with UFH or LMWH therapy. Therapy should be overlapped for a minimum of 5 days and until the INR is therapeutic. Warfarin should be continued for at least 3 months for provoked VTE and 6 months for unprovoked VTE.[55] DOACs are attractive alternatives in pediatric patients due to oral administration and no need for routine coagulation monitoring; however, safety and effectiveness in this population have not been established.[48,49,50,51] Thrombolysis and thrombectomy have been successfully employed in pediatric patients, but published data are very limited—routine use is not recommended.[55]

Patients with Cancer

Cancer-related VTE is associated with threefold higher rates of recurrent VTE, 2.5 to 6-fold higher rates of bleeding, and more resistance to standard warfarin-based therapy compared to patients without cancer.[56] Warfarin therapy in cancer patients is often complicated by drug interactions (eg, chemotherapy and antibiotics) and the need to interrupt therapy for invasive procedures. Maintaining stable INR control is also more difficult in this patient population because of nausea, anorexia, and vomiting.[5]

Randomized trials provide evidence that long-term LMWH monotherapy for cancer-related VTE significantly decreases recurrent VTE rates without increasing bleeding risks compared with warfarin-based therapy; most consensus guideline panels therefore recommend LMWH monotherapy for VTE treatment in patients with cancer.[5,16,57,58] Advantages of LMWH over warfarin for VTE treatment in cancer are expected to be greatest in those with one or more of the following: metastatic disease, treatment with aggressive chemotherapy, extensive VTE at presentation, liver dysfunction, poor or unstable nutritional status, or desire to avoid frequent blood draws for coagulation monitoring.[5]

For patients with cancer and VTE receiving LMWH, therapy should continue for at least the first 3 to 6

months of long-term treatment, at which time LMWH can be continued or warfarin therapy substituted. Anticoagulation therapy should continue for as long as the cancer is "active" and while the patient is receiving antitumor therapy.[5] A risk-to-benefit assessment should be performed on a regular basis considering overall clinical status, bleeding risk, quality of life, and life expectancy.[5] For patients with cancer who have VTE recurrence despite receiving anticoagulant therapy, LMWH appears to be more effective than warfarin-based therapy in preventing further recurrences and increasing the anticoagulant intensity may not be necessary in this situation.[56] A meta-analysis evaluated the outcomes of the subset of patients with cancer within the phase three VTE treatment trials comparing DOACs and conventional therapy with LMWH followed by warfarin.[59] There were similar recurrent VTE and major bleeding rates in the two groups suggesting DOACs are not inferior to conventional warfarin therapy for cancer-associated VTE management.[59] However, until DOACs are compared to LMWH monotherapy they cannot be recommended as first-line agents for cancer-related VTE.

Patients with Renal Insufficiency

Patients with acute or chronic kidney disease often require anticoagulation for VTE prevention or treatment. With the exception of warfarin, most anticoagulants have at least some dependency on renal elimination. Accumulation of drug is possible during treatment with LMWH, fondaparinux, and DOACs.[6,54] In addition, patients with chronic kidney disease are at increased risk of bleeding, independent of drug clearance.[60]

Low-molecular-weight heparins are renally eliminated and should be used with caution in patients with severe renal impairment.[61] Enoxaparin has specific labeling for patients with CrCL less than 30 mL/min (less than 0.5 mL/s), but supporting evidence is limited to pharmacokinetic modeling analyses.[62] Bleeding and recurrent VTE outcomes for patients with CrCL less than 30 mL/min (less than 0.5 mL/s) receiving enoxaparin 1 mg/kg once daily for acute VTE treatment were observed to be comparable to patients with normal renal function in one retrospective study.[43] However, UFH remains preferred for acute VTE treatment in this setting until further evidence becomes available.[5]

Direct oral anticoagulants rely to varying degrees on renal elimination and require dose adjustment for renal impairment.[48,49,50,51] Use of these anticoagulants in patients with CrCL less than 30 mL/min (less than 25 mL/min for apixaban) (or less than 0.5 mL/s and less than 0.42 mL/s for apixaban) should be avoided.

Patients Undergoing Invasive Procedures

Patients scheduled to undergo invasive procedures often require temporary discontinuation of anticoagulation therapy.[63] The decision to withhold anticoagulation therapy should be based on the type of surgical procedure being performed and the patient's bleeding and thromboembolic risk. Anticoagulation therapy should generally not be discontinued in patients undergoing minimally invasive procedures such as dental work, cataract surgery, or minor dermatologic procedures.[64] If the bleeding risk from the procedure is considerable, near-normal hemostasis should be achieved prior

to the procedure. For DOACs, the time required for restoration of normal hemostasis after interrupting therapy is dependent on renal function. Stopping DOACs 2 days prior to invasive procedures is usually sufficient to restore near normal hemostasis for patients with normal renal function. Additional days off therapy may be required for patients with impaired renal function.[48,49,50,51] The anticoagulant effect of dabigatran can be rapidly reversed with idarucizumab for patients requiring urgent surgical interventions.[65] Up to 5 days may be required for restoration of normal hemostasis after warfarin discontinuation. Patients at high thromboembolic risk (ie, DVT or PE in the previous month) can be considered for so-called bridge therapy with UFH or an LMWH before and/or after the procedure.[64] Bridge therapy has been associated with increased major bleeding without offering additional recurrent VTE risk reduction; therefore, most patients with VTE can safely interrupt warfarin for invasive procedures without using bridge therapy.[63]

DRUG CLASS INFORMATION

8 Optimal use of anticoagulant therapies requires knowledge of pharmacologic and pharmacokinetic characteristics as well as systematic management and ongoing patient education to reduce the risks of bleeding and therapeutic failure (**Tables 19-10** and **19-11**).

TABLE 19-10 Comparison of the Chemical and Pharmacokinetic Properties of Antithrombotic Drugs Used for Venous Thrombosis

Agent	FDA Approved	Method of Preparation	Mean Molecular Weight (d)	Plasma Half-Life	Anti-Xa: Anti-IIa Activity	Bioavailability
Unfractionated heparin	Yes	Extracted from porcine gut mucosa or beef lung	≈15,000	30-90 minutes (dose dependent)	1:1	SC: 30%-70% (dose dependent)
Low-molecular-weight heparins						
Dalteparin (Fragmin)	Yes	Nitrous acid depolymerization	≈6,000	119-139 minutes	2.7:1	SC: 87%
Enoxaparin (Lovenox)	Yes	Benzoylation and alkaline depolymerization	≈4,200	129-180 minutes	3.8:1	SC: 92%
Anti–factor Xa inhibitors						
Fondaparinux (Arixtra)	Yes	Synthetic	1,728	15-18 hours	100% anti-Xa	SC: 100%
Rivaroxaban (Xarelto)	Yes	Synthetic	436	7-11 hours	100% anti-Xa	Oral: 80%-100%
Apixaban (Eliquis)	Yes	Synthetic	459	9-14 hours	100% anti-Xa	Oral: 50%

Agent	FDA Approved	Method of Preparation	Mean Molecular Weight (d)	Plasma Half-Life	Anti-Xa: Anti-IIa Activity	Bioavailability
Edoxaban (Savaysa)	Yes	Synthetic	548	10-14 hours	100% anti-Xa	Oral: 62%
Direct thrombin inhibitors						
Dabigatran (Pradaxa)	Yes	Synthetic	471	14 hours	100% anti-IIa	Oral: 7%
Vitamin K antagonists						
Warfarin (Coumadin)	Yes	Synthetic	330	40 hours	1:1	Oral: 90%-100%

SC, subcutaneous.

TABLE 19-11 Risk Factors for Major Bleeding While Taking Anticoagulation Therapy

Anticoagulation intensity
Initiation of therapy (first few days and weeks)
Unstable anti-coagulation response
Age >65 years
Concurrent antiplatelet therapy
Concurrent nonsteroidal anti-inflammatory drug use
History of GI bleeding
Recent surgery or trauma
High risk for fall/trauma
Heavy alcohol use
Renal failure
Cerebrovascular disease
Malignancy

Direct Oral Anticoagulants

Shortcomings with warfarin, LMWH, fondaparinux, and UFH have driven the search for replacements with rapid anticoagulant onset and oral administration without the need for monitoring. The DOACs represent a major advance in VTE prevention and treatment (see Fig. 19-9).

Pharmacology/Mechanism of Action

Rivaroxaban, apixaban, and edoxaban are potent and selective inhibitors of both free and clot-bound factor Xa and do not require antithrombin to exert their anticoagulant effect.[48,50,51] Dabigatran is a

selective, reversible, direct factor IIa inhibitor.[49]

Pharmacokinetics

All Factor Xa inhibitors have good oral bioavailability (80%, 60%, and 62% for rivaroxaban, apixaban, and edoxaban, respectively) whereas dabigatran is formulated as a prodrug (dabigatran etexilate) to overcome poor oral bioavailability.[48,49,50,51] All DOACs reach peak plasma concentrations in about 2 hours. Each drug is renally eliminated to some degree (33%, 27%, 50%, and 80% for rivaroxaban, apixaban, edoxaban, and dabigatran, respectively) with terminal half-lives of 9 to 12 hours for the Factor Xa inhibitors, and 14 to 17 hours for dabigatran.[48,49,50,51] DOACs should be used with caution in patients with renal dysfunction.[66] Rivaroxaban and apixaban are substrates of cytochrome p450 (CYP) 3A4, and the P-glycoprotein (P-gp) transporter.[48,50] Neither edoxaban nor dabigatran undergo significant CYP 3A4 metabolism, but both are P-gp substrates.[49,51] Inhibitors and inducers of CYP 3A4 enzymes or P-gp may cause changes in DOAC exposure and increase risk of bleeding or VTE events.[48,49,50,51]

Efficacy

Direct oral anticoagulants are noninferior to warfarin therapy overlapped with LMWH during initiation for reducing recurrence during VTE treatment.[48,49,50,51] Similarly, compared to LMWH, the Xa inhibitors are noninferior for preventing VTE following hip or knee replacement surgery.[48,49,50,51] Approved DOAC indications for prevention and treatment of VTE are summarized in **Table 19-12**.

TABLE 19-12 Approved Indications and Dosing for the Direct Oral Anticoagulants

	VTE prophylaxis following Orthopedic Surgery	Acute VTE Treatment	Extended VTE Treatment (after the first 6 months of anticoagulant therapy)
Dabigatran	Not approved for use	150 mg PO twice daily with or without food FOLLOWING at least 5 days of parenteral anticoagulant therapy	150 mg PO twice daily with or without food
Rivaroxaban	10 mg PO once daily with or without food beginning 6-10 hours after surgery as soon as hemostasis is achieved and continuing for 12-35 days postoperatively	15 mg PO twice daily with food for Days 1-21, then 20 mg PO once daily with food beginning on Day 22	20 mg PO once daily with food
Apixaban	2.5 mg PO twice daily with or without food beginning 12-24	10 mg PO twice daily with or without food for Days	2.5 mg PO twice daily with or without food

	VTE prophylaxis following Orthopedic Surgery	Acute VTE Treatment	Extended VTE Treatment (after the first 6 months of anticoagulant therapy)
	hours after surgery and continuing for 12-35 days postoperatively	1-7, then 5 mg PO twice daily with or without food beginning on Day 8	
Edoxaban	Not approved for use	60 mg PO once daily with or without food FOLLOWING at least 5 days of parenteral anticoagulant therapy	Not approved for use

PO, by mouth; VTE, venous thromboembolism.

Data from references [48,49,50,51].

Adverse Effects

The most common adverse effect associated with DOAC therapy is bleeding.[48,49,50,51] The International Society for Thrombosis and Haemostasis defines major bleeding as fatal bleeding, any bleeding into a critical anatomic space (eg, intracranial bleeding, hemarthrosis, pericardial bleeding, or intraocular bleeding), bleeding that requires transfusion of 2 or more units of whole blood or red cells, or bleeding that leads to a greater than 2 g/dL (20 g/L; 1.24 mmol/L) drop in hemoglobin concentration. Bleeding that does not meet the major bleeding criteria but requires medical intervention or alteration of therapy is sometimes termed clinically relevant non-major bleeding. All other bleeding is considered minor and is common during anticoagulation therapy even in the most expertly managed patients. Patients presenting with significant bleeding during DOAC therapy should receive routine supportive care (fluid resuscitation, blood transfusion, maintenance of renal function, bleeding source identification, and surgical intervention if needed), and discontinuation of anticoagulation therapy.[67] Because DOACs have relatively short half-lives, these measures may control bleeding in many patients, especially those with normal renal function.[67] Activated charcoal may provide some benefits if drug intake occurred within a couple of hours of presentation, and hemodialysis may be of benefit for reversal of dabigatran.[67] Idarucizumab rapidly reverses the dabigatran anticoagulant effect following IV administration.[65] Idarucizumab can be used during emergency situations such as life-threatening bleeding and when there is need for urgent surgical intervention. Specific reversal agents for apixaban, edoxaban, and rivaroxaban are not available at this time, although several are in development: andexanet alfa for rivaroxaban, apixaban, and LMWH and ciraparantag for UFH, LMWH, and each of the DOACs (**Table 19-13**). If traditional hemostatic measures fail in a life-threatening bleeding situation in patients receiving Xa inhibitors, it may be reasonable to consider the use of prothrombin complex concentrates (PCCs) (3-factor, 4-factor, or activated PCCs) or recombinant Factor VIIa, while weighing the associated risk for thrombotic events. Animal, in vitro, and healthy volunteer studies have shown that these agents reverse coagulation

laboratory parameters, but controlled studies of these agents in bleeding patients taking DOACs are not available. Fresh-frozen plasma (FFP) is unlikely to provide clinical benefit.[67] The most frequent nonbleeding adverse events in clinical trials of DOACs were gastrointestinal complaints.[48,49,50,51]

TABLE 19-13 Reversal Agents for the Direct Oral Anticoagulants

Reversal Agent	Target	Outcomes and Current Status
Idarucizumab (monoclonal antibody fragment)	Dabigatran	Reversed anticoagulant effect of dabigatran in patients with serious bleeding or needing urgent reversal for a procedure Approved by FDA October 2015
Andexanet (modified recombinant Factor Xa)	Rivaroxaban, Apixaban, LMWH	Reversed anticoagulant effect of rivaroxaban and apixaban in healthy volunteers Phase III clinical trial underway
Ciraparantag (synthetic molecule)	UFH, LMWH, Rivaroxaban, Apixaban, Edoxaban, Dabigatran	Reversed anticoagulant effect of Rivaroxaban, Apixaban, Edoxaban, and Dabigatran in animal studies Reversed anticoagulant effect of Rivaroxaban, Apixaban, and Edoxaban in human in vitro studies Reversed anticoagulant effect of Edoxaban in healthy volunteers Phase III trials not yet begun

Data from references 65, 86, and 87.

Drug–drug and Drug–food Interactions

Adding aspirin to DOAC therapy nearly doubles bleeding rates and should be avoided in most patients with VTE. All DOACs are P-gp substrates and subject to changes in anticoagulant effect when coadministered with P-gp inhibitors or inducers. Rivaroxaban and apixaban are subject to interactions involving inhibitors or inducers of CYP 3A4.[48,49,50,51] During DOAC therapy, concurrent use of interacting drugs should be avoided because the anticoagulant effect cannot be easily monitored. When interacting drugs cannot be avoided it may be best to switch to warfarin for dose adjustment guided by INR monitoring.

Clinical Controversy…

Should aspirin be used for VTE prevention after major surgery? For more than a decade, the ACCP recommended against the use of aspirin as a sole agent for prophylaxis after high VTE risk, such as major orthopedic sugery. The rationale provided for this recommendation was not that aspirin was

ineffective but rather that anticoagulants were substantially more effective. The evidence supporting the superiority of anticoagulants relied heavily on trials including a primary outcome of asymptomatic DVT found on screening ultrasound or venography. AT9 focused on symptomatic VTE and bleeding events in their comparison of pharmacologic agents. As a result, aspirin was included as an option for VTE prophylaxis in AT9 and added to the list of approved VTE prophylaxis strategies in the Surgical Care Improvement Project (SCIP) guidelines in 2014. However, NICE guidelines do not include aspirin or other antiplatelet agents as an approved option for VTE prophylaxis in high-risk medical or surgical populations.

Dosing and Administration

Rivaroxaban and apixaban utilize a single-drug approach for acute VTE treatment, whereas at least 5 days of parenteral anticoagulant therapy is required prior to edoxaban or dabigatran initiation for acute VTE (see Fig. 19-9). The 15- and 20-mg doses of rivaroxaban should be taken with food to enhance oral absorption, but all other DOACs can be taken irrespective of food.[48,49,50,51] Dosing information for VTE prevention and treatment is summarized in Table 19-12.

Low-Molecular-Weight Heparin

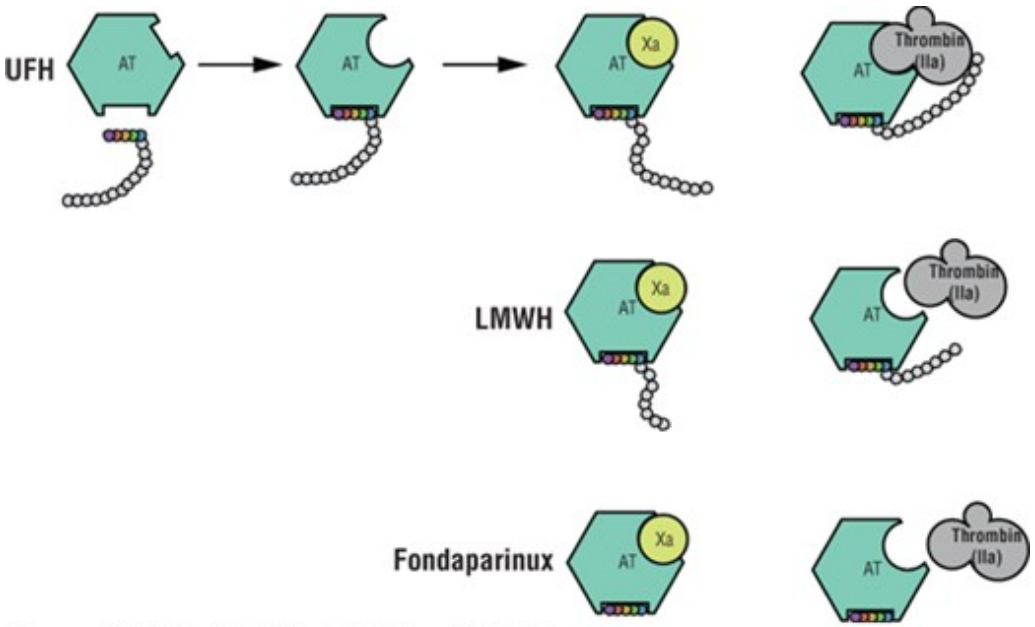
Low-molecular-weight heparin fragments produced by either chemical or enzymatic depolymerization of UFH (see Table 19-10) are heterogeneous mixtures of sulfated glycosaminoglycans with approximately one-third the mean UFH molecular weight.[6] Advantages of LMWH over UFH include predictable anticoagulation dose response, improved subcutaneous bioavailability, dose-independent clearance, longer biologic half-life, lower incidence of thrombocytopenia, and reduced need for routine laboratory monitoring.[6]

Pharmacology/Mechanism of Action

Low-molecular-weight heparin prevents thrombus growth and propagation by enhancing and accelerating the activity of antithrombin similar to UFH.[6] The principal difference in the pharmacologic activity of LMWH and UFH is their relative inhibition of factor Xa and thrombin. Because of smaller chain lengths, LMWH has limited activity against thrombin (**Fig. 19-11**). The ratio of anti–factor Xa: IIa activity varies between 4:1 and 2:1. By comparison, UFH has an anti–factor Xa:IIa activity ratio of 1:1.[6]

FIGURE 19-11

Pharmacologic activity of unfractionated heparin, low-molecular-weight heparins (LMWHs), and fondaparinux.



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Pharmacokinetics

Compared with UFH, LMWH has a more predictable anticoagulation response. The improved pharmacokinetic profile of LMWH is the result of reduced binding to proteins and cells.[6] The bioavailability of LMWH is about 90% when administered subcutaneously. The peak anticoagulation effect is seen in 3 to 5 hours.[6] The predominant mode of elimination for LMWH is renal. Consequently, biologic half-life may be prolonged in patients with renal impairment.[6] The plasma half-life of LMWH preparations is 3 to 6 hours. The clearance of LMWH is independent of dose.[6]

Efficacy

The efficacy of LMWH for prevention of VTE was established in clinical trials in comparison to LDUH and placebo. For treatment of VTE, the efficacy of fixed weight-based LMWH was compared to aPTT-adjusted intravenous UFH; all patients were transitioned to warfarin for long-term therapy.[62,68]

Adverse Effects

As with other anticoagulants, bleeding is the most common LMWH adverse effect.[60] The frequency of major bleeding is purported to be less with LMWH than with UFH, but this has not been consistently demonstrated in clinical trials.[60] Although there is no proven method for reversing LMWH anticoagulation if major bleeding occurs, IV protamine sulfate can be administered. However, because of limited binding to the shorter LMWH chains, protamine sulfate neutralizes only around 60% to 75% of LMWH anticoagulant activity.[6] The recommended dose of protamine sulfate is 1 mg/1 mg of enoxaparin or 1 mg/100 anti–factor Xa units of dalteparin administered in the previous 8 hours. A second protamine sulfate dose of 0.5 mg/1 mg or 100 anti–factor Xa units can be given if bleeding continues. Smaller doses of protamine sulfate can be used if the LMWH dose was given in

the previous 8 to 12 hours. The use of protamine sulfate is not recommended if LMWH was administered more than 12 hours earlier.[6] Two additional agents are in development that may have an important role in the future of management of LMWH-related bleeding. Andexanet alfa is a recombinant modified Factor Xa molecule that lacks enzymatic activity while binding to anticoagulant medications and ciraparantag (also known as PER977) may have utility in rapidly reversing LMWH.[69]

Although thrombocytopenia can occur with LMWH use, the incidence of HIT is three times lower than that observed with UFH, perhaps due to the reduced propensity of LMWH to bind to platelets.[6] Because LMWH exhibits nearly 100% cross-reactivity with heparin antibodies in vitro, LMWH should be avoided in patients with an established diagnosis or history of HIT.[6] The risk of osteoporosis appears to be lower with LMWH than with UFH, but both agents have been associated with osteopenia.[6]

Drug–drug Interactions

Drugs enhancing bleeding risk should be avoided during LMWH therapy, if possible. This includes aspirin, non-steroidal anti-inflammatory drugs, dipyridamole, or sulfinpyrazone.[62,68]

Dosing and Administration

Low-molecular-weight heparin is given in fixed or weight-based doses based on the product and indication (see Table 19-5). Doses should be based on actual body weight and dose capping is not recommended.[61] The dose for enoxaparin is expressed in milligrams, whereas dalteparin doses are expressed in units of anti–factor Xa activity. LMWH is given by subcutaneous injection as described in Table 19-6.

Significant LMWH accumulation is possible in patients with severe renal impairment.[6] The enoxaparin dose should be reduced or the dosing interval extended to once daily in patients with CrCL less than 30 mL/min (less than 0.5 mL/s).[62] Dalteparin pharmacokinetics are less well characterized in renal insufficiency.[70] LMWH use in patients with end-stage renal disease receiving hemodialysis is poorly understood; thus, UFH is preferred for these patients.[6] Some experts recommend measuring anti–factor Xa activity if LMWH therapy is continued for more than a few days in patients with severe renal disease.[6] For patients with CrCL less than 30 mL/min (less than 0.5 mL/s) who require VTE prophylaxis, enoxaparin 30 mg once daily is recommended.[6]

Fondaparinux

Fondaparinux is a synthetic molecule consisting of the five critical saccharide units that bind specifically, but reversibly, to antithrombin. Unlike UFH or LMWH, fondaparinux inhibits only factor Xa activity.[6]

Pharmacology/Mechanism of Action

Fondaparinux prevents thrombus generation and clot formation by indirectly inhibiting factor Xa activity through its interaction with antithrombin (see Fig. 19-11). Fondaparinux is not destroyed during this process and is released to bind other antithrombin molecules.[6]

Pharmacokinetics

Fondaparinux is rapidly and completely absorbed following subcutaneous administration achieving peak plasma concentrations approximately 2 hours after a single dose and 3 hours with repeated once-daily dosing. At therapeutic concentrations fondaparinux does not bind to red blood cells or other plasma proteins.[6] Fondaparinux is primarily eliminated unchanged in the urine. The terminal elimination half-life is 17 to 21 hours.[6] The anticoagulant effect of fondaparinux persists for 2 to 4 days following discontinuation of the drug in patients with normal renal function.

Efficacy

The efficacy of fondaparinux for prevention of VTE was established in clinical trials in comparison to LMWH. For treatment of VTE, the efficacy of fixed weight-based fondaparinux was compared to fixed weight-based LMWH; all patients were transitioned to warfarin for long-term therapy.[42]

Adverse Effects

The primary adverse effect associated with fondaparinux therapy is bleeding.[42] Fondaparinux should be used with extreme caution with neuraxial anesthesia or following spinal puncture because of the risk for spinal or epidural hematoma formation.[42] Some case reports have implicated fondaparinux as a cause of HIT, while others have documented successful HIT treatment with fondaparinux.[71] A specific antidote to reverse the antithrombotic activity of fondaparinux is not currently available.[6]

Drug–drug Interactions

Fondaparinux has no known pharmacokinetic drug interactions; other drugs with anticoagulant, fibrinolytic, or antiplatelet activity increase the risk of bleeding.[42]

Dosing and Administration

The dose of fondaparinux for VTE prevention is 2.5 mg injected subcutaneously once daily starting 6 to 8 hours following surgery if hemostasis has been established. It is important to avoid initiating fondaparinux too soon because there is a significant relationship between first dose timing and major bleeding risk.[6] Patients weighing less than 50 kg should not receive VTE prophylaxis with fondaparinux.[42] The usual duration of prophylaxis is 5 to 9 days, but extended prophylaxis for up to 35 days following hospital discharge may be used.[4] For the treatment of DVT or PE, the dose of fondaparinux is 5 mg for patients up to 50 kg, 7.5 mg for 50 to 100 kg, and 10 mg for more than 100 kg.[42]

Unfractionated Heparin

Unfractionated heparin has been used for VTE prevention and treatment for decades. Commercially available UFH preparations are derived from bovine lung or porcine intestinal mucosa. Although some differences exist between the two sources, no differences in antithrombotic activity have been demonstrated.[6]

Pharmacology/Mechanism of Action

Unfractionated heparin is a heterogeneous mixture of sulfated mucopolysaccharides of variable lengths and pharmacologic properties (see Table 19-10).[6] The anticoagulant profile and clearance of each UFH molecule varies based on its length. Smaller chains are cleared less rapidly than their longer counterparts.[6]

The anticoagulant effect of UFH is mediated through a specific pentasaccharide sequence that binds to antithrombin, provoking a conformational change (see Fig. 19-11). Only one-third of the UFH molecules possess the unique pentasaccharide sequence with affinity for antithrombin. The UFH–antithrombin complex is 100 to 1,000 times more potent as an anticoagulant compared with antithrombin alone. Antithrombin inhibits factor IXa, Xa, XIIa, and IIa activity. UFH prevents thrombus growth and propagation allowing endogenous thrombolytic systems to lyse the clot.[6]

Thrombin and Xa are most sensitive to UFH–antithrombin complex inhibition. To inactivate thrombin, the heparin molecule must form a ternary complex bridging between antithrombin and thrombin (see Fig. 19-11).[6] Only molecules containing more than 18 saccharides are able to bind to both antithrombin and thrombin simultaneously. Smaller heparin molecules cannot facilitate the interaction between antithrombin and thrombin. In contrast, the inactivation of factor Xa does not require UFH to form a bridge with antithrombin, but requires only UFH binding to antithrombin via the specific pentasaccharide sequence. UFH molecules with as few as five saccharide units are able to catalyze the inhibition of factor Xa. After it has produced its effect UFH uncouples from antithrombin and quickly recouples with another antithrombin molecule.[6]

Pharmacokinetics

Unfractionated heparin is not reliably orally absorbed as a result of its large molecular size and anionic structure. The bioavailability and biologic activity of UFH is limited by a propensity to bind plasma proteins, platelet factor-4, macrophages, fibrinogen, lipoproteins, and endothelial cells. This may explain the substantial interpatient and intrapatient variability observed in the anticoagulation response to UFH.[6]

The onset of anticoagulant effect after subcutaneous injection is 1 to 2 hours, peaking at 3 hours.[6] Continuous infusion is preferred for intravenous UFH administration.[5] Intramuscular administration is discouraged because of the risk of large hematoma formation.

Unfractionated heparin has a dose-dependent half-life of approximately 30 to 90 minutes.[6] There are

two primary mechanisms for UFH elimination, a rapid, but saturable zero-order process involving enzymatic inactivation of heparin molecules bound to endothelial cells and macrophages, and renal elimination via a slower, nonsaturable first-order process. With typical therapeutic UFH regimens the zero-order process predominates.[6]

Efficacy

The clinical effectiveness of UFH for prevention and treatment of VTE has been determined through many years of clinical use.

Adverse Effects

Low-dose subcutaneous UFH is associated with a minimal major bleeding risk, while rates for patients receiving therapeutic UFH doses range from 0% to 2%.[60] Close monitoring for bleeding signs and symptoms during UFH therapy is crucial.[6,60] When major bleeding occurs, UFH should be discontinued and the underlying bleeding source identified and treated. Protamine sulfate in a dose of 1 mg per 100 units of UFH (maximum of 50 mg) can be administered via slow intravenous infusion to reverse the anticoagulant effects of UFH.[6] Protamine sulfate neutralizes UFH in 5 minutes, and persists for 2 hours. Multiple doses or prolonged infusion of protamine sulfate may be necessary if bleeding continues.[6]

Heparin-induced thrombocytopenia is a rare drug-induced immunologic reaction requiring immediate intervention.[72] The most common complication of HIT is VTE; arterial thromboembolic events occur less frequently. Approximately 5% to 10% of patients with HIT die, usually from thrombotic complications.[72] Thrombocytopenia (defined as a platelet count less than $150 \times 10^3/mm^3$ [less than $150 \times 10^9/L$]) is the most common clinical HIT manifestation. Thrombocytopenia occurs in up to 95% of patients with confirmed HIT if platelet counts that decrease by 30% to 50% but remain above $150 \times 10^3/mm^3$ ($150 \times 10^9/L$) are included in the definition.[72] The characteristic onset of falling platelet count in HIT is 5 to 10 days after initiation of UFH (day 0 being the first day of UFH), particularly when administered perioperatively.[72] Thrombocytopenia alone is not sufficient for diagnosing HIT; serologic confirmation of heparin antibodies using an assay available only in a few specialty laboratories is required.[72] Falsely diagnosing HIT can have serious consequences including unnecessary anxiety, unnecessary UFH withdrawal, and the use of alternative anticoagulants with higher bleeding risk. One decision analysis found that strict adherence to platelet monitoring for HIT could, at best, prevent one thrombosis per 1,000 patients screened at the cost of one major bleeding event.[72] For these reasons, AT9 suggests monitoring platelet counts every 2 to 3 days from day 4 to 14 of UFH only in populations where the expected HIT risk exceeds 1%.[72] The use of a clinical prediction rule, such as the four Ts score (*T*hrombocytopenia, *T*iming of platelet count fall or thrombosis, *T*hrombosis, o*T*her explanation for thrombocytopenia), can improve the predictive value of platelet count monitoring and heparin antibody testing.[72,73] A four Ts score should be calculated when HIT is suspected in patients receiving heparin (UFH or LMWH). If the four Ts score is low, no further workup is needed, whereas, further HIT workup including serologic testing should be undertaken if the four Ts score is moderate or high.[74] In the setting of new thrombosis occurring in

conjunction with falling platelets and a moderate or high four Ts score all sources of heparin should be discontinued. Alternative anticoagulation with a direct thrombin inhibitor should then be initiated. If warfarin therapy is being used, it should be discontinued and reversed with vitamin K; once platelet counts have recovered warfarin can be carefully resumed with direct thrombin inhibitor overlap until the INR is more than or equal to 2.0.[72]

Using UFH in doses more than or equal to 20,000 units/day for more than 6 months, especially during pregnancy, is associated with significant bone loss and may lead to osteoporosis.[6]

Drug–drug and Drug–food Interactions

Few drug interactions are reported with UFH, but concurrent use with other anticoagulant, thrombolytic, and antiplatelet agents increases bleeding risk.[6]

Dosing and Administration

Unfractionated heparin dose is expressed in units of activity. For VTE prevention, UFH is given by subcutaneous injection in the abdominal fat layer. The typical prophylaxis dose is 5,000 units every 8 to 12 hours. When immediate and full anticoagulation is required, an intravenous bolus dose followed by a continuous infusion is preferred (see Table 19-7).[6] Subcutaneous UFH (initial dose of 333 units/kg followed by 250 units/kg every 12 hours) also provides adequate therapeutic anticoagulation for the treatment of acute VTE.[6]

Warfarin

Because of its narrow therapeutic index, predisposition to drug and food interactions, and propensity to exacerbate bleeding, warfarin requires continuous patient monitoring and education to achieve optimal outcomes.[54]

Pharmacology/Mechanism of Action

Warfarin exerts its anticoagulation effect by inhibiting the enzymes responsible for the cyclic vitamin K interconversion in the liver.[54] Vitamin K in its reduced form is a required cofactor for vitamin K-dependent carboxylation of factors II, VII, IX, and X, as well as the endogenous anticoagulant proteins C and S. Hepatic carboxylation of the N-terminal region of these proteins is required for biologic activity. By inhibiting the reduced vitamin K supply used in the production of these proteins, warfarin therapy produces partially carboxylated and decarboxylated coagulation proteins with reduced activity.[54] Warfarin has no direct effect on previously circulating clotting factors or previously formed thrombus. The time required for warfarin to achieve its pharmacologic effect is dependent on coagulation protein elimination half-lives (6 hours for factor VII and 72 hours for prothrombin).[54] Full antithrombotic effect is not achieved for at least 6 days after warfarin therapy initiation. By suppressing fully functional clotting factor production, warfarin prevents initial thrombus formation and propagation.[54]

Pharmacokinetics

Warfarin is a racemic mixture of *R* and *S* isomers, with *S*-warfarin being 2.7 to 3.8 times more potent than *R*-warfarin.[54] Warfarin is rapidly and extensively absorbed from the GI tract (bioavailability more than 90%) and reaches peak plasma concentration within 4 hours of oral administration. Warfarin is 99% bound to plasma proteins and undergoes stereoselective metabolism via CYP 1A2, 2C9, 2C19, 2C8, 2C18, and 3A4 isoenzymes in the liver, with 2C9 being the main enzyme to modulate in vivo anticoagulant activity.[75] Warfarin pharmacokinetics varies substantially between individuals leading to large interpatient differences in dose requirements. Genetic variations in the 2C9 isoenzyme and vitamin K epoxide reductase (VKOR) have been shown to correlate with warfarin dose requirements.[54] Given the greater potency of *S*-warfarin, coadministration of drugs that induce or inhibit the CYP 2C9 isoenzyme is more likely to cause clinically significant interactions.[54]

Efficacy

The clinical effectiveness of warfarin for prevention and treatment of VTE has been determined through many years of clinical use.

Adverse Effects

Warfarin's primary adverse effect is bleeding that can range from mild to life threatening.[54] Although warfarin does not cause bleeding per se, it exacerbates bleeding from existing lesions and enables massive bleeding from ordinarily minor sources.[54] Anticoagulation therapy intensity is an important bleeding risk factor; the likelihood of bleeding rises with increasing INR values.[54] Therefore, correcting high INR values is important to reduce bleeding risk. For INR more than 4.5 without evidence of bleeding, AT9 suggests withholding warfarin, decreasing the warfarin dose, and/or providing a small dose of vitamin K to shorten the time required to return to normal INR.[33] Vitamin K can be administered parenterally or orally; the oral route is preferred in the absence of serious bleeding. AT9 suggests against routine vitamin K use if the INR is between 4.5 and 10 and no bleeding is present as it has not been shown to affect the risk of developing subsequent bleeding or thromboembolism compared with simply withholding warfarin alone. For INRs more than 10 without evidence of bleeding, oral vitamin K 2.5 mg is suggested.[33] Vitamin K should be used cautiously in patients at high thromboembolism risk due to the possibility of INR overcorrection. Conversely, simply withholding warfarin therapy may not lower high INRs quickly enough in patients at high bleeding risk. Most patients with asymptomatic INR elevations can be safely managed by withholding warfarin alone.

Patients with warfarin-associated major bleeding require supportive care, and in addition AT9 suggests rapid reversal of anticoagulation with four-factor PCCs (rather than FFP) and 5 to 10 mg of vitamin K administered via slow intravenous injection.[33]

Other adverse effects associated with warfarin are uncommon, but can be serious.[54] The etiology of the "purple toe syndrome" is unknown, but is thought to be the result of cholesterol

microembolization into the arterial circulation of the toes.[54] Warfarin-induced skin necrosis is a serious dermatologic reaction usually manifesting in the first week of therapy as a painful maculopapular rash and ecchymosis or purpura that subsequently progresses to necrotic gangrene. Areas of the body rich in subcutaneous fat, such as the breasts, thighs, buttocks, and abdomen are most commonly affected.[54] If skin necrosis is suspected, warfarin therapy should be discontinued immediately and reversed with FFP or PCC and vitamin K, and full-dose UFH or LMWH therapy initiated. Patients with a history of skin necrosis should restart warfarin with extreme caution, if at all, using small doses and gradual titration under full-dose UFH or LMWH coverage until a therapeutic INR is achieved.[54]

Drug–drug and Drug–food Interactions

The pharmacokinetic and pharmacodynamic properties of warfarin predispose to numerous clinically important food and drug interactions.[76] Vitamin K can reverse warfarin's pharmacologic activity, and many foods contain sufficient vitamin K to reduce the anticoagulation effect if consumed in large portions or repetitively within a short period of time.[54] Patients should be instructed to maintain a relatively consistent intake of vitamin K-rich foods (**Table 19-14**). It is important to stress consistency rather than abstinence.

TABLE 19-14 Vitamin K Content of Select Foods[a]

Very High (>200 mcg)	High (100-200 mcg)	Medium (50-100 mcg)	Low (<50 mcg)
Brussel sprouts	Basil	Apple, green	Apple, red
Chickpea	Broccoli	Asparagus	Avocado
Collard greens	Chive	Cabbage	Beans
Coriander	Coleslaw	Cauliflower	Breads, grains
Endive	Cucumber (with peel)	Mayonnaise	Carrot
Kale	Canola oil	Nuts, pistachio	Cereal
Lettuce, red leaf	Green onion/scallion	Squash, summer	Celery
Parsley	Lettuce, butterhead		Coffee
Spinach	Mustard greens		Corn
Swiss chard	Soybean oil		Cucumber (without peel)
Tea (green)			Dairy products
Tea (black)			Eggs
Turnip greens			Fruit (varies)

Very High (>200 mcg)	High (100-200 mcg)	Medium (50-100 mcg)	Low (<50 mcg)
			Lettuce, iceberg
			Meats, fish, poultry
			Pasta
			Peanuts
Watercress			Peas
			Potato
			Rice
			Tomato

[a]Approximate amount of vitamin K per 100 g (3.5 oz) serving.

Data from reference 88.

Pharmacokinetic drug interactions with warfarin primarily result from alterations in hepatic metabolism. Drugs inhibiting or inducing CYP 2C9, 1A2, and 3A4 isoenzymes have the greatest potential to significantly alter warfarin therapy response.[54] Drugs altering hemostasis or platelet function (eg, aspirin, clopidogrel) can increase bleeding risk without altering warfarin metabolism.[54] Clinicians should advise patients on warfarin to seek information about potential interactions whenever a drug product, dietary supplement, or herbal product is initiated or stopped, whether prescribed or available over the counter. If there is a known drug interaction or doubt about potential to alter the response to warfarin, more frequent INR testing is recommended with warfarin dose adjustments as needed to maintain INRs in the target range.[76]

Dosing and Administration

The dose of warfarin is individualized based on the desired target INR range and anticoagulant response.[54] The pharmacodynamic response and pharmacokinetic disposition of warfarin between and within patients are highly variable. Therefore, the dose of warfarin must be individualized based on continual clinical and laboratory monitoring.[54]

The average weekly warfarin dose is between 25 and 55 mg, but some patient-related variables are associated with lower than usual dose requirement including advanced age (more than 65 years), elevated baseline INR, poor nutritional status, liver disease, genetic polymorphisms in CYP 2C9 and VKOR, and concurrent use of medications known to enhance the effect of warfarin.[54] It is important to collect a complete medication history, including use of herbal and nutritional products as these can influence warfarin's metabolism and/or increase the risk of bleeding.[54]

Initiating warfarin therapy with 5 to 10 mg daily and adjusting the dose based on the INR response

will produce therapeutic INRs in 4 to 5 days for most patients (see Fig. 19-10). Lower starting doses may be acceptable based on patient-related factors such as advanced age, malnutrition, liver disease, or heart failure. Starting doses more than 10 mg should be avoided.[54] When warfarin therapy is initiated in the outpatient setting the INR should be measured every 1 to 3 days until stabilized. For patients with acute VTE, UFH, LMWH, or fondaparinux should be overlapped with warfarin therapy for at least 5 days regardless of whether the target INR has been achieved earlier.[5,54]

It is important to allow sufficient time for changes in the INR to occur when adjusting the dose of warfarin. In general, maintenance dose changes should not be made more frequently than every 3 days. When adjusting maintenance warfarin doses the weekly dose should be reduced or increased by 5% to 25%; the full effect of dose changes may not become evident for 5 to 7 days or longer.[54]

Personalized Pharmacotherapy

To personalize anticoagulation therapy for the prevention or treatment of VTE several factors should be considered.

Prevention vs Treatment of VTE

Lower doses of LMWH and DOACs are used for VTE prevention than during VTE treatment. Warfarin may be targeted to traditional INR (ie, 2.0 to 3.0) or reduced intensity (INR 1.5 to 2.5) for VTE prophylaxis. Orthopedic surgeons frequently prefer the lower INR range due to perceived lower bleeding risk. VTE prophylaxis in high-risk hospitalized patients is typically discontinued at discharge. In contrast, after major orthopedic surgery VTE prophylaxis continues following discharge for up to 35 days.

Venous thromboembolism treatment requires full therapeutic anticoagulant doses. Patients unwilling to self-administer LMWH or fondaparinux injections may prefer apixaban or rivaroxaban. Duration of anticoagulant therapy after acute VTE is principally determined by whether the clot was provoked or recurrent. Three months of therapeutic anticoagulation is sufficient following a first episode of VTE provoked by major transient risk factors such as surgery, pregnancy, or trauma. Appropriately selected patients with unprovoked or recurrent VTE should receive long-term anticoagulation for secondary VTE prevention. Patients selected for long-term secondary anticoagulation traditionally receive standard therapeutic doses of anticoagulant agents with one exception. Prophylactic dose apixaban (2.5 mg twice daily) may be used for long-term secondary VTE prevention after 6 months of therapeutic intensity has been completed. Switching to aspirin for long-term secondary VTE prevention is also an option, but is less effective than continuing anticoagulation therapy.[77,78]

Renal Function

Periodic renal function assessment is important during long-term DOAC therapy, especially for patients with CrCL less than 50 mL/min (less than 0.83 mL/s). DOACs should not be used in patients with CrCL less than 25 mL/min (less than 0.42 mL/s) (apixaban) or 30 mL/min (0.5 mL/s) (rivaroxaban and dabigatran). Edoxaban dosing is reduced to 30 mg once daily in patients with CrCL 15 to 50

mL/min (0.25 to 0.83 mL/s).[48,49,50,51] LMWHs also rely upon renal elimination and UFH remains preferred in patients with severe renal compromise (eg, CrCL less than 30 mL/min [less than 0.5 mL/s]).[28]

Weight

Patients at extremes of body weight were underrepresented in DOAC VTE treatment trials. There is speculation regarding whether very obese or very small patients receive equivalent on-treatment DOAC exposure compared to other patients. DOACs should be used with caution in very obese or very small patients until additional information substantiating equivalent outcomes becomes available.

Low-molecular-weight heparin dosing in obesity frequently causes concern. Patients weighing more than 90 kg would exceed the maximum dose specified in approved labeling for dalteparin (18,000 units). However, evidence supports similar anti-Xa exposure to LMWH and no increase in bleeding risk compared to non-obese patients when doses based on actual body weight without capping are administered.[79] Fondaparinux is a convenient option for obese patients as the 10 mg dose is suitable for acute VTE treatment in patients more than 100 kg.[42] Obese patients requiring VTE prophylaxis may need higher than normal LMWH doses. For example enoxaparin 40 mg subcutaneously twice daily may be more effective than usual VTE prophylaxis doses for patients undergoing bariatric surgery.[80]

Response to Previous Therapy

Other than bleeding, anticoagulants are generally well tolerated. However, adverse reactions, treatment failure, or allergies during previous therapy may necessitate preferential use of one anticoagulant over another.

Warfarin allergy is rare and often related to dyes or tablet excipients rather than the active ingredient. Warfarin 10 mg tablets contain no dye and can be considered when allergy is suspected. Patients experiencing dabigatran-related dyspepsia can try taking the dose with a full glass of water or food. Transitioning to another DOAC or warfarin may be necessary.

Cost is an important aspect of personalizing anticoagulant therapy for VTE prevention and treatment. For patients unable to afford DOACs, warfarin may remain the lone cost-effective option.

Patient having recurrent VTE during anticoagulant therapy should be assessed for nonadherence and have imaging compared to historical data to ensure the clot is in fact new. Determining and correcting the causes of nonadherence to anticoagulation therapy should occur before pursuing alternate anticoagulant therapy. Investigation for malignancy should be considered when nonadherence is ruled out. Switching to LMWH is recommended for management of breakthrough VTE during oral anticoagulation therapy.[28] Patients having breakthrough VTE during LMWH should be switched to twice daily injections (if receiving once daily LMWH) and considered for dose escalation of 25% to 33%.[28] Switching between oral anticoagulants in response to a breakthrough

VTE is less desirable since DOACs and warfarin showed similar efficacy in preventing VTE recurrence when compared head-to-head. Patients with cancer experiencing recurrent VTE during warfarin therapy should be switched to LMWH.[28]

Pharmacogenomics

CYP2C9 is the hepatic microsomal enzyme responsible for metabolism of the more potent S-enantionmer of warfarin. Polymorphisms in CYP2C9 and the gene coding for VKOR (known as Vitamin K Epoxide Reductase Complex 1) explain a substantial proportion of warfarin dose variability between patients. Dosing algorithms using CYP2C9 and VKOR pharmacogenomics, as well as clinical and drug interaction information, have been developed to assist providers more accurately select initial warfarin doses based upon a predicted maintenance warfarin dose for an individual patient (see www.warfarindosing.org). The FDA updated the warfarin package label to include use of pharmacogenetic testing in 2007.[75]

There are several barriers to the widespread application of pharmacogenomic testing for warfarin. First, and most important, is the INR. The ability to rapidly assess a patient's physiologic response to warfarin using an inexpensive and widely available test limits the need for pharmacogenomic information. Second is the timeliness of receiving pharmacogenomic test results. Pharmacogenomic information is most valuable when selecting the first 3 or 4 warfarin doses. However, pharmagenomic testing outside of clinical trials may require several days or longer before results become available. Delaying warfarin initiation is rarely a safe alternative, thus pharmacogenomic test results are only meaningfully if they available in the first 2 to 3 days after treatment initiation. Although poor metabolizing CYP2C9 subtypes have been associated with increased risk of bleeding compared to wild-type, clinical trials have not demonstrated improved bleeding or thromboembolic outcomes with the application of pharmacogenomic warfarin information compared to usual care.[81,82] As a result, the clinical utility and cost-effectiveness of warfarin pharmacogenomics is poorly defined and AT9 suggests against routine use.[33]

Evaluation of Therapeutic Outcomes

Warfarin dose titration based on INR monitoring and UFH dose titration based on aPTT monitoring allows a degree of personalized therapy not available with other anticoagulants. The intensity of warfarin or UFH therapy can be easily titrated in high-risk situations such as invasive procedures, accidental or intentional overdose, suspected nonadherence, or concomitant therapy with interacting drugs. Titrating DOAC therapy in similar situations cannot be accomplished due to lack of readily available quantitative coagulation assays.[83]

While laboratory coagulation monitoring is unnecessary during DOAC therapy, clinical surveillance may be beneficial. In clinical trials comparing DOACs to warfarin, patients receiving DOAC therapy had healthcare provider contact at least every 4 weeks where screenings for bleeding, changes in renal or hepatic function, drug adherence, potential drug interactions, and planning for invasive procedures occurred. A recent study performed in patients with atrial fibrillation taking dabigatran found that pharmacist involvement in appropriate initial drug selection, education, and follow-up

contacts improved drug adherence.[84] Adherence is essential to preventing recurrent VTE during DOAC therapy due to their short half-lives. Pharmacist involvement during DOAC initiation may be especially important to ensure proper transitions from LMWH to dabigatran or edoxaban or from initiation to maintenance dosing with rivaroxaban or apixaban. An ABCDEF checklist may be helpful for DOAC therapy clinical surveillance: A—Adherence with DOAC therapy, B—Bleeding risk assessment, C—Creatinine clearance/renal function monitoring, D—Drug interaction evaluation, E—Examination for adverse events and therapeutic effectiveness, and F—Final assessment and recommendations regarding the need for ongoing DOAC therapy.[85] What remains unclear is how frequently DOAC clinical surveillance should be performed, and whether it should be performed for all patients taking DOACs or only those at highest-risk.

Because LMWH anticoagulant response is predictable when given subcutaneously, routine laboratory monitoring is unnecessary.[6] Prior to LMWH initiation, baseline complete blood cell counts with platelets, and serum creatinine should be obtained. The complete blood cell count can be checked every 5 to 10 days during the first 2 weeks of LMWH therapy and every 2 to 4 weeks thereafter to monitor for occult bleeding. If neuraxial anesthesia has been used, patients should be closely monitored for signs and symptoms of neurologic impairment.[62]

Anti–factor Xa activity is the most widely used test to monitor the anticoagulant effect of LMWH in clinical practice. Routine anti–factor Xa activity measurement is unnecessary in uncomplicated patients in stable condition.[6] Measuring anti–factor Xa activity may be helpful in patients who have significant renal impairment (eg, CrCL less than 30 mL/min [less than 0.5 mL/s]), weigh less than 50 kg, are morbidly obese, and require prolonged therapy (eg, longer than 14 days). Periodic anti–factor Xa activity monitoring may also be useful in women treated with LMWH during pregnancy due to changing volume of distribution and renal function.[6]

When anti–factor Xa activity is used to monitor LMWH therapy, the sample should be drawn during the peak anti–factor Xa activity—once steady state has been achieved (after the second or third dose) and approximately 4 hours after the subcutaneous injection.[6] The anti–factor Xa activity therapeutic range is not well defined and has not been clearly correlated with efficacy or the risk of bleeding. For the treatment of VTE, an acceptable target range for the peak anti-Xa level for twice-daily enoxaparin dosing is 0.6 to 1 unit/mL (kU/L). For once daily dosing likely peak targets are more than 1 unit/mL (kU/L) for enoxaparin and 1.05 units/mL (kU/L) for dalteparin.[6] The suggested target range for peak anti-Xa concentrations during cancer-associated VTE treatment with dalteparin is 0.5 to 1.5 units/mL (kU/L).[68]

Prior to initiating fondaparinux baseline kidney function should be determined as fondaparinux is contraindicated when CrCL is less than 30 mL/min (less than 0.5 mL/s).[42] Signs and symptoms of bleeding should be monitored daily, particularly in patients with a baseline CrCL between 30 and 50 mL/min (0.5 and 0.83 mL/s). If neuraxial anesthesia has been used, patients should be closely monitored for signs and symptoms of neurologic impairment.[42] Fondaparinux does not alter coagulation tests such as the aPTT and PT. The role of anti–factor Xa monitoring during fondaparinux is not well defined, but routine coagulation testing is not required.[42]

Administration of UFH requires close monitoring because of the unpredictable anticoagulant patient response.[6] Although the aPTT has several limitations, most experts advocate using the aPTT to monitor UFH provided that institution-specific therapeutic ranges are defined.[6] The aPTT should be measured prior to the initiation of therapy to determine the patient's baseline. With intravenous infusion, the aPTT response to UFH therapy should be measured 6 hours after initiation or dose changes. UFH doses should be adjusted based on patient response and the institution-specific aPTT therapeutic range (see Table 19-7).[6]

The prothrombin time (PT) measures the biologic activity of factors II, VII, and X and has been used for decades to monitor the anticoagulation effects of warfarin. The PT is performed by measuring the time required for clot formation after adding calcium and thromboplastin to citrated plasma.[54] Interpreting the PT is problematic because thromboplastins of differing sensitivity produce substantially different results, some of which could lead to inappropriate dosing decisions. The World Health Organization (WHO) addressed the need for standardization in the late 1970s by developing a reference thromboplastin and recommending the use of the INR to monitor warfarin therapy.[54] The INR attempts to correct for differences in thromboplastin reagents through the following formula:

$$\mathrm{INR} = \left(\frac{\mathrm{PT}^{\mathrm{patient}}}{\mathrm{PT}^{\mathrm{control}}} \right)^{\mathrm{ISI}}$$

The International Sensitivity Index (ISI) is a measure of thromboplastin responsiveness compared with the WHO reference standard.[54] The ISI for each thromboplastin reagent should be used to calculate the INR, and although the INR system has a number of potential problems, it remains the preferred method for monitoring warfarin therapy.[54]

The recommended target INR for treatment of VTE is 2.5 with an acceptable range of 2.0 to 3.0.[54] A baseline INR and complete blood cell count should be obtained prior to initiating warfarin therapy. In patients with an acute thromboembolic event, an INR should be measured minimally every 3 days during the first week of therapy (daily INRs are common in hospitalized patients). Once the patient's dose–response is established, an INR should be determined every 7 to 14 days until it stabilizes and optimally every 4 to 12 weeks thereafter.[33]

At each encounter and especially when the INR is not in range, patients on warfarin therapy should be questioned regarding adherence to prior dosing instructions, other medication use, changes in health status, and symptoms related to bleeding and thromboembolic complications. Any changes in medications, including changes in dose as well as nonprescription drug and dietary supplement use, should be carefully explored. Dietary intake of vitamin K–rich foods should also be evaluated.[54]

Anticoagulation therapy management services can optimize the care of patients who take warfarin therapy by providing structured care, comprehensive patient education, and evaluation of outcomes. When anticoagulation management services are not available, individual clinicians should strive to implement similar structured care processes.[33]

Portable finger-stick INR devices are available for monitoring warfarin therapy. These devices permit

clinicians to do “real-time” therapeutic INR monitoring, and enable patients to engage in self-testing and/or management at home.[33] Patients who engage in INR self-monitoring and warfarin self-management report high levels of satisfaction with care and maintain INRs within the therapeutic range slightly more frequently than those managed by “usual care.” However, home INR testing and self-management is not for everyone and requires careful patient selection and considerable patient education.[33] Finger-stick INR devices are relatively expensive, but some patients qualify for limited coverage of the monitor and testing supplies.

CONCLUSION

Venous thromboembolism is a significant public health issue, yet there is little public awareness of the life-threatening nature of this commonly occurring condition. Given the number and variety of clinical conditions or circumstances that place individuals at VTE risk, improvements in VTE prevention and care have the potential to benefit many patients. Over the past decade, the focus on quality healthcare has included systematic measures to improve the use of effective VTE prophylaxis and evidence-based VTE treatments. The concerted efforts of government and accrediting agencies working with hospitals and other healthcare institutions will hopefully reduce VTE rates. Systematic approaches to this problem are needed at every level, starting with increased public and health practitioner awareness, continuing with the uniform use of effective prophylactic strategies in patients at risk, and concluding with greater accountability for quality VTE treatment strategies using expanding anticoagulant drug options.

Chapter 20: Stroke

Susan C. Fagan; David C. Hess

INTRODUCTION

KEY CONCEPTS

- 1 Stroke can be either ischemic (87%) or hemorrhagic (13%) and the two types are treated differently.
- 2 Transient ischemic attacks (TIAs) require urgent intervention to reduce the risk of stroke, which is known to be highest in the first few days after TIA.
- 3 Carotid endarterectomy should be performed in ischemic stroke patients with 70% to 99% stenosis of the ipsilateral carotid artery, provided that it is done in an experienced center.
- 4 Carotid stenting is an option for stroke patients eligible for carotid endarterectomy, especially in patients younger than 70 years.
- 5 Early reperfusion (less than 4.5 hours from onset) with tissue plasminogen activator (tPA) has been shown to reduce the ultimate disability due to ischemic stroke.
- 6 Endovascular thrombectomy with a stent retriever (within 6 hours) improves stroke outcomes in selected patients with proximal large artery occlusion and preservable penumbral tissue.
- 7 Antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of noncardioembolic ischemic stroke.
- 8 Oral anticoagulation is recommended for the secondary prevention of cardioembolic stroke in patients with atrial fibrillation.
- 9 Blood pressure lowering is effective in both the primary and secondary prevention of both ischemic and hemorrhagic stroke.

- 10 Blood pressure lowering in the acute ischemic stroke period (first 7 days) may result in decreased cerebral blood flow and worsened symptoms.

1 Stroke is the leading cause of disability among adults and the fifth leading cause of death in the United States, behind cardiovascular disease, cancer, chronic lower respiratory diseases, and accidental death.[1] Despite a 35% reduction in stroke mortality between 2001 and 2011, stroke occurs in the United States at a rate of almost 800,000 per year and resulted in 128,932 deaths in 2011.[1,2] Aggressive efforts to organize stroke care at the local and regional levels and increased utilization of evidence-based recommendations and national guidelines may have contributed to the improved outcomes.

EPIDEMIOLOGY

There are currently 6.6 million stroke survivors in the United States, and stroke is the leading cause of adult disability.[2] Of those free of the diagnosis of stroke or transient ischemic attack (TIA), however, almost 20% of individuals older than 45 years reported at least one stroke symptom,[3] suggesting rampant underdiagnosing. Owing in part to the need for expensive posthospitalization rehabilitation and nursing home care, the annual cost of stroke in the United States is estimated to be $33.6 billion.[2]

Not all groups have benefitted equally from advances in care and prevention of stroke. African Americans have stroke rates that are twice those of whites, and the difference is exaggerated at younger ages.[2] In addition, geographic disparity in stroke incidence exists, such that many states in the southeastern United States have stroke mortality rates 40% higher than the national average.[2] Lastly, case fatality due to hemorrhagic stroke has not declined in the past decade, with 30-day rates remaining around 40%.

Etiology

2 Stroke can be either ischemic or hemorrhagic (87% and 13%, respectively, of all strokes in the 2015 American Heart Association [AHA] report).[2] Hemorrhagic strokes include subarachnoid hemorrhage (SAH) and intracerebral hemorrhage (ICH). SAH occurs when blood enters the subarachnoid space (where cerebrospinal fluid is housed) owing to trauma, rupture of an intracranial aneurysm, or rupture of an arteriovenous malformation (AVM). By contrast, ICH occurs when a blood vessel ruptures within the brain parenchyma itself, resulting in the formation of a hematoma. These types of hemorrhages very often are associated with uncontrolled high blood pressure and sometimes antithrombotic or thrombolytic therapy. Hemorrhagic stroke, although less common, is significantly more lethal than ischemic stroke, with 30-day case-fatality rates of 46.5% compared to 9% to 23% in ischemic stroke.[4]

Ischemic strokes are caused either by local thrombus formation or by embolic phenomena, resulting in occlusion of a cerebral artery. Atherosclerosis, particularly of the cerebral vasculature, is a causative factor in most cases of ischemic stroke, although 30% are cryptogenic. Emboli can arise from either

intracranial or extracranial arteries (including the aortic arch) or, as is the case in 20% of all ischemic strokes, the heart. Cardiogenic embolism is presumed to have occurred if the patient has concomitant atrial fibrillation, valvular heart disease, or any other condition of the heart that can lead to clot formation.[2] Distinguishing between cardiogenic embolism and other causes of ischemic stroke is important in determining long-term pharmacotherapy in a given patient.

Risk Factors

Risk factors for stroke can be subdivided into nonmodifiable, modifiable, and potentially modifiable. In addition, risk factors can be either well documented or less well documented.[5] The main risk factors of stroke are listed in **Table 20-1**. Recommendations for risk factor reduction aggressively target the modifiable, well-documented risk factors, even in individuals with nonmodifiable risk.[5] The nonmodifiable risk factors are age, race, sex, low birth weight, and genetic factors. An individual's risk of having a stroke increases substantially as he or she ages, with a doubling of risk for each decade older than 55 years. African Americans, Asian-Pacific Islanders, and Hispanics experience higher death rates than their white counterparts.[2] Men are at a higher risk of stroke than women at younger ages, but women who suffer from a stroke are more likely to die from it.[2]

TABLE 20-1 Risk Factors for Ischemic Stroke

Nonmodifiable risk factors or risk markers
Age
Low birth weight
Race
Genetic factors
Modifiable, well documented
Cigarette smoking
Hypertension
Diabetes
Asymptomatic carotid stenosis
Dyslipidemia
Atrial fibrillation
Sickle cell disease
Poor diet
Obesity

Physical inactivity

Other cardiac diseases (coronary heart disease, heart failure, PAD)

Potentially modifiable, less well documented

Migraine

Metabolic syndrome

Drug and alcohol abuse

Inflammation and Infection

Elevated Lp(a)

Homocysteinemia

Sleep-disordered breathing

Lp(a); lipoprotein(a); PAD, peripheral arterial disease.

Data from reference 5.

The most common modifiable, well-documented risk factors for stroke include hypertension, cigarette smoking, diabetes, atrial fibrillation, and dyslipidemia. Hypertension is the most common of all, affecting almost one in three adults in the United States. A second very important risk factor for stroke is cardiac disease. Patients with coronary artery disease, congestive heart failure, left ventricular hypertrophy, and especially atrial fibrillation are at increased risk of stroke.[5] In fact, the presence of atrial fibrillation is one of the most potent risk factors for ischemic stroke, with stroke rates from 5% to 20% per year depending on the patient's comorbid conditions.[5] Other known risk factors for atherosclerosis are also known to place patients at risk of stroke. Diabetes mellitus, dyslipidemia, and cigarette smoking are known atherogenic states that lead to cerebrovascular disease and ischemic stroke.[5]

PATHOPHYSIOLOGY

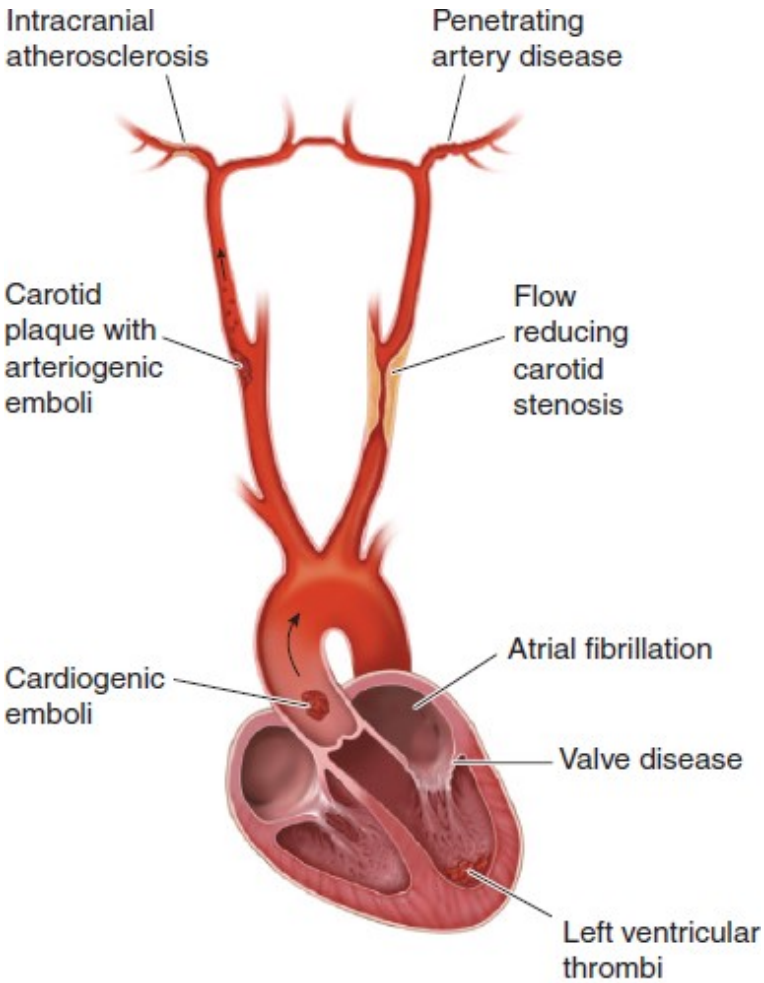
Ischemic Stroke

Ischemic stroke results from an occlusion of a cerebral artery, leading to a reduction in cerebral blood flow. The pathophysiologic mechanisms of ischemic stroke are given in **Fig. 20-1**. Normal cerebral blood flow averages 50 mL/100 g per minute, and this is maintained over a wide range of blood pressures (mean arterial pressures of 50-150 mm Hg) by a process called *cerebral autoregulation*. Cerebral blood vessels dilate and constrict in response to changes in blood pressure, but this process can be impaired by atherosclerosis, chronic hypertension, and acute injury, such as stroke. Arterial occlusion leads to severe reductions in cerebral blood flow leading to *infarction*. Tissue that is ischemic but maintains membrane integrity is referred to as the *ischemic penumbra* because it usually

surrounds the infarct core.[6] This penumbra is potentially salvageable through therapeutic intervention and is assessed urgently prior to endovascular intervention with a stent retriever.

FIGURE 20-1

Pathophysiology of ischemic stroke. Diagram illustrating the three major mechanisms underlying ischemic stroke including occlusion of an intracranial vessel by an embolus that arises from a distant site (eg, cardiogenic embolus), in situ thrombosis of an intracranial vessel, typically affecting the small penetrating arteries, and hypoperfusion caused by flow-limiting stenosis of a major extracranial artery. *(Reproduced with permission from Chapter 370. Cerebrovascular Diseases. In: Longo DL, Fauci AS, Kasper DL, et al.* Harrison's Principals and Practice of Internal Medicine, *18th ed. New York: McGraw-Hill, 2012.)*



Reduction in the provision of nutrients to the ischemic cell eventually leads to depletion of the high-energy phosphates (eg, adenosine triphosphate [ATP]) and accumulation of extracellular potassium, intracellular sodium, and water, leading to cell swelling and eventual lysis. The increase in intracellular calcium that follows results in the activation of lipases, proteases, and endonucleases and the release of free fatty acids from membrane phospholipids. In addition, there is a release of

excitatory amino acids, such as glutamate and aspartate, which perpetuate the neuronal damage and the accumulation of free fatty acids, including arachidonic acid, and result in the formation of prostaglandins, leukotrienes, and free radicals. In ischemia, the magnitude of free radical production overwhelms normal scavenging systems, leaving these reactive molecules to attack cell membranes and contribute to the mounting intracellular acidosis. All these events occur within 2 to 3 hours of the onset of ischemia and contribute to the ultimate cell death.[6]

Later targets for intervention in the pathophysiologic process involved after cerebral ischemia include inflammation and apoptosis, or programmed cell death, occurring many hours after the acute insult and can interfere with recovery and repair of brain tissue.[6]

Hemorrhagic Stroke

Intensive worldwide interest and attention has led to recent advances in the diagnosis and management of ICH. Urgent imaging of ICH patients has revealed that up to 38% expand dramatically more than 3 hours after the onset of symptoms and expansion is associated with worsened outcomes. Ultimately, clot volume is a very important predictor of outcome, and the ICH score has been shown to reliably predict 30-day mortality rates.[7] The highest mortality is seen in patients with low Glasgow Coma Score (GCS; 3-4), ICH volumes greater than 30 cc, intraventricular extension, brain stem involvement and age older than 80 years.[4] The presence of blood in the brain parenchyma causes mechanical compression of vulnerable tissue and subsequent activation of inflammation and neurotoxins. The molecular mediators of secondary brain injury and perihematomal edema are being investigated for potential therapeutic targets but no clinically proven pharmacologic intervention exists.[4]

CLINICAL PRESENTATION (INCLUDING DIAGNOSTIC CONSIDERATIONS)

Stroke is a term used to describe an abrupt-onset focal neurologic deficit that lasts at least 24 hours and is of presumed vascular origin. A TIA is the same but lasts less than 24 hours and usually less than 30 minutes. The abrupt onset and the duration of the symptoms are determined through the history. The use of sensitive imaging techniques (magnetic resonance imaging [MRI] with diffusion-weighted imaging [DWI]) has revealed that symptoms lasting more than 1 hour and less than 24 hours are associated with infarction, making TIA and minor stroke clinically indistinguishable. The location of the central nervous system (CNS) injury and its reference to a specific arterial distribution in the brain are determined through the neurologic examination and confirmed by imaging studies such as computed tomography (CT) scanning and MRI. The main arterial supply to the cerebral hemispheres is illustrated in **Fig. 20-2**. Further diagnostic tests are performed to identify the cause of the patient's stroke and to design appropriate therapeutic strategies to prevent further events.[8]

FIGURE 20-2

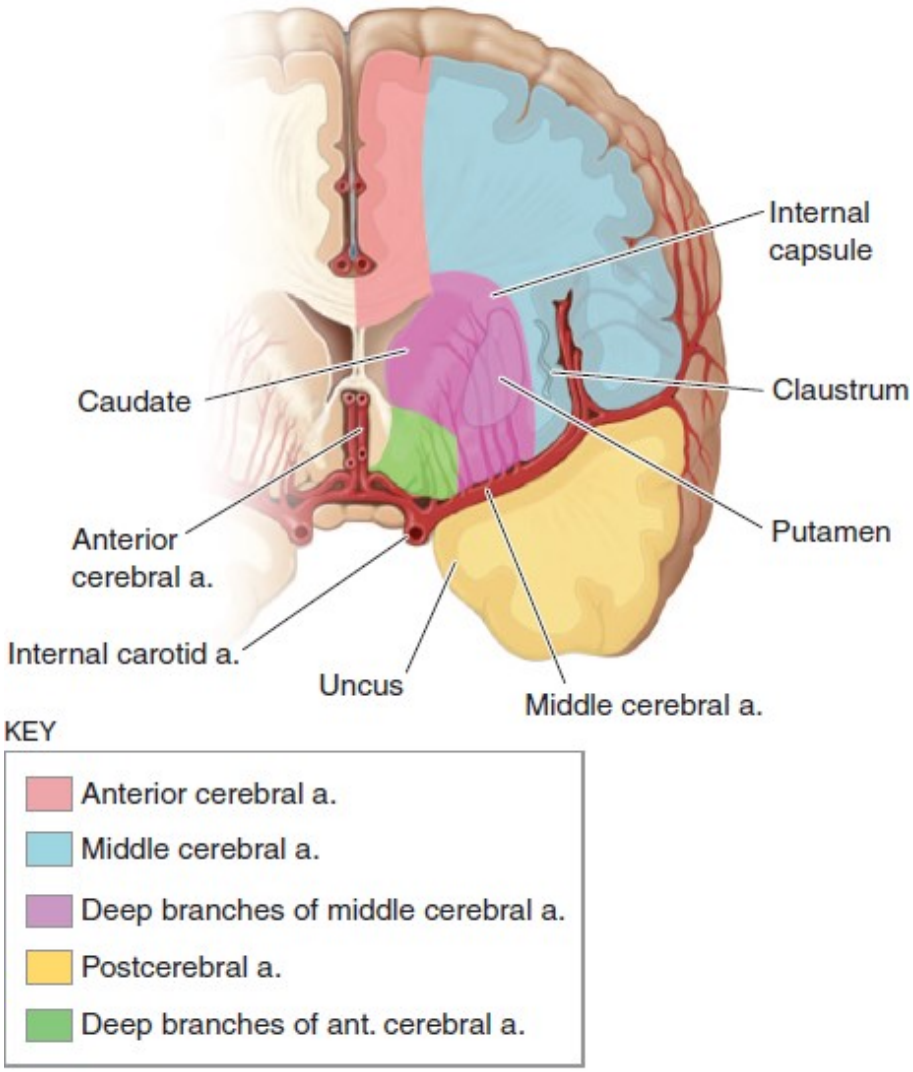
vessels branching from the internal carotid arteries. *(Reproduced with permission from Chapter 370. Cerebrovascular Diseases. In: Longo DL, Fauci AS, Kasper DL, et al. Harrison's* Principals and Practice of Internal Medicine, *18th ed. New York: McGraw-Hill, 2012.)*



CLINICAL PRESENTATION: Stroke General

- The patient may not be able to reliably report the history owing to cognitive or language deficits. A reliable history may have to come from a family member or another witness.

Symptoms

- The patient may complain of weakness on one side of the body, inability to speak, loss of vision, vertigo, or falling. Ischemic stroke is not usually painful, but patients may complain of headache, and with hemorrhagic stroke, it can be very severe.

Signs

- Patients usually have multiple signs of neurologic dysfunction, and the specific deficits are determined by the area of the brain involved.
- Hemiparesis or monoparesis occurs commonly, as does a hemisensory deficit.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.
- Aphasia is seen commonly in patients with anterior circulation strokes.
- Patients may also suffer from dysarthria, visual field defects, and altered levels of consciousness.

Laboratory Tests

- Tests for hypercoagulable states (protein C deficiency, antiphospholipid antibody) should be done only when the cause of the stroke cannot be determined based on the presence of well-known risk factors for stroke. Protein C, protein S, and antithrombin III are best measured in the "steady state," not in the acute stage. Antiphospholipid antibodies as measured by anticardiolipin antibodies, β_2-glycoprotein I, and lupus anticoagulant screen are of higher yield than protein C, protein S, and antithrombin III but should be reserved for patients who are young (less than 50 years), have had multiple venous/arterial thrombotic events, or have livedo reticularis (a skin rash).

Other Diagnostic Tests

- CT scan of the head will reveal an area of hyperintensity (white) in the area of hemorrhage and will be normal or hypointense (dark) in the area of infarction. The CT scan may take 24 hours (and rarely longer) to reveal the area of infarction.
- MRI of the head will reveal areas of ischemia with higher resolution and earlier than the CT scan. DWI will reveal an evolving infarct within minutes.
- Carotid Doppler (CD) studies will determine whether the patient has a high degree of stenosis in the carotid arteries supplying blood to the brain (extracranial disease).
- An electrocardiogram (ECG) will determine whether the patient has atrial fibrillation, a potent etiologic factor for stroke.
- Transthoracic echocardiography (TTE) will determine whether valve abnormalities or wall-motion abnormalities are sources of emboli to the brain. A "bubble test" can be done to look for an intra-atrial shunt indicating an atrial septal defect or a patent foramen ovale.
- Transesophageal echocardiography (TEE) is a more sensitive test for thrombus in the left atrium. It is effective at examining the aortic arch for atheroma, a potential source of emboli.
- Transcranial Doppler (TCD) will determine whether the patient is likely to have intracranial stenosis (eg, middle cerebral artery stenosis).

TREATMENT Desired Outcomes

The goals of treatment of acute stroke are to (a) reduce the ongoing neurologic injury and decrease mortality and long-term disability, (b) prevent complications secondary to immobility and neurologic dysfunction, and (c) prevent stroke recurrence.[9] Primary prevention of stroke is reviewed elsewhere.[5]

General Approach to Treatment

The initial approach to the patient with a presumed acute stroke is to ensure that the patient is supported from a respiratory and cardiac standpoint and to quickly determine whether the lesion is ischemic or hemorrhagic, based on a CT scan. Ischemic stroke patients presenting within hours of the onset of their symptoms should be evaluated for reperfusion therapy. TIAs also require urgent intervention to reduce the risk of stroke, which is known to be highest in the first few days after TIA.[10] According to the American Stroke Association guidelines, patients with elevated blood pressure should remain untreated unless their blood pressure exceeds 220/120 mm Hg, or they have evidence of aortic dissection, acute myocardial infarction (AMI), pulmonary edema, or hypertensive encephalopathy. If blood pressure is treated, short-acting parenteral agents, such as labetalol and nicardipine, are favored. Current recommendations regarding management of arterial hypertension in ischemic stroke patients are given in **Table 20-2**.[9] In ICH patients with blood pressure between 150 and 220 mm Hg systolic, early treatment designed to achieve a pressure of less than 140 mm Hg systolic has been shown to be safe and improve functional outcome.[7] Once the patient is out of the hyperacute phase, attention is placed on preventing worsening, minimizing complications, and instituting appropriate secondary prevention strategies. The acute phase of the stroke includes the first week after the event.[9]

TABLE 20-2 Blood Pressure Treatment Guidelines in Acute Ischemic Stroke Patients Treated with tPA

Treatment	Received tPA
None	<180/105
Labetalol IV[a] or nicardipine IV[b]	180-230/105-120
Nitroprusside[c]	Diastolic >120

tPA, tissue plasminogen activator.

[a]Labetalol IV: 10 mg, followed by an infusion of 2-8 mg/min.

[b]Nicardipine IV: infusion starting at 5 mg/h up to 15 mg/h.

[c]Nitroprusside IV: infusion starting at 0.5 mcg/kg/min, with continuous arterial blood pressure monitoring.

Data from reference 9.

Nonpharmacologic Therapy

Ischemic Stroke In 2015, AHA/ASA performed a focused update of the acute ischemic stroke

guidelines to consider the evidence from eight clinical trials of endovascular intervention to reperfuse the ischemic brain.[11] Although early thrombectomy trials were disappointing, later investigations with more sophisticated devices called "stent retrievers" and careful selection of patients with proximal artery occlusions and salvageable tissue (on imaging), were universally positive. If administered within 6 hours of symptom onset (after intravenous [IV] tissue plasminogen activator [tPA]) in these patients, stent retrievers double the likelihood of recanalization, compared to tPA alone, and significantly increased the proportion of patients independent at 90 days (53%-70% vs 29.3%-40%). These findings dramatically changed the way in which stroke patients with large artery occlusion are managed in comprehensive stroke centers and increased the need for interventionalists in ischemic stroke care.

In less than 10% of patients with a large infarction in the middle cerebral artery territory, decompressive surgery to reduce intracranial pressure has been shown to significantly reduce mortality. However, the surgery must be performed within 48 hours of stroke onset in patients younger than 60 years to significantly improve functional outcome and this is at the cost of an increased number of surviving patients with severe disability.[12] In cases of significant swelling associated with a cerebellar infarction, surgical decompression can be lifesaving. Beyond surgical intervention, however, the use of an organized, multidisciplinary approach to stroke care that includes early rehabilitation has been shown to be very effective in reducing the ultimate disability owing to ischemic stroke. In fact, the use of "stroke units" has been associated with outcomes similar to those achieved with early thrombolysis when compared with usual care.[9]

4 In secondary prevention, carotid endarterectomy of an ulcerated and/or stenotic carotid artery is a very effective way to reduce stroke incidence and recurrence in appropriate patients and in centers where the operative morbidity and mortality are low. In fact, in ischemic stroke patients with 70% to 99% stenosis of an ipsilateral internal carotid artery, recurrent stroke risk can be reduced by up to 48% compared with medical therapy alone when combined with aspirin 325 mg daily.[13] In patients younger than 70 years, carotid stenting is a less invasive alternative and can be effective in reducing recurrent stroke risk.[14] However, in patients with intracranial stenosis, aggressive medical management was shown to be superior to stenting in reducing recurrent stroke.[15]

Hemorrhagic Stroke In patients with SAH owing to a ruptured intracranial aneurysm or AVM, surgical intervention to either clip or ablate the offending vascular abnormality substantially reduces mortality owing to rebleeding.[16] In the case of primary ICH, surgical evacuation may be of benefit in patients with intermediate hemorrhage volumes (20-50 mL) but this remains under investigation.[17] Insertion of an external ventricular drain (EVD) for hydrocephalus and subsequent monitoring of intracranial pressure are done commonly and are the least invasive of the procedures done in these patients.

Pharmacologic Therapy

Ischemic Stroke

Drug Treatments of First Choice: Published Guidelines The Stroke Council of the American Stroke

Association have created and published guidelines that address the management of acute ischemic stroke.[9] For acute treatment, the only two pharmacologic agents with class I recommendations are IV tPA within 4.5 hours of onset and aspirin within 48 hours of onset.[9]

5 Early reperfusion (less than 4.5 hours from onset) with IV tPA has been shown to reduce the ultimate disability caused by ischemic stroke.[18,19] Caution must be exercised when using this therapy, and adherence to a strict protocol is essential to achieving positive outcomes.[9] The essentials of the treatment protocol can be summarized as (a) stroke team activation, (b) treatment as early as possible within 4.5 hours of onset, (c) CT scan to rule out hemorrhage, (d) meeting inclusion and exclusion criteria (**Table 20-3**), (e) administration of tPA 0.9 mg/kg over 1 hour, with 10% given as initial bolus over 1 minute, (f) avoidance of antithrombotic (anticoagulant or antiplatelet) therapy for 24 hours, and (g) close patient monitoring for elevated blood pressure, response, and hemorrhage.[9]

6 Endovascular thrombectomy with a stent retriever is indicated after tPA but within 6 hours, for patients with proximal vessel occlusion and a small core injury on imaging.[11]

TABLE 20-3 Inclusion and Exclusion Criteria for tPA Use in Acute Ischemic Stroke[9]

Inclusion criteria

- Age 18 years or older
- Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit
- Time of symptom onset well established to be <4.5 hours before treatment would begin

Exclusion criteria

- History of previous intracranial hemorrhage
- Symptoms suggestive of SAH
- Active internal bleeding
- Acute bleeding diathesis, including but not limited to a platelet count <100,000/mm^3 (<100 × 10^{12}/L)
- Patient has received heparin within 48 hours, resulting in an elevated APTT
- Recent anticoagulant use and elevated INR (>1.7) or PT (>15 seconds)
- Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (such as aPTT, INR, platelet count, and ECT; TT; or appropriate factor Xa activity assays)
- Significant head trauma or previous stroke within 3 months
- Arterial puncture at noncompressible site within 7 days

- Intracranial neoplasm, arteriovenous malformation, or aneurysm
- SBP >185 mm Hg or DBP >110 mm Hg
- Blood glucose <50 mg/dL (2.7 mmol/L)
- CT demonstrates multilobar infarction (hypodensity >1/3 cerebral hemisphere)

Relative exclusion criteria (considering risk to benefit in individual patients, may be wise to administer tPA despite 1 or more of the following:)

- Only minor or rapidly improving symptoms
- Pregnancy
- Seizure at onset with postictal residual impairments
- Major surgery or serious trauma within 14 days
- Gastrointestinal or urinary tract hemorrhage within 21 days
- Acute myocardial infarction within 3 months

Additional exclusion criteria if within 3–4.5 hours of onset:

- Age greater than 80 years
- Current treatment with oral anticoagulants
- NIH Stroke Scale Score >25 (severe stroke)
- Imaging evidence of large infarct (>1/3 MCA territory)
- History of both stroke and diabetes

APTT, activated partial thromboplastin time; CT, computed tomography; DBP, diastolic blood pressure; ECT, Ecarin clotting time; INR, international normalized ratio; MCA, middle cerebral artery; PT, prothrombin time; SBP, systolic blood pressure; SAH, subarachnoid hemorrhage; TT, thrombin time.

Early aspirin therapy has also been shown to reduce long-term death and disability[20,21] but should never be given within 24 hours of the administration of tPA because it can increase the risk of bleeding in such patients.[9]

Antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of ischemic stroke and should be used in noncardioembolic strokes. Acetylsalicylic acid (ASA), extended-release dipyridamole plus aspirin (ERDP-ASA) and clopidogrel are all recommended for secondary

stroke prevention.[10] In patients with atrial fibrillation and a presumed cardiac source of embolism, oral anticoagulation with either vitamin K antagonism (warfarin), apixaban, dabigatran, or rivaroxaban is recommended for secondary stroke prevention.[10] Other pharmacotherapy recommended for secondary prevention of stroke includes blood pressure lowering and statin therapy. Current recommendations regarding the acute treatment and secondary prevention of stroke are given in **Table 20-4**.

TABLE 20-4 Recommendations for Pharmacotherapy of Ischemic Stroke

	Recommendation	Evidence[a]
Acute treatment	tPA 0.9 mg/kg IV[9] (maximum 90 mg) over 1 hour in selected patients within 3 hours of onset	IA
	tPA 0.9 mg/kg IV[9] (maximum 90 mg) over 1 hour between 3 and 4.5 hours of onset	IB
	ASA 160-325 mg daily[9] started within 48 hours of onset	IA
Secondary prevention		
Noncardioembolic	Antiplatelet therapy	IA
	Aspirin 50-325 mg daily[10]	IB
	Aspirin 25 mg + extended-release dipyridamole 200 mg twice daily[10]	IB
	Clopidogrel 75 mg daily[10]	IIaB
Cardioembolic (especially atrial fibrillation)	VKA (INR = 2.5)[10]	IA
	Apixaban 5 mg twice daily[10]	IA
	Dabigatran 150 mg twice daily[10]	IB
	Rivaroxaban 20 mg daily[10]	IIaB
Atherosclerosis + LDL > 100 mg/dL	High intensity statin therapy[10]	IB
BP > 140/90	BP reduction[10]	IB

ASA, acetylsalicylic acid; INR, international normalized ratio; IV, intravenous; LDL, low-density lipoprotein; tPA, tissue plasminogen activator; VKA, vitamin K antagonist.

[a]Classes: I, evidence or general agreement about usefulness and effectiveness; II, conflicting evidence about the usefulness; IIa, weight of evidence in favor of the treatment; IIb, usefulness less well established; III, not useful and maybe harmful. Levels of evidence: A, multiple randomized clinical trials; B, a single randomized trial or nonrandomized studies; C, expert opinion or case studies.[10]

Data from Jauch et al.,[9] and Kernan et al.[10]

General Information Regarding Safety and Efficacy (Including Pivotal Clinical Trials)

tPA The effectiveness of IV tPA in the treatment of ischemic stroke was first demonstrated in the National Institute of Neurologic Disorders and Stroke (NINDS) Recombinant Tissue-Type Plasminogen Activator (rtPA) Stroke Trial, published in 1995.[18] In 624 patients treated in equal numbers with either tPA 0.9 mg/kg IV or placebo within 3 hours of the onset of their neurologic symptoms, 39% of the treated patients achieved an "excellent outcome" at 3 months compared with 26% of the placebo patients. An "excellent outcome" was defined as minimal or no disability by several different neurologic scales. This beneficial effect was reported despite a 10-fold increase in the risk of symptomatic ICH in the tPA-treated patients (0.6% vs 6.4%). Overall mortality was not significantly different between the two groups (17% with tPA and 21% with placebo). Patients with very severe symptoms at baseline (National Institutes of Health Stroke Scale [NIHSS] greater than 20) and early ischemic changes on CT scan were shown to be at highest risk for the development of symptomatic intracranial hemorrhage. Even in patients at highest risk for bleeding, however, those receiving tPA had better outcomes at 90 days than those who received placebo.[18]

Thirteen years after the NINDS trial, the European Cooperative Acute Stroke Study (ECASS) III demonstrated that, even when administered between 3 and 4.5 hours after the onset of symptoms, ischemic stroke patients benefit from tPA when compared with placebo (52.4% vs 45.2% excellent outcome; $P = 0.04$).[19] The benefit was less than that reported with earlier treatment but the rate of excess hemorrhage was similar, leading to a change in AHA guidelines to recommend extension of the window.[9] An important caveat was that the exclusion criteria for later treatment are more strict and are given in Table 20-3. The International Stroke Trial (IST)-3 reported subsequently, in a large group of 3,035 patients treated within 6 hours of ischemic stroke onset, that even patients outside the rigid criteria set forth by both the NINDS and ECASS III trials may experience improved functional outcome.[22] These investigators advocate that patients over the age of 80, presenting outside the 3-hour treatment window, may benefit from a personalized assessment of risk and benefit prior to excluding them from thrombolytic therapy.

ASA The use of early ASA to reduce long-term death and disability owing to ischemic stroke is supported by two large randomized clinical trials. In the IST,[21] aspirin 300 mg/day significantly reduced stroke recurrence within the first 2 weeks without effect on early mortality, resulting in a significant decrease in death and dependency at 6 months. In the Chinese Acute Stroke Trial (CAST),[20] aspirin 160 mg/day reduced the risk of recurrence and death in the first 28 days, but long-term death and disability were not different than with placebo. In both trials, a small but significant increase in hemorrhagic transformation of the infarction was demonstrated. Overall, the beneficial effects of early aspirin have been embraced and adopted into clinical guidelines.

Antiplatelet Agents All patients who have had an acute ischemic stroke or TIA should receive long-term antithrombotic therapy for secondary prevention.[10] 7 In patients with noncardioembolic stroke, this will be some form of antiplatelet therapy. In a comprehensive meta-analysis, the overall benefit of antiplatelet therapy in patients with atherothrombotic disorders was estimated to be 22%.[23] ASA is the best studied of the available agents but published literature has supported the use of the combination product ERDP-ASA and clopidogrel as additional first-line agents in secondary stroke prevention.[10]

In the European Stroke Prevention Study 2 (ESPS-2), ASA 25 mg and ERDP 200 mg twice daily were compared alone and in combination with placebo for their ability to reduce recurrent stroke over a 2-year period.[24] In a total of more than 6,600 patients, all three treatment groups were shown to be superior to placebo—ASA alone (18% relative risk reduction [RRR]), ERDP alone (16% RRR), and the combination (37% RRR). In addition, the combination demonstrated a significant advantage over the ASA-alone group (23% RRR; $P = 0.006$) and the ERDP-alone group (24% RRR; $P = 0.002$). Headache resulting in discontinuation occurred in approximately 15% of the ERDP groups (four times more common than in the placebo group), and the ASA-treated patients, even at the low dose of 50 mg/day, experienced significantly more bleeding than the other groups. In a large, multinational trial (Prevention Regimen for Effectively Avoiding Second Strokes [PRoFESS]) comparing ERDP-ASA with clopidogrel, the risk of recurrent stroke was similar for the two antiplatelet agents, but clopidogrel was better tolerated with less bleeding and headache.[25]

The efficacy of clopidogrel as an antiplatelet agent in atherothrombotic disorders was demonstrated in the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial.[26] In this study of more than 19,000 patients with a history of myocardial infarction (MI), stroke, or peripheral arterial disease (PAD), clopidogrel 75 mg/day was compared with ASA 325 mg/day for its ability to decrease MI, stroke, or cardiovascular death. In the final analysis, clopidogrel was slightly (8% RRR) more effective than ASA ($P = 0.043$) and had a similar incidence of adverse effects. It is not associated with the blood dyscrasias (neutropenia) common with its congener, ticlopidine, and is used widely in patients with atherosclerosis.

Oral Anticoagulants 8 Oral anticoagulation is the treatment of choice for the prevention of stroke in patients with atrial fibrillation.[5,10] In patients with atrial fibrillation and a recent history of stroke or TIA, the risk of recurrence places these patients in one of the highest risk categories known. In the European Atrial Fibrillation Trial (EAFT), 669 patients with nonvalvular atrial fibrillation (NVAF) and a prior stroke or TIA were randomized to warfarin (international normalized ratio [INR] = 2.5-4), ASA 300 mg/day, or placebo. Patients in the placebo group experienced stroke, MI, or vascular death at a rate of 17% per year compared with 8% per year in the warfarin group and 15% per year in the ASA group. This represents a 53% reduction in risk with anticoagulation.[27] Subsequent studies in the primary prevention of stroke in patients with NVAF have demonstrated that targeting an INR of 2.5 prevents stroke with the lowest bleeding risk (Stroke Prevention in Atrial Fibrillation [SPAF III]); therefore, a target INR of 2.5 is recommended in the secondary prevention of stroke.[5,10] Newer oral anticoagulants including dabigatran (direct thrombin inhibitor), rivaroxaban, and apixaban (direct factor Xa inhibitors) have significant advantages over warfarin in terms of ease of dosing and less food and drug interactions. In addition, in the prevention of stroke in selected patients with atrial fibrillation, all three agents have been shown to be as effective as, and in some cases, superior to, warfarin in reducing recurrent events and intracranial hemorrhage.[28,29,30]

Blood Pressure Lowering 9 Elevated blood pressure is very common in ischemic stroke patients, and treatment of hypertension in these patients is associated with a decreased risk of stroke recurrence.[38] In the Perindopril pROtection aGainst REcurrent Stroke Study (PROGRESS), a multinational stroke population (40% Asian) was randomized to receive either blood pressure

lowering with the angiotensin-converting enzyme (ACE) inhibitor perindopril (with or without the thiazide diuretic indapamide) or placebo.[31] Treated patients achieved an overall 9 mm Hg systolic and 4 mm Hg diastolic blood pressure reduction, and this was associated with a 28% reduction in stroke recurrence. In the patients who received the combination treatment (clinician's discretion), the average blood pressure lowering achieved was 12 mm Hg systolic and 5 mm Hg diastolic, and this was associated with an even larger reduction in stroke recurrence (43%). Similar results were achieved in patients with and without hypertension. AHA/ASA guidelines recommend reduction of blood pressure greater than 140/90 in patients with stroke or TIA.[10] Early blood pressure lowering can worsen symptoms; however, therefore, recommendations are limited to patients outside of the acute stroke period (first 7 days).[10]

Statins The statins have been shown to reduce the risk of stroke by approximately 30% in patients with coronary artery disease and elevated plasma lipids.[32] The Stroke Prevention by Aggressive Reduction in Cholesterol (SPARCL) study demonstrated that atorvastatin 80 mg daily reduced the risk of recurrent stroke by 16% and coronary events by 42% in patients with no cardiac history. Although the high-dose statin caused an increase in liver enzymes, there was no increase in myopathy.[33] It is now recommended that patients experiencing ischemic stroke of presumed atherosclerotic origin, with low-density lipoprotein (LDL) greater than 100 mg/dL, be treated with high-intensity statin therapy for secondary stroke prevention.[10]

Heparin for Prophylaxis of Deep Vein Thrombosis (DVT) The use of low-molecular-weight heparins or low-dose subcutaneous unfractionated heparin (5,000 units three times daily) can be recommended for the prevention of DVT in hospitalized patients with decreased mobility owing to their stroke and should be used in all but the most minor strokes.[9] In ICH patients, intermittent pneumatic compression (IPC) devices in combination with thigh high elastic stockings should be employed for DVT prophylaxis until the risk of further expansion of the hematoma is thought to be low.[7]

Alternative Drug Treatments

ASA Plus Clopidogrel In the Management of ATherothrombosis with Clopidogrel in High-risk patients (MATCH) study, clopidogrel in combination with ASA 75 mg daily was no better than clopidogrel alone in secondary stroke prevention.[34] Also, when clopidogrel was used with ASA, the risk of life-threatening bleeding increased from 1.3% to 2.6%.[34] Again, in the Stroke Prevention in Subcortical Stroke (SPS)-3 trial of patients with recent minor strokes, the arm of the trial studying the combination of clopidogrel and ASA was stopped early because of excess mortality due to bleeding in this group.[35] However, the combination has been studied in patients with TIA or minor stroke, and short-term (3-month) use of the combination of clopidogrel and ASA was associated with improved outcomes.[36]

Heparins The use of full-dose unfractionated heparin in the acute stroke period has never been proven to positively affect stroke outcome, and it significantly increases the risk of ICH. Trials of low-molecular-weight heparins or heparinoids have been largely negative and do not support their

routine use in stroke patients.[37,38,39] Other potential but unproven uses for treatment doses of either unfractionated or low-molecular-weight heparins include bridge therapy in patients being initiated on warfarin, carotid dissection, or continuous worsening of ischemia despite adequate antiplatelet therapy.[40]

Drug Class Information

ASA ASA exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase, which, in platelets, prevents conversion of arachidonic acid to thromboxane A_2 (TXA_2), which is a powerful vasoconstrictor and stimulator of platelet aggregation. Platelets remain impaired for their life span (5-7 days) after exposure to aspirin. ASA also inhibits prostacyclin (PGI_2) activity in the smooth muscle of vascular walls. PGI_2 inhibits platelet aggregation, and the vascular endothelium can synthesize PGI_2 such that the platelet antiaggregating effect is maintained.[40] There is probably a point at which lower doses of ASA do not completely block TXA_2, and recent studies indicate that the lowest effective dose may be in the range of 50 mg/day.[41] Upper gastrointestinal (GI) discomfort and bleeding are the most common adverse effects of ASA and have been shown to be dose related. The highest rates of GI bleeding (5%) have been reported in patients receiving 1,200 mg/day as compared with rates of 2% in patients taking the more commonly prescribed 300 mg/day. Upper GI symptoms are much more common than frank bleeding; however, with 40% of patients affected at 1,200 mg/day and 25% at 300 mg/day.[42] In the ESPS-2 study, even 50 mg/day of ASA was associated with a twofold increase in bleeding over the placebo group.[24]

The onset of the antiplatelet effect of ASA is less than 60 minutes.[43] It has been reported, however, that some patients either have or develop "aspirin resistance" and can require higher doses to achieve the desired antiplatelet effect.[44] Despite this, routine testing for ASA resistance is not recommended. It was observed that administration of ibuprofen prior to the administration of a daily aspirin dose inhibits the ASA from binding irreversibly to the cyclooxygenase and can decrease its antiplatelet effect.[45] Current recommendations are to administer ASA at least 2 hours before ibuprofen or to wait at least 4 hours after an ibuprofen dose.

Clopidogrel Clopidogrel has a unique platelet antiaggregatory effect in that it is an inhibitor of the adenosine diphosphate (ADP) pathway of platelet aggregation and inhibits known stimuli to platelet aggregation.[26,40] This effect causes an alteration of the platelet membrane and interference with the membrane–fibrinogenic interaction leading to a blocking of the platelet glycoprotein IIb/IIIa receptor. A time lag of 3 to 7 days before the antiplatelet effect is maximal should be expected. The tolerability of clopidogrel 75 mg/day is at least as good as medium-dose (325 mg/day) ASA, and there is less GI bleeding.[26] Clopidogrel is associated with an increased risk of diarrhea and rash, but discontinuation rates owing to adverse effects are similar to those with ASA 325 mg/day (5.3% and 6%, respectively).[26] There is no excess neutropenia in patients taking clopidogrel, and rates of thrombotic thrombocytopenic purpura probably are no greater than background rate.

Extended-Release Dipyridamole Plus ASA Early studies of the role of dipyridamole in stroke prevention failed to show a benefit over that realized by ASA alone. Dipyridamole in high doses is

thought to inhibit platelet aggregation by inhibiting phosphodiesterase, leading to accumulation of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) intracellularly, which prevent platelet activation. In addition, dipyridamole also enhances the antithrombotic potential of the vascular wall.[46] The ESPS-2 demonstrated the efficacy of high-dose ERDP alone and in combination with ASA in secondary stroke prevention.[24] The extended-release formulation of dipyridamole is important in that it allows twice-daily administration and higher doses to be tolerated in patients. The use of immediate-release generic dipyridamole in combination with regular ASA, in order to reduce costs, is unproven and should be discouraged.

In the ESPS-2, 25% of the patients who received combination dipyridamole and ASA discontinued the therapy early, and the rate of discontinuation owing to headache was more than three times as common (10%) as in the aspirin-alone group (3%).[24] Even when patients were carefully educated and coached in the PRoFESS trial, discontinuation due to headache was six times higher in the ERDP-ASA group (5.9% vs 0.9%).[25]

Investigational Strategies

Neuroprotection and Neurorestoration Although many different neuroprotective agents have been studied in clinical trials of acute ischemic stroke, all have been unsuccessful[47] and the drug development pipeline for acute neuroprotection is essentially nonexistent. However, hope exists that clinicians will be able to enhance the reparative process of the brain (neurorestoration) through targeted neurorehabilitation, growth factor enhancement, and the use of neural and cell transplantation.[48]

Hemorrhagic Stroke

There are currently no standard pharmacologic strategies for treating ICH.[7] Medical guidelines for the management of blood pressure, raised intracranial pressure, and other medical complications of ICH are those required for the management of any acutely ill patient in a neurointensive care unit.[7] When ICH occurs in a patient on oral anticoagulants, reversal of anticoagulation to prevent expansion and allow surgical intervention is recommended. The methods recommended to achieve reversal include IV vitamin K, fresh-frozen plasma (FFP), and hemostatic agents (factor VIIa and prothrombin complex concentrate [PCC]).[7] All patients with warfarin-associated ICH should receive IV vitamin K and therapy to replace the affected clotting factors. PCC has advantages over FFP alone in this regard in that it results in a faster normalization of the INR and less chance of fluid overload. In a large clinical trial, 4-factor PCC was noninferior to FFP alone in warfarin reversal with no excess in thromboembolic events: 7.4% versus 6.4%, respectively.[49]

SAH owing to aneurysm rupture is associated with a high incidence of delayed cerebral ischemia (DCI) in the 2 weeks following the bleeding episode. Vasospasm of the cerebral vasculature is thought to be responsible for DCI and occurs between 4 and 21 days after the bleed, peaking at days 5 to 9.[16] The calcium channel blocker nimodipine (60 mg every 4 hours for 21 days), along with maintenance of intravascular volume with pressor therapy, is recommended to reduce the incidence

and severity of neurologic deficits owing to DCI.[16]

PERSONALIZED PHARMACOTHERAPY

Clopidogrel is a thienopyridine prodrug and needs to be biotransformed by the liver to an active metabolite. Evidence suggests that the antiplatelet effects of clopidogrel can be diminished in patients with reduced-function cytochrome P450 2C19 (CYP2C19)[50] or in those receiving agents that inhibit hepatic metabolism.[51] In patients receiving clopidogrel after stent placement, reduced-function CYP2C19 is associated with an increase in recurrent vascular events.[51]Although high doses of the lipophilic statins atorvastatin and simvastatin can diminish the effectiveness of clopidogrel to inhibit platelet aggregation in vitro, there does not appear to be any adverse effect on atherothrombotic event rates.[52] In contrast, in a retrospective analysis of 8,205 patients, concomitant proton pump inhibitor and clopidogrel treatment was associated with increased adverse vascular outcomes after acute coronary syndromes.[50] Careful consideration should be given to using clopidogrel in patients with reduced ability to biotransform the agent to its active metabolite.

The availability of genetic testing to identify patients with altered sensitivity to warfarin has led to questions regarding the ability of the tests to improve patient care. Polymorphisms in CYP2C9 and vitamin K epoxide reductase complex subunit 1 (VKORC1) contribute to the variability in warfarin response, but it is unclear whether knowledge of these genetic variations will improve dosing accuracy and reduce adverse events.[53] Clinical trial evidence is needed prior to instituting these tests in stroke patients who are candidates for warfarin therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

Patients with acute stroke should be monitored intensely for the development of neurologic worsening (recurrence or extension), complications (thromboembolism or infection), or adverse effects from pharmacologic or nonpharmacologic interventions. The most common reasons for deterioration in a stroke patient are (a) extension of the original lesion—ischemic or hemorrhagic—in the brain, (b) development of cerebral edema and raised intracranial pressure, (c) hypertensive emergency, (d) infection (urinary and respiratory most common), (e) venous thromboembolism (DVT and pulmonary embolism), (f) electrolyte abnormalities and cardiac rhythm disturbances (can be associated with brain injury), and (g) recurrent stroke.

The approach to monitoring drug therapy in the hospitalized stroke patient is summarized in **Table 20-5**. The plan should be customized for individual patients based on their comorbidities and ongoing disease processes.

TABLE 20-5 Monitoring Stroke Therapy

Drug	Adverse Effect	Monitoring Parameters	Comments

Drug	Adverse Effect	Monitoring Parameters	Comments
tPA	Bleeding	Neurologic examination	Every 15 minutes × 1 hour; every 0.5 hour × 6 hours; every 1 hour × 17 hours; every shift after
ASA	Bleeding		Daily
Clopidogrel	Bleeding		Daily
ERDP-ASA	Headache, bleeding		Daily
Warfarin	Bleeding	INR, Hb/Hct	Daily
Oral anticoagulants	Bleeding		Daily

ERDP-ASA, extended-release dipyridamole plus aspirin; Hb/Hct, hemoglobin/hematocrit; INR, international normalized ratio; tPA, tissue plasminogen activator.

Clinical Controversy…

It is unclear when it is safe to start oral anticoagulation with one of the newer agents (apixaban, dabigatran, or rivaroxaban) in a stroke patient with atrial fibrillation and a large infarction.

In patients requiring rapid reversal of warfarin anticoagulation in the setting of ICH, it is unclear whether to target an INR of less than 1.3 or less than 1.5.

ABBREVIATIONS

Chapter 21: Dyslipidemia

Robert L. Talbert

INTRODUCTION

KEY CONCEPTS

- 1 Hypercholesterolemia, elevated low density lipoprotein, and low high density lipoprotein are unequivocally linked to increased risk for coronary heart disease (CHD) and cerebrovascular morbidity and mortality; LDL is the primary target.
- 2 Multiple genetic abnormalities and environmental factors are involved in clinical lipid abnormalities and routinely used clinical laboratory measurements do not define the underlying abnormalities.
- 3 Initial therapy for any lipoprotein disorder is therapeutic life-style changes with restricted intake of total and saturated fat and cholesterol and a modest increase in polyunsaturated fat intake along with a program of regular exercise and weight reduction if needed.
- 4 If pharmacologic therapy is insufficient after therapeutic lifestyle changes (TLC), lipid-lowering agents should be chosen based on the specific lipoprotein disorder presentation and the severity of the lipid abnormality.
- 5 Considering compliance, adverse effects and effectiveness, statins are the drugs of choice for patients with hypercholesterolemia because they are the most potent form of monotherapy and are cost-effective in patients with known coronary artery disease (CAD) or multiple risk factors and in high-risk primary prevention patients.
- 6 Patients not responding to statin monotherapy may be treated with combination therapy for hypercholesterolemia, but should be monitored closely because of an increased risk for adverse effects and drug interactions.
- 7 Hypertriglyceridemia usually responds well to niacin, gemfibrozil, and fenofibrate; high dose niacin should be used cautiously in diabetics because of worsening glycemic control. Statins lower triglycerides to a variable extent depending on baseline triglyceride concentration and statin potency.
- 8 Low HDL-C is addressed with life-style modifications such as smoking cessation and increased exercise; niacin and gemfibrozil and fenofibrate can significantly increase HDL-C as well.
- 9 Reductions in elevated total cholesterol and LDL-C reduce CHD mortality and total mortality; increasing HDL reduces CHD events as well. Aggressive treatment of hypercholesterolemia results in fewer patients progressing to myocardial infarction, angina, and stroke, and reduces the need for interventions such as

coronary artery bypass graft and percutaneous transluminal coronary angioplasty.

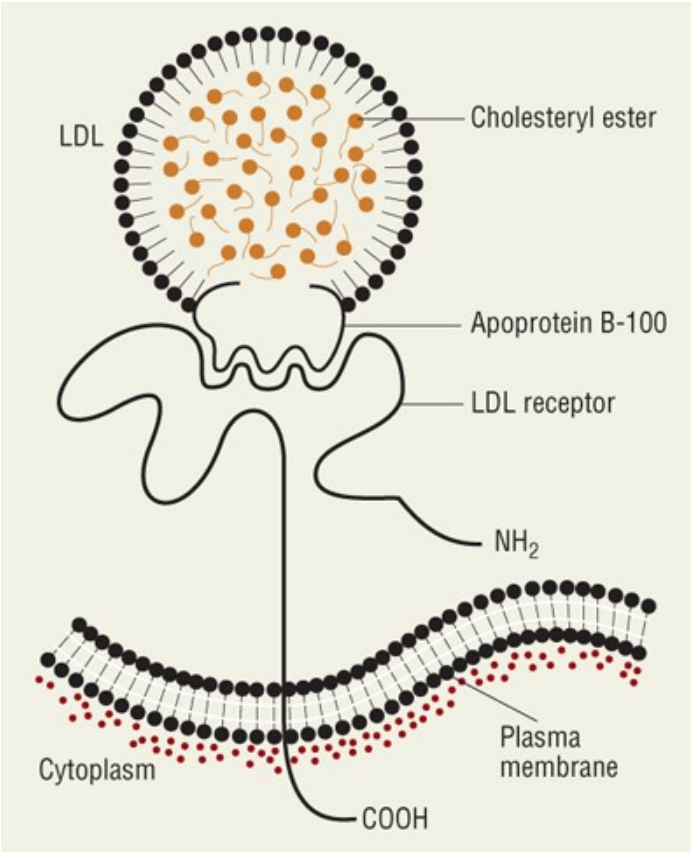
- 10 Lipid lowering therapy is generally considered to be cost effective, particularly in secondary intervention and high risk patients.

- 11 Lomitapide, mipomersen, alirocumab, and evolocumab have been recently approved for the treatment of homozygous familial hypercholesterolemia. All have novel mechanisms of action to lower total and LDL cholesterol and are used as adjuncts to statin therapy or in lieu of statins if patients are statin intolerant.

Cholesterol, triglycerides, and phospholipids are the major lipids in the body and they are transported as complexes of lipid and proteins known as lipoproteins. Plasma lipoproteins are spherical particles with surfaces that consist largely of phospholipid, free cholesterol, and protein, and cores that consist mostly of triglyceride and cholesterol ester (**Fig. 21-1**). The three major classes of lipoproteins found in serum are low density lipoproteins (LDL),[1] high density lipoproteins (HDL),[2] and very low density lipoproteins,[3] VLDL is carried in the circulation as triglyceride and VLDL can be estimated by dividing the triglyceride concentration by five if the triglyceride concentration is below 250 mg/dL (2.83 mmol/L). Intermediate density lipoprotein resides between VLDL and LDL and is included in the LDL measurement in routine clinical measurement. Abnormalities of plasma lipoproteins can result in a predisposition to coronary, cerebrovascular, and peripheral vascular arterial disease and constitutes one of the major risk factors for coronary heart disease (CHD). Accumulating evidence over the last decades had linked elevated total and LDL cholesterol and reduced HDL to the development of CHD. Premature coronary atherosclerosis, leading to the manifestations of ischemic heart disease (IHD) (see Chapter 16), is the most common and significant consequence of dyslipidemia. In 2014 the American Heart Association (AHA) and the American College of Cardiology published revised guidelines on the treatment of blood cholesterol to reduce atherosclerotic risk in adults. This report supersedes the National Cholesterol Education Program[4] Adult Treatment Panel III (ATP III) published more than a decade ago.[5,6,170] The 2014 guidelines did not find sufficient evidence to recommend specific targets for any lipid, but rather, it identifies four groups of patients who qualify for treatment with statins. The other substantive change is the method used for risk assessment resulting in identifying significantly more patients who would qualify for therapy. The AHA also provides guidelines for primary and secondary prevention of CHD.[7,8,9]

FIGURE 21-1

Diagrammatic representation of the structure of lowdensity lipoprotein (LDL), the LDL receptor, and the binding of LDL to the receptor via apolipoprotein B-100. (Reproduced with permission from Chapter 17. Energy Balance, Metabolism, and Nutrition. In: Ganong WF. Review of Medical Physiology, 22nd ed. New York: McGraw-Hill, 2005.)



Total cholesterol and LDL-C increase throughout life in men and women, representing an atherogenic pattern characteristic of Westernized society diets.[10] Based on estimates from the AHA, 42.8% or 100,100,000 million American adults over age 20 years have total cholesterol levels of 200 mg/dL (5.17 mmol/L) or higher.[11] More than half of individuals at borderline-high risk remain unaware that they have hypercholesterolemia and fewer than half of highest risk persons (those with symptomatic CHD) are receiving lipid-lowering treatment. About one third of treated patients are achieving their LDL goal; fewer than 20% of CHD patients are at their LDL goal. Changes in the NCEP guidelines have increased the number of persons eligible for therapeutic life style changes (TLC) or lipid-lowering therapy by millions.[171,172] NCEP estimates that only 26% of patients have an optimal LDL-C (less than 100 mg/dL [less than 2.59 mmol/L]) and that large numbers of patients are either untreated or under-treated.[5] Unfortunately, those patients at highest risk are less likely to be treated to desirable levels of LDL.[12] Although these numbers seem staggering in their enormity, substantial progress has been made, and the number of Americans with a desirable blood cholesterol level (less than 200 mg/dL [less than 5.17 mmol/L]) has risen to 49% from 45% from the earlier survey (1976-1980), while the average total cholesterol in this country has fallen from 220 mg/dL (5.69 mmol/L) in 1960 to 195 mg/dL for men and 201 mg/dL for women.[13] Patients who are at risk but who have not yet experienced their first cardiovascular or cerebrovascular event (eg, myocardial infarction [MI]) are termed primary prevention, whereas those with manifest vascular disease are termed secondary intervention.

1 Data from the Framingham study and from other studies demonstrate that the risk for developing cardiovascular disease is related to the degree of total cholesterol and LDL elevation in a graded, continuous fashion.[14] Hypercholesterolemia is additive to the other non-lipid risk factors for CHD, including cigarette smoking, hypertension, diabetes, low HDL levels, and electrocardiographic abnormalities. The presence of established CHD or prior MI increases the risk of MI five to seven times that seen in men or women without CHD,

and LDL is a significant predictor of subsequent morbidity and mortality. About 50% of all myocardial infarctions and at least 70% of CHD deaths occur in patients with known CHD, and these patients should therefore be a target for screening, identification, and treatment. Unfortunately, the identification of patients at high risk because of hypercholesterolemia or other lipid disorders is too frequently overlooked, because blood lipid levels are not always evaluated in this population even after an event such as MI.

A comparison of the United States to other countries shows similar relationships between total cholesterol, LDL, and an inverse relationship with HDL to coronary artery disease (CAD) mortality.[14] On a positive note, the U.S. mortality rate is midway among the countries studied, and this country has had the greatest decline in CAD mortality (35%-40%) in men and women over the last 10 years as compared to other countries. A decline in the prevalence of hypercholesterolemia in certain segments of the U.S. population parallels these trends in mortality.[5] LDL and the ratio of LDL to HDL have also been used to assess risk, but their use adds little information to total cholesterol alone unless HDL is abnormally high or low. McQueen et al. found that the ratio of apolipoprotein (Apo) B to ApoA1 was more predictive and consistent across gender and ethnic groups.[15] HDL transports cholesterol from lipid-laden foam cells to the liver. HDL has been shown to be protective for the occurrence of CHD, and an inverse relationship exists between CHD and HDL levels.[16] Recent clinical trials attempting to raise HDL have failed to demonstrate clinically meaningful reductions in cardiovascular endpoints challenging the importance of increasing HDL fractions and ApoA1.[17]

Very low density lipoproteins, the major lipoprotein associated with triglycerides is enriched with cholesterol esters, is smaller, denser, and more atherogenic than less-dense VLDL. Routine measurement of triglycerides cannot distinguish between the types of VLDL present in plasma. Elevation of triglyceride-rich lipoproteins is associated with low HDL, and this ratio predicts increased risk. The 8-year follow-up of the Copenhagen male study found a clear gradient of risk of IHD with increasing triglyceride levels within each level of HDL cholesterol. When compared to the lowest tertile of triglyceride concentrations; the highest tertile had 2.2 relative risk for IHD and the relationship extended across all concentrations of HDL.[18] The Helsinki Heart Study shows that hypertriglyceridemia and low HDL are associated with obesity (body mass index [BMI] greater than 26 kg/m^2), smoking, sedentary life-style, blood pressure of greater than or equal to 140/90 mm Hg, and blood glucose above 79 mg/dL (4.4 mmol/L), and that the benefit of gemfibrozil (risk reduction 68%, $P < 0.03$) was largely confined to overweight subjects.[19] Hypertriglyceridemia in certain instances—for example, diabetes mellitus, nephrotic syndrome, and chronic renal disease, and perhaps in women—is associated with increased cardiovascular risk. This is thought to be a consequence of the presence of atherogenic lipoproteins and of hypertriglyceridemia being a marker for them, as triglycerides are usually not independently predictive for CHD.[20]

LIPOPROTEIN METABOLISM AND TRANSPORT

Cholesterol and triglycerides, as the major plasma lipids, are essential substrates for cell membrane formation and hormone synthesis, and provide a source of free fatty acids.[21] Dyslipidemia may be defined as an elevation total cholesterol, elevation in LDL cholesterol, elevation in triglycerides or low HDL cholesterol concentration or some combination of these abnormalities. Lipids, being water immiscible, are not present in free form in the plasma, but rather circulate as lipoproteins. Hyperlipoproteinemia describes an increased concentration of the lipoprotein macromolecules that transport lipids in the plasma. The density of plasma lipoproteins is determined by their relative content of protein and lipid. Density, composition, size, and electrophoretic mobility divide lipoproteins into four classes (**Table 21-1**).

TABLE 21-1 Composition of Lipoprotein Isolated from Normal Subjects

	Composition (Weight %)
	Cholesterol

Lipoprotein Class*	Density Range (g/mL)	Diameter (nm)	Protein	Triglyceride	Free	Ester	Phospholipid
Chylomicrons	<0.94	75-1,200	1-2	80-95	1-3	2-4	3-9
VLDL	0.94-1.006	30-80	6-10	55-80	4-8	16-22	10-20
LDL	1.006-1.063	18-25	18-22	5-15	6-8	45-50	18-24
HDL	1.063-1.21	5-12	45-55	5-10	3-5	15-20	20-30

*VLDL, very-low-density lipoprotein; LDL, low-density lipoprotein; HDL, density lipoprotein.

Low density lipoproteins has been further divided into LDL_1, or IDL (density 1.006-1.019 g/mL), and LDL_2 (1.019-1.063 g/mL). LDL_2 is the major LDL component in plasma and it carries 60% to 70% of the total serum cholesterol. HDL has been subfractionated into HDL_2 (density 1.063-1.125 g/mL) and HDL_3 (1.125-1.21 g/mL). Fluctuations in HDL are usually caused by alterations in the levels of HDL_2. HDL normally carries about 20% to 30% of the total cholesterol. VLDL has also been subdivided into three classes, and it carries about 10% to 15% of serum cholesterol and most of the triglyceride in the fasting state. VLDL is the precursor for LDL, and VLDL remnants may also be atherogenic. **Table 21-2** shows the characteristics of the protein constituent of lipoproteins known as apolipoproteins. The structure of LDL, the LDL receptor, and the binding of the LDL to the receptor via apolipoprotein (Apo) B-100 is shown in Fig. 21-1.

TABLE 21-2 Characteristics and Functions of Apolipoproteins

Apolipoprotein	Lipoprotein Density Class	Approximate Plasma Concentration, mg/dL (g/L)	Approximate Molecular Weight (kDa)	Reported Functions	Major Site of Synthesis
A-I	Chylomicrons, HDL	120 (1.2)	28	Cofactor with LCAT, structural protein on HDL, ligand for HDL receptor	Liver, intestine
A-II	Chylomicrons, HDL	35 (0.35)	17	Structural protein for HDL, ligand for HDL receptor	Liver
A-IV	Chylomicrons, 1.21B	15 (0.15)	46	Possibly facilitates transfer of other apos between HDL and chylomicrons	Intestine
ApoLp(a)	LDL, HDL	10 (0.10)	500±	Bound to B-100, high homology with plasminogen, may prevent LDL uptake by B, E receptor	Liver
B-100	VLDL, LDL, IDL	100 (1.0 g/L)	540	Necessary for assembly and secretion of VLDL from the liver, structural protein of VLDL, IDL, LDL, ligand for LDL receptor	Liver
B-48	Chylomicrons	Trace	264	Necessary for assembly and secretion of chylomicrons from the small intestine	Intestine
C-I	Chylomicrons, VLDL, HDL	7 (0.07)	6.6	Cofactor with LCAT; may inhibit hepatic uptake of chylomicron and VLDL remnants	Liver

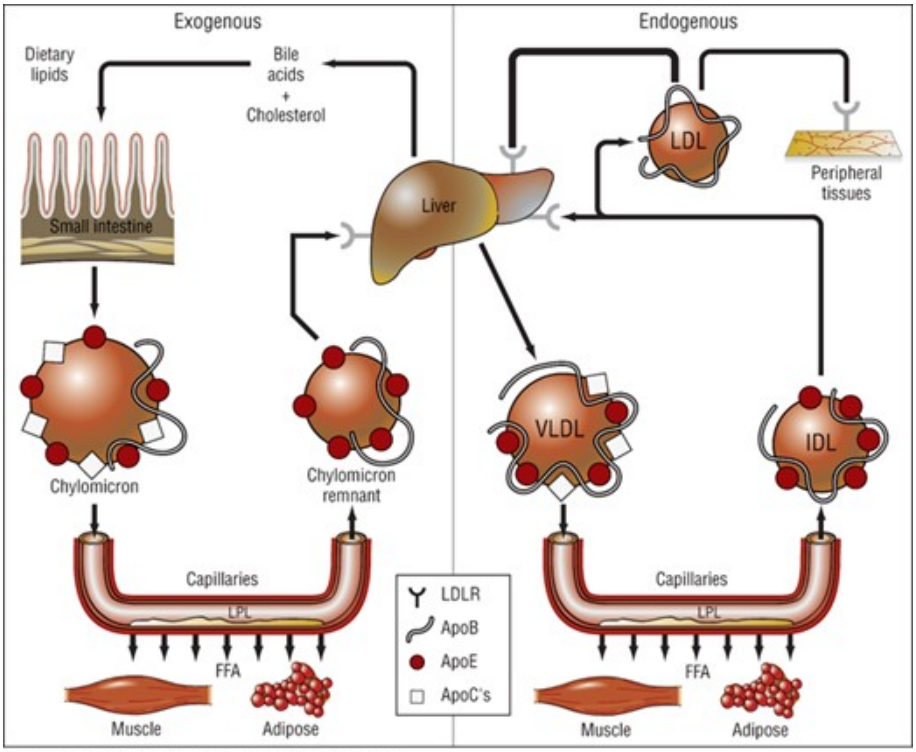
Apolipoprotein	Lipoprotein Density Class	Approximate Plasma Concentration, mg/dL (g/L)	Approximate Molecular Weight (kDa)	Reported Functions	Major Site of Synthesis
C-II	Chylomicrons, VLDL, HDL	4 (0.04)	8.9	Activator of LPL	Liver
C-III	Chylomicrons, VLDL, HDL	13 (0.13)	8.8	Inhibitor with LPL; may inhibit hepatic uptake of chylomicron and VLDL remnants	Liver
D	HDL	6 (0.06)	32	?	?
E2-E4	Chylomicrons, VLDL, HDL	5 (0.05)	34	Ligand for several lipoproteins to LDL receptor, LRP and possibly to a separate hepatic apo E receptor	Liver

LCAT, lecithin-cholesterol acyltransferase; HL, hepatic lipase; IDL, intermediate density lipoprotein; LRP, LDL receptor related protein. Other abbreviations are in Table 19.1.

Chylomicrons, large triglyceride-rich particles containing apolipoprotein B-48, B-100, and E, are formed from dietary fat solubilized by bile salts in intestinal mucosal cells. Chylomicrons are normally not present in the plasma after a fast of 12 to 14 hours and are catabolized by lipoprotein lipase (LPL), which is activated by apolipoprotein C-II and in the vascular endothelium and hepatic lipase to form chylomicron remnants. The remnants that contain apolipoprotein E (**Fig. 21-2**) are taken up by the "remnant receptor," which may be an LDL receptor-related protein, in the liver. Free cholesterol is liberated intracellularly after attachment to the remnant receptor. Chylomicrons also function to deliver dietary triglyceride to skeletal muscle and adipose tissue. During the catabolism of nascent chylomicrons to remnants, triglyceride is converted to free fatty acids and apolipoproteins A-I, A-II, A-IV (free in plasma), C-I, C-II, and C-III, and phospholipids are transferred to HDL. Apolipoprotein E and apolipoprotein C-II are transferred to chylomicrons from HDL and eventually back through these metabolic events. Hepatic VLDL synthesis is regulated in part by diet and hormones, and is inhibited by uptake of chylomicron remnants in the liver. VLDL is secreted from the liver and serially converted via LPL to intermediate-density lipoprotein (IDL), and, finally, to LDL. VLDL receptors are found in adipose tissue and muscle, and bear close homology to the structure of LDL receptors.

FIGURE 21-2

Simplified diagram of lipoprotein systems for transporting lipids in humans. In the exogenous system, chylomicrons rich in triglycerides of dietary origin are converted to chylomicron remnants rich in cholesteryl esters by the action of lipoprotein lipase (LPL). In the endogenous system, very-low-density lipoproteins (VLDL) rich in triglycerides are secreted by the liver and converted to intermediate density lipoproteins (IDL) and then to low-density lipoproteins (LDL) rich in cholesteryl esters. Some of the LDLs enter the subendothelial space of arteries, are oxidized, and then are taken up by macrophages, which become foam cells. The letters on the chylomicrons, chylomicron remnants, VLDL, IDL, and LDL identify the primary apoproteins (ApoB, ApoC, ApoE) found in them. (LDLR, low-density lipoprotein receptor.) (Reproduced with permission from Kasper DL, Braunwald E, Fauci AS, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York, McGraw-Hill, 2005, p. 2289.)

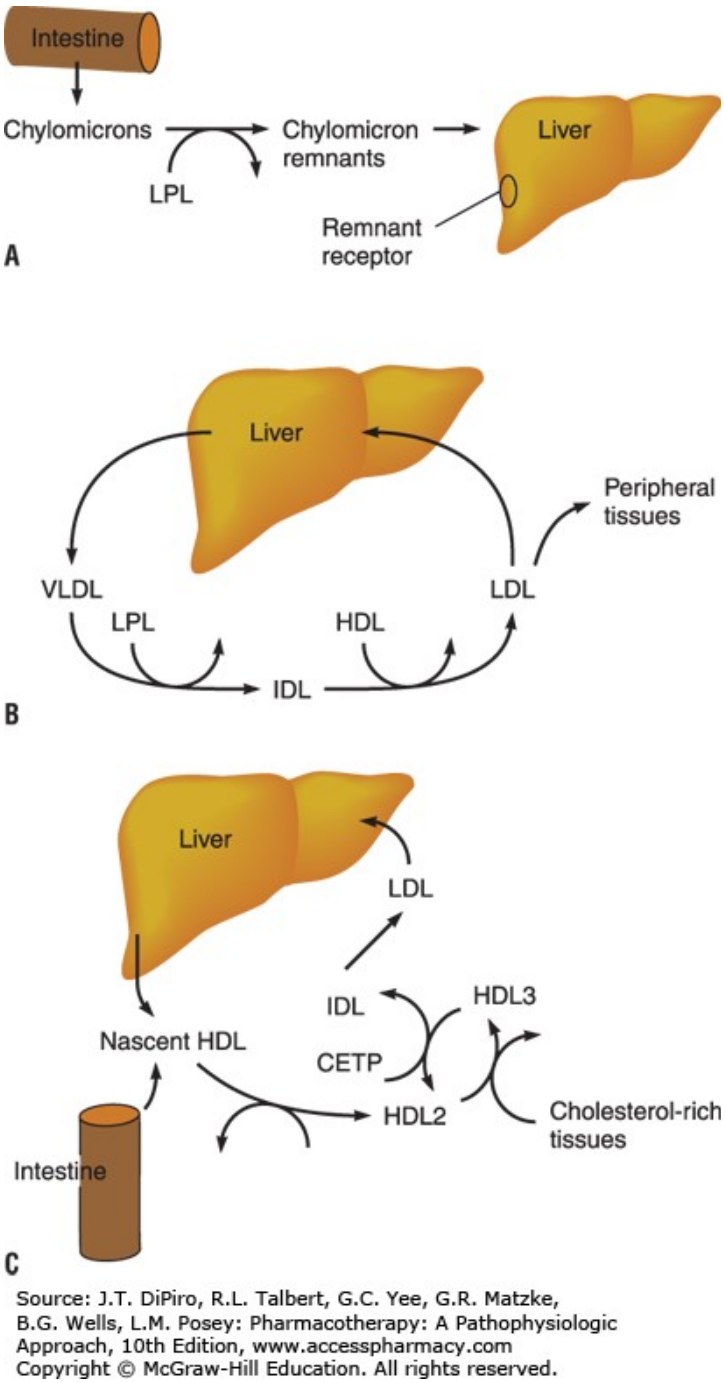


Low density lipoproteins, the major cholesterol transport lipoprotein and having virtually only apolipoprotein B-100, is mostly derived from VLDL catabolism and cellular synthesis. When fasting and on low-fat intake in normal subjects, most cholesterol is synthesized and used in the extrahepatic organs, while most of the cholesterol carried by LDL is taken up by the liver for catabolism. In patients with homozygous familial hypercholesterolemia, enhanced synthesis of LDL may occur, because LDL clearance is reduced as a consequence of the lack of LDL receptors. LDL is catabolized through interaction of cell surface receptors found on liver, adrenal, and peripheral cells (including fibroblasts and smooth-muscle cells). These cells recognize apolipoprotein B-100 on LDL, and after binding to a receptor on the cell membrane, LDL is internalized and degraded. In the normal fasting state, approximately 70% of LDL is cleared through receptor-dependent mechanism, although this is highly dependent on the availability and type of saturated and mono- or polyunsaturated fat from dietary sources. Ingestion of cholesterol and saturated fatty acids such as C12:0, C14:0, and C16:0 is associated with reduction in LDL receptor activity, increased LDL production rate, and elevation in LDL plasma concentration. Receptor-independent mechanisms are also involved to a lesser extent in the catabolism of LDL, and these receptors are present in many tissues but are most active in animals in the adrenals and ovary. Increased intracellular cholesterol resulting from LDL catabolism inhibits the activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase), the rate-limiting enzyme for intracellular cholesterol biosynthesis (**Fig. 21-3**). Additional consequences of increased intracellular cholesterol include reduced synthesis of LDL receptors, which limits subsequent cholesterol uptake from the plasma, and accelerated activity of acyl coenzyme-A: cholesterol acyltransferase to facilitate cholesterol storage within cells. LDL cholesterol may also be excreted into bile and become part of the enterohepatic pool or may be lost in the stool. Lp(a) is a cholesterol-rich lipoprotein similar to LDL in composition and density and with close homology to fibrinogen; it is reported to be an important independent risk factor for the development of premature cardiovascular disease.

FIGURE 21-3

Biosynthetic pathway for cholesterol. The ratelimiting enzyme in this pathway is 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase). (CETP, cholesterolester transfer protein; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL,

very-low-density lipoprotein.) *A.* Exogenous pathway; *B.* Endogenous pathway; C. Reverse cholesterol transport. (Adapted from Breslow JL. Genetic basis of lipoprotein disorders. J Clin Invest 1989;84:373.)



Nascent HDL is derived from liver and gut synthesis primarily in the form of apolipoprotein A-I phospholipid discs.[16] Esterification of free cholesterol in nascent HDL and from peripheral tissues to cholesteryl esters by lecithin-cholesterol acyltransferase (LCAT) results in the production of HDL_3. Further addition of tissue cholesterol to HDL_3 results in the formation of HDL_2. HDL_2 can also be formed from remodeling of chylomicrons and VLDL catabolism. HDL_2 may be converted back to HDL_3 by the action of hepatic lipase and by the transfer of cholesteryl esters to the liver, LDL, and VLDL. Apolipoprotein A-I production is increased by estrogens, leading to higher HDL levels in women and in individuals receiving estrogen. Transfer of excess cholesterol from peripheral tissues by HDL is called *reverse cholesterol transport.* Putative HDL receptors in peripheral cells facilitate the uptake of cholesterol by HDL, which transfers cholesterol to either VLDL and LDL or to the liver for secretion into bile or conversion into bile acids. These processes serve to rid peripheral tissue (eg, coronary arteries) of excessive

amounts of cholesterol, and account for some of the protective effects noted with increasing HDL in women and other factors that elevate HDL levels. Variants of the cholesterol ester transfer protein (CETP) have been demonstrated in humans, and the B1B1 genotype is associated with lower HDL and progression of coronary atherosclerosis. Inhibition of CETP leads to elevations in HDL, unfortunately when CETP inhibitors have been tested in clinical trials they did not induce regression of atherosclerotic plaque and were associated with higher blood pressure and CHD events.[22,23,24,25] The effect of CETP inhibition on blood pressure and HDL is disconcordant with some of these agents and several compounds continue to be investigated.[26,27]

The "response-to-injury" hypothesis states that risk factors such as oxidized LDL, mechanical injury to the endothelium (eg, percutaneous transluminal angioplasty), excessive homocysteine, immunologic attack, or infection-induced (eg, *Chlamydia,* herpes simplex virus-1) changes in endothelial and intimal function lead to endothelial dysfunction and a series of cellular interactions that culminate in atherosclerosis. C-reactive protein (CRP) is an acute phase reactant and a marker for inflammation; it may be useful in identifying patients at risk for developing CAD.[28] The transcription factor Kruppel-like factor 2 (KLF2) may be induced by statins in liver sinusoidal endothelial cells (SEC), orchestrating an efficient vasoprotective response. Upregulation of hepatic endothelial KLF2-derived transcriptional programs by statins confers vasoprotection and stellate cells deactivation, reinforcing the therapeutic potential of these drugs for liver diseases that course with endothelial dysfunction.

The eventual outcomes of this atherogenic cascade are clinical events such as angina, MI, arrhythmias, stroke, peripheral arterial disease, abdominal aortic aneurysm, and sudden death. Atherosclerotic lesions are thought to arise from transport and retention of plasma LDL-cholesterol through the endothelial cell layer into the extracellular matrix of the subendothelial space. Once in the artery wall, LDL is chemically modified through oxidation and non-enzymatic glycation. Mildly oxidized LDL then recruits monocytes into the artery wall, which become transformed into macrophages. Macrophages have tremendous potential for accelerating LDL oxidation and apolipoprotein B accumulation, and altering the receptor-mediated uptake of LDL into the artery wall from the usual LDL-receptor to a "scavenger receptor" not regulated by cell content of cholesterol. Oxidized LDL increases plasminogen inhibitor levels (promotion of coagulation), induces the expression of endothelin (vasoconstrictive substance), inhibits the expression of nitric oxide (a vasodilator and platelet inhibitor), and is toxic to macrophages if highly oxidized. As oxidation of biologically active lipids proceeds, other lipids such as lysophosphatidylcholine, hydroperoxides, aldehydic breakdown products of fatty acids and oxysterol are formed, which continue the reaction within the tissue. These events lead to a massive accumulation of cholesterol. The cholesterol-laden macrophages become foam cells; foam cells are the earliest recognized cells of the arterial fatty streak.

Oxidized LDL provokes an inflammatory response, which is mediated by a number of chemoattractants and cytokines. Examples of each that appear to be involved at different stages of lesion development include monocyte chemoattractant protein 1 (MCP-1); monocyte colony stimulating factor (M-CSF); *gro;* vascular cell adhesion molecule (VCAM-1); E-selectin (ELAM-1); intercellular adhesion molecule (ICAM-1); platelet-derived growth factor (PDGF); vascular endothelial growth factor (VEGF); transforming growth factors (TGFα and TGFβ); interleukin-1 and interleukin-6 (IL-1, IL-6); and the ratio of interleukin-10 and interleukin-12 (IL-10, IL-12). It appears that some of these factors (eg, MCP-1 and M-CSF) participate early in the process of monocyte-macrophage attachment and transmigration across the endothelium, whereas others (PDGF and VCAM-1) promote later lesion growth.[29] The extent of oxidation and the inflammatory response is under genetic control of a major gene termed *Ath*-1 based on murine model studies. The process of aging may lead to lipoproteins that are more susceptible to oxidation and have longer resident time in the vascular compartment. Two proteins associated with HDL—apolipoprotein J (apoJ) and paraxonase (PON)—appear to play an important role to minimize the oxidation of LDL-C.[30] Increased recognition of the role of these growth-regulatory molecules provides the possibility of future directions for antagonists to regulatory molecules such as PDGF, TGFβ, and the interleukins. Repeated injury and repair within an atherosclerotic plaque eventually leads to a fibrous cap protecting the underlying core of lipids, collagen, calcium, and inflammatory cells such as T-lymphocytes.

Maintenance of the fibrous plaque is critical to prevent plaque rupture and subsequent coronary thrombosis.[31] An imbalance between plaque synthesis and degradation may lead to a weakened or vulnerable plaque prone to rupture. The fibrous cap may become weakened through decreased synthesis of the extracellular matrix or increased degradation of the matrix. The cytokine interferon-γ, produced by T-lymphocytes, inhibits the ability of smooth-muscle cells to synthesize collagen, a structurally important component of the fibrous cap. A family of enzymes known as matrix metalloproteinases can degrade all major constituents of the vascular extracellular matrix: collagen, elastin, and proteoglycans.[32]

Lipoprotein disorders are classified into six categories, which are commonly used for phenotypical description of dyslipidemia (**Table 21-3**). Specific genetic defects with disrupted protein, cell, and organ function give rise to several disorders within each family of lipoproteins (**Table 21-4**). In other words, an elevated cholesterol level does not necessarily equate with familial hypercholesterolemia or type IIa, as cholesterol may also be elevated in other lipoprotein disorders and the lipoprotein pattern does not describe the underlying genetic defect. The preceding discussion has focused on primary or genetic dyslipoproteinemia; it should be remembered that secondary forms exist and that several drugs may also elevate lipid levels (**Table 21-5**). These secondary forms of hyperlipidemia should be initially managed by correcting the underlying abnormality, including modification of drug therapy when appropriate.

TABLE 21-3 Fredrickson-Levy-Lees Classification of Hyperlipoproteinemia

Type	Lipoprotein Elevation
I	Chylomicrons
IIa	LDL
IIb	LDL + VLDL
III	IDL (LDL1)
IV	VLDL
V	VLDL + Chylomicrons

IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

TABLE 21-4 Lipoprotein Disorders

		Lipoproteins		
Lipid Phenotype	Plasma Lipid Levels, mg/dL (mmol/L)	Elevated	Phenotype	Clinical Signs
Isolated Hypercholesterolemia				
Familial hypercholesterolemia	Heterozygotes TC = 275-500 (7.1-12.9)	LDL	IIa	Usually develop xanthomas in adulthood and vascular disease at 30-50 years
	Homozygotes TC > 500 (>12.9)	LDL	IIa	Usually develop xanthomas in adulthood and vascular disease in childhood
Familial defective apo B100	Heterozygotes TC = 275-500 (7.1-12.9)	LDL	IIa	
Polygenic hypercholesterolemia	TC = 250-350 (6.5-9.0)	LDL	IIa	Usually asymptomatic until vascular disease develops; no xanthomas
Isolated Hypertriglyceridemia				
Familial hypertriglyceridemia	TG = 250-750 (2.8-8.5)	VLDL	IV	Asymptomatic; maybe associated with increased risk of vascular disease

Lipoproteins				
Familial LPL deficiency	TG > 750 (>8.5)	Chylomicrons, VLDL	I, V	May be asymptomatic; may be associated with pancreatitits, abdominal pain, hepatosplenomegaly
Familial apo CII deficiency	TG > 750 (>8.5)	Chylomicrons, VLDL	I, V	As above
Hypertriglyceridemia and Hypercholesterolemia				
Combined hyperlipidemia	TG = (250-750 (2.8-8.5); TC = 250-500 (6.5-12.9)	VLDL, LDL	IIb	Usually asymptomatic until vascular disease develops; familial form may also present as isolated high TG or an isolated high LDL cholesterol
Dysbetalipoproteinemia	TG = 250-750 (2.8-8.5); TC = 250-500 (6.5-12.9)	VLDL, IDL; LDL normal	III	Usually asymptomatic until vascular disease develops; may have palmar or tuboeruptive xanthomas

LPL, lipoprotein lipase. Other abbreviations as in Table 23.1; TC, total cholesterol; TG, triglycerides.

TABLE 21-5 Secondary Causes of Lipoprotein Abnormalities

Hypercholesterolemia	• Hypothyroidism • Obstructive liver disease • Nephrotic syndrome • Anorexia nervosa • Acute intermittent porphyria • Drugs: progestins, thiazide diuretics, glucocorticoids, beta-blockers, isotretinoin, protease inhibitors, cyclosporine, mirtazapine, sirolimus
Hypertriglyceridemia	• Obesity • Diabetes mellitus • Lipodystrophy • Glycogen storage disease • Ileal bypass surgery • Sepsis • Pregnancy • Acute hepatitis • Systemic lupus erythematous • Monoclonal gammopathy: multiple myeloma, lymphoma

	• Drugs: Alcohol, estrogens, isotretinoin, beta blockers, glucocorticoids, bile-acid resins, thiazides; asparaginase, interferons, azole antifungals, mirtazapine, anabolic steroids, sirolimus, bexarotene
Hypocholesterolemia	• Malnutrition • Malabsorption • Myeloproliferative diseases • Chronic infectious diseases: AIDS, tuberculosis • Monoclonal gammopathy • Chronic liver disease
Low HDL	• Malnutrition • Obesity • Drugs: non-ISA beta blockers, anabolic steroids, probucol, isotretinoin, progestins

Familial hypercholesterolemia is characterized by (a) a selective elevation in the plasma level of LDL; (b) deposition of LDL-derived cholesterol in tendons (xanthomas) and arteries (atheromas); and (c) inheritance as an autosomal dominant trait with homozygotes more severely affected than heterozygotes. Homozygotes (prevalence 1 in 1,000,000) have severe hypercholesterolemia (650-1,000 mg/dL [16.8-25.9 mmol/L]), with the early appearance of cutaneous xanthomas and fatal CHD generally before the age of 20. The primary defect in familial hypercholesterolemia is the inability to bind LDL to the LDL receptor (LDL-R) or, rarely, a defect of internalizing the LDL-R complex into the cell after normal binding. Homozygotes have essentially no functional LDL receptors. This leads to lack of LDL degradation by cells and unregulated biosynthesis of cholesterol, with total cholesterol and LDL-C being inversely proportional to the deficit in LDL receptors. Heterozygotes have only about one-half of the normal number of LDL receptors, total cholesterol levels in the range of 300-600 mg/dL (7.76-15.52 mmol/L) and cardiovascular events beginning in the third and fourth decades of life.

Familial LPL deficiency is a rare, autosomal recessive trait characterized by a massive accumulation of chylomicrons and corresponding increase in plasma triglycerides or a type I lipoprotein pattern. VLDL concentration is normal. The presenting manifestations include repeated attacks of pancreatitis and abdominal pain, eruptive cutaneous xanthomatosis, and hepatosplenomegaly beginning in childhood. Symptom severity is proportional to dietary fat intake, and consequently to the elevation of chylomicrons. LPL is normally released from vascular endothelium or by heparin and hydrolyzes chylomicrons and VLDL (see Fig. 21-2). Diagnosis is based on low or absent enzyme activity with normal human plasma or apolipoprotein C-II, a cofactor of the enzyme. Accelerated atherosclerosis is not associated with this disease. Abdominal pain, pancreatitis, eruptive xanthomas, and peripheral polyneuropathy characterize type V (VLDL and chylomicrons). Symptoms may occur in childhood, but usually the disorder is expressed at a later age. The risk of atherosclerosis is increased with this disorder. These patients are commonly obese, hyperuricemic, and diabetic, and alcohol intake, exogenous estrogens, and renal insufficiency tend to be exacerbating factors.

Patients with familial type III hyperlipoproteinemia (also called dysbetalipoproteinemia, broad-band or β-VLDL) develop these clinical features after 20 years of age: xanthoma striata palmaris (yellow discolorations of the palmar and digital creases); tuberous or tuberoeruptive xanthomas (bulbous cutaneous xanthomas); and severe

atherosclerosis involving the coronary arteries, internal carotids, and abdominal aorta. A defective structure of apolipoprotein E does not allow normal hepatic surface receptor binding of remnant particles derived from chylomicrons and VLDL (known as IDL); aggravating factors such as obesity, diabetes, or pregnancy may promote overproduction of apo-B-containing lipoproteins. Although homozygosity for the defective allele (E_2/E_2) is common (1 in 100), only 1 in 10,000 express the full-blown picture, and interaction with other genetic or environmental factors, or both, is needed to produce clinical disease.

Familial combined hyperlipidemia is characterized by elevations in total cholesterol, triglycerides, decreased HDL, increased apolipoprotein B and small, dense LDL.[33] It is associated with premature CHD and may be difficult to diagnose since the lipid levels do not consistently display the same pattern.

Type IV hyperlipoproteinemia is common and occurs in adulthood primarily in patients who are obese, diabetic, and hyperuricemic and do not have xanthomas. It may be secondary to alcohol ingestion and can be aggravated by stress, progestins, oral contraceptives, thiazides, or β-blockers. Two genetic patterns occur in type IV hyperlipoproteinemia: familial hypertriglyceridemia, which does not carry a great risk for premature CAD, and familial combined hyperlipidemia, which is associated with increased risk of cardiovascular disease.

Rare forms of lipoprotein disorders may include hypobetalipoproteinemia, abetalipoproteinemia, Tangier disease, LCAT deficiency (fish-eye disease), cerebrotendinous xanthomatosis, and sitosterolemia. Most of these rare lipoprotein disorders do not result in premature atherosclerosis, with the exceptions of familial LCAT deficiency, cerebrotendinous xanthomatosis (CTX), and sitosterolemia with xanthomatosis. Their treatment consists of dietary restriction of plant sterols (sitosterolemia with xanthomatosis), chenodeoxycholic acid (CTX), or, potentially, blood transfusion (LCAT deficiency).

CLINICAL PRESENTATION General

- Most patients are asymptomatic for many years prior to clinically evident disease.
- Patients with the metabolic syndrome may have 3 or more of the following: abdominal obesity, atherogenic dyslipidemia, raised blood pressure, insulin resistance ± glucose intolerance, prothrombotic state or proinflammatory state.

Symptoms

- None to chest pain, palpitations, sweating, anxiety, shortness of breath, loss of consciousness or difficulty with speech or movement, abdominal pain, and sudden death.

Signs

- None to abdominal pain, pancreatitis, eruptive xanthomas, peripheral polyneuropathy, high blood pressure, BMI greater than 30 kg/m^2 or waist size greater than 40 inches (102 cm) in men (35 inches [89 cm] in women).

Laboratory tests

- Elevations in total cholesterol, LDL, triglycerides, apolipoprotein B, and high sensitivity C-reactive protein (hsCRP).
- Low HDL

Other diagnostic tests

- Lipoprotein (a), and small, dense LDL (pattern B), HDL subclassification, apolipoprotein E isoforms,

apolipoprotein A-1, fibrinogen, folate, lipoprotein-associated phospholipase A_2.

Various screening tests for manifestations of vascular disease (ankle-brachial index, exercise testing, and magnetic resonance imaging) and diabetes (fasting glucose, oral glucose tolerance test, and hemoglobin A_{1c}).

PATIENT EVALUATION

A fasting (preferred) lipoprotein profile including total cholesterol, LDL-C, HDL-C, and triglycerides should be measured in all adults 20 years of age or older at least once every 5 years.[5] If the profile is obtained in the nonfasted state, only total cholesterol and HDL-C will be usable because LDL-C is usually a calculated value; if total cholesterol is greater than or equal to 200 mg/dL (greater than or equal to 5.17 mmol/L), or if HDL-C is less than 40 mg/dL (less than 1.03 mmol/L), a follow-up fasting lipoprotein profile should be obtained. After a lipid abnormality is confirmed (**Table 21-6**), major components of the evaluation are the history (including age, gender, and, if female, menstrual and hormone replacement status), physical examination, and laboratory investigations. A complete history and physical exam should assess (a) presence or absence of cardiovascular risk factors or definite cardiovascular disease in the individual; (b) family history of premature cardiovascular disease or lipid disorders; (c) presence or absence of secondary causes of lipid abnormalities, including concurrent medications (see Table 21-5); and (d) presence or absence of xanthomas or abdominal pain, or history of pancreatitis, renal or liver disease, peripheral vascular disease, abdominal aortic aneurysm, or cerebral vascular disease (carotid bruits, stroke, or transient ischemic attack). Diabetes mellitus is regarded as a CHD risk equivalent.[5] The presence of diabetes in patients without known CHD is associated with the same level of risk as patients without diabetes but having confirmed CHD.[34,35] ATP III identified four categories of risk that modify the goals and modalities of LDL-lowering therapy (**Table 21-8**).[6] However in the current guidelines, pooled cohort equations are currently recommended. The components of the estimator include gender, age, race, total cholesterol, HDL, systolic blood pressure, hypertension that is being treated, presence of diabetes, and smoking status. Cohort Equations and lifetime risk prediction tools can be found at: http://tools.acc.org/ASCVD-Risk-Estimator/. The expert panel was unable to find sufficient evidence from randomized clinical trials to support the use of specific LDL or non-LDL treatment targets (no recommendation).[36] Rather than specific treatment targets, the panel identified four groups most likely to benefit from treatment with statins to reduce the 10-year risk of atherosclerotic cardiovascular disease in secondary and primary intervention.

TABLE 21-6 Classification of Total-, Ldl-, Hdl-Cholesterol and Triglycerides

Total Cholesterol	
<200 mg/dL (<5.17 mmol/L)	Desirable
200-239 mg/dL (5.17-6.20 mmol/L)	Borderline high
≥240 mg/dL (≥6.21 mmol/L)	High
LDL Cholesterol	
<100 mg/dL (<2.59 mmol/L)	Optimal
100-129 mg/dL (2.59-3.35 mmol/L)	Near or above optimal
130-159 mg/dL (3.36-4.13 mmol/L)	Borderline high
160-189 mg/dL (4.14-4.90 mmol/L)	High
≥190 mg/dL (≥4.91 mmol/L)	Very high

HDL Cholesterol

<40 mg/dL (<1.03 mmol/L)	Low
≥60 mg/dL (≥1.55 mmol/L)	High

Triglycerides

<150 mg/dL (<1.70 mmol/L)	Normal
150-199 mg/dL (1.70-2.25 mmol/L)	Borderline high
200-499 mg/dL (2.26-5.64 mmol/L)	High
≥500 mg/dL (≥5.65 mmol/L)	Very high

HDL, high-density lipoproteins; LDL, low-density lipoproteins.

TABLE 21-7 Key Recommendations to Reduce the Risk of ASCVD in Adults

Recommendations	ACC/AHA COR	ACC/AHA LOE
Heart healthy lifestyle for everyone		
Appropriate intensity of statin therapy should be initiated or continued		
1. Clinical ASCVD*		
a. Age <75 y and no safety concerns: High-intensity statin therapy	I	A
b. Age >65 y or safety concerns: Moderate-intensity statin therapy	I	A
2. Primary prevention—Primary LDL ≥190 mg/dL		
a. Rule out secondary causes of dyslipidemia	I	B
b. Age ≥21 y: High-intensity statin therapy	I	B
c. Achieve at least a 50% reduction in LDL	IIa	B
d. LDL lowering nonstatin therapy may be considered to further reduce LDL	IIb	C
3. Primary prevention—Diabetes 40-75 years of age and LDL 70-189 mg/dL		
a. Moderate-intensity statin therapy	I	A
b. Consider high-intensity statin when ≥7.5% 10-y ASCVD risk using the Pooled Cohort Equations	II	B
4. Primary prevention—no diabetes, 40-75 years of age and LDL 70-189 mg/dL		
a. Estimate 10-y ASCVD risk based on Pooled Cohort Equations in those not receiving a statin; estimate risk every 4-6 y	I	B
	IIa	C
b. To determine if statin should be initiated, engage in a clinical-patient discussion concerning risk adverse reactions, drug interactions and patient preferences	I	A
	I	A

Recommendations	ACC/AHA COR	ACC/AHA LOE
c. Re-emphasize heart-healthy lifestyle and address other risk factors		
i. ≥7.5% 10-y ASCVD risk: Moderate or high-intensity statin therapy		
ii. 5%-7.5% 10-y ASCVD risk: Consider moderate-intensity statin therapy	IIb	C
iii. Other risk factors may be considered: LDL ≥160 mg/dL, family history of premature ASCVD, hs-CRP ≥2 mg/dL, CAC score ≥300 Agaston units, ABI <0.9 or lifetime risk	IIb	C
5. Primary prevention when LDL <190 mg/dL and age <40 or >75 y, or <5% 10-y ASCVD risk		
a. Statin therapy may be considered in selected individuals	IIb	C
6. Statin therapy is not routinely recommended for individuals with NYHA Class 11-IV heart failure or who are receiving maintenance hemodialysis		

ABI, ankle brachial index; ACC/AHA, American College of Cardiology/American Heart Association; ASCVD, Atherosclerotic cardiovascular disease; y, years; CAC, coronary artery calcium; COR, Class of recommendation; hsCRP, high-sensitivity C reactive protein; LDL-, low density lipoprotein; LOE, Level of evidence; NYHA, New York Heart Association.

*Clinical ASCVD includes nonfatal MI, CHD death, and nonfatal and fatal stroke, TIA or peripheral arterial disease presumed to be of atherosclerotic origin.

TABLE 21-8 Intensity of Statin Therapy by Drug and Dose

High-intensity Statin Therapy	Moderate-intensity Statin Therapy	Low-intensity Statin Therapy
	Daily dose lowers LDL on average by 30 to <50%	
	Atorvastatin 10 (20) mg	Daily dose lowers LDL on average by <30%
Daily dose lowers LDL on average by ≥50%	**Rosuvastatin (5)-20 mg**	Simvastatin 10 mg
Atorvastatin (40)-80 mg	**Simvastatin 20-40 mg***	**Pravastatin 10-20 mg**
Rosuvstatin (20)-40 mg	**Pravastatin 40-(80) mg**	**Lovastatin 20 mg**
	Lovastatin 40 mg	Fluvastatin 20-40 mg
	Fluvastin XL 80 mg	Pitavastin 1 mg
	Fluvastatin 40 mg BID	
	Pitavastatin 2-4 mg	

*Simvastatin is not recommended by the FDA to be started at 80 mg/day due to increased risk of myopathy and rarely rhabdomyolysis .

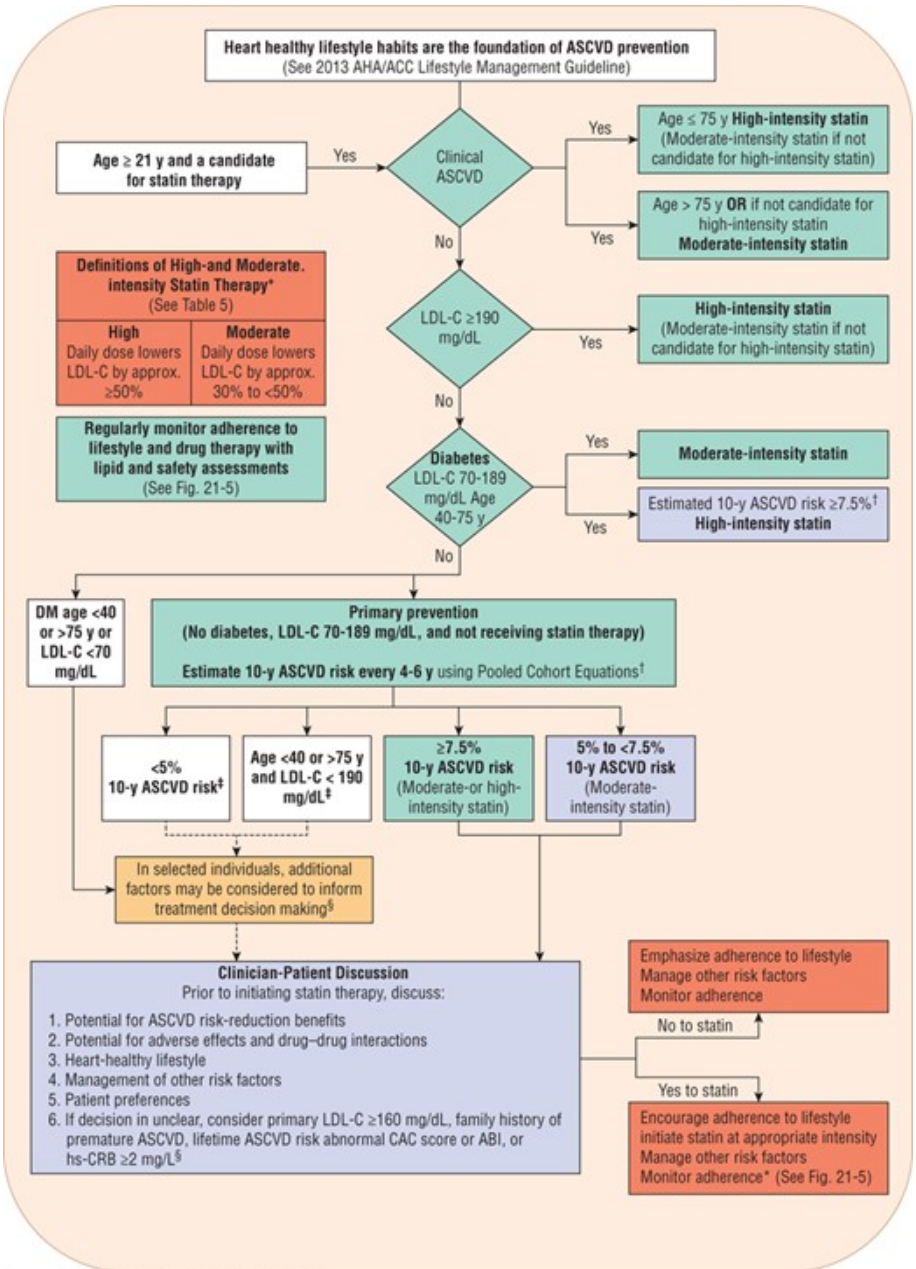
Boldface type indicates specific states that have been tested in RCT.

Legend: FDA, Food and Drug Administration; RCT, Randomized clinical trials.

Heart-healthy lifestyle and habits should be encouraged for all individuals (I/A). Table 21-7 outlines the key recommendations for treatment of blood cholesterol to reduce ASCVD risk in adults. Other recommendations not appearing in Table 21-7 address adherence, lipid panel testing, screening for comorbidities and monitoring. The Expert Panel established categories of statin intensity including High-, Moderate-, and Low-intensity statin therapy (see Table 21-8) based on evidence from randomized clinical trials and package insert information. **Figure 21-4** further outlines the process for statin initiation for the treatment of blood cholesterol to reduce ASCVD risk in adults.

FIGURE 21-4

Statin Initation.



Measurement of plasma cholesterol (which is about 3% lower than serum determinations), triglyceride, and HDL-C

levels after a 12-hour or longer fast is important, as triglycerides may be elevated in non-fasted individuals; total cholesterol is only modestly affected by fasting. Analytic and biologic variability can have a major impact on the measurement and interpretation of cholesterol (or any other laboratory test). Analytic variability can be minimized through the use of adequate quality-control procedures, including internal training, routine calibration and monitoring, and external proficiency testing. Even with these measures, the coefficient of variability in the best procedures can acceptably be up to 5%, and when combined with average biologic variability, total variability may be as high as about 22%. Analytic variability with desktop equipment generally is greater in the fingerstick capillary blood methods, usually yielding measurements less than those from a clinical laboratory, and this technology should be considered for use only as a screening method. Reliance on desktop methods can result in misclassification of 7% to 14% of patients if capillary blood is used. Two determinations, 1 to 8 weeks apart, with the patient on a stable diet and weight, and in the absence of acute illness, are recommended to minimize variability and to obtain a reliable baseline.[5,36] If the total cholesterol is greater than 200 mg/dL (5.17 mmol/L), a second determination is recommended, and if the values are more than 30 mg/dL (0.78 mmol/L) apart, the average of three values should be used. Familiarity with the method and quality control procedures employed by local laboratories is essential for interpretation of reported values. If the physical examination and history are insufficient to diagnose a familial disorder, then agarose-gel lipoprotein electrophoresis is useful to determine which class of lipoproteins is affected. If the triglyceride levels are below 400 mg/dL (4.52 mmol/L) and neither type III hyperlipidemia nor chylomicrons are detected by electrophoresis, then one can calculate VLDL and LDL concentrations: VLDL = triglyceride/5; LDL = total cholesterol - (VLDL + HDL).

Because total cholesterol is comprised of cholesterol derived from LDL, VLDL, and HDL, determination of HDL is useful when total plasma cholesterol is elevated. HDL may be elevated by moderate alcohol ingestion (less than two drinks per day), physical exercise, smoking cessation, weight loss, oral contraceptives, phenytoin, and terbutaline. Smoking, obesity, a sedentary life-style and drugs such as *β*-blockers lower HDL. Only exercise and smoking cessation could be recommended as interventions for low HDL concentrations. Niacin and gemfibrozil also increase HDL concentrations.

The range of lipid concentrations represents a population mean plus or minus two standard deviations and does not define the risk of disease. Reference values for plasma total, LDL, and HDL cholesterol concentrations for men and women, as well as various ethnic groups, are available from the NHANES III.[10] Cholesterol and triglycerides increase throughout life until about the fifth decade for men and the sixth decade for women. Past these ages, total cholesterol and LDL plateau and fall slightly. HDL tends to fall slightly with time and more rapidly after menopause in women. Institution of a population-based approach for cholesterol reduction should shift the entire curve to the left, and the potential reduction in cardiovascular mortality would be proportional to mean reductions at any cholesterol concentration.

Based on a careful review of the experimental pathologic, genetic, and epidemiologic evidence relating to the relationship between blood cholesterol levels and CHD, the ATP III of the NCEP recommends that a fasting lipoprotein profile and risk factor assessment be used in the initial classification of adults.[5,37] If total cholesterol is less than 200 mg/dL (5.17 mmol/L), then the patient has a *desirable blood cholesterol level* (see Table 21-6). Cholesterol levels between 200 and 239 mg/dL (5.17 and 6.18 mmol/L) are classified as *borderline-high blood cholesterol levels,* and assessment of risk factors (see Table 21-7) is needed to more clearly define disease risk. Blood cholesterol levels of 240 mg/dL (6.21 mmol/L) and above are classified as *high blood cholesterol levels*. If the total cholesterol is below 200 mg/dL (5.17 mmol/L) and the HDL is above 40 mg/dL (1.03 mmol/L), no further follow-up is recommended for patients without known CHD and who have fewer than two risk factors. An increasing number of persons have the metabolic syndrome that is characterized by abdominal obesity, atherogenic dyslipidemia (elevated triglycerides, small LDL particles, and low HDL-C), raised blood pressure, insulin resistance (with or without glucose intolerance), and prothrombotic and proinflammatory states. Non-HDL is calculated by subtracting HDL from total cholesterol and the targets are 30 mg/dL (0.78 mmol/L) greater than LDL for each risk stratum. Non-HDL takes into consideration atherogenic particles such as remnant lipoproteins and

IDL that are not measured in routine clinical laboratory testing.[38] HDL-raising has potential benefit but no specific goals are set in the current guidelines and the evidence is modest to support aggressively increasing HDL levels.[39]

The Expert Panel on Children and Adolescents of the NCEP recommends screening in higher-risk children (positive family history or parental high blood cholesterol, greater than or equal to 240 mg/dL [greater than or equal to 6.21 mmol/L]).[40] The American Academy of Pediatrics categorizes total and LDL cholesterol into Acceptable (less than 75th percentile; total cholesterol less than 170 mg/dL [less than 4.40 mmol/L]), Borderline (75th-95th percentile; total cholesterol 170-199 mg/dL [4.40-5.15 mmol/L], LDL cholesterol 110-129 mg/dL [2.84-3.34 mmol/L]) and Elevated (greater than 95th percentile; total cholesterol greater than 200 mg/dL [greater than 5.17 mmol/L], LDL cholesterol greater than 130 mg/dL [greater than 3.36 mmol/L]).[40] The rationale, in part, for this approach is based on the recognition that atherosclerosis begins in the childhood and adolescent years as documented in the pathobiologic determinants of atherosclerosis in youth (PDAY) and the Bogalusa studies.[41] Similarly, if children with high blood lipids or lipoprotein levels are identified, and the levels in the parents are unknown, the parents should be screened as well, as they are likely to be at high risk. Racial and gender differences do exist in the determination of lipoprotein fractions, and these factors should be considered in screening. Use of the serum cholesterol level alone may be of insufficient specificity or sensitivity, depending on the cut points used in screening, and other discretionary factors, such as hypertension, smoking, obesity, high-fat diet, and use of cholesterol-raising medication, may be needed to correctly identify children at risk. Presently, children over the age of 10 years are candidates for drug therapy if a trial of diet (6 months-1 year) proves to be inadequate and LDL-C remains above 190 mg/dL (4.91 mmol/L), or above 160 mg/dL (4.14 mmol/L) if two or more risk factors or CHD are present in the child or adolescent, or if there is a history of premature CHD. In children with diabetes mellitus, pharmacologic treatment should be considered when LDL cholesterol is greater than or equal to 130 mg/dL (greater than or equal to 3.36 mmol/L).[40] The Dietary Intervention Study in Children (DISC) in pubertal children found that a fat restricted diet modestly lowered LDL-C and maintained psychologic well-being and dietary changes are acceptable to children.[42,43] Although bile acid sequestrants have been the recommended drugs for this population, clinical trials demonstrate that statin therapy is effective and well tolerated in pediatric populations.[44,45] The long-term consequences of drug therapy in this population are unknown. In special instances, familial hypercholesterolemia (particularly the homozygous form), or the existence of CHD or two or more risk factors in the child, would prompt the earlier institution of drug therapy after a trial of dietary intervention.

TREATMENT

Desired Outcomes

The goals of therapy expressed as LDL-C levels and the level of initiation of TLC and drug therapy are provided in Tables 21-7 and **21-9** for adults and children, respectively. While these goals are surrogate endpoints, the primary reason to institute TLC and drug therapy is reduce the risk first or recurrent events such as MI, angina, heart failure, ischemic stroke, or other forms of peripheral arterial disease such as carotid stenosis or abdominal aortic aneurysm.

TABLE 21-9 Cut Points for Total Cholesterol and LDL Concentrations in Children and Adolescents

Category	Percentile	Total Cholesterol, mg/dL (mmol/L)	LDL Cholesterol, mg/dL (mmol/L)
Acceptable	<75th	<170 (<4.40)	<110 (<2.84)
Borderline	75th-95th	170-199 (4.40-5.16)	110-129 (2.84-3.35)
Elevated	>95th	>200 (>5.17)	>130 (>3.36)

Adapted from American Academy of Pediatrics. National Cholesterol Education Program: report of the expert panel on blood cholesterol levels in children and adolescents. Pediatrics. 1992;89(3 pt 2): 525 -584.

General Approach[1]

Establishing targeted changes and outcomes with consistent reinforcement of goals and measures at follow up visits to attain goals are important to reduce barriers for optimizing TLC and pharmacologic therapy.[3] TLC should be implemented in all patients prior to considering drug therapy. The components of TLC include reduced intakes of saturated fats and cholesterol, dietary options to reduce LDL such as plant stanols and sterols and increased soluble fiber intake, weight reduction, and increased physical activity. In general, physical activity of moderate intensity 30 minutes per day for most days of the week should be encouraged.[46,47] Patients with known CAD or at high risk should be evaluated before undertaking vigorous exercise. Weight and BMI should be determined at each visit and lifestyle patterns to induce a weight loss of 10% should be discussed in persons who are overweight. All patients should also be counseled to stop smoking and to meet the Joint National Committee VII guidelines for control of hypertension.

Nonpharmacologic Therapy

Individualized diet counseling that provides acceptable substitutions for unhealthy foods and ongoing reinforcement by a registered dietitian are necessary for maximal effect. The objectives of dietary therapy are to progressively decrease the intake of total fat, saturated fatty acids (ie, saturated fat), and cholesterol, and to achieve a desirable body weight. Typical American diets now include 13% to 20% of total calories from saturated fat and a cholesterol intake of 350 to 450 mg/day, both in excess of a "heart healthy" diet for normal Americans, let alone patients with a lipid disorder. Excessive dietary intake of cholesterol and saturated fatty acids leads to decreased hepatic clearance of LDL and deposition of LDL and oxidized LDL in peripheral tissues. The targeted saturated fatty acids have carbon chain lengths of 12 (lauric acid), 14 (myristic acid), and 16 (palmitic acid). The rationale for using a nutritionally balanced low-fat, low-cholesterol diet for the treatment of hypercholesterolemia is based on these principles: (a) it represents a reasonable extension of the diet recommended for the general public; (b) it progressively decreases the major cholesterol-raising constituent of the diet; (c) it precludes large intakes of polyunsaturated fats; and (d) it facilitates weight reduction by removing foods of high caloric density.[48,49,50,51]

Dietary expertise in providing a wide range of options and suggestions in preparation of food can make the difference between a good or an inadequate response to diet. Information concerning eating out in a healthy fashion and advice for shopping are also important factors for success in diet therapy. An example is being aware of products with misleading labels such as coffee creamers that state they contain "no cholesterol," when they may contain hydrogenated (saturated) fats or oils (eg, palmitic acid, palm kernel oil, or coconut oil), which makes them undesirable because of their saturated fat content. Variations in polyunsaturated and saturated fat and cholesterol intake influence the LDL concentration, but the amount of cholesterol has been found to have a greater effect than the proportion of polyunsaturated or saturated fat. There were also racial differences in elevation of LDL with high saturated fat diets being greater in whites than in other racial groups. The isomeric form of fatty acids is also important.[48] Fatty acids with the *cis* configuration are the preferred substrate for the ACAT reaction and significantly increase hepatic LDL receptor clearance while reducing LDL cholesterol production rate. The *trans* isomeric form cannot be used by ACAT and is biologically inactive with no effect on LDL concentration.

Ideally, therapeutic TLC including reduced intake of saturated fats and cholesterol, increased stanol/sterol and fiber intake, weight reduction, and increased physical activity should be used to attain lower LDL-C and to achieve reductions in CHD risk (**Table 21-10**). TLC may obviate the need for drug therapy, augment LDL-lowering drug therapy, and allow for lower doses. Weight control plus increased physical activity reduces risk beyond LDL-cholesterol lowering, is the primary management approach for the metabolic syndrome, raises HDL and reduces non-HDL cholesterol.[52,53] Many persons should be given a three-month trial (two visits spaced 6 weeks

apart) of dietary therapy and TLC before advancing to drug therapy unless patients are at very high risk (severe hypercholesterolemia, known CHD, CHD risk equivalents, multiple risk factors, and strong family history). Although changes in blood lipid levels may change before three months, adoption of a different eating pattern may require a longer period of time. It is important to involve all family members, especially if the patient is not the primary person preparing food. The NCEP and AHA both have excellent internet based resources to aid patients in altering their diet in a culturally sensitive manner (http://www.americanheart.org/presenter.jhtml?identifier=1200009; http://www.nhlbi.nih.gov/health/index.htm). If all of the recommended dietary changes from NCEP, the estimated reduction, on average, in LDL would range from 20% to 30%.[5] Adherence to diet and inter-individual variability in macronutrient intake would obviously influence the eventual LDL level achieved. Based on the NHANES data, less than one-half of the patients who should be instructed on heart healthy diet receive any dietary instructions.

TABLE 21-10 Macronutrient Recommendations for the TLC Diet

Component*	Recommended Intake
Total fat	25%-35% of total calories
Saturated fat	Less than 7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Carbohydrates#	50%-60% of total calories
Cholesterol	<200 mg/day
Dietary Fiber	20-30 grams/d
Plant sterols	2 grams/d
Protein	Approximately 15% of total calories
Total calories	To achieve and maintain desirable body weight

*Calories from alcohol not included.

#Carbohydrates should derive from foods rich in complex carbohydrates such as whole grains, fruits, and vegetables.

Other dietary interventions or diet supplements may be useful in certain patients with lipid disorders. Increased intake of soluble fiber in the form of oat bran, pectins, certain gums, and psyllium products can result in useful adjunctive reductions in total and LDL cholesterol, but these dietary alterations or supplements should not be substituted for more active forms of treatment. Total daily fiber intake should be about 20 to 30 g/d, with about 25% or 6 g/d, being soluble fiber.[5] Studies with psyllium seed in doses of 10 to 15 g/d show reductions in total and LDL cholesterol ranging from about 5% to 20%.[54,55] They have little or no effect on HDL-C or triglyceride concentrations. These products may also be useful in managing constipation associated with the bile acid sequestrants. Psyllium binds cholesterol in the gut but also reduces hepatic production and clearance. Fish oil supplementation provides an increased amount of the omega-3 polyunsaturated fatty acids such as eicosapentaenoic acid and docosahexaenoic acid. In epidemiologic studies, ingestion of large amounts of cold water, oily fish is associated with a reduction in CHD risk, but it is unclear whether the same advantage is conferred with commercially prepared fish oil products. Each 20 gm per day ingestion of fish lowers CHD risk by 7% and eating fish once weekly or more should reduce CHD mortality.[56] Fish oil supplementation has a fairly large effect in reducing triglycerides and VLDL-C, but it either has no effect on total and LDL cholesterol or may cause elevations in these fractions. Other actions of fish oil may account for their protective effects. These effects include quantitative and qualitative alterations in the synthesis of prostanoid substances, changes in immune function and cellular proliferation, and potential antioxidative actions.[57] Responses noted with fish oil are further discussed

under drug therapy.[58]

Fat substitutes such as Olestra (Olean, sucrose polyester, Procter and Gamble), a mixture of hexa-, hepta-, and octa-esters formed from the reaction of sucrose with long-chain fatty acids, are approved by the FDA as a nondigestible, nonabsorable, and noncaloric fat substitute for snack foods. Olestra is heat stable, an advantage over several other fat substitutes, enabling it to be used in the preparation of fried and baked foods. It is similar in composition to triglycerides, but Olestra is not hydrolyzed in the gastrointestinal tract by pancreatic lipase, and, consequently, is not taken up by the intestinal mucosa. The principal adverse effects associated with Olestra use are bloating, flatulence, diarrhea, and "anal leakage." Because of the ability of Olestra to solubilize lipophilic substances, there has been concern over potential drug interactions in which lipophilic drugs (eg, cyclosporin, or colchicine) or vitamins (vitamins A, D, E, and K) are solubilized in Olestra and excreted in the feces.

Recent studies have demonstrated the LDL-lowering effect of plant sterols, which are isolated from soybean and tall pine-tree oils. Ingestion of 2 to 3 grams per day will reduce LDL by 6% to 15%.[5] Plant sterols can be esterified to unsaturated fatty acids (creating sterol esters) to increase lipid solubility. Hydrogenating sterols produces plant stanols and, with esterification, stanol esters. The efficacy of plant sterols and plant stanols is considered to be comparable. Because lipids are needed to solubilize stanol/sterol esters, they are usually available in commercial margarines. The presence of plant stanols/sterols is listed on the food label. When margarine products are used, persons must be advised to adjust caloric intake to account for the calories contained in the products. Benecol® (McNeil), as an example, is a butter-like spread that contains a plant stanol ester, an ingredient that can lower cholesterol and which is derived from plant stanols found naturally in small amounts in foods like wheat, rye, and corn.[59] In August 2007, the Food and Drug Administration issued a warning about the consumption of red yeast rice and red yeast rice/policosonal containing products. These products contained lovastatin that could interact with other drugs and would have the same toxicity of statins but would not be recognized by the consumer and the reduction in LDL is minimal.[60]

Drug therapy is indicated following an adequate trial of TLC changes as outlined in Tables 21-8 and 21-9.

Pharmacologic Therapy

There are now numerous randomized, double-blinded clinical trials demonstrating that reduction of LDL reduces CHD event rates in primary prevention, secondary intervention, and in angiographic trials.[61] Generally speaking, for every 1% reduction in LDL, there is a 1% reduction in CHD event rates.[5] However, if treatment extends beyond the typical duration of a clinical trial (2-5 years), the accumulated benefit could be greater. Elevations of HDL of 1% result in approximately 2% reduction in CHD events.[16,62] Of interest, angiographic trials, which typically cause small changes in luminal diameter (eg, about a 0.04-mm difference in change between placebo and active treatment), result in fewer clinical events such as MI or the need for revascularization. This unexpected finding suggests that plaque size and luminal encroachment by plaque may be less important than the effects that cholesterol lowering may have on the activity in the plaque and endothelial dysfunction. These studies provide a strong rationale for attempting to lower plasma cholesterol and LDL in patients with hypercholesterolemia.

4 Although many efficacious lipid-lowering drugs exist, none is effective in all lipoprotein disorders, and all such agents are associated with some adverse effects.[63] Lipid-lowering drugs can be broadly divided into agents that decrease the synthesis of VLDL and LDL, agents that enhance VLDL clearance, agents that enhance LDL catabolism, agents that decrease cholesterol absorption, agents that elevate HDL, or some combination of these characteristics (**Table 21-11**). **Table 21-12** lists recommended drugs of choice for each lipoprotein phenotype and alternate agents. **Table 21-13** lists available products and their doses.

TABLE 21-11 Effects of Drug Therapy on Lipids and Lipoproteins

Drug	Mechanism of Action	Effects on Lipids	Effects on Lipoproteins	Comment
Cholestyramine, colestipol and colesevelam	↑ LDL catabolism Cholesterol ↓ absorption	↓ Cholesterol	↓ LDL ↑ VLDL	Problem with compliance; binds many co-administered acidic drugs
Niacin	↓ LDL and VLDL ↓ synthesis	↓ Triglyceride and ↓ cholesterol	↓ VLDL, ↓ LDL, ↑ HDL	Problems with patient acceptance; good in combination with bile acid resins; extended release niacin causes less flushing and is less hepatotoxic than sustained release
Gemfibrozil, fenofibrate, clofibrate	↑ VLDL clearance ↓ VLDL synthesis	↓ Triglyceride and cholesterol	↓ VLDL, ↓ LDL, ↑ HDL	Clofibrate causes cholesterol gall stones; modest LDL lowering; raises HDL; gemfibrozil inhibits glucuronidation of simvastatin, lovastatin and atorvastatin
Lovastatin, Pravastatin, Simvastatin, Fluvastatin, Atorvastatin Rosuvastatin	↑ LDL catabolism; inhibit LDL synthesis	↓ Cholesterol	↓ LDL	Highly effective in heterozygous familial hypercholesterolemia and in combination with other agents
Ezetimibe	Blocks cholesterol absorption across the intestinal border	↓ Cholesterol	↓ LDL	Few adverse effects; effects additive to other drugs
Mipomerson	Inhibitor of Apolipoprotein B-100	↓ Cholesterol, LDL, non-HDL	↓ LDL, non-HDL	Increase in transaminases, risk of hepatosteatosis and hepatotoxicity; must be given by SQ injection. Only indicated for familial hypercholesterolemia. To be used along with other lipid lowering therapies (statins)
Lomitapide	Microsomal triglyceride transfer protein inhibitor	↓ Cholesterol	↓ LDL, non-HDL	Hepatotoxicity must be monitored via Juxtapid Risk Evaluation and Mitigation Strategy program. Only indicated for familial hypercholesterolemia. To be used along with other lipid lowering therapies (statins)
Alirocumab	PCSK9 inhibitor	↓ Cholesterol, ↓ Lpa	↓ Cholesterol and LDL	Given by SQ injection, injection site pain, low risk of hepatoxicity
Evolocumab	PCSK9 inhibitor	↓ Cholesterol, ↓ Lpa	↓ Cholesterol and LDL	Given by SQ injection, injection site pain, low risk of hepatoxicity

TABLE 21-12 Lipoprotein Phenotype and Recommended Drug Treatment

Lipoprotein Type	Drug of Choice	Combination Therapy
I	Not indicated	___

Lipoprotein Type	Drug of Choice	Combination Therapy
		Niacin or BAR
	Statins	Statins or niacin
II[a]	Cholestyramine or colestipol	Statins or BAR
	Niacin	Ezetimibe
		Mipomersen, lomitapide[b]
		BAR or Fibrates or niacin
	Statins	
		Statins or niacin or BAR[a]
II[b]	Fibrates	
		Statins or Fibrates
	Niacin	
		Ezetimibe
		Statins or niacin
	Fibrates	
III		Statins or Fibrates
	Niacin	
		Ezetimibe
	Fibrates	Niacin
IV		
	Niacin	Fibrates
	Fibrates	Niacin
V		
	Niacin	Fish oils

BAR, bile acid resins; fibrates includes gemfibrozil or fenofibrate.

[a]BAR are not used as first-line therapy if triglycerides are elevated at baseline since hypertriglyceridemia may be worsen with BAR alone.

[b]Mipomersen and lomitapide are used in combinations with other lipid lowering therapy, in particular, statins for patients with familial hypercholestermia (homozygotes or heterzygotes) and in patient who cannot be managed adequately with maximally tolerated statin therapy.

TABLE 21-13 Comparison of Drugs Used in the Treatment of Hyperlipidemia

Drug	Manufacturer	Dosage Forms	Usual Daily Dose	Maximum Daily Dose
Cholestyramine (Questran)	BMS	Bulk powder/4-g packets	8 g tid	32 g
Cholestyramine (Questran Light)	BMS	Bulk powder/4-g packets		
Cholestyramine (Cholybar)	Parke-Davis	4-g resin per bar		
Colestipol hydrochloride (Colestid)	Upjohn	Bulk powder/5-g packets	10 g bid	30 g
Colesevelam (Welchol)	Sankyo	625 mg tablets	1,875 mg bid	4,375 mg

Drug	Manufacturer	Dosage Forms	Usual Daily Dose	Maximum Daily Dose
Niacin	Various	50-, 100-, 250-, and 500-mg tablets; 125-, 250-, and 500-mg capsules	2 g tid	9 g
Extended release niacin (Niaspan)	Kos	500, 750 and 1,000 mg tablets	500 mg	2,000 mg
		Niacin/lovastatin 500 mg/20 mg tablets		
Extended release niacin + lovastatin (Advicor)*	Kos	Niacin/lovastatin 750 mg/20 mg tablets	Niacin/lovastatin 500 mg/20 mg	Niacin/lovastatin 1,000 mg/20 mg
		Niacin/lovastatin 1,000 mg/20 mg tablets		
Fenofibrate (Tricor and others)	Abbott, various	67, 134 and 200 mg capsules (micronized); 54 and160 mg tablets; 40, 120 mg tablets; 50, 160 mg tablets	54 mg or 67 mg	201 mg
Gemfibrozil (Lopid)	Parke-Davis	300-mg capsules	600 mg bid	1.5 g
Lovastatin (Mevacor)	MSD	20- and 40-mg tablets	20-40 mg	80 mg
Pravastatin (Pravachol)	Bristol-Myers Squibb	10- and 20-mg tablets	10-20 mg	40 mg
Simvastatin (Zocor)	MSD	5, 10, 20, 40, and 80-mg tablets	10-20 mg	80 mg
Atorvastatin (Lipitor)	Pfizer	10 mg tablets	10 mg	80 mg
Rosuvastatin (Crestor)	Astra-Zeneca	5- and 10-mg tablets	5 mg	40 mg
Pitavastatin (Livalo)	Kowa	1, 2, and 4 mg tablets	2 mg	4 mg
Ezetimibe (Zetia)	MSD	10 mg tablet	10 mg	10 mg
		Atorvastatin/amlodipine 10 mg/5 mg		
		Atorvastatin/amlodipine 20 mg/5 mg		
		Atorvastatin/amlodipine 40 mg/5 mg		
Atorvastatin/amlodipine (Caduet)	Pfizer	Atorvastatin/amlodipine 80 mg/5 mg	Atovastatin/amlodipine 10 mg/5 mg	Atovastatin/amlodipine 80 mg/10 mg
		Atorvastatin/amlodipine 10 mg/10 mg		
		Atorvastatin/amlodipine 20 mg/10 mg		
		Atorvastatin/amlodipine		

Drug	Manufacturer	Dosage Forms	Usual Daily Dose	Maximum Daily Dose
Pravastatin/aspirin (Pravigard PAC)	BMS	40 mg/10 mg Atorvastatin/amlodipine 80 mg/10 mg Pravastatin/aspirin 20 mg/81 mg Pravastatin/aspirin 20 mg/325 mg Pravastatin/aspirin 40 mg/81 mg Pravastatin/aspirin 40 mg/325 mg Pravastatin/aspirin 80 mg/81 mg Pravastatin/aspirin 80 mg/325 mg Simvastatin/ezetimibe 10 mg/ 10 mg		
Simvastatin/ezetimibe (Vytorin)	Merck/Schering-Plough	Simvastatin/ezetimibe 20 mg/ 10 mg Simvastatin/ezetimibe 40 mg/ 10 mg	Simvastatin/ezetimibe 20 mg/10 mg	Simvastatin/ezetimibe 40 mg/10 mg
Omega-3 acid ethyl esters (Lovaza)	Reliant	Eicosapentaenoic acid (EPA) 465 mg, docosahexaenoic acid (DHA) 375 mg	41 gram capsules QD or 21 gram capsules BID	41 gram capsules QD or 21 gram capsules BID
Lomitapide	Aegerion	5, 10, 20 mg capsules	5 mg QD increasing at 2 week intervals to response or maximum dose; dose 2 hours after evening meal	60 mg QD
Mipomersen	Genzyme	200 mg/ml for SQ injection	200 mg SQ once weekly	200 mg SQ once weekly
Alirocumab		75 or 150 mg	SQ every two weeks	150 mg
Evolocumab		140 mg or 420 mg	SQ 140 mg every 2 weeks or 420 mg once a month	420 mg

BID, twice daily; probucol is no longer on the market in the US; gemfibrozil, fenofibrate, and lovastatin are available as generic products. BMS, Bristol-Myers Squibb; MSD, Merck Sharp & Dohme; SQ, subcutaneously.

*The manufacturer does not recommend use of the fixed combination as initial therapy of primary

hypercholesterolemia or mixed dyslipidemia. It is specifically indicated in patients receiving lovastatin alone plus diet who require an additional reduction in triglyceride levels or increase in HDL-cholesterol levels; it is also indicated in those treated with niacin alone who require additional decreases in LDL cholesterol. Lomitapide and mipomersen can be hepatotoxic and close monitoring is recommended for both.

Treatment of type I hyperlipoproteinemia is directed toward reduction of chylomicrons derived from dietary fat with the subsequent reduction in plasma triglycerides. Total daily fat intake should be no more than 10 to 25 g/d, or approximately 15% of total calories. Secondary causes of hypertriglyceridemia (see Table 21-5) should be excluded or, if present, the underlying disorder should be treated appropriately. Type V hyperlipoproteinemia also requires a stringent restriction of the fat component of dietary intake; in addition, drug therapy is indicated, as outlined in Table 21-12, if the response to diet alone is inadequate. Medium-chain triglycerides, which are absorbed without chylomicron formation, may be used as a dietary supplement for caloric intake if needed for types I and V. Hepatic fibrosis has been reported with medium-chain triglycerides. Omega-3 fatty acids may be useful in LPL deficiency in some patients. In patients with apolipoprotein C-II deficiency, infusion of plasma may normalize plasma triglyceride levels.

Primary hypercholesterolemia (familial hypercholesterolemia, familial combined hyperlipidemia, and type IIa hyperlipoproteinemia) is treated with the bile acid resins or sequestrants (BAR, colestipol, cholestyramine, and colesevelam), HMG Co-A reductase inhibitors (statins), niacin or eztimibe.[5] Of these choices, statins are first choice because they are the most potent LDL lowering agents. Statins interrupt the conversion of HMG-CoA to mevalonate, the rate-limiting step in de novo cholesterol biosynthesis, by inhibiting HMG-CoA reductase (see Fig. 21-3). Currently available products include lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and pitvastatin.[64] Rosuvastatin is the most potent statin currently on the market. **Table 21-14** lists the pharmacokinetic properties of the statins.[65] The plasma half-lives for all the statins are reported to be short except for atorvastatin and rosuvastatin, and this may account for their potency. In CURVES, the largest head-to-head comparison of statins, atorvastatin was found to be the most potent drug for lowering total cholesterol and LDL-C, with reductions in LDL-C of 38%, 46%, 51%, and 54% for the 10-, 20-, 40-, and 80-mg doses, respectively.[66] Metabolic studies with statins in normal volunteers and patients with hypercholesterolemia suggest reduced synthesis of LDL-C, as well as enhanced catabolism of LDL mediated through LDL receptors, as the principal mechanisms for lipid-lowering effects. Total and LDL cholesterol are reduced in a dose-related fashion by 30% or more on average when added to dietary therapy, with the effects being more pronounced in nonfamilial than in familial hypercholesterolemia.[6] Combination therapy with bile acid sequestrants and lovastatin is rational as LDL receptor numbers are increased, leading to greater degradation of LDL-C; intracellular synthesis of cholesterol is inhibited, and enterohepatic recycling of bile acids is interrupted. Combination therapy with a statin plus eztimibe is also so rational since eztimibe inhibits cholesterol absorption across the gut border and adds 12% to 20% further reduction when combined to a statin or other drugs.[67] However, the combination of a statin and eztimibe has not been shown to affect surrogate endpoints such as carotid intimal medial thickness (CIMT) even with further reduction in LDL cholesterol.[68] Elevation of serum transaminase levels (primarily alanine aminotransferase) to greater than three times the upper limit of normal occurs in approximately 1.3% of patients on moderate to high doses of statins and serious muscle toxicity occurs in less than 0.6% of patients.[69] Meta-analysis of placebo controlled studies with statins demonstrate a low risk of abnormal ALT or CK and a low risk of myopathy without or with rhadomyolysis.[70] Lens opacities have been reported with lovastatin; however, in the age groups studied, these abnormalities are common and tend to wax and wane with time irrespective of drug therapy, and no statistical association is known to exist. As a category of monotherapy, the HMG-CoA reductase inhibitors are the most potent total and LDL cholesterol-lowering agents and among the best tolerated.[69,70] In an analysis of more than 75,000 patients allocated to statins in clinical trials, Alsheikh-Ali et al. found that risk of statin-associated elevated liver enzymes or rhabdomyolysis is not related to the magnitude of LDL-C lowering. A highly significant inverse relationship between achieved LDL-C levels and rates of newly diagnosed cancer was observed (R^2 = 0.43,

p = 0.009).[71] The WHO Foundation Collaborating Centre for International Drug Monitoring has issued a report suggesting that a rare relationship may exist between statin use and the onset of upper motor neuron diseases such as amyotrophic lateral sclerosis but this association remains uncertain.[72] Statin use is associated with a small risk of diabetes (9%).[73] There are numerous pharmacokinetic and pharmacodynamic differences among statins and patients that give rise to variable response to therapy.[74]

TABLE 21-14 Pharmacokinetics of the Statins

Parameter	Lovastatin	Simvastatin	Pravastatin	Fluvastatin	Atorvastatin	Rosuvastatin	Pitavastatin
Isoenzyme	3A4	3A4	None	2C9	3A4	2C9/2C19	UGT1A3/UGT2B7
Lipophilic	Yes	Yes	No	Yes	Yes	No	Yes
Protein binding (%)	>95	95-98	~50	>90	96	88	99
Active metabolites	Yes	Yes	No	No	Yes	Yes	No
Elimination half-life (h)	3	2	1.8	1.2	7-14	13-20	12

Isoenzyme refers to the specific isoenzyme in the cytochrome P450 system which is responsible for the metabolism of each drug. Pharmacokinetic parameters in this table are based on studies and reviews presented in the literature.

The primary action of BAR is to bind bile acids in the intestinal lumen, with a concurrent interruption of enterohepatic circulation of bile acids and a markedly increased excretion of acidic steroids in the feces. This decreases the bile acid pool size and stimulates hepatic synthesis of bile acids from cholesterol. Depletion of the hepatic pool of cholesterol results in an increase in cholesterol biosynthesis and an increase in the number of LDL receptors on the hepatocyte membrane. The increased number of receptors stimulates an enhanced rate of catabolism from plasma and lowers LDL levels. CETP, which is correlated with total and LDL cholesterol concentrations, is also reduced by BAR, perhaps by interfering with hepatic microsomal cholesterol content but this effect is not as great as with statins.[75] Patients with homozygous familial hypercholesterolemia genetically lack the ability to increase synthesis of LDL receptors and bile acid resins are generally ineffective. The increase in hepatic cholesterol biosynthesis may be paralleled by increased hepatic VLDL production and, consequently, bile acid resins may aggravate hypertriglyceridemia in patients with combined hyperlipidemia. Gastrointestinal complaints of constipation, bloating, epigastric fullness, nausea, and flatulence are most commonly reported.[5] With intensive education, patients can learn to tolerate resins on a long-term basis as evidenced by adherence in clinical trials to active drug regimens but in routine clinical practice 40% or more of patients will discontinue therapy within 1 year but with pharmacists interventions, adherence rates can be improved.[76,77] These adverse effects can be managed by increasing the fluid intake, modifying the diet to increase bulk, and using stool softeners. The other major limiting complaint is the gritty texture and bulk; these problems may be minimized by mixing the powder with orange drink or juice. Tablet forms of bile acid sequestrants should help in improving compliance with this form of therapy, whereas the bar does not improve compliance.[78] Other potential adverse effects include impaired absorption of fat-soluble vitamins A, D, E, and K; hypernatremia and hyperchloremia; gastrointestinal obstruction; and reduced bioavailability of acidic drugs such as coumarin anticoagulants, nicotinic acid, thyroxine, acetaminophen, hydrocortisone, hydrochlorothiazide, loperamide, and possibly iron. Hyperchloremic metabolic acidosis, hypernatremia, and gastrointestinal obstruction have been reported almost exclusively in children, and malabsorption of fat-soluble vitamins is probably most common with high doses (eg, 30 g/d of cholestyramine) of the bile acid resins. Drug interactions may be avoided by alternating administration times with an interval of 6 hours or greater between the bile acid resin and other drugs. Colestipol and cholestyramine have comparable side effects; however, colestipol may have better palatability because it is odorless and tasteless. Colesevelam is the newest BAR and total and LDL-C reduction is dose related. The adverse

effects are qualitatively similar to the older BAR but may occur less often. Because of adverse effects occurring commonly with BAR at higher doses, BARs are increasingly used in combination with other drugs, as low doses are tolerated well and they work in a complementary fashion with other agents.

Niacin (nicotinic acid) may also be used in primary hypercholesterolemia in combination with bile acid sequestrants or as monotherapy for this disorder and others (see Table 21-12). Niacin reduces the hepatic synthesis of VLDL, which, in turn, leads to a reduction in the synthesis of LDL. Factors responsible for decreased production of VLDL include inhibition of lipolysis with a decrease in free fatty acids in plasma, decreased hepatic esterification of triglycerides, and a possible direct effect on the hepatic production of apolipoprotein B.[79] The complementary action of niacin and bile acid sequestrants to increase catabolism and decrease synthesis of LDL may account for the additive effects of this combination in hyperlipidemia. Niacin also increases HDL by reducing its catabolism. Niacin selectively decreases hepatic removal of HDL apoA-I but not removal of cholesterol esters, thereby increasing the capacity of retained apoA-I to augment reverse cholesterol transport in isolated hepatic cells. The principal use of niacin is for mixed hyperlipemia or as a second-line agent in combination therapy for hypercholesterolemia. It is also considered to be the first-line agent or an alternative for the treatment of hypertriglyceridemia and diabetic dyslipidemia.[80,81] There are numerous smaller trials suggesting that lower doses of niacin may be combined with statins or gemfibrozil to minimize adverse effects and maximize response. One meta-analysis showed that combination therapy was no more effective than high dose statin therapy.[82] These combinations require careful monitoring because interactions do occur.

Niacin has many adverse drug reactions that occur commonly; fortunately, most of the symptoms and biochemical abnormalities seen do not require discontinuation of therapy. Cutaneous flushing and itching appear to be prostaglandin mediated and can be reduced by aspirin 325 mg given shortly before niacin ingestion.[5,83] Flushing seems to be related to rising plasma concentrations of niacin; taking the dose with meals and slowly titrating the dose upward may minimize these effects. Laropiprant is a selective antagonist of the prostaglandin D[84] receptor subtype 1 (DP1), which may mediate niacin-induced vasodilation. Coadministration of laropiprant 30, 100, and 300 mg with extended-release (ER) niacin significantly lowered flushing symptom scores (by approximately 50% or more) and also significantly reduced malar skin blood flow measured by laser Doppler perfusion imaging.[85,86] Gastrointestinal intolerance and flushing are common problems. Acanthosis nigricans, a darkening of the skin in skinfold areas and an external marker of insulin resistance, may be seen with high doses of niacin. Sustained-release products may minimize these complaints in some patients, but controlled trials with regular-release products do not demonstrate much of a difference between sustained- and regular-release products. The only legend form of niacin, Niaspan® (Abbott), is an extended release form of niacin with pharmacokinetics intermediate between instant and sustained-release products which are sold as food supplements rather than legend products. In controlled trials, Niaspan® is reported to have fewer dermatologic reactions and has a low risk for hepatoxicity. When combined with statins, this combination produces large reductions in LDL and increases in HDL.[87] Potentially important laboratory abnormalities occurring with niacin therapy include elevated liver function tests, hyperuricemia, and hyperglycemia. Recent experience with niacin in diabetes suggests that some diabetic patients do not have worsened glycemic control with dose-titration and sustained-release products.[88] BMI and fasting plasma glucose predict loss of blood glucose control.[89] With less than 3 grams per day, the degree of liver function test elevation is generally not marked and often transient, and a temporary reduction in dosage frequently corrects the problem. Niacin-associated hepatitis is more common with sustained-release preparations, and their use should be restricted to patients intolerant of regular-release products.[88,90] Sustained-release products are often more expensive and given the lack of data for reduced adverse effects and increased incidence of hepatitis, regular-release products should always be used first. Preexisting gout and diabetes may be exacerbated by niacin; these patients should be monitored more closely and their medication titrated appropriately. Patients with well controlled Type 2 diabetes mellitus do not have significant changes in glycemic control with niacin at doses of 2 grams per day or less.[90] Niacin is contraindicated in patients with active liver

disease. Dry eyes and other ophthalmologic complaints are also occasionally noted. Concomitant alcohol and hot drinks may magnify flushing and pruritus with niacin and they should be avoided at the time of ingestion. Nicotinamide should not be used in the treatment of hyperlipidemia, as it does not effectively leads to lower cholesterol or triglyceride levels.

Combined hyperlipoproteinemia (type IIb) may be treated with statins, niacin, or gemfibrozil combinations to lower LDL cholesterol without elevating VLDL and triglycerides. Niacin is the most effective agent and may be combined with a bile acid sequestrant. Bile acid resins alone in this disorder may elevate VLDL and triglycerides, and their use as single agents for treating combined hyperlipoproteinemia should be avoided. Fibric acid (gemfibrozil, fenofibrate) monotherapy is effective in reducing VLDL, but a reciprocal rise in LDL may occur, and total cholesterol values may remain relatively unchanged. Gemfibrozil reduces the synthesis of VLDL and, to a lesser extent, apolipoprotein B, with a concurrent increase in the rate of removal of triglyceride-rich lipoproteins from plasma. Plasma HDL concentrations may rise 10% to 15% or more with fibrates. Fenofibrate may have fewer drug interactions than gemfibrozil but fenofibrate has been reported to worsen renal function.[91] Ezetimibe could also be used in combination therapy in Type IIb. Gastrointestinal complaints with fibric acid derivatives occur in 3% to 5% of patients; rash in 2% of patients; dizziness in 2.4% of patients; and transient elevations in transaminase levels and alkaline phosphatase in 4.5% and 1.3% of patients, respectively.[92] Gemfibrozil and probably fenofibrate may enhance the formation of gallstones associated with an increase in the lithogenic index; however, the rate is low (0.5%-7%) and similar to that seen with placebo in the Helsinki heart study.[92] Fibric acid derivatives may potentiate the effects of oral anticoagulants and international normalized ratio (INR) should be monitored very closely with this combination.

Type III hyperlipoproteinemia may be treated with fibric acid derivatives or niacin. Although fibric acid derivatives have been suggested as the drugs of choice for this disorder, given the lack of data supporting its efficacy in altering cardiovascular mortality in the major studies on hypercholesterolemia, and numerous, well-documented, and serious adverse effects, it is reasonable to consider niacin. Gemfibrozil increases the activity of LPL and reduces to a lesser extent the synthesis or secretion of VLDL from the liver into the plasma. A myositis syndrome of myalgia, weakness, stiffness, malaise, and elevations in creatinine phosphokinase and aspartate aminotransaminase is seen with the fibric acid derivatives, and it seems to be more common in patients with renal insufficiency.[92] Enhanced hypoglycemic effects are reported to occur when fibric acid derivative is given to patients on sulfonylurea compounds, but the mechanisms for these interactions are not well understood.

Three fibric acid derivatives (gemfibrozil and fenofibrate) are approved in the United States. Both reduce LDL-C by 20% to 25% in heterozygous familial hypercholesterolemia. The response of LDL-C, HDL-C, and triglycerides to this category of drug is very dependent on the specific lipoprotein type (eg, type IIa vs IIb) and the baseline triglyceride concentration.[93]

As a potential alternative therapy, for this phenotype, numerous epidemiologic and normal volunteer studies have found that diets high in omega-3 polyunsaturated fatty acids (from fish oil), mostly commonly eicosapentaenoic acid, reduce cholesterol, triglycerides, LDL-C, and VLDL-C, and may elevate HDL-C.[58] The effects of fish oil on lipoprotein metabolism are mediated through a reduction in VLDL production and suppression of VLDL apolipoprotein B. In patients with hypertriglyceridemia, either phenotypes type IIb or type V, a diet high in omega-3 fatty acids given for 4 weeks reduced cholesterol 27% and 45%, and triglyceride 64% and 79%, in the type IIb and type V patients, respectively.[56] A diet high in eicosapentaenoic acid given to hyperlipidemic hemodialysis patients resulted in significant decreases in cholesterol and triglycerides for as long as 13 weeks. Fish oil supplementation may be most useful in patients with hypertriglyceridemia; however, its role in treatment is not well defined. Potential complications of fish oil supplementation, such as thrombocytopenia and bleeding disorders, have been noted, especially with high doses (eicosapentaenoic acid 15 to 30 g/d); and well-controlled trials are needed to determine if fish oils are safe and effective before their use may be broadly recommended. Based on a recent meta-analysis, fish consumption lowers the risk of CHD but nutraceuticals have not been

adequately tested.[56] Recently, a prescription form of concentrated fish oil, Lovaza®, has become available.[58] This product lowers triglycerides by 14% to 30% and raises HDL by about 10% depending on baseline values. Another fish oil derivative product being considered by the FDA, Epanova contains EPA and DHA in their free fatty acid form at a total concentration of 50% to 60% EPA and 15% to 25% DHA along with other potentially active omega-3 fatty acids stored in a patent—protected capsule with a patent—protected coating, designed to maximize bioavailability and tolerability™. There is no convincing evidence that fish supplementation in any form reduces the risk of ASCVD.

Combination drug therapy may be considered after adequate trials of monotherapy and for patients documented compliant to the prescribed regimen. Two or three lipoprotein profiles at 6-week intervals should confirm lack of response prior to initiation of combination therapy. Cholestyramine may be added in patients with fasting hypertriglyceridemia, but it should not be used as the initial drug, because triglycerides are likely to increase. Contraindications to and drug interactions with combined therapy should be carefully screened, as well as consideration of the extra cost of drug product and monitoring that may be required. In general, a statin and a BAR or niacin with a BAR provide the greatest reduction in total and LDL cholesterol. Regimens intended to increase HDL levels should include either gemfibrozil or niacin, and it should be remembered that statins combined with either of these drugs may result in a greater incidence of hepatotoxicity or myositis. This is particularly important for statins that are eliminated via cytochrome 3A4 or through glucuronidation.[65] Familial combined hyperlipidemia may respond better to a fibric acid and a statin than to a fibric acid and a BAR.[94]

Severe forms of hypercholesterolemia—such as familial hypercholesterolemia, familial defective apolipoprotein B-100, severe polygenic hypercholesterolemia, familial combined hyperlipidemia, and familial dysbetalipoproteinemia (type III)—may require more intensive therapy. In particular, familial hypercholesterolemia patients often require combination therapy (two or three drugs) and are managed with surgical therapy (partial ileal bypass), plasmapheresis (LDL-apheresis), and liver transplantation (to replace LDL receptors).

HYPERTRIGLYCERIDEMIA

It is important to remember that lipoprotein pattern types I, III, IV, and V are associated with hypertriglyceridemia, and that these primary lipoprotein disorders and underlying diseases should be excluded prior to implementing therapy (see Table 21-5). In a national survey, approximately one third of participants tested had a triglyceride concentration exceeding 150 mg/dL (1.70 mmol/L).[95] A positive family history of CHD is important in identifying patients at risk for premature atherosclerosis.[20,96] If a patient with CHD has elevated triglycerides, the associated abnormality is probably a contributing factor to CHD and should be treated.[37]

High serum triglycerides (see Tables 21-6 and 21-12) should be treated by achieving desirable body weight, consumption of a low saturated fat and cholesterol diet, regular exercise, smoking cessation, and restriction of alcohol (in selected patients). ATP III identifies the sum of LDL + VLDL (termed *non-HDC* [total cholesterol - HDL]) as a secondary target of therapy in persons with high triglycerides (greater than or equal to 200 mg/dL [greater than or equal to 2.26 mmol/L]).[5,37] This approach is used when triglycerides exceed 200 mg/dL (2.26 mmol/L) and accounts for atherogenic particles carried in VLDL and remnant particles. The goal for non-HDL in persons with high serum triglycerides can be set at 30 mg/dL (0.78 mmol/L) higher than that for LDL on the premise that a VLDL level less than or equal to 30 mg/dL (less than or equal to 0.78 mmol/L) is normal. In patients with borderline-high triglycerides but with accompanying risk factors of established CHD disease, family history of premature CHD, concomitant LDL elevation or low HDL, and genetic forms of hypertriglyceridemia associated with CHD (familial dysbetalipoproteinemia, familial combined hyperlipidemia), drug therapy with niacin should be considered. Niacin may be used cautiously in diabetics based on the results of the ADMIT trial, which found triglycerides were reduced by 23%, HDL-C increased by 29%, only a slight increase in glucose (mean 8.7 mg/dL

[0.5 mmol/L]), and no change in hemoglobin A_{1c}.[97] Elevated BMI and plasma glucose predict loss of glycemic control.[89] Alternative therapies include gemfibrozil or fenofibrate, statins, and fish oil.[20,98,99] Fibrates may increase LDL, and their use in borderline-high triglyceridemia requires careful monitoring to detect this deleterious change in lipid profile. Statins may also be used, because they provide modest reductions in triglycerides and modest elevations in HDL. Higher doses of statins may reduce HDL as well as LDL and triglycerides with amount of reduction related to the baseline concentration and dose.[20,99] The goal of therapy in this situation is to lower triglycerides and VLDL particles that may be atherogenic, increase HDL, and reduce LDL.

Very high triglycerides are associated with pancreatitis and other consequences of the chylomicron syndrome. At this level of elevation of triglycerides, a genetic form of hypertriglyceridemia often coexists with other causes of elevated triglycerides such as diabetes. Dietary fat restriction (10%-20% of calories as fat), weight loss, alcohol restriction, and treatment of the coexisting disorder are the basic elements of management. Drugs useful in hypertriglyceridemia include gemfibrozil or fenofibrate, niacin, and higher potency statins (atorvastatin, rosuvastatin, pitvastatin, and simvastatin). Gemfibrozil or fenofibrate are the preferred drugs in diabetics because of the effect of niacin on glycemic control unless the newer ER forms are used. Fenofibrate may be preferred in combination with statin therapy since it does not impair glucuronidation and minimizes potential drug interactions. Success in treatment is defined as a reduction in triglycerides below 500 mg/dL (5.65 mmol/L).[5]

LOW HDL CHOLESTEROL

Low HDL is a strong independent risk predictor of CHD. ATP III redefined low HDL-C as less than 40 mg/dL (less than 1.03 mmol/L), but specified no goal for HDL-C raising.[5] Low HDL may be a consequence of insulin resistance, physical inactivity, Type 2 diabetes, cigarette smoking, very high carbohydrate intake, and certain drugs (see Table 21-5). In low HDL the primary target remains LDL according to ATP III, but emphasis shifts to weight reduction, increased physical activity, and smoking cessation, and if drug therapy is required, to fibric acid derivatives and niacin. Niacin has the potential for the greatest increase in HDL and the effect is more pronounced with regular or immediate-release forms than with sustained-release forms; however, no randomized clinical trial data have shown a reduction in ASCVD risk by raising HDL.[100]

DIABETIC DYSLIPIDEMIA

Diabetic dyslipidemia is characterized by hypertriglyceridemia, low HDL, and LDL that is minimally elevated. Small, dense LDL (pattern B) in diabetes is more atherogenic than larger, more buoyant forms of LDL (pattern A); routine lipoprotein profiles do not differentiate between pattern A and pattern B.[101,102103] Diabetes in ATP III is a CHD risk equivalent and the primary target is LDL with a goal of treatment being to lower LDL-C less than 100 mg/dL (less than 2.59 mmol/L).[5] When LDL is greater than 130 mg/dL (greater than 3.36 mmol/L), most patients will require simultaneous therapeutic life-style changes and drug therapy. When LDL-C is between 100 and 129 mg/dL (2.59 and 3.34 mmol/L), intensifying glycemic control, adding drugs for the atherogenic dyslipidemia (fibric acid derivatives, niacin) and intensifying LDL-C-lowering therapy are options. Because the primary target is LDL-C in diabetic dyslipidemia, statins are considered by many to be initial drugs of choice.[5,37] The relative risk reduction for CHD in diabetics versus nondiabetics is greater in the West of Scotland, (37% vs 20%)[104] AFCAPS/TexCAPS (43% vs 36%),[105] CARE (25% vs 23%),[106] and 4S (55% vs 32%) trials.[107] All statins are fairly comparable in triglyceride lowering and because statins differ in potency for LDL reduction, a ratio of LDL reduction to triglyceride reduction can be applied. Statin therapy may protect against the development of diabetes.[34] The most recent trial LDL lowering in Type 2 diabetes mellitus is the Collaborative Atorvastatin Diabetes Study (CARDS).[108] This was a randomized, double-blind placebo comparison of atorvastatin 10 mg per day versus placebo in 2838 diabetes to reduce first CHD events. Baseline LDL was 118 mg/dL (3.05 mmol/L) and with atorvastatin LDL fell by

46 mg/dL (1.19 mmol/L). The primary end point, a composite of acute CHD death, nonfatal MI, hospitalized unstable angina, resuscitated cardiac arrest, coronary revascularization or stroke, was reduced by 37%. This study suggests that all diabetics should have a LDL much lower than 100 mg/dL (2.59 mmol/L) and these results are consistent with the Heart Protection Study analysis of diabetic patients.[109]

Fenofibrate, according to the DIAS trial, reduced the angiographic progression of CAD in Type 2 diabetes.[110] Fewer CHD events were seen with fenofibrate compared with placebo but the difference was not significant. Fibric acids principally lower VLDL and triglycerides while increasing HDL with only modest lowering of total and LDL cholesterol; on occasion, fibric acid derivatives may increase LDL levels. Fibric acid derivatives tend to improve glucose tolerance, in contrast to niacin; the greatest effect has been seen with bezafibrate. The Helsinki Heart Study found gemfibrozil to be most effective in diabetic dyslipidemia.[111] Although the effect of statins on triglycerides and HDL abnormalities commonly seen in diabetes is less than with fibric acids, the subgroup analyses cited earlier suggest that they reduce CHD risk significantly. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) the combination of a statin and fenofibrate in patients with Type 2 diabetes did not reduce the rate of fatal cardiovascular events, nonfatal myocardial infarction, or nonfatal stroke compared to simvastatin alone.[112] Cholestyramine in diabetic patients may result in lower LDL levels, but VLDL and triglyceride levels, which are commonly elevated in diabetes, may be further increased in this population. Resins may aggravate constipation, which is common in diabetics. As demonstrated in the ADMIT and ADVENT trials, immediate-release and ER niacin are very effective in raising HDL and lowering triglycerides and LDL.[97,113]

SPECIAL CONSIDERATIONS

Elderly

Hypercholesterolemia is an independent risk factor for CHD in the elderly (greater than 65 years old), as it is in the younger patient. The attributable risk, which is the difference in absolute rates of CHD between segments of the population with higher or lower serum cholesterol levels, increases with age. Older patients potentially benefit to a greater extent from cholesterol lowering than younger populations. Data from studies of elderly men in a variety of settings are consistent with a relative risk of at least 1.5 in the highest compared to the lowest quartile of cholesterol levels and a relative risk reduction of 22% for heart-related mortality.[114,115,116] Treatment of hypercholesterolemia in the elderly may bring about a comparable reduction in absolute risk to that obtained in younger persons.[5] Subgroup analyses of the West of Scotland (primary) and 4S (secondary) intervention studies show that elderly patients have lower CHD risk reduction (relative risk reduction of 27% and 29%, respectively) as compared to younger patients (relative risk reduction of 40% and 39%, respectively).[104,117] The Framingham study suggests that elderly women are at higher risk because of high blood cholesterol levels, but no other large studies included women; and their risks or benefits from cholesterol reduction are not well defined. Primary prevention in younger patients requires about 2 years before reduction in CHD risk is apparent, and this lag time should be taken into consideration in patient selection for therapy. Non-lipid CHD risk factors do not decline in relative risk with aging, and aggressive management of the modifiable non-lipid risk factors is important in the older patient. High-risk elderly patients are less likely to be prescribed statins and their potent benefits are not realized.[118] Because most women with CHD are elderly and also at risk for osteoporosis, they are logical candidates for diet therapy with consideration of calcium intake consistent with osteoporosis prevention, exercise, and perhaps estrogen replacement therapy. Recent evidence suggests that statins may reduce the risk of osteoporosis; however, there are conflicting data from various studies.[119]

Drug therapy in principle differs little from younger patients, and older patients respond to lipid-lowering drugs as well as younger patients.[120,121] Based on the Heart Protection Study with more elderly patients than any other trial, simvastatin 40 mg per day produced the CHD event rate reduction in patients over 70 years of age as in

younger patients.[122] The gain in life expectancy may be small depending on the age at the start of treatment and the magnitude of cholesterol reduction. Changes in body composition, renal function, and other physiologic changes of aging may make older patients more susceptible to adverse effects of lipid-lowering drug therapy. In particular, older patients are more likely to have constipation (bile acid resins), skin and eye changes (niacin), gout (niacin), gallstones (fibric acid derivatives), and bone/joint disorders (fibric acid derivatives, statins). Therapy should be started with lower doses and titrated up slowly to minimize adverse effects.

Women

Cholesterol is an important determinant of CHD in women, but the relationship is not as strong as that seen in men. HDL may be a more important predictor of disease in women.[8] LDL and HDL genetic regulation in women and men does not appear to be different. Based on the Nurses' Health Study, obesity is an important determinant of CHD in women, with the relative risk being 3.3 in the highest Quetelet index (weight in kilograms divided by the square of the height in meters) as compared to the lowest category (ie, less than 21 vs greater than or equal to 29); low HDL levels usually accompany obesity.[123] No major differences exist in the influence of exercise, alcohol ingestion, and smoking on lipid levels between men and women. Women in the highest tertile of cholesterol appear to be more responsive to dietary therapy than those in the lower tertiles, and more responsive than formulas based on men predict.

Based on the HERS[124] and WHI trials,[125,126,126,127] published national guidelines recommended similar types of lifestyle and risk factor goals and interventions as recommended by NCEP for the entire population.[8] Hormone therapy may continue to have a role for postmenopausal symptoms; however, a notable exception is hormone replacement therapy and heart protection. Combined estrogen plus progestin hormone therapy should not be initiated to prevent CVD in postmenopausal women. Combined estrogen plus progestin hormone therapy should not be continued to prevent CVD in postmenopausal women. Other forms of menopausal hormone therapy (eg, unopposed estrogen) should not be initiated or continued to prevent CVD in postmenopausal women pending the results of ongoing trials. Results of the WISDOM trial confirm lack of benefit as seen in HERS and WHI.[128] In a recent, post-hoc analysis of the WHI, women who initiated hormone therapy closer to menopause tended to have reduced CHD risk compared with the increase in CHD risk among women more distant from menopause, but this trend did not meet statistical signifance.[125] Based on the Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) trial, women experience the same benefit of LDL cholesterol lowering as men with rosuvastatin.[129]

Cholesterol and triglyceride levels rise progressively throughout pregnancy, with an average increment in cholesterol of 30 to 40 mg/dL (0.78-1.03 mmol/L) occurring around the 36th to 39th weeks. Triglyceride levels may go up by as much as 150 mg/dL (1.70 mmol/L). Drug therapy is not instituted nor is it usually continued during pregnancy. If the patient is very high risk, a bile acid resin may considered since there is no systemic drug exposure.[5] Statins are category X and are contraindicated. Ezetimibe might be an alternative since it is a Category C drug (animal studies have shown that the drug exerts teratogenic or embryocidal effects, and there are no adequate, well-controlled studies in pregnant women, or no studies are available in either animals or pregnant women) but no data are available in humans. Dietary therapy is the mainstay of treatment, with emphasis on maintaining a nutritionally balanced diet as per the needs of pregnancy.

Children

Drug therapy in children is not recommended until the age of 8 years or older, and the guidelines for institution of therapy and the goals of therapy are different from those in adults (see Table 21-9).[130] Younger children are generally managed with therapeutic life-style changes until after the age of 2 years.[5,51] Although bile acid sequestrants have been recommended in the past as first line therapy, there is now evidence that statins are safe

and effective in children and provide greater lipid lowering than BAR.[131,132,133,134] Severe forms of hypercholesterolemia (eg, familial hypercholesterolemia) may require more aggressive treatment.

Concurrent Disease States

Nephrotic syndrome, end-stage renal disease and nephrotic syndrome, and hypertension compound the risk of dyslipidemia and may present difficult-to-treat lipid abnormalities. Abnormalities of lipoprotein metabolism in the nephrotic syndrome include elevated total and LDL cholesterol, Lp(a), VLDL, and triglycerides. The apolipoprotein C-III to C-II ratio is elevated, consistent with greater LPL inhibitor activity, and the extent of hypoalbuminemia is correlated with dyslipidemia. The basic abnormality appears to be one of overproduction of LDL-apoB from VLDL, rather than reduced clearance of LDL-C and related proteins. Protein restriction and a "vegan" diet corrects lipid abnormalities to some extent. Statins have been shown to be effective in reducing elevated total and LDL cholesterol in the nephrotic syndrome, although the levels do not usually return to normal.[135] Fibric acid derivatives and statins reduce small, dense LDL-C by different mechanisms, suggesting a potential role for combination therapy to optimize lowering of small, dense LDL-C and remnant lipoproteins. Statins appear to be safe and effective for lowering LDL cholesterol in renal insufficiency but they may not affect CHD endpoints.[136,137]

Renal insufficiency without proteinuria leads to hypertriglyceridemia, slightly elevated total and LDL cholesterol (particularly with chronic ambulatory peritoneal dialysis), and low HDL levels (especially during hemodialysis). These abnormalities are thought to be caused by a deficiency in apolipoprotein C-II, perhaps as a result of sustained use of heparin during hemodialysis and depletion of LPL, carbohydrate-induced obesity and hypertriglyceridemia, loss of carnitine during hemodialysis, use of acetate buffer (acetate is a precursor to fatty acid synthesis) during hemodialysis, and decreased LCAT activity during hemodialysis. Dialysis does not correct the lipid abnormalities. Renal transplantation may correct lipid abnormalities in some patients; however, in others, the use of transplantation-related medications, such as corticosteroids, cyclosporine, and certain antihypertensive agents, may aggravate the lipid abnormalities. Cyclosporine interferes with the metabolism of statins metabolized by cytochrome P450 3A4 (see Table 21-14), and patients need to be observed closely for myositis and worsening renal function. Of interest, correction of lipid abnormalities may improve renal hemodynamics. Pravastatin and fluvastatin may be safer than other statins, but this needs to be validated in larger, long-term trials. Diet will modify lipoprotein levels and polyunsaturated fatty acids may have a role in impeding the progression of renal disease as well as the cardiovascular complications. Bile acid sequestrants do not correct the lipid abnormalities seen in renal insufficiency. Lovastatin or its active metabolite may accumulate in renal insufficiency, and lower doses of reductase inhibitors should be used to avoid adverse effects. Gemfibrozil may be used with caution as its pharmacokinetics are unchanged and it lowers triglycerides and increases HDL.[138] Statins (simvastatin, lovastatin, and atorvastatin) and fibric acid derivatives may increase the risk of severe myopathy, and attention to symptoms of myositis is needed. Niacin may also be useful in nondiabetic patients with renal insufficiency.

Hypertensive patients have a greater-than-expected prevalence of high blood-cholesterol levels and, conversely, patients with hypercholesterolemia have a higher than expected prevalence of hypertension caused by the metabolic syndrome. Recommendations for the management of hypertension in patients with hypercholesterolemia include avoiding the use of drugs that elevate cholesterol such as diuretics and β-blockers and using agents that are either lipid-neutral or that may reduce cholesterol slightly.[5] Bile acid sequestrants may bind to thiazide diuretics and some β-blockers, and may interfere with their absorption; reaction may be avoided by giving the antihypertensive 1 hour before or 4 hours after the resin. Niacin may magnify the hypotensive effects of vasodilators.

PHARMACOECONOMIC CONSIDERATIONS

The clinical benefits of lipid-lowering therapy for primary and secondary intervention are now well established

based on the results of studies showing a reduction in CHD morbidity and mortality.[139,140,141] The balance of benefits and costs has been examined in a few studies. The cost per year of life saved has been estimated to range from less than $10,000 to over $1 million dollars depending on the presence or absence of CHD, age of the patient, baseline total or LDL-C level and reduction in cholesterol, and number of risk factors present. In general, intervention in patients with known CHD, those who have CHD risk equivalents or those with a 10-year risk of 10% to 20% are cost-effective with statin therapy, while other types of therapy may be cost-effective if certain assumptions concerning compliance, efficacy, and so forth, are met. The range for secondary intervention based on the 4S study is $3,800 for a 70-year-old man with a high cholesterol level to $27,400 per year of life gained for a middle-aged woman with an average cholesterol level.[142] In contrast, primary prevention in men based on the West of Scotland trial averages about $35,000 per year of life gained.[143] These studies demonstrate that primary and secondary interventions are well within the accepted boundary of less than $50,000 for a medical intervention to be considered cost-effective. Based on the specific lipoprotein phenotype, fibric acid derivatives, niacin, or combination therapy of statins plus BAR may be cost-effective. Cost-effectiveness is maximized by treating high-risk patients and those with established CHD.

Specialty lipid clinics have become increasingly popular and many use pharmacists to provide direct patient care in this setting. An interesting recent analysis shows that a specialty clinic may be more expensive ($659 ± $43 vs $477 ± $42 per patient, $P < 0.001$) than usual care. However, the overall cost-effectiveness is improved when expressed as program costs per unit (mmol/L) reduction in the LDL-C, a measure of cost-effectiveness that was significantly lower for specialized care ($758 ± $58 vs $1,058 ± $70, $P = 0.002$) because more patients achieve their targeted goal.[144] Project ImPACT demonstrated that pharmacists, working collaborative with patients and physicians, can improve persistence and compliance and that nearly two thirds of patients achieved their NCEP lipid goal.[145] Other programs show similar trends.[77,146,147]

OTHER THERAPIES

Partial ileal bypass has been used in severe heterozygous and homozygous familial hypercholesterolemia; however, it is ineffective in the latter case. Ileal bypass removes the site of bile acid reabsorption, depleting the bile acid pool and increasing the catabolism of cholesterol. A randomized trial of diet versus surgery, program on the surgical control of the hyperlipidemias (POSCH), reported that total and LDL cholesterol were decreased (23.3% and 37.7%, respectively) and HDL increased (4.3%) in patients who had undergone ileal bypass for hypercholesterolemia.[148] Overall death was delayed by nearly 3 years ($P = 0.032$) and CHD mortality was delayed by nearly 4 years ($P = 0.046$) by surgery, as compared to the control group. Revascularization procedures were delayed by an average of 7 years ($P < 0.001$). Post-surgery diarrhea was more common in the surgical group, as was the rate of kidney stones (4% vs 0.4%), gallstones (10% vs 2%), and bowel obstruction (13.5% vs 3.6%).

Portacaval shunts have been used to decrease the formation of LDL-C and reductions of 10% to 20% have been reported. Plasma exchange combined with niacin was found to reduce plasma cholesterol levels by about 50% in homozygous familial hypercholesterolemia over 5 years, and coronary atherosclerosis did not progress as documented by angiography. LDL-apheresis, selective removal of LDL-C via a filtering system, plus statin therapy is effective in LDL-C and appears to affect the progression of vascular disease. LDL-apheresis may be combined with statin therapy for greater effect. Combined liver and heart transplantation in homozygous familial hypercholesterolemia reduces total and LDL cholesterol concentrations from about 1,100 and 900 mg/dL (28.45 and 23.27 mmol/L) to about 300 and 185 mg/dL (7.76 and 4.78 mmol/L), prior to and after surgery, respectively. Liver transplantation replaced the missing LDL receptors, enhanced catabolism, and reduced lipoprotein synthesis in this patient.

SUMMARY OF MAJOR STUDIES

9 Primary and secondary prevention diet and drug trials have been performed to determine whether lowering of cholesterol will prevent CHD; **Tables 21-15** and 21-16 summarize these trials. A number of earlier angiographic studies demonstrated that cholesterol reduction leads to regression of atherosclerosis and plaque stabilization. Most of the primary and secondary studies were double blinded, randomized, and placebo controlled, lasting for 5 years or longer, and most had sufficient patient numbers to be meaningful. Exceptions to these qualifications were seen in the early studies such as the Newcastle and Edinburgh trials, which were small and generally did not show much benefit; and the Coronary Drug Project (CDP) using dextrothyroxine, which was terminated early due to adverse effects on CHD mortality. The Helsinki heart study, using gemfibrozil, resulted in a reduction in nonfatal MI, which was the primary contributor to reduced CHD incidence (see Table 21-15).[19]

TABLE 21-15 Primary Prevention Trials with Lipid Lowering Drugs

Trial	F/U (yr)	*N*	Treatment	Control Events (%)	Treatment Events (%)	*p* Value	RRR	ARR (%)	NNT

Total and LDL cholesterol were reduced to an average of 13.4% and 20.3%, respectively, by cholestyramine in the LRC-CPPT, and the reduction of lipid levels was related to the amount of drug ingested (eg, 1 to 2 packets, 5.4%

reduction in total cholesterol, versus 5 or more packets, 19.0% reduction).[149] The prescribed dose of cholestyramine was 24 g, or 6 packets, per day. The cholestyramine group experienced a 19% reduction in risk ($P < 0.05$) of the primary end point—definite CHD death and/or definite nonfatal MI—reflecting a 24% reduction in definite CHD death and a 19% reduction in nonfatal MI. Other end points were reduced by 25%, 20%, and 21% for new positive exercise tests, angina, and coronary bypass surgery, respectively. Death from all causes was not significantly reduced by cholestyramine secondary to more accidents and violence in this group. The mean falls in total and LDL cholesterol in the cholestyramine group were 8% and 12% relative to levels in placebo-treated men, providing evidence that for every 1% reduction in cholesterol, a 2% decline in CHD mortality can be realized.

AFCAPS/TexCAPS, a primary prevention trial conducted in 6,605 men and women aged 57 to 63 years with average total cholesterol and LDL (less than 221 mg/dL and less than 150 mg/dL [less than 5.72 and less than 3.88 mmol/L], respectively) who were treated with lovastatin 20 to 40 mg/d for 5.2 years, a 37% reduction ($P < 0.001$) was shown in the risk for first acute major coronary event (fatal or nonfatal MI, unstable angina, or sudden cardiac death).[105] The need for revascularization procedures was also reduced by 33% ($P < 0.001$). The implications of this trial are enormous; potentially millions of "normal" people could benefit from lipid-lowering with statins based on these results. The number of patients that need to be treated (NNT, see Table 21-15) for primary prevention ranges from 43 in the West of Scotland trial to 71 in the Helsinki Heart Study. This range is within the typical boundary used for treatment decisions and described previously; cost-effectiveness is achieved routinely in patients with moderate to high risk. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) tested pravastatin 40 mg per day versus placebo in hypertensive patients with at least one CHD risk factor. Pravastatin did not reduce either all-cause mortality or CHD significantly when compared with usual care in older participants with well-controlled hypertension and moderately elevated LDL-C. The results may be due to the modest differential in total cholesterol (9.6%) and LDL-C (16.7%) between pravastatin and usual care compared with prior statin trials supporting cardiovascular disease prevention.[150] The Women's Health Initiative trial proved to be disappointing with no beneficial effects on CHD event reduction in the hormone replacement arm (conjugated equine estrogens [CEE] + medroxgprogesterone) or the CEE alone arm compared to placebo.[124,126] Women did experience greater risk for thromboembolism and a slight increase in breast cancer and a reduced risk of hip fracture. Consequently, hormone replacement therapy can no longer be recommended for cardiovascular protection.[8] Publication of the recent WISDOM trial found that when combined hormone therapy ($n = 2196$) was compared with placebo ($n = 2189$), there was a significant increase in the number of major cardiovascular events (7 vs 0, $P = 0.016$) and venous thromboembolism (22 vs 3, hazard ratio 7.36 [95% CI 2.20-24.60]) confirming the findings of HERS and WHI. There were no statistically significant differences in numbers of breast or other cancers cerebrovascular events, fractures, and overall death.[128]

Niacin in the CDP significantly reduced definite, nonfatal MI as compared to placebo (10.1% vs 13.9%), whereas clofibrate did not reduce death from any cause or nonfatal or fatal MI at the 5-year followup period.[151]

One of the most important studies published in the last few years is the 4S trial, a secondary intervention trial in a large number of patients.[152] Simvastatin, 20 to 40 mg/d, reduced LDL cholesterol by 35% and reduced the risk of death from any cause by 30%. Coronary deaths were also reduced with simvastatin (relative risk, 0.58; confidence interval, 0.46-0.73). Therapy was also shown to be effective in women (18%-19% of patients enrolled) and in the elderly (greater than or equal to 60 years). Indeed, the relative risk of death or major coronary event was reduced to a greater extent in the elderly than in younger patients. Death from noncardiovascular causes was similar for simvastatin and placebo (2.1% and 2.2%, respectively). The survival curves for simvastatin and placebo began to separate at 1 year and became more divergent with additional follow-up. The 4S study clearly demonstrates the benefit in cholesterol lowering and placates long-held fears of death from non-CHD causes. The long-term intervention with pravastatin in ischemic disease (LIPID) study ($N = 7,498$ men and 1,516 women) has investigated the effect of pravastatin on CHD mortality in patients with prior MI or unstable angina and mean cholesterol level of 219 mg/dL (5.66 mmol/L) over 6 years.[153] Pravastatin reduced the risk of CHD mortality by 24% (8.3% vs 6.4%,

P = 0.0004) and total mortality by 23% (14.1% vs 11.0%, *P* = 0.00002); stroke was also reduced by 20% (4.3% vs 3.5%, *P* = 0.22) as well as reduction in the need for coronary artery bypass graft (11.3% vs 8.9%, *P* = 0.0001) or percutaneous transluminal coronary angioplasty (5.3% vs 4.4%, *P* = 0.04).

The Veterans Administration High-Density Lipoprotein intervention trial [154] was a double-blind trial that compared gemfibrozil (1,200 mg/day) with placebo in 2,531 men with CHD, an HDL cholesterol level of less than or equal to 40 mg/dL (less than or equal to 1.03 mmol/L), and an LDL cholesterol level of less than or equal to 140 mg/dL (less than or equal to 3.62 mmol/L).[155] The primary study outcome was nonfatal MI or death from coronary causes. The median follow-up was 5.1 years. At 1 year, the mean HDL cholesterol level was 6% higher, the mean triglyceride level was 31% lower, and the mean total cholesterol level was 4% lower in the gemfibrozil group than in the placebo group. LDL cholesterol levels did not differ significantly between the groups. A primary event occurred in 21.7% of the patients assigned to placebo and in 17.3% of the patients assigned to gemfibrozil. The overall reduction in the risk of an event was 4.4 percentage points, and the reduction in relative risk was 22% (*P* = 0.006). This trial presents the strongest evidence to date that raising HDL-C and lowering triglycerides reduces risk for CHD.

The Atorvastatin Versus Revascularization Treatments[156] study compared atorvastatin 80 mg/day with percutaneous transluminal coronary angioplasty.[157] The follow-up period was 18 months. Of the patients who received aggressive lipid-lowering treatment with atorvastatin, 13% had ischemic events, as compared to 21% of the patients who underwent angioplasty. The incidence of ischemic events was thus 36% lower in the atorvastatin group over an 18-month period (*P* = 0.048, which was not statistically significant after adjustment for interim analyses). This reduction in events was because of a smaller number of angioplasty procedures, coronary-artery bypass operations, and hospitalizations for worsening angina (the most common end point). As compared to the patients who were treated with angioplasty and usual care, the patients who received atorvastatin had a significantly longer time to the first ischemic event (*P* = 0.03). In low-risk patients with stable CAD, aggressive lipid-lowering therapy is at least as effective as angioplasty and usual care in reducing the incidence of ischemic events.

Pravastatin in the elderly individuals at risk for vascular disease[158] studied men and women in the age range of 70 to 82 years and found that pravastatin 40 mg per day reduced CHD events by 24% with no effect on cognitive function.[158] A more recent trial, TIMI-22 (also known as PROVE-IT, Pravastatin or Atorvastatin Evaluation and Infection Therapy) enrolled 4162 patients who had been hospitalized for an acute coronary syndrome within the preceding 10 days and compared 40 mg of pravastatin daily (standard therapy) with 80 mg of atorvastatin daily (intensive therapy).[159] An intensive lipid lowering statin regimen with atorvastatin 80 mg per day provided greater protection against death or major cardiovascular events than does a standard regimen. This study clearly points to 'lower is better' for LDL concentration and will likely lead to revision in guideline goals to lower LDL levels. The Treatment to New Targets (TNT) assessed the efficacy and safety of lowering LDL cholesterol levels below 100 mg per deciliter (2.6 mmol per liter) in patients with stable CHD.[160,161] Intensive lipid-lowering therapy with 80 mg of atorvastatin per day in patients with stable CHD provides significant clinical benefit beyond that afforded by treatment with 10 mg of atorvastatin per day providing further evidence that intensive lipid lowering brings greater benefits.

Statins reduce the incidence of strokes among patients at increased risk for cardiovascular disease; whether they reduce the risk of stroke after a recent stroke or transient ischemic attack (TIA) was addressed by Stroke Prevention by Aggressive Reduction in Cholesterol Levels[162]. During a median follow-up of 4.9 years, 265 patients (11.2 percent) receiving atorvastatin 80 mg/day and 311 patients (13.1 percent) receiving placebo had a fatal or nonfatal stroke (5-year absolute reduction in risk, 2.2%; adjusted hazard ratio, 0.84; 95% confidence interval, 0.71-0.99; *P* = 0.03; unadjusted *P* = 0.05).[163] JUPITER randomized healthy patients to rosuvastatin on placebo the basis of elevated CRP found a 55% reduction in vascular events (event rate 1.11 vs 0.51 per 100 person-years;

hazard ratio 0.45, $p < 0.0001$).[28]

Recent clinical trials attempting to increase HDL-C have been disappointing and one was stopped early due to futility.[164] Neither the AIM-HIGH or HPS2-THRIVE trial demonstrated a reduction in cardiovascular endpoints.[17] Both trials included background therapy with statins ± ezetimibe and the changes in HDL-C was somewhat smaller than expected. Some have suggested that extensive prior treatment may have depleted the lipid core making plaque less susceptible to rupture leading to clinical events.

Clinical Controversy…

The CETP inhibitor torcetrapib was associated with a substantial increase in HDL cholesterol and decrease in LDL cholesterol. It was also associated with an increase in blood pressure, and there was no significant decrease in the progression of coronary atherosclerosis. The lack of efficacy may be related to the mechanism of action of this drug class or to molecule-specific adverse effects. Other means of raising HDL cholesterol (HDL mimetics, which include ApoA1 mutants and peptide mimetics of ApoA1 and HDL Milano A, a synthetic form of HDL) still hold hope of HDL modification leading a reduction in clinical events.

The enzyme acyl-coenzyme A: cholesterol acyltransferase[165] esterifies cholesterol in a variety of tissues. In some animal models, ACAT inhibitors have antiatherosclerotic effects. Unfortunately, when tested in clinical trials, ACAT inhibition is not an effective strategy for limiting atherosclerosis and may promote atherogenesis.[165]

With the failure of AIM-HIGH and HPS2-THRIVE, the HDL hypothesis, raising HDL-C lowers cardiovascular risk, may called into question. Others argue that trial design limited the outcome in these studies and a true test of the HDL-C hypothesis remains to be completed.

Statins differ in their pharmacokinetic properties and in pleotropic effects (ie, non-lipid lowering). The contribution of lipid lowering alone (a class effect) versus other effects (anti-inflammatory, antithombotic, etc.) continues to create controversy.

Proteinuria has been associated with high dose rosuvastatin therapy (40 mg/day) but a review of a clinical trial database revealed that an increase in eGFR for rosuvastatin-treated patients was consistent across all major demographic and clinical subgroups of interest, including patients with baseline proteinuria, baseline eGFR less than 60 mL/min/1.73 m^2 (less than 0.58 mL/s/m^2), and in patients with hypertension and/or diabetes.[166]

Mipomersen is an oligonucleotide inhibitor of apolipprotein B-100 synthesis indicated as an adjunct to lipid lowering medications and diet to reduce LDL-cholesterol, apolipoprotein B, total cholesterol and non-high density lipoprotein cholesterol in patients with homozygous familial hypercholesterolemia. The average reduction in LDL-cholesterol is ~25% with the most common adverse events being injection site pain (~10%).[167] Lomitapide oral capsule is a microsomal triglyceride transfer protein (MTP) inhibitor. Inhibiting MTP reduces the level of cholesterol that the liver and intestines assemble and secrete into the circulation.[168] The average decrease in LDL-cholesterol beyond baseline is ~40%. Hepatic steatosis associated with lomitapide may be a risk factor for progressive liver disease including steatohepatitis and cirrhosis. Gastrointestinal complaints and mild to moderate elevations in liver enzymes have been reported with both drugs.

A new category of LDL lowering therapy was approved by the Food and Drug Administration in 2015. Currently, there are two agents in this category including alirocumab and evolcumab. Their mechanism of action is to inhibit proprotein convertase subtilisin/kexin type 9 (PCKS9). PCSK9 promotes intracellular degradation of hepatic LDL, prevents LDL recycling to the cell surface, and reduces LDL clearance from the circulation. Therefore, inhibiting PCSK9 will lower LDL concentrations significantly. Alirocumab and evolocumb are given by subcutaneous injection. Alirocumb is given every 2 weeks at either 75 or 150 mg dose per injection. Evolocumab is given every 140 mg every 2 weeks or 420 mg every month as 3 × 140 mg subcutaneous injections. The typical LDL reduction ranges

from about 40% to over 60% with both drugs. The most common adverse effect reported in clinical trials is injection site pain.

Cholesterol ester transport inhibitors (CETP) are currently being studied but early trials with torcetrapib were disappointing with increased CV events that were attributed to increases in blood pressure. Other analogs (eg, anacetrapib and evacetrapib) are continuing under development. Both reduce LDL by approximately 40% to 50% and raise HDL by 80% to 130%. Randomized trials with hard CVD outcomes are needed before large-scale use is possible.

The role of non-traditional risk factors (hsCRP, homocysteine, etc.) is continuing to be clarified and may lead to recommendations for the use of these tests in patient evaluation.

EVALUATION OF THERAPEUTIC OUTCOMES

Short-term evaluation of therapy for hyperlipidemia is based on response to diet and drug treatment as measured in the clinical laboratory by total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides for patients being treated for primary intervention, as well as on response to secondary intervention. The interval for follow-up is dependent on the severity of illness, and patients with known CAD or multiple risk factors should be monitored more closely. Less commonly used laboratory measurements include CRP, homocysteine, apolipoprotein B, and Lp(a) levels. Because many patients being treated for primary hyperlipidemia have no symptoms and may not have any clinical manifestations of a genetic lipid disorder such as xanthomas or eruptions, monitoring and outcome are solely laboratory based. In patients treated for secondary intervention, symptoms of atherosclerotic cardiovascular disease, such as angina or intermittent claudication, may improve over months to years. If patients have xanthomas or other external manifestations of hyperlipidemia, these lesions should regress with therapy. Lipid measurements should be obtained in the fasted state to minimize interference from chylomicrons, and once the patient is stable, monitoring is needed at intervals of 6 months to 1 year.

Patients with multiple risk factors and established CHD should also be monitored and evaluated for progress in managing their other risk factors such as hypertension, smoking cessation, exercise and weight control, and glycemic control if diabetic. The goals are to maintain a blood pressure of below 140/80 mm Hg or less (presence of diabetes or renal insufficiency), stop smoking, maintain an ideal body weight, exercise for at least 20 minutes three or more times per week, and keep plasma glucose below 100 mg/dL (5.6 mmol/L) (threshold for glucose intolerance). Invasive evaluation, such as cardiac catheterization, is useful in patients with established CHD and is typically used for planning revascularization rather than monitoring of lipid-lowering therapy.

Evaluation of dietary therapy is part of the outcome evaluation for treating hyperlipidemia and the assistance of a dietitian is recommended. Use of diet diaries and recall survey instruments enable information about diet to be collected in a systematic fashion and may improve patient adherence to dietary recommendations. Patients on resin therapy should have a FLP panel checked every 4 to 8 weeks until a stable dose; triglycerides should be checked at stable dose to insure they have not increased. Niacin requires baseline liver function tests, uric acid and glucose; repeat tests are appropriate at doses of 1,000 to 1,500 mg per day. Symptoms myopathy or diabetes-like symptoms should be investigated and may require CK or glucose determinations; more frequent monitoring in diabetics may be necessary. A FLP 4 to 8 weeks after the initial dose or dose changes with statins is appropriate. Liver function tests should be obtained at baseline and periodically thereafter based on package insert information; recognized experts believe that monitoring for hepatotoxicity and myopathy should be symptom-triggered.[63,70] Ezetimibe requires little specific monitoring however, with the publication of the SEAS trial, there is concern over the increased risk of cancer.[169] More recent meta-analyses have not noted a relationship nor were any signal see in the IMPROVE-IT trial. IMPROVE-IT also demonstrated a small reduction in overall cardiovascular events (32.7 vs 34.7%, p = 0.016, relative risk reduction of 6.4%.[173]

Chapter e22: Peripheral Arterial Disease

FIGURE e22-1

Sheryl L. Chow; Barbara J. Hoeben

INTRODUCTION

KEY CONCEPTS

- 1 The prevalence of peripheral arterial disease (PAD) is dependent on age and the presence of traditional risk factors for cardiovascular disease (CVD) and many patients are undiagnosed; undiagnosed patients have substantial risk for coronary and cerebrovascular events.
- 2 The clinical presentation of PAD is variable and includes a range of symptoms. The two most common characteristics of PAD are intermittent claudication (IC) and pain at rest in the lower extremities.
- 3 The ankle-brachial index (ABI) is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific tool in the diagnosis of PAD.
- 4 As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of peripheral vascular disease. Many of these risk factors are modifiable with the help of various nonpharmacologic and pharmacologic interventions.
- 5 Nonpharmacologic interventions such as smoking cessation and walking exercise programs have the ability to positively impact several of the pathophysiologic abnormalities present in patients with PAD.[1]
- 6 Data proving that antiplatelet therapies can prevent or delay the progression of PAD are currently unavailable. However, aspirin therapy has repeatedly been proven to significantly reduce serious vascular events in these “high-risk” patients and, in the absence of contraindications, is highly recommended.

- 7 After appropriate exercise therapy and therapeutic lifestyle changes (TLC) have been implemented, patients who continue to experience severe IC may benefit from additional pharmacologic therapy with cilostazol.

Peripheral arterial disease (PAD), the most common form of peripheral vascular disease, is a manifestation of progressive narrowing of arteries due to atherosclerosis.[1] PAD is associated with elevated risk of cardiovascular disease (CVD) morbidity and mortality, even in the absence of history of acute myocardial infarction (AMI), stroke, or other manifestations of CVD.[2] Patients with PAD have approximately the same relative risk of death from CVD as do patients with a history of coronary or cerebrovascular disease, and PAD should be considered a surrogate marker of subclinical coronary artery disease (CAD) and other vascular territories. The treatment of PAD focuses on decreasing the functional impairment caused by symptoms of intermittent claudication (IC) through nonpharmacologic and pharmacologic therapy and by minimizing the impact of other cardiovascular risk factors.[3]

EPIDEMIOLOGY

1 PAD affects approximately 8.5 million with an estimated prevalence of 2.76% of adults aged 40 years and older in the United States.[1] The prevalence of PAD is highly dependent on age, being infrequent in younger individuals and common in older individuals (**Fig. e22-1**). In age- and gender-adjusted logistic regression analyses, black race/ethnicity (odds ratio [OR] 2.83), current smoking (OR 4.46), diabetes (OR 2.71), hypertension (HTN; OR 1.75), hypercholesterolemia (OR 1.68), and impaired renal function (estimated glomerular filtration rate less than 60 mL/min/1.73 m^2) (OR 2) were associated with more prevalent PAD.[4] Individuals with PAD are also more likely to have a self-reported history of any CAD or CVD but, interestingly, no association with elevated body mass index. The reported relative risk of death from CVD in patients with PAD is reported to range from 2 to 5.1 in patients with or without CVD and 2.9 to 5.7 in patients with known CVD.[5] CVD accounts for 75% of all deaths in patients with PAD.[6] The risk of death is approximately the same in men and women and is elevated even in asymptomatic patients. Annual mortality is 25% in patients with critical leg ischemia who have the lowest ankle-brachial index (ABI).[7]

FIGURE e22-1

Prevalence of peripheral arterial disease by age and gender.

More than ~8.5 million adults aged 40 years have PAD. Ninety-five percent of individuals with PAD have at least one cardiovascular risk factor; the majority of patients have multiple risk factors for CVD.[4] Based on the PAD Awareness, Risk, and Treatment: New Resources for Survival (PARTNERS) program, the prevalence of PAD in primary care practices is high, yet physician awareness of the PAD diagnosis is relatively low.[8] In this cross-sectional study, PAD was detected in 29% of 6,979 patients. Eighty-three percent of the patients were aware of their diagnosis, but only 49% of their patients' physicians were aware. The reason for this observation is that patient self-report of symptoms and the use of questionnaires to detect PAD are not sufficiently sensitive and specific to reproducibly diagnose PAD and the cardinal symptom of PAD-IC is present in the minority of patients (1%-27%, typically ~10%).[1,3,5] A simple ABI measurement will identify a large number of patients with previously unrecognized PAD. Atherosclerosis risk factors were very prevalent in PAD patients, but these patients received less intensive treatment for lipid disorders and HTN, and were prescribed antiplatelet therapy less frequently than were patients with CVD. These results demonstrate that underdiagnosis of PAD in primary care practice may be a barrier to effective secondary prevention of the high ischemic cardiovascular risk associated with PAD.[8] Because of the systemic nature of atherosclerosis and the high risk of ischemic events, patients with PAD should be considered for secondary prevention strategies including aggressive risk factor modification and antiplatelet drug therapy.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

PAD is most commonly a manifestation of systemic atherosclerosis in which the arterial lumen of the lower extremities becomes progressively occluded by atherosclerotic plaque.[3,6] The major risk factors for the development of atherosclerosis are older age (greater than 40 years), cigarette smoking, diabetes mellitus, hypercholesterolemia, HTN, and hyperhomocysteinemia.[3,4,9] The arteries most

commonly involved, in order of occurrence, are the femoropopliteal-tibial, aortoiliac, carotid and vertebral, splenic and renal, and brachiocephalic.[9] Familial hypercholesterolemia (FH) leading to hypercholesterolemia and elevated low-density lipoprotein (LDL) levels are associated with accelerated development of atherosclerosis earlier and with more severe symptoms (eg, IC) and abnormal blood flow studies compared with controls.[9,10] Intima–media thickness can be used as a surrogate phenotype for cardiovascular risk in FH. Carotid and/or femoral artery atherosclerosis results in increased intima–media thickness and it is correlated to cardiovascular risk in FH patients compared with normolipidemic individuals.

CLINICAL PRESENTATION AND DIAGNOSIS

2 The clinical presentation of PAD is variable, ranging from no symptoms at all (typically early in the disease) to pain and discomfort (**Table e22-1**). This finding was illustrated in a study by Wang et al.[11] who attempted to aid the diagnosis of PAD by using defined categories of exertional leg pain in patients with and without PAD. They determined that none of the five categories of leg pain (no pain, pain on exertion and rest, noncalf pain, atypical calf pain, and classic claudication) was sufficiently sensitive or specific to enable a link to a PAD diagnosis. The two most common characteristics of PAD are IC and pain at rest in the lower extremities.[11,12] IC is generally regarded as the primary indicator of PAD. It is described as reproducible fatigue, discomfort, cramping, pain, or numbness in the affected extremities (typically the buttock, thigh, or calf) during exercise and is resolved within a few minutes with rest.[3] Symptoms of IC occur during exercise as the increase in blood flow is limited by occlusive atherosclerotic lesions in the peripheral arteries leading to an inability for oxygen supply to meet the demands of increased metabolic demand by the muscles.[13] Resting pain typically occurs later in the disease when the blood supply is not adequate to perfuse the extremity (critical limb ischemia). This most often can be felt at night in the feet (typically the toes or heel) while the patient is lying in bed. Although IC is the primary indicator of PAD, it alone cannot be used to diagnose PAD. Unfortunately only ~10% of patients present with classical IC.[3] As explained by the Inter-Society Consensus for the Management of Peripheral Arterial Disease (TransAtlantic Inter-Society Consensus [TASC] II),[13] patients with PAD may not have symptoms of IC because they may have a sedentary lifestyle or some other condition that may be limiting the ability to exercise. The Fontaine and Rutherford classification systems[14] have been used to categorize clinical symptoms with associated functional limitations (**Table e22-2**).

TABLE e22-1 Clinical Presentation

General

- Patients with PAD are likely to be 40 years of age and older with HTN, hypercholesterolemia, diabetes, impaired renal function, a history of CAD or CVD, and/or a history of smoking.

Signs and symptoms

- The clinical presentation of PAD is variable and includes symptoms ranging from no symptoms at all (typically early in the disease) to pain and discomfort.

- The two most common characteristics of PAD are IC and pain at rest in the lower extremities.
- IC is generally regarded as the primary indicator in PAD. It has been described as fatigue, discomfort, cramping, pain, or numbness in the affected extremities (typically the buttock, thigh, or calf) during exercise and resolves within a few minutes with rest.
- Physical examination may reveal nonspecific signs of decreased blood flow to the extremities (eg, cool skin temperature, thickened toenails, lack of hair on the calf, feet, and/or toes).

Laboratory tests

- None specific to PAD.

Other diagnostic tests

- The ABI is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific (≥90%) tool in the diagnosis of PAD.

ABI, ankle-brachial index; CAD, coronary artery disease; CVD, cardiovascular disease; HTN, hypertension; IC, intermittent claudication; PAD; peripheral arterial disease.

Data from references 6, 9.

TABLE e22-2 Fontaine and Rutherford Classification of Clinical Symptoms

Fontaine Classification			Rutherford Classification		
Stage	**Symptoms**	**Proposed Universal Criteria**	**Grade**	**Category**	**Symptoms**
I	Asymptomatic	Asymptomatic	0	0	Asymptomatic
II	IC/other exertional limb symptoms	Mild claudication/limb symptoms (no limitation in walking)	0	1	Mild claudication
IIa		Moderate claudication/limb symptoms (able to walk without stopping >2 blocks or 200 m or 4 min)	1	2	Moderate claudication
IIb		Severe claudication/limb symptoms (only able to walk without stopping <2 blocks or 2000 m or 4 min)	1	3	Severe claudication
III	Ischemic rest pain	Ischemic rest pain (pain in the distal limb at rest felt to be due to limited arterial perfusion)	II	4	Ischemic rest pain
IV	Ulceration or gangrene	Ischemic ulcers on distal leg	III	5	Ischemic ulceration
		Ischemic gangrene	III	6	Ischemic gangrene

IC, intermittent claudication.

Adapted from reference 14.

A detailed patient history of symptoms and associated atherosclerosis risk factors (eg, smoking, HTN, hyperlipidemia, and diabetes) is also an important component of PAD assessment. However, as illustrated by the PARTNERS program, providers who rely on a history alone will miss approximately 85% to 90% of patients with PAD.[8] Therefore, examination of the patient is vital to proper diagnosis. Requesting the patient to remove socks and shoes may reveal nonspecific signs of decreased blood flow to the extremities (eg, cool skin temperature, shiny skin, thickened toenails, lack of hair on the calf, feet, and/or toes) or, in severe cases, visible sores or ulcers that are slow to heal and may even be black in appearance.[15]

An important criterion for the accurate diagnosis of PAD is the exclusion of other conditions that possess similar signs and symptoms. Differential diagnosis should rule out other neurologic conditions (eg, peripheral neuropathy), inflammatory conditions (eg, arthritis), and vascular conditions (eg, deep venous thrombosis or venous congestion) that may mimic PAD.

3 The ABI is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific (≥90%) tool in the diagnosis of PAD.[3,16] For measurement of the ABI, the patient lies in the supine position as the systolic blood pressure is measured at the brachial arteries on both arms and the dorsalis pedis and posterior tibial arteries of the legs with a standard sphygmomanometer and a continuous-wave Doppler device. The pressures obtained at the dorsalis pedis and posterior tibial arteries are averaged and divided by the mean measurement taken at the left and right brachial arteries. An ABI of 1 to 1.40 is considered normal while a measurement under 0.9 is consistent with PAD. ABI from 0.7 to 0.9 correlates with mild PAD, 0.4 to 0.7 indicates moderate disease, and under 0.4 denotes severe PAD.[3] An ABI of more than 1.40 is consistent with noncompressible arteries. In addition to providing diagnostic information, the ABI measurement has been shown to be a strong predictor of future cardiovascular events associated with PAD.[17] The ABI can also be useful after a test of exercise tolerance (eg, 5 minutes on a treadmill or 30-50 repetitions of heel raises). Patients with PAD will demonstrate a significant drop in the ABI after exercise, but their pain remain normal or unchanged, unless IC is present. ABI can rule out PAD and suggest alternate diagnoses and can be considered a useful tool in diagnosing both symptomatic and nonsymptomatic patients at high risk of PAD.[8,18]

Other noninvasive tools are available for the diagnosis of PAD.[3,14] One study has suggested a calculation that takes into consideration the patient's history of AMI and the number of auscultated and palpated posterior tibial arteries.[19,20] A duplex ultrasound combines standard Doppler imaging using ultrasound with speed and direction of arterial flow. This noninvasive technique is frequently used to determine the degree of stenosis as well as peak systolic velocity index. However, its accuracy is less reliable when PAD is present in lower extremity popliteal and tibial arteries given the smaller diameter, increased depth, and frequent calcifications of these vessels. Magnetic resonance angiography (MRA) can be used to examine the presence and location of significant stenosis, or lack thereof, and is a reasonable option in patients who are being considered for surgical

revascularization. Similarly, computed tomographic angiography (CTA) can be used to determine the presence of significant stenosis and soft-tissue diagnostic information that may be associated with PAD (eg, aneurysms). However, as ABI is a sufficient means of diagnosis, arteriography is not necessary or encouraged.

TREATMENT

Goals of Treatment

PAD is the result of atherosclerotic plaque formation in the arteries that results in decreased blood flow to the legs. Several of the treatment goals for these patients involve the reduction of confounding variables that attribute to the disease process, progress, and eventual outcome. Specific goals should include increasing maximal walking distance, duration, and pain-free walking, improving control of comorbid conditions contributing to the morbidity of the condition (eg, HTN, hyperlipidemia, and diabetes), improvement in overall quality of life, and reduction in cardiovascular complications and death.

General Approach to Treatment

4 As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of PAD. Many of these risk factors are modifiable with the help of various nonpharmacologic and pharmacologic interventions.

Nonpharmacologic Therapy

Smoking Cessation

5 Not only does cigarette smoking increase the risk of developing PAD and other cardiovascular disorders, but the duration and quantity smoked can negatively impact disease progression (eg, increase the risk of amputation) and increase mortality.[4,21,22] As a result, providers must advise patients to quit and should offer nonpharmacologic and pharmacologic means to aid the patient in that goal. Individual or group behavior modification therapy with or without the addition of certain antidepressants (eg, bupropion), varenicline, or nicotine replacement therapy (eg, gum or patches) has been proven effective in numerous studies. Varenicline has demonstrated superior quit rates compared with nicotine replacement therapy and bupropion.[3] Other forms of tobacco use should be discouraged as well. Reassessment of smoking status and progress encouragement at each encounter can help to reemphasize to the patient the vital importance of this lifestyle change.

Exercise

5 Walking exercise programs for patients with PAD have been proven to result in an increase in walking duration and distance, an increase in pain-free walking, and a delayed onset of claudication by 179%.[3,23] Walking, or any aerobic exercise program conducted under the supervision of a

healthcare provider, has the ability to positively impact several of the pathophysiologic abnormalities present in patients with PAD. Benefits of exercise programs include improving diabetes and lipid management, reducing weight, improving blood viscosity and flow, and reducing blood pressure.[24] Walking distance can also be used as a prognostic tool for future outcomes in patients with normal and impaired ABIs. A study conducted by de Liefde et al.[25] examined patients with normal ABI (≥0.90) and impaired ABI (less than 0.90) in relation to walking distance. It was demonstrated that walking impairment in conjunction with impaired ABI was associated with higher cardiovascular events, including death. Other studies have likewise observed a link between impaired exercise/walking distance and negative long-term outcomes in patients with PAD.[26,27]

The American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for the Management of PAD recommend supervised exercise training for patients with IC, for a minimum of 30 to 45 minutes, to be performed at least three times per week for a minimum of 12 weeks.[3] During exercise sessions, walking should be performed at a speed and grade of incline to produce the symptoms of IC within 3 to 5 minutes. The patient should stop walking when the symptoms become moderate in intensity, wait for the symptoms to resolve, and then resume walking, thus repeating the cycle for the duration of the session.[13] A prospective, observational study performed by Gardner et al.[28] concluded that PAD patients with higher physical activity (as measured with a vertical accelerometer) have reduced mortality and cardiovascular events compared with those with low physical activity, regardless of confounders. Exercise treadmill walking testing should be repeated at regular intervals (eg, quarterly to biannually) to assess improvement or decline in walking duration and distance, as well as time to assess pain onset while performing this activity. The type of aerobic activity recommended, as well as the duration and frequency of the activity, should be individually designed on a patient-to-patient basis.

Interventional Procedures

Various procedures are available for patients with severe, debilitating claudication who have attempted, and failed, other means of nonpharmacologic and pharmacologic therapy. The TASC document on PAD provides clear recommendations for invasive therapy.[13] First, there must be a lack of adequate response to exercise therapy and risk factor modification. Second, the patient must have severe disability from IC resulting in impairment of daily activities. Third, there must be a thorough evaluation of the risks versus benefits of intervention including probability of success, the anticipated future course of the disease if an intervention is not performed, and an evaluation of concomitant disease states.[29]

The decision to attempt percutaneous revascularization is often made with the guidance of diagnostic angiography. Percutaneous transluminal angioplasty (PTA) is an example of a minimally invasive procedure for PAD. PTA typically is reserved for patients whose lifestyle and/or job performance are compromised secondary to claudication despite adequate pharmacologic interventions and exercise.[3,23] A randomized controlled clinical trial performed by Whyman et al.[30] determined that in a 2-year post inter vention, PTA outcomes on maximum walking distance and ABI were not significantly different than in patients who had only received daily low-dose aspirin

(acetylsalicylic acid [ASA]).

For patients with severe IC resulting in critical leg ischemia, more invasive surgical interventions such as aortofemoral bypass or femoral popliteal bypass may be an equivalent if not better option than PTA. A large prospective study evaluating open vascular surgery versus endovascular procedures using PTA found no significant difference in amputation-free survival and overall survival between groups. However, bypass surgery–first approach improved survival by 7.3 months (95% confidence interval [CI]: 1.2-13.4 months; *P* 0.02) in those patients who survived at least 2 years after randomization.[3]

Pharmacologic Therapy

Hypertension

HTN is a major risk factor for PAD and can lead to AMI, stroke, heart failure (HF), and death.[31] Current guidelines recommend the treatment goal for blood pressure in patients with PAD to mirror those in patients with documented CVD. PAD patients with HTN should achieve a target goal of less than 140/90 mm Hg in nondiabetics or less than 130/80 mm Hg in diabetics to reduce risk factors for PAD. β-Blockers are effective and safe for treatment of HTN in patients with PAD. The safety of β-blockers with PAD was evaluated in a meta-analysis of six randomized controlled trials[32] suggesting no evidence of harm in patients with PAD. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are also reasonable antihypertensive agents for patients with symptomatic or asymptomatic PAD. The Heart Outcomes Prevention Evaluation (HOPE)[33] study demonstrated that ACE inhibitors reduced not only blood pressure but also other cardiovascular events (eg, AMI, stroke, and death) in high-risk patients, including those with PAD. Further selection of drug therapy for HTN should be made in accordance with comorbid disease states, drug costs and availability, drug allergies, or other possible limiting factors.[34] For example, patients with concomitant Raynaud phenomenon may benefit from calcium channel blockers while patients with documented CAD may receive a dual benefit by the selection of a β-blocker.[34] Dosing, monitoring guidelines, and contraindications for specific agents used in the treatment of HTN may be found in Chapter 13.

Hyperlipidemia

Although it has been shown that a reduction in lipid levels can reduce the progression of PAD and the severity of claudication, the current recommendations for the management of hyperlipidemia in PAD are based on only a few small studies and sub-hoc analyses from larger trials.[3,9] The 2013 ACC/AHA cholesterol guideline[9] classifies PAD as a coronary heart disease (CHD) risk equivalent and at highest risk for recurrent atherosclerotic cardiovascular disease (ASCVD) and ASCVD death. Therefore high-intensity statin therapy is recommended over moderate intensity for secondary prevention of events in patients younger than or aged 75 years with PAD. Atovastatin 80 mg and rosuvastatin 20 mg daily have been shown to reduce ASCVD events and are recommended in PAD patients. However, patients older than 75 years and the risk of adverse effects and tolerability are also important factors when weighing risk versus benefit of therapy. Specific recommendations can be

found in Chapter 21.

Diabetes Mellitus

A meta-analysis of over 95,000 diabetic patients provided additional support for the accepted premise that glycemic control serves as a risk factor for CVD.[35] The analysis demonstrated an increasing risk of death from cardiovascular events as blood glucose concentrations increased, with the same relationship observed even at levels below the threshold of clinically defined diabetes mellitus. This relationship is just one illustration of the criticality of good glycemic control. Due to the high prevalence of PAD among diabetic patients, the American Diabetes Association recommends ABI screening for PAD in all diabetics older than 50 years.[36] Due to the presence of peripheral neuropathy, patients with diabetes may be less likely to experience or report symptoms of PAD and the first sign may be as drastic as the appearance of a gangrenous foot ulcer. Therefore, although there is currently a lack of randomized controlled studies illustrating that the degree of glycemic control is predictive of the extent of PAD present, it is widely recommended that all patients with concomitant diabetes and PAD maintain good glycemic control, and a target hemoglobin A-1c level of less than 7% (less than 0.07; less than 53 mmol/mol hemoglobin [Hb]).[3,36] This recommendation is supported by a prospective cohort study of 1,894 diabetic patients, which demonstrated that patients with poor glucose control (A-1c greater than 7.5% [greater than 0.075; greater than 58 mmol/mol Hb]) were five times more likely to develop IC and also to be hospitalized for PAD compared with those with a Hb A-1c less than 6% (less than 0.06; less than 42 mmol/mol Hb).[37] Despite this, a study of 365 patients with known PAD and concomitant diabetes done by Rehring et al.[38] showed that only 45.8% of these patients had a Hb A-1c les than 7% (less than 0.07; less than 53 mmol/mol Hb). Oral antidiabetic agents, insulin regimens, as well as other pharmacologic and nonpharmacologic strategies to reduce the risk of complications associated with diabetes mellitus are discussed at length in Chapter 74.

Antiplatelet Drug Therapy

See **Table e22-3**.

TABLE e22-3 Pharmacotherapy Options for Patients with Peripheral Arterial Disease

Agent	Daily Dose (Oral)	Mechanism of Action (MOA)	Side Effects	Contraindications	Level of Evidence[a]
Aspirin	81-325 mg	Irreversibly inhibits prostaglandin cyclooxygenase in platelets, prevents formation of thromboxane A_2	GI upset and/or bleeding	Active bleeding; hemophilia; thrombocytopenia	With coronary or cerebrovascular (Grade 1A), without (Grade 1C+)
Dipyridamole ER	400 mg (+	May act by inhibiting platelet	Angina; dyspnea; hypotension;	Active bleeding; CAD ("coronary	Recommendation for use not

Agent	Daily Dose (Oral)	Mechanism of Action (MOA)	Side Effects	Contraindications	Level of Evidence[a]
(Aggrenox)	aspirin 50 mg)	aggregation (complete MOA unknown)	headache; dizziness	steal syndrome")	specified in report
Cilostazol (Pletal)[b]	100 mg twice daily	Phosphodiesterase inhibitor, suppresses platelet aggregation; direct artery vasodilator	Fever: infection; tachycardia	All CHF patients (decreased survival)	With IC (Grade 2A)
Clopidogrel (Plavix)	75 mg	Inhibits binding of ADP analogues to its platelet receptor causing irreversible inhibition of platelets	Chest pain; purpura generalized pain; rash	Active pathologic bleeding (eg, peptic ulcer, intracranial hemorrhage)	Recommend clopidogrel over no antiplatelet therapy (Grade 1C+)
Pentoxifylline (Trental)	1.2 g	Alters RBC flexibility; decreases platelet adhesion; reduces blood viscosity; decreases fibrinogen concentration	Dyspnea; nausea; vomiting; headache; dizziness	Recent retinal or cerebral hemorrhage; active bleeding	Not recommended in patients with IC (Grade 1B)
Ticlopidine (Ticlid)	500 mg	Inhibits binding of ADP analogues to its platelet receptor causing irreversible inhibition of platelets	Leukopenia; rash; thrombocytopenia; neutropenia; agranulocytosis; aplastic anemia	Active bleeding; hemophilia; thrombocytopenia	Clopidogrel recommended over ticlopidine (Grade 1C+)

ADP, adenosine 5′-diphosphate; CAD, coronary artery disease; CHF, congestive heart failure; ER, extended release; GI, gastrointestinal; IC, intermittent claudication; MOA, mechanism of action; RBC, red blood cell.

[a]Grades of recommendation for antithrombotic and thrombolytic therapy are part of the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy.[73]

[b]Cilostazol should be used in combination with antiplatelet therapy.

Data from references 15, 23, 36, 42, 48.

Aspirin

6 By far, the most compelling evidence for the use of any pharmacologic agent in PAD can be found for ASA. The Antithrombotic Trialists' Collaboration (ATC)[39] conducted a meta-analysis of 195 randomized trials, composed of over 135,000 patients at high risk for occlusive arterial disease, and concluded that low-dose ASA (75-160 mg) and medium-dose ASA (160-325 mg/day) lead to a significant reduction in serious vascular events (12%) in "high-risk" patients, such as those with PAD. The ATC also noted in this analysis that the risk of major extracranial bleed was similar between the low-dose and medium-dose regimens.

Tran and Anand[40] conducted a systematic review of the literature in an effort to summarize the best evidence for oral antiplatelet therapy in patients with cerebrovascular disease, CAD, and PAD. This review included 111 trials (42 of which included patients with PAD, *n* = 9,214) and concluded that patients with PAD should use ASA (160-325 mg/day) or clopidogrel (75 mg/day) when ASA is not tolerated or contraindicated. This is in concordance with the recommendations of the Ninth American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy that recommends lifelong ASA (75-325 mg/day) over clopidogrel and ticlopidine, and no antithrombotic therapy in patients with PAD.[41,42] Unfortunately, no data are currently available from large, clinical, randomized trials that ASA, or any other antiplatelet therapies, can actually prevent or delay the onset of PAD.

Aspirin + Dipyridamole Extended Release (Aggrenox)

The ATC also examined the use of aspirin-dipyridamole extended release (Aggrenox) in combination with ASA in "high-risk" patients, such as those with PAD. The meta-analysis of 25 trials (which included greater than 10,000 patients) concluded that the addition of dipyridamole to ASA led to an additional reduction in serious vascular events over ASA alone (6%); however, this reduction was unable to reach statistical significance (*P* = 0.32).[39,40] It should also be taken into consideration that most of the reduction in nonfatal stroke in this analysis came from one trial, and these data are not replicated in the other studies. The addition of dipyridamole to ASA may cause an increased risk of bleeding and gastrointestinal (GI) side effects when compared with placebo and should not be used with CAD.[43]

Clopidogrel (Plavix)

Clopidogrel, a P2Y12 adenosine diphosphate (ADP)-receptor antagonists can be used an alternate to ASA. The ATC meta-analysis also reviewed the effectiveness of clopidogrel (Plavix) 75 mg/day in "high-risk" patients, including those with PAD. The ATC concluded that although clopidogrel was able to reduce serious vascular events by 10%, this was significantly less than the reduction seen with ASA (12%, *P* = 0.03) described previously.[39] Included in this meta-analysis was the report from the Clopidogrel versus ASA in Patients at Risk of Ischemic Events (CAPRIE) trial[44] that had concluded that clopidogrel (75 mg daily) was more effective than ASA (325 mg daily) in preventing vascular events in "high-risk" patients. In comparison to the ASA therapy, the clopidogrel regimen resulted in an overall reduction in ischemic stroke, myocardial infarction (MI), or vascular death from 5.83% to 5.32% (*P* = 0.043). This difference was even more pronounced in the subgroup analysis of PAD patients, in which

clopidogrel therapy led to a significant reduction of 4.86% versus 3.71% in the ASA group (P = 0.0028). Although a generic clopidogrel product is now available, it remains significantly more expensive than ASA therapy and may be less accessible by prescription than ASA, an over-the-counter (OTC) product. For this reason and established safety and efficacy with ASA in the PAD population, clopidogrel is recommended only when ASA therapy is not tolerated or contraindicated.[39]

Ticlopidine (Ticlid)

Although ticlopidine causes ADP inhibition and has the same mechanism of action as clopidogrel, results of clinical trials among the two agents are strikingly different. The Swedish Ticlopidine Multicenter Study (STIMS)[45] demonstrated that ticlopidine therapy (500 mg/day) was able to reduce total mortality in comparison to placebo in patients with IC (P = 0.015). However, the once promising results seen with ticlopidine therapy have now been overshadowed by the severe hematologic side effects unique to this agent. Ticlopidine is not currently available in the United States and has a "boxed" warning from the Food and Drug Administration (FDA) warning providers that use of this agent can cause neutropenia/agranulocytosis, thrombotic thrombocytopenic purpura, and aplastic anemia. Other agents, namely, clopidogrel, are now used recommended over ticlopidine.[3]

Intermittent Claudication

See Table e22-3.

Cilostazol (Pletal)

Cilostazol works through cyclic nucleotide phosphodiesterase (PDE3) to degrade cyclic adenosine monophosphate (cAMP) which may benefit PAD patients with IC through vasodilation and antiplatelet effects. In a head-to-head, randomized, placebo-controlled study in 698 patients with moderate-to-severe claudication, Dawson et al.[46] assigned patients to cilostazol (100 mg twice a day), pentoxifylline (400 mg three times a day), or placebo in an effort to improve maximal walking distance. After 24 weeks, the cilostazol group demonstrated a 54% mean increase in distance compared to a 30% mean increase with pentoxifylline (P less than 0.001) which was similar to placebo. Similarly, a meta-analysis of eight randomized, double-blind, placebo-controlled, parallel-design trials supported this conclusion with a reported increase in maximal walking distance and pain-free walking distance with cilostazol at doses of 50 and 100 mg twice daily (P less than 0.05 for all) over placebo. Furthermore, cilostazol received a "boxed" warning from the FDA cautioning use with coexisting HF of any severity due to risk of ventricular tachyarrhythmias and reduced survival from phosphodiesterase III inhibition.[47] However, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does suggest a potential use of this agent in refractory patients with PAD without HF who are not candidates for surgical interventions.[39]

Pentoxifylline (Trental)

Unlike cilostazol, pentoxifylline is a xanthine derivative and improves peripheral blood flow and tissue oxygenation through its vasoactive effects. However, data have been less promising than cilostazol in clinical trials. In a randomized study,[46] cilostazol outperformed pentoxifylline in improvement in walking distance; any improvement with pentoxifylline was not found to be different from placebo (P = 0.82). Likewise, other meta-analyses have shown minimal improvements with pentoxifylline over placebo.[48] For these reasons, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does not recommend the use of this agent for PAD.

EVALUATION OF THERAPEUTIC OUTCOMES

It is vital that the patient be counseled on the evaluation measures that will be used to monitor the outcomes of therapeutic interventions for PAD. Various laboratory measurements will assess patient progress in glycemic control (eg, Hb A-1c) and lipid management (eg, total cholesterol, LDL, high-density lipoprotein [HDL], and non-HDL cholesterol), while blood pressure checks in the clinic and patient home blood pressure monitoring can assess the effectiveness of antihypertensive therapy. Exercise treadmill walking testing should be repeated at regular intervals (eg, quarterly to biannually) to assess improvement or decline in walking duration and distance, as well as the time to pain onset while performing this activity. Repeat ABI measurements should be assessed at each patient visit to determine if there has been stabilization or progression of the disease process. Most importantly, collecting patient feedback about changes in daily quality of life will provide an overall impression of the patient's general state of health.

Chapter 23: Use of Vasopressors and Inotropes in the Pharmacotherapy of Shock

Robert Maclaren; Scott W. Mueller; Joseph F. Dasta

INTRODUCTION

KEY CONCEPTS

- 1 Continuous hemodynamic monitoring with an arterial catheter and/or a central venous catheter should be used early and throughout the course of septic shock to assess mean arterial pressure (MAP), intravascular fluid status and arterial and venous oxygenation and monitor response to therapies. They can be used for monitoring the response to drug therapy and guiding dosage titration.

- 2 Lactate production is increased under anaerobic conditions. Mixed venous oxygen saturation (Svo_2) or central venous oxygen saturation ($Scvo_2$) are indicative of tissue perfusion. Elevated serum lactate concentrations or low Svo_2/$Scvo_2$ represent global perfusion abnormalities. Lactate clearance or Svo_2/$Scvo_2$ may be used to assess repayment of oxygen to the tissues. Gastrointestinal tonometry and sublingual capnometry represent methods of assessing regional perfusion but are used infrequently.

- 3 Early goal-directed therapy with aggressive fluid resuscitation within the first 6 hours of presentation improves survival of patients with sepsis and septic shock.

- 4 Goals of therapy with vasopressors and inotropes in septic shock should be predetermined and should optimize global and regional perfusion parameters (eg, cardiac, renal, mesenteric, and periphery) to normalize cellular metabolism. This can be accomplished by continuous or intermittent measurements. Targeted goals should be central venous pressure (CVP) of 8 to 12 mm Hg (up to 15 mm Hg in mechanically ventilated patients, patients with preexisting left ventricular dysfunction, or patients with abdominal distension), MAP more than or equal to 65 mm Hg, urine production more than or equal to 0.5, mL/kg/h, and either lactate clearance of more than or equal to 20% or Svo_2 more than or equal to 65% or $Scvo_2$ more than or equal to 70%.

- 5 Derangements in adrenergic receptor sensitivity or activity frequently result in resistance to catecholamine vasopressor and inotropic therapy in critically ill patients. These changes may be a function of endogenous catecholamine concentrations, dosage/duration of exposure to and type of exogenously administered vasopressors, stage of septic shock, preexisting illness, and other factors.

- 6 In refractory septic shock, rational use of vasopressor or inotropic agents should be guided by receptor activity, pharmacologic and pharmacokinetic characteristics, and regional and systemic hemodynamic effects of the drug and should be tailored to the patient's physiologic needs. Pharmacologically sound combinations of vasopressor and/or inotrope agents should be initiated early to optimize and facilitate rapid response.

- 7 Dose titration and monitoring of vasopressor and inotropic therapy should be guided by the "best clinical response" while observing for and minimizing evidence of myocardial ischemia (eg, tachydysrhythmias, electrocardiographic changes, troponin elevation), renal (decreased glomerular filtration rate and/or urine production), splanchnic/gastric (low intramucosal pH, bowel ischemia), or peripheral (cold extremities) hypoperfusion, and worsening of partial pressure of arterial oxygen (PaO_2), pulmonary artery occlusive pressure, and other hemodynamic variables.

- 8 Much higher dosages of all vasopressors and inotropes than traditionally recommended are required to improve hemodynamic and oxygen-transport variables in patients with septic shock. Arbitrarily targeting vasopressor and inotrope therapy to supranormal values of global oxygen-transport variables cannot be recommended because of the lack of clear benefit and possible increased morbidity.

- 9 First-line therapy of septic shock is aggressive volume resuscitation with crystalloid or colloid types of fluids. Norepinephrine is the preferred initial vasopressor agent for hemodynamic support. Norepinephrine achieves greater hemodynamic response than dopamine and is less likely to cause tachydysrhythmias and a decrease in splanchnic oxygen utilization. Dopamine is also limited by its inability to adequately increase CO and complications of increased pulmonary artery occlusive pressure and decreased splanchnic oxygen use. Low-dose dopamine should not be used to prevent renal failure.

- 10 Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmia associated with the use of other agents. Its effects on cardiac performance and splanchnic oxygen utilization are variable.

- 11 Epinephrine is an effective initial agent and as an add-on agent. It is particularly useful in the young, in patients with otherwise healthy myocardium, and potentially in patients when used early in the course of treatment. However, because epinephrine causes a significant increase in lactate and worsening of splanchnic oxygen utilization, it is not the agent of first choice in patients with septic shock and is reserved as adjunctive therapy when other vasopressors do not adequately increase MAP. It should be used cautiously in patients with a

history of coronary artery disease or underlying cardiac disturbances.

- 12 Dobutamine may be used as adjunctive therapy for its inotropic effect. It enhances CO and may increase global perfusion. Concurrent vasopressor therapy is needed because dobutamine causes vasodilation. Dobutamine therapy may be limited by tachycardia and dysrhythmias.

- 13 Therapy with vasopressors and inotropes is continued until the myocardial depression and vascular hyporesponsiveness of septic shock improve, usually measured in hours to days. Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be "weaned" to avoid a precipitous worsening in regional and systemic hemodynamics.

- 14 Vasopressin produces vasoconstriction independent of adrenergic receptors and reduces the dosages of catecholamine vasopressors. Physiologic replacement dosages of vasopressin (0.01-0.04 units/min) can be considered in patients with septic shock refractory to catecholamine vasopressors despite adequate fluid resuscitation. Dosage rates should not be titrated upward. Vasopressin may enhance urine production but it may worsen splanchnic and peripheral perfusion. Given the current data, corticosteroids can be administered to patients with septic shock refractory to vasopressors or when adrenal insufficiency is suspected. Side effects of short-term corticosteroids are minimal.

Shock is an acute, generalized state of inadequate perfusion of critical organs that can produce serious pathophysiologic consequences, including death, when therapy is not optimal. Shock is defined as systolic blood pressure less than 90 mm Hg or reduction of at least 40 mm Hg from baseline with perfusion abnormalities despite adequate fluid resuscitation.[1] Previously, mortality from septic or cardiogenic shock exceeded 70% but now ranges between 20% and 40%.[1,2,3,4,5] This chapter reviews the theory and current status of hemodynamic monitoring and presents an update on the optimal use of inotropes and vasopressor drugs in shock states, specifically septic shock.[1,2,4,5,6,7,8,9]

The general goal of therapy during resuscitation from shock is to achieve and maintain mean arterial pressure (MAP) consistently above 65 mm Hg while ensuring adequate perfusion to the critical organs.[1,2,4,5,6,7,8,9] Hemodynamic and perfusion monitoring can be categorized into two broad areas: global versus regional monitoring. Global parameters, such as systemic blood pressure, oxygen tension, and lactate, assess perfusion and oxygen utilization of the entire body. Regional monitoring techniques focus on tissue-specific oxygen delivery and subsequent changes in functional indices of individual organs.[1,2,4,5,6,7,8,9,10,11,12,13,14,15,16] These measurements include coagulation abnormalities (disseminated intravascular coagulation), altered renal and/or hepatic function, altered gastrointestinal perfusion, cool extremities, cardiac ischemia, and altered sensorium. Although none of these indices alone is a reliable indicator of adequate resuscitation, they offer immediate detection and may be prognostic of recovery when combined and defined at the level of organ function. As a result, these indices are frequently used as surrogate end points for the goals of resuscitation.[1,2,4,5,6,7,8,9,10,11,12,13,14,15,16] While it is assumed that normalization of these parameters infers benefit, the clinician must first treat the patient clinically rather than relying solely on data from continuous monitoring to guide therapy.[1,2,4,5,6,7,8,9,10,11,12,13,14,15,16]

Patients in shock generally have several modes of monitoring so therapies are based on all gathered information and correlated with the patient's dynamic clinical response. Normal values for commonly monitored parameters are listed in **Table 23-1**. Evidence-based goals of therapy are listed in **Table 23-2**.[2,4,5,6,7,8,9,10,11,12,13,14,15,16]

TABLE 23-1 Hemodynamic and Oxygen-Transport Monitoring Parameters

Parameter	Normal Value[a]
Blood pressure (systolic/diastolic)	100-130/70-85 mm Hg
Mean arterial pressure (MAP)	80-100 mm Hg
Pulmonary artery pressure (PAP)	25/10 mm Hg
Mean pulmonary artery pressure (MPAP)	12-15 mm Hg
Central venous pressure (CVP)	8-12 mm Hg
Pulmonary artery occlusion pressure (PAOP)	12-15 mm Hg
Heart rate (HR)	60-80 beats/min
Cardiac output (CO)	4-7 L/min
Cardiac index (CI)	2.8-3.6 L/min/m^2
Stroke volume index (SVI)	30-50 mL/m^2
Systemic vascular resistance index (SVRI)	1,300-2,100 dyne • s/m^2 • cm^5
Pulmonary vascular resistance index (PVRI)	45-225 dyne • s/m^2 • cm^5
Arterial oxygen saturation (Sao_2)	97% (range, 95%-100%)
Mixed venous oxygen saturation (Svo_2)	70%-75%
Arterial oxygen content (Cao_2)	20.1 vol% (range, 19-21)
Venous oxygen content (Cvo_2)	15.5 vol% (range, 11.5-16.5)
Oxygen content difference (C[a-v]O_2)	5 vol% (range, 4-6)
Oxygen consumption index (VO_2)	131 mL/min/m^2 (range, 100-180)
Oxygen delivery index (Do_2)	578 mL/min/m^2 (range, 370-730)
Oxygen extraction ratio (O_2ER)	25% (range, 22-30)
Intramucosal pH (pHi)	7.40 (range, 7.35-7.45)
Index (I)	Parameter indexed to body surface area

[a]Normal values may not be the same as values needed to optimize the management of a critically ill patient.

TABLE 23-2 Evidence-Based Treatment Recommendations for Management of Severe Sepsis or Septic Shock

Recommendations	Grade
Crystalloids are the initial fluid resuscitation of severe sepsis.	1B

Recommendations	Grade
Albumin is additional therapy after substantial amounts of crystalloid have been used in the initial resuscitation regimen of severe sepsis and septic shock.	2C
Hydroxyethyl starches with molecular weights exceeding 200 Da or molar substitution exceeding 0.4 should not be used.	1B
An incremental fluid challenge technique of fluid boluses should be applied wherein fluid administration is continued until hemodynamic improvement, either based on dynamic (eg, pulse pressure and stroke volume variation) or static (arterial pressure and heart rate) variables.	1C
The following therapies should be completed within THREE hours of presentation: measure lactate, obtain cultures and administer antibiotics, administer 30 mL/kg of crystalloid for hypotension or lactate blood lactate more than or equal to 4 mmol/L.	Ungraded
The following therapies should be completed within SIX hours of presentation: apply vasopressors to maintain MAP more than or equal to 65 mm Hg, reassess volume status, remeasure blood lactate if the initial lactate was elevated.	Ungraded
Resuscitation of patients with sepsis-induced shock, defined as tissue hypoperfusion (hypotension persisting after fluid challenge or blood lactate more than or equal to 4 mmol/L) should be protocolized. This protocol should be initiated as soon as hypoperfusion is recognized and should not be delayed pending ICU admission. The goal of initial resuscitation of sepsis-induced hypotension during the initial 6 hours should include all of the following: (1) CVP 8-12 mm Hg,[a] (2) MAP more than or equal to 65 mm Hg, (3) urine production more than or equal to 0.5 mL/kg/h, and (4) lactate clearance or Svo_2 more than or equal to 65% or $Scvo_2$ more than or equal to 70%.	1C
Resuscitation should target normal lactate concentrations in patients with elevated lactate levels as a marker of tissue hypoperfusion.	2C
Use vasopressors to initially target MAP more than or equal to 65 mm Hg.	1C
Norepinephrine is the initial vasopressor of choice.	1B
Epinephrine (added or substituted) should be used when an additional agent is needed to maintain adequate blood pressure.	2B
Dopamine should be used as an alternative vasopressor agent to norepinephrine in highly select patients with low CO and/or low heart rate and at very low risk of arrhythmias.	2C
A trial of dobutamine infusion should be administered or added to vasopressor therapy in the presence of (1) myocardial dysfunction as suggested by elevated filling pressures, low CO, or left ventricular dysfunction or (2) ongoing signs of hypoperfusion despite achieving adequate intravascular volume and adequate MAP.	1C
Vasopressin 0.03 U/min may be added to norepinephrine with the intent of raising MAP or decreasing norepinephrine dosage.	Ungraded
Do not use corticosteroid in adult septic shock patients if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability. If hemodynamic stability is not achieved, hydrocortisone at daily doses of 200 mg by continuous intravenous infusion may be administered.	2C

Recommendations	Grade
ACTH stimulation test should not be used to identify the subset of adult patients with septic shock who should receive hydrocortisone.	2B
Corticosteroid therapy may be weaned once vasopressors are no longer required.	2D
Do not use corticosteroids to treat sepsis in the absence of shock unless the patient's endocrine or corticosteroid history warrants it.	1D

ACTH, adrenocorticotropic hormone; CO, cardiac output; CVP, central venous pressure; MAP, mean arterial pressure; $Scvo_2$, central-venous oxygen saturation; Svo_2, mixed venous oxygen saturation. Level of recommendations: 1, a strong recommendation indicating that the intervention's desirable effects clearly outweigh its undesirable effects; 2, a suggestion indicating that the tradeoff between desirable and undesirable effects is less clear. Quality of evidence: A, supported by a randomized control trial; B, supported by a downgraded randomized control trial or upgraded observational studies; C, supported by observational studies; D, supported by case series or expert opinion.

[a]A higher target CVP of 12-15 mm Hg may be required in the presence of mechanical ventilation or preexisting left ventricular dysfunction or abdominal distension.

Data from references 2 and 4,5,6,7,8,9,10,11,12.

GLOBAL PERFUSION MONITORING

Arterial Blood Pressure Measurement

Mean arterial pressure is the product of cardiac output (CO) and systemic vascular resistance (SVR). Conditions that may lower blood pressure through diminished CO in critically ill patients include cardiac failure (etiology may be myocardial infarction, arrhythmia, acute heart failure, or valvular disease), cardiac obstruction to reduce blood flow into or out of the heart (etiology may be cardiac tamponade, cardiac tumors, massive pulmonary embolism, or tension pneumothorax) and hypovolemia (etiology may be hemorrhage, intractable diarrhea, or heat stroke).[1] Vasodilatory conditions, such as sepsis, anaphylaxis, pancreatitis, acute hepatic failure, or neurotrauma, lower blood pressure by reducing SVR.[1] Arterial blood pressure is the commonly used end point of therapy; however, restoration of adequate perfusion pressure is the primary criterion of effectiveness.[1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16] Profound hypotension (MAP less than 60 mm Hg) is associated with pressure-dependent decreases in coronary, cerebral, and renal blood flow and may rapidly produce myocardial, cerebral, and renal ischemia. Therefore, a goal MAP of 65 mm Hg is often targeted for shock to maintain perfusion; however, patient specific characteristics must be considered in establishing a MAP goal and determining an adequate perfusion response to resuscitation.

Arterial blood pressure can be determined by noninvasive and invasive methods. All noninvasive blood pressure monitoring techniques depend on the use of an occluding cuff. Systolic and diastolic blood pressures are further determined by oscillometry, auscultation, palpation (systolic pressure only), or Doppler technique (systolic pressures are most reliable). Oscillometry is the only noninvasive

method used in the intensive care unit (ICU) to measure MAP because the data are valid during low-flow states and the method provides automatic cycling and serial measurements (every 1-3 minutes) that do not require operator intervention. The oscillometry method operates by sensing arterial blood pressure changes, or oscillation amplitudes, against an inflated cuff. Unexpected high or low readings should be investigated as the use of improperly fitting cuffs can result in erroneous values. Fingertip devices offer another avenue for continuous indirect blood pressure measurement, but their accuracy in ICU patients may be significantly diminished by concurrent administration of vasoactive drugs.

1 The use of invasive arterial catheters makes possible the continuous measurement of MAP as well as procurement of blood samples for laboratory testing. The radial artery is the most commonly used vessel, but the dorsalis pedis, femoral, brachial, and axillary arteries and the umbilical artery in the newborn also can be accessed. This method of blood pressure monitoring is the standard technique used in the ICU against which all other methods are compared. Major complications of peripheral artery catheterization include infection and distal ischemia. Acute distal ischemia and catheter-related bacteremia occur in less than 1% of catheter insertions. This translates to 2.3 to 2.9 bloodstream infections per 1,000 catheter-days.[2] Ischemia is most common in patients with multiple or prolonged arterial cannulations, hypertension, or vasopressor therapy.[2] Invasive techniques are labor intensive, require aseptic techniques, and offer potential sources of equipment errors, such as length and quality of tubing, air bubbles, stopcocks, thrombus formation, tube kinking, and transducer placement. Hypertension, advanced age, and atherosclerosis also may affect the accuracy of invasive blood pressure readings.

Central Venous Catheter

1 2 The central venous catheter is used to measure the central venous pressure (CVP), to obtain venous samples for laboratory testing, and to administer drugs or fluids directly to the central circulation. A triple-lumen catheter frequently is used, whereby drugs with known incompatibility can be administered. Blood volume, venous wall compliance, right-sided cardiac function, intra-abdominal and intrathoracic pressures, and vasopressor therapy affect CVP. The CVP is not a reliable estimate of blood volume but can be used to qualitatively assess blood volume changes in patients during the early phases of fluid resuscitation.[2,17,18] The goal of fluid administration is to maintain the CVP at 8 to 12 mm Hg, but values of 15 mm Hg may be targeted in mechanically ventilated patients or patients with abdominal distension or preexisting ventricular dysfunction.[2,6,17,18] Sustained elevated pressures may be indicative of fluid overloading. While the results of early studies showed CVP monitoring of fluid therapy during resuscitation of septic shock was associated with reduced mortality,[19,20] recent trials suggest the uniform use of central catheters for CVP monitoring is not associated with reduced mortality and is unlikely to be cost-effective.[21,22,23,24] Therefore, resuscitative therapies should not be delayed in the absence of CVP monitoring or while a central venous catheter is being inserted.

Pulmonary Artery Catheter

1 Pulmonary artery catheterization provides multiple cardiovascular parameters, including CVP, pulmonary artery pressure, pulmonary artery occlusion pressures (PAOP, commonly called the "wedge pressure"), CO, SVR, and the mixed-venous oxygen saturation (Svo_2).[25] Ideally, the pulmonary artery catheter should be positioned fluoroscopically; however, satisfactory placement also may be obtained by observing pulmonary artery pressure readings and electrocardiographic waveforms during catheter advancement. Proper positioning, or wedging, in the lower lung (zone 3) is essential to measure PAOP and to prevent distal pulmonary artery collapse. Inflation of the balloon at the catheter tip occludes the pulmonary artery, isolates the distal catheter tip from the right side of the heart, and allows the user to measure the PAOP, an approximate measure of the left ventricular end-diastolic volume and a major determinant of left ventricular preload. Poor wedging may be caused by catheter migration, patient movement, mechanical ventilation, or eccentric balloon inflation. Pulmonary artery catheters equipped with a distal thermistor also allow measurement of CO by thermodilution. Rapid injection of cold saline or dextrose solutions via the right atrial port allows complete mixing of blood with the injectate, and the resulting change in blood temperature is measured in the pulmonary artery. From the temperature change, the patient's CO can be calculated. Some pulmonary artery catheters contain a temperature coil or filament that intermittently warms the blood in the right ventricle for near-continuous CO measurement. Significant tricuspid regurgitation, an intracardiac shunt, the respiratory phase, and significant positive end-expiratory pressure decrease the accuracy of CO measurements. The most common complications of pulmonary artery catheterization include mural thrombus formation (14%-91%), transient ventricular tachydysrhythmias (11%-63%), pulmonary infarction (1%-7%), pulmonary artery rupture (0.06%-2.0%), and sepsis (0.3%-0.5%).[25,26] Most pulmonary artery catheters are heparin bonded which requires consideration in patients with unexplained thrombocytopenia. The relative risk (RR) of infection is 2.6 per 1,000 patient-days, similar to the risk with central venous catheters.[25,26] Controversy surrounds the utility and safety of the pulmonary artery catheter, including issues of correct placement and impact of the device on patient outcome as studies have failed to demonstrate beneficial outcomes with the use of the pulmonary artery catheter.[2,6,26] Careful evaluation of the indications and the risk of placing a pulmonary artery catheter for resuscitation of critically ill patients is warranted.[2,6,26,27]

1 The optimal PAOP needs to be individualized for each patient. Administering a fluid bolus followed by simultaneous PAOP and CO measurements with the goal of increasing the PAOP until CO does not change can be accomplished and is based on Starling's law of the heart. However, clinical experience suggests that most patients have an optimal response to PAOP values in the range from 12 to 15 mm Hg. CVP and PAOP guided therapies are equivalent in terms of clinical outcomes, including mortality.[27] Therefore, a pulmonary artery catheter should only be inserted when hemodynamic data are needed that cannot be obtained from a central venous catheter or when the validity of measurements from the central venous catheter or other assessments of perfusion are questionable.

1 Other methods used to assess CO include carbon dioxide (CO_2) partial rebreathing, esophageal Doppler, transpulmonary (ultrasound) indicator dilution, and the passive leg raise test.[1,2,7,13,14,15,16] The CO_2 partial rebreathing technique compares end-tidal CO_2 partial pressure obtained during a

nonrebreathing period with that obtained during a subsequent rebreathing period. The ratio of change in end-tidal CO_2 and CO_2 elimination estimates CO but must be corrected for blood shunting. Poor to acceptable agreement exists between this method and the thermodilution method of assessing CO in critically ill patients. Also, low minute ventilation, a high shunt fraction, or a high CO produces inaccurate results. The esophageal Doppler technique measures flow velocity in the descending aorta by means of a Doppler transducer. CO is calculated based on the diameter of the aorta, the distribution of CO to the aorta, and the flow velocity of blood in the aorta. The CO reported by this method correlates with therapeutic interventions and demonstrates excellent agreement with the pulmonary artery catheter. Unfortunately, this method is technologically difficult and may not produce reliable measurements over time. The transpulmonary (ultrasound) indicator dilution method is functionally similar to the pulmonary artery catheter in that it employs thermodilution to calculate CO but it uses a central venous catheter rather than introducing a catheter into the pulmonary artery. This method of measuring CO correlates well with the values obtained from the pulmonary artery catheter and may display less respiratory phase variations. It also may estimate global end diastolic volume but other hemodynamic variables are not readily obtained. Passively lifting a leg 45° for 60 to 90 seconds when a patient is fully supine provides a 250 to 500 mL bolus of fluid as pooled venous blood is mobilized to the heart and increases stroke volume. A dynamic increase in blood pressure of 10% reflects increased CO and is highly sensitive and specific that the patient requires fluid resuscitation.[6] Special hemodynamic monitors are available that specifically assess changes in stroke volume and CO in response to a passive leg raise but they are rarely used in practice due to cost and technical requirements.

Oxygen Tension and Saturation Monitoring

Partial pressure of arterial oxygen (PaO_2) and arterial oxygen saturation (SaO_2) can be assessed subjectively by assessing capillary refill or invasively by obtaining an arterial blood sample. Arterial blood gases measured by conventional arterial sampling are considered standard, but their accuracy and usefulness are affected by poor sampling techniques, transportation and analysis delays, analyzer accuracy, sample cellular metabolism, and inability to trend results. Indwelling fiberoptic and electrochemical systems that allow continuous monitoring and trend analyses of blood pH, Pao_2, and partial pressure of arterial carbon dioxide ($Paco_2$) while decreasing patient blood loss from less frequent sampling are available but rarely employed due to cost. Svo_2 and central-venous oxygen saturation ($Scvo_2$) reflect oxygen delivery (Do_2, or Do_2I, indexed to body surface area) with low values indicative of inadequate tissue perfusion that may occur during the early stages of septic shock, cardiogenic shock, or hypovolemic shock. Both measurements depend on CO, oxygen demand, hemoglobin, and Sao_2.

2 Mixed-venous oxygen saturation is measured in patients using a pulmonary artery catheter. Initially, critically ill septic patients may present with a low Svo_2 value (less than 65%), indicating high extraction of oxygen by tissues or lack of adequate Do_2 to tissues. In patients with sepsis and other conditions who present with low Svo_2 values, rapid intervention should be undertaken to increase Do_2 to tissues, with the goal of obtaining Svo_2 more than or equal to 65%.[17,19,28,29] The length of time Svo_2 is less than 65% is associated with mortality.[17] As sepsis worsens, however, Svo_2 may be

more than or equal to 65%. This occurs because extraction of oxygen in the arteriolar beds is hampered and is indicative of poor outcome.

1 2 3 Central-venous oxygen saturation is a less invasive measure of venous oxygen saturation because the catheter is placed at the junction of the inferior and superior venae cavae rather than at the pulmonary artery.[13,14,15,16,28,29] It is as accurate as Svo_2 but provides slightly higher normal values. Concentrations of $Scvo_2$ less than 70% reliably indicate inadequate oxygenation in shock states and detect subclinical ("cryptic") shock much earlier than hypotension. Targeting fluid and hemodynamic resuscitation to achieve $Scvo_2$ more than or equal to 70% is a sensitive indicator and measure of the extent of global tissue hypoxia and a determinant of the adequacy of hemodynamic resuscitation. While the results of early studies showed $Scvo_2$ monitoring as a determinant of resuscitation was associated with improved survival in patients with sepsis and septic shock,[19,20] recent studies failed to show a reduction in mortality.[21,22,23,24] This likely reflects practice changes over time to provide more aggressive early resuscitation with response measured by clinical outcomes rather than laboratory parameters.[20,24] As a result, $Scvo_2$ (or Svo_2) monitoring to guide resuscitation should not be used routinely and should be reserved for cases when clinical monitoring parameters are conflicting or difficult to measure. Resuscitative therapies should not be delayed in the absence of $Scvo_2$ (or Svo_2) measurements or while a catheter is being inserted.

Oxygen Delivery and Consumption

1 2 Tissue oxygen debt is indicative of organ damage in critical illness. In normal individuals, oxygen consumption (Vo_2 or Vo_2I, indexed to body surface area) depends on Do_2 (or Do_2I) up to a certain critical level (Vo_2 flow dependency). At this point, tissue oxygen requirements apparently are satisfied and further increases in Do_2 will not alter Vo_2 (Vo_2 flow independency). The point that Vo_2 becomes dependent on Do_2 represents a pathologic transition from aerobic to anaerobic cellular metabolism and lactate production.[16,17,28,29,30,31] Although animal models of sepsis substantiate this relationship, studies in critically ill humans show a continuous, pathologic dependence relationship of Vo_2 with Do_2.[16,17,28,29,30,31] The Vo_2/Do_2 ratio, or oxygen extraction ratio (O_2ER), can be used to assess adequacy of perfusion and metabolic response.[16,17,28,29,30,31] Maintaining the O_2ER at less than 25% without decreasing Vo_2 may be helpful in maintaining or improving the body's reserve in meeting the oxygen demands. Low Vo_2 and O_2ER values are indicative of poor oxygen utilization and greater mortality. Patients who are able to increase Vo_2 when Do_2 is increased show improved survival. This finding became the basis for targeting supranormal Do_2 and Vo_2 values in the treatment of ICU patients in the 1970s and 1980s but this practice is no longer favored as the results of studies failed to show improved regional organ blood flow or oxygenation and survival with the achievement of supranormal Do_2 and Vo_2.[16,28,29]

The apparent linear relationship between Do_2 and Vo_2 has been questioned because both share variables, and this *mathematical coupling* can produce artifactual relationships between variables.[16,17] Inconsistent relationships between Do_2 and Vo_2 are observed when Vo_2 is measured independently

by indirect calorimetry. While the systematic assessments of Do_2 and Vo_2 and their dependence are rarely practiced, the concepts of enhancing Do_2 are frequently applied. The Do_2 and Vo_2 indexed parameters are calculated as follows:

$Do_2 = CI \times Cao_2$
$Vo_2 = CI \times (Cao_2 - Cvo_2)$

where CI = cardiac index, Cao_2 = arterial oxygen content determined by hemoglobin concentration and Sao_2, and Cvo_2 = mixed venous oxygen content determined by hemoglobin concentration and Svo_2.

2 3 4 The rapid initiation of therapy to optimize the components of Do_2 (CO, hemoglobin, and Sao_2) improves survival. In a prospective, randomized controlled trial, Rivers et al. demonstrated a significant reduction in hospital mortality (30.5% vs 46.5%; $P < 0.001$) in patients with severe sepsis and septic shock randomized to receive therapy based on goal-directed hemodynamic end points that were achieved within 6 hours of hospital presentation.[19] They used a systematic strategy to optimize Do_2 of serially administering (1) fluids rapidly to achieve CVP 8 to 12 mm Hg, (2) vasopressor agents to achieve MAP at least 65 mm Hg, (3) red blood cell transfusion to maintain hematocrit more than or equal to 30%, and (4) dobutamine to achieve $Scvo_2$ more than or equal to 70%. During the 6-hour window, the goal-directed therapy group received substantially more fluid, blood transfusions, and dobutamine administration but required less vasopressor and ventilator support later. While this approach demonstrates the benefits of initiating therapy early in the course of sepsis, the benefit of directing therapies toward clearly defined goals for the purpose of optimizing Do_2 has been challenged by the results of three multicenter studies.[21,22,23] Nearly 3,800 patients with severe sepsis and septic shock were randomized across three multicenter trials to receive therapies based on the same goal-directed hemodynamic end points as the Rivers et al. trial or receive usual care of practice as directed by the clinician. In general, subjects randomized to goal-directed therapies were more likely to receive vasopressors, blood transfusions, and dobutamine administration but 60-day and 90-day mortality rates were comparable to the usual care groups (18.2%-29.5% vs 18.8%-29.2%). Unlike the Rivers et al. trial, the volume of fluid during the initial periods of resuscitation did not differ between study regimens suggesting that usual care practices have changed over time to encourage aggressive early fluid administration. Another study demonstrated no benefit of administering blood transfusions to maintain hematocrit more than or equal to 30% for the purpose of increasing Do_2 and achieving $Scvo_2$ more than or equal to 70%.[32] While current guidelines endorse the application of defined goals for optimizing Do_2 (eg, $Scvo_2$ more than or equal to 70%),[6] many clinicians only apply clinical monitoring parameters or use other measurements of tissue oxygen debt (eg, serum lactate concentration) or indicators of Do_2 optimization. Experts generally agree on the importance of aggressive early resuscitation regardless of whether components of Do_2 are systematically measured.

Blood Lactate

2 Lactate is a metabolic product of pyruvate. Its production is increased under anaerobic conditions when Vo_2 exceeds Do_2, such as may occur during shock.[16,28,33,34,35] Blood lactate concentrations are used as a diagnostic and prognostic tool in sepsis; they also are used to measure the repayment of oxygen debt to tissues.[16,28,33,34,35] Several studies have demonstrated risk stratification of mortality rates based on initial lactate concentrations.[33,34,35,36] Serial lactate concentrations may show better correlation with outcome than oxygen transport parameters and may be superior to hemodynamic markers in determining adequacy of restoration of systemic oxygenation. Continuously elevated concentrations are predictive of morbidity and mortality. Lactate elimination (commonly termed "clearance") of 10% for 6 hours during initial resuscitation produces similar survival outcomes as achieving $Scvo_2$ more than or equal to 70%.[37] The utility of blood lactate measurements in guiding therapy was demonstrated in a study of 348 septic patients that showed targeting a 20% lactate reduction during the first 2 hours of resuscitation reduced hospital mortality compared to conventional assessment methods (hazard ratio [HR], 0.61; 95% CI, 0.43-0.87; P = 0.006).[38] The results of a meta-analysis of four trials of septic patients (N = 547) showed reduced mortality with therapies directed toward early lactate clearance (RR, 0.65; 95% CI, 0.49-0.85; P = 0.002). Therefore, lactate clearance (or normalization) should be targeted as a goal of resuscitation in patients with evidence of tissue hypoperfusion and is preferred to $Scvo_2$ (or Svo_2).[6]

Several caveats guide the use of lactate concentrations in septic patients. First, lactate may accumulate in patients with other conditions, such as significant hepatic dysfunction or acute respiratory distress syndrome, who are not in shock. Second, both well-perfused and poorly perfused tissues contribute to arterial and mixed venous lactate concentrations and therefore are not reflective of regional perfusion. Third, elevated lactate concentrations may result from cellular metabolic failure or medications rather than global hypoperfusion in shock. Fourth, evidence of organ perfusion and function should always be considered in conjunction with lactate clearance.[6]

REGIONAL PERFUSION MONITORING

4 Blood pressures, CO, blood lactate, and global oxygen homeostasis parameters do not offer information about perfusion to individual organs. Organ-specific hypoxia may be evident by coagulopathy as indicated by thrombocytopenia (platelet count less than 100,000/L) and/or prolonged clotting times (international normalized ratio greater than 1.5 or activated partial thromboplastin time at least 1.5-fold the upper limit of normal), impaired renal function with urine production less than 0.5 mL/kg/h and/or increased serum concentrations of blood urea nitrogen and creatinine, altered hepatic function with substantially increased serum concentrations of transaminases and bilirubin, altered gastrointestinal perfusion manifested by ileus and diminished bowel sounds, cool extremities, cardiac ischemia with elevated troponin levels and electrocardiogram or echocardiography changes, pulmonary ischemia with worsening PaO_2, and altered sensorium.[1,2,5,6] The success of resuscitation should be based on the combination of blood pressure, organ-specific parameters of regional perfusion, and global perfusion measurements. For example, early resuscitation goals in septic shock may include CVP, MAP, urine production, echocardiography sensorium, and lactate (or possibly $Scvo_2$ or Svo_2).

Gastrointestinal Tonometry

2 Other measurements of regional perfusion to detect inadequate tissue oxygenation have focused on the mesenteric/splanchnic circulation, which is sensitive to changes in blood flow and oxygenation for several reasons.[13,14,15,29,30,31] Normally, most blood flow to the gut mucosa is redistributed toward the serosa and muscularis. Second, the gut may have a higher critical Do_2 threshold than other organs. Third, the tip of the villus has a countercurrent oxygen-exchange mechanism, rendering it highly sensitive to alterations in regional blood flow and oxygenation.

Gastric tonometry measures gut luminal partial pressure of carbon dioxide (Pco_2) at equilibrium by placing a saline- or air-filled gas-permeable balloon in the gastric lumen. Assuming that CO_2 permeates freely among tissues and that the arterial bicarbonate (HCO^-_3) concentration is equal to that of the gut mucosa, the intramucosal pH (pHi) may be calculated using the Henderson-Hasselbalch equation:

$pHi = 6.1 \log (HCO^-_3)\ 0.03 \times Pco_2$

Increases in mucosal Pco_2 and calculated decreases in pHi are associated with mucosal hypoperfusion.[13,14,15,29,30,31] Calculation of pHi can be confounded by increases in luminal Pco_2, such as may occur when buffering antacids are used. Histamine$_2$-receptor antagonists or proton pump inhibitors can be used instead. The presence of respiratory acid-base disorders; systemic bicarbonate administration; arterial blood gas measurement errors; or enteral feeding products, blood, or stool in the gut may confound pHi determinations. As a result, the change in gastric mucosal Pco_2 may be more accurate than pHi. Furthermore, because mucosal Pco_2 is influenced by arterial Pco_2, the mucosal-arterial Pco_2 difference (Pco_2 gap) likely is the optimal measurement.[13,14,15,29,30,31] The clinical utility of gastric tonometry is minimal as clinical trials of pHi-directed therapy do not show that it aids resuscitation when other goals are concomitantly targeted. Gastric tonometry, in general, inconsistently predicts mortality but has provided insight into perfusion differences of vasopressor activity.

2 Evidence suggests that the most proximal part of the gastrointestinal tract, the sublingual mucosa, may be an acceptable location for monitoring regional perfusion and Pco_2.[13,14,15,29,30,31] Unlike gastrointestinal circulation, limited intra- and interpatient variability exists in the microvasculature and only few arterioles are available for assessment. Sublingual capnometry is noninvasive, is not technically complex, and provides results within minutes. Small studies of critically ill patients with and without sepsis and septic shock show that the sublingual carbon dioxide pressure ($Pslco_2$) and the sublingual-to-arterial Pco_2 gap correlate better with the enhancement of Do_2 with dobutamine than the mucosal Pco_2 and the mucosal-to-arterial Pco_2 gap.[13,14,15,29,30,31] The initial sublingual-to-arterial Pco_2 gap is a better predictor of mortality. These pilot studies must be expanded before this technology becomes part of routine practice, but it offers the possibility of noninvasive measurement of regional perfusion.

Myocardial Dysfunction

1 4 Although loss of vascular tone is the hallmark of septic shock, myocardial dysfunction characterized by transient impairment of contractility is a recognized complication.[39] The range of left ventricular ejection fraction (LVEF) upon presentation is wide, but approximately 35% of patients with septic shock have left ventricular hypokinesis (mean ejection fraction 38% ± 17%) and low CO.[39] Because LVEF also is affected by preload and afterload, the low SVR of septic shock may mask depressed myocardial contractility that may be revealed upon restoration of MAP by administration of fluid and vasopressors. Therefore, CO may not reflect the extent of myocardial dysfunction. While it requires technical and interpretive training, echocardiography is a relatively simple method of assessing cardiac function and ventricular response to therapies.[40] It can assess chamber size, ventricular contractility, valve function, blood flow, and CO. Patients with tissue hypoxia or a hypercontractile left ventricle may benefit from fluid administration or vasopressor therapy; whereas, patients with poor left ventricular function may require inotropic intervention.

Cardiac troponin release in septic patients occurs in the absence of flow-limiting disease, likely due to a loss in membrane integrity with subsequent leakage or microvascular thrombosis. Elevation of cardiac troponin concentrations in patients with sepsis indicates left ventricular dysfunction and portends a poor prognosis.[39,40,41] Troponin concentrations also correlate with the duration of hypotension and the intensity of vasopressor therapy. Early recognition of myocardial dysfunction is crucial for administration of appropriate therapy. In the absence of other mechanisms for assessing cardiac function, echocardiographic findings and troponin concentrations may help guide and monitor therapy. Whereas cardiac troponins may be integrated into the monitoring of myocardial dysfunction to identify patients requiring aggressive therapy, natriuretic peptides show variable correlation with LVEF and should not be routinely monitored.[39,40,41]

VASOPRESSORS AND INOTROPES

6 Vasopressors and inotropes in patients with septic shock are required when volume resuscitation fails to maintain adequate blood pressure (MAP more than or equal to 65 mm Hg) and organs and tissues remain hypoperfused.[5,6,7,8,9,10,11,12] In addition, vasopressors may be needed temporarily to treat life-threatening hypotension when filling pressures are inadequate despite aggressive fluid resuscitation. Inotropes are frequently used to optimize Do_2 in cases of septic shock and cardiac function in cases of cardiogenic shock.[2,3,4,5,6] The clinician must decide on the choice of agent, therapeutic end points, and safe and effective doses of vasopressors and inotropes to be used. This section reviews adrenergic receptor pharmacology, exogenous catecholamine use, and alterations in receptor function in critically ill patients. It also provides guidance for the clinical use of adrenergic agents, optimization of pharmacotherapeutic outcomes, and minimization of adverse effects in critically ill patients with septic shock.

Vasopressin and corticosteroids, as they relate to septic shock, also are emphasized because they have pharmacologic interactions with catecholamine vasopressors, possess hemodynamic effects, and are frequently used. Other agents such as phosphodiesterase III inhibitors, naloxone, nitric oxide

(NO) synthase (NOS) inhibitors, and calcium sensitizers have been used as inotropes and vasopressors in shock states. These therapies are not discussed below as they are rarely used for septic shock and pharmacologic principles of other shock etiologies are discussed in other chapters.

Catecholamine Receptor Pharmacology

5 Comparative receptor activities of endogenous and exogenously administered catecholamines is summarized in **Table 23-3**.[6,7,8,9,10,11,12,42,43] Endogenous catecholamines are responsible for regulation of vascular and bronchiolar smooth muscle tone and myocardial contractility. These effects are mediated by sympathetic adrenergic receptors of the autonomic nervous system located in the vasculature, myocardium, and bronchioles. Postsynaptic adrenoceptors are located at or near the synaptic junction. These receptors can be activated by naturally circulating or exogenous catecholamines (eg, norepinephrine, epinephrine, and phenylephrine), whereas presynaptic adrenoceptors are stimulated by locally released neurotransmitters (eg, norepinephrine) and are controlled by a negative feedback mechanism.

TABLE 23-3 Adrenergic, Dopaminergic, and Vasopressin Receptor Pharmacology and Organ Distribution

Effector Organ	Receptor Subtype	Physiologic Response
Heart		
Sinoatrial node	β_1, β_2	Increased heart rate
Atria	β_1, β_2	Increased contractility
		Increased conduction velocity
Atrioventricular node	β_1, β_2	Increased automaticity
		Increased conduction velocity
His-Purkinje system	β_1, β_2	Increased automaticity
		Increased conduction velocity
Ventricles	β_1, β_2	Increased contractility
		Increased conduction velocity
		Increased automaticity
		Increased rate idioventricular pacemaker cells
Arterioles		
Coronary	α_1, α_2, V_1; β_2, D_1, V_2 (via NO)	Constriction; dilation
Skin and mucosa	α_1, α_2, V_1	Constriction
Skeletal muscle	α_1, V_1; β_2	Constriction; dilation
Cerebral	α_1, V_1; V_2 (via NO)	Constriction (slight); dilation
Pulmonary	α_1; β_2, V_2 (via NO)	Constriction; dilation

Effector Organ	Receptor Subtype	Physiologic Response
Abdominal viscera (mesentery)	α_1, V_1; β_2, D_1	Constriction; dilation
Renal	α_1, α_2, V_1; β_1, β_2, D_1	Constriction; dilation
Veins (systemic)	α_1, α_2; β_2	Constriction; dilation
Lungs		
Tracheal/ bronchial smooth muscle	β_2	Relaxation
Bronchial glands	α_1; β_2	Decreased; increased secretion
Stomach		
Motility and tone	α_1, α_2, β_1, β_2	Decreased (usually)
Sphincter	α_1	Contraction (usually)
Secretions	α_2	Inhibition
Intestine		
Motility and tone	α_1, α_2, β_1, β_2; V_1	Decreased (usually); increased?
Sphincters	α_1	Contraction
Secretions	α_2	Inhibition
Kidney		
Renin secretion	α_1; β_1	Decreased; increased
Reabsorption of water	V_2	Increased
Skeletal muscle	β_2	Increased contractility, glyconeogenesis, K^+ uptake
Liver	α_1, β_2	Glycogenolysis and gluconeogenesis
Fat cells	α_1, β_1, β_2	Lipolysis (thermogenesis)

D, dopamine; NO, nitric oxide; V, vasopressin.

Data from references 6,7,8,9,10,11,12, 42 and 43.

The signal transduction pathways associated with catecholamine and vasopressin-induced effects in the heart and blood vessels are illustrated in **Fig. 23-1**.[6,7,8,9,10,11,12,42,43] Agonists of β-adrenoceptors and dopamine (D_1) receptors stimulate adenylate cyclase by a G-protein (G_s)-dependent mechanism (see Fig. 23-1, top). Adenylate cyclase generates cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). cAMP-dependent protein kinase A, which is activated by elevations in intracellular cAMP, phosphorylates target proteins to modify cellular function. Through these mechanisms, β_1-adrenoceptor activation exerts positive inotropic and chronotropic effects in the heart, and β_2-adrenoceptor and D_1-receptor activation induces vascular smooth muscle relaxation. Agonists of α_1-adrenoceptors stimulate phospholipase C-β (PLC-β) through a G-protein (G_q)-dependent process (see Fig. 23-1, bottom). PLC-β produces inositol trisphosphate and

diacylglycerol from cell membrane phosphatidylinositol bisphosphate. Diacylglycerol activates protein kinase C, an enzyme that phosphorylates several key proteins (eg, extracellular signal-regulated kinases, c-Jun NH2-terminal kinases, and mitogen-activated protein kinases) that modify cellular function (eg, hypertrophy). Inositol trisphosphate elicits the release of calcium from intracellular stores, such as the sarcoplasmic reticulum. Calcium forms a complex with calmodulin, which then activates calcium–calmodulin-dependent protein kinases (CaMK). CaMKs phosphorylate target proteins to alter cellular function. Myosin light-chain kinase is an example of a CaMK. Its action of phosphorylating myosin light chain leads to vascular smooth muscle contraction.

FIGURE 23-1

Signal transduction pathways in heart and blood vessels. *Top:* Catecholamine (CCA)-induced effects mediated in heart (β_1) or vascular smooth muscle (β_2, D_1). (Abbreviations: AC, adenylate cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; PKA, cAMP-dependent protein kinase; +, stimulation.) *Bottom:* CCA (α_1) and vasopressin (VP)-induced actions in vascular smooth muscle. (Abbreviations: Ca^{++}, calcium ion; CaMK, calcium/calmodulin-dependent protein kinase; DAG, diacylglycerol; IP3, inositol trisphosphate; NO, nitric oxide; PIP2, phosphatidylinositol bisphosphate; PKC, protein kinase C; PLC-β, phospholipase C-β; SR, sarcoplasmic reticulum.) These pathways have been extensively simplified, and denoted cellular effects represent one of many produced. *(Data from references 6, 7, 8, 9, 10, 11, 12, 42, 43.)*

The normal heart contains primarily postsynaptic β_1-receptors, which when stimulated cause increased rate and force of contraction. This effect is mediated by activation of adenylate cyclase and subsequent generation and accumulation of cAMP. Stimulation of postsynaptic cardiac α_1-receptors causes a significant increase in contractility without an increase in rate, an effect mediated by PLC rather than adenylate cyclase. The increased contractility is more pronounced at lower heart rates and has a slower onset and longer duration in comparison with β_1-mediated inotropic response. Presynaptic α_2-adrenoceptors also are found in the heart and appear to be activated by norepinephrine released by the sympathetic nerve itself. Their activation inhibits further norepinephrine release from the nerve terminal.

Both presynaptic and postsynaptic adrenoceptors are present in the vasculature. Postsynaptic α_1- and α_2-receptors mediate vasoconstriction, whereas postsynaptic β_2-receptors induce vasodilation.

Presynaptic α_2-receptors inhibit norepinephrine release in the vasculature, also promoting vasodilation. Presynaptic β_1-adrenoceptors promote neurotransmitter release. Stimulation of peripheral D_1-receptors produces renal, coronary, and mesenteric vasodilation and a natriuretic response. Stimulation of D_2-receptors inhibits norepinephrine release from sympathetic nerve endings, sequesters prolactin and aldosterone, and may induce nausea and vomiting. D_1- and D_2-receptor stimulation also suppresses peristalsis and may precipitate ileus.

5 Vasopressin-induced vasoconstriction occurs through a variety of direct and indirect mechanisms.[12,42,43] Stimulation of vascular vasopressin (V_1) receptors causes vasoconstriction by receptor-coupled activation of PLC and calcium release from intracellular stores via secondary messengers similar to α_1-adrenergic stimulation (see Fig. 23-1, bottom). Vasopressin also directly inhibits vascular potassium-sensitive ATP channels to produce vasoconstriction (see Fig. 23-1, bottom). V_1-receptor stimulation inhibits the actions of interleukin (IL)-1β and thereby facilitates vasoconstriction. Vasopressin also increases the activity of adrenergic receptors. The greatest vasoconstriction occurs in the skin and soft tissue, skeletal muscle, fat tissue, pancreas, and thyroid gland. In contrast, vasopressin causes vasodilation in the cerebral, pulmonary, coronary, and selected renal vascular beds by enhancing endothelial NO release through V_1-receptor stimulation in these tissues.[12,42,43] Vasopressin has minimal to no inotropic or chronotropic effects.

V_2 receptors located in the kidneys are responsible for the antidiuretic properties of vasopressin.[12,42,43] Stimulation of V_2 receptors facilitates integration of aquaporins into the luminal cell membrane of distal tubules and collecting duct capillaries to increase permeability and thus retain intravascular volume. However, vasopressin stimulation of V_1 receptors causes vasoconstriction of efferent arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate to enhance urine production.

Vasopressin rapidly increases serum cortisol concentration by stimulating V_3 receptors in the pituitary gland to enhance the release of adrenocorticotropic hormone (ACTH).[12,42,43] Cortisol helps regulate the proinflammatory state associated with sepsis and increases blood pressure through several mechanisms, including inhibition of inducible NOS (iNOS) to reduce NO production, reversal of adrenergic receptor desensitization, and increased intravascular volume through retention of sodium and water.

Altered Adrenoceptor Function: Implications for Critically Ill Patients

5 Most of the work describing receptor function and associated clinical pharmacology has been performed in either animal models or human volunteers. In critically ill septic patients, derangements in adrenergic receptor activity may result in resistance to exogenously administered catecholamine.[6,7,8,9,10,11,12,42,43] This "desensitization" frequently is characterized by myocardial and vascular hyporesponsiveness to high dosages of inotropes and vasopressor agents. Prolonged exposure of vascular endothelial tissue to vasopressor drugs (α-adrenergic agonists) or endogenous catecholamines may promote additional receptor downregulation. Increased endogenous

catecholamine concentrations have been reported in endotoxemic and other critically ill patients, suggesting an acquired adrenergic receptor defect and desensitization of adrenergic receptors and alteration in voltage-sensitive calcium channels. The problem in critically ill patients may be related to decreased receptor activity or density. However, in patients with septic shock, catecholamine concentrations are even higher, so abnormalities in adrenergic receptor function are greater, with associated reductions in the concentrations of intracellular signal transduction mediators. The worsened receptor abnormality may be explained by defects distal to the receptor site, such as uncoupling of adrenergic receptors from adenylate cyclase or PLC, or dysfunction in the regulatory G-protein unit of signal transduction pathways.

In addition to catecholamines, circulating inflammatory cytokines may be partly responsible for distal alterations.[12,42,43] Macrophage-derived IL-1 and tumor necrosis factor (TNF)-α produce impaired coupling of β-adrenoceptors to adenylate cyclase. Patients with septic shock exhibit impaired β-adrenergic receptor stimulation of cAMP associated with myocardial hyporesponsiveness to various vasopressors and inotropes. However, increased chronotropic sensitivity to β-adrenergic stimulation with hypersensitivity of the adenylate cyclase system to isoproterenol stimulation also has been reported in animal models of bacteremia and endotoxemia. In the presence of intrinsic myocardial dysfunction and increased metabolic demands, this dysfunctional adrenergic system is incapable of mobilizing functional cardiac reserve to maintain adequate myocardial performance.[39,42,43]

IL-1 and TNF-α suppress gene expression of α_1-adrenoceptors, resulting in fewer receptor proteins. Overproduction of NO by iNOS directly contributes to vasodilation by cyclic guanosine monophosphate-mediated smooth muscle relaxation. NO indirectly produces vasodilation by combining with superoxide to form peroxynitrite, a highly toxic reactive species that causes endothelial dysfunction, uncoupling of α_1-adrenoceptors to PLC, and deactivation of catecholamines. The result of sepsis-induced inflammation is a system that promotes adrenergic receptor dysfunction to accentuate vasodilation and shock.[39,42,43]

5 Functional α_1-adrenergic receptor changes occur at various stages of sepsis; thus, adrenoceptor sensitivity may be time dependent during progression of sepsis to septic shock. The findings are not always consistent in various animal models of sepsis and in critically ill septic patients. Time-dependent alterations in the production of NO, a potent vasodilator, may explain the apparent differences in vascular reactivity to phenylephrine during the phases of endotoxemia. Furthermore, β-adrenergic receptor changes are present within 24 to 48 hours of septic shock. These findings suggest that the clinical response to vasopressors and possibly inotropic agents is variable during the stages of hemodynamic, myocardial, and peripheral vascular derangements of septic shock. In summary, α- and β-adrenergic receptor derangements may vary among patients and during each bacteremic insult; therefore, dose responsiveness of catecholamines vary among patients and during the insult.[6,7,8,9,10,11,12,39,42,43] For these reasons, these drugs should be dosed to clinical end points and not to arbitrary maximal dosages. High dosages are frequently required.

Relative Deficiencies of Vasopressin and Cortisol

14 Endogenous arginine vasopressin, a peptide hormone also known as antidiuretic hormone, is important for osmoregulation under normal physiologic conditions. Vasopressin is produced in the hypothalamus, stored in the posterior pituitary, and released from magnocellular neurons of the hypothalamus.[12,43] Increased serum osmolality and hypovolemia are the major stimuli for vasopressin release.[43] Other stimuli commonly associated with shock are dopamine, histamine, angiotensin II, prostaglandins, pain, hypoxia, acidosis, hypotension, hypercarbia, and α_1-adrenergic receptor stimulation. Vasopressin release is inhibited by NO, natriuretic peptides, γ-aminobutyric acid, β-adrenergic receptor stimulation, and α_2-adrenergic receptor stimulation.[43]

Normal serum vasopressin concentrations are less than 4 pg/mL.[43] Serum vasopressin concentrations are elevated with hypotension. Vasopressin response in septic shock is biphasic. During the first 8 hours of septic shock requiring catecholamine adrenergic therapy, serum concentrations of vasopressin are appropriately high to help maintain blood pressure and organ perfusion. Thereafter, serum vasopressin concentrations decline dramatically over the next 96 hours to physiologically normal but inappropriately low values, resulting in a state of "relative deficiency." In contrast, serum vasopressin concentrations remain elevated in patients with cardiogenic shock. Administration of vasopressin at 0.01 to 0.06 units/min produces concentrations similar to those observed in early septic shock and other hypotensive states; however, vasopressin concentrations do not correlate with blood pressure.[43] Administration of vasopressin augments the decline of inflammatory mediators and improves arterial pressure while minimizing the dosage of catecholamine vasopressors.[43,44]

The mechanism of vasopressin insufficiency in septic shock is not well understood. Neurohypophyseal stores in the posterior lobe of the pituitary gland are depleted during septic shock, likely as a result of excessive and continuous baroreceptor stimulation that eventually exhausts the limited vasopressin secretory stores. In addition, secretion of vasopressin is inhibited by enhanced endothelial production of NO, high circulating concentrations of adrenergic agonists (both endogenous and exogenous), and tonic inhibition by stretch receptors in response to volume replacement and mechanical ventilation.[43]

14 As with vasopressin, during sepsis a state of "relative adrenal insufficiency" is produced by continuous activation of the hypothalamic-pituitary-adrenal axis by IL-1, IL-6, and TNF-α that causes depletion of cortisol in the adrenal glands.[45,46] Administration of corticosteroids improves arterial pressure while minimizing the dosage of catecholamine vasopressors. Current proposed mechanisms of the vasoconstrictor effect of corticosteroids include increasing the number and stimulating the function of α_1- and β-adrenergic receptors and attenuating the production of inflammatory mediators responsible for vasodilation.

The use of corticosteroids for treatment of septic shock has been a topic of controversy for many years. Early studies of steroids in patients with sepsis demonstrated a lack of benefit and potential harm in sepsis and septic shock. Interest in corticosteroid use is driven by the awareness of adrenocortical insufficiency in critically ill patients with septic shock.[45] Relative adrenal insufficiency has been defined as a random cortisol concentration less than 10 mcg/dL (278 nmol/L) or an increase of less than 9 mcg/dL (250 nmol/L) following a dose of synthetic ACTH irrespective of the initial

serum cortisol concentration.[46] Although absolute insufficiency is rare, relative adrenocortical insufficiency is present in 50% to 70% of patients with septic shock and is associated with a poor outcome.[46,47,48,49]

Conversely, an elevated random cortisol concentration (more than 34 mcg/dL) is also a predictor of mortality.[46] Mortality is further increased if ACTH response is less than 9 mcg/dL, suggesting that the risk of mortality is greatest in situations of adrenal gland "fatigue" (ie, degree of stress is not matched by sufficient cortisol production by the adrenal glands despite operating at maximal functional capacity).

Clinical Pharmacology of Vasopressors and Inotropes

5 14 The receptor selectivity of clinically used, catecholamine-based vasopressors and inotropes and hemodynamic effects are listed in **Table 23-4**.[5,6,7,8,9,10,11,12,42,43,50,51,52] In general, these drugs are fast acting, with short durations of action. As such, these drugs are given as continuous infusions and titrated rapidly to predetermined effects with the exception of vasopressin which is administered as a replacement dosage of 0.01 to 0.04 units/min and should not be titrated.[6,43] Careful monitoring and calculation of infusion rates are advised for all vasopressors because dosing adjustments are made frequently, and varying admixtures and concentrations are used.

TABLE 23-4 Receptor Pharmacology and Adverse Events of Selected Inotropic and Vasopressor Agents Used in Septic Shock[a]

Agent (Adverse Events)	α_1	α_2	β_1	β_2	D	V_1	V_2
Dobutamine (0.5-4 mg/mL D_5W or NS)	Tachycardia, dysrhythmias, hypotension						
2-10 mcg/kg/min	+	0	++++	++	0	0	0
>10-20 mcg/kg/min	++	0	++++	+++	0	0	0
Dopamine (0.8-3.2 mg/mL D_5W or NS)	Tachycardia, dysrhythmias, decreased PaO_2, mesenteric hypoperfusion, gastrointestinal motility inhibition, T-cell inhibition						
1-3 mcg/kg/min	0	0	+	0	++++	0	0
3-10 mcg/kg/min	0/+	0	++++	+	++++	0	0
>10-20 mcg/kg/min	+++	0	++++	+	0	0	0
Epinephrine (0.008-0.016 mg/mL D_5W or NS)	Tachycardia, dysrhythmias, decreased PaO_2, mesenteric hypoperfusion, increased lactate, hyperglycemia, immunomodulation						
0.01-0.05 mcg/kg/min	++	++	++++	+++	0	0	0
0.05-3 mcg/kg/min	++++	++++	+++	+	0	0	0
Norepinephrine (0.016-0.064 mg/mL D_5W)	Mixed effects on myocardial performance and mesenteric perfusion, peripheral ischemia						
0.02-3 mcg/kg/min	+++	+++	+++	+/++	0	0	0

Agent (Adverse Events)	α_1	α_2	β_1	β_2	D	V_1	V_2
Phenylephrine (0.1-0.4 mg/mL D_5W or NS)	Mixed effects on myocardial performance, peripheral ischemia						
0.5-9 mcg/kg/min	+++	+	+	0	0	0	0
Vasopressin (0.8 units/mL D_5W or NS)	Mixed effects on myocardial performance, mesenteric hypoperfusion, peripheral ischemia, hyponatremia, thrombocytopenia						
0.01-0.04 units/min	0	0	0	0	0	+++	+++

D, dopamine; D_5W, dextrose 5% in water; NS, normal saline; PaO_2, partial pressure of arterial oxygen; V, vasopressin.

Data from references 5, 6, 7, 8, 9, 10, 11, 12, 42, 43 and 50, 51, 52.

[a]Activity ranges from no activity (0) to maximal (++++) activity.

9 Norepinephrine is a combined α- and β-agonist that produces vasoconstriction primarily via its more prominent α-effects on all vascular beds, thus increasing SVR. Norepinephrine administration generally produces either no change or some increase in CO. Norepinephrine is considered the first-line option for initial vasopressor therapy of septic shock.[2,6,50,51,52]

10 Phenylephrine is a pure α_1-agonist and increases blood pressure through vasoconstriction.[6,7,8,9,10,11,12,42,50,51,52] Given the presence of cardiac α_1-receptors, phenylephrine also may increase contractility and CO although no change or a slight reduction in CO is often observed. It is a therapeutic option in hypotensive patients experiencing a tachyarrhythmia when a vasopressor with minimal to no β_1-agonist activity is indicated.[2,6]

11 Epinephrine exerts combined α- and β-agonist effects.[6,7,8,9,10,11,12,42,51,52] At the high epinephrine infusion rates used for patients with septic shock, predominantly α-adrenergic effects are observed, and SVR and MAP are increased. While epinephrine traditionally has been reserved as the vasopressor of last resort due to peripheral vasoconstriction, particularly in the splanchnic and renal beds, it is considered second-line therapy in septic shock according to the current guidelines.[6] It is commonly used in other countries where other agents may not be readily available or are relatively expensive.

9 Dopamine has been described as having dose-related receptor activity at D_1-, D_2-, β_1-, and α_1-receptors (see Table 23-4).[5,6,7,8,9,10,11,12,42,43,50,51,52] This dose-response relationship has not been confirmed in critically ill patients. In patients with septic shock, great overlap of hemodynamic effects occur, even at dosages as low as 3 mcg/kg/min. Tachydysrhythmias are common and it is no longer considered a first-line therapy for septic shock.[6] Dopamine may increase PAOP through pulmonary vasoconstriction. It may depress ventilation and worsen hypoxemia in patients dependent on the hypoxic ventilatory drive.

12 Dobutamine, a synthetic catecholamine, is primarily a selective β_1-agonist with mild β_2- and vascular α_1-activity, resulting in strong positive inotropic activity without concomitant vasoconstriction.[6,7,8,9,10,11,12,42,51,52] In comparison with dopamine, dobutamine produces a larger increase in CO and is less arrhythmogenic. α_1-Adrenoceptors in the heart are directly stimulated by the (–) isomer of dobutamine, but β_1 and β_2 activity resides in the (+) isomer. The strong inotropic action of dobutamine is a function of its structure, the additive effect of cardiac α_1- and β_1-agonist activity, and a relatively weak chronotropic effect limited to the (+) isomer action on the β-receptors. Clinically, β_2-induced vasodilation and the increased myocardial contractility with subsequent reflex reduction in sympathetic tone lead to a decrease in SVR. Optimal uses of dobutamine in septic shock are for patients with low CO and high filling pressures (eg, low CI, left ventricular dysfunction demonstrated with echogardiography) or ongoing signs of global or regional hypoperfusion despite adequate resuscitation; however, vasopressors may be needed to counteract arterial vasodilation.[6]

Clinical Controversy… DOBUTAMINE THERAPY

Increasing Do_2 by enhancing cardiac output with dobutamine is based on obtaining Svo_2 or $Scvo_2$ more than or equal to 70% or more than or equal to 65%, respectively in the original study of early goal directed therapy.[19] In the absence of measuring Svo_2 or $Scvo_2$, current guidelines suggest considering dobutamine if cardiac output is low or left ventricular dysfunction is present.[6] The assessment of either of these, however, requires technical methods such as echocardiography that may not be readily available to the bedside clinician. Instead, dobutamine may be tried if regional hypoperfusion is indicated by organ-specific dysfunction despite adequate arterial pressure and fluid resuscitation. This warrants caution as dobutamine may lower systemic vascular resistance and cause hypotension.

14 Unlike adrenergic receptor agonists, the vasoconstrictive effects of vasopressin are preserved during hypoxia and severe acidosis. Initiating vasopressin at less than or equal to 0.04 units/min in patients with septic shock increases SVR and arterial blood pressure to reduce the dosage requirements of catecholamine adrenergic agents.[43,52,53,54] These effects are rapid and sustained. Organ-specific vasodilation reduces pulmonary artery pressure and may preserve cardiac and renal function. It may enhance urine production, likely due to increased glomerular filtration rate.[43,55] At dosages exceeding 0.04 units/min, however, vasopressin is associated with ischemia of the mesenteric mucosa, skin, and myocardium. Limiting the dosage to a maximum of 0.04 units/min may minimize the development of these adverse effects. At present, vasopressin is not recommended as a replacement for norepinephrine in patients with septic shock but may be considered as adjunctive therapy in patients who are refractory to catecholamine vasopressors despite adequate fluid resuscitation.[6] If used for septic shock, vasopressin should be administered at a dosage of 0.03 or 0.04 units/min to not exceed 0.04 units/min.[6,43,52,53]

Desired Outcomes and Clinical Application

Resuscitation Goals of Septic Shock

4 7 9 Initial hemodynamic therapy for septic shock is the administration of intravenous fluid (30 mL/kg of crystalloid fluid), with the aim of using the least amount of fluid and lowest CVP to achieve end organ perfusion. If assessed, the recommended goal CVP is 8 to 12 mm Hg or 15 mm Hg in mechanically ventilated patients or patients with abdominal distension or preexisting ventricular dysfunction.[2,5,6,7,8,9,10,11,12] Greater than 30 mL/kg of crystalloid fluids may be needed to obtain goal MAP, reverse global hypoperfusion (lactate clearance, $Scvo_2$ more than or equal to 70%), or achieve clinical indication of regional organ-specific perfusion (eg, urine production). Therefore dynamic fluid response and clinical assessment should occur frequently following each fluid challenge.[5,6] Current recommendations are to measure serum lactate and administer 30 mL/kg of crystalloid for hypotension within three hours of presentation and obtain MAP more than or equal to 65 mm Hg with vasopressors, reassess volume status, and remeasure serum lactate if the initial lactate was elevated within 6 hours of presentation.[6]

6 9 Crystalloid fluids (eg, normal saline and Ringer lactate) and colloid fluids (eg, albumin, gelatins, dextrans, and blood products) are arguably considered equivalent for shock resuscitation.[6,56,57,58,59,60,61,62] The Saline vs Albumin Fluid Evaluation (SAFE) study randomly assigned 6,997 patients requiring resuscitation to albumin 4% or normal saline (sodium chloride 0.9% solution) and found similar 28-day mortality rates (20.9% vs 21.1%; $P = 0.87$).[56] Secondary outcomes also did not differ although a trend toward lower mortality was apparent in the albumin group in patients with sepsis (30.7% vs 35.3%; $P = 0.09$). A pragmatic multicenter trial of 1,857 patients with hypovolemic shock (including sepsis) also found similar 28-day mortality rates with colloid and crystalloid resuscitation strategies (25.4% vs 27%; $P = 0.26$) but secondary outcomes including 90-day mortality (30.7% vs 34.2%, RR, -0.92; 95% CI, 0.86-0.99; $P = 0.03$) and days alive without mechanical ventilation or vasopressor therapy were improved with colloid therapy.[57] These outcomes were not reported for the subgroup of patients with sepsis. In contrast, exogenous replacement with albumin 20% to target a serum albumin concentration of 3 g/dL found no difference in 28-day mortality (31.8% vs 32%; $P = 0.94$) or 90-day mortality (41.1% vs 43.6%; $P = 0.29$) when compared to crystalloid resuscitation in 1,818 patients with severe sepsis and septic shock.[58] The results of meta-analyses are conflicting with regard to a survival benefit associated with colloid administration; however, they are in agreement that resuscitation with albumin achieves higher values of CVP and MAP more rapidly than crystalloid fluids with a lower overall fluid balance.[59,60,61] Crystalloid fluids are generally preferred as they are readily available at a lower cost unless patients are at risk for adverse events from redistribution of intravenous fluids to extravascular tissues and/or are fluid restricted (eg, patients with renal dysfunction, decompensated heart failure, ascites compromising diaphragmatic function).[2,6,59,60,61,62] In contrast, hydroxyethyl starch (a colloid) is associated with increased risks of acute kidney injury in a dose-dependent manner and mortality.[63,64] The use of hydroxyethyl starch warrants extreme caution and consideration of a dosage threshold if not avoided altogether.

Clinical Controversy... CHOICE OF FLUID FOR RESUSCITATION

Crystalloid fluids (eg, normal saline and Ringer lactate) and colloid fluids (eg, albumin) are arguably considered equivalent for shock resuscitation. Studies are conflicting with respect to mortality differences between normal saline and albumin as this outcome was either similar between groups or

favored albumin. Current guidelines recommend normal saline as the initial fluid of choice for resuscitation and reserving albumin for refractory cases or in situations of clinical evidence of hypervolemia.[6] Many clinicians prefer albumin as this fluid achieves higher values of arterial pressure more rapidly with lower overall fluid balance. Also, the large quantities of chloride in normal saline may contribute to metabolic acidosis. For this reason, some experts suggest the preferred crystalloid is Ringer lactate.

6 8 Norepinephrine is the preferred initial vasopressor agent in septic shock patients not responding to fluid administration.[2,6,50,51,52] Other agents include phenylephrine, epinephrine, dopamine, and the inotrope, dobutamine. Optimizing MAP to 65 mm Hg as the goal of vasopressor therapy does not uniformly correlate with decreased mortality in patients with septic shock but global perfusion may be improved.[13,14,15,16,65] A randomized trial of 776 patients with septic shock failed to show reduced mortality when targeting a higher MAP of 80 to 85 mm Hg compared to 65 to 70 mm Hg (36.6% vs 34%; P = 0.57).[66] Therefore, the goal of resuscitation is a MAP more than or equal to 65 mm Hg, reversal of global hypoperfusion (eg, lactate clearance or $Scvo_2$ more than or equal to 70%), and evidence of regional organ-specific perfusion (eg, urine production).[6,7,8,9,10,11,12] Initial resuscitation of septic shock should be protocolized with quantitative goals achieved within 3 to 6 hours.[6]

6 7 9 10 11 12 13 Dosage titration and monitoring of vasopressor and inotropic therapy should be guided by the "best clinical response," the goals of early goal-directed therapy, and lactate clearance.[2,5,6,7,8,9,10,11,12] Norepinephrine is considered the agent of choice as initial vasopressor therapy.[5,6] Epinephrine may be added to (or substituted for) norepinephrine when suboptimal hemodynamic response is obtained from norepinephrine alone.[6] Phenylephrine may be tried in cases of severe tachydysrhythmias, when CO is known to be high, or as salvage therapy when combination vasopressors including low dose vasopressin fail to achieve goals.[6] Dobutamine is used in states of low CO despite adequate fluid resuscitation pressures (eg, CI less than 3 L/min/m^2, left ventricular dysfunction demonstrated with echocardiography) or ongoing signs of global or regional hypoperfusion despite adequate resuscitation. Low dosage rates of these medications are initiated and titrated rapidly (usually every 5-15 minutes) to clinical response. Clinically effective dosing of vasopressors and inotropes in septic shock often requires dosages much higher than recommended by most references.[2,5,6,7,8,9,10,11,12] These large infusion rates must be tempered with the development of adverse effects. The goal is to use the lowest effective infusion rate while minimizing evidence of global hypoperfusion (lactate, $Scvo_2$) and regional hypoperfusion such as myocardial ischemia (eg, tachydysrhythmias, electrocardiographic changes, and troponin elevations), renal (decreased glomerular filtration rate and/or urine output), splanchnic/gastric (low pHi, bowel ischemia, and elevated transaminases), pulmonary (worsening Pao_2), or peripheral (cold extremities).

14 Vasopressin 0.03 units/min may be considered as adjunctive therapy in patients who are refractory to catecholamine vasopressors despite adequate fluid resuscitation.[5,6] Dosages of less than or equal to 0.04 units/min increases SVR and arterial blood pressure to reduce the dose requirements of catecholamine adrenergic agents.[43,53]

13 Therapy with catecholamine vasopressors and inotropes is continued until myocardial depression and vascular hyporesponsiveness (ie, blood pressure) of septic shock improve, usually measured in hours to days.[6] Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be "weaned" to avoid a precipitous worsening in regional and systemic hemodynamics. Careful monitoring of global and regional end points also should be geared toward discontinuation of vasopressors and inotropes as soon as the patient is hemodynamically stable. This requires constant observation. Because vasopressors and inotropes often are started while the patient is not yet optimally volume resuscitated, clinicians should reevaluate intravascular volume status continuously so that the patient can be weaned from the vasopressor as soon as possible. Dosage rates should be titrated downward approximately every 10 minutes to determine if the patient can tolerate gradual withdrawal and eventual discontinuation of the vasopressor and/or inotrope. Discontinuation of agents may occur only minutes to hours after their initiation, or it may take days to weeks. Septic shock requiring vasopressor and/or inotropic support usually resolves within several days to 1 week.

Comparative Studies of Catecholamine Vasopressors

7 9 The results of several observational and randomized studies support norepinephrine as the first-line vasopressor for septic shock.[6] A meta-analysis of 11 trials (N = 1,718) showed norepinephrine was associated with survival compared to dopamine with an absolute risk reduction of 11% (RR, 0.89; 95% CI, 0.81-0.98; *P* = 0.02).[52] Tachydysrhythmias were less common with norepinephrine (RR, 0.48; 95% CI, 0.40-0.58; *P* < 0.001). The results of two studies contribute to the majority of data. The first randomized 1,679 patients with shock unresponsive to volume resuscitation to norepinephrine or dopamine and found similar 28-day mortality rates (48.5% vs 52.5% of patients; *P* = 0.10) although death from refractory shock tended to occur less frequently with norepinephrine (41% vs 46%; *P* = 0.05).[67] Mortality rate was significantly lower in the subgroup of 280 patients with cardiogenic shock that received norepinephrine (*P* = 0.03). Overall, patients receiving norepinephrine had fewer arrhythmic events (12.4% vs 24.2%; *P* < 0.001) despite using dobutamine more frequently, had more vasopressor-free days, and were less likely to require open-label vasopressor support (20% vs 26%; *P* < 0.001). Limitations of this landmark study include combining heterogeneous shock etiologies (cardiogenic, septic, hypovolemic, and other), the use of a relatively conservative definition of "shock unresponsive to fluid administration" (only 1 L of crystalloid or 0.5 L of colloid), the use of open-label norepinephrine in patients with inadequate hemodynamic response to study drug regimens, and the lack of standardization of other shock therapies that affect hemodynamic variables (eg, corticosteroids, vasopressin, dobutamine, additional fluid administration). Another prospective study of 252 septic shock patients found statistically similar 28-day mortality rates between norepinephrine and dopamine (43% vs 50%; *P* = 0.282).[68] Similar to the aforementioned study, arrhythmic events were less likely to occur with norepinephrine (5.3% vs 23.3%; *P* < 0.0001).

7 9 11 Two randomized, double blind studies compared epinephrine with norepinephrine in 330 and 280 patients with septic shock, respectively.[69,70] Both studies found similar 28-day mortality rates with epinephrine and norepinephrine (40% vs 31%; *P* = 0.31; and 22.5% vs 26.1%; *P* = 0.48). Time to hemodynamic recovery and vasopressor withdrawal were also similar between agents in both studies.

One study found more events of tachydysrhythmias with epinephrine leading to study discontinuation.[69] Both studies also showed that epinephrine was associated with lower arterial pH values and higher serum lactate concentrations over the first days of therapy, possibly demonstrating deleterious circulation, exaggerated glycogenolysis and glycolysis, or mobilization of lactate with epinephrine. These findings support the use of epinephrine in septic shock but it is considered second-line therapy due to its association with impaired lactate clearance.[6]

Vasopressin

14 Small studies of septic shock patients demonstrate that initial therapy with vasopressin achieves blood pressure control as effectively as traditional catecholamine vasopressors but the response is delayed.[43] Therefore, vasopressin therapy should not be initiated as first-line therapy. Several small studies showed that adjunctive vasopressin therapy reduces the dose requirements of catecholamine vasopressors and maintains blood pressure to expedite the discontinuation of catecholamine vasopressors with some documenting enhanced urine production.[43,55] A meta-analysis of 10 trials (N = 1,134) confirmed a negative correlation between vasopressin and norepinephrine dosages.[54] The results of a randomized, double-blind study of 776 patients with septic shock requiring catecholamine vasopressors showed that 28-day mortality rates were similar when vasopressin 0.01 to 0.03 units/min or norepinephrine 5 to 15 mcg/min was added to traditional catecholamine therapy (35.4% vs 39.3%; *P* = 0.26).[53] A trend toward reduced 28-day mortality favored vasopressin in the subset of patients categorized as having less severe septic shock defined by a baseline norepinephrine requirement of less than 15 mcg/min (26.5% vs 35.7%; *P* = 0.05). This trend was evident when sepsis severity was defined by lactate quartiles or number of organ failures, suggesting that adjunctive vasopressin may be most beneficial when it is started prior to escalation of therapy with catecholamine vasopressors. Posthoc analyses demonstrated greatest benefit with early vasopressin treatment relative to the onset of shock. The adverse event profiles were similar between groups. Of note, vasopressin therapy expedited the discontinuation of catecholamine vasopressors in all patients and helped preserve renal function in patients with acutely declining urine production as defined by the injury (doubling of serum creatinine concentration, glomerular filtration rate reduced by half, or urine production less than 0.5 mL/kg/h) category of Risk, Injury, Failure, Loss, End-stage renal disease (RIFLE) criteria.[55] Whereas V_2 stimulation promotes water retention from the distal tubules and collecting ducts, V_1 receptors cause vasoconstriction of efferent arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate, enhancing urine production. Adjunctive use of fixed dosage vasopressin for preventing dose escalation of adrenergic or reducing their dosages should be considered, but the risks must be weighed prior to initiating therapy. At present, vasopressin should not be used for the sole purpose of improving or maintaining renal function nor should dosages exceed 0.04 units/min.[6]

Clinical Controversy… EPINEPHRINE OR VASOPRESSIN

Current guidelines suggest epinephrine or vasopressin may be added to norepinephrine but do not delineate which agent is preferred or when this should occur with respect to resuscitation goals.[6] Adding epinephrine may worsen lactate clearance while adding vasopressin may enhance the

occurrence of ischemic events to digits. Both agents may worsen splanchnic circulation.

Corticosteroids

14 Several randomized controlled trials of low-dose corticosteroids in vasopressor-dependent septic shock patients have been published.[46,47,48] In general, studies demonstrating a survival benefit with corticosteroids administer lower total doses (hydrocortisone equivalents: 1,209 mg vs 23,975 mg; P = 0.01) starting later in septic shock (23 hours vs less than 2 hours; P = 0.02) for longer courses (6 days vs 1 day; P = 0.01) to patients with higher control group mortality rates (mean, 57% vs 34%; P = 0.06) who were more likely to be vasopressor dependent (100% vs 65%; P = 0.03). The results of meta-analyses are conflicting with regard to a survival benefit associated with corticosteroid administration; however, they are in agreement that corticosteroid use improves hemodynamics with more rapid shock reversal and shorter durations of vasopressor support.[47,71,72,73] Corticosteroids do not alter the rates of gastrointestinal bleeding, super infections, and neuromuscular weakness.

14 Two, somewhat discordant, studies contribute to the majority of data surrounding corticosteroid use in septic shock.[48,49] The first randomized 300 patients with septic shock within 8 hours of hypotension to placebo or a daily combination of hydrocortisone 50 mg IV every 6 hours and fludrocortisone 0.05 mg enterally for 7 days and found reduced 28-day mortality with corticosteroid therapy (OR, 0.65; 95% CI, 0.39-1.07; P = 0.09)[48] The placebo group was more likely to continually require vasopressor therapy (HR, 1.54; 95% CI, 1.10-12.16; P = 0.01). These beneficial outcomes were exhibited only in the 77% of patients with adrenal insufficiency as defined by the lack of cortisol response to ACTH administration. The second study randomized 499 of 800 intended subjects with severe sepsis or shock within 72 hours of presentation to placebo or hydrocortisone 50 mg IV every 6 hours for 5 days followed by a 6-day taper.[49] Mortality rates were similar between groups (32% vs 34%), irrespective of adrenal function. Median time to shock reversal was shorter in patients receiving corticosteroid therapy (3.3 vs 5.8 days; P < 0.001), again irrespective of adrenal function. Reversal of organ dysfunction was also expedited with corticosteroid therapy. Unlike the previous study, however, only 47% of patients demonstrated adrenal insufficiency likely reflective of the entry criteria and lower overall mortality rate of the study population.

Clinical Controversy… CORTICOSTEROID THERAPY

Current guidelines do not suggest assessing adrenal function to determine the need for corticosteroid therapy.[6] Instead, they recommend initiating corticosteroids when hemodynamic goals are not achieved with fluid resuscitation or vasopressor therapy. This is controversial given the limitations and differences between studies and the difficulty of determining the adequate achievement of hemodynamic goals in patients requiring vasopressor therapy.

14 A post hoc analysis of the large vasopressin study revealed a significant interaction between vasopressin and corticosteroids.[74] In patients receiving vasopressin therapy, concurrent corticosteroid administration increased vasopressin concentrations by 33% to 67% over the initial 24 hours compared with patients only receiving vasopressin. The addition of corticosteroids to vasopressin was

associated with reduced mortality compared with concurrent administration of corticosteroids and norepinephrine (35.9% vs 44.7%; *P* = 0.03). In the absence of corticosteroid therapy, however, mortality was greater with vasopressin therapy compared with norepinephrine (33.7% vs 21.3%; *P* = 0.06). Similar results have been reported in cohort studies but have not been validated in a prospective trial.

Hemodynamic Considerations and Adverse Effects

5 7 9 10 11 Catecholamine vasopressors may result in adverse peripheral vasoconstrictive, metabolic, and dysrhythmogenic effects that limit or outweigh their positive effects on the central circulation.[6,7,8,9,10,11,12,42,43] Table 23-4 lists potential adverse effects of commonly used vasopressors and inotropes.[5,6,7,8,9,10,11,12,42,43,50,51,52] Excessive peripheral vasoconstriction may cause ischemia or necrosis of already poorly perfused tissues such as the skin and the mesenteric and splanchnic circulations. Some of these profound vasoconstrictive effects may be compounded by under resuscitation with fluid administration prior to initiating the vasopressor or the concurrent use of other vasopressor agents. When these agents are used in the context of late septic shock, where hypotension is refractory to less selective vasoconstrictors (eg, dopamine), large doses of norepinephrine, epinephrine, or phenylephrine are required but provide little or no benefit. Myocardial ischemia and dysrhythmias may occur in patients with coronary artery disease, atherosclerosis, cardiomyopathies, left ventricular hypertrophy, congestive heart failure, or underlying dysrhythmias because of their inability to tolerate β_1 cardiac stimulation that mediates increases in CO. However, in young patients with healthy myocardium, β_1 cardiac stimulation is usually well tolerated, leading to decreased ventricular filling pressures and increased CO and Do_2, with a resulting increase in peripheral perfusion. The dysrhythmogenic potential of catecholamine vasopressors includes a variety of atrial and ventricular arrhythmias. Norepinephrine, phenylephrine, and especially epinephrine can produce lactic acidosis secondary to excessive constriction in peripheral arterioles or enhanced glycogenolysis, or as a result of mobilization of lactate from peripheral tissues as a result of improved oxygenation. Catecholamine vasopressors also have been found to possess immunomodulatory actions, primarily mediated by β_2-adrenergic actions (eg, epinephrine) because almost all immune cells express this receptor. In general, catecholamines inhibit the production of inflammatory cytokines (eg, IL-6 and TNF-α), may enhance anti-inflammatory cytokines (eg, IL-4 and IL-10), suppress oxygen-free radical production from neutrophils, and direct proapoptotic effects. Dopamine suppresses prolactin secretion from the anterior pituitary gland, which may lead to reduced T-cell responsiveness. These anti-inflammatory effects may be either beneficial or deleterious by dampening harmful effects of oxygen-free radical–mediated tissue injury or by reducing neutrophilic defense against bacteria. The clinical significance of these actions on overall mortality in sepsis remains unknown.

Vasopressor catecholamines have the potential to cause extravasation-associated tissue damage if infusions infiltrate during peripheral administration. In the event of infiltration, an α-receptor antagonist such as phentolamine (10 mg in 10 mL saline) should be injected intradermally to reverse local vasoconstriction, with administration of vasopressor drugs into a large central vein.

Norepinephrine

Norepinephrine is the first-line therapy for septic shock as it effectively increases MAP.[2,6,7,8,9,10,11,12] It has combined strong α_1-activity and less potent β_1-agonist effects while maintaining weak vasodilatory effects of β_2-receptor stimulation.[5,6,7,8,9,10,11,12,50] Several studies have demonstrated improved MAP and mortality in ICU patients with severe hypotension treated with norepinephrine either as first-line therapy or after therapeutic failure with fluid resuscitation treatment.[50,51,52]

Norepinephrine infusions are initiated at 0.05 to 0.1 mcg/kg/min and rapidly titrated to preset goals of MAP (usually more than or equal to 65 mm Hg), improvement in global and regional peripheral perfusion (eg, restore urine production, decrease blood lactate), and/or achievement of desired oxygen-transport variables while not compromising the cardiac index. Norepinephrine 0.01 to 2 mcg/kg/min reliably and predictably improves hemodynamic parameters to "normal" values in most patients with septic shock. As with other vasopressors, norepinephrine dosages exceeding those recommended by most references frequently are needed in critically ill patients with septic shock to achieve predetermined goals. A significant increase in MAP generally is caused by an increase in SVR. Heart rate generally does not increase significantly with norepinephrine because of diminished stimulation of cardiac β_1-receptors in septic shock and reflex bradycardia from increased SVR.[5,6,7,8,9,10,11,12,50,51,52] Increasing norepinephrine doses to maintain higher MAPs may increase heart rates, cardiac index, Do_2, and cutaneous blood flow but these results are inconsistent. Older patients may benefit from the combined α- and β-adrenergic effects of norepinephrine given the higher incidence of coronary disease and compromised ventricles in this patient population. By virtue of restored MAP and hence coronary perfusion, cardiac index is increased in older patients, whereas in younger patients with less coronary artery disease and a higher cardiac index at baseline, norepinephrine acts primarily as a vasoconstrictor. Norepinephrine does not influence PAOP.

The effect of norepinephrine on oxygen transport parameters is variable and depends on baseline values and concurrently administered vasoactive agents. In most studies of norepinephrine alone, either an increase or no change in Do_2 is seen with no change in O_2ER, particularly when Do_2 values were "supranormal" prior to therapy. Norepinephrine demonstrates either no effect or improvement in Pco_2 gap, pHi, or serum lactate concentrations. Splanchnic blood flow and fractional blood flow are higher with norepinephrine than either dopamine or epinephrine despite higher CO with the two latter agents.

Taken together, these data suggest that norepinephrine is the primary vasopressor of choice in patients in septic shock because of its multiple benefits: (1) norepinephrine may decrease mortality in septic shock; (2) it reverses inappropriate vasodilation and low global oxygen extraction; (3) it attenuates myocardial depression at unchanged or increased CO and increased coronary blood flow; (4) it improves renal perfusion pressure and renal filtration; (5) it enhances splanchnic perfusion; and (6) it is less likely than other vasopressors to cause tachydysrhythmias.[5,6,7,8,9,10,11,12,50,51,52,53] The primary limitation to use is that norepinephrine is not commercially available as premixed ready-to-use solutions so use requires preparation time. Institutions may stock compounded admixtures in preparation for administration, but they must follow sterile compounding and storage regulations.

Phenylephrine

7 8 10 13 Despite its purported use in refractory septic shock, little information is available regarding the clinical efficacy of phenylephrine. Nevertheless, it is an attractive agent for use in sepsis because of its selective α-agonism with primarily vascular effects.[5,6,7,8,9,10,11,12,51,52] As with other vasopressors, phenylephrine dosages required to achieve goals of therapy are significantly higher than dosages traditionally recommended for use.

Phenylephrine 0.5 to 9 mcg/kg/min, used alone or in combination with dobutamine or low dosages of dopamine, improves blood pressure and myocardial performance in fluid-resuscitated septic patients. Incremental doses of phenylephrine result in linear dose-related increases in SVR and MAP when administered alone as a single agent in stable, nonhypotensive but hyperdynamic, volume-resuscitated surgical ICU patients. In septic shock, phenylephrine does not significantly impair the cardiac index, PAOP, or peripheral perfusion. In sepsis, phenylephrine improves MAP by increasing SVR and stroke index through enhanced venous return to the heart. It improves myocardial performance in hyperdynamic, normotensive septic patients but worsens myocardial performance in cardiac controls. In cardiac patients, myocardial performance worsens as a result of a decrease in the cardiac index and an increase in SVR. Therefore, phenylephrine use warrants caution and should not be used as an initial vasopressor in septic shock patients with impaired myocardial performance.

In septic shock, phenylephrine appears to increase global tissue oxygen use, although data regarding the relationship of the oxygen-transport variables with increases in MAP and cardiac index are conflicting. Increases in Vo_2 appear to be dissociated from Do_2, representing an increase in O_2ER as the cardiac index remains unchanged. Increases in Vo_2 may result from redistribution of blood flow to previously underperfused areas, improving oxygen use as a result of changes in MAP and SVR. Evidence of globally improved peripheral tissue perfusion is observed as lactic acid concentration declines or remains unchanged and urine production increases significantly at increased or maximal Vo_2. An increased O_2ER may contribute to improved tissue response.

Few data regarding the effect of phenylephrine on regional hemodynamics and oxygen-transport variables are available. When phenylephrine replaced norepinephrine in patients with septic shock, phenylephrine selectively reduced splanchnic blood flow and thus splanchnic Do_2 and splanchnic lactate uptake rate without changing the overall splanchnic Vo_2. Concomitantly, pHi decreased and arterial lactate concentrations increased. Because all of these parameters normalized when norepinephrine was reinstated, these data suggest that exogenous β-adrenergic stimulation (norepinephrine) may determine hepatosplanchnic perfusion and oxygen availability but not utilization in septic shock. Phenylephrine and norepinephrine demonstrate similar short-term hemodynamic profiles and indices of global and regional perfusion when used as an initial vasopressor in septic shock.[6,7,8,9,10,11,12]

The available data on hemodynamics, oxygen-transport variables, and mortality with phenylephrine in septic shock patients may not be generalizable because of the small numbers of patients evaluated. Adverse effects, such as tachydysrhythmias, are notably infrequent with phenylephrine, particularly when it is used as a single agent or at higher doses, because phenylephrine does not

exert any activity on β_1-adrenergic receptors. Whether the beneficial effects can be sustained with longer administrations of phenylephrine is unclear. Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmias with use of dopamine or norepinephrine and in patients who are refractory to dopamine or norepinephrine (because of β-adrenergic receptor desensitization).[6,51,52] Its use in patients with myocardial dysfunction warrants caution. Like norepinephrine, it is not commercially available as premixed ready-to-use solutions. Institutions may stock compounded admixtures in preparation for administration but they must follow sterile compounding and storage regulations.

Epinephrine

7 8 11 13 Epinephrine is an acceptable choice for hemodynamic support of septic shock because of its combined vasoconstrictor and inotropic effects but it is associated with tachydysrhythmias and lactate elevation.[5,6,7,8,9,10,11,12,51,52,69,70] As a result, it is considered second line or as adjunctive therapy to norepinephrine.[6] It is as effective as norepinephrine for blood pressure control. Epinephrine infusion rates of 0.04 to 1 mcg/kg/min alone increase hemodynamic and oxygen-transport variables to "supranormal" values without adverse effects in septic patients without coronary artery disease. Large dosages (0.5-3 mcg/kg/min) often are required. Smaller dosages (0.10-0.50 mcg/kg/min) are effective when epinephrine is added to other vasopressors and inotropes. In addition, younger patients appear to respond better to epinephrine, possibly due to greater β-adrenergic reactivity.

Despite a linear dose-response curve with rapid improvement of hemodynamic variables and Do_2, epinephrine has deleterious effects on regional hemodynamics and oxygen utilization. Although Do_2 increases mainly as a function of increases in the cardiac index and a more variable increase in SVR, Vo_2 may not increase, and O_2ER may fall. A decrease in pHi may be seen during epinephrine administration but the impairment in gastric mucosal perfusion can be counteracted in part by dobutamine. This may be explained by the vasodilatory effect of dobutamine on gastric mucosal microcirculation resulting in a redistribution of blood flow toward the mucosa. In contrast to other vasopressors, lactate concentrations frequently rise during epinephrine therapy resulting in variable arterial pH values. When compared with a combination of norepinephrine and dobutamine, epinephrine preferentially decreases splanchnic Do_2, worsens pHi, and increases systemic lactate concentration without increasing Vo_2. The effects of epinephrine on absolute and fractional splanchnic blood flow are more pronounced during severe shock. The increase in lactate may be a result of worsened Do_2 to the liver (and subsequent anaerobic metabolism) or to the hepatosplanchnic circulation, direct increase in calorigenesis and breakdown of glycogen (enhanced aerobic lactate production via β_2-adrenergic receptor stimulation), or lactate mobilization. However, evidence suggests that epinephrine, in contrast to dopamine, increases the proportion of total CO delivered to the splanchnic circulation, although Vo_2 is not increased sufficiently. As a result, O_2ER values are usually lower with epinephrine than with other vasopressors but the concomitant administration of dobutamine helps maintain O_2ER. Of all the vasopressors, epinephrine exhibits the most pronounced capacity to induce hyperglycemia by increased gluconeogenesis and glycogenolysis with α-mediated suppression of insulin secretion.[42]

Despite the administration of high doses, epinephrine-associated clinically important dysrhythmias or cardiac ischemia occur at variable rates irrespective of age or underlying cardiac status.[5,6,7,8,9,10,11,12,51,52,69,70] Nevertheless, caution must be exercised before considering epinephrine for managing hypoperfusion in hypodynamic patients with coronary artery disease, in whom ischemia, chest pain, or myocardial infarction may result. Based on the current evidence, epinephrine may be used as a second-line vasopressor or added on to norepinephrine in patients with septic shock refractory to fluid administration.[6] Although it effectively increases CO and Do_2, it has deleterious effects on the splanchnic circulation. If it is used, factors that may influence successful therapy with epinephrine include the time from onset of septic shock to effective therapy, the age of the population, and the selection of concurrent vasopressors and inotropes. Like norepinephrine and phenylephrine, it is not commercially available as premixed ready-to-use solutions. Institutions may stock compounded admixtures in preparation for administration but they must follow sterile compounding and storage regulations.

Dopamine

7 8 9 13 Dopamine is a natural precursor to norepinephrine and epinephrine and generally not as effective as these two agents for achieving goal MAP in patients with septic shock.[5,6,7,8,9,10,11,12,42,50,51,52] Most studies of patients with septic shock have shown that dopamine at dosages of 5 to 10 mcg/kg/min increase the cardiac index by improving contractility and heart rate, primarily from its β_1 effects. It increases MAP and SVR as a result of both increased CO and, at higher doses (more than 10 mcg/kg/min), its α_1 effects.

The clinical utility of dopamine as a vasopressor in the setting of septic shock is limited because large dosages are frequently necessary to maintain CO and MAP. At dosages exceeding 20 mcg/kg/min, further improvement in cardiac performance and regional hemodynamics is limited. Its clinical use frequently is hampered by tachycardia and tachydysrhythmias, which may lead to myocardial ischemia. Although tachydysrhythmias theoretically should not be expected to occur until administration of dopamine 5 to 10 mcg/kg/min, these β_1 effects are observed with dosages as low as 3 mcg/kg/min. They seem to be more prevalent in patients who are inadequately resuscitated (hypovolemic), in the elderly, in those with preexisting or concurrent cardiac ischemia or dysrhythmias, and in patients currently receiving other dysrhythmogenic agents, including vasopressors and inotropes.

Dopamine increases PAOP and pulmonary shunting to decrease Pao_2. The increase in PAOP may be due to changes in diastolic volumes from decreased cardiac compliance or increased venous return to the heart by α-adrenergic receptor-mediated venoconstriction. This may affect gas exchange and decrease Pao_2. The increase in pulmonary shunting also may result from acute enhancement of pulmonary blood flow to nonhomogeneous lung regions. Thus, dopamine should be used with caution in patients with elevated preload because the drug may worsen pulmonary edema. In the instance of high filling pressures, tachycardia, or tachydysrhythmias, dopamine should be replaced by another vasopressor and/or inotrope such as norepinephrine, dobutamine, phenylephrine, or epinephrine, depending on the desired effect.

The effect of dopamine on global oxygen-transport variables parallels the hemodynamic effects. Although dopamine improves global Do_2 in septic patients, it may compromise O_2ER in the splanchnic and mesenteric circulations by α_1-mediated vasoconstriction. Splanchnic blood flow and Do_2 increase with dopamine, but with no preferential increase in splanchnic perfusion as a fraction of CO and systemic increases in Do_2. Large doses of dopamine worsen pHi and the Pco_2 gap. This is reflected by a decrease or lack of change in regional Vo_2 and a decrease in tissue O_2ER. Dopamine at low or vasopressor dosages directly impedes gastric motility in critical illness and may aggravate gut ischemia in septic shock. Similar to high-dose administration, low-dose dopamine increases splanchnic blood flow but lowers splanchnic Vo_2 in sepsis. Therefore, dopamine at all dosages impairs hepatosplanchnic metabolism despite an increase in regional perfusion. Low dosages increase renal blood flow and glomerular filtration rate in studies of animals and healthy volunteers but did not demonstrate improved renal function in a randomized, placebo-controlled study of 328 critically ill patients with early renal dysfunction.[75] A meta-analysis of 61 trials (N = 3,359) confirmed that low-dose dopamine fails to enhance renal function or survival in critically ill patients.[76]

While dopamine may improve hemodynamic function, the use of dopamine for septic shock is questionable because regional hemodynamics, oxygen-transport variables, and functional parameters of improved organ perfusion are not consistently enhanced in a sustained manner and may be negatively impaired.[6] The negative findings of low-dose dopamine use and the deleterious effects of inotropic and vasopressor dosages of dopamine on regional hemodynamics, oxygen transport, and functional performance of organ perfusion raise concern over whether dopamine should even be considered in patients with severe sepsis or septic shock.[6,75] Unlike other vasopressor agents, however, dopamine is commercially available as premixed ready-to-use solutions of various concentrations that can be stored in automated dispensing systems for rapid initiation.

Dobutamine

6 7 12 13 Dobutamine is an inotrope with vasodilatory properties (an "inodilator").[5,6,7,8,9,10,11,12,42] It is used for treatment of septic and cardiogenic shock to increase the cardiac index, typically by 25% to 50%.[6] In septic shock, LVEF and right ventricular function are depressed despite a high cardiac index, whereas ventricular volumes and compliance are increased. Stroke index is maintained by an increased heart rate and ventricular dilation. In survivors, myocardial depression is reversible and normalizes 5 to 10 days after the onset of sepsis. Dobutamine increases stroke index, left ventricular stroke work index, and thus cardiac index and Do_2 without increasing PAOP.[6,7,8,9,10,11,12] It also enhances chronotropy effect. However, dosage increments of dobutamine beyond 20 mcg/kg/min are limited by complications of tachycardia, ischemic changes on electrocardiogram, hypertension, and tachydysrhythmias despite the absence of preexisting cardiac abnormalities. The combination of dobutamine and norepinephrine results in a lower increase in heart rate compared with use of epinephrine alone.

Increased cardiac performance measures in response to adjunctive dobutamine therapy are predictive of survival during sepsis. However, the achievement of supranormal oxygen transport values with dobutamine is of little value compared with treatment to normal values. In addition,

administration of dobutamine to achieve these high values may increase mortality rate and/or the incidence of adverse effects. Dobutamine increases Do_2 without affecting Vo_2, resulting in decreased O_2ER. Arterial lactate concentrations decrease significantly with norepinephrine and dobutamine compared with dopamine and epinephrine infusions.

Studies have focused on the effects of dobutamine on gastric mucosal flow and the splanchnic circulation. The addition of dobutamine to other vasopressors improves gastric mucosal perfusion without increasing the cardiac index. This is consistent with findings that dobutamine may improve pHi and mucosal perfusion in septic patients. The addition of dobutamine to norepinephrine or epinephrine treatment improves gastric mucosal perfusion as measured by improvements in pHi and Pco_2 gap. This effect may relate to blood flow redistribution toward gastric mucosa, due to either an increase in the fraction of CO distributed to the global hepatosplanchnic blood flow and/or a redistribution of blood flow within gastric wall layers toward the mucosa by "stealing" blood away from the muscularis potentially as a result of greater β_2-mediated vasodilation. Sublingual microcirculation improves after dobutamine is added to vasopressor-dependent septic shock patients in a manner unrelated to arterial pressure or cardiac index, suggesting that enhanced perfusion is the result of the "steal" phenomenon. Of note, gastric mucosal perfusion and tissue oxygen utilization are most improved with concurrent norepinephrine and dobutamine therapies compared with other vasopressor combinations at the same level of MAP.

Dobutamine should be started at dosages ranging from 2.5 to 5 mcg/kg/min. In the studies of early goal-directed therapy, dobutamine was administered to 13.7% to 18.1% of patients within 6 hours of resuscitation to achieve $Scvo_2$ more than or equal to 70%.[19,20,21,22,23,24] While dobutamine was only administered to 0.8% to 7.5% of subjects in the groups receiving usual aggressive care which did not include $Scvo_2$ monitoring, overall mortality rates across all studies did not differ.[24] Therefore, dobutamine administration purely to achieve a $Scvo_2$ more than or equal to 70% is not best clinical practice. Current guidelines recommend a trial of dobutamine infusion up to 20 mcg/kg/min in the presence of myocardial dysfunction (elevated cardiac filling pressures, low CO, and echocardiography displaying left ventricular dysfunction) or continued signs of global or regional hypoperfusion despite meeting volume and MAP goals.[6] Although a dose response may be seen, evidence suggests that dosages more than 5 mcg/kg/min may provide limited beneficial effects on oxygen transport values and hemodynamics and may increase adverse cardiac effects. If given to patients who are intravascularly depleted, dobutamine will result in hypotension and a reflexive tachycardia. Pathophysiologic factors influence dosing requirements and pharmacokinetic parameters over the time course of the illness and the duration of the infusion. Decreases in PaO_2, as well as myocardial adverse effects such as tachycardia, ischemic changes on electrocardiogram, tachydysrhythmias, and hypotension are seen. Thus, infusion rates should be guided by clinical end points, echocardiography, and global perfusion goals. Dobutamine, like other inotropes, usually is given until improvement in myocardial function with resolution of the septic episode or dose-limiting side effects are observed. Dobutamine is commercially available as premixed ready-to-use solutions.

Vasopressin

14 Studies involving vasopressin infusion for management of septic shock show rapid and sustained improvement in hemodynamic parameters.[43,53,54,55] These effects are evident with administration of dosages not exceeding 0.04 units/min. Administration of dosages more than 0.04 units/min are associated with negative changes in CO and mesenteric mucosal perfusion. The reduction in CO likely is the result of lowered stroke volume.[43] The studies that reported cardiac function indicate patients had adequate CO prior to initiating vasopressin therapy. Cardiac ischemia appears to be a rare occurrence when low dosage rates are used. Therefore, higher dosages of vasopressin in septic shock patients with cardiac dysfunction warrant extreme caution.

Mesenteric ischemia associated with vasopressin may be clinically relevant. Increased hepatic transaminases and total bilirubin concentrations may occur with vasopressin therapy, suggesting impaired hepatic blood flow or a direct effect on excretory hepatic function.[43] While mesenteric vasoconstriction occurs at vasopressin serum concentrations as low as 10 pg/dL, the results of studies indicate that vasopressin dosages exceeding 0.04 units/min worsen pHi or PCO_2 gap when it is added to low or high doses of catecholamine vasopressors.[43] The effect is additive with norepinephrine despite substantially reduced dosages of norepinephrine when vasopressin is initiated.

Vasopressin's strongest vasoconstrictive action occurs in the skin and soft tissues, skeletal muscles, and fat tissues.[43] As a result, ischemic skin lesions have been observed in several studies, with an occurrence rate as high as 30% after vasopressin was added to norepinephrine-resistant shock.[43] Although vasopressin may have deleterious effects on mesenteric and skin perfusion, studies report vasodilation of cerebral, pulmonary, coronary, and some renal vasculature beds. The clinical outcomes associated with selective vasodilation are not yet known except for the possibility of enhanced urine production in patients not anuric at baseline.[55]

In order to minimize the potential for adverse events and maximize the beneficial effects, vasopressin should be used as add-on therapy to catecholamine adrenergic agents rather than as first-line therapy or salvage therapy and dosages should be limited to 0.04 units/min (generally fixed dose of 0.03-0.04 units/min).[5,6,43] The results of studies showed that vasopressin markedly reduced the requirements for adrenergic agents, but few studies demonstrated complete discontinuation of these therapies.[43,53,54] Therefore, vasopressin should be used when response to one or two adrenergic agents is inadequate or as a method for reducing the dosage of these therapies.[6] Increased arterial pressure should be evident within the first hour of vasopressin therapy, at which time the dose(s) of adrenergic agent(s) should be reduced while maintaining goal MAP. This method should help limit the degree of ischemia.

Most studies evaluated vasopressin use for less than 48 hours, and several studies reported difficulty discontinuing vasopressin therapy. Whether additional benefits, deleterious effects, or tolerance is observed with longer infusions remains unclear. Long-term administration of vasopressin is associated with hyponatremia and thrombocytopenia. Because vasopressin is being used to replace a physiologic deficiency, it stands to reason that the requirement for vasopressin will subside with reversal of the septic process. Attempts to discontinue vasopressin should occur when the dosage(s) of adrenergic agent(s) has been minimized (eg, dopamine less than or equal to 5 mcg/kg/min,

norepinephrine less than or equal to 0.1 mcg/kg/min, phenylephrine less than or equal to 1 mcg/kg/min, and epinephrine less than or equal to 0.15 mcg/kg/min). Vasopressin is not available as premixed ready-to-use solutions.

Corticosteroids

14 Corticosteroids can be initiated in cases of septic shock when adrenal insufficiency is suspected (eg, patients receiving long-term corticosteroid therapy for other indications prior to the onset of shock), when vasopressor dosages are escalating, or when weaning of vasopressor therapy proves futile.[5,6,45,46,47,48,72,73] Assessment of adrenal function to guide therapy is not recommended.[6] Adverse events are few because corticosteroids are administered for a finite period of time, usually 7 days. Acutely, elevated serum concentrations of blood urea nitrogen, white blood cell count, glucose, and sodium occur. Although long-term administration of corticosteroids is associated with several chronic disease states, meta-analyses do not show an increase in major adverse events, including gastrointestinal hemorrhage, superinfections, and neuromuscular weakness.[46,47,72,73] Therefore, therapy of septic shock with corticosteroids improves hemodynamic variables and lowers catecholamine vasopressor dosages with minimal to no effect on patient safety.[6]

EXPERIMENTAL THERAPIES

Nitric Oxide Inhibitors

Nitric oxide is a short-acting, potent vasodilator derived from enzymatic oxidation of arginine. Its production is under control of NOS. This enzyme is present (expressed) in two forms: (1) a constitutive form (ecNOS) and (2) an inducible form (iNOS). Small amounts of NO normally are produced by the vascular endothelium under the control of ecNOS for physiologic control of vascular tone and blood flow distribution. Under pathophysiologic conditions such as stimulation by lipopolysaccharide or cytokines, iNOS becomes diffusely expressed, producing large amounts of NO. The latter has been implicated in the cardiovascular failure of septic shock.

Pharmacologic inhibition of NO production has been investigated as an adjunct to standard therapies of septic shock.[77,78] L-Arginine analogs, such as monomethyl-L-arginine (L-NMMA) and L-arginine-methylester (L-NAME), are competitive inhibitors of NOS and have been shown to increase blood pressure, partially restore vascular reactivity, and reduce vasopressor use. However, because these arginine analogs nonselectively block ecNOS and iNOS, their use has been associated with extensive vasoconstriction, decreased CO, and regional hypoperfusion, thus promoting organ failure and mortality.[78,79] Some *S*-substituted thiourea derivatives have demonstrated, both in vitro and in vivo (rodent), dose-dependent selectivity for iNOS inhibition, but the clinical application must be evaluated. Several phase I/IIa clinical trials of septic shock patients are underway.

Pyridoxalated hemoglobin polyoxyethylene is a scavenger of NO. A phase II study of 62 patients with vasodilatory shock requiring vasopressors showed that an infusion of 20 mg/kg/h for up to 100 hours rapidly increased blood pressure and shortened the duration of vasopressor therapy.[80] However, a

Phase III study was terminated early due to a signal of increased mortality in more severely ill patients with pyridoxalated hemoglobin polyoxyethylene despite favorable vasopressor-free survival time.[81]

Methylene Blue

Methylene blue counteracts ecNOS, iNOS, and soluble guanylate cyclase to reduce serum concentrations of NO and cyclic guanosine monophosphate.[82] Despite these effects, methylene blue does not alter the expression of inflammatory cytokines. Clinically, methylene blue at dosages of 0.25 to 3 mg/kg/h increases SVR, MAP, myocardial contractility, and Do_2 in septic shock patients refractory to vasopressors while improving Pco_2 gap.[82] Dosages exceeding 3 mg/kg/h worsen splanchnic perfusion. It may increase pulmonary vascular resistance, potentially worsening oxygenation. Additional studies are needed before methylene blue can be recommended; at present, it has been used only for salvage therapy.

Terlipressin

Terlipressin, a prodrug that is converted into lysine vasopressin, has been used in septic shock patients and is available in other countries.[12] This drug has a half-life of 6 hours and acts via vascular V_1 receptors and renal tubular V_2 receptors. Terlipressin increases MAP to a greater extent than norepinephrine when it is used as the initial vasopressor in septic shock. Despite a decrease in CO, heart rate, and Do_2I, terlipressin increases gastric mesenteric perfusion, urine production, and creatinine clearance while reducing lactate concentration. Both terlipressin and vasopressin increase blood pressure and decrease heart rate to the same extent but terlipressin is associated with less supplemental norepinephrine usage and improved mesenteric perfusion.[12] These preliminary findings suggest that a clinical trial evaluating mortality as well as hemodynamic effects should be conducted with terlipressin.

Levosimendan

Levosimendan is a novel inotropic and vasodilator calcium-sensitizing drug.[83] In acute decompensated heart failure, it improves cardiac contractility by sensitizing troponin C to calcium. In septic shock patients with and without left ventricular dysfunction, levosimendan 0.1 to 0.2 mcg/kg/min decreases PAOP, increases LVEF and cardiac index, improves mesenteric and sublingual perfusion, and enhances urine production.[83] Levosimendan improves $Scvo_2$ to the same extent as dobutamine when it is used in early goal-directed therapy. Levosimendan is associated with declining serum lactate concentrations. The results of a meta-analysis of seven studies (N = 246) suggest it is associated with reduced mortality compared to traditional inotropes when used in severe sepsis.[84] While additional clinical trials of levosimendan in septic shock are needed, increased mortality was demonstrated in studies of acute decompensated heart failure.

Esmolol

High sympathetic stress and excessive adrenergic tone may, in part, lead to many sequelae seen in

late septic shock including myocardial dysfunction.[85] Contrasting the proposed benefits of stimulating β-adrenergic activity in septic shock, a study of 154 hemodynamically "optimized" patients (PAOP more than or equal to 12 mm Hg, CVP more than or equal to 8 mm Hg, Svo_2 more than 65% and MAP more than or equal to 65 mm Hg) with septic shock requiring norepinephrine with a heart rate more than 94 beats per minute were randomized to receive esmolol to a goal heart rate of 80 to 94 beats per minute or standard of care.[86] Patients were excluded if they had cardiac dysfunction or significant valvular heart disease. The esmolol group had significantly lower heart rate and higher stroke volume while maintaining similar MAP values despite lower SVR and norepinephrine requirements. Do_2, Vo_2, fluid requirements, acidosis, serum lactate, and markers of myocardial injury were decreased in the esmolol group. Mortality at day 28 was lower in the esmolol group (49.4% vs 80.5%; $P < 0.001$), although this was a secondary outcome. The concept of targeted heart rate control requires additional study before application occurs in practice.

Other Therapies

As with vasopressin and cortisol, critical illness impairs hypothalamic-pituitary function, producing relative deficiencies of triiodothyronine (T_3) and thyroxine (T_4). This condition, referred to as *euthyroid sick syndrome*, may contribute to hypotension and mortality.[87] Concentrations of thyrotropin-releasing hormone and thyroid-stimulating hormone are inappropriately low. Measured concentrations of free T_3 and T_4 may be low or normal, but synthesis is consistently impaired. Only scant data regarding the replacement of these hormones in critically ill patients are available, and the results are variable, depending on the extent of additional hormone replacement (growth hormone, gonadotropin-releasing hormone, leptin, insulin, thyrotropin-releasing hormone, and thyroid-stimulating hormone). Given the data for replacing vasopressin and cortisol in septic shock, it is reasonable to assume that one day a "thyroid replacement" regimen will be offered as an adjunctive treatment to vasopressors.

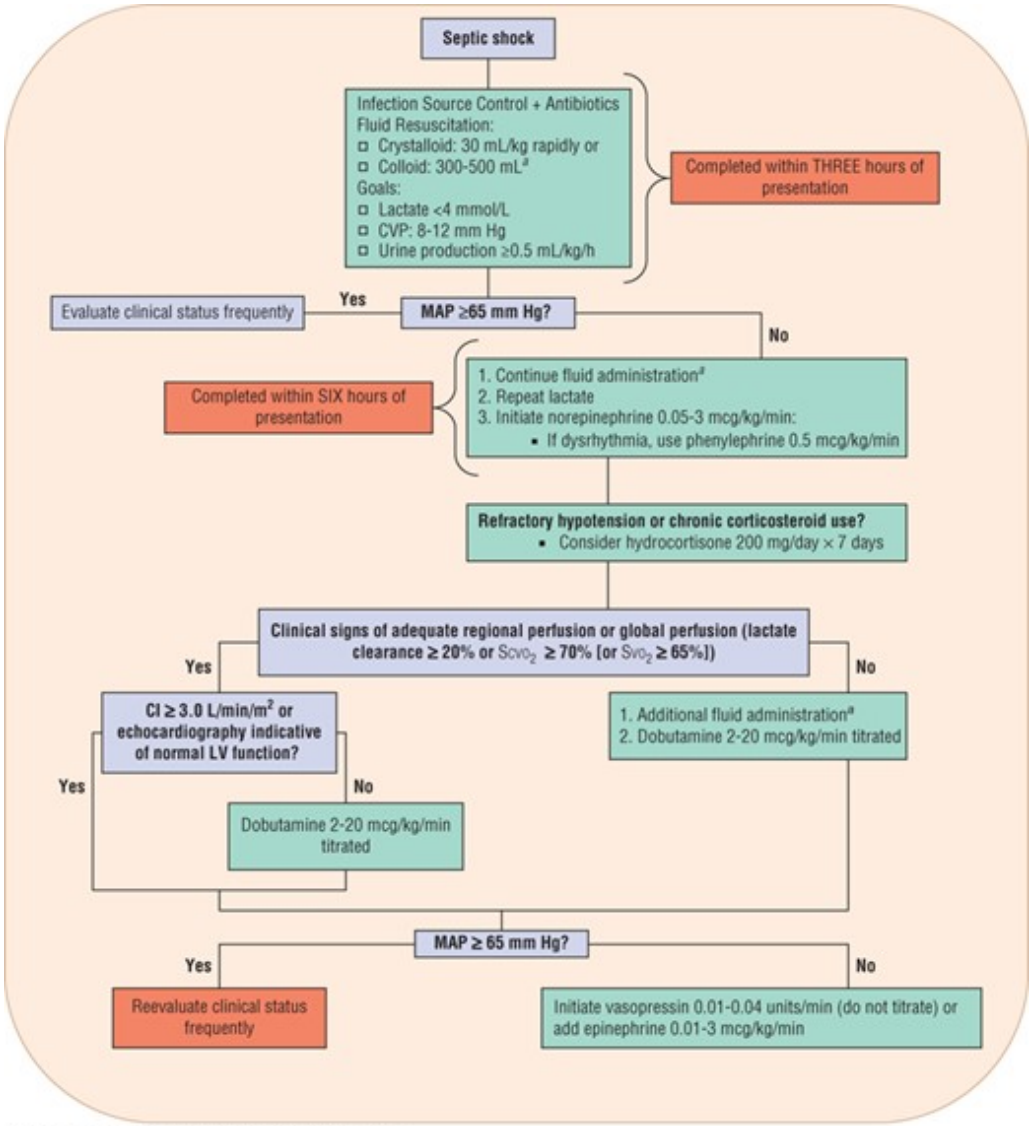
GENERAL CONCLUSION AND RECOMMENDATIONS

Norepinephrine is the recommended first-line vasopressor for septic shock.[6] The choice of additional vasopressor or inotropic agents should be made according to the clinical needs of the patient and the data obtained from hemodynamic and global and regional perfusion monitoring.[2,5,6,7,8,9,10,11,12,13,14,15] **Figure 23-2** presents an algorithm for the management of septic shock.[2,5,6,7,8,9,10,11,12] This algorithm suggests a stepwise approach of early goal-directed therapy to optimize MAP, first with fluid resuscitation and using norepinephrine. Dobutamine may be added for states low CO or left ventricular dysfunction or to optimize lactate clearance or Svo_2/$Scvo_2$. Occasionally, epinephrine and phenylephrine are used when necessary. Although this approach is empirical, it is used broadly in clinical practice and has been justified by the desire to avoid the adverse events associated with strong vasoconstriction. Developing a strategy to rapidly titrate therapy early in the course of illness to predetermined values reduces mortality. Goals of initial resuscitation should include fluids to achieve CVP of 8 to 12 mm Hg, vasopressor agents to achieve MAP at least 65 mm Hg, and frequent clinical assessments to meet global and regional perfusion

goals (eg, additional fluid challenge or inotropic therapy to achieve lactate clearance more than or equal to 20% or $Scvo_2$ more than or equal to 70% or urine production output to more than or equal to 0.5mL/kg/h).[2,5,6] For all catecholamine vasopressors, doses higher than recommended traditionally are required for goal-directed therapy to achieve goal MAP and for normalization of oxygen-transport variables. Patients who develop supranormal Do_2 and Vo_2 values have lower mortality, but targeting these with exogenous administration of vasopressors/inotropes is not beneficial and cannot be recommended. Further work is required to better elucidate the differential effects of vasopressors on regional hemodynamic and oxygen-transport values as measures of local tissue perfusion.

FIGURE 23-2

Algorithmic approach to resuscitative management of septic shock. Algorithmic approach is intended to be used in conjunction with clinical judgment, hemodynamic monitoring parameters, global and regional perfusion goals, and therapy end points, as discussed in the text. [a]Colloid (albumin) may be initiated in patients at risk for adverse events from redistribution of intravenous fluids to extravascular tissues (eg, patients with renal dysfunction, decompensated heart failure, ascites compromising diaphragmatic function), those that are fluid restricted, or those not responding to crystalloid therapy. (Abbreviations: CI, cardiac index; CVP, central venous pressure; echo, echocardiography; Hct, hematocrit; MAP, mean arterial pressure; $Scvo_2$, central venous oxygen saturation; Svo_2, mixed venous oxygen saturation.) (*Data from references 2, 5, 6, 7, 8, 9, 10, 11, 12.*)



Clinical Controversy… PERFUSION GOALS OF EARLY GOAL-DIRECTED THERAPY

The goal of resuscitation is to reverse tissue hypoxia by facilitating Do_2. Both Svo_2 and $Scvo_2$ measure global tissue perfusion. Current guidelines recommend targeting Svo_2 or $Scvo_2$ more than or equal to 70% or more than or equal to 65%, respectively, based on the original study of early goal directed therapy.[6,19] In contrast, the results of three large multicenter studies conducted after the guidelines were published found usual care without the assessment of Svo_2 or $Scvo_2$ resulted in similar survival outcomes as strategies of early goal directed therapy that incorporated these as goals of global perfusion.[21,22,23] Lactate clearance reliably assesses tissue perfusion and predicts survival. The decision to use Svo_2 or $Scvo_2$ as a goal of early goal directed therapy will depend on clinician's preference and patient's characteristics but the guidelines will be revised to include lactate clearance. Many clinicians already apply lactate clearance as a goal of global perfusion in addition to organ-specific indicators of regional perfusion as end points of early goal directed therapy that should be achieved within 3 to 6 hours of sepsis presentation.

This algorithmic approach (see Fig. 23-2) is consistent with the recommendations made in the

Surviving Sepsis Campaign[6] and the American College of Critical Care Medicine's guidelines to the hemodynamic support of adult patients with sepsis (see Table 23-2).[2,4,5,6,7,8,9,10,11,12,13,14,15,16] Personalized pharmacotherapy (**Table 23-5**) for hemodynamic support of shock may be rationale in certain situations (such as long standing baseline hypertension, or home corticosteroid use) but may be difficult to achieve because patient response is variable and the acute nature of emergent resuscitation often necessitates treatment before pharmacotherapy can be personalized. In the future, vasopressor therapies may be directed to pharmacogenomic profiles as recent research indicates effectiveness and safety may be influenced by gene polymorphisms.

TABLE 23-5 Personalized Pharmacotherapy for Shock

Situational Considerations	Pharmacotherapy
Initial vasopressor of choice for resuscitation	Norepinephrine
Rapidly progressing shock requiring IMMEDIATE therapy	Dopamine
Presence of tachydysrhythmia	Phenylephrine
Healthy myocardium (eg, young patients)	Epinephrine
Acutely declining renal function	Vasopressin
Myocardial dysfunction (elevated filling pressures and low CO)	Dobutamine
Regional hypoperfusion despite adequate intravascular volume (eg, lactate clearance <20% or $ScvO_2$ <70% or SvO_2 <65%)	Dobutamine
MAP <65 mm Hg despite norepinephrine	Vasopressin or epinephrine
Vasopressor refractory shock	Corticosteroid

CO, cardiac output; MAP, mean arterial pressure; $Scvo_2$, central-venous oxygen saturation; Svo_2, mixed venous oxygen saturation.

Although difficult to demonstrate, true differences in clinical outcomes as a result of differences in the pharmacologic activity of vasopressors and inotropes may exist. For example, evidence suggests that norepinephrine, when used appropriately with fluid replenishment, is safe and effective in treating septic shock; it decreases mortality, particularly when started early in the course of septic shock. It is effective in optimizing hemodynamic variables and improving systemic and regional (eg, renal, gastric mucosal, and splanchnic) perfusion. Epinephrine causes a greater increase in the cardiac index and Do_2 and increases gastric mucosal flow but may not preserve splanchnic circulation adequately. It may cause increases in lactic acid. Epinephrine, however, may be particularly useful when used earlier in the course of septic shock in young patients. Unlike epinephrine, dopamine does not increase the proportion of CO that preferentially goes to the splanchnic circulation. The ability of dopamine to increase CO by no more than 35% accompanied by a tachycardia or tachydysrhythmias limits its utility. Dopamine, as opposed to norepinephrine, has been shown to worsen splanchnic Vo_2 and O_2ER and is of limited value in improving urine production. Low-dose dopamine has not been shown consistently to increase the glomerular filtration rate, does not prevent renal failure, and actually worsens splanchnic tissue oxygen utilization and therefore should not be used. Phenylephrine may be used when a pure vasoconstrictor is desired in patients who may not require

or cannot tolerate the β-effects of other vasopressors or inotropes. In patients with a high filling pressure and hypotension, the combination of phenylephrine and dobutamine may be useful.

Shortcomings of study methodology prevent the establishment of definitive conclusions regarding catecholamines. As a consequence, published guidelines for the management of severe sepsis and septic shock have many inconclusive recommendations (see Table 23-2). Short infusions during studies may show differences that are not clinically significant after 24 hours, as demonstrated for epinephrine and dobutamine. Most studies comparatively evaluated vasopressors once patients were hemodynamically stable as the process of obtaining consent and randomization precluded the initiation of study drug during early resuscitation. Clinically, vasopressors and inotropes are used for hours to days. Possible confounding factors are the variable times at which studies are initiated with respect to the stage of sepsis or septic shock, the inherent differences in circulating catecholamine concentrations, changes in receptor activity, as well as differences in prestudy duration and type of exogenous catecholamine administration.

Initial studies with vasopressin suggest a potential role in the management of vasopressor-dependent septic shock patients. Vasopressin reduces the requirements of adrenergic agents while maintaining hemodynamic function. While it may enhance urine production, it is associated with mesenteric and peripheral ischemia. Therefore, fixed dose vasopressin should be used if response to one or two adrenergic agents is inadequate or as a method for reducing the dosage of these therapies. Close monitoring of ischemic events is needed. Data indicate that moderate doses of hydrocortisone (200-300 mg/day) administered over several days may reverse septic shock and dependency on vasopressor agents. Given the discrepancy of the current data, corticosteroids may be administered to patients with septic shock refractory to vasopressors or when adrenal insufficiency is suspected. Data on optimal dosage regimens and definitive outcomes still are needed.

Further pharmacotherapeutic and outcomes studies are required to elucidate the place in therapy of individual vasopressors and inotropes or their combinations in the supportive care of patients with bacteremia or septic shock. As supportive therapy, it is imperative that primary therapy aimed at the source of (antimicrobials) and consequences of (anticytokines) infection be initiated quickly to afford the patient the best chance of survival.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACTH	adrenocorticotropic hormone
ATP	adenosine triphosphate
CaMK	calcium–calmodulin-dependent protein kinase
cAMP	cyclic adenosine monophosphate
CaO_2	arterial oxygen content
CI	cardiac index
CO	cardiac output
CO_2	carbon dioxide

Cvo_2	venous oxygen content
CVP	central venous pressure
Do_2	oxygen delivery
Do_2I	oxygen delivery index
ecNOS	constitutive nitric oxide synthase
HR	hazard ratio
ICU	intensive care unit
IL	interleukin
iNOS	inducible nitric oxide synthase
L-NAME	L-arginine-methylester
L-NMMA	monomethyl-L-arginine
LVEF	left ventricular ejection fraction
MAP	mean arterial pressure
NO	nitric oxide
NOS	nitric oxide synthase
O_2ER	oxygen extraction ratio
OR	odds ratio
$Paco_2$	partial pressure of arterial carbon dioxide pressure (tension)
Pao_2	partial pressure of arterial oxygen (tension)
PAOP	pulmonary artery occlusion pressure
Pco_2	gut luminal partial pressure of carbon dioxide
pHi	intramucosal pH
PLC	phospholipase
$Pslco_2$	sublingual carbon dioxide pressure
RR	relative risk
SAFE	Saline vs Albumin Fluid Evaluation
Sao_2	arterial oxygen saturation
$Scvo_2$	central-venous oxygen saturation
Svo_2	mixed-venous oxygen saturation
SVR	systemic vascular resistance
T_3	triiodothyronine
T_4	thyroxine
TNF	tumor necrosis factor
Vo_2	oxygen consumption
Vo_2I	oxygen consumption index

Chapter 24: Hypovolemic Shock

Brian L. Erstad

INTRODUCTION

KEY CONCEPTS

- 1 Plasma does not have to be lost from the body for hypovolemic shock to occur.
- 2 Patients may die of hypovolemic shock despite having normal serum electrolyte concentrations.
- 3 Although the Starling's equation of fluid transport is useful for understanding the factors involved in fluid shifting between compartments, it is not a practical tool for use in the clinical setting.
- 4 Patients may have complications and death as a result of reperfusion injury as well as the initial insult.
- 5 The clinical presentation of patients with hypovolemic shock can vary substantially, depending on concomitant disease states, medications, and cause of hypovolemia.
- 6 The initial monitoring of a patient with suspected intravascular depletion always should include vital signs, urine output, mental status, and physical examination.
- 7 The need for intravenous (IV) (vs oral) rehydration in children often is overestimated.
- 8 Crystalloid (sodium-containing) solutions should be used for most forms of circulatory insufficiency that are associated with hemodynamic instability.
- 9 Neither crystalloids nor colloids have the oxygen-carrying properties of red blood cells.
- 10 Vasoactive medications should not be considered for hypovolemic shock until fluid resuscitation has been optimized.

This chapter discusses the assessment and management of hypovolemic shock. Other forms of shock

such as obstructive (eg, cardiac tamponade), distributive (eg, spinal cord injury, septic or anaphylactic shock), and left ventricular dysfunction (eg, myocardial infarction, arrhythmia) often are considered separately from hypovolemic shock because fluid loss from the body is not necessary for their occurrence. Although these forms of shock are not discussed in detail, it is important to note that intravenous (IV) fluid administration (in conjunction with vasoactive medications) is a mainstay of therapy because circulating volume is decreased. In this regard, adequate fluid resuscitation to maintain circulating blood volume is a common principle in managing all forms of shock.

EPIDEMIOLOGY

Because shock is not a reportable category by state and federal agencies that track causes of death, the incidence is unknown. Estimates of deaths due to shock are complicated by differences in definitions and classification systems. Part of the problem is defining when progressive circulatory insufficiency results in the loss of normal compensatory responses by the body, which could reverse the processes leading to irreversible organ dysfunction. This loss of appropriate compensation varies from patient to patient and is not always readily apparent during the initial patient presentation. Therefore, forms of hypovolemic shock, such as hemorrhagic shock, are subsumed by more readily identifiable categories of death, such as accidental injuries and homicides. Crude and conservative estimates of death due to hypovolemic shock are available for some of its forms. More than 39 deaths per 100,000 standard population occur each year in the United States due to unintentional injuries that frequently involve bleeding,[1] and more than 600 deaths each year are due to natural heat-related illness.[2] The figures are much higher when considered on a global basis. For example, electrolyte depletion and dehydration due to diarrheal disease result in approximately 2 million deaths each year in children younger than 5 years.[3] The most liberal estimates of death include all causes of circulatory failure (ie, the last stage of shock).

ETIOLOGY

1 Hypovolemic shock is extracellular volume depletion that may result from blood loss (plasma and red blood cells) due to trauma, surgery, or internal hemorrhage or from plasma loss due to fluid sequestered within the body or lost from the body (**Table 24-1**). In some cases, such as in postoperative patients, a number of these problems occur at the same time. For example, a patient may have blood loss secondary to trauma or surgery, with additional fluid being third spaced (eg, as tissue edema in the gastrointestinal [GI] tract with a concomitant ileus) and lost through a high-output GI fistula postoperatively. As this example of third-spaced fluid indicates, fluid (ie, plasma) does not have to be lost from the body for a person to develop hypovolemic shock, although the fistula output would clearly aggravate the situation. Approximately 10 L of fluid is secreted and reabsorbed daily in the GI tract; so, it is not surprising that volume loss could be substantial depending on the location of the fistula and function of the tract preceding the fistula.

TABLE 24-1 Causes of Hypovolemic Shock[a]

Decreased blood (plasma + red blood cells) volume

External: Surgery or trauma

Internal (eg, cerebral, chest, GI and other abdominal sources, long bone fractures, and retroperitoneum)

Decreased plasma volume

External: Losses from urine, GI tract (eg, vomiting, nasogastric suctioning, fistula, and diarrhea), lungs, or skin (including thermal injury)

Internal (decreased oncotic pressure or increased capillary permeability): fluid accumulation in bowel, peritoneal or pleural cavities

GI, gastrointestinal.

[a]Shock may result from various combinations of blood and plasma volume losses listed (ie, causes are not mutually exclusive).

The term dehydration implies primary intracellular water depletion, in contrast to volume depletion, which implies extracellular, and particularly intravascular, sodium and water loss. However, there is substantial overlap in the definitions and use of terms such as dehydration and volume depletion in the medical literature, so the reader must be cognizant of the intended meaning. Dehydration may result from primary water deficiency, usually because of decreased intake, but in some instances (eg, diabetes insipidus) it may result from increased losses of water. With most forms of dehydration, such as those caused by diarrheal disease and heat-related illness, a combination of inadequate intake and higher than normal losses occurs. Initially with intracellular water depletion, the patient may be thirsty and possibly have some mental status changes, such as confusion. If cellular dehydration occurs slowly, intracellular substances, referred to as *idiogenic osmoles,* develop that limit progressive complications (eg, cerebral edema or coma). Death due to primary water deficit, if it occurs, is usually a result of delayed circulatory failure. With combined water and salt deficiencies, such as might occur with GI (eg, diarrhea) and skin losses (eg, heat stroke), interstitial and intravascular depletion is an early occurrence. Fortunately, dehydration is relatively easy to prevent with routine vigilance and water replacement compared with some of the other causes of shock.

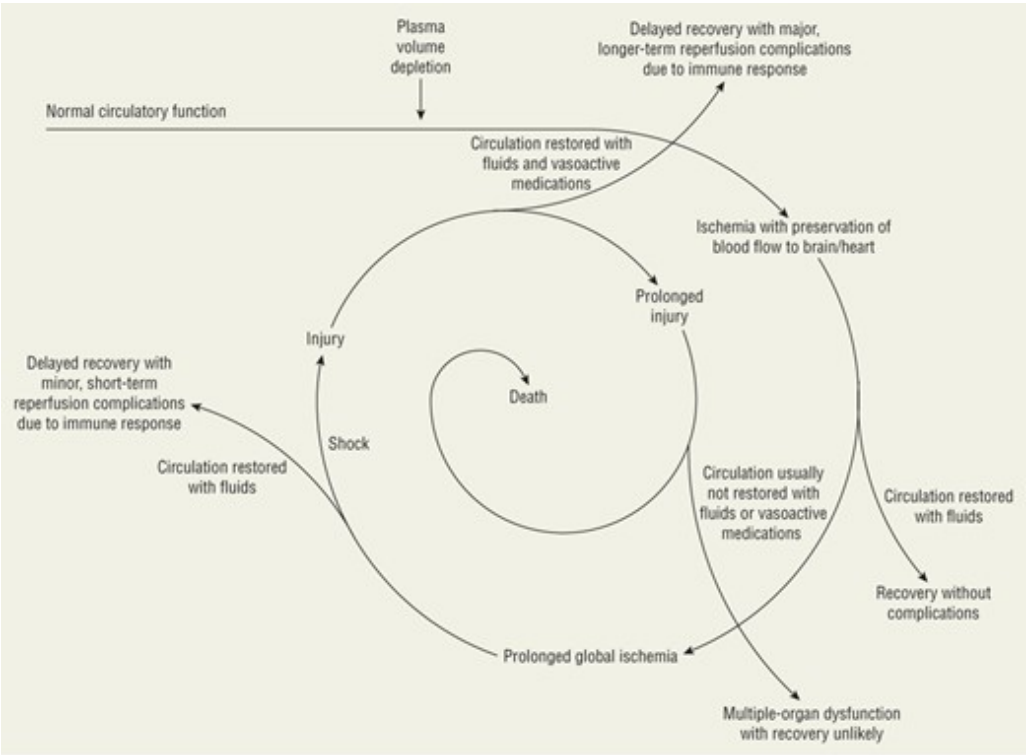
PATHOPHYSIOLOGY

2 Hypovolemic shock often is described in terms of monitoring parameters such as lowered blood pressure, but patients with shock may die despite normal surrogate markers of circulatory insufficiency. Therefore, an appropriate definition should mention the underlying problem, which is inadequate tissue perfusion resulting from circulatory failure. In the case of hypovolemic shock, the cause of the altered perfusion is fluid (or volume) depletion resulting from trauma, surgery, thermal injury, or some form of dehydration. **Figure 24-1** provides a simplified view of the pathophysiology of circulatory insufficiency assuming the acute insult causing the plasma volume depletion did not result in immediate patient death. Cell damage and death may occur from the primary insult or from reperfusion injury. The latter problem is associated most frequently with trauma and blood loss that

cause a systemic inflammatory response syndrome (SIRS) with the release of a multitude of mediators of inflammation and injury that have complex interactions. Cells have varying responses to hypoxia, ranging from astrocytes that quit functioning almost immediately to other cells that may tolerate more prolonged periods of hypoperfusion. Left unmitigated, cell death occurs with prolonged injury and is usually heralded by acidosis, hypothermia, and coagulopathy—referred to as the *lethal triad*.

FIGURE 24-1

Pathophysiology of circulatory insufficiency and failure (shock).



The body attempts to compensate for volume depletion beginning with autoregulatory changes involving smaller blood vessels. When the cause of circulatory insufficiency continues unabated, local mechanisms eventually fail to provide adequate compensation, and macrocirculatory changes ensue. The majority of blood volume is contained in venous capacitance vessels, with gravity being the major impedance to flow back to the heart. With increasing volume depletion, blood flow to the heart (preload) is decreased, with subsequent activation of baroreceptors and chemoreceptors leading to sympathetic discharge. Also, fluid shifting from the interstitial space to the intravascular space occurs through a phenomenon known as *transcapillary refill*, and hormones (eg, adrenocorticotropic hormone, angiotensin, catecholamines, and vasopressin) that cause sodium and water retention by the kidneys are released. The phenomenon of transcapillary refill means that the body can have fluid losses exceeding normal plasma volume. These responses cause alterations in stroke volume, heart rate, and peripheral vascular resistance so that blood pressure and hence tissue perfusion can be maintained.

The microcirculatory changes associated with shock are complex and difficult to study. Although

some mediators such as catecholamines, angiotensin II, arginine vasopressin, and endothelin-1 cause vasoconstriction, other mediators, such as adenosine and nitric oxide, yield vasodilation. These changes result in hypoperfusion or hyperperfusion, depending on the organs involved. As these microcirculatory changes fail to maintain adequate organ perfusion, more widespread sympathetic nervous system activation and vasoconstriction ensue. Even assuming general circulation is restored, capillaries may not function properly due to ongoing edema and ischemia. Failure to respond to sympathetic stimulation and fluid administration is indicative of the vasodilation that occurs in the final phase of circulatory failure leading to death.

The factors involved in fluid shifting between the intravascular and interstitial spaces are described by the modified Starling's equation:

$$J_V = K_{f,c}[(P_c - P_t) - [\sigma\ (\pi_{esl} - \pi_t)]]$$

where J_V is the net transvascular flow rate (cannot be measured in the clinical setting), $K_{f,c}$ is the capillary filtration coefficient for fluids (cannot be measured in the clinical setting), P_c is the capillary hydrostatic pressure (indirectly estimated in the clinical setting, eg, pulmonary artery occlusive pressure), P_t is the tissue or interstitial hydrostatic pressure (cannot be measured in the clinical setting), σ is the reflection coefficient for proteins (cannot be measured in the clinical setting), π_{esl} is the oncotic pressure in the endothelial surface layer (not usually measured in the clinical setting, but technology is available), and π_t is the oncotic pressure below the endothelial surface layer that determines the tissue or interstitial oncotic pressure (cannot be measured in the clinical setting).

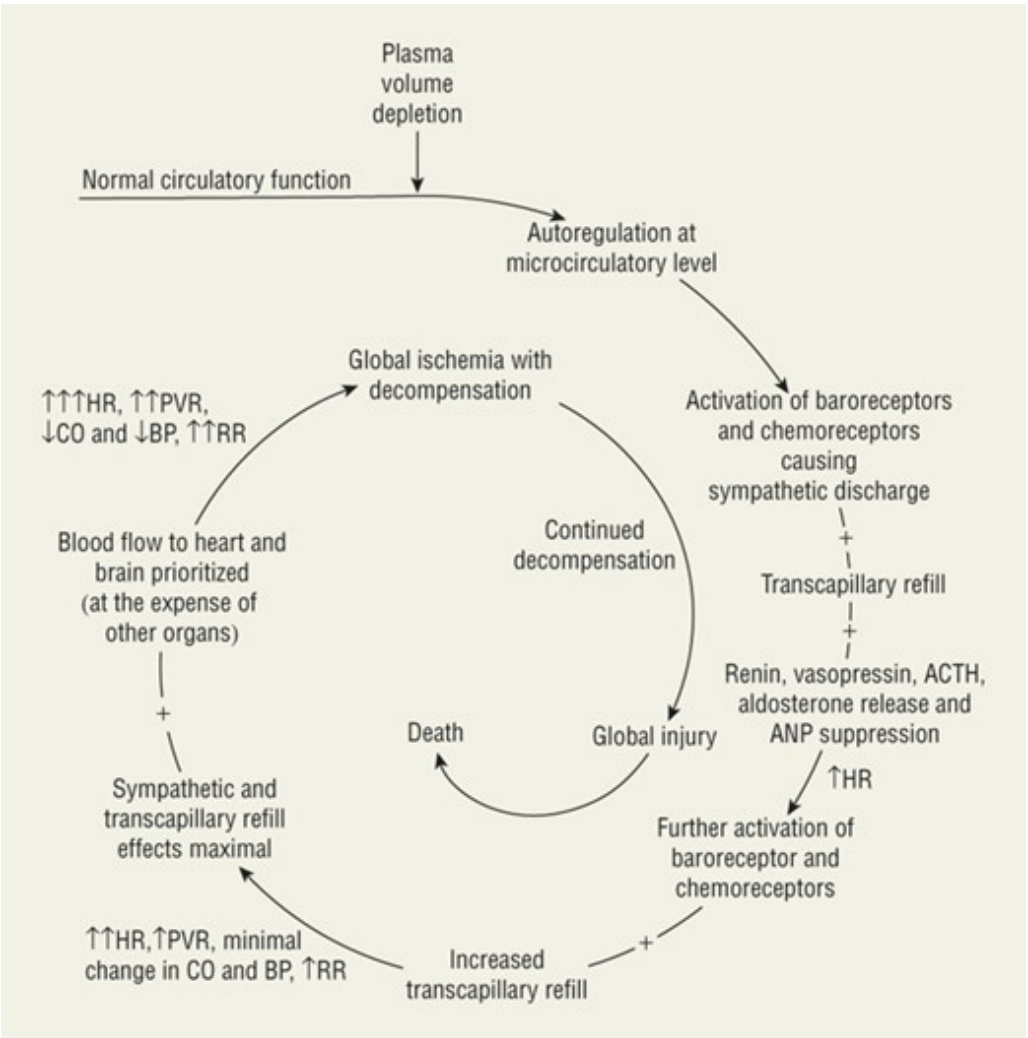
Proteins act as oncotic agents in each of these spaces to attract fluid, whereas hydrostatic forces push fluid into or out of the vessels. The equation has distinct permeability values for water and protein because each crosses the vascular membrane at a different rate. The values for the variables listed in the equation are not the same for capillaries in all parts of the body. For example, on a scale from 0 to 1 with 0 being free passage of protein and 1 being impermeable to protein, the typical value for the reflection coefficient in most capillaries is more than 0.9. Capillaries in the central nervous system and glomeruli have coefficients near 1 so in the absence of disease states minimal protein transport occurs. However, in the pulmonary capillaries the value is closer to 0.7 and approaches 0 in inflammatory states associated with increased capillary permeability.[4] As the value approaches 0, the capillaries are freely permeable not only to the usual fluid and electrolytes but also to plasma proteins such as albumin. Because albumin accounts for approximately 80% of the plasma oncotic pressure, its free passage into the interstitial space effectively negates its intravascular oncotic benefit. [3] Although the Starling's equation is useful to practitioners in terms of understanding the factors involved in fluid shifting between compartments, the rate and direction of transvascular flow cannot be calculated accurately in the clinical setting because most factors cannot be measured directly and the values for the factors vary in different capillaries in the body.

The body's compensatory mechanisms may have beneficial and harmful consequences. For example, cardiac output can be increased substantially by increases in stroke volume or heart rate. Although this may be useful for providing blood flow to inadequately perfused tissues, it may cause large increases in oxygen consumption by the heart that could aggravate preexisting ischemia in patients

with underlying coronary artery disease (CAD). Another example is the sympathetic nervous system–mediated vasoconstriction that causes blood to shift from the skin, skeletal muscle, and some internal organs such as the kidneys and GI tract to organs (eg, heart and brain) that are less tolerant of inadequate flow. If the vasoconstriction continues unabated, the hypoperfused organs eventually become damaged. **Figure 24-2** provides an overview of the compensatory changes that occur with a loss of circulating blood volume.

FIGURE 24-2

Activation of compensatory mechanisms with loss of circulatory volume. Certain stages may be absent, depending on a number of factors, such as age, preexisting disease states, and cause of circulatory insufficiency. (ACTH, adrenocorticotropin; ANP, atrial natriuretic peptide; BP, blood pressure; CO, cardiac output; HR, heart rate; PVR, peripheral vascular resistance; RR, respiratory rate.)



4 In addition to the more acute implications of hypovolemia and attendant complications, reperfusion damage is likely to occur, particularly after prolonged resuscitation attempts. In addition to edematous obstruction of capillaries and oxygen-free radical damage of cell membranes, a

number of cellular (eg, white blood cells and platelets) and humoral (eg, procoagulants, anticoagulants, complement, and kinins) components are activated, causing the release of other inflammatory mediators. The resulting reperfusion injury may range from readily reversible organ dysfunction to multiple-organ failure and death. The lungs are frequently the first system affected either by excessive fluid resuscitation or by the mediators of secondary reperfusion injury. The latter form of injury often results in the acute respiratory distress syndrome that is defined by an arterial oxygen tension-to-fraction of inspired oxygen ratio of less than or equal to 300 (with additional subdivisions of mild, moderate, and severe) with bilateral lung opacities in the absence of hypervolemia.

Although the basic pathophysiology is similar for the various causes of hypovolemic shock, there are unique considerations relative to each. For example, whereas isolated head injuries associated with trauma typically do not result in substantial blood loss or shock, long bone or pelvic fractures may sequester several liters of blood. Patients with traumatic or thermal injuries, as well as postoperative patients, may have substantial fluid accumulation in sites where the fluid cannot be readily transferred back into blood vessels (ie, third-spaced fluid) for maintaining pressure. With these types of injuries, prompt control of compressible bleeding sources with rapid patient transfer to the hospital for definitive treatment may preclude the cascade of events leading to shock. Indeed, with trauma patients, a “scoop and run” approach that places a priority on rapid transport to a hospital is used by most urban hospitals.

In the case of hemorrhagic shock, prompt attention must be given to cellular as well as plasma losses. Red blood cells lost during the bleeding episode may lead to ischemic damage in vital organs. Packed red blood cell transfusions may be needed to increase the oxygen-carrying capacity of the blood because oxygen transport is a function not only of cardiac output but also of hemoglobin concentration and saturation and of hemoglobin affinity for oxygen. Once hemostasis has been achieved, a more restrictive transfusion strategy (ie, transfusion if hemoglobin less than 7 g/dL [less than 70 g/L; 4.34 mmol/L]) is indicated for the majority of patients without severe cardiovascular disease (see Trauma/Perioperative Patients below).

Clotting factors and platelets are also lost in hemorrhage. The resulting bleeding problems may be aggravated by the dilutional effect of fluid resuscitation on clotting factor activity. Fresh-frozen plasma that contains necessary clotting factors and platelets is needed in massive blood loss to restore adequate coagulation. On the other hand, trauma patients are at increased risk for deep vein thrombosis and pulmonary embolism caused by multiple factors, including vessel damage, abnormal blood flow patterns, and the hypercoagulable state associated with injury. Therefore, some form of venous thromboembolism prophylaxis usually is indicated in multiple-trauma patients or patients with severe single-system injuries (eg, spinal cord damage) once hemostasis of major injury-related bleeding has been achieved.

The pathophysiology becomes more complicated if the severity of shock is sufficient to require patient admission to the intensive care unit (ICU) after initial resuscitation or surgery. Most patients admitted to the ICU have SIRS, which is the body’s response to injury. This syndrome is defined by a number of hypermetabolic changes reflected in the patient’s temperature, white blood cell count and differential, and respiratory and heart rates. The stress response involves complex interactions

between the nervous system and immunomodulating substances and has similar (if not the same) harmful and helpful consequences described with reperfusion following shock. If the underlying problems are left untreated, the patient with SIRS may develop multiple-organ dysfunction syndrome (MODS) during the final stages of illness.

CLINICAL PRESENTATION

5 The initial presentation of patients with suspected volume depletion can vary markedly, depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion (see Clinical Presentation of Hypovolemic Shock box). Intravascular depletion as a consequence of blood loss is signified by postural vital sign changes (ie, changes in pulse and blood pressure between supine, sitting, and standing measurements), and such measurements should be performed unless the diagnosis is obvious, as in the case of bleeding associated with trauma. Early signs and symptoms of dehydration and intravascular depletion caused by GI or urinary losses often are relatively nonspecific. Plasma volume losses of less than 10 mL/kg of body weight usually are associated with minor signs and symptoms of distress. Larger losses are not likely to be well tolerated (**Table 24-2**), particularly in patients older than 65 years. An 18-year-old athlete and a 65-year-old sedentary individual are likely to have much different responses to a similar amount of fluid loss. The young patient may lose one-fourth of his or her circulating blood volume with minimal changes in arterial blood pressure and a relatively low heart rate. However, the elderly patient may have orthostatic changes in blood pressure that are not well tolerated by organs such as the kidneys. Unfortunately, this same elderly patient may not have common signs and symptoms of volume depletion, such as skin turgor changes or thirst, but instead may have more subtle changes (eg, mental status alterations).

TABLE 24-2 Acute Circulatory Insufficiency: Initial Presentation and Therapy[a]

	Mild	Severe
Plasma/blood loss	Adult: 10 mL/kg	Adult: 30 mL/kg
	Child: 20 mL/kg	Child: 35 mL/kg
Mental status/level of consciousness	None to small changes (eg, anxious, irritable)	Marked changes (eg, confusion to unconsciousness)
Vital signs/orthostatic changes	Minor changes	Marked changes
Therapy	20 mL/kg lactated Ringer or normal saline IV[a] over 10-15 minutes Unlikely to need blood cell	Lactated Ringer or normal saline IV as rapidly as possible until response in adult, and then decrease rate of infusion 20 mL/kg lactated Ringer or normal saline IV in child (repeat quickly if minimal response); likely to need blood cell replacement and surgery if hemorrhagic

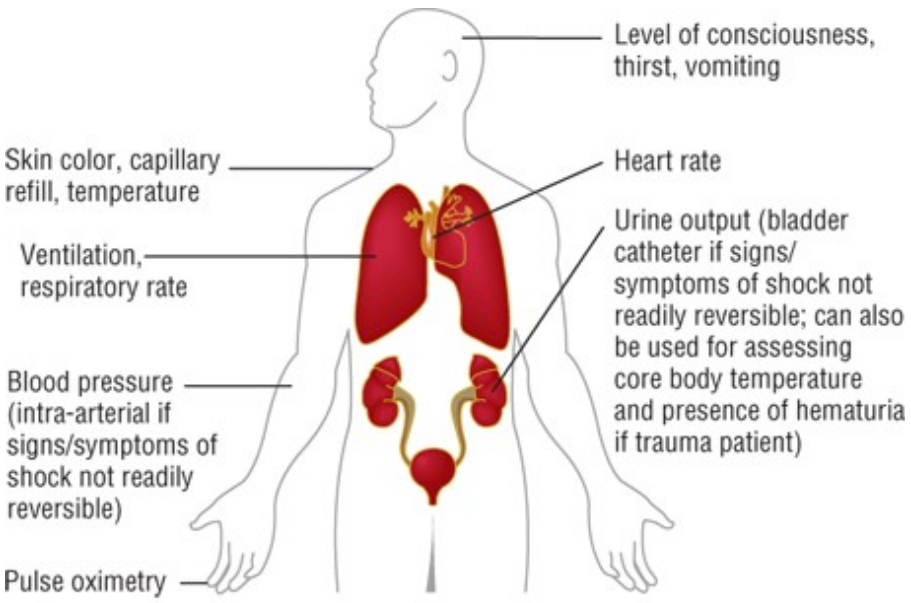
	Mild	Severe
	replacement even if hemorrhagic loss	

[a]Patients may have intermediate degrees of volume loss in addition to those listed, but the amount of loss often is difficult to quantify. The presentations may also vary greatly in patients with similar amounts of loss (young athlete vs sedentary, elderly person). In patients particularly prone to complications associated with fluid overload, the fluid can be administered in multiple smaller boluses titrated to clinical response. See text for a more in-depth discussion of some of the guidelines in this table.

The diagnosis of dehydration and intravascular depletion in children is complicated by difficulties in obtaining an accurate history. However, some excellent resources are available for healthcare providers, such as the Centers for Disease Control and Prevention (CDC) guidelines (*www.cdc.gov*), which discuss the evaluation and management of diarrhea in patients of all ages. In younger children, parental observations are important for estimating fluid deficits and deciding whether hospitalization is necessary. Fortunately, prospective data suggest that parental histories are predictive of acidosis and the need for hospitalization.[5] [6] Regardless of patient age or preexisting conditions, the initial monitoring of a patient with suspected volume depletion should include the following noninvasive parameters: vital signs, urine output, mental status, and physical examination (**Fig. 24-3**). An increase in blood pressure with passive leg raising may also be useful for the assessment of suspected hypovolemia, but should not be used to guide responsiveness to fluid administration.

FIGURE 24-3

Noninvasive assessment of circulatory insufficiency.



Although the presenting signs and symptoms of circulatory insufficiency are variable, patients usually have decreased blood pressure, increased heart and respiratory rates, and a normal or low–normal temperature (eg, 36°C-37°C [96.8°F-98.6°F]) in the absence of infection, exposure to extremes of temperature, and medications that impair thermoregulation. As mentioned earlier, recordings of vital signs must be interpreted in light of known or suspected baseline conditions. For example, alcohol, β-blockers, diuretics, and medications with anticholinergic effects may impair thermoregulation. Medications such as β-blockers and calcium channel blockers may alter resting blood pressure and heart rate, as well as the subsequent response to therapeutic interventions.

Although a blood pressure reading of 110/70 mm Hg (systolic/diastolic) may be acceptable in many patients, it may be inadequate in a patient with preexisting hypertension who normally has a blood pressure of 170/105 mm Hg. At the other extreme, patients with very low blood pressure may have inaudible or inaccurate determinations with cuff (sphygmomanometric) measurements. Chapters e11 and 13 detail blood pressure measurement (eg, cuff size, position). In this case, intra-arterial monitoring is indicated. The respiratory rate may be elevated because of anxiety or as a compensatory mechanism for the metabolic acidosis caused by lactic acidosis associated with poor tissue perfusion.

Although the kidneys continually produce urine, the bladder stores the urine for intermittent elimination. For the initial diagnosis and management of acute circulatory insufficiency, a catheter can be inserted into the bladder for measuring urine output. In contrast to thirst, which is a relatively insensitive indicator of volume depletion, urine output is generally diminished with inadequate fluid administration and increases with appropriate resuscitation. This presumes, of course, that acute renal failure or medications such as diuretics are not altering the expected response. Adults should produce at least 0.5 to 1 mL/kg/h of urine, whereas children up to 12 years should produce at least 1 mL/kg/h (2 mL/kg/h if younger than 1 year).

Mental status changes associated with volume depletion, if present, may range from subtle fluctuations in mood to unconsciousness. Although the latter finding typically is indicative of more severe depletion, less dramatic findings should not be interpreted as indicating mild fluid deficits. Losses of 3 to 4 L of plasma volume may be associated only with lassitude in an otherwise healthy adult patient. Similar interpretation difficulties must be considered when performing the initial physical examination. An orderly progression from warm, reddish skin with appropriate capillary refill (rapid return of blood flow to the extremity after removal of compression) to cold, cyanotic discoloration with impaired refill may not occur. Also, dry mucous membranes in elderly patients may be caused by mouth breathing or medications and not by fluid depletion.

TREATMENT

Milder forms of volume depletion may be managed in outpatient settings. For example, supplemental fluids can be added to the usual estimated daily requirements of 30 to 35 mL/kg in patients older than 12 years with dehydration. Commercially available carbohydrate/electrolyte drinks generally are more palatable than water and may promote earlier recovery. The rationale for combining carbohydrates with sodium is based on the cotransport absorption mechanism in the intestinal tract. With diarrheal states in particular, sodium absorption is impaired. Because water

follows sodium, the diarrhea is likely to continue despite oral crystalloid fluid administration until the intestinal pathology resolves. However, when dextrose and sodium are combined in 1:1 equimolar amounts, both are absorbed via the cotransport mechanism, which also allows for absorption of water. This concept forms the basis for the World Health Organization's (WHO) oral rehydration solution, which contains 75 mmol/L of dextrose, 75 mmol/L of sodium, 20 mmol/L of potassium, 65 mmol/L of chloride, and 10 mmol/L of citrate for a total osmolarity of 245 mOsm/L.[3] Commercially available nonprescription rehydration drinks for children in the United States also have an osmolarity of approximately 250 mOsm/L but typically contain 50 mmol/L or less of sodium, and the dextrose-to-sodium ratio often is 3:1. How these differences between commercially available formulations and the WHO rehydration formula might affect hospitalization rates is unclear, but ad hoc attempts to alter the commercially available products to make them more consistent with the WHO formula may be dangerous and are not recommended.

CLINICAL PRESENTATION Hypovolemic Shock General

- The initial presentation of adult patients with suspected volume depletion could vary markedly, depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion.
- Plasma volume losses of less than 10 mL/kg of body weight usually are associated with minor signs and symptoms of distress.

Symptoms

- Patients may present with thirst, nausea, anxiousness, weakness, light-headedness, and dizziness.
- Patients may report scanty urine output and dark yellow urine.

Signs

With more severe volume loss:

- Patients would have marked increases in heart rate (eg, greater than 120 beats/min) and respiratory rate (eg, greater than 30 breaths/min).
- Blood pressure would be decreased (eg, systolic blood pressure less than 90 mm Hg).
- Mental status changes or unconsciousness may occur.
- Agitation may be present if the patient is conscious.
- Body temperature would be low or normal (eg, 36°C-37°C [96.8°F-98.6°F]) in the absence of concomitant infection with cold extremities and decreased capillary refill on physical examination.

Laboratory Tests

- Sodium and chloride concentrations usually are high with acute depletion but may be low or normal depending on type of fluid intake.
- The ratio of blood urea nitrogen (BUN) to creatinine is likely to be elevated initially, but the creatinine level would increase as renal dysfunction occurs.
- Elevated base deficit and lactate concentrations in conjunction with decreased bicarbonate concentrations and pH due to metabolic acidosis.
- The complete blood count should be normal in the absence of concomitant disease states such as infection; in hemorrhagic shock, the red cell count, hemoglobin, and hematocrit would decrease over time, while the prothrombin time (PT) and international normalized ratio would increase.
- With more severe volume depletion, other organs may become dysfunctional, which may be reflected in laboratory testing (eg, elevated transaminase levels with hepatic dysfunction).

Other Diagnostic Tests

- Urine output would be decreased to less than 0.5 to 1 mL/h.

Outpatient rehydration of children usually is recommended for those with uncomplicated (eg, vomiting less than 48 hours) acute gastroenteritis and relatively mild dehydration after the exclusion of more severe illnesses such as bowel obstruction. 7 The need for IV rehydration often is overestimated. Randomized studies conducted in pediatric emergency departments have found oral or nasogastric rehydration to be at least as effective as IV rehydration using end points such as length of stay and need for hospital admission.[6,7] While dehydration is primarily a problem of intracellular fluid depletion, ongoing losses will result in extracellular fluid depletion as well. The remainder of this chapter will focus on more severe forms of volume depletion (ie, hypovolemic shock) that are not amenable to oral rehydration.

Desired Outcome

Reduce morbidity and mortality by preventing disease progression with subsequent organ damage.

To the extent possible, reverse organ dysfunction that has already taken place.

General Approach to Treatment

Hospitalization is indicated for more severe forms of circulatory insufficiency. If access to the circulatory system for administration of fluids and medication is not obtained prior to hospitalization, this should be a priority. Venous access generally is obtained during the preliminary examination process that includes the ABCs of life support (ie, airway, breathing, and circulation), assessment of vital signs and mental status, and determination of urine output after catheterization. Whenever large-volume fluid resuscitation is expected, as in hemorrhagic shock, at least two IV catheters are desirable. Because flow is a function of tubing length and catheter diameter, large-bore peripheral IV

lines are preferred over longer central lines. Unfortunately, vascular access in some patients may be problematic, and other routes such as intraosseous infusion may be necessary. Prior to the past decade, use of intraosseous fluid and drug administration in the United States was mostly restricted to children with IV access issues, but it is increasingly being used in adult patients as well. One interesting method of fluid administration that has been investigated in elderly patients is subcutaneous infusion, or hypodermoclysis. With hypodermoclysis, common dextrose- and sodium-containing fluids typically given by the IV route are given by subcutaneous infusion at sites such as the upper arm, chest, abdomen, or thigh, depending on factors such as patient or provider preference. Hyaluronidase has been used as a spreading agent to facilitate fluid absorption by this route, but its benefit versus risk profile has yet to be clearly elucidated; in particular, allergic reactions with this agent have been a concern, although a recombinant form is now available that has the potential for fewer reactions compared with the older bovine-derived products. Hypodermoclysis is not used commonly in the United States, probably because of concerns of adverse effects that were found in early studies that used excessively hypotonic or hypertonic solutions, as well as issues related to reimbursement when considered in ambulatory, home, or palliative care settings. Although relatively high fluid administration rates have been achieved in some studies involving hypodermoclysis, this method of infusion should not be used in patients with more severe forms of dehydration or hypovolemia until additional supportive information from clinical trials is available. Although alternative methods of fluid administration, such as hypodermoclysis, are desirable, well-conducted trials are needed before such methods can be recommended for routine use.

After the immediate postresuscitation phase of the treatment of hypovolemic shock, proper attention must be paid to general supportive care measures that include appropriate assessment and management of pain, anxiety/agitation, and delirium. This is particularly true for patients who develop shock after trauma, surgery, or thermal injury and require admission to an ICU.

Nonpharmacologic Therapy

Nonpharmacologic therapy for shock is dependent on the inciting event, although the basic life support measures such as a secure airway with appropriate oxygenation apply to all patients. For patients with more severe traumatic injury, additional measures would include surgery, stabilization of fractures, control of blood loss by physical compression or surgical control, and prevention of heat loss since hypothermia may aggravate other problems such as bleeding. For patients with heat exposure, cooling measures are indicated. Patients with thermal injuries should have the wound sites covered with cool, moist sterile dressings until more definitive care can take place.

Pharmacologic Therapy

Since IV fluids are the primary therapy for hypovolemic shock, they will be considered pharmacologic agents for this discussion.

Drug Treatments of First Choice

8 Dextrose-in-water solutions may be appropriate for uncomplicated dehydration caused by water

deprivation, but isotonic crystalloid (sodium-containing) solutions should be used for forms of circulatory insufficiency that are associated with hemodynamic instability. In the latter situation, IV solutions with sodium concentrations approximating normal serum sodium values usually are indicated because they cause more expansion of the intravascular and interstitial spaces compared with dextrose solutions (**Table 24-3**). Lactated Ringer and normal saline solutions are examples of such crystalloid solutions that frequently need to be administered in large volumes when given to patients with more severe forms of hypovolemia. A "large" amount of fluid does not mean a single bolus volume typically used as fluid challenge in a critically ill patient. An isolated bolus (eg, 250-500 mL) in a young adult trauma patient is unlikely to cause a substantial change in blood pressure or acid–base balance.[8] Therefore, multiple fluid boluses usually are often needed in such patients to achieve hemodynamic stability in the perioperative period. On the other hand, overly aggressive fluid administration should be avoided, especially in patients with heart failure or impending pulmonary edema. In a randomized trial involving patients with acute lung injury and radiographic presence of pulmonary edema, a more conservative fluid management strategy beginning postresuscitation (~40 hours after admission in the study) led to significantly fewer ventilator-free days and days not spent in an ICU (*P* less than 0.001).[9]

TABLE 24-3 Fluid Distribution and Major Indications[a]

Fluid	Intracellular	Interstitial	Intravascular	Major Indication
Normal saline or lactated Ringer	None	750 mL	250 mL	Intravascular repletion in symptomatic patients
3% sodium chloride	→	750 mL+	250 mL+	Small amounts (eg, 250 mL) by intermittent infusion have been used in conjunction with normal saline or lactated Ringer for intravascular depletion in patients with head trauma
5% dextrose/0.45% sodium chloride	333 mL	500 mL	167 mL	Maintenance fluid in euvolemic or dehydrated (sodium and water loss) patients with mild signs/symptoms of volume depletion
5% dextrose	667 mL	250 mL	83 mL	Dehydration (primarily water loss) in patients with mild signs/symptoms of volume depletion
5% albumin	None	None	1,000 mL[b]	Intravascular repletion in symptomatic patients
25% albumin	→	→	1,000 mL+++[b]	Usually given by intermittent infusion of small volumes (eg, 50-100 mL) or by continuous infusion titrated to response in hypovolemic patients with excess interstitial fluid accumulation

[a]Based on administration of 1 L of each solution *for comparative purposes only*. This amount of fluid, particularly for 3% saline and 25% albumin, would be inappropriate and likely harmful if given over a

short period of time. Numbers are approximations and are likely not reflective of actual fluid distribution in critically ill patients; arrows indicate direction of fluid shift and plus signs indicate fluid pulled from other compartments.

[b]After distribution and attainment of steady-state conditions, 60% of albumin (and associated fluid) is in interstitial compartment and 40% is in intravascular compartment.

Published Guidelines or Treatment Protocols

Recommendations for shock associated with trauma have been published as part of the Advanced Trauma Life Support (ATLS) course (http://www.facs.org/trauma/atls/).[10] In the past, the ATLS guidelines were derived more from consensus of expert participants than evidence, but this has changed in more recent revisions. Guidelines for prehospital fluid administration in patients with trauma have been published by the Eastern Association for the Surgery of Trauma (EAST).[11] Other evidence relative to fluid choice for resuscitation is available from systematic reviews,[12,13,14] a guideline for perioperative fluid resuscitation,[15] and a guideline pertaining to burn shock resuscitation.[16] Taken as a whole, the recommendations from all of these sources are consistent in that isotonic (or near isotonic) crystalloid solutions are the initial fluid of choice for resuscitation in hypovolemic shock (**Table 24-4**).

TABLE 24-4 Summary of Evidence for Choice of Plasma Expander for Hypovolemic Shock

Source	Type of Evidence	Recommendation/Conclusion
ATLS recommendations[10]	Evidence-based consensus recommendations of fluids in trauma patients with shock	Warmed isotonic crystalloid solutions such as normal saline or lactated Ringer should be used (LOE3); hypertonic sodium chloride is an alternative with no mortality advantage (LOE4)
EAST guideline[11]	Evidence-based consensus recommendations for prehospital fluids in trauma patients	Insufficient data to recommend one fluid over another when comparing normal saline, lactated Ringer, 3% sodium chloride, or 7.5% sodium chloride (level I)
Cochrane Collaboration[12]	Systematic review of colloids versus crystalloids in critically ill patients	No evidence that colloids reduce mortality compared with crystalloids in patients with trauma or burns, or after surgery; hydroxyethyl starch products may increase mortality
Cochrane Collaboration[13]	Systematic review of different colloids for fluid resuscitation	No evidence that one colloid is more effective than another in terms of efficacy or safety; could not exclude clinically important differences due to wide confidence intervals; did not include trials after December 1, 2011

Source	Type of Evidence	Recommendation/Conclusion
Cochrane Collaboration[14]	Systematic review of albumin solutions versus no albumin or crystalloids for fluid resuscitation in critically ill patients	No evidence that albumin reduces mortality when compared with crystalloid solutions such as normal saline but cannot exclude benefit in specific subsets of critically ill patients
British consensus guidelines[15]	Guidelines for perioperative fluid prescribing	Balanced salt solutions such as lactated Ringer's are preferred over normal saline for crystalloid resuscitation unless hypochloremia is present (level 1b); balanced salt solutions or colloids until packed red blood cells are available for hypovolemia with blood loss (level 1b)
American Burn Association[16]	Guidelines for burn shock resuscitation that include fluid recommendations	Near isotonic crystalloid recommended for initial resuscitation (grade C); hypertonic sodium chloride reserved for clinicians experienced with use (grade B); addition of colloid after 12-24 hours postburn may decrease fluid requirements (grade A)

ATLS, Advanced Trauma Life Support; EAST, Eastern Association for the Surgery of Trauma; grade A, at least one large prospective trial with clear-cut results; grade B, several small prospective trials with similar results; grade C, single small prospective trial, retrospective studies, or expert opinion; level 1b, randomized controlled trial with narrow confidence interval, or quality cohort studies (specific definitions); level I, convincingly justifiable; LOE3, level of evidence based on case–control or retrospective cohort studies, or a systematic review with at least three studies; LOE4, level of evidence based on case series.

General Information Reporting Efficacy and Safety

The choice between normal saline and lactated Ringer solutions for hypovolemia is largely based on clinician preference and adverse effect concerns (**Table 24-5**). Lactated Ringer solution has been recommended for patients with hemorrhage because it is unlikely to cause the hyperchloremic metabolic acidosis and possibly acute kidney injury due to excess chloride administration that is seen with infusions of large volumes of normal saline. But concerns have been raised relative to the proinflammatory effects (eg, neutrophil activation) of the d-isomer form of lactate that is contained along with the l-isomer in commercially available racemic isomer solutions. There are advocates for the use of lactated Ringer solution containing only l-isomer lactate, particularly for more severe forms of hemorrhagic shock, since it avoids the proinflammatory effects of the racemic solution, while avoiding the hyperchloremia associated with normal saline.[17] Additionally, other substitutes for racemic lactate such as ketone or pyruvate have shown beneficial effects on neutrophil activation and gene expression in vitro and are the subject of ongoing studies.

TABLE 24-5 Adverse Effects of Plasma Expanders: Crystalloids

Normal saline

Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy)

Hyperchloremic metabolic acidosis (has 154 mEq/L [154 mmol/L] of chloride)

Hypernatremia (has 154 mEq/L [154 mmol/L] of sodium)

Lactated Ringer

Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy)

Hyponatremia (has 130 mEq/L [130 mmol/L] of sodium)

Aggravation of preexisting hyperkalemia (has 4 mEq/L [4 mmol/L] of potassium)

Hypertonic saline

Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy; intracellular volume depletion)

Hypernatremia (has 513 mEq/L [513 mmol/L] of sodium)

Hyperchloremia (has 513 mEq/L [513 mmol/L] of chloride)

Although lactated Ringer solution does contain lactate, it does not cause substantial elevations in circulating lactate concentrations when used as a resuscitation solution.[18] Once adequate plasma volume has been restored by fluid administration, the body can readily clear the blood of the excess lactate that has accumulated from both anaerobic metabolism and lactated Ringer solution. However, blood samples for lactate determinations drawn through catheters (arterial and venous) that have not been cleared appropriately may have spurious increases or decreases in lactate concentrations because of retained lactated Ringer and nonlactated solutions (eg, varying concentrations of dextrose-in-water or sodium chloride), respectively.[19] Therefore, blood samples for lactate concentration determinations should be drawn from a catheter that has been cleared adequately (eg, 5 mL) of infusate after temporarily stopping the fluid infusion.

Alternative Drug Treatments

A number of pharmacologic therapies show promise in animal models of shock, but few demonstrate success in subsequent trials involving patients with shock. In large part this is a result of the lack of acceptable animal models of shock that mimic the pathophysiology of patients. In cases in which a relevant animal model is available, care must be taken when extrapolating the information to forms of shock other than the one under study. This may be the problem with naloxone, which has been shown to raise blood pressure in some studies of shock but not in others.

While research continues on medications that improve oxygen transport, optimize oxygen utilization, and reduce reactive oxygen species and reperfusion injuries, fluids remain the mainstay of therapy for shock. Hypertonic sodium chloride solutions have been studied as alternatives to isotonic crystalloid solutions for hypovolemic shock, particularly in patients with traumatic brain injuries. By causing

redistribution (ie, pulling fluid) from the intracellular space, hypertonic solutions cause rapid expansion of the intravascular compartment, which is essential for vital organ perfusion. In head-injured patients, it has been postulated that this redistribution should decrease intracranial pressure because the vessels of the brain are more impermeable to sodium ions than are vessels in other areas of the body. Additionally, hypertonic sodium chloride solutions have beneficial immunomodulating actions when compared with more isotonic solutions in experiments with animals. Unfortunately, the theoretical benefits associated with hypertonic sodium chloride solutions have not translated into improved outcomes when used for the initial resuscitation of patients with hypovolemic shock.

From a safety standpoint, hypertonic sodium chloride is considered to be a high-risk concentrated electrolyte solution. Potential dosing and administration errors and related adverse events can occur when hypertonic sodium solution is ordered and administered by clinicians relatively unfamiliar with its use. Potential adverse events include cellular crenation and damage caused by the dramatic fluid shifts associated with hypernatremia, hyperchloremic metabolic acidosis from hyperchloremia, and peripheral vein destruction from high osmolality. The osmolarity of 3% sodium chloride is 1,026 mOsm/L. Although there are some notable exceptions (eg, peripheral parenteral nutrition solutions often approach 1,000 mOsm/L), IV solutions with osmolarity values above 600 mOsm/L are usually recommended for administration by central lines. In the limited number of studies conducted in humans to date, adverse effects related to hypertonic sodium solutions have been uncommon and apparently of little clinical importance.

Larger-molecular-weight solutions (ie, greater than 30,000 Da) known as *colloids* have been recommended in conjunction with or as replacements for crystalloid solutions, although their use is controversial. The major theoretical advantage of these compounds is their prolonged intravascular retention time compared with crystalloid solutions. In contrast to isotonic crystalloid solutions that have substantial interstitial distribution within minutes of IV administration, colloids remain in the intravascular space for hours or days, depending on factors such as the size of the colloid molecules and capillary permeability. Examples of colloids used as plasma expanders in the United States include albumin, hydroxyethyl starch, and much less commonly, dextran. Albumin is known as a *monodisperse colloid* because all its molecules are of the same molecular size and weight (~67,000 Da), whereas hydroxyethyl starch and dextran solutions are *polydisperse compounds* with molecules of varying molecular size that are roughly proportional to molecular weight (weight-*averaged* molecular weights of 600,000 Da [range 450,000-800,000 Da] for 6% hetastarch in normal saline 450/0.75, 670,000 Da [range 450,000-800,000 Da] for 6% hetastarch in lactated electrolyte 670/0.75, 130,000 Da [range 110,000-150,000 Da] for 6% tetrastarch in normal saline 130/0.4, 40,000 Da [range 10,000-90,000 Da] for dextran 40, or 70,000 to 75,000 Da [range 20,000-200,000 Da] for dextran 70 or dextran 75, respectively). In light of these differences, colloid comparisons are based on weight-averaged ([number of molecules at each weight × particle weight]/total weight of all molecules) or number-averaged (arithmetic mean of all particles' weights) molecular weight.[20] The size and weight differences of the colloids have important implications for the distribution of the products because lower-molecular-weight substances are retained in the intravascular space for a shorter period of time as a result of more rapid leakage across the vessel membrane. The theoretical benefit common to all colloids is based on their increased molecular weight (average molecular weight in the case of

hydroxyethyl starch and dextran) that corresponds to increased intravascular retention time in the absence of increased capillary permeability compared with crystalloids. Even in patients with intact capillary permeability, small and intermediate size colloid molecules such as albumin eventually will leak through capillary membranes with a few notable exceptions (eg, those in the central nervous system and glomeruli). In the case of albumin with a distribution half-life of 15 hours in normal subjects, approximately 60% of administered albumin molecules (and associated fluid) would be shifted to the interstitial space within 3 to 5 days of exogenous administration. In patients with altered permeability (eg, acute respiratory distress syndrome), the leakage of albumin from the intravascular to the interstitial space may occur within hours, not days. The primary adverse effect concern of all colloids is fluid overload, which is an extension of their pharmacologic action. Another adverse effect of increasing concern is renal dysfunction that seems to be related to hyperoncotic (eg, 25%) albumin and other starch and dextran products. The mechanism of this adverse effect may be related to alteration of normal glomerular oncotic pressure differences or formation of lesions in the kidney.[21]

Clinical Controversy...

There is no widespread agreement on the upper limit of osmolarity for hypertonic sodium solutions that are given by peripheral vein infusion under emergent conditions, but 600 or 900 mOsm/L is the usual recommended upper limit for prolonged IV infusions.

Albumin is available in 5% and 25% concentrations. Plasma protein fraction has oncotic actions similar to a 5% albumin solution, which is not surprising because albumin is the predominant protein in this product. When given in equipotent amounts, albumin is much more costly than crystalloid solutions. Additionally, the 5% and 25% albumin solutions typically are priced such that no cost saving is associated with dilution of the 25% product to make a 5% concentration. In general, dilution should be avoided because of the possibility of preparation errors; cases of hemolysis and death have occurred when 25% albumin was inappropriately diluted with sterile water for injection, causing a dramatic lowering of effective osmolarity. The 5% albumin solution is relatively *iso-oncotic*, which means that it does not pull fluid into the compartment in which it is contained. In contrast, 25% albumin is referred to as *hyperoncotic* albumin because it tends to pull fluid into the compartment containing the albumin molecules. In general, the 5% albumin solution is used for hypovolemic states. The 25% solution should not be used for acute circulatory insufficiency unless it is used in combination with other fluids or it is being used in patients with excess total body water but intravascular depletion as a means of pulling fluid into the intravascular space. An example of the latter condition is cirrhosis with ascites in which total body water is substantially increased, but the patient is hypotensive as a consequence of lack of intravascular volume. To justify this use of hyperoncotic albumin from a cost-effectiveness standpoint presumes that there is evidence of adverse effects associated with the excess water (eg, interstitial fluid accumulation in the lungs) and that the albumin remains in the intravascular space long enough to be of benefit. Albumin has a variety of functions beyond plasma expansion, such as binding properties, inflammatory gene modification, and antioxidant and free radical scavenging effects, which have been used to justify its administration instead of less expensive crystalloid or other colloid products. Although appealing theoretically, improved patient outcomes related to these properties have not been documented in adequately powered, randomized controlled trials. Additionally, the clinician must realize that the

properties of commercially available albumin products are not biologically identical to those of native albumin. For example, denaturation of the products may lead to inefficient binding and decreased oncotic activity.

Hydroxyethyl starch products have been developed as synthetic alternatives to albumin that is derived through the fractionation of donated human blood. The various products are differentiated by two numbers, one for the average mean molecular weight and one for the degree of hydroxyethyl substitution of glucose. For example, hetastarch is expressed as 450/0.7 based on weight and substitution, respectively. Most of the trials comparing albumin with hydroxyethyl starch products for volume expansion were inadequately powered and found no significant differences in clinically important outcomes (eg, mortality). Two large randomized trials have directly compared hydroxyethyl starch products with crystalloid solutions for intravascular expansion. Although these trials used newer, low-molecular-weight (140), low-substitution (0.4 or 0.42) starch products, hemostasis and renal function problems noted in older trials involving high-molecular-weight, high-substitution starch products were found, suggesting these are class adverse effects. One of these large trials (Scandinavian Starch for Severe Sepsis/Septic Shock, also known as the 6S trial) found significantly higher rates of renal replacement therapy, red blood cell transfusions, and 90-day mortality in patients receiving hydroxyethyl starch versus a Ringer acetate solution.[22] The second trial (Crystalloid versus Hydroxyethyl Starch Trial referred to as the CHEST trial) involved 7,000 general ICU patients, making it the largest randomized study to date involving a starch product. As in the other large trial, patients in the hydroxyethyl starch group required significantly more renal replacement therapy versus patients receiving normal saline, but the 90-day mortality rates were similar.[23] Possible explanations for the lack of a mortality difference include the relatively low overall mortality that might be related to the exclusion criteria (eg, patients unlikely to survive), or to the use of normal saline as a control solution since saline has a high concentration of chloride ion and a low strong ion difference compared to plasma.

Hydroxyethyl starch may aggravate bleeding through mechanisms specific to this colloid (eg, decreased factor VIII/von Willebrand factor). These mechanisms have not been well elucidated and often are difficult to distinguish from the dilutional effects on clotting factors caused by all plasma expanders; however, the risk of coagulopathy appears to be related to increasing doses and durations of administration.[22] Renal dysfunction associated with hydroxyethyl starch products may also be a function of dose and duration of administration. Regardless of potential mechanisms, the Food and Drug Administration (FDA) considers the serious adverse effects of the hydroxyethyl starch products to be class effects that warrant changes to product labeling. The changes include a boxed warning that states these products are contraindicated in critically ill patients. Additional warnings have also been added about excessive bleeding when used in patients undergoing cardiopulmonary bypass. Hydroxyethyl starch may cause elevations in serum amylase concentrations but does not cause pancreatitis.

Clinical Controversy...

The mechanisms by which hydroxyethyl starch products cause bleeding and acute kidney injury have yet to be fully elucidated, but these problems are of sufficient concern to question the use of such products outside the confines of well-controlled trials.

Dextran 40, dextran 70, and dextran 75 are available for use as plasma expanders in the United States. The numbers refer to the average molecular weight of the solutions. In general, dextran solutions are not used as often as albumin for plasma expansion because of a lack of adequately powered randomized trials, and because of concerns related to aggravation of bleeding (ie, anticoagulant actions related to inhibiting stasis of microcirculation), acute kidney injury, and anaphylaxis that is more likely to occur with the higher-molecular-weight solutions. There are few comparative trials involving the dextran solutions, but the intravascular expansion within hours after infusion is approximately equal to the amount of dextran infused. Apart from the acute kidney injury and bleeding associated with starch and dextran products, adverse effects associated with colloids generally are extensions of their pharmacologic activity (**Table 24-6**).

TABLE 24-6 Adverse Effects of Plasma Expanders: Colloids

Albumin
Primarily extensions of pharmacologic actions (eg, fluid overload; dilutional coagulopathy)
Amino acid profile and catabolism alterations (clinical significance?); potential protein overload if given with exogenous protein (eg, parenteral nutrition)
Anaphylactoid/anaphylaxis reactions (life-threatening reactions rare; higher in patients with immunoglobulin A deficiency)
Infectious complications (all reported cases have been associated with improper handling by manufacturer or institution; no reported cases of human immunodeficiency virus or hepatitis transmission)
Interactions with medications and nutrients (clinical significance varies)
Metal loading, particularly aluminum (long-term administration in patients with renal failure)
Negative inotropic effect; reductions in ionized calcium concentrations (not well documented)
Pyrogenic reactions (not well documented)
Renal dysfunction with hyperoncotic albumin
Hydroxyethyl starch
Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy)
Bleeding; not recommended in critically ill patients or in patients with bleeding conditions such as subarachnoid hemorrhage
Macroamylase formation may cause elevation in blood amylase that leads to inaccurate diagnosis of pancreatitis
Anaphylactoid/anaphylaxis reactions

Pruritus (particularly when large amounts are given; may take months to resolve)

Renal dysfunction; not recommended in critically ill patients, patients at risk for renal dysfunction or patients with preexisting renal dysfunction

Dextrans

Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy)

Anaphylactoid/anaphylaxis reactions (increased incidence of anaphylaxis with increased molecular weight)

Bleeding (sometimes used for anticoagulant activity, so not recommended for patients with or at risk for bleeding)

Renal dysfunction

From a historical perspective, the so-called crystalloid versus colloid debate was intensified when a meta-analysis by the well-respected Cochrane group found an overall increase in mortality associated with albumin using pooled results of randomized investigations.[24] The meta-analysis involved 30 randomized trials with 1,419 patients (relative risk of death with albumin vs no administration or crystalloid administration, 1.68; 95% confidence interval [CI], 1.26-2.23). For hypovolemia (caused by blood loss in the majority of studies), the risk of death associated with albumin administration was not quite statistically significant (relative risk, 1.46; 95% CI, 0.97-2.22). With the notable exception of trauma patients, a subsequent and more comprehensive systematic review did not find increased mortality attributable to albumin.[25] Furthermore, a landmark investigation involving almost 7,000 critically ill patients (conducted after the previously mentioned meta-analyses) did not find statistically significant differences in 28-day mortality between patients resuscitated with either normal saline or 4% albumin.[26] As in the previous meta-analysis, there was a trend toward increased mortality in patients with trauma, which became statistically significant (P = 0.003) when analyzed at 24 months in a subset of patients with traumatic brain injury.[27] This multicenter, randomized, double-blind investigation, referred to as the *Saline versus Albumin Fluid Evaluation* (SAFE) study, involved a heterogeneous group of ICU patients and was not sufficiently powered to look at various subsets, so clinicians must be cautious when extrapolating the results to more specific patient populations.

The colloids are expensive solutions. Therefore, it is difficult to justify the additional cost of colloidal products unless the benefit-to-risk ratio is substantially greater than that associated with inexpensive crystalloid solutions. This does not appear to be the case based on randomized controlled studies and meta-analyses comparing colloid and crystalloid solutions for acute circulatory insufficiency. While the use of albumin in specific patient populations (eg, septic shock) is still debated, the documented adverse effect profile of hydroxyethyl starch products and the lack of adequately powered trials for dextran products renders them all unsuitable for use in critically ill patients including those with shock.

In contrast to other forms of shock such as anaphylactic or septic, medications are a distant

alternative to the primary therapy for hypovolemic shock, fluids. In hypovolemic shock, peripheral resistance is high due to compensatory mechanisms aimed at maintaining tissue perfusion. Early or overzealous use of vasopressors in lieu of fluids may exacerbate this resistance to the point that flow is stopped. Therefore, vasoactive agents that dilate the peripheral vasculature such as dobutamine are preferred if the blood pressure is stable and high enough to tolerate the vasodilation. Vasopressors are only used as a temporizing measure or as a last resort when all other measures to maintain perfusion have been exhausted.[28] Because vasopressors have such a limited role in hypovolemic shock, there are very few studies that compare various agents. In one of the few studies that included patients with hypovolemic shock, norepinephrine and dopamine had similar effects on mortality, but dopamine was associated with more adverse effects, particularly atrial fibrillation.[29]

Special Populations

Trauma/Perioperative Patients

The need for immediate treatment of hemorrhagic circulatory insufficiency with plasma expanders (ie, crystalloids or colloids) seems obvious, but no large, well-controlled trials conducted in humans have supported this practice. To the contrary, evidence suggests that fluid resuscitation beyond minimal levels (ie, mean arterial pressure greater than 60 mm Hg) is harmful in patients with penetrating abdominal trauma due to hemodilution and clot destabilization. One prospective study involving 598 adult patients with gunshot or stab wound injuries to the torso and systolic blood pressure measurements of 90 mm Hg or less found that delayed fluid resuscitation until operation was associated with increased survival and discharge from the hospital (P = 0.04).[30] Since concerns were expressed about the comparability of the immediate and delayed resuscitation groups, particularly because true randomization did not take place, a follow-up randomized trial was conducted to verify the findings. There were no differences in survival (four deaths in each group) in the second trial regardless of whether systolic blood pressure was titrated to greater than 100 mm Hg or to 70 mm Hg.[31] Both studies were conducted in populated urban areas with approximately 2 hours from the time of injury to operation. Therefore, the results may not be applicable to rural areas with extended transport times. There also is a concern in applying the results of these investigations to patients with certain kinds of single-system injuries, particularly head trauma, where cerebral perfusion pressure is of primary importance. Although the applicability of these studies to other populations and settings is debatable, the *presumption* of benefits from immediate plasma expansion in all preoperative patients with circulatory insufficiency caused by hemorrhage is no longer valid. Instead, the initial priority should be surgical control of the bleeding source; until this is possible, fluids should be given in small aliquots to yield a palpable pulse and to maintain mean arterial pressures no more than 60 mm Hg and systolic pressures no more than 90 mm Hg based on accurate measurements (eg, arterial monitoring).

Beneficial outcome data attributable to hypertonic sodium chloride solutions are lacking. Most of these studies were conducted in prehospital and emergency department settings using 250 mL of 7.5% sodium chloride with or without 6% dextran 70. For example, a double-blind, randomized controlled trial involving 229 patients with hypotension and severe brain injury demonstrated no significant differences in neurologic function at 6 months when 250 mL of 7.5% saline or lactated

Ringer solution was administered as part of a prehospital resuscitation regimen.[32] Part of the explanation for this finding may be related to supplemental crystalloid fluids that were given routinely to patients in both the treatment and control groups, which probably would increase the number of patients needed to demonstrate a statistically significant difference in mortality.

In order to address ongoing questions of efficacy, the National Heart, Lung, and Blood Institute evaluated hypertonic sodium chloride solutions with or without a colloid (ie, 7.5% sodium chloride or 7.5% sodium chloride in 6% dextran 70) for prehospitalized trauma patients with shock and severe traumatic brain injury in two trials conducted by a network of sites known as the Resuscitation Outcomes Consortium (ROC). Both the parallel trials were stopped when it was determined that the hypertonic sodium chloride solutions were no better than normal saline and further enrollment would not change the 33 outcomes.[33,34] Therefore, normal saline is the fluid of choice since it is equal in efficacy with a lower risk of adverse effects compared with hypertonic solutions that are high-risk electrolyte solutions. Given their relatively poor intravascular expansion and association with poor outcome in animal models of closed head injury, hypotonic solutions should be avoided in this population.

In addition to crystalloid solutions, colloids have been used for plasma expansion in trauma patients with perioperative circulatory insufficiency. No large randomized studies have compared crystalloids and colloids for circulatory insufficiency in trauma patients. Until such studies are performed, there is no compelling reason to suspect that colloids have any substantial clinical benefits beyond crystalloids in these patients given the results of previous trials and systematic reviews performed in more general critical care populations. Further, bleeding and renal injury concerns for both starch and dextran products precludes their use in critically ill trauma patients.

The preceding discussion dealt primarily with acute circulatory insufficiency, but there are other considerations with regard to fluid replacement in other patients undergoing surgical procedures. Preoperative fluid deficits in patients undergoing minor procedures may be associated with increased perioperative morbidity, some of which (eg, drowsiness, dizziness) may be reduced by appropriate fluid administration prior to surgery. However, care must be taken to avoid overhydration in the perioperative period because excess fluid will lead to weight gain and decreased pulmonary function. Some evidence suggests that fluid restriction on the day of surgery may reduce postoperative morbidity in patients undergoing major surgical procedures. In one randomized, multicenter trial, use of a restricted intraoperative and postoperative IV fluid protocol led to significantly fewer cardiopulmonary (7% vs 24%; $P = 0.007$) and wound (16% vs 31%; $P = 0.04$) complications.[35] As the preceding discussion indicates, the benefits and risks of fluid administration in the perioperative period are not just a function of too little or too much fluid but involve other patient- and procedure-related issues.

Another consideration in the patient with penetrating injuries or surgery is the potential need for blood product administration (**Table 24-7**) to replace oxygen-carrying and clotting functions. Although a small group of trauma patients respond to the initial fluid bolus and remain stable, most patients respond initially and then deteriorate. The latter patients, as well as patients undergoing blood loss associated with surgery, frequently need blood components such as packed red blood

cells. In the case of the latter component, red blood cells contain hemoglobin that delivers oxygen to tissues. Neither crystalloids nor colloids perform this function.

TABLE 24-7 General Indications for Blood Products in Acute Circulatory Insufficiency due to Hemorrhage

Packed red blood cells
Increase oxygen-carrying capacity of blood: Usually indicated in patients with continued deterioration after volume replacement or obvious exsanguination; must be warmed, particularly when used in children
Fresh-frozen plasma
Replacement of clotting factors: Generally overused; indicated if ongoing hemorrhage in patients with PT/PTT >1.5 times normal, severe hepatic disease, or other bleeding diathesis
Platelets
Used for bleeding due to severe thrombocytopenia (ie, platelet count <10,000/μL [$<10 \times 10^9$/L]) or rapidly dropping platelet counts as would occur with massive bleeding
Other products
With the exception of recombinant activated factor VII, which is currently undergoing trials for use in life-threatening hemorrhage unresponsive to traditional blood product administration, components such as cryoprecipitate and factor VIII are generally not indicated in acute hemorrhage but rather are used after specific deficiencies are identified

PT, prothrombin time; PTT, partial thromboplastin time.

[a]Although whole blood can be used for large-volume blood loss, most hospitals use component therapy, and use crystalloids or colloids for plasma expansion.

Administration of excessive blood products may be counterproductive. In the case of red blood cells, attempts to raise the hematocrit to high–normal or supranormal concentrations may decrease oxygen delivery by increasing blood viscosity. Additionally, there are immunomodulatory concerns with red blood cell administration. Although there is no optimal hematocrit value for all patients, a minimum hematocrit of 30% (0.30) (equivalent to a hemoglobin concentration of 10 g/dL [100 g/L; 6.21 mmol/L]) traditionally has been used as the threshold for transfusion, particularly in patients at risk for ischemia, such as those with CAD. Use of a more liberal transfusion strategy has been curtailed in many institutions with the publication of a randomized, multicenter trial involving critically ill patients that found 30-day mortality to be similar whether patients were transfused at a hemoglobin concentration less than 7 or 10 g/dL (70-100 g/L; 4.34-6.21 mmol/L) (18.7% vs 23.3%, respectively; $P = 0.11$).[36] The mortality during hospitalization was significantly lower in the restrictive group (22.2% vs 28.1%; $P = 0.05$). Although the investigators were cautious about extrapolating the results of this investigation to patients with myocardial ischemia, a subsequent study performed in

patients undergoing cardiac surgery found similar results.[37] With the exception of the critically ill or perioperative patient with acute exsanguination, there is little justification for a liberal transfusion strategy based solely on hemoglobin concentrations.

Blood products have risks beyond immunomodulation. There is the rare but important risk of virus transmission (eg, human immunodeficiency virus [HIV], hepatitis). Citrate that is added to stored blood to prevent coagulation may bind to calcium, resulting in hypocalcemia, although potassium and phosphate concentrations often are elevated in stored blood, particularly when hemolysis has occurred during storage. In patients receiving large amounts of blood, prophylactic calcium administration may be warranted until levels are available. Other issues that must be considered with blood product administration include monitoring for transfusion-related reactions and attention to appropriate warming, particularly when large volumes are given to pediatric patients, because hypothermia is associated with increased fluid requirements and mortality.

Since its commercial release in the United States, recombinant factor VIIa has been used for a variety of off-label uses related to trauma and bleeding. For example, in patients with massive blood loss a cocktail of cryoprecipitate, platelets, and recombinant factor VIIa has been suggested to rapidly attain hemostasis. These more severe forms of blood loss are a function of not only the type of injury but also factors such as medications (eg, aspirin, Coumadin, clopidogrel, enoxaparin, newer oral anticoagulants) and disease states that impair normal coagulation. Large well-controlled trials are needed to define the role of recombinant factor VIIa in clinical practice given its high cost and potential thromboembolic complications. Concerns with its use in trauma patients are issues related to appropriate dose, timing, and diminished effectiveness in patients with acidosis and severe hypothermia. Evidence of efficacy in a general trauma population that would offset these concerns is lacking. In the largest randomized controlled trial conducted to date that enrolled patients with penetrating and blunt trauma, factor VIIa did not decrease mortality compared with placebo when the trial was prematurely terminated due to futility.[38]

The periodic shortages, high costs, and adverse effect concerns related to blood products have prompted investigations of alternative “bloodless” strategies. In addition to the use of more restrictive transfusion thresholds, as mentioned previously, these strategies have included hemoglobin-based oxygen carriers and perfluorocarbon compounds to deliver oxygen to tissues. Other strategies have aimed at reducing blood loss through the use of improved procedural and surgical techniques, as well as the administration of hemostatic medications. The only hemostatic medication with a proven mortality benefit is the antifibrinolytic agent, tranexamic acid. The best evidence for efficacy was data from a multicenter trial involving more than 20,000 adult trauma patients with significant bleeding (or risk for significant bleeding) who were randomized to IV tranexamic acid (1 g over 10 minutes followed by 1 g over 8 hours by infusion) or matching placebo within 8 hours of injury.[39] There was a significant reduction in all-cause mortality with tranexamic acid compared with placebo (14.5% vs 16%, $P = 0.0035$) with no increase in vascular or other adverse events. A more in-depth review of the results of this trial suggests that the beneficial effects are most likely to occur if tranexamic acid is given within the first 3 hours of injury. While additional data are still needed in specific subpopulations such as patients with traumatic brain injuries, this study is relatively unique in that an intervention apart from surgery and blood product administration was

demonstrated to reduce mortality.

Patients with Thermal Injuries

There are a number of formulas for estimating fluid requirements in thermally injured patients, but there is little reason to choose one over another based on well-controlled studies. In general, the amount of loss corresponds to the size of the thermal injury. Guidelines recommend approximately 2 to 4 mL/kg of isotonic fluid (lactated Ringer solution) for each percent burn can be used for calculating the expected fluid requirements for the first 24 hours after the burn.[16] For example, a 60-kg person with 30% body surface area (BSA) burns is expected to require 5,400 to 7,200 mL of fluid over the initial 24 hours. Regardless of the calculated deficit, fluids should be administered until adequate tissue perfusion has been documented (eg, maintenance of urine output of 0.5-1 mL/kg in adults) or adverse effects (eg, pulmonary edema) occur. Crystalloids are preferred as initial therapy for burn victims because there is no substantial evidence that colloids mobilize edematous fluid, and there is a theoretical concern that extravascular fluid accumulation might be prolonged by the oncotic actions of albumin and other colloid products that have leaked through vessel walls. Additionally, there is no evidence that colloids reduce mortality in patients with thermal injuries and there is a concern that hydroxyethyl starch and dextran products might even increase mortality through deleterious effects on coagulation and renal function. Some novel therapies for thermal resuscitation have been studied, although larger confirmatory trials are needed prior to use apart from research protocols. For example, in a prospective study involving patients with more than 30% BSA burns, antioxidant therapy with extremely high doses of IV vitamin C (66 mg/kg/h for 24 hours) reduced resuscitation fluid requirements and wound edema.[40] The proposed mechanism is reduction in free radical–induced increases in capillary permeability.

Personalized Pharmacotherapy

At this time there is little genetic/genomic information that is available to guide personalized pharmacotherapy in patients with hypovolemic shock. Further, as stressed throughout this chapter, fluids are by far the first choice of therapy in conjunction with other definitive interventions such as surgery for traumatic injuries. Nevertheless, there are individual factors that may influence the specific fluid being administered. For example, the lower chloride concentration in lactated Ringer would usually make it preferred over normal saline in patients with a hyperchloremic metabolic acidosis, while the increased osmolarity of normal saline would usually make it preferred over lactated Ringer in a patient with increased intracranial pressure.

Clinical Controversies

Some clinicians believe that hypertonic sodium-containing solutions should be the intervention of choice to lower intracranial pressure in patients with head injuries.

The appropriate use of invasive hemodynamic monitoring tools, such as right-sided heart catheterization in patients with hypovolemic shock, is controversial.

Some clinicians believe that more balanced crystalloid solutions are preferred over normal saline for IV fluid resuscitation given the association between high-chloride-containing solutions and acute kidney injury.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

One form of monitoring that may take place in the emergency and operating rooms, as well as in the ICU, requires placement of a central venous pressure (CVP) line. Monitoring of CVP provides the clinician with a somewhat insensitive yet useful estimate of the relationship between increased right atrial pressure and cardiac output. A protocol that used a particular type of central catheter to perform continuous monitoring of central venous oxygen saturation in conjunction with so-called early goal-directed therapy (EGDT) in the first 6 hours of patient arrival in an urban emergency department resulted in decreased mortality compared with standard monitoring (30.5% vs 46.5%; P = 0.009).[41] However, the results of this landmark study that used continuous central venous oxygen saturation monitoring as part of an EGDT protocol have been called into question by two more recent studies (Protocolized Care for Early Septic Shock [ProCESS] and Australasian Resuscitation in Sepsis Evaluation [ARISE]).[42,43] In ProCESS and ARISE, no significant differences were found in mortality (or a variety of other secondary endpoints) between groups that received the continuous invasive monitoring versus groups receiving usual, less invasive monitoring. These follow-up investigations suggest it may have been the protocols of care and not the invasive catheter that was responsible for the mortality benefit noted in the original landmark study. Also of note is that patients in all of these studies had severe sepsis and septic shock, so the results might not be applicable to other forms of shock with different pathophysiologic considerations. For example, in hemorrhagic shock due to trauma, the most important intervention is surgical control of bleeding, and anything that delays this control is likely to increase, not decrease, mortality. In fact, so-called "upstream" measurements of perfusion such as CVP are not a useful guide for fluid management in hospitalized patients, and are being replaced by "downstream" markers such as urine output and lactate levels that are more likely to reflect end-organ dysfunction.[44] A more complete discussion of invasive and noninvasive hemodynamic monitoring is given in Chapter e11.

Clinical Controversy…

The most appropriate, cost-effective, and practical parameter(s) for monitoring adequacy of fluid resuscitation in shock is unresolved.

A number of laboratory tests are indicated for subacute monitoring of shock in the ICU setting. These include a renal battery for assessing possible electrolyte alterations and kidney perfusion (eg, BUN and creatinine). Among other things, a complete blood count will enable assessment of possible infection (white blood cell count), oxygen-carrying capacity of the blood (hemoglobin, hematocrit), and ongoing bleeding (hemoglobin, hematocrit, and platelet count). The PT or international normalized ratio and partial thromboplastin time (PTT) will give an indication of the ability of the blood to clot because, in the case of hemorrhagic shock, clotting factors are lost and diluted. An

increasing lactate concentration (arterial, mixed venous, or central venous), an increasing arterial base deficit, or a decreasing bicarbonate concentration are global markers indicative of inadequate perfusion leading to anaerobic metabolism with accumulation of lactic acid. Although the value of these surrogate markers for improving patient outcomes is more controversial, they are considered traditional end points of resuscitation in certain populations such as trauma patients. Other tests may be indicated if organ dysfunction is likely. For example, when blood flow to the liver is interrupted because of sustained hypotension, a condition known as *shock liver* may occur. In this condition, the levels of transaminases on a liver panel may be markedly elevated in the first couple of days after marked hypotension, although the concentrations should decrease over time. Along with laboratory testing, a more extensive history can be obtained during the subacute monitoring period.

The value of pulmonary artery catheters (also known as *right-sided heart* or *Swan-Ganz catheters*) has been debated hotly since their introduction. Such catheters are placed to obtain various oxygen-transport variables, some of which cannot be determined reliably from peripheral or other central vessels. The debate was intensified when early studies suggested improved outcomes when cardiac output and other oxygen-transport variables were raised to supranormal levels, the monitoring of which required placement of a pulmonary artery catheter. The controversy led to consensus conferences and workshops, the development of organizational guidelines, and the publication of a meta-analysis (which found a statistically significant reduction in *morbidity* using pulmonary artery catheters to guide therapy).[45] Ultimately, a large randomized controlled trial involving pulmonary artery catheters was conducted in high-risk surgical patients.[46] The trial involved 1,994 patients. The mortality was almost identical for the catheter and control groups (7.8% vs 7.7%; 95% CI, 2.3-2.5). There were no episodes of pulmonary embolism in the catheter group and eight episodes in the control group (P = 0.004). This trial is important not only because of the implications for high-risk surgical patients but also because it allows for the conduct of future trials in other patient populations without some of the ethical issues raised about such trials in the past.

Part of the concern regarding pulmonary artery catheterization relates to interpretation of its results by inexperienced practitioners. Studies in Europe and the United States found that one of two physicians incorrectly interpreted a tracing from a pulmonary artery catheter.[47] This could explain some of the results of studies finding no benefits to pulmonary artery catheterization or, in some cases, worse outcomes in the pulmonary artery catheterization group by actions taken as a result of inaccurate measurements or misinterpretation of information obtained from the monitoring process.

Complications related to pulmonary artery catheter insertion, maintenance, and removal include damage to vessels and organs during insertion, arrhythmias, infections, and thromboembolic damage. To avoid the complications associated with pulmonary artery catheterization, other less invasive tools were developed to obtain similar information. For example, cardiac output determinations have been made by Doppler, bioimpedance, dye, and ionic dilution techniques, although such measurements would not provide other data that are obtained routinely with pulmonary artery catheters (eg, left-sided heart filling pressure). Additionally, advances in pulmonary artery catheter technology that expand the information obtained from such monitoring (eg, mixed venous oxyhemoglobin) are under investigation. However, given the lack of well-defined outcome data associated with pulmonary artery catheterization, its use is best reserved for complicated cases

of shock not responding to conventional fluid and medication therapies.

Commonly measured and calculated hemodynamic and oxygen-transport indices associated with invasive monitoring are primarily global indicators of tissue perfusion. Attempts have been made to find regional and local indicators of hypoperfusion so that circulatory insufficiency could be treated before overt shock occurs. One focus of recent research has been monitoring modalities involving the GI tract. Although the literature is fairly consistent concerning low gastric intramucosal pH (pHi) values being predictive of death, pHi-guided therapy to decrease mortality has not been demonstrated.[48] Additionally, a number of technical considerations remain to be resolved when using pHi or, more recently, capnometry (luminal PCO_2 tonometry) for monitoring and therapy. Despite these concerns, measures of regional tissue oxygenation continue to be investigated through a variety of novel monitoring techniques.

In addition to regional monitoring of tissue perfusion, local methods of monitoring are being studied. For example, subcutaneous measurement of tissue oxygen pressure shows promise in preliminary investigations. Regional and local measurements likely will not replace more global indicators of perfusion; rather, the methods will complement each other.

Monitoring of the Pharmaceutical Care Plan after Initial Fluid Resuscitation

Proper attention to monitoring of plasma volume must be continued into the intraoperative and postoperative periods. A number of neurohormonal changes take place that affect urine output, and patients may have substantial third spacing of fluid depending on the operation and preexisting conditions. Furthermore, postoperative patients are prone to hyponatremia from renal generation of electrolyte-free water and from antidiuretic hormone release. As in acute resuscitation, the administration of hypotonic solutions in the perioperative period does not prevent the decrease in extracellular volume that often occurs. Therefore, although excess fluid administration is to be avoided in the perioperative setting, isotonic crystalloid solutions should be used when fluids are indicated to prevent intravascular depletion and circulatory insufficiency.

Of the randomized studies comparing albumin with crystalloid solutions in the perioperative period, the majority found no statistically significant differences between groups. Any significant differences found involved isolated hemodynamic or respiratory variables with no obvious clinical correlates (eg, duration of mechanical ventilation). Therefore, albumin cannot be recommended for the prevention or initial treatment of circulatory insufficiency, although its use may be appropriate in patients who are not responding to crystalloids and are developing problems such as interstitial fluid accumulation.

There is no evidence that vasoactive medications improve outcome in patients with hypovolemic shock assuming that fluid therapy is adequate. 10 In a multicenter cohort study of blunt-injured patients with hemorrhagic shock, the use of vasopressors within 12 hours of injury was associated with significantly higher mortality at 24 hours (P = 0.001).[49] Therefore, pressor agents such as norepinephrine and high-dose dopamine are to be avoided, if possible, because they may increase blood pressure at the expense of peripheral tissue ischemia. Some sources use stronger language

and state that vasopressors are contraindicated in certain forms of shock (eg, hemorrhagic). This does not help the clinician who is treating a patient with unstable blood pressure despite massive fluid replacement and increasing interstitial fluid accumulation. Although the search for a cryptogenic source (eg, intra-abdominal bleeding in a trauma patient) should continue, the clinician may need to administer vasoactive medications to improve perfusion. In such situations, inotropic agents such as dobutamine are preferred if blood pressure is adequate (eg, systolic blood pressure ≥80-90 mm Hg) because they should not aggravate the existing vasoconstriction. The inotropic agents are justified by presumed inadequate cardiac output for the specific situation, although the measured values may be in the normal range.

When pressure cannot be maintained with inotropic agents or when inotropic agents with vasodilatory properties cannot be used because of inadequate blood pressure concerns, pressors may be required as a last resort. In general, the need for pressors is predictive of the development of MODS and increased length of hospital stay. Although the response to pressor agents may be variable in hypovolemic shock, there does not appear to be resistance as a consequence of altered receptor response, as is sometimes seen in patients with septic shock. Potent vasoconstrictors such as norepinephrine and phenylephrine should be given through central veins because of the possibility of extravasation and necrosis with peripheral administration.

In managing patients with hypovolemic shock, the clinician must be aware of potential adverse effects of medications being used for supportive care purposes. For example, some patients are particularly susceptible to the histamine release associated with morphine and may have substantial decreases in blood pressure. Sodium bicarbonate would seem to be a logical therapy in patients with shock who typically have a metabolic acidosis, but bicarbonate administration has not been shown to improve surrogate hemodynamic markers or patient outcomes and has known disadvantages such as the associated increase in arterial carbon dioxide levels and decrease in serum ionized calcium levels.[50] Agents such as propofol and dexmedetomidine are commonly used for sedation in the ICU, but they may cause substantial decreases in blood pressure. The initial doses of such agents should be substantially reduced or preferably the agents should be avoided in patients with hemorrhagic shock who may not be fully resuscitated.

A number of interesting treatments for shock are under investigation, including autotransfusion for removing harmful cytokines from the body. Various alternatives to conventional blood components also are being studied, such as stroma-free hemoglobin and perfluorocarbon compounds, as virus-free alternatives to red blood cell transfusion. Hopefully, these methods will be useful adjuncts to adequate volume replacement, which is the primary therapeutic intervention in managing acute circulatory insufficiency as a result of volume depletion.

CLINICAL BOTTOM LINE

Figure 24-4 is an algorithm that summarizes many of the treatment principles discussed in this chapter. The algorithm is an example of one approach to the adult patient presenting with hypovolemic shock. It presumes that initial rehydration attempts (ie, outpatient or prehospital) were unsuccessful in restoring circulation. Obviously, modifications may be needed for patient-specific

forms of hypovolemic shock. For example, in patients with severe traumatic brain injury albumin would be contraindicated as a plasma expander, while hypertonic sodium solution might be considered for its ability to lower elevated intracranial pressure without causing the diuresis associated with mannitol administration. Other limitations of the algorithm should be recognized, particularly the decisions to add or to substitute medication therapies when crystalloid solutions are not yielding desired results and when to perform pulmonary artery catheterization for more invasive monitoring. Medications become more important for the ongoing management of hypovolemic shock, but only when the patient is unresponsive to fluids (**Fig. 24-5**). Medications for more complicated cases of hemorrhagic shock should not detract from the primary effective resuscitative measure—surgical stabilization of bleeding.

FIGURE 24-4

Hypovolemia protocol for adults. Normal saline (or a lower chloride-containing isotonic crystalloid) may be used instead of lactated Ringer solution. This protocol is not intended to replace or delay therapies such as surgical intervention or blood products for restoring oxygen-carrying capacity or hemostasis. For the resuscitation of patients with trauma prior to bleeding control, usually no more than 1 L of crystalloid should be given initially in an attempt to use the minimal amount of fluid necessary to maintain perfusion and not exacerbate bleeding. If available, some measurements can be used in addition to those listed in the algorithm, such as mean arterial pressure or pulmonary artery catheter recordings. The latter can be used to assist in medication choices (eg, agents with primary pressor effects may be desirable in patients with normal cardiac outputs, whereas dopamine or dobutamine may be indicated in patients with suboptimal cardiac outputs). Lower maximal doses of the medications in this algorithm should be considered when pulmonary artery catheterization is not available. See text for an in-depth discussion of these and other issues involved in this protocol. (CHF, congestive heart failure; LR, lactated Ringer solution.)

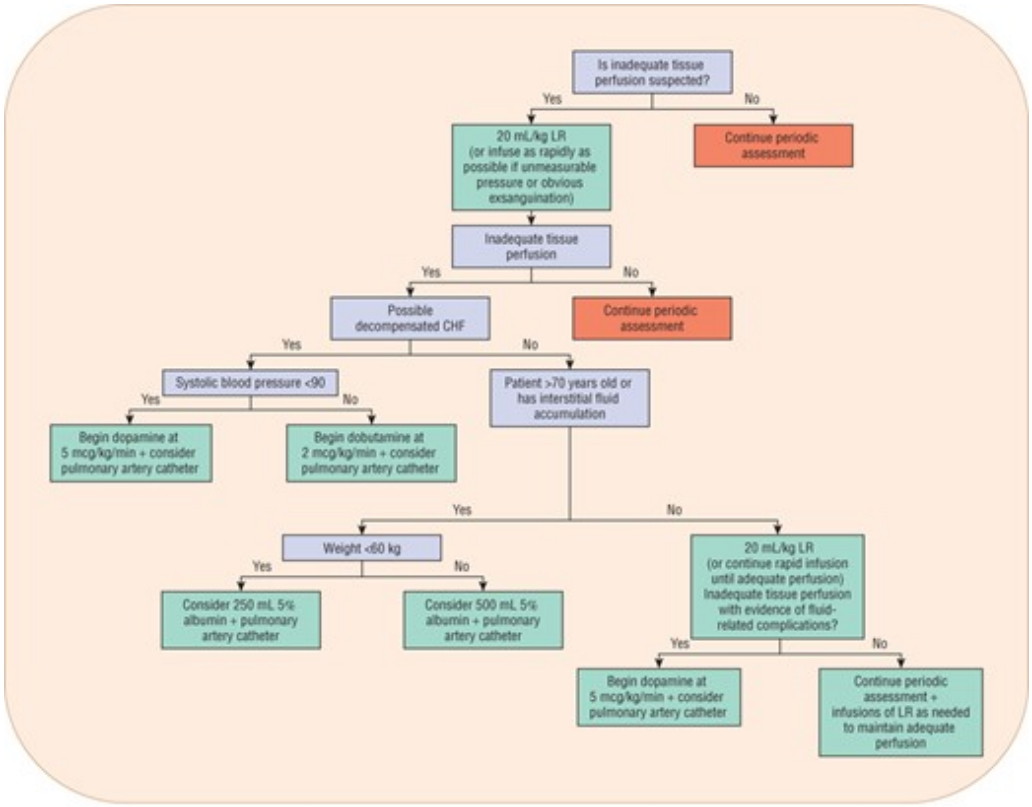


FIGURE 24-5

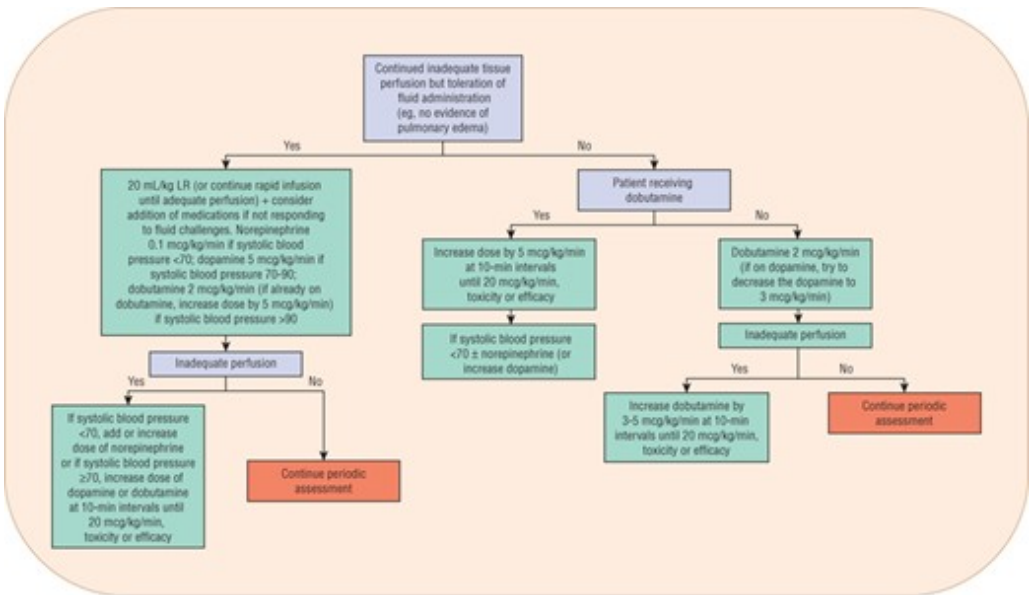
Ongoing management of inadequate tissue perfusion. Normal saline (or a lower chloride-containing isotonic crystalloid) may be substituted for lactated Ringer solution in this figure. (LR, lactated Ringer solution.)



The algorithm in Fig. 24-4 attempts to incorporate economic considerations and potential fluid

shortages. The institutional cost of 1 L of most crystalloid solutions is less than $1. Assuming that such fluids are used, the associated costs of personnel and equipment then become the primary economic considerations in the resuscitation of patients with hypovolemic shock. However, as mentioned, many clinicians recommend that colloid plasma expanders (eg, albumin, hydroxyethyl starch, or dextrans) be used to replace some or all of the standard crystalloid solutions. Although the costs of these solutions vary, depending on contractual arrangements, in general, albumin solutions are more expensive than older hydroxyethyl starch and dextran products. All these solutions are markedly more costly than crystalloid solutions; in some cases, the differences are 50- to 100-fold, even when used in equipotent amounts. It is important to note that these cost minimization statements assume no differences in efficacy or toxicity between colloids and crystalloids when given in equipotent amounts. This is almost certainly not the case with respect to adverse effects of hydroxyethyl starch and dextran products. A cost-effectiveness analysis that takes into account adverse effects would be needed for the latter products and such an analysis would likely demonstrate they are not cost-effective versus crystalloids even if equipotent efficacy is presumed.

Because medications are not simply alternatives to crystalloids but rather are used when crystalloid therapy has been optimized, there is little reason to compare medication and fluid therapies from an economic perspective. Furthermore, there are no economic comparisons of the various inotropic and vasopressor medications used in the treatment of hypovolemic shock.

Chapter e25: Introduction to Pulmonary Function Testing

Maria I. Velez; Tamara D. Simpson; Stephanie M. Levine; Jay I. Peters

INTRODUCTION

KEY CONCEPTS

- 1 Normal ventilation–perfusion ratio. The function of the lungs is to maintain arterial partial pressure of oxygen (PaO_2) and arterial partial pressure of carbon dioxide ($PaCO_2$) within normal ranges. This goal is accomplished by matching 1 mL mixed venous blood with 1 mL fresh air ($\dot{V}/\dot{Q} = 1$). Normally, ventilation ($\dot{V}$) is less than perfusion ($\dot{Q}$), and $\dot{V}/\dot{Q}$ ratio is 0.8.

- 2 The air in the lung is divided into four compartments: tidal volume—air exhaled during quiet breathing; inspiratory reserve volume (IRV)—maximal air inhaled above tidal volume; expiratory reserve volume (ERV)—maximum air exhaled below tidal volume; and residual volume (RV)—air remaining in the lung after maximal exhalation. The sum of all four components is the total lung capacity (TLC).

- 3 Obstructive lung disease is defined as an inability to get air out of the lung. It is identified on spirometry when forced expiratory volume in the first second of expiration (FEV_1)/forced vital capacity (FVC) (total amount of air that can be exhaled during a forced exhalation) (FEV_1/FVC) is less than 70% to 75% (or below the lower limit of normal (LLN) based on population studies).

- 4 Reversible airway obstruction is common in asthma and is sometimes seen in chronic obstructive pulmonary disease (COPD). An increase in FEV_1 of 12% (and greater than 0.2 L in adults) after an inhaled β-agonist suggests an acute bronchodilator response.

- 5 Restrictive lung disease is defined as an inability to get air into the lung and is best defined as a reduction in TLC (usually less than 80% predicted). It is suspected when FVC is low (less than 80% predicted) and FEV_1/FVC is normal.

- 6 Restrictive lung disease can be produced by a number of defects, such as increased elastic

recoil (interstitial lung disease), respiratory muscle weakness (myasthenia gravis), mechanical restrictions (pleural effusion or kyphoscoliosis), and poor effort.

The primary function of the respiratory system is to maintain normality of arterial blood gases, that is, arterial partial pressure of oxygen (PaO_2) and arterial partial pressure of carbon dioxide ($PaCO_2$). To achieve this goal, several processes must be accomplished, including alveolar ventilation, pulmonary perfusion, ventilation–perfusion matching, and gas transfer across the alveolar–capillary membrane. Alveolar ventilation is achieved by the cyclic process of air movement in and out of the lung. During inspiration, the inspiratory muscle contracts and generates negative pressure in the pleural space. This pressure gradient between the mouth and the alveoli draws fresh air (tidal volume [V_T]) into the lung. Approximately one third of the inspired gas stays in the conducting airways (dead space), and two third reaches the alveoli.

1 The human lung contains a series of branching, progressively tapering airways that originate at the glottis and terminate in a matrix of thin-walled alveoli. Coursing through this matrix of alveoli is a rich network of capillaries that originates from the pulmonary arterioles and terminates in the pulmonary venules. The adequacy of respiration in each gas exchange unit depends on the apposition of a thin film of mixed venous blood with just the right amount of fresh alveolar gas. During "ideal" gas exchange, blood flow and ventilation are uniform; accordingly, there is no alveolar–arterial difference (or gradient) in the partial pressure of oxygen ($P[A–a]O_2$, sometimes called the A–a gradient). However, gas exchange is not perfect, even in the normal lung. Normally, alveolar ventilation is less than pulmonary blood flow, and the overall ventilation–perfusion ratio is 0.8 (not 1.0).

Normal expiration is a passive process, and when the inspiratory muscles end their contraction, the elastic recoil of the lung pulls the lung back to its original size and shape. This process makes the alveolar pressure positive relative to the pressure at the mouth, and air flows out of the lung. During inspiration, the respiratory muscles must overcome the elastic properties of the lung (elastic recoil) and the resistance to air flow by the airways. During expiration, the flow of air is determined primarily by the elastic recoil and airway resistance.

Different pulmonary function tests (PFTs) are used to evaluate the physiologic processes of the respiratory system. Physiologic abnormalities that can be measured by pulmonary function testing include obstruction to airflow, restriction of lung size, and decrease in transfer of gas across the alveolar–capillary membrane. Simple spirometry is frequently used to screen patients for evidence of obstruction or restrictive lung disease when they present with pulmonary complaints. Abnormal values on PFTs are outside the range of values obtained from a group of normal individuals matched according to age, height, sex, and race. A PFT is labeled abnormal when the results fall outside the range in which 95% of people of same age, height, and sex would be found (95% confidence interval). This definition is arbitrary and may misclassify a small percentage of normal individuals as having lung dysfunction; it also may miss patients with mild pulmonary disease. Therefore, clinical correlation and serial pulmonary function testing may be necessary for optimal interpretation of PFTs.

Potential uses of pulmonary function testing include evaluation of patients with known or suspected lung disease; evaluation of symptoms such as chronic cough, dyspnea, or chest tightness; monitoring

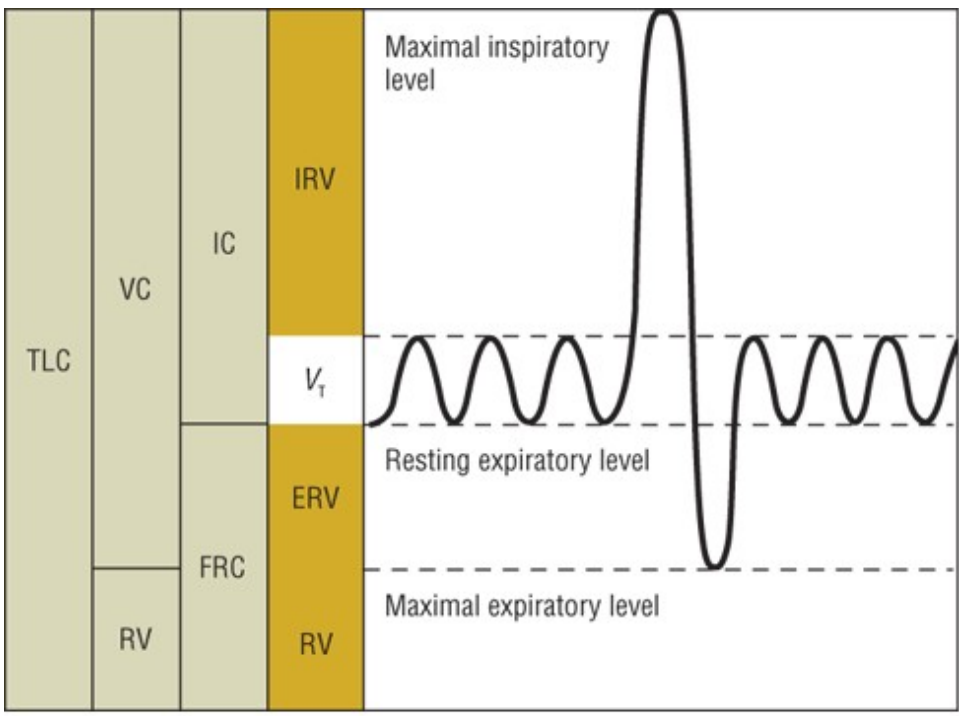
of the effects of exposure to dust, chemicals, or pulmonary toxic drugs; risk stratification prior to surgery; monitoring of the effectiveness of therapeutic interventions; and objective assessment of impairment or disability.[1]

DEFINITIONS OF LUNG VOLUMES AND EXPIRATORY FLOWS

2 The air within the lung at the end of a forced inspiration can be divided into four compartments or lung volumes (**Fig. e25-1**). The volume of air exhaled during normal quiet breathing is the V_T. The maximal volume of air inhaled above V_T is the *inspiratory reserve volume* (IRV), and the maximal air exhaled below V_T is the *expiratory reserve volume* (ERV). The *residual volume* (RV) is the amount of air remaining in the lungs after a maximal exhalation.

FIGURE e25-1

Lung volumes and capacities. (ERV, expiratory reserve volume; FRC, functional residual capacity; IC, inspiratory capacity; IRV, inspiratory reserve volume; RV, residual volume; TLC, total lung capacity; VC, vital capacity; V_T, tidal volume.)



The combinations or sums of two or more lung volumes are termed *capacities* (see Fig. e25-1). *Vital capacity* (VC) is the maximal amount of air that can be exhaled after a maximal inspiration. It is equal to the sum of IRV, V_T, and ERV. When measured on a forced expiration, it is called the *forced vital capacity* (FVC). When measured over an exhalation of at least 30 seconds, it is called the *slow vital capacity* (SVC). The VC is approximately 75% of the *total lung capacity* (TLC), and when the SVC is within the normal range, a significant restrictive disorder is unlikely. Normally, the values for SVC and

FVC are very similar unless airway obstruction is present.

Total lung capacity is the volume of air in the lung after the maximal inspiration and is the sum of the four primary lung volumes (IRV, V_T, ERV, and RV). Its measurement is difficult because the amount of air remaining in the chest after maximal exhalation, RV, must be measured by indirect methods. The definition of restrictive lung disease is based on a reduction in TLC (ie, an inability to get air into the lung or restriction to air movement on inhalation).

The *functional residual capacity* (FRC) is the volume of air remaining in the lungs at the end of a quiet expiration. It is the sum of RV and ERV. FRC is the normal resting position of the lung; it occurs when there is no contraction of either inspiratory or expiratory muscles and normally is 40% of TLC. *Inspiratory capacity* (IC) is the maximal volume of air that can be inhaled from the end of a quiet expiration and is the sum of V_T and IRV.

Forced vital capacity, which represents the total amount of air that can be exhaled, can be expressed as a series of timed volumes. The *forced expiratory volume in the first second of expiration* (FEV_1) is the volume of air exhaled during the first second of the FVC maneuver. Although FEV_1 is a volume, it conveys information on obstruction because it is measured over a known time interval. FEV_1 depends on the volume of air within the lung and the effort during exhalation; therefore, it can be diminished by a decrease in TLC or by a lack of effort. A more sensitive way to measure obstruction is to express FEV_1 as a ratio of FVC. This ratio is independent of the patient's size or TLC; therefore, FEV_1/FVC is a specific measure of airway obstruction with or without restriction. Normally, in adults older than 20 years this ratio is greater than or equal to 80% (0.75), and any value less than 80% to 75% suggests obstruction.

In children and young adults (age 5-20) an FEV_1/FVC ratio less than or equal to 85% is considered a sign of obstruction.[2]

Although FEV_1/FVC ratio is considered the "Gold standard" for the definition of obstruction, the effort required to obtain reliable values can be difficult to achieve in the elderly, patients with very severe obstruction and debilitated patients. To avoid this, some authors and the National Lung Health Education program recommended the use of the replacement of the FVC with forced expiratory volume in 6 seconds (FEV_6), which is easier to achieve and more reproducible, and the use of the FEV_1/FEV_6 ratio as an acceptable surrogate for the FEV_1/FVC ratio.[3]

Because *flow* is defined as the change in volume with time, forced expiratory flow (FEF) can be determined graphically by dividing the volume change by the time change. The *FEF during 25% to 75% of FVC* ($FEF_{25\%-75\%}$) represents the mean flow during the middle half of the FVC. $FEF_{25\%-75\%}$, formerly called the *maximal midexpiratory flow*, is reported frequently in the assessment of small airways. The 95% confidence limit is so wide that $FEF_{25\%-75\%}$ has limited utility in the early diagnosis of small airways disease in an individual subject. The *peak expiratory flow* (PEF), also called *maximum forced expiratory flow* (FEF_{max}), is the maximum flow obtained during FVC. This measurement is used often in the outpatient management of asthma because it can be measured with inexpensive peak flow meters.

All lung volumes and flows are compared with normal values obtained from healthy subjects. There are significant ethnic and racial variations in normal values, and all PFTs should report that race/ethnic adjustment factors have been used. This is especially important in African American subjects who exhibit a greater proportion of their height in the waist-to-leg length. If not corrected for ethnicity, many subjects will appear to have restrictive lung functions. The 2005 American Thoracic Society–European Respiratory Society (ATS–ERS) guidelines for interpretation of PFT results recommend that, for spirometry in the United States, the National Health and Nutrition Examination Survey (NHANES) III reference be used for subjects aged 8 to 80 years and the Wang equation used in subjects younger than 8 years.[4]

Spirometry/Flow–Volume Loop

Spirometry[5] is the most widely available and useful PFT. It takes only 15 to 20 minutes, carries no risks, and provides information about obstructive and restrictive disease. Spirometry allows for measurement of all lung volumes and capacities except RV, FRC, and TLC; it also allows assessment of FEV_1 and $FEF_{25\%-75\%}$. Spirometry measurements can be reported in two different formats—standard spirometry (**Fig. e25-2**) and the flow–volume loop (**Fig. e25-3**). In standard spirometry, the volumes are recorded on the vertical (*y*) axis and the time on the horizontal (*x*) axis. In flow–volume loops, volume is plotted on the horizontal (*x*) axis, and flow (derived from volume/time) is plotted on the vertical (*y*) axis. The shape of the flow–volume loop can be helpful in differentiating obstructive and restrictive defects and in diagnosing upper airway obstruction (**Fig. e25-4**). This curve gives a visual representation of obstruction because the expiratory descent becomes more concave with worsening obstruction.

FIGURE e25-2

Standard spirometry. Curve 1 is for a normal subject with normal FEV_1; curve 2 is for a patient with mild airway obstruction; curve 3 is for a patient with moderate airway obstruction; curve 4 is for a patient with severe airway obstruction. (BPTS, body temperature saturated with water vapor.)

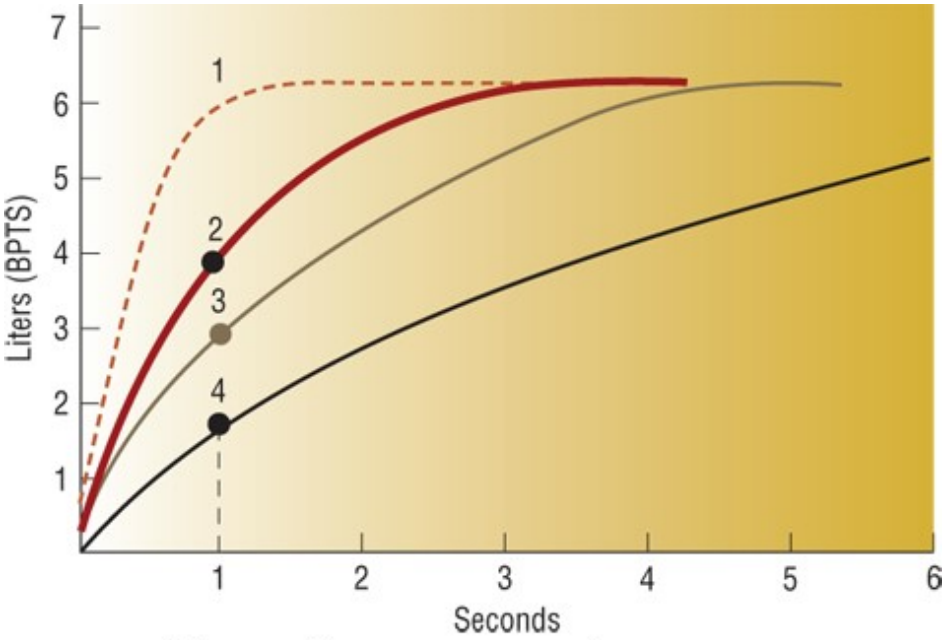


FIGURE e25-3

Normal flow–volume loop. Flows are measured on the vertical (*y*) axis, and lung volumes are measured on the horizontal (*x*) axis. Forced vital capacity (FVC) can be read from the tracing as the maximal horizontal deflection. Instantaneous flow ($\dot{V}_{max}$) at any point in FVC also can be measured directly. ($FEF_{50\%}$, forced expiratory flow at 50% of FVC; PEF, peak expiratory flow; PIF, peak inspiratory flow; RV, residual volume; TLC, total lung capacity.)

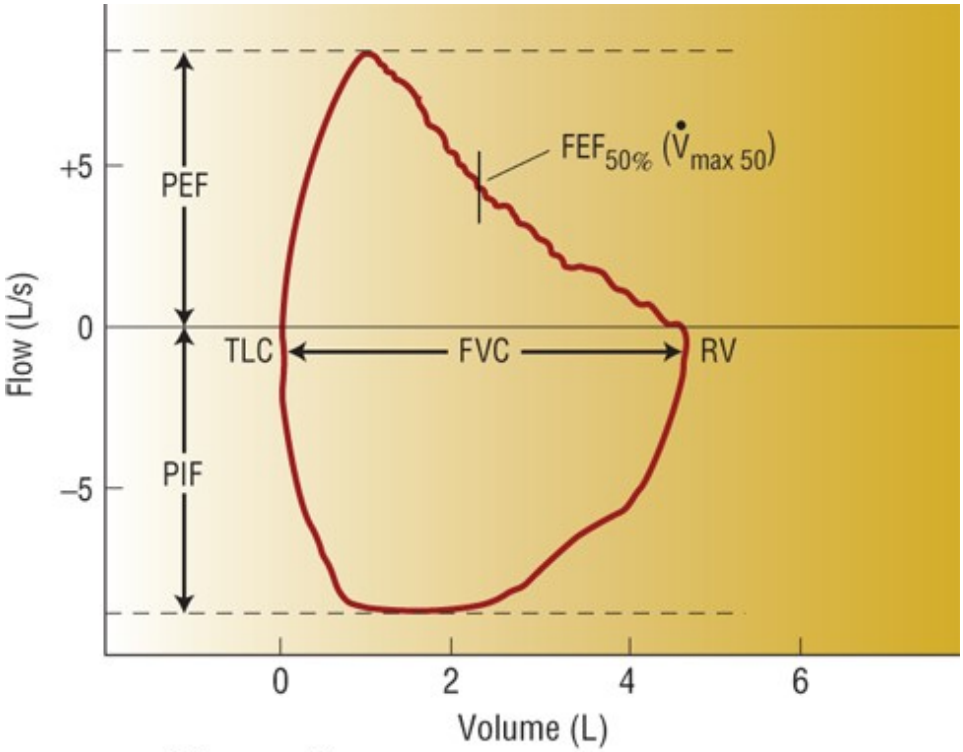

FIGURE e25-4

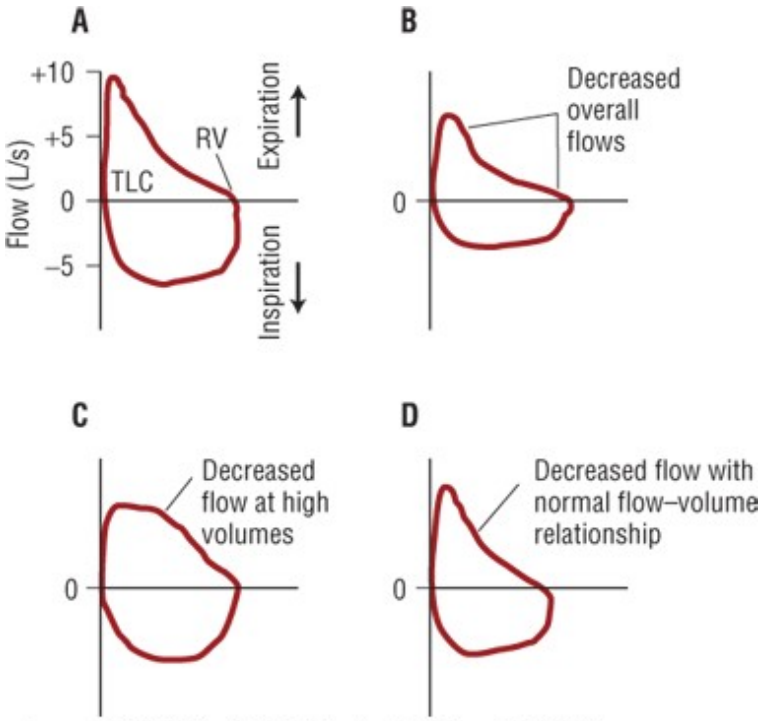
A. Flow–volume loop depicting mild obstruction characterized by decreased flow at low lung volumes. *B*. Moderate airflow obstruction characterized by a more concave curve. *C*. Variable intrathoracic obstruction in which peak flow is decreased at higher lung volumes with normalization of curve at lower lung volumes. *D*. Restrictive lung disease with a curve that is decreased in width but with a normal shape. (RV, residual volume; TLC, total lung capacity.)



Lung Volumes

Spirometry measures three of the four basic lung volumes but cannot measure RV. RV must be measured to determine TLC. TLC should be measured anytime VC is reduced. In the setting of chronic obstructive pulmonary disease (COPD) and a low VC, measurement of TLC can help to determine the presence of a superimposed restrictive disorder. The four methods for measuring TLC are helium dilution, nitrogen washout, body plethysmography, and chest x-ray measurement (planimetry).[6] The first two methods are called *dilution techniques* and only measure lung volumes in communication with the upper airway. In patients with airway obstruction who have trapped air, dilution techniques will underestimate the actual volume of the lungs. Planimetry measures the circumference of the lungs on the posteroanterior view and lateral views of a chest x-ray film and estimates the total lung volume.

Body plethysmography, or body box, is the most accurate technique for lung volume determinations. It measures all the air in the lungs, including trapped air. The principle of the measurement of the body box is Boyle's gas law ($P_1V_1 = P_2V_2$): a volume of gas in a closed system varies inversely with the pressure applied to it. The changes in alveolar pressure are measured at the mouth, as well as pressure changes in the body box. The volume of the body box is known. Lung volumes can be determined measuring the changes in pressures caused by panting against a closed shutter. Measurement of lung volumes provides useful information about elastic recoil of the lungs. If elastic recoil is increased (as in interstitial lung disease), lung volumes (TLC) are reduced. When elastic recoil is reduced (as in emphysema), lung volumes are increased.

Carbon Monoxide Diffusing Capacity

The diffusing capacity of the lungs (D_L) is a measurement of the ability of a gas to diffuse across the alveolar–capillary membrane.[7] Carbon monoxide is the usual test gas because normally it is not present in the lungs and is much more soluble in blood than in lung tissue. When the diffusing capacity is determined with carbon monoxide, the test is called the *diffusing capacity of lung for carbon monoxide* (D_{LCO}). Because D_{LCO} is directly related to alveolar volume (V_A), it frequently is normalized to the value D_L/V_A, which allows for its interpretation in the presence of abnormal lung volumes (eg, after surgical lung resection).

The diffusing capacity will be reduced in all clinical situations where gas transfer from the alveoli to capillary blood is impaired. Common conditions that reduce D_{LCO} include lung resection, emphysema (loss of functioning alveolar–capillary units), and interstitial lung disease (thickening of the alveolar–capillary membrane). Normal PFTs with reduced D_{LCO} should suggest the possibility of pulmonary vascular disease (eg, pulmonary embolus and pulmonary hypertension), anemia or early interstitial lung disease as well as mild *Pneumocystis jiroveci* pneumonia (PJP) infection.

Obstructive Lung Disease

3 Obstructive lung disease implies a reduced capacity to get air through the conducting airways and out of the lungs. This reduction in airflow may be caused by a decrease in the diameter of the airways (bronchospasm), a loss of their integrity (bronchomalacia), or a reduction in elastic recoil (emphysema) with a resulting decrease in driving pressure. The most common diseases associated with obstructive pulmonary functions are asthma, emphysema, and chronic bronchitis; however, bronchiectasis, infiltration of the bronchial wall by tumor or granuloma, aspiration of a foreign body, and bronchiolitis also cause obstructive PFTs. The standard test used to evaluate airway obstruction is the forced expiratory spirogram.

Standard spirometry and flow–volume loop measurements include many variables; however, according to ATS guidelines, the diagnosis of obstructive and restrictive ventilatory defects should be made using the basic measurements of spirometry.[4,5] A reduction in FEV_1 (with normal FVC) establishes the diagnosis of obstruction. When both FEV_1 and FVC are reduced, FEV_1 cannot be used to assess airway obstruction because such patients may have either obstruction or restriction. In restrictive lung disease, the patient has an inability to get air into the lung, which results in a reduction of all expiratory volumes (FEV_1, FVC, and SVC). In obstructed patients, a better measurement is the ratio FEV_1/FVC. Patients with restrictive lung disease have reduced FEV_1 and reduced FVC, but FEV_1/FVC remains normal. Although a normal FEV_1/FVC ratio is greater than 75% to 80% (greater than 0.75-0.8), the ratio is age dependent, and slightly lower values may be normal in older patients. Younger children have increased lung elastic recoil and may have higher ratios. Children should have a FEV_1/FVC greater than or equal to 85% to 90% (greater than or equal to 0.85-0.9). According to the 2007 National Asthma Education and Prevention Program and the most recent Global Imitative for Asthma (GINA) guidelines any value below this value should be considered a sign of obstruction, even if the FEV_1 and FVC are within the normal range. Caution should be used in interpreting obstruction when FEV_1/FVC is below normal, but both FEV_1 and FVC are within the normal range, because this pattern can be seen with healthy, athletic subjects as well as subjects with

mild asthma. Clinical judgment and response to bronchodilator challenge are often required to separate out these two groups. In children, the improvement in FEV_1 often is the only way to document mild-to-moderate obstructive lung disease.

In screening spirometry performed in office practice, forced expiratory volume in 6 seconds (FEV_6) can be used in place of FVC. FEV_6 is a more reproducible number when obtained by less skilled personnel. The measurement of $FEF_{25\%-75\%}$ also is abnormal in patients with obstructive airways disease. In general, this test has so much variability that it adds little to the measurement of FEV_1 and FEV_1/FVC.

Although there is no standardization for interpretation of severity of obstruction, most pulmonary laboratories state that FEV_1/FVC less than 70% (less than 0.70) of the predicted value is diagnostic for obstruction, and the degree of obstruction then is based on the percent predicted of FEV_1. FEV_1 between 80% and 100% of the predicted value is mild obstruction, 79% and 50% of the predicted value is moderate obstruction, between 49% and 30% is consistent with severe obstruction and less than 30% of the predicted value is classified as very severe obstruction. In patients with obstruction, a dose of a bronchodilator (eg, albuterol or isoproterenol) by metered-dose inhaler is given during the initial examination. An increase in FEV_1 of greater than 12% and greater than 0.2 L suggests an acute bronchodilator response.[4,5] It is important to remember that bronchodilator responsiveness is variable over time and therefore the lack of an acute bronchodilator response should not preclude a short trial of albuterol and/or corticosteroids.

Although all patients with obstructive lung disease of any etiology will have reduced flow rates on forced exhalation, the pattern on PFTs may be helpful in differentiating among the various etiologies (**Table e25-1**). Asthma is characterized by variable obstruction that often improves or resolves with appropriate therapy. Because asthma is an inflammatory disorder of the airways (predominantly large airways), D_{lco} is usually normal or even slightly above the normal range. Most patients with acute asthma have a bronchodilator response greater than 15% to 20%; Chronic bronchitis may be limited to the airways, but the vast majority of patients with chronic bronchitis and airway obstruction have a mixture of bronchitis and emphysema and have a reduction in D_{lco}. Therefore, D_{lco} is the best PFT for separating asthma from COPD.

TABLE e25-1 Specific Patterns of Pulmonary Function in Patients with Chronic Obstructive Pulmonary Disease

		COPD	
	Asthma	**Chronic Bronchitis**	**Emphysema**
Decreased FEV_1	++++	++++	++++
Decreased FEV_1/FVC	++++	++++	++++
Increased airway resistance	++++	++++	+
Decreased D_{lco}	–	–/++[a]	++++
Response to bronchodilators	++++	+[b]	–[b]

D_{LCO}, diffusing capacity of lung for carbon monoxide; FEV_1, forced expiratory volume in the first second of expiration; FVC, forced vital capacity.

[a]Most smokers with chronic bronchitis have reduced D_{LCO}.

[b]Twenty percent of patients with chronic obstructive pulmonary disease (COPD) have a large (++++) bronchodilator response.

A recently described entity Asthma-COPD overlap syndrome (ACOS) encompasses patients with persistent airflow limitation as seen in COPD and several features usually associated with asthma including airway hyperresponsiveness and marked bronchodilator response.

After the diagnosis of obstructive airways disease is established, the course and response to therapy are best followed by serial spirometry. Smoking cessation has the greatest capacity to influence the natural history of COPD. The multicenter Lung Health Study demonstrated an abnormally rapid decline of FVC of 90-150 mL/y in patients with COPD who continue to smoke.[8] Smoking cessation often resulted in an increase in FEV_1 during the first year and a near-normal rate of decline (30-50 mL/y) in subsequent years.

AIRWAY HYPERREACTIVITY

4 *Airway hyperreactivity* or *hyperresponsiveness* is defined as an exaggerated bronchoconstrictor response to physical, chemical, or pharmacologic stimuli. Individuals with asthma, by definition, have hyperresponsive airways. The Lung Health Study Research Group observed nonspecific hyperresponsiveness in a significant number of patients with COPD. This group of patients with airway hyperreactivity appears to have a worse prognosis and an accelerated rate of decline in FEV_1.[9]

Some patients with asthma (especially cough-variant asthma) present with no history of wheezing and normal PFTs. The diagnosis of asthma still can be established by demonstrating hyperresponsiveness to provocative agents. The agents used most widely in clinical practice are methacholine and mannitol. Other agents used for bronchial provocation include distilled water, hypertonic saline, cold air, histamine, and exercise. Medications that can potentially affect the test giving false negative results include B2 agonist, anticholinergics, corticosteroids, theophylline and leukotriene receptors antagonists[10] (**Table e25-2**). During a typical methacholine bronchoprovocation test, baseline FEV_1 is measured after inhalation of isotonic saline, and then increasing doses of methacholine are given at set intervals. Hyperresponsiveness is defined as a decline in FEV_1 greater than or equal to 20% and reversibility of obstruction to bronchodilators. The result can best be expressed as the provocative concentration needed to cause a 20% fall in FEV_1 (PC_{20}). A test is considered positive if methacholine demonstrates a PC_{20} less than or equal to 4 mg/mL or less than 60 to 80 cumulative breath units. The test is considered negative if the PC_{20} is greater than 16 mg/dL. Values between 4 and 16 are considered borderline.[9] The bronchoprovocation tests (methacholine, mannitol test) is contraindicated in severe airway obstruction (FEV_1 less than 50% or 1 L), uncontrolled hypertension (SBP greater than 200 mm Hg DBP

greater than 100 mm Hg), recent myocardial infarction or cerebrovascular accident (in the 3 previous months) and known aortic aneurysm.[10]

TABLE e25-2 Recommended Time to Withhold Medication Prior to Bronchoprovocation Study

- 8 hours- short acting beta 2 agonist
- 12 hours- inhaled corticosteroids
- 12 hours- short acting anticholinergics
- 24 hours- inhaled corticosteroids plus long acting beta 2 agonists
- 24 hours- long acting beta 2 agonists
- 24 hours- theophylline
- 72 hours- antihistamines
- 96 hours- leukotriene-receptor antagonists

Mannitol comes in inhaled dry-powder capsules of graduated doses, which makes its administration convenient.[11] When using mannitol, a drop in FEV_1 greater than or equal to 15% from baseline (0 mg) up to a dose of 635 mg or a 10% reduction in FEV_1 between consecutive doses is considered significant and is referred to as provocative dose 15 (PD15). This test is used most frequently to establish a diagnosis of asthma in patients with normal PFTs, but it also may be useful in following patients with occupational asthma, establishing the severity of asthma, and assessing the response to treatment.

UPPER AIRWAY OBSTRUCTION

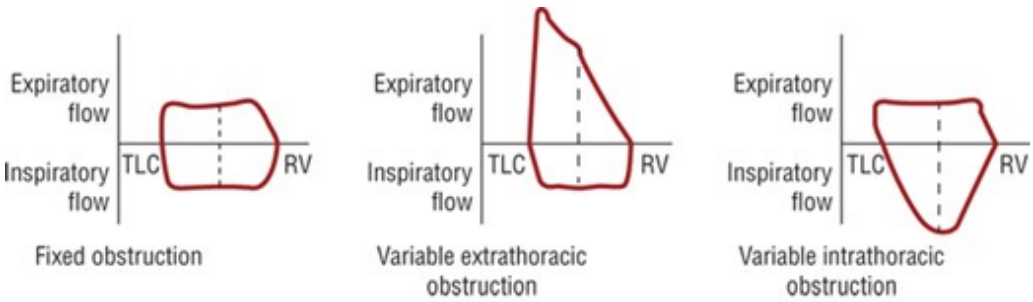
Obstruction of airflow by abnormalities in the upper airway often goes undiagnosed or misdiagnosed because of improper interpretation of PFTs. Patients have obstructive physiology and often are misclassified as having asthma or COPD. The shape of the flow–volume loop, which includes inspiratory and expiratory flow–volume curves, and the ratio of forced expiratory and inspiratory flow at 50% of VC ($FEF_{50\%}/FIF_{50\%}$ greater than 1) may be useful in the diagnosis of upper airway obstruction.[4,12]

The shape of the flow–volume curve differs depending on whether the obstruction is fixed or variable (**Fig. e25-5**). Fixed lesions, as in strictures from previous intubations or tracheostomy, cause a uniform caliber of airway during inspiration and expiration. With variable lesions, the airway caliber changes with changes in intrathoracic pressure. Variable lesions are subclassified into variable intrathoracic and variable extrathoracic. If the lesion is intrathoracic, as with tumors of the trachea, the negative pressure generated during inspiration opens the obstruction, whereas the positive pressure during expiration worsens the obstruction. If the lesion is a variable extrathoracic

obstruction, as with vocal cord dysfunction, the negative pressure within the airways will pull the vocal cord toward the midline and potentiate the obstruction. In this case, there will be a plateau on the inspiratory limb of the flow–volume loop, and $FEF_{50\%}/FIF_{50\%}$ will be greater than 1. Typical flow–volume curves from upper airway obstruction are shown in Fig. e25-5. While 80% of subjects with vocal cord dysfunction demonstrate the classical variable extrathoracic pattern, 18% present with a pattern of variable intrathoracic obstruction, and 2% present with a pattern of fixed obstruction.

FIGURE e25-5

Maximum expiratory flow–volume curves from patients with fixed obstruction, variable extrathoracic obstruction, and variable intrathoracic obstruction. (RV, residual volume; TLC, total lung capacity.)



Another test used to distinguish upper airway obstruction from COPD and asthma is $FEV_1/FEV_{0.5}$ (FEV at 0.5 second). This ratio usually is greater than 1.5 in patients with upper airway obstruction.[12] This is so because $FEV_{0.5}$ is proportionately more reduced in upper airway obstruction because forced expiration measured at 0.5 second better reflects obstruction at high lung volumes. The abnormality seen on the flow–volume loop has been referred to as "straightening" of the curve during early expiration.

RESTRICTIVE LUNG DISEASE

5 *Restrictive lung disease* is defined as an inability to get air into the lungs and to maintain normal lung volumes. Restrictive lung disease reduces all the subdivisions of lung volumes (IRV, TV, ERV, and RV) without reducing airflow. Patients have normal airway resistance and FEV_1/FVC greater than 75% (greater than 0.75). A recent combined consensus statement from the ATS and the ERS defines restrictive and obstructive disorders.[13]

Although *restriction* could be defined as a reduction in vital capacity (VC or FVC) with normal FEV_1/FVC, poor effort also will reduce FVC with normal FEV_1/FVC. A reduction in TLC is the most accurate measurement of restrictive lung function. TLC can be measured by various techniques. The gas dilution methods (eg, helium dilution and nitrogen washout) are unable to measure gas trapped in cysts or bullae and may underestimate the true lung volume. Therefore, TLC is best measured by plethysmography. Most restrictive lung disease is associated with impairment or destruction of the

alveolar–capillary membrane; therefore, D_{lco} is reduced in most patients with restrictive lung disease. The reduction in D_{lco} may occur prior to a reduction in lung volumes and is used as a marker of early interstitial (restrictive) lung disease. D_{lco} may be abnormal even with a normal chest x-ray film, and thin-sliced high-resolution computed tomographic scans of the chest (HRCT = 0.625-1.5 mm thickness) or a CT with thin cuts (2-3 mm thickness) may be required to diagnose early interstitial lung disease. Because peribronchiolar inflammation and fibrosis occur in some patients with restrictive parenchymal lung disease, $FEF_{25\%-75\%}$ may be reduced and fail to respond to bronchodilators.

The severity of restrictive disease has not been standardized; however, many laboratories classify patients with reduced TLC as mild (TLC less than or equal to 80%), moderate (TLC less than or equal to 69%), or severe (TLC less than or equal to 50%). These definitions are completely arbitrary because a patient with obstructive lung disease may start with TLC above the upper limit of normal (ie, 120%) and subsequently develop restrictive lung disease while maintaining TLC within the normal range. On flow–volume loop, patients with restrictive disease have normal-shaped curves with a reduction in the height and width of the curve because both PEF rate and VC depend on the amount of air within the lung prior to performance of expiratory maneuvers (see Figs. e25-3 and e25-4).

6 Restrictive lung function can be produced by increased elastic recoil of the lung parenchyma (interstitial lung disease), respiratory muscle weakness, mechanical restrictions (chest wall deformities), and/or poor effort. **Table e25-3** lists common causes of restrictive lung disease.

TABLE e25-3 Causes of Restrictive Lung Disease

- Interstitial lung diseases
- Idiopathic pulmonary fibrosis
- Sarcoidosis
- Collagen vascular disease
- Pneumoconiosis
- Drug-induced lung disease
- Pulmonary edema

Infiltrative lung diseases

- Granulomatosis
- Tumor

Pleural diseases

- Pleural effusion

- Fibrothorax
- Pneumothorax

Chest wall diseases

- Kyphoscoliosis
- Ankylosing spondylitis
- Neuromuscular disease

Miscellaneous causes

- Obesity
- Pregnancy
- Ascites
- Paralyzed diaphragm

Lung resection

Restrictive lung function from parenchymal lung disease usually can be differentiated from processes causing mechanical restriction as a result of chest bellows malfunction (**Table e25-4**). Restrictive parenchymal diseases are associated with a reduction in V_A and an increase in lung elastic recoil. All lung volumes, as well as D_{lco}, are reduced. A reduction in D_{lco} may be the earliest pulmonary function finding of interstitial lung disease (restrictive lung disease) and may occur before either the FVC or TLC falls. Subjects with an isolated reduction in D_{lco} often are evaluated with high-resolution CT scan of the chest; however, it is important to realize that anemia, pulmonary hypertension, and pulmonary emboli can also cause an isolated reduction in D_{lco}. Compared to patients with restriction secondary to neuromuscular disease, in patients with interstitial lung disease, the RV/TLC (normal less than or equal to 30%) and measurements of maximal inspiratory pressure (normal = –75 cm H_2O in males, –50 cm H_2O in females) remain normal. In addition, patients exhibit mild resting hypoxemia that worsens with exercise. Monitoring gas exchange during exercise may be the most sensitive test for detecting progression of interstitial lung disease; however, this involves obtaining arterial blood during exercise and D_{lco} and exercise pulse oximetry is often used in its place.

TABLE e25-4 Patterns of Pulmonary Function

	Obstructive Lung Disease		**Restrictive Lung Disease**	
	Asthma	**COPD**	**Parenchymal Disease**	**Chest Bellows Disease**
FVC	Nl or I	Nl or I	D	D
FEV_1	D	D	D	D
FEV_1/FVC	<70% (<0.70)	<70% (<0.70)	≥75%-80% (≥0.75%-0.8%)	≥75%-80% (≥0.75%-0.8%)
TLC	Nl or I	Nl or I	D	D

	Obstructive Lung Disease		Restrictive Lung Disease	
	Asthma	**COPD**	**Parenchymal Disease**	**Chest Bellows Disease**
RV/TLC	Nl or I	Nl or I	Nl	I
Airway resistance	I	I	N	Nl
Dlco	Nl	D	D	Nl

D, decreased; I, increased; Nl, normal.

Mechanical restriction caused by chest bellows malfunction may result from chest wall or skeletal deformity, loss of neuromuscular function, fibrosis of the pleural space, and abdominal overdistension causing upward displacement of the diaphragm, as well as decreased diaphragm movement. The most common pulmonary function pattern seen in these patients is a decrease in TLC and VC with only a slight decrease in RV. RV is maintained in these diseases because lung compliance remains normal. D_{lco} is normal or only minimally reduced, and D_{lco}/V_A (corrected for V_A) is normal. RV/TLC often is increased in patients with restrictive chest bellows disease.

PULMONARY GAS EXCHANGE

The essential function of the lungs is to maintain blood gas homeostasis. Arterial blood gas measurement plays an important role in the diagnosis and management of patients with pulmonary disease and should be ordered whenever hypoxemia, hypercapnia (CO_2 retention), and/or acid-base disorders are suspected clinically. Every time arterial blood gas determinations are ordered, the A–a gradient (difference between partial pressure of oxygen [PO_2] in the alveolus and PO_2 in arterial blood) should be calculated. This is accomplished by computer on all automated blood gas machines, and a normal $P(A–a)O_2$ can be calculated using the formula (Age/4) + 4 or 2.5 (0.21 × age). The presence of hypoxemia with a normal A–a gradient usually implies alveolar hypoventilation (eg, sedative overdose). Most patients develop hypoxemia secondary to mismatching of ventilation and perfusion, and $P(A–a)O_2$ will be significantly elevated.

Oxygen saturation as measured by pulse oximetry (SpO_2) is widely used in clinical practice for monitoring arterial saturation. A pulse oximeter is a small battery-operated device that is placed on the finger or the earlobe. The device emits and reads the reflected light from capillary blood, and estimates the saturation. Although SpO_2 is clinically very useful, SpO_2 is only an estimate of arterial saturation. Actual arterial oxygen saturation (SaO_2) can be ±2% to 4% (±0.02-0.04) of the oximetric reading. The error may be even greater with saturation less than 80% (0.80). Pulse oximeters do not measure carboxyhemoglobin, and SpO_2 may be overestimated significantly in patients with smoke inhalation or in recent smokers. An initial validation of pulse oximetry with direct measurement of SaO_2 is recommended in any critically ill patient.

EXERCISE TESTING

Cardiopulmonary exercise testing allows for assessment of multiple organs involved in exercise and

has benefits over assessment of either the cardiac system or pulmonary system alone. The major indications for exercise testing are determination of exercise capacity, evaluation of dyspnea on exertion, evaluation of exercise-induced bronchospasm, and further assessment of suspected arterial desaturation during exercise.[14,15,16,17,18] Exercise testing also can be useful in the evaluation of ventilatory or cardiovascular limitations to work, assessment of general fitness or conditioning, evaluation of disability, establishment of safe levels for exercise, evaluation of drug therapy, determining the need and liter flow for supplemental oxygen therapy during exercise, assessment of the effects of a rehabilitation program, and preoperative assessment before lung resection.[14,15,16,17,18,19]

Tests for general fitness include the 6-minute walking distance and the Harvard step test.[14,16,17,18,19] For the 6-minute walking distance, the subject simply walks a predetermined route or circuit as fast as possible for 6 minutes. The subject is allowed to stop and rest, but the clock continues to run. The greater the distance covered, the better the patient's general fitness and exercise tolerance. For healthy elderly subjects, a distance of 631 meters ± 93 meters is considered normal and a change of 54 meters in between tests is considered significant. For the Harvard step test, the subject steps up and down on a 20-in step at a set rate for 5 minutes. A 1-minute rest period is followed by measurement of the subject's recovery heart rate. The lower the recovery heart rate, the better the subject's general fitness.

Exercise testing sometimes is performed to determine if exercise results in arterial oxygen desaturation (SaO_2 less than 90% [less than 0.90]).[15,16] The test may be useful for quantifying the level of exertion the patient can perform during the activities of daily living as well as determining appropriate levels of supplemental oxygen therapy. Typically, this test is done using a treadmill or cycle ergometer. A baseline measurement of arterial blood gas values or pulse oximetry is followed by up to 6 minutes of exercise, during which time the patient is monitored for oxygen desaturation using pulse oximetry. If significant desaturation occurs (saturation less than or equal to 88%-90% [less than or equal to 0.88-0.90]), the test is terminated. In the event of oxygen desaturation, the test can be repeated to determine the level of supplemental oxygen therapy needed to compensate for the desaturation that otherwise would occur.

When more formal exercise testing is needed for some of the indications previously listed (eg, dyspnea evaluation, evaluation of ventilatory or cardiovascular limitations to work, evaluation of disability, and preoperative assessment before lung resection), exercise tolerance tests or cardiopulmonary stress testing can be performed. Tests include measurement of oxygen consumption ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$), minute volume ($\dot{V}E$), $\dot{V}T$, respiratory rate, SpO_2, heart rate, blood pressure, and recording or monitoring of the electrocardiogram. During exercise, $\dot{V}O_2$ increases with workload in a linear fashion until a maximum oxygen consumption level ($\dot{V}O_{2max}$) is reached. Consequently, $\dot{V}O_{2max}$ is a measure of an individual's muscular work capacity.[14,15,16,17,18] Normal $\dot{V}O_{2max}$ is approximately 1,700 mL/min (28 mL/s) for a sedentary person and up to 5,800 mL/min (97 mL/s) for a trained athelete.[16] This compares with a resting $\dot{V}O_2$ of approximately 250 mL/min (4.1 mL/s). Ventilatory equivalents for oxygen, carbon dioxide, and O_2 pulse are often calculated. Ventilatory equivalent for oxygen is a measure of the efficiency of the

ventilatory pump at various workloads[14,16,17] and is calculated as follows:

$$\text{Ventilatory equivalent for } O_2 = \frac{\dot{V}_e}{\dot{V}O_2}$$

A normal ventilatory equivalent for oxygen is 20 to 30.[14,16]

O_2 pulse is an estimate of oxygen consumption per cardiac cycle and can be decreased with cardiac problems. It can be calculated as follows:

$$O_2 \text{ pulse} = \frac{\dot{V}O_2[\text{L/min}] + 1{,}000}{\text{heat rate}}$$

A normal O_2 pulse is 2.5 to 4 mL per beat at rest and increases to 10 to 15 mL per beat during strenuous exercise.[14,16]

The anaerobic threshold is the point during strenuous exercise at which anaerobic metabolism and lactic acid production begin.[14,16,17] $\dot{V}O_{2max}$ increases with exercise at about the same rate as $\dot{V}CO_2$ until the subject's anaerobic threshold is reached. From that point on, $\dot{V}CO_2$ increases faster than $\dot{V}O_2$, and this change can be used to estimate the anaerobic threshold. A breath-by-breath plot of the ventilatory equivalents for O_2 and CO_2 also can be used to determine the anaerobic threshold. Anaerobic threshold is a measure of fitness in normal subjects, and aerobic training can delay the anaerobic threshold.[14,16]

For exercise tolerance testing, the patient typically is subjected to either a constant workload (steady-state tests) or an increasing workload (progressive multistage tests) using a cycle ergometer or treadmill.[14,16] With progressive multistage tests, the patient exercises to exhaustion or the occurrence of an adverse reaction, at which point the test is stopped. Safety during exercise testing is of major importance, and rigorous guidelines for termination of the test should be followed. Both types of tests can be used to determine $\dot{V}O_{2max}$. A limit to exercise, as indicated by a decrease in $\dot{V}O_{2max}$, can result from (a) poor conditioning, (b) pulmonary limitation, (c) cardiac limitation, or (d) poor effort. In the case of poor conditioning, SpO_2 and O_2 pulse will be normal. With a pulmonary limitation to exercise, SpO_2 will be reduced and O_2 pulse will be normal or reduced. With a cardiac limitation to exercise, SpO_2 will be normal and O_2 pulse will be reduced.

Table e25-5 summarizes the indications and contraindications for exercise testing. **Table e25-6** summarizes the findings during maximum exercise associated with poor conditioning, pulmonary limitations to exercise, and cardiac limitations to exercise.

TABLE e25-5 Indications and Contraindications for Exercise Testing

Indications

- Dyspnea on exertion
- Exercise-induced bronchospasm

- Suspected arterial desaturation with exercise
- Evaluation of ventilatory limitations to exercise
- Evaluation of cardiac limitations to exercise
- Assessment of general fitness or conditioning
- Evaluation of cardiopulmonary disability
- Establishment of safe levels for exercise
- Evaluation of drug therapy
- Determining appropriate use of supplemental oxygen therapy
- Establishing an exercise prescription for a rehabilitation program
- Assessment of the effect of a rehabilitation program
- Evaluation of specific disease states or conditions (eg, asthma, chronic obstructive pulmonary disease [COPD], interstitial lung disease, pulmonary vascular disorders, coronary artery disease, other vascular disorders, neuromuscular disorders, obesity, anxiety-induced hyperventilation)
- Assessment before resection
- Assessment before lung volume reduction surgery or lung transplantation

Contraindications

- PaO_2 < 40 mm Hg on room air
- $PaCO_2$ > 70 mm Hg
- FEV_1 < 30% of predicted
- Recent (within 4 weeks) myocardial infarction
- Unstable angina pectoris
- Second- or third-degree heart block
- Rapid ventricular/atrial arrhythmias
- Orthopedic impairment
- Severe aortic stenosis
- Congestive heart failure

- Uncontrolled hypertension
- Limiting neurologic disorders
- Dissecting/ventricular aneurysms
- Severe pulmonary hypertension
- Thrombophlebitis or intracardiac thrombi
- Recent systemic or pulmonary embolus
- Acute pericarditis

TABLE e25-6 Typical Findings During Maximum Exercise with Poor Conditioning, Pulmonary Limitations to Exercise, and Cardiac Limitations to Exercise

Test Parameter	Poor Conditioning	Pulmonary Limitation	Cardiac Limitation
$\dot{V}O_{2max}$	↓	↓	↓
SpO_2	N	↓	N
O_2 pulse	N or ↓	N or ↓	↓
Anaerobic threshold	↓ or N	↓ or N	↓
Ventilatory reserve[a] (MVV – V_{Emax})	N	↓	N or ↓

N, normal.

[a]Ventilatory reserve = maximum voluntary ventilation (MVV) – minute volume during maximum exercise (V_{emax}).

ERV	expiratory reserve volume

FEF	forced expiratory flow
$FEF_{25\%-75\%}$	forced expiratory flow during 25% to 75% of forced vital capacity
$FEF_{50\%}$	forced expiratory flow at 50% of vital capacity
FEF_{max}	maximum forced expiratory flow
$FEV_{0.5}$	forced expiratory volume at 0.5 second
FEV_1	forced expiratory volume in the first second of expiration
FEV_6	forced expiratory volume in 6 seconds
$FIF_{50\%}$	forced inspiratory flow at 50% of vital capacity
FRC	functional residual capacity
FVC	forced vital capacity
GINA	Global Imitative for Asthma
IC	inspiratory capacity
IRV	inspiratory reserve volume
NHANES	National Health and Nutrition Examination Survey
$P(A–a)O_2$	alveolar–arterial difference in the partial pressure of oxygen
$PaCO_2$	arterial partial pressure of carbon dioxide
PaO_2	arterial partial pressure of oxygen
PC_{20}	provocative concentration needed to cause a 20% fall in FEV_1
PD15	provocative dose 15
PEF	peak expiratory flow
PFT	pulmonary function test
PJP	*Pneumocystis jiroveci* pneumonia
PO_2	partial pressure of oxygen
RV	residual volume
SaO_2	arterial oxygen saturation
SpO_2	oxygen saturation as measured by pulse oximetry
SVC	slow vital capacity
TLC	total lung capacity
V_A	alveolar volume
VC	vital capacity
V_T	tidal volume

Chapter 26: Asthma

Christine A. Sorkness; Kathryn V. Blake

INTRODUCTION

KEY CONCEPTS

- 1 Asthma is a disease of increasing prevalence that is a result of genetic predisposition and environmental interactions; it is one of the most common chronic diseases of childhood.
- 2 Asthma is primarily a chronic inflammatory disease of the airways of the lung for which there is no known cure or primary prevention; the immunohistopathologic features include cell infiltration by neutrophils, eosinophils, T-helper type 2 lymphocytes, mast cells, and epithelial cells.
- 3 Asthma is characterized by either the intermittent or persistent presence of highly variable degrees of airflow obstruction from airway wall inflammation and bronchial smooth muscle constriction; in some patients, persistent changes in airway structure occur.
- 4 The inflammatory process in asthma is treated most effectively with corticosteroids, with the inhaled corticosteroids (ICSs) having the greatest efficacy and safety profile for long-term management.
- 5 Bronchial smooth muscle constriction is prevented or treated most effectively with inhaled β_2-adrenergic receptor agonists.
- 6 Variability in response to medications requires individualization of therapy within existing evidence-based guidelines for management. This is most evident in patients with severe asthma phenotypes.
- 7 Ongoing patient education, for a partnership in asthma care, is essential for optimal patient outcomes and includes trigger avoidance and self-management techniques.

Asthma has been known since antiquity, yet it is a disease that still defies precise definition. The word *asthma* is of Greek origin and means "panting." More than 2,000 years ago, Hippocrates used the word *asthma* to describe episodic shortness of breath; however, the first detailed clinical description of the asthmatic patient was made by Aretaeus in the second century.[1] The National Institutes of Health, National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3 (EPR3), has provided the following working definition of asthma[2]:

"Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, T-lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in the existing bronchial hyper-responsiveness (BHR) to a variety of stimuli. Reversibility of airflow limitation may be incomplete in some patients with asthma."

The Global Initiative for Asthma (GINA) provides a new practical asthma definition[3]:

"Asthma is a *heterogeneous* disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation."

These definitions encompass the important heterogeneity of the clinical presentation of asthma by describing the scientific and clinically accepted characteristics of asthma.

EPIDEMIOLOGY

An estimated 25.7 million persons in the United States have asthma (about 8.4% of the population).[4] Asthma is the most common chronic disease among children in the United States, with approximately 7 million children affected. The prevalence rate is highest in children 0 to 17 years of age at 9.5%.[4] In the United States, as in other industrialized countries, the prevalence of asthma has increased from 7.3% in 2001. Asthma prevalence is higher in persons with incomes below 100% of poverty level at 11.2% and in blacks 11.2% and multiple races 14.1%. Asthma accounts for 1.6% of all ambulatory care visits (10.6 million physician office visits and 1.2 million hospital outpatient visits) and resulted in 479,000 hospitalizations and 2.1 million emergency department (ED) visits in 2009 (both declined from peaks in the 1990s).[5] It is still a leading cause of preventable hospitalization in the United States; however, hospitalizations decreased 24% between 2003 and 2010. Asthma accounts for more than 14.4 million lost school days per year.[5] In young children (0-10 years of age), the risk of asthma is greater in boys than in girls, becomes about equal during puberty, and then is greater in women than in men.[5]

Ethnic minorities continue to share the burden of asthma disproportionately. African Americans are two times as likely to be hospitalized and approximately two times more likely to die from asthma than whites.[4] Hispanics in general, with the exception of Puerto Ricans, have lower disease and hospitalization rates than African Americans or whites.

The estimated direct healthcare costs of asthma in the United States from 2002 to 2007 was $50.1 billion.[5] The societal burden of asthma (indirect medical expenditures: loss of productivity and death) in the United States was $5.9 billion. Prescription drugs were the largest single direct medical expenditure.[5]

The natural history of asthma is still not well defined. Although asthma can occur at any time, it is principally a pediatric disease, with most patients being diagnosed by 5 years of age and up to 50% of children having symptoms by 2 years of age.[2] Between 30% and 70% of children with asthma will improve markedly or become symptom-free by early adulthood; chronic disease persists in about 30% to 40% of patients, and generally 20% or less develop severe chronic disease.[2] Predictors of persistent adult asthma include atopy, onset during school age, and presence of bronchial hyper-responsiveness (BHR).[2] Diminished lung growth may occur in some children (approximately 10%) with asthma.[2]

In adults, most longitudinal studies have suggested a more rapid rate of decline in lung function in asthmatics than in non-asthmatic normals, primarily reflected in forced expiratory volume in 1 second (FEV_1).[2] However, the annual decline in FEV_1 is less than in smokers or in patients with a diagnosis of emphysema. In general, individuals with less frequent asthma attacks and normal lung function on initial assessment have higher remission rates, whereas smokers have the lowest remission and highest relapse rates.[2] The level of BHR tends to predict the rate of decline in FEV_1, with a greater decline with high levels of BHR.[2] Thus, airway obstruction in asthma may become irreversible and also worsen over time owing to airway remodeling (see below).[2] However, most patients do not die from long-term progression of their disease and their life span is not different from the general population.[2]

As with prevalence and morbidity, mortality from acute exacerbations of asthma has been decreasing over the past 10 years, with a death rate of 0.14 per 1,000 persons with asthma reported in 2009.[3] Despite the relatively low number of asthma deaths, 80% to 90% are preventable.[2] Most deaths from asthma occur outside the hospital, and death is rare after hospitalization. The most common cause of death from asthma is inadequate assessment of the severity of airway obstruction by the patient or healthcare professional and inadequate therapy. The most common cause of death in hospitalized patients is also inadequate or inappropriate therapy. Thus, the key to prevention of death from asthma, as advocated by both US NAEPP and GINA, is education.[2,3]

ETIOLOGY

Epidemiologic studies strongly support the concept of a genetic predisposition plus environmental interaction to the development of asthma, yet the picture remains complex and incomplete.[6] Genetic factors account for 60% to 80% of the susceptibility. Asthma represents a complex genetic disorder in that the asthma phenotype is likely a result of polygenic inheritance or different combinations of genes. Initial searches focused on establishing links between atopy (genetically determined state of hypersensitivity to environmental allergens) and asthma, but genome-wide searches have also found linkages with genes for metalloproteinases involved in the airway remodeling process (eg, *ADAM33*) and those associated with asthma development and disease deterioration (*CHI3L1*).[6] Although genetic predisposition to atopy is a significant risk factor for developing asthma, not all atopic individuals develop asthma, nor do all patients with asthma exhibit atopy. Disparate phenotypes of asthma (progressive or remodeled vs non-progressive) are likely genetically determined.[6]

Environmental risk factors for the development of asthma include socioeconomic status, family size, exposure to secondhand tobacco smoke in infancy and in utero, allergen exposure, ambient air pollution, urbanization, viral respiratory infections including respiratory syncytial virus (RSV) and rhinovirus, and decreased exposure to common childhood infectious agents.[7,8] The "hygiene hypothesis" proposes that genetically susceptible individuals develop allergies and asthma by allowing the allergic immunologic system (T-helper cell type 2 [Th_2] lymphocytes) to develop instead of the system to fight infections (T-helper type 1 [Th_1] lymphocytes) and may explain the

increase of asthma in developed countries.[7,8] The first 2 years of life appear to be most important for the exposures to produce an alteration in the immune response system.[7] The hygiene hypothesis is supported by studies demonstrating a lower risk for asthma in children who are exposed to high levels of bacteria or endotoxin, in those with a large number of older siblings, in those with early enrollment into child care, in those with exposure to cats, dogs, and farm animals early in life, or in those with exposure to fewer antibiotics.[6,7,8,9]

Risk factors for early (less than 3 years of age) recurrent wheezing associated with viral infections include low birth weight, male gender, and parental smoking. However, this early pattern is due to smaller airways, and these risk factors are not necessarily risk factors for asthma in later life.[7] Atopy is the predominant risk factor for children to have continued asthma.[7,8] Asthma can begin in adults later in life. Occupational asthma in previously healthy individuals emphasizes the effect of environment on the development of asthma.[10] The heterogeneity of the asthma phenotype appears most obvious when listing the diverse triggers of bronchospasm[2,7] (**Table 26-1**). The various triggers have relative degrees of importance from patient to patient. Environmental exposures are the most important precipitants of severe asthma exacerbations (see Table 26-1). Epidemics of severe asthma in cities have followed exposures to high concentrations of aeroallergens. Viral respiratory tract infections remain the single most significant precipitant of severe asthma in children and are an important trigger in adults as well.[11] Other possible factors include air pollution, sinusitis, and drugs.

TABLE 26-1 List of Agents and Events Triggering or Increasing Susceptibility to Asthma

Respiratory infection
Respiratory syncytial virus (RSV), rhinovirus, influenza, parainfluenza, *Mycoplasma pneumonia*, *Chlamydia*
Allergens
Airborne pollens (grass, trees, weeds), house dust mites, animal dander, rodents, cockroaches, fungal spores
Environment
Cold air, fog, ozone, sulfur dioxide, nitrogen dioxide, tobacco smoke (including 2nd and 3rd hand), wood smoke, energy efficient buildings (increase indoor air pollution), meteorological conditions related to climate change, scented home products, cleaners, and perfumes
Emotions
Anxiety, stress, laughter
Exercise
Particularly in cold, dry climate
Drugs/preservatives
Acetaminophen, Aspirin, NSAIDs (cyclooxygenase inhibitors), sulfites, benzalkonium chloride, nonselective β-blockers
Occupational stimuli
Bakers (flour dust); farmers (hay mold); spice and enzyme workers; occupational cleaners, printers (arabic gum); chemical workers (azo dyes, anthraquinone, ethylenediamine, toluene diisocyanates, polyvinyl chloride); plastics, rubber, and wood workers (formaldehyde, western cedar, dimethylethanolamine, anhydrides)
Host factors: obesity, African American race, Hispanic ethnicity, low socioeconomic status

PATHOPHYSIOLOGY

2 Major characteristics of asthma include a variable degree of airflow obstruction (related to bronchospasm, edema, and mucous hypersecretion), BHR, and airway inflammation (**Fig. 26-1**). To understand the pathogenetic mechanisms that underlie the many phenotypes of asthma, it is critical to identify factors that initiate, intensify, and modulate the inflammatory response of the airways and to determine how these processes produce the characteristic airway abnormalities.

FIGURE 26-1

Representative illustration of the pathology found in the asthmatic bronchus compared with a normal bronchus (*upper right*). Each section demonstrates how the lumen is narrowed. Hypertrophy of the basement membrane, mucus plugging, smooth muscle

hypertrophy, and constriction contribute (*lower section*). Inflammatory cells infiltrate, producing submucosal edema, and epithelial desquamation fills the airway lumen with cellular debris and exposes the airway smooth muscle to other mediators (*upper left*).

Acute Inflammation

Inhaled allergen challenge models contribute most to our understanding of acute inflammation in asthma.[8] Inhaled allergen challenge in allergic patients leads to an early phase reaction that, in some cases, may be followed by a late-phase reaction. The activation of cells bearing allergen-specific immunoglobulin E (IgE) initiates the early phase reaction. It is characterized by the rapid activation of airway mast cells and macrophages leading to the rapid release of pro-inflammatory mediators such as histamine, eicosanoids, and reactive oxygen (O_2) species that induce contraction of airway smooth muscle, mucous secretion, and vasodilation.[8] The bronchial microcirculation has an essential role in this inflammatory process. Inflammatory mediators induce microvascular leakage with exudation of plasma in the airways.[8] Acute plasma protein leakage induces a thickened, engorged, and edematous airway wall and a consequent narrowing of the airway lumen. Plasma exudation may compromise epithelial integrity, and the presence of plasma in the lumen may reduce mucus clearance.[8] Plasma proteins also may promote the formation of exudative plugs mixed with mucus and inflammatory and epithelial cells. Together these effects contribute to airflow obstruction (see Fig. 26-1).

The late-phase inflammatory reaction occurs 6 to 9 hours after allergen provocation and involves the recruitment and activation of eosinophils, $CD4^+$ thymically derived lymphocytes (T cells), basophils, neutrophils, and macrophages.[8] There is selective retention of airway T cells, the expression of adhesion molecules, and the release of selected pro-inflammatory mediators and cytokines involved in the recruitment and activation of inflammatory cells.[8] The activation of T cells after allergen challenge leads to the release of Th_2-like cytokines that may modulate the late-phase response.[8] The release of preformed cytokines by mast cells is the likely initial trigger for the early recruitment of inflammatory cells that then recruit and induce the more persistent involvement by T cells.[8] The enhancement of nonspecific BHR usually can be demonstrated after the late-phase reaction but not after the early phase reaction following allergen or occupational challenge.

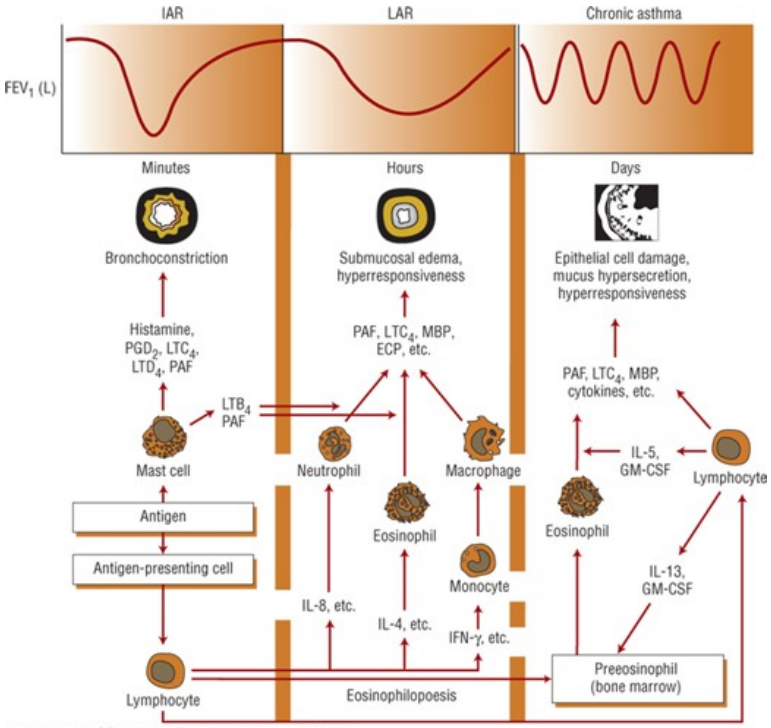
Chronic Inflammation

Airway inflammation has been demonstrated in all forms of asthma, and an association between the extent of inflammation and the clinical severity of asthma has been demonstrated in selected studies.[8] It is accepted that both central and peripheral airways are inflamed.

In asthma, all cells of the airways are involved and become activated (**Fig. 26-2**). Included are eosinophils, neutrophils, T cells, mast cells, alveolar macrophages and dendritic cells, epithelial cells, fibroblasts, and bronchial smooth muscle cells. These cells also regulate airway inflammation and initiate the process of remodeling by the release of cytokines and growth factors.[8,12]

FIGURE 26-2

Diagrammatic presentation of the relationship between inflammatory cells, lipid and preformed mediators, inflammatory cytokines, and proposed pathogenesis and clinical presentation in asthma. See text for details. (GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LT, leukotriene; MBP, major basic protein; PAF, platelet-activating factor; PG, prostaglandin.)



Epithelial Cells

Bronchial epithelial cells participate in mucociliary clearance and removal of noxious agents; however, they also enhance inflammation by releasing eicosanoids, peptidases, matrix proteins, cytokines, chemokines, and nitric oxide (NO).[8] Epithelial cells can be activated by IgE-dependent mechanisms, viruses, pollutants, or histamine. In asthma, especially fatal asthma, extensive epithelial shedding occurs. The functional consequences of epithelial shedding may include heightened BHR, release of the chemokine eotaxin that attracts eosinophils, altered permeability of the airway mucosa, depletion of epithelial-derived relaxant factors, and loss of enzymes responsible for degrading pro-inflammatory neuropeptides. The integrity of airway epithelium may influence the sensitivity of the airways to various provocative stimuli. Epithelial cells also may be important in the regulation of airway remodeling and fibrosis.[8,12]

Eosinophils

Eosinophils play an effector role in asthma by releasing pro-inflammatory mediators, cytotoxic mediators, and cytokines.[8] Circulating eosinophils migrate to the airways by cell rolling, through interactions with selectins, and eventually adhere to the endothelium through the binding of integrins to adhesion proteins (vascular cell adhesion molecule 1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]). As eosinophils enter the matrix of the membrane, their survival is prolonged by interleukin 5 (IL-5) and granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, eosinophils release inflammatory mediators such as leukotrienes (LTs) and granule proteins to injure airway tissue.[8]

Lymphocytes

Mucosal biopsy specimens from patients with asthma contain lymphocytes, many of which express surface markers of inflammation. There are two types of T-helper $CD4^+$ cells. Th_1 cells produce IL-2 and interferon-γ (IFN-γ), both essential for cellular defense mechanisms. Th_2 cells produce cytokines (IL-4, 5, and 13) that mediate allergic inflammation. It is known that Th_1 cytokines inhibit the production of Th_2 cytokines, and vice versa. It is hypothesized that allergic asthmatic inflammation results from a Th_2-mediated mechanism (an imbalance between Th_1 and Th_2 cells).[8] However, it has also been observed that there exists a low Th_2 cytokine phenotype of asthma in adults that appears more resistant to usual therapies for asthma.[13]

Th_1 and Th_2 Cell Imbalance

The T-cell population in the cord blood of newborn infants is skewed toward a Th_2 phenotype.[7,8] The extent of the imbalance between Th_1 and Th_2 cells (as indicated by diminished IFN-γ production) during the neonatal phase may predict the subsequent development of allergic disease, asthma, or both. It has been suggested that infants at high risk of asthma and allergies should be exposed to stimuli that upregulate Th_1-mediated responses in order to restore the balance during a critical time in the development of the immune system and the lungs.[7]

The basic premise of the hygiene hypothesis is that the newborn's immune system needs timely and appropriate environmental stimuli to create a balanced immune response. Factors that enhance Th_1-mediated responses include infection with *Mycobacterium tuberculosis*, measles virus, and hepatitis A virus; endotoxin exposure; increased exposure to infections through contact with older siblings; and daycare attendance during the first 6 months of life. Restoration of the balance between Th_1 and Th_2 cells may be impeded by frequent administration of oral antibiotics, with concomitant alterations in GI flora. Other factors favoring the Th_2 phenotype include residence in an industrialized country, urban environment exposure, diet, and sensitization to house dust mites and cockroaches.[7] Immune "imprinting" may begin in utero by transplacental transfer of allergens and cytokines.

Mast Cells

Mast cell degranulation is important in the initiation of immediate responses following exposure to allergens.[2] Mast cells reside throughout the walls of the respiratory tract, and increased numbers of these cells (threefold to fivefold) have been described in the airways of allergic asthmatics.[8] Once binding of allergen to cell-bound IgE occurs, mediators such as histamine; eosinophil and neutrophil chemotactic factors; LTs C_4, D_4, and E_4; prostaglandins; platelet-activating factor (PAF); and others are released from mast cells (see Fig. 26-2). Histologic examination has revealed decreased numbers of granulated mast cells in the airways of patients who have died from acute asthma attacks, suggesting that mast cell degranulation is a contributing factor. Sensitized mast cells are also activated by osmotic stimuli to account for exercise-induced bronchospasm (EIB).[14]

Alveolar Macrophages

The primary function of alveolar macrophages in the normal airway is to serve as "scavengers," engulfing and digesting bacteria and other foreign materials. Macrophages are found in large and small airways, ideally located for affecting the asthmatic response. A number of mediators produced and released by macrophages have been identified, including proinflammatory and anti-inflammatory cytokines, reactive oxygen species, and eicosanoids.[7] In addition, alveolar macrophages are able to produce neutrophil chemotactic factor and eosinophil chemotactic factor, which in turn amplify the inflammatory process.

Neutrophils

The role of neutrophils in the pathogenesis of asthma remains somewhat unclear because they normally may be present in the airways and usually do not infiltrate tissues showing chronic allergic inflammation despite the potential to participate in late-phase inflammatory reactions. However, high numbers of neutrophils have been observed in the airways of patients who died from sudden-onset fatal asthma and in those with severe disease.[15] This suggests that neutrophils may play a pivotal role in the disease process, at least in some patients with long-standing or corticosteroid-resistant asthma.[13,15] The neutrophil also can be a source for a variety of mediators, including PAF, prostaglandins, thromboxanes, and LTs, that contribute to BHR and airway inflammation.[15]

Fibroblasts and Myofibroblasts

Fibroblasts are found frequently in connective tissue. Human lung fibroblasts may behave as inflammatory cells on activation by IL-4 and IL-13. The myofibroblast may contribute to the regulation of inflammation via the release of cytokines and to tissue remodeling. In asthma, myofibroblasts are increased in numbers beneath the reticular basement membrane, and there is an association between their numbers and the thickness of the reticular basement membrane.[8,12]

Inflammatory Mediators

Associated with asthma for many years, histamine is capable of inducing smooth muscle constriction and bronchospasm and is thought to play a role in mucosal edema and mucous secretion.[2] Lung mast cells are an important source of histamine. The release of histamine can be stimulated by exposure of the airways to a variety of factors, including physical stimuli (airway drying with exercise) and relevant allergens.[8] Histamine is involved in acute bronchospasm following allergen exposure; however, other mediators such as LTs are also involved.

Besides histamine release, mast cell degranulation releases ILs, proteases, and other enzymes that activate the production of other mediators of inflammation. Several classes of important mediators, including arachidonic acid and its metabolites (ie, prostaglandins, LTs,

and PAF), are derived from cell membrane phospholipids.

Once arachidonic acid is released, it can be metabolized by the enzyme cyclooxygenase to form prostaglandins. Prostaglandin D_2 is a potent bronchoconstricting agent; however, it is unlikely to produce sustained effects and its role in asthma remains to be determined. Similarly, prostaglandin $F_{2\alpha}$ is a potent bronchoconstrictor in patients with asthma and can enhance the effects of histamine.[2,8] However, its pathophysiologic role in asthma is unclear. Another cyclooxygenase product, prostacyclin (prostaglandin I_2), is known to be produced in the lung and may contribute to inflammation and edema owing to its effects as a vasodilator.

Thromboxane A_2 is produced by alveolar macrophages, fibroblasts, epithelial cells, neutrophils, and platelets within the lung.[8] It may have several effects, including bronchoconstriction, involvement in the late asthmatic response, and involvement in the development of airway inflammation and BHR.

The 5-lipoxygenase pathway of arachidonic acid metabolism is responsible for the production of the *cysteinyl LTs*.[8] LTC_4, LTD_4, and LTE_4 are released during inflammatory processes in the lung. LTs D_4 and E_4 share a common receptor (LTD_4 receptor) that, when stimulated, produces bronchospasm, mucous secretion, microvascular permeability, and airway edema, whereas LTB_4 is involved with granulocyte chemotaxis.

Thought to be produced by macrophages, eosinophils, and neutrophils within the lung, PAF is involved in the mediation of bronchospasm, sustained induction of BHR, edema formation, and chemotaxis of eosinophils.[8]

Adhesion Molecules

Adhesion molecules are glycoproteins that facilitate infiltration and migration of inflammatory cells to the site of inflammation. They have additional functions involved in the inflammatory process aside from promoting cell adhesion, including activation of cells and cell–cell communication, and promoting cellular migration and infiltration.[2] Many adhesion molecules are divided into families on the basis of their chemical structure. These families are the integrins, cadherins, immunoglobulin supergene family, selectins, vascular adressins, and carbohydrate ligands.[8] Those thought to be important in inflammation include the integrins, immunoglobulin supergene family, selectins, and carbohydrate ligands, including ICAM-1 and VCAM-1.[8] Adhesion molecules are found on a variety of cells, such as neutrophils, monocytes, lymphocytes, basophils, eosinophils, granulocytes, platelets, endothelial cells, and epithelial cells, and can be expressed or activated by the many inflammatory mediators present in asthma.[8]

Clinical Consequences of Chronic Inflammation

Chronic inflammation is associated with nonspecific BHR and increases the risk of asthma exacerbations. Exacerbations are characterized by increased symptoms and worsening airway obstruction over a period of days or even weeks, and rarely hours. Hyper-responsiveness of the airways to physical, chemical, and pharmacologic stimuli is a hallmark of asthma.[2] BHR also occurs in some patients with chronic bronchitis and allergic rhinitis.[2] Normal healthy subjects also may develop a transient BHR after viral respiratory infections or ozone exposure. However, the degree of BHR in patients with asthma is quantitatively greater than in other populations. Bronchial responsiveness of the general population fits a unimodal distribution that is skewed toward increased reactivity; individuals with clinical asthma represent the extreme end of this distribution. The degree of BHR within asthma correlates with its clinical course and medication requirement necessary to control symptoms.[2] Patients with mild symptoms or in remission demonstrate lower levels of BHR.

The current understanding is that the BHR seen in asthma is at least in part due to and correlative with the extent of airway inflammation.[2] Airway remodeling also correlates somewhat with BHR.[12]

Remodeling of the Airways

Acute inflammation is a beneficial, nonspecific response of tissues to injury and generally leads to repair and restoration of the normal structure and function. In contrast, asthma represents a chronic inflammatory process of the airways followed by healing that in some may result in altered structure referred to as *remodeling*.[12] Repair involves replacement of injured tissue by parenchymal cells of the same type and replacement by connective tissue and its maturation into scar tissue. In asthma, remodeling presents as extracellular matrix fibrosis, an increase in smooth muscle and mucous gland mass, and angiogenesis.[12]

The precise mechanisms of remodeling of the airways are under intense study. Airway remodeling is of concern because it may represent an irreversible process that can have more serious sequelae such as the development of chronic obstructive pulmonary disease (COPD).[2,12] Observations in children with asthma indicate that some loss of lung function may occur during the first 5 years of life.[7] Importantly, no current therapies have been shown to alter either early decreased lung growth or later progressive loss of lung function.

Mucus Production

The mucociliary system is the lung's primary defense mechanism against irritants and infectious agents. Mucus, composed of 95% water and 5% glycoproteins, is produced by bronchial epithelial glands and goblet cells.[8] The lining of the airways consists of a continuous aqueous layer controlled by active ion transport across the epithelium in which water moves toward the lumen along the concentration gradient. Catecholamines and vagal stimulation enhance the ion transport and fluid movement. Mucus transport depends on its viscoelastic properties. Mucus that is either too watery or too viscous will not be transported optimally. The exudative inflammatory process and sloughing of epithelial cells into the airway lumen impair mucociliary transport. The bronchial glands are increased in size and the goblet cells are increased in size and number in asthma. Expectorated mucus from patients with asthma tends to have a high viscosity. The mucous plugs in the airways of patients who died in status asthmaticus are tenacious and tend to be connected by mucous strands to the goblet cells. Asthmatic airways also may become plugged with casts consisting of epithelial and inflammatory cells. Although it is tempting to speculate that death from asthma attacks is a result of the mucous plugging resulting in irreversible obstruction, there is no direct evidence for this. Autopsies of asthmatics who died from other causes have shown similar pathology. In addition, some patients who have died of sudden severe asthma did not show the characteristic mucous plugging on necropsy.[8]

Airway Smooth Muscle

The airway smooth muscle extends from the trachea through the respiratory bronchioles. When expressed as a percentage of wall thickness, the smooth muscle represents 5% of the large central airways and up to 20% of the wall thickness in the bronchioles. Total smooth muscle mass decreases rapidly past the terminal bronchioles to the alveoli, so the contribution of smooth muscle tone to airway diameter in this region is relatively small. In the large airways of asthmatics, smooth muscle may account for 11% of the wall thickness. It is possible that the increased smooth muscle mass of the asthmatic airways is important in magnifying and maintaining BHR in persistent disease. However, it appears that the hypertrophy and hyperplasia are secondary processes caused by chronic inflammation and are not the primary cause of BHR.[16]

Neural Control/Neurogenic Inflammation

The airway is innervated by parasympathetic, sympathetic, and non-adrenergic inhibitory nerves.[2] Parasympathetic innervation of the smooth muscle consists of efferent motor fibers in the vagus nerves and sensory afferent fibers in the vagus and other nerves.[16] Normal resting tone of human airway smooth muscle is maintained by vagal efferent activity. Maximum bronchoconstriction mediated by vagal stimulation occurs in the small bronchi and is absent in the small bronchioles. The non-myelinated C fibers of the afferent system lie immediately beneath the tight junctions between epithelial cells lining the airway lumen.[16] These nerve endings probably represent the irritant receptors of the airways. Stimulation of these irritant receptors by mechanical stimulation, chemical and particulate irritants, and pharmacologic agents such as histamine produces reflex bronchoconstriction.[8]

The non-adrenergic, non-cholinergic (NANC) nervous system has been described in the trachea and bronchi. Substance P, neurokinin A, neurokinin B, and vasoactive intestinal peptide (VIP) are the best characterized neurotransmitters in the NANC nervous system.[8] VIP is an inhibitory neurotransmitter. Inflammatory cells in asthma can release peptidases that can degrade VIP, producing exaggerated reflex cholinergic bronchoconstriction. NANC excitatory neuropeptides such as substance P and neurokinin A are released by stimulation of C-fiber sensory nerve endings. The NANC system may play an important role in amplifying inflammation in asthma by releasing NO.

Nitric Oxide

NO is produced by cells within the respiratory tract. It has been thought to be a neurotransmitter of the NANC nervous system.[17] Endogenous NO is generated from the amino acid L-arginine (L-Arg) by the enzyme NO synthase.[17] Three isoforms of NO synthase exist. One isoform is induced in response to pro-inflammatory cytokines, inducible NO synthase (iNOS), in airway epithelial cells and inflammatory cells of asthmatic airways.[17] NO produces smooth muscle relaxation in the vasculature and bronchials; however, it appears to amplify the inflammatory process and is unlikely to be of therapeutic benefit. Investigations measuring the fraction of exhaled NO (FeNO) concentrations have suggested that it may be a useful measure of ongoing lower airway inflammation in patients with asthma and for guiding asthma therapy.[17]

CLINICAL PRESENTATION Chronic Ambulatory Asthma General

- Asthma is a disease of exacerbation and remission, so the patient may not have any signs or symptoms at the time of examination.

Symptoms

- The patient may complain of episodes of shortness of breath, chest tightness, coughing (particularly at night), wheezing, or a whistling sound when breathing. These often occur in association with exercise, but also occur spontaneously or in association with known allergens.

Signs

- Expiratory wheezing (rhonchi) on auscultation, dry hacking cough, or signs of atopy (allergic rhinitis and/or atopic dermatitis) may occur.

Laboratory

- Spirometry demonstrates obstruction (reduced FEV_1/forced vital capacity [FVC]) with reversibility following inhaled β_2-agonist administration (FEV_1 increases by more than 12% and 200 mL). The FEV_1/FVC ratio is normally more than 0.75 to 0.80 in adults, and more than 0.90 in children.

Other Diagnostic Tests

- Excessive variability in twice daily peak expiratory flow (PEF) over 2 weeks (greater than 10% in adults and greater than 13% in children). A fall in FEV_1 of at least 10% following 6 minutes of near maximal exercise. Elevated eosinophil count and IgE concentration in blood. Elevated FeNO (greater than 20 ppb in children younger than 12 years of age and greater than 25 ppb in adults). Positive methacholine challenge (PC_{20} FEV_1 less than 12.5 mg/mL) or mannitol challenge (FEV_1 decrease of at least 15% from baseline after 635 mg or less).

CLINICAL PRESENTATION

Chronic Asthma

3 Classic asthma is characterized by episodic and variable respiratory symptoms; however, the clinical presentation of asthma is as diverse as the number of triggering events (see Clinical Presentation: Chronic Ambulatory Asthma above). Although wheezing is the characteristic symptom of asthma, the medical literature is replete with the warning that "not all that wheezes is asthma." A wheeze is a high-pitched, whistling sound created by turbulent airflow through an obstructed airway, so any condition that produces significant obstruction can result in wheezing as a symptom. In addition, "all of asthma does not wheeze" is an equally justifiable warning. Patients may present with a chronic persistent cough (cough variant asthma) as their only symptom.[2,3]

There is no single diagnostic test for asthma. The diagnosis is based primarily on a good history.[2,3] The patient may have a family history of allergy or asthma or have symptoms of allergic rhinitis, or atopic dermatitis.[2,3] Reversibility of airway obstruction following administration of a short-acting inhaled β_2-agonist provides confirmation but is not by itself diagnostic. GINA adds excessive variability in twice daily PEF over 2 weeks as an alternative diagnostic test.[3] Patients with normal values of spirometry can be challenged by exercise or substances that produce bronchoconstriction, such as methacholine or mannitol, to determine if they have BHR, but, again, positive challenges are not diagnostic. Newer tests of inflammation in the airways such as induced sputum eosinophil and/or neutrophil counts and FeNO measurements are consistent with but not diagnostic of asthma.

GINA recommends confirmation of the diagnosis of asthma in patients already taking controller treatment using objective testing. The process depends on the patient's symptoms and lung function, and may include a trial of either a lower or a higher dose of controller treatment.[3]

Asthma has a widely variable presentation from chronic daily symptoms to only intermittent symptoms. The intervals between symptoms can be days, weeks, months, or years. Asthma also can vary as to its severity, the intrinsic intensity of the disease process. Severity is most easily and directly measured in a patient who is not currently receiving asthma treatment. The NAEPP has provided a means of classifying asthma severity that is divided into two domains: impairment and risk.[2] This classification system is individualized for three age groups (0-4, 5-11, and greater than or equal to 12 years) and summarized in **Table 26-2**. GINA has provided a means of determining chronic therapy for children and adults aged 6 years and older based on symptom control and future risk of adverse outcomes, described later in this chapter.

TABLE 26-2 Classifying Asthma Severity for Patients Who Are Not Currently Taking Long-Term Control Medications

		Children 0-4 and 5-11 Years of Age			
			Persistent		
	Components	Intermittent	Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/wk	>2 days/wk but not daily	Daily	Throughout the day
	Nighttime awakenings (0-4 years)	0	1-2 × month	3-4 × month	>1 × week
	5-11 years	≤2 × month	3-4 × month	>1 × week, but not nightly	Often 7 × week
	SABA use for Sx control	≤2 days/wk	>2 days/wk but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	FEV_1 > 80%	FEV_1 > 80%	FEV_1 60%-80%	FEV_1 < 60%
	5-11 years	FEV_1/FVC >85% (>0.85)	FEV_1/FVC >80% (>0.80)	FEV_1/FVC 75%-80% (0.75-0.80)	FEV_1/FVC <75% (<0.75)
	Exacerbations	**Intermittent**	**Persistent**		
Risk	0-4 years	0-1/y	≥2 in 6 months or ≥4 wheezing episodes/1 year lasting >1 day		
	5-11 years	0-2/y	>2 in 1 year →		
	Recommended step for initiating treatment	Step 1	Step 2	Step 3 and consider short course of oral corticosteroids	
		Youths ≥ 12 Years of Age and Adults			
			Persistent		
	Components	Intermittent	Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/wk	>2 days/wk but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2 × month	3-4 × month	>1 × week, but not nightly	Often 7 × week
	SABA use for Sx control	≤2 days/wk	>2 days/wk, but not >1 × day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function[a]	FEV_1 > 80%	FEV_1 > 80%	FEV_1 60%-80%	FEV_1 < 60%
		FEV_1/FVC normal	FEV_1/FVC normal	FEV_1/FVC reduced 5% (0.05)	FEV_1/FVC reduced >5% (> 0.05)
	Exacerbations	**Intermittent**	**Persistent**		
Risk		0-2/y	>2 in 1 year →		
	Recommended step for initiating treatment	Step 1	Step 2	Step 3 and consider short course of oral corticosteroids	Step 4 or 5 and consider course of oral corticosteroid

SABA, short-acting β-agonist.

[a]Normal FEV_1/FVC: 8-19 years 85% (0.85); 20-39 years 80% (0.80); 40-59 years 75% (0.75); 60-80 years 70% (0.70).

The intermittent and/or chronic nature of symptoms does not necessarily determine the severity of symptoms during exacerbations. Asthma severity is determined by lung function, symptoms, nighttime awakenings, and interference with normal activity prior to therapy. Patients can present with a range from intermittent symptoms that require no medications or only occasional use of short-acting inhaled β_2-agonists to severe persistent asthma symptoms despite treatment with multiple medications.

CLINICAL PRESENTATION Acute Severe Asthma General

- An episode can progress over several days or hours (usual scenario) or progresses rapidly over 1 to 2 hours.

Symptoms

- The patient is anxious in acute distress and complains of severe dyspnea, shortness of breath, chest tightness, or burning. The patient is only able to say a few words with each breath. Symptoms are unresponsive to usual measures (short-acting inhaled β_2-agonist administration).

Signs

- Signs include expiratory and inspiratory wheezing on auscultation (breath sounds may be diminished with very severe obstruction), dry hacking cough, tachypnea, tachycardia, pale or cyanotic skin, hyper-inflated chest with intercostal and supraclavicular retractions, and hypoxic seizures if very severe.

Laboratory

- Peak expiratory flow and/or FEV_1 less than 40% of normal predicted values. Decreased arterial O_2 (PaO_2), and O_2 saturations by pulse oximetry (SaO_2 less than 90% [0.90] on room air is severe). Decreased arterial or capillary CO_2 if mild, but in the normal range or increased in moderate to severe obstruction.

Other Diagnostic Tests

- Blood gases to assess metabolic acidosis (lactic acidosis) in severe obstruction. Complete blood count if there are signs of infection (fever and purulent sputum). Serum electrolytes as therapy with β_2-agonist and corticosteroids can lower serum potassium, magnesium, and phosphate, and increase glucose. Chest radiograph if signs of consolidation on auscultation.

Acute Severe Asthma

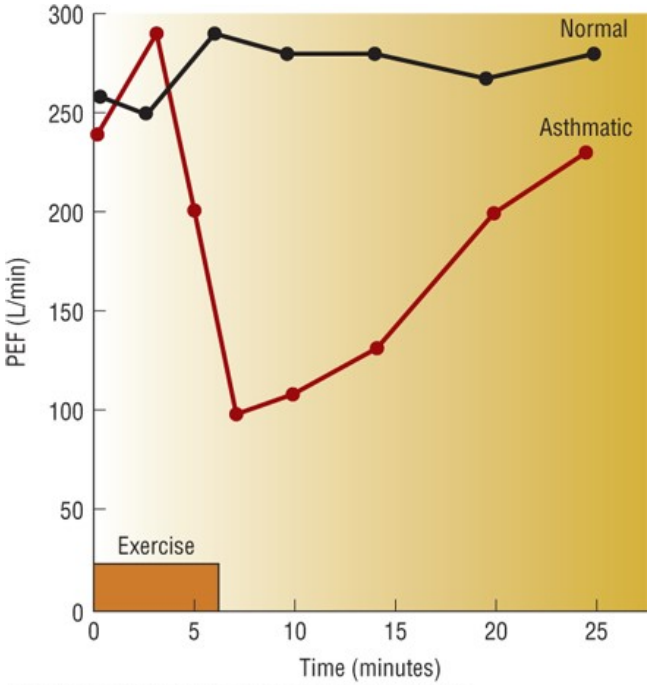
Uncontrolled asthma, with its inherent variability, can progress to an acute state where inflammation, airway edema, excessive mucus accumulation, and severe bronchospasm result in a profound airway narrowing that is poorly responsive to usual bronchodilator therapy[2,3] (see Clinical Presentation: Acute Severe Asthma above). Although this progression is the most common scenario, some patients experience rapid-onset or hyper-acute attacks.[2,3] Hyper-acute attacks are associated with neutrophilic as opposed to eosinophilic infiltration and resolve rapidly with bronchodilator therapy, suggesting that smooth muscle spasm is the major pathogenic mechanism.[15] In most cases, ED visits for acute severe asthma represent the failure of an adequate therapeutic regimen to control persistent asthma. Underutilization of anti-inflammatory drugs and excessive reliance on short-acting inhaled β_2-agonists are the major risk factors for severe exacerbations.[2,3] However, frequent exacerbations may represent a specific phenotype of asthma. A blunted perception of airway obstruction may predispose certain individuals to fatal asthma attacks.[2]

Exercise-Induced Bronchospasm

During vigorous exercise, pulmonary function measurements (FEV_1 and PEF) in patients with asthma increase during the first few minutes but then begin to decrease after 6 to 8 minutes (**Fig. 26-3**).[2] EIB is defined as a drop in FEV_1 of 10% or greater from baseline (pre-exercise value).[14] Most studies suggest that many patients with persistent asthma experience EIB.[2] The exact pathogenesis of EIB is unknown, but heat loss and/or water loss from the central airways appears to play an important role.[14] EIB is provoked more easily in cold, dry air, ambient ozone, and airborne particulate matter; alternatively, warm, humid air can blunt or block it.[14] Studies have demonstrated increased plasma histamine, cysteinyl leukotrienes, prostaglandins, and tryptase concentrations during EIB, suggesting a role for mast cell degranulation.[14] These findings led to the development of inhaled mannitol, an osmotic agent, as an indirect pharmacologic bronchoprovocation test to assist in the diagnosis of asthma.[18]

FIGURE 26-3

Typical responses to exercise in a normal subject and an asthmatic subject. Note the initial bronchodilation. (PEF, peak expiratory flow.)



A refractory period following EIB lasts up to 4 hours after exercise in some patients. During this period, repeat exercise of the same intensity produces either no decrease in pulmonary function or a drop of less than 50% of the initial response.[14] The refractory period is thought to be caused by an acute depletion of mast cell mediators and time required for their repletion.

Exercise-induced bronchospasm is believed to be a reflection of increased BHR associated with asthma. A correlation, though not perfect, exists between EIB and reactivity to histamine, methacholine, and mannitol.[14] Other patient groups with BHR (eg, after viral infection, cystic fibrosis, or allergic rhinitis) show bronchoconstriction after exercise to a lesser degree (5%-10% drops) than patients with asthma (15%-40% drops).[14] Patients will not always demonstrate the same sensitivity. During periods of remission, a decreased sensitivity to the same degree of exercise is often observed. Finally, a number of children and adults with EIB are otherwise normal, without symptoms or abnormal pulmonary function except in association with exercise.[2] Elite athletes have a higher prevalence of EIB than the general population.[14]

Nocturnal Asthma

3 Worsening of asthma during sleep is referred to as *nocturnal asthma*. Patients with nocturnal asthma exhibit significant falls in pulmonary function between bedtime and awakening.[2] Typically, their lung function reaches a nadir at 3 to 4 am. Although the pathogenesis of this phenomenon is unknown, it has been associated with diurnal patterns of endogenous cortisol secretion and circulating epinephrine.[2] Direct evidence for an inflammatory component to nocturnal asthma includes increased circulating histamine and activated eosinophils and LT excretion at night associated with increased BHR to methacholine.[2]

Numerous other factors that may affect nocturnal worsening of asthma, including allergies and improper environmental control, gastroesophageal reflux, obstructive sleep apnea, and sinusitis, also must be considered when evaluating these patients.[2] Experts consider nocturnal symptoms to be a sign of inadequately treated persistent asthma.[2] Awakening from nocturnal asthma is a sensitive indicator of both severity and inadequate control.[2]

FACTORS CONTRIBUTING TO ASTHMA SEVERITY

Viral Respiratory Infections

Viral respiratory infections are primarily responsible for exacerbations of asthma, particularly in children under age 10.[11] Children aged 5 or younger may have wheezing (which may or may not be asthma) associated with upper respiratory tract infections up to 6 to 8 times per year.[3] Infants are particularly susceptible to airway obstruction and wheezing with viral infections because of their small airways. Approximately 50% of infants who have severe RSV bronchiolitis will subsequently be diagnosed with asthma. The most common cause

of exacerbations in both children and adults is the rhinovirus, which is the most frequent virus associated with the common cold and distributed worldwide.[11] Other viruses isolated include RSV, parainfluenza virus, adenoviruses, coronavirus, and influenza viruses. Certain viruses (RSV and parainfluenza virus) are capable of inducing specific IgE antibodies, and rhinovirus can activate eosinophils directly in asthmatics.[11] The increase in asthma symptoms and BHR that occurs may last for days or weeks following resolution of the symptoms of the viral infection. Evidence does not support a beneficial effect of influenza vaccine for preventing asthma exacerbations from subsequent influenza infections.[2] However, patients with moderate-severe asthma should be vaccinated against influenza annually.[3]

Environmental and Occupational Factors

The development and heterogeneity of persistent asthma is driven by complex gene-environment interactions. Agents and events that are known to trigger asthma are listed in Table 26-1. The mechanisms for inducing symptoms are as varied as the exposure factor and include both IgE and cell-mediated reactions.[3] The World Allergy Organization predicts an increase in the incidence and prevalence of asthma due to environmental exposures from climate change. Greater temperature variability, industrial pollution, more frequent forest fires, higher concentration of ground level ozone, increased trans-boundary movement of respiratory infectious agents, and changes in aeroallergen distribution are all cited factors. Exposure to 0.2 ppm ozone for 2 to 3 hours can induce bronchoconstriction and increase BHR in asthmatics.[2,10] Sulfur dioxide in the ambient atmosphere is highly irritating and presumably induces bronchoconstriction through mast cell or irritant-receptor involvement.[2] Asthma produced by repeated prolonged exposure to industrial inhalants is a significant health problem. It has been estimated that occupational asthma accounts for 15% of all asthmatic persons.[3] An estimated 5% to 20% of new cases of adult-onset asthma can be attributed to occupational exposure.[3] Occupational asthma can be difficult to diagnose as the latency between exposure and symptom development can extend from months to years.[3] Persons with occupational asthma have the typical symptoms of asthma with cough, dyspnea, and wheeze. Typically, the symptoms are related to workplace exposure and improve on days off and during vacations.[10] Once occupational asthma has developed, the symptoms persist in most patients even after exposure is no longer present. [GINA Appendix 2015][3]

Stress, Depression, and Psychosocial Factors in Asthma

Observational studies demonstrate an association between increased stress and worsening asthma, but the role is not clearly defined.[2] Bronchoconstriction from psychological factors appears to be mediated primarily through excess parasympathetic input. Atropine has been shown to block experimental psychogenic bronchoconstriction. Persons with asthma are more likely to have depression than those without asthma. The episodic nature of both diseases may be related to abnormal expression of Th2 cytokines which have effects in the brain as well as the airway. It is most important to emphasize to both patients and parents that asthma is not an emotional disease; however, coping skills may benefit the patient who becomes emotionally distraught during an asthma attack.

Chronic Rhinosinusitis

Disorders of the upper respiratory tract, particularly rhinitis and sinusitis, have been linked with asthma for many years. As many as 40% to 50% of asthmatics have abnormal sinus radiographs.[2] The prevalence of allergic sensitization increases with asthma severity; nasal polyposis is often seen in those with allergic rhinitis. It has been postulated that transport of mucus chemotactic factors and inflammatory mediators from nasal passages during allergic rhinitis into the lungs may accentuate BHR. However, chronic sinusitis may just represent a nonbacterial coexisting condition with allergic asthmatics because the histologic changes in the paranasal sinuses are similar to those seen in the lung and nose.[2] Thus, it would seem that treatment of upper airway disease could optimize overall asthma control. However, a large study of children and adults found that treatment of chronic sinonasal disease with intranasal corticosteroids for six months did not improve asthma control nor improve BHR, suggesting that the treatment of sinus disease and asthma be managed separately.[19]

Gastroesophageal Reflux Disease

Symptoms of gastroesophageal reflux disease (GERD) as well as asymptomatic reflux are common in both children and adults who have asthma.[2] Nocturnal asthma may be associated with nighttime reflux.[2] Reflux of acidic gastric contents into the esophagus is thought to initiate a vagally mediated reflex bronchoconstriction.[2] Also of concern is that most medications that decrease airway smooth muscle tone may have a relaxant effect on gastroesophageal sphincter tone. There is no benefit from treating asymptomatic reflux in asthma.[3,20] Treatment with proton pump inhibitors does not improve asthma control even in those with documented reflux.[20] Symptomatic reflux should be treated for its general health benefits.[3]

Female Hormones and Asthma

Asthma symptoms may vary significantly during different stages of the menstrual cycle. Premenstrual worsening of asthma has been

reported in as many as 30% to 40% of women in some studies, whereas worsening of pulmonary functions has been reported even in women not aware of worsening symptoms.[21] The pathophysiology is uncertain because estrogen replacement in postmenopausal women has been shown to worsen asthma, whereas estradiol and progesterone administration has been variably reported to improve or have no effect on asthma in women with premenstrual asthma.[21,22] The clinical significance of menstruation-related asthma is still unclear because some studies have reported that up to 50% of ED visits by women were premenstrual, whereas others have reported no association with menstrual phase.[21,22] Pregnancy may cause worsening, improvement or no change in asthma symptoms and the changes seem to occur with equal frequency. These changes are suspected to be related to altered sex hormones, stress, and fetal antigens.[22]

FOODS, DRUGS, ADDITIVES AND VITAMINS

Documentation in the literature of food allergens as triggers for asthma is not available.[2] However, additives, specifically sulfites used as preservatives, can trigger life-threatening asthma exacerbations. Beer, wine, dried fruit, and open salad bars, in particular, have high concentrations of metabisulfites.[2] Severe oral corticosteroid-dependent patients should be warned about ingesting foods processed with sulfites.

Aspirin and other nonsteroidal anti-inflammatory drugs can cause severe asthma exacerbations (aspirin-exacerbated respiratory disease).[3] The mechanism is related to cyclooxygenase-1 (COX-1) inhibition, and inhaled corticosteroids (ICSs) are the primary preventive treatment although oral corticosteroids may be required; leukotriene receptor antagonists (LTRAs) may be useful.[3] The prevalence increases with age and severity of asthma.[2] The greatest frequency occurs in severe corticosteroid-resistant asthmatics in their fourth and fifth decades who also have perennial rhinitis and nasal polyposis (presence of several polyps).[2] Other drugs that do not precipitate bronchospasm but that prevent its reversal are the nonselective β-blocking agents.[2,3]

Children with vitamin D insufficiency have been considered at greater risk of uncontrolled asthma (increased hospitalizations, BHR, and eosinophil counts).[25] Vitamin D helps regulate T cells and improves their secretion of anti-inflammatory cytokines in response to corticosteroids.[25] In adults with asthma, Vitamin D supplementation in those with levels below 30 ng/mL does not provide protection against exacerbations compared with placebo.[26] There are no published data evaluating Vitamin D treatment in children with asthma.

Obesity

Epidemiologic data suggest that obesity increases the prevalence of asthma and may reduce asthma control, although it may be difficult to distinguish obesity-induced respiratory symptoms from true asthma symptoms particularly because obesity often precedes the onset of asthma.[23] Lung volume and tidal volume are reduced in obesity, promoting airway narrowing. Obesity also produces low-grade systemic inflammation that may act on the lung to worsen asthma.[23] The mechanism may be the release of adipose-derived pro-inflammatory mediators such as IL-6, IL-10, eotaxin, tumor necrosis factor-α, transforming growth factors-β_1, C-reactive protein, leptin, and adiponectin or a result of common predisposing dietary factors. Although not all studies find relationship between body mass index and asthma control, management of asthma in obese patients should include weight loss measures.[24] Additional co-morbidities of obesity that may independently contribute to asthma symptoms include obstructive sleep apnea, GERD, and metabolic syndrome.[3]

Smoking History

During performance of a history that considers age, respiratory symptoms (onset, exacerbations, progression, variability, seasonality or periodicity, and persistence), past history, and previous diagnoses and treatment and response to treatment, the query of social and occupational risk factors may identify a smoking history of importance. The clinician is then faced with distinguishing asthma from COPD. Some patients have clinical features of both, now termed asthma COPD Overlap Syndrome (ACOS).[27] Physical examination findings, lung function measures, and radiology data are then combined with the history, to confirm this syndromic diagnosis. GINA and the Global Initiative for Chronic Obstructive Lung Disease provide recommendations for initial therapy of ACOS, if the differential diagnosis is equally balanced between asthma and COPD.[27] Referral for expert advice and further diagnostic evaluation may be necessary. A recent literature review has been published to characterize the prevalence of ACOS and the effect of different disease definitions on these estimates, to help guide decision making for both refining the ACOS definition and trial design aimed at effective treatment.[28]

TREATMENT

Asthma

Aerosol Therapy for Asthma

Aerosol delivery of drugs for asthma has the advantage of being site specific and thus enhancing the therapeutic ratio.[2,29] Inhalation of short-acting β_2-agonists provides more rapid bronchodilation than either parenteral or oral administration, as well as the greatest degree of protection against EIB and other challenges.[2] ICSs have been developed with rapid oral and systemic clearance to enhance lung activity and reduce systemic activity. Specific agents (eg, formoterol, salmeterol, and ipratropium bromide) are only effective by inhalation.[2] Therefore, an understanding of aerosol drug delivery is essential to optimal asthma therapy. **Table 26-3** lists the factors determining lung deposition of therapeutic aerosols.

TABLE 26-3 Factors Determining Lung Deposition of Aerosols

Device	Device Factors	Patient Factors
Metered-dose inhaler (MDI)	Canister held inverted	Inspiratory flow (slow, deep)
	Formulation (solution or suspension)	Breath-holding
	Actuator cleanliness	Tilting head back
	Addition of a spacer device	Coordinating actuation with inhalation
	Device cleanliness	Priming and shaking the device
Dry powder inhaler (DPI)	Resistance to inhalation	Inspiratory flow (deep, forceful)
	Humidity	Tilting head back
	Volume fill (3-6 mL)	Maintaining parallel to ground once activated
Jet nebulizer (small volume)	Gas flow (6-12 L/min)	Inspiratory flow (slow, deep)
	Dead space volume	Breath-holding
	Open vs closed system	Tapping nebulizer
	Thumb-activating valve	
	Mouthpiece vs face mask	
Ultrasonic nebulizer	Volume fill	Inspiratory flow (slow, deep)
	Not effective for suspensions	Breath-holding
	Mouthpiece vs face mask	Tapping nebulizer
Spacer device	Volume (≥650 mL)	Inspiratory flow (slow, deep)
	One-way valves	Time between actuation and inhalation (<5 seconds)
	Holding chamber vs open-ended	Cleaning with detergent to reduce static
	Antistatic lining	Multiple actuations (all at once) decrease delivery
	Mouthpiece vs face mask	Coordination of actuation and inhalation for the simple open-tube spacers

Device Determinants of Delivery

Devices used to generate therapeutic aerosols include jet nebulizers, ultrasonic nebulizers, metered-dose inhalers (MDIs), and dry powder inhalers (DPIs). The single most important device factor determining the site of aerosol deposition is particle size.[29] Devices for delivering therapeutic aerosols generate particles with mass median aerodynamic diameters (MMAD) from 0.5 to 35 µm.[29] Particles larger than 10 µm deposit in the oropharynx, particles between 5 and 10 µm deposit in the trachea and large bronchi, particles 1 to 5 µm in size reach the lower airways, and particles smaller than 0.5 µm act as a gas and are exhaled. As a result of the Montreal Protocol of 1987, chlorofluorocarbon (CFC) propellants in MDIs were phased out and replaced with hydrofluoroalkane (HFA) propellants that do not have ozone depleting properties.[29] The resultant MDIs, particularly for corticosteroid inhalers, are solution aerosols (vs suspensions) with extra-fine particle size distributions (MMAD of 1.1 µm) and high lung deposition. It has been suggested, but not robustly proven in clinical trials, that ICS HFA MDIs may improve asthma outcomes in patients due to greater penetration into the peripheral airways.

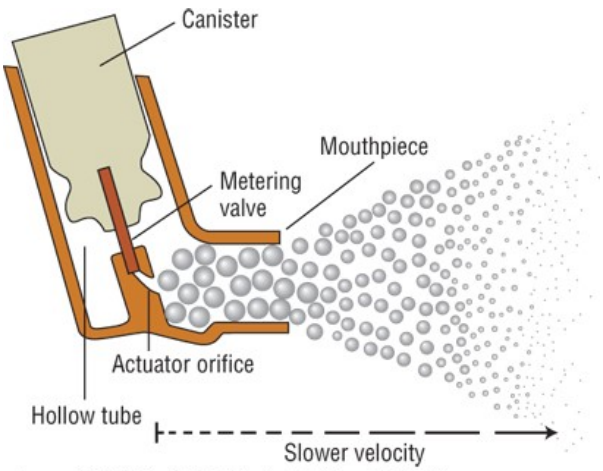
In asthma, the airways, not the alveoli, are the target for delivery. Respirable particles are deposited in the airways by three mechanisms: (a) inertial impaction, (b) gravitational sedimentation, and (c) Brownian diffusion.[29] The first two mechanisms are the most important for therapeutic aerosols and probably are the only factors that can be manipulated by patients.

Each delivery device within a classification generates specific aerosol characteristics, so extrapolation of delivery data from one device cannot be applied to the other devices in the class. For instance, MDIs can deliver 15% to 50% of the actuated dose; DPIs, 10% to 30% of the labeled dose; and nebulizers, 2% to 15% of the starting dose.[29] MDIs and DPIs are portable and convenient, unlike jet nebulizers. Small portable ultrasonic nebulizers have also been developed.

Metered-dose inhalers consist of a pressurized canister with a metering valve; the canister contains active drug, low-vapor-pressure propellants such as HFA, co-solvents, and/or surfactants.[29] With any change in the components of an MDI, the FDA considers it to be a new drug that requires stability, safety, and efficacy studies prior to approval. The MDI drug is either in solution or a suspended micronized powder. In order to disperse the suspension for accurate delivery, the canister must be shaken. The metering chamber measures a liquid volume, and, therefore, the device must be held with the valve stem downward so that the chamber is covered with liquid[29] (**Fig. 26-4**). If not used for a period of time the drug in the chamber evaporates which could lead to an inadequate therapeutic dose. Inhalers have to be primed before first use to fill the chamber and after an interval of nonuse.[29] When the canister is actuated, the device releases the propellant and drug in a forceful spray whose particles are large (MMAD = 45 µm)[29] (see Fig. 26-4). As evaporation occurs, the particle size is reduced to a final MMAD of 0.5 to 5.5 µm depending on the MDI. The aerosol cloud extends about 6 inches beyond the MDI at the lowest MMAD.[29] Each MDI has different conditions for storage, priming, and durations to expiration, so the clinician must become familiar with and counsel the patient on these factors.

FIGURE 26-4

Illustration of a metered-dose inhaler demonstrating the particle size difference as the aerosol cloud extends outward.



Spacer devices are used frequently with an MDI to decrease oropharyngeal deposition and enhance lung delivery.[2,3] However, not all spacer devices produce similar effects. The design of spacers varies from simple open-ended tubes that separate the MDI from the mouth to valved holding chambers (VHCs) with one-way valves that open during inhalation (the preferred system); some VHCs have a face mask to accommodate drug delivery in children 5 years or younger.[3] A VHC allows evaporation of the propellant prior to inhalation permitting a greater number of drug particles to achieve a respirable droplet size. VHC use also allows inhalation after actuation of the MDI, obviating the need for good hand–lung coordination.[29] Additionally, the large particles that normally would deposit in the oropharynx "rain out" in the spacer.[29] Spacer size may affect the amount of drug available for inhalation; a lower volume spacer (less than 350 mL) is advantageous in very young children.[3]

All the available spacers significantly reduce oropharyngeal deposition from MDIs, with the VHCs being superior to the open-ended tubes.[29] This reduction in oropharyngeal deposition is an important factor in reducing local adverse effects (eg, hoarseness and thrush) from ICSs.[29] The change in lung delivery depends on both the MDI and the drug, where one spacer device may enhance delivery with one MDI preparation and decrease delivery with others.[29] Therefore, once a patient is stabilized on a drug and chamber combination, the chamber should not be substituted in order to avoid changes in the dose delivered to the lungs. Finally, over time, holding chambers (eg, plastic) can build up static electricity that attracts small particles to the sides of the chamber, significantly reducing aerosol availability. Some spacers should be washed weekly with household detergent with a single rinse and allowed to drip dry.[2] Other VHCs have been

developed with antistatic materials.

Dry micronized powders can be inhaled directly into the lungs. A number of DPIs are now available for use in the United States.[29] Currently, there are no generic DPIs as each drug plus device has its own patent. Each DPI has unique characteristics with advantages and disadvantages (**Table 26-4**). The primary advantage of DPIs is that they are breath actuated and require minimal hand–lung coordination, and it is thus easier to teach patients proper technique.[29] Some DPIs are more flow dependent than others.[29] Thus, similar to MDIs and spacers, delivery data from one DPI cannot be extrapolated to another.

TABLE 26-4 Characteristics of Various Inhalation Devices

Device	Drugs	Breath Activated	Dose Counter	Other Excipients	Disadvantages
MDI	All classes	No	No/yes	Propellants, surfactants, cosolvents	Requires coordination of actuation and inhalation. Large pharyngeal deposition. Difficult to teach
Pressair	aclidinium	Yes	Yes	Lactose filler	Requires rapid inhalation to activate
Respiclick	albuterol	Yes	Yes	Lactose filler	Requires rapid inhalation to activate
MDI plus valved holding chamber	All classes	No	No		More expensive than MDI alone; less portable; some payers will not pay; inconsistent effect on delivery; nonstatic preferred
Jet nebulizers	All classes	No	—	Preservatives in some solutions	Significant interbrand variability; expensive and time consuming; less efficient than MDIs; contamination possible; preparations may be light and temperature sensitive (short shelf life)
Ulrasonic nebulizer	Cromolyn solution, short-acting β_2-agonist solutions	No	—	Preservatives in some solutions	Same as for jet nebulizers plus cannot be used for suspensions; battery operated are portable
Flexhaler	Budesonide	Yes	Yes	Lactose filler	Requires high inspiratory flow (60 L/min) Pharyngeal deposition
Diskus	Fluticasone; salmeterol; fluticasone/salmeterol	Yes	Yes	Lactose filler	Not approved for <6 years of age Not approved for <4 years of age Requires inspiratory flow of 30-60 L/min
Ellipta	Fluticasone furoate Fluticasone/vilanterol	Yes	Yes	Lactose filler	Not approved for <12 years of age (18 years for fluticasone/vilanterol) Requires inspiratory flow of 60 L/min
Aerolizer	Formoterol	Yes	—	Lactose filler	Single-dose capsules. Not approved for <5 years of age Requires flow of 30-60 L/min
Neohaler	Indacaterol	Yes	—	Lactose filler	Single-dose capsules. Not approved for children Requires flow of 60 L/min
Handihaler	Tiotropium	Yes	—	Lactose filler	Single-dose capsule. Not approved for children Requires flow of 20 L/min
Twisthaler	Mometasone Tiotropium	Yes	Yes	Lactose filler	Not approved for <4 years of age
Respimat	Albuterol/Ipratropium Olodaterol	No	Yes	Preservative	Requires slow deep breath. Not approved for <12 years of age

Nebulizers come in two basic types, the jet nebulizer and the ultrasonic nebulizer. Jet nebulizers produce an aerosol from a liquid solution or suspension placed in a cup. A tube connected to a stream of compressed air or O_2 flows up through the bottom and draws the liquid up an adjacent open-ended tube.[29] The air and liquid strike a baffle, creating a droplet cloud that is then inhaled.[29] Ultrasonic nebulizers produce an aerosol by vibrating liquid lying above a transducer at speeds of about 1 mHz.[29] Both produce similar degrees of lung deposition, with the exception that ultrasonic nebulizers are ineffective for nebulizing currently available micronized suspensions.[29] The aerosol output and lung delivery vary significantly among the commercially available jet nebulizers even when operated in the same manner.[29] Increasing fill volume will increase the total amount of drug delivered; however, it also will take longer for the patient to

nebulize the dose.[29] The MMAD of the droplets is related directly to the gas flow, with flows of 5 to 12 L/min providing an aerosol cloud with an MMAD of 4 to 8 µm for most jet nebulizers.[29] Each jet nebulizer comes with its optimal operating and cleaning instructions.

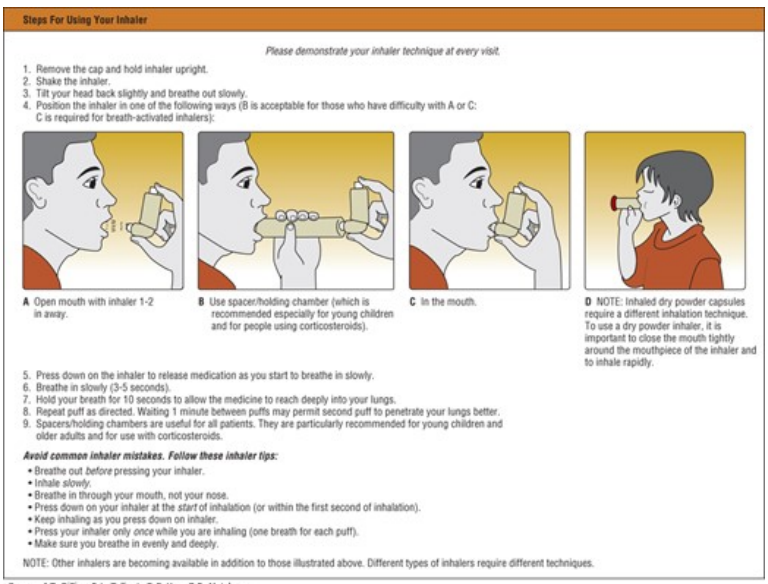
Patient Determinants of Delivery

6 7 The most important patient factor determining aerosol deposition is inspiratory flow (see Table 26-3).[2,29] High inspiratory flows with MDIs increase the degree of deposition owing to impaction of particles of any size, thereby increasing deposition centrally (ie, throat and large airways) and decreasing peripheral deposition. Optimal inspiratory flow for most MDIs is slow and deep (approximately 30 L/min or 5 seconds for a full inhalation).[2,3] In general, DPIs require higher inspiratory flows (greater than or equal to 60 L/min) and a change in inhalation technique (ie, deep, forceful inspiration) for optimal dispersion of the powder, which, in turn, increases the amount of drug delivered to the larger central airways.[29] However, this difference in delivery may not produce clinically significant differences.[29] Patients should be cautioned not to exhale into DPIs because this causes loss of dose and moistens the dry powder, causing aggregation into larger particles. Patient factors that cannot be controlled include interpatient variability in airway geometry (particularly the differences between children and adults)[29] and the effects of bronchospasm, edema, and mucus hypersecretion. Mild obstruction increases aerosol deposition; however, severe obstruction probably leads to increased central deposition from impaction.[29] The absolute delivery to the lung is not as important as consistency of delivery, assuming that a sufficient dose to produce the desired therapeutic effect is achieved. No single inhalation device is the best for all patients. Table 26-4 lists the differing characteristics of inhalation devices.

Appropriate inhalation technique is essential to achieve optimal drug delivery and therapeutic effect.[2,3] The components are illustrated in **Fig. 26-5**. Approximately 50% to 80% of a dose from MDIs and DPIs impacts on the oropharynx and is then swallowed; the rest is either left in the device or exhaled.[29] It is important that MDI actuation occurs during inhalation, although the time during inspiration is unimportant.[2,29] Although radiolabeled studies with MDIs indicate improved delivery by holding the actuator 2 to 3 cm in front of an open mouth to allow more evaporation and less impaction, physiologic studies with bronchodilators have failed to document an advantage for this method.[2,29] Many patients do not use their MDIs optimally, and patient instruction with demonstration is the most effective means of improving inhaler technique.[2,3] Even with instruction, up to 30% of patients, particularly young children and the elderly, cannot master the use of an MDI. For these patients, attachment of a VHC to the MDI can improve efficacy significantly.[2,29] However, addition of a VHC offers no advantage in patients who can use an MDI optimally alone.[29] Mouth rinsing following treatment with MDI- and DPI-ICSs is important to minimize local adverse effects and oral absorption.[2,29]

FIGURE 26-5

Instructions for inhaler use from the adapted NAEPP Expert Panel Report 2. *http://www.nhlbi.nih.gov/guidelines/archives/epr-2/index.htm. (Data from reference 3.)*



Delivery from high-resistance DPIs is more flow dependent than from low-resistance DPIs. Thus, younger children and possibly elderly adults will have more variability in delivery from high-resistance devices.[29] Most children younger than 4 years of age cannot generate a sufficient inspiratory flow to use DPIs. Young children (younger than 4 years) and infants generally require the use of a face mask attached to either an MDI plus VHC or nebulizer. The use of a face mask results in a reduction in lung delivery due to the portion of the

aerosol inhaled nasally, so the doses of drugs used in these patients are often not decreased.

TREATMENT

Acute Severe Asthma in the Emergency Department

The primary goal is prevention of life-threatening asthma by early recognition of signs of deterioration and early intervention. Initial assessment includes history, physical examination, and objective assessments. It is important that therapy not be delayed, so the history and physical examination should be obtained while initial therapy is being provided. The brief history will assess for: onset and causes of the exacerbation; severity of symptoms and if associated with anaphylaxis; medication use, adherence, and response to current therapy; and risk factors for asthma-related death. The asthma-related risk factors for death include: a history of near-fatal asthma requiring intubation and mechanical ventilation; hospitalization or emergency care in the past year; current or recent use of oral corticosteroids; no current use of ICSs; over use of short-acting β_2-agonist therapy (more than one canister per month); history of psychiatric disease or psychosocial problems; poor medication adherence; lack of a written asthma action plan; and food allergy.[3]

The physical exam will assess vital signs and any complicating factors such as pneumonia or anaphylaxis as well as other comorbid conditions that could be causing acute shortness of breath such as inhaled foreign body, congestive heart failure, pulmonary infection, and pulmonary embolism.[3]

Objective assessments are keys to monitoring response to therapy and should be made before initiation of oxygen or drug treatment. Lung function testing by PEF or FEV_1 should be measured before treatment if possible and thereafter at one hour after start of treatment and then periodically until response is achieved or no further improvement is evident.[3] Oxygen saturation is also monitored closely preferably by pulse oximetry and is a key parameter in young children who may not be able to perform lung function. Arterial blood gases are typically reserved for patients who are poorly responsive to initial treatment or deteriorating. A chest X-ray is rarely indicated unless there are physical signs of other or additional complicating features such as foreign body aspiration.

Oxygen therapy is initiated to achieve an arterial oxygen saturation of 93% to 95% in adolescents and adults and 94% to 98% in school-aged children and pregnant women or those with cardiac disease.[2,3] Oxygen therapy is continued until the patient has stabilized with continued use of pulse oximetry to monitor further oxygen need and response to medications.

The primary therapy of acute exacerbations is pharmacologic, which includes short-acting inhaled β_2-agonists and, depending on the severity, systemic corticosteroids, inhaled ipratropium, and O_2. Treatments are typically administered concurrently to facilitate rapid improvement (**Figs. 26-6** and **26-7**).[2] New evidence supports the use of heliox versus oxygen for nebulized β_2-agonist administration in patients with moderate to severe exacerbations who do not respond to standard therapy.[3,30] Heliox is a combination of helium and oxygen (often 70:30) that has a lower density than air which reduces resistance to flow and increases ventilation by converting turbulent flow to more efficient laminar flow.[31] Limited data suggest that the benefits with heliox therapy are apparent in those with severe exacerbations by improving PEF and reducing the risk of hospitalizations in both children and adults.[30]

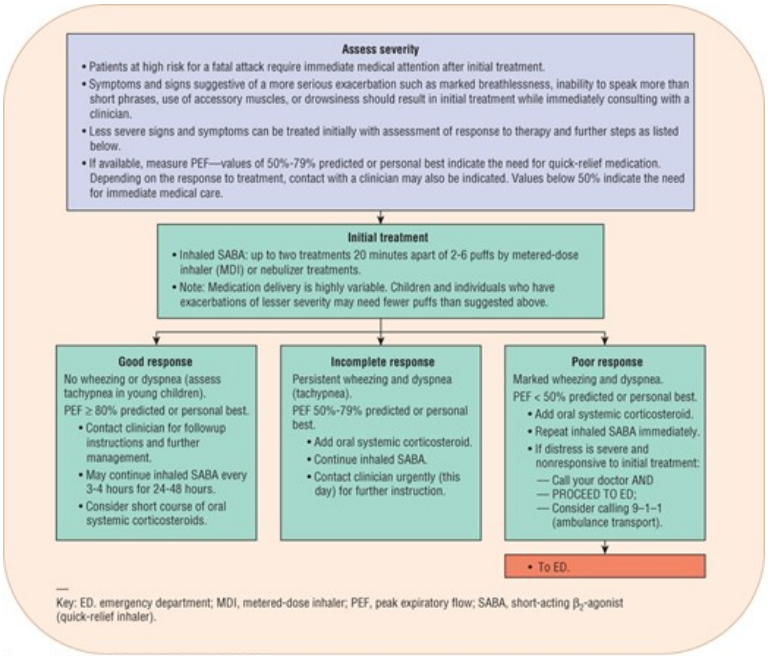

FIGURE 26-7

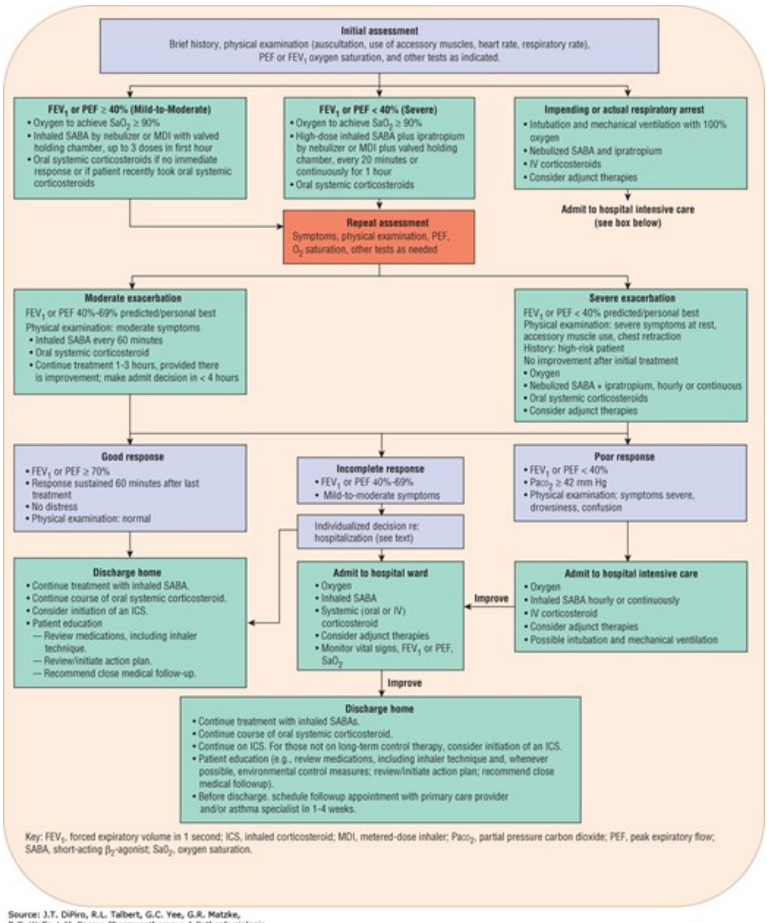
Management of asthma exacerbations in acute care facility, For example, emergency department. *(Used with permission from Global Initiative for Asthma. Global strategy for asthma management and prevention, 2015. Available from: www.ginasthma.org.)*



A complete blood count may be appropriate for patients with fever or purulent sputum, but modest leukocytosis is common in asthma exacerbations due to viral infection or secondary to corticosteroid administration. Leukocytosis associated with corticosteroid

administration does not cause a shift to the left as is seen in bacterial infections. Serum electrolytes should be monitored in patients who take diuretics regularly and in patients with coexistent cardiovascular disease as short-acting inhaled β_2-agonists can produce transient decreases in potassium, magnesium, and phosphate.[2] The combination of high-dose β_2-agonists and systemic corticosteroids occasionally may result in excessive elevations of glucose and lactic acid.[31]

Initial response is measured one hour after the first three inhaled bronchodilator treatments are administered and provides the best indicator for the need for hospitaliztion.[3] Indicators for hospitalization include an initial FEV_1 less than 25% predicted or PEF that is less than 40% of their personal best, and post-treatment FEV_1 or PEF that is 40% to 60%.[3] Other indicators of severe asthma include monosyllabic speech, inaudible breath sounds, sitting hunched forward, and use of accessory muscles.[3] Patients with lung function that is 40% to 60% predicted *may* be considered for discharge after assessment of risk factors for death from asthma and the likelihood for follow up care. Those with higher lung function can be discharged after risk factor and follow-up care assessment.[3]

Discharge planning after an ED visit or hospitalization includes arrangement for follow-up care within one week as well as review of strategies to improve asthma management. Referral to a specialist is suggested for those who have been hospitalized or frequently seek care in the ED despite having regular primary care. Strategies for preventing future urgent care visits includes ensuring the patient understands the cause of the exacerbation, how to modify risk factors, how to use medications correctly and for what purpose, and has a written asthma action plan that includes self-assessment of worsening symptoms and home PEF values.[3]

Figures 26-6 and 26-7 illustrate the recommended therapies for the treatment of acute asthma exacerbations in home and ED/hospital settings, respectively.[2] The dosages of the drugs for acute severe exacerbations are provided in **Table 26-5**.[2] Institutions should strongly consider developing critical pathways/treatment algorithms for their EDs because their implementation has been shown to improve outcomes and decrease the cost of care.[32]

TABLE 26-5 Dosages of Drugs of Acute Severe Exacerbations of Asthma in the Emergency Department or Hospital

Medications	Dosages		Comments
	≥12 Years Old	<12 Years Old	
Inhaled β-Agonists			
Albuterol nebulizer solution (5 mg/mL, 0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL)	2.5-5 mg every 20 minutes for three doses, and then 2.5-10 mg every 1-4 hours as needed, or 10-15 mg/h continuously	0.15 mg/kg (minimum dose 2.5 mg) every 20 minutes for three doses, and then 0.15-0.3 mg/kg up to 10 mg every 1-4 hours as needed, or 0.5 mg/kg/h by continuous nebulization	Only selective β_2-agonists are recommended. For optimal delivery, dilute aerosols to minimum of 4 mL at gas flow of 6-8 L/min. Use face mask if <4 years
Albuterol MDI (90 mcg/puff)	4-8 puffs every 30 minutes up to 4 hours, and then every 1-4 hours as needed	4-8 puffs every 20 minutes for three doses, and then every 1-4 hours as needed	In patients in severe distress, nebulization is preferred; use VHC-type spacer with face mask if <4 years old
Levalbuterol nebulizer solution (0.31 mg/3 mL, 0.63 mg/3 mL, 2.5 mg/1 mL, 1.25 mg/3 mL)	Give at one half the milligram dose of albuterol above	Give at one half the milligram dose of albuterol above	The single isomer of albuterol is twice as potent on a milligram basis
Levalbuterol MDI (45 mcg/puff)	See albuterol dose MDI dose	See albuterol dose MDI dose above	Not recommended See albuterol MDI dose one half as potent as albuterol on a microgram basis Not recommended
Anticholinergics			
Ipratropium bromide nebulizer solution (0.25 mg/mL)	500 mcg every 30 minutes for three doses, and then every 2-4 hours as needed	250 mcg every 20 minutes for three doses, and then 250 mcg every 2-4 hours	May mix in same nebulizer with albuterol; only add to β_2-agonist therapy
Ipratropium bromide MDI (18 mcg/puff)	8 puffs every 20 minutes as needed for up to 3 hours	4-8 puffs as needed every 2-4 hours	Not to be continued once hospitalized
Corticosteroids			
Prednisone, methylprednisolone, prednisolone	50 mg in one or two divided doses (prednisone equivalent)	1 mg/kg (maximum 40 mg/day) in two divided doses (prednisone equivalent)	For outpatient "burst" use 1-2 mg/kg/day, maximum 60 mg, for 3-5 days in children and 40-60 mg/day in one or two divided doses for 5-7 days in adults

Note: No advantage has been found for very-high-dose corticosteroids in acute severe asthma, nor is there any advantage for IV administration over oral therapy. The usual regimen is to continue the oral corticosteroid for duration of hospitalization. The final duration of therapy following a hospitalization or emergency department visit may be from 3 to 10 days. If patients are then started on ICSs, there is no need to taper the systemic corticosteroid dose. ICSs can be started at any time during the exacerbation.

Data from reference 3.

Acute Severe Asthma in Children 5-Years and Younger

Infants and children younger than 5 years of age may be at greater risk of respiratory failure than older children and adults. Although treated with the same drugs, these younger children require the use of a face mask as opposed to a mouthpiece for delivery of aerosolized medication. The face mask should be sized appropriately and should fit snugly over the nose and mouth. Use of the "blow-by" method, where the respiratory therapist or parent places the mask or extension tubing near the child's nose and mouth, should be discouraged because holding the mask as few as 2 cm from the patient's face reduces lung delivery of the aerosol by 80%.[2,29]

Children with severe exacerbations present with oxygen saturation of 92% or less, speak in monosyllabic words, have increased heart rate (above 200 beats/min if 0-3 years or above 180 beats/min if 4-5 years), central cyanosis, and inaudible breath sounds which indicate minimal ventilation sufficient to cause wheezing.[3] Hypoxemia is treated using a face mask with oxygen at 24% to achieve oxygen saturation of 94% to 98%. Avoidance of hypoxemia is critical and treatment should be initiated with nebulized β_2-agonists delivered by an oxygen-driven nebulizer. Treatment should begin immediately even if a full assessment has not been taken. Children with less severe symptoms can be treated with 2.5 mg of albuterol by nebulizer or 2 to 6 inhalations of albuterol with a spacer/facemask every 20 minutes for 3 doses with re-assessment at the end of this treatment. Subsequent doses by nebulizer or 2 to 3 inhalations by spacer/facemask can be given every hour, but if symptoms do not resolve after 10 inhalations administered over 3 to 4 hours then a hospital admission is required.[3] As in older children and adults, oral corticosteroids are administered at the time of inhaled β_2-agonists or systemically in children unable to swallow. Inhaled ipratropium bromide can be administered with β_2-agonist treatment but should not be continued for more than 3 doses in an hour. There is no evidence for continuing inhaled anticholinergics added to β_2-agonists in hospitalized children.[33] Nebulized magnesium sulfate may be administered as 3 doses in the first hour in children 2 years and older with severe exacerbations.[3] As in older children and adults, young children should be discharged with a prescription for oral corticosteroids for a 3 to 5 day treatment course and followed up within 7 days by a primary care provider.

Non-pharmacologic and Ancillary Therapy

Infants and young children may be mildly dehydrated owing to increased insensible loss, vomiting, and decreased intake.[2] Unless dehydration has occurred, increased fluid therapy is not indicated in acute asthma management because the capillary leak from cytokines and increased negative intrathoracic pressures may promote edema in the airways.[2] Correction of significant dehydration is always indicated, and the urine specific gravity may help to guide therapy in young children, in whom the state of hydration may be difficult to determine.[2] Chest physical therapy and mucolytics are not recommended in the therapy of acute asthma.[2] Sedatives should not be given because anxiety may be a sign of hypoxemia, which could be worsened by central nervous system depressants. Antibiotics also are not indicated routinely because viral respiratory tract infections are the primary cause of asthma exacerbations.[2] Antibiotics should be reserved for patients who have signs and symptoms of pneumonia (eg, fever, pulmonary consolidation, and purulent sputum from polymorphonuclear leukocytes). *Mycoplasma* and *Chlamydia* are infrequent causes of severe asthma exacerbations but should be considered in patients with high O_2 requirements.[2,34]

Respiratory failure or impending respiratory failure as measured by rising $PaCO_2$ (greater than or equal to 45 mm Hg [greater than or equal to 6 kPa]) or failure to correct hypoxemia with supplemental O_2 therapy is treated with intubation and mechanical ventilation.[3]

Pharmacotherapy

***β_2*-Agonists**

4 The short-acting inhaled β_2-agonists are the most effective bronchodilators and the treatment of first choice for the management of acute severe asthma.[3] In adults, administration as either continuous or intermittent (every 20 minutes for 3 doses) over 1 hour results in equivalent improvement.[2] In the subset of more severely obstructed patients, continuous nebulization decreases the hospital admission rate, provides greater improvement in the FEV_1 and PEF, and reduces duration of hospitalization when compared with intermittent (hourly) nebulized albuterol in the same total dose.[2] Thus, continuous nebulization is recommended for patients having an unsatisfactory response (achieving less than 50% of normal FEV_1 or PEF) following the initial three doses (every 20 minutes) of aerosolized β_2-agonists and potentially for patients presenting initially with PEF or FEV_1 values of less than 30% of predicted normal.[2] Intravenous β_2-agonists do

not have a role in the routine management of patients with severe exacerbations.[3] Effective doses of aerosolized β_2-agonists can be delivered successfully through mechanical ventilator circuits to infants, children, and adults in respiratory failure secondary to severe airway obstruction.[29]

The doses of inhaled β_2-agonists for acute severe asthma exacerbations (see Table 26-5) have been derived empirically. The β_2-agonists follow a log-linear dose–response curve. In addition, the dose–response curve is shifted to the right by more severe bronchospasm or by increased concentrations of bronchospastic mediators, which is characteristic of functional antagonists.[35] The ability to increase the dose of the short-acting aerosolized β_2-agonists by as much as 5- to 10-fold over doses producing adequate bronchodilation in chronic stable asthma is what contributes to their efficacy in reversing the bronchospasm of acute severe exacerbations. The nebulizer dose of inhaled β_2-agonists for children often is listed on a weight basis (milligrams per kilogram). However, a fixed minimal dose (2.5 mg albuterol or equivalent), as opposed to a weight-adjusted dose, is more appropriate in younger children because children younger than 5 years of age receive a lower lung dose.[2] Adults dosed on a weight basis demonstrate excessive cardiac stimulation, so they have fixed maximal doses[2] (see Table 26-5). Initial doses of inhaled β_2-agonists can produce vasodilation, worsening ventilation–perfusion mismatch, slightly lowering O_2 saturation or PaO_2.[32] High doses of inhaled β_2-agonists can produce a decrease in serum potassium concentration, an increase in heart rate, and an increase in serum glucose and lactic acid concentration.[3] Electrolyte monitoring may be needed in patients with preexisting heart disease who receive frequent doses for an acute exacerbation.[3] Hyperlactatemia is common but is not accompanied by metabolic acidosis and does not increase the risk of hospitalization.[31] Both children and adults receiving continuously nebulized β_2-agonists have demonstrated decreased heart rate as their lung function improves.[2] Thus, an elevated heart rate is not an indication to use lower doses or to avoid using inhaled β_2-agonists.

There is no evidence to support the use of levalbuterol over albuterol for the treatment of acute severe exacerbations in either children or adults with respect to efficacy or adverse effects.[35] A meta-analysis which showed a lower risk for hospitalization in the levalbuterol treated patients was driven by one study only.[35]

The inhaled β_2-agonists produce similar efficacy whether delivered by MDI plus VHC or nebulization in treating acute severe exacerbations in the ED and hospital; thus, the choice depends on the experience and comfort of the treating clinicians.[3] The DPIs are currently not indicated for the treatment of acute severe asthma exacerbations due to the higher inspiratory flows required for adequate drug delivery.[2]

Corticosteroids

Systemic corticosteroids are indicated in all patients with acute severe asthma exacerbations not responding completely to initial inhaled β_2-agonist administration (every 20 minutes for three doses) and should be administered within one hour of presentation.[2,3] Clinical improvement is noted after approximately 4-hours. IV therapy offers no therapeutic advantage over oral administration except in patients who are too dyspneic to swallow, vomiting, or intubated.[2,3] This therapy usually is continued until hospital discharge. Tapering the systemic corticosteroid dose following discharge from the hospital appears unnecessary, provided that patients are prescribed ICSs for outpatient therapy.[3] Adults are effectively treated with a 5 to 7 day course of therapy but children typically require only 3 to 5 days.[3] It is recommended that a full dose of the corticosteroid be continued until the patient's PEF reaches 70% of predicted normal or personal best.[2] Dexamethasone as 1 or 2 doses versus a 5-day course of prednisone/prednisolone may be an option for children and has the benefit of causing less vomiting.[36]

Multiple daily dosing of systemic corticosteroids for the initial therapy of acute asthma exacerbations appears warranted because receptor binding affinities of lung corticosteroid receptors are decreased in the face of airway inflammation.[37] However, patients with less severe exacerbations may be treated adequately with once-daily administration. High-dose and very-high-pulse-dose corticosteroid regimens have not been shown to enhance the outcomes in severe acute asthma but are associated with a higher likelihood of side effects.[37]

Inhaled corticosteroids initiated within one hour of presentation to the ED reduce hospitalization rate in those not treated with systemic corticosteroids.[3] However, current evidence suggests there is no rationale for combining inhaled and systemic therapy nor for replacing systemic with inhaled therapy.[3]

Anticholinergics

Inhaled ipratropium bromide produces a further improvement in lung function of 10% to 15% over inhaled β_2-agonists alone. In children and adults, multiple-dose ipratropium bromide added to initial therapy reduces hospitalization rate in the subset of patients with moderate to severe asthma exacerbations.[3] However, there is no benefit to continuing combined anticholinergic and β_2-agonist therapy during hospitalization on duration of stay or clinical outcomes.[33] Ipratropium bromide, a quaternary amine, is poorly absorbed and

produces minimal or no systemic effects.[38] Care should be taken when administering ipratropium bromide by nebulizer. If a tight mask or mouthpiece is not used, the ipratropium bromide that deposits in the eyes may produce pupillary dilation and difficulty in accommodation.[2]

Magnesium Sulfate

Intravenous and nebulized magnesium sulfate have been used in addition to standard therapies (β_2-agonists, systemic corticosteroids, anticholinergics, and oxygen) in children and adults with severe or life-threatening asthma. Magnesium sulfate is a moderately potent bronchodilator, producing relaxation of smooth muscle by blocking calcium ion influx into smooth muscles and it may have anti-inflammatory effects. [39] A meta-analysis found strong evidence that single infusion of 1.2 or 2 g magnesium sulfate administered to adults with moderate, severe, or life-threatening asthma who had not sufficiently responded to β_2-agonists, systemic corticosteroids, and oxygen reduced hospital admission rate (7 fewer admissions per 100 treated) and improved lung function.[40] Previous meta-analyses have shown inconsistent effects in adults on respiratory function and hospitalization rate when administered by the intravenous or nebulized route but it was not clear if magnesium sulfate was given concurrently with standard therapy or after failure to respond to standard therapy.[41,42] There are fewer studies in children with severe or life-threatening asthma though one meta-analysis found intravenous use improved respiratory function and reduced hospitalizations but again it was not clear exactly when in the course of care magnesium was administered.[42] For patients with severe asthma exacerbations, current guidelines suggest that a single 2 g intravenous infusion can be helpful in reducing hospital admissions in adults who have a FEV_1 less than 25% to 30% predicted upon arrival in the ED, children and adults who have persistent hypoxemia after standard treatment, and children whose FEV_1 remains below 60% predicted after 1 hour of standard treatment.[3] The adverse effects of magnesium sulfate include hypotension, facial flushing, sweating, depressed deep tendon reflexes, hypothermia, cardiac, CNS and respiratory depression.

Alternative Therapies

The inhalational anesthetics halothane, isoflurane, and enflurane all have been reported to have a positive effect in children and adults with acute severe asthma on mechanical ventilation that is unresponsive to standard medical therapy.[43] The proposed mechanisms for inhalational anesthetics include β_2-adrenergic receptor stimulation, direct relaxation on bronchial smooth muscle, inhibition of airway reflexes, attenuation of histamine-induced bronchospasm, and alteration of the nitric oxide pathway in epithelial cells.[43] Well-controlled trials with these agents have not been completed.[43] Potential adverse effects include myocardial depression, vasodilation, arrhythmias, and depression of mucociliary function.[43] In addition, the practical problem of delivery and scavenging these agents in the intensive care environment as opposed to the operating room and the avoidance of environmental pollution to treating caregivers is a concern. The use of volatile anesthetics cannot be recommended based on insufficient evidence of efficacy.

Ketamine has been recommended for rapid induction of anesthesia in patients with asthma who require intubation and mechanical ventilation.[44,45] In addition, intravenous ketamine has been used as a bolus followed by continuous infusion in both intubated and non-intubated patients with severe asthma exacerbations but controlled trials have not provided evidence of efficacy.[2] Purported mechanisms for beneficial effects in asthma include inhibition of histamine and acetylcholine-induced bronchoconstriction and acting as a sympathomimetic agent.[2] Ketamine has several significant adverse effects, including the anesthesia emergence reaction, which can alter mood and cause delirium. These emergence phenomena occur in at least 25% of patients over 16 years of age; the incidence seems to be much lower in younger patients.[2] Other adverse effects include hypertension and sinus tachycardia or hypotension and sinus bradycardia

Drug Class Information for Management of Acute Asthma

Short-Acting β_2-Agonists

5 6 The β_2-agonists are the most effective bronchodilators available. The β_2-adrenergic receptors are transmembrane proteins consisting of clusters of seven helices of amino acids that form the ligand-binding core.[46] The human β_2-adrenergic receptors are polymorphic in structure, with the most common polymorphisms in the amino terminus of the receptor at amino acid positions 16 (encoding either arginine [Arg] or glycine [Gly]) and 27 (encoding either glutamine [Gln] or glutamic acid [Glu]).[47] This activation, in turn, decreases unbound intracellular calcium, producing smooth muscle relaxation, mast cell membrane stabilization, and skeletal muscle stimulation.[46] Despite the fact that β_2-agonists are potent inhibitors of mast cell degranulation in vitro, they do not inhibit the late asthmatic response to allergen challenge or the subsequent BHR.[2,46] Long-term administration of β_2-agonists does not reduce BHR, confirming a lack of significant anti-inflammatory activity. β_2-Adrenergic stimulation also activates Na^+-K^+-ATPase, produces gluconeogenesis, and enhances insulin secretion, resulting in a mild to moderate decrease in serum potassium concentration by driving potassium intracellularly.[32] The chronotropic response to β_2-agonists is mediated in part by baroreceptor reflex mechanisms as a result

of the drop in blood pressure from vascular smooth muscle relaxation, as well as by direct stimulation of cardiac β_2-receptors and some β_1 stimulation at high concentrations.[32] **Table 26-6** lists the pharmacologic effects of adrenergic receptor stimulation. Because β_1-receptor stimulation produces excessive cardiac stimulation, resulting in cardiac arrhythmias, and because the inotropic effect enhancing myocardial O_2 consumption leads to myocardial necrosis, there is no rationale for using non-β_2-selective agonists in the treatment of asthma.[2]

TABLE 26-6 Pharmacologic Responses to Sympathomimetic Agonists

Tissue	Receptor Type	Response
Airways	β_2	Smooth muscle relaxation (bronchodilation), increased ciliary beat, increased serous secretion, and inhibition of mast cell degranulation
	α	Smooth muscle contraction (bronchoconstriction?)
Heart	β_1	Inotropic and chronotropic
	β_2	Chronotropic
Vasculature	β_2	Vasodilation, decreased microvascular leakage
	α	Vasoconstriction
Skeletal	β_2	Increased neuromuscular transmission (tremor and increased strength of contraction)
Uterus	β_2	Relaxation (tocolysis)
Metabolic	α, β_1	Glycogenolysis, lipolysis
	β_2	Gluconeogenesis, hypokalemia, increased lactate production

Table 26-7 compares the various short-, long-, and ultra-long-acting β-adrenergic agonists used in asthma in terms of selectivity, potency, and onset and duration of action.[75] The β_2-agonists are functional or physiologic antagonists in that they relax airway smooth muscle regardless of the mechanism for constriction.[46] When administered in equipotent doses, all the short-acting drugs produce the same intensity of response; the only differences are in duration of action and cardiac toxicity.[2,46] The catecholamine derivatives all have the disadvantage of rapid inactivation of their 3,4-hydroxyl catechol group from catechol-*O*-methyltransferase located in the GI tract, rendering them orally inactive. In addition, catecholamines are taken up rapidly into tissues by secondary uptake mechanisms that limit their receptor occupancy and thus have a shorter duration of action.[46] All the β_2-agonists are more bronchoselective when administered by the aerosol route. Aerosol administration of the short-acting β_2-agonists provides more rapid response and greater protection against provocations that induce bronchospasm such as exercise and allergen challenges than does systemic administration.[2,46] Differences in myocardial effects are discernible between selective and nonselective agents even when administered as aerosols, particularly at the higher doses used for acute severe asthma. The β_2-agonists also differ in efficacy or ability to activate the β_2-adrenergic receptors. Full agonists include the catecholamines while the synthetic β_2-agonists all exhibit various levels of partial agonism (see Table 26-7).[46] Although partial agonists by definition cannot produce maximum dilation or protection as full agonists and can potentially block the effect of a full agonist, these differences have not been proven to be clinically significant.

TABLE 26-7 Relative Selectivity, Potency, Onset and Duration of Action of the β-Adrenergic Agonists

Agent	β_2 Activity		Agonist at β_2 (full/partial)	Onset and Duration of Action[a]		
	β_2 Intrinsic Efficacy	β_2 Selectivity over β_1		Bronchodilation (hours)	Protection (hours)[a]	Onset of bronchodilation
Isoproterenol	1	0.24	Full	0.5-2	0.5-1	1-2 minutes
Albuterol/levalbuterol	Not done	27	Partial	4-8	2-4	1-2 minutes
Formoterol	0.95	150	Full	≥12	≥12	1-2 minutes
Salmeterol	0.41	3000	Partial	≥12	≥12	10 minutes
Indacaterol	0.86	16	Nearly full	≥24	≥24	1-2 minutes
Olodaterol	Not done	Not done	Nearly full	≥24	≥24	1-2 minutes
Vilanterol	0.70	2400	Nearly full	≥24	Not studied	1-2 minutes

[a]Protection refers to the prevention of bronchoconstriction induced by exercise or nonspecific bronchial challenges.

The majority of synthetic β_2-agonists are 1:1 racemic mixtures of two mirror images (enantiomers) owing to an asymmetric or chiral carbon.[46] Since most physiologic functions (receptor occupancy and activation and enzymatic metabolism) are stereoselective, the (*R*)-enantiomers of the β_2-agonists are the most pharmacologically active isomer.[46] While it was felt initially that the (*S*)-enantiomers

were essentially inactive owing to the 100- to 1,000-fold potency difference between the enantiomers, studies in animal models and isolated in vitro tissue preparations have suggested that the (*S*)-enantiomer of albuterol may be pro-inflammatory and could induce BHR.[46] However, evidence that this occurs consistently in humans or is clinically relevant is lacking.[46] The pharmacokinetics are stereoselective as well, although not predictable. (*R*)-Albuterol is metabolized more rapidly than (*S*)-albuterol, which could lead to accumulation of (*S*)-albuterol with continued dosing.[46] Levalbuterol tartrate is the (*R*)-enantiomer of albuterol, and is a comparable selective beta$_2$-adrenergic receptor agonist.

Both the intensity and duration of response are dose dependent, and, more important, the dose–response relationship is dynamic.[46] At increasing levels of baseline bronchoconstriction (irrespective of the stimulus), the dose–response curve is shifted to the right, and the duration of bronchodilation is decreased.[46] This shift is reflected in the need for higher, more frequent doses in acute asthma exacerbations; the duration of protection against significant provocation is much less than the duration of bronchodilation in chronic stable asthma for short-acting B$_2$-agonists (see Table 26-7).[46]

Chronic administration of β_2-agonists leads to downregulation (decreased number of β_2-receptors) and a decreased binding affinity (desensitization) for these receptors.[46] Systemic corticosteroid therapy can both prevent and partially reverse this phenomenon.[2,46] However, the use of ICSs appears to have minimal ability to prevent tolerance to β_2-agonists.[46] Tolerance primarily reduces duration of bronchodilation as opposed to peak response, although the latter can occur as well. A significantly greater tolerance develops in other tissues (eg, lymphocytes and cardiac and skeletal muscle) compared with the lung, primarily as a result of the surplus β_2-receptors found in respiratory smooth muscle.[46] Tolerance to the extra-pulmonary effects (cardiac stimulation and hypokalemia) may account for a lack of significant cardiac effects with retention of the bronchodilator response despite chronic inhaled β_2-agonist therapy, whereas tolerance to mast cell stabilization may be a drawback to chronic use.[46] Thus, chronic β_2-agonist administration produces a tolerance of minimal clinical significance that is overcome easily by increasing the dose or by administering corticosteroids.[2,46] Most of the tolerance occurs within a week of regular administration and does not worsen with continued administration. As would be expected from a receptor phenomenon, tolerance is a cross-tolerance to all β_2-agonists.[46] Regular treatment (four times daily) does not improve symptom control over as-needed use and is not indicated.[2,3] Regular treatment with the long-acting inhaled β_2-agonists (LABAs) is discussed in Chronic Asthma below.

In conclusion, the short-acting inhaled selective β_2-agonists are indicated for the as-needed treatment of intermittent episodes of bronchospasm. They are the first treatment of choice for acute severe asthma and EIB.[2,3,14] They inhibit EIB in a dose-dependent fashion and provide complete protection for a 2-hour period following inhalation with varying levels of patient-dependent protection over 4 hours.[14] Although the regular administration of β_2-agonists slightly decreases the protective effect, two inhalations prior to exercise still essentially block EIB completely (1% vs 5% drop in FEV$_1$).[14,46]

Systemic Corticosteroids

4 The corticosteroids are the most effective anti-inflammatories available to treat asthma.[2,3] Actions useful in treating asthma include (a) increasing the number of β_2-adrenergic receptors and improving the receptor responsiveness to β_2-adrenergic stimulation, (b) reducing mucus production and hypersecretion, (c) reducing BHR, and (d) reducing airway edema and exudation.[2,47] The glucocorticoid receptor is found in the cytoplasm of most body cells, explaining the multiple effects of systemic corticosteroids. There is no difference between glucocorticoid receptors found throughout the body; however, genetic differences between glucocorticoid receptors from different individuals may determine some of the variations in response.[47] The corticosteroids are lipophilic, readily cross the cell membrane, and combine with the glucocorticoid receptor. The activated complex then enters the nucleus, where it acts as a transcription factor leading to gene activation or suppression.[48] This leads to specific mRNA production, resulting in increased production of anti-inflammatory mediators; suppression of several pro-inflammatory cytokines such as IL-1, GM-CSF, IL-4, IL-5, IL-6, and IL-8, reducing inflammatory cell activation, recruitment, and infiltration; and decreasing vascular permeability.[48] In addition, the activated glucocorticoid receptor complex can act directly with cytoplasmic transcription factors, nuclear factor-κB, and activating protein 1 to prevent the action of pro-inflammatory cytokines on the cell.[48]

Owing to the mechanism that modifies gene expression, the time required to see a particular effect depends on the time required for new protein synthesis, decreased formation of the particular mediator, and resolution of the inflammatory response.[48] Generally, the cellular and biochemical effects are immediate, but varying amounts of time are required to produce a clinical response. β_2-Receptor density increases within 4 hours of corticosteroid administration.[48] Improved responsiveness to β_2-agonists occurs within 2 hours.[48] In acute severe asthma, 4 to 12 hours may be required before any clinical response is noted.[38,48] Reversal of seasonally increased BHR requires at least 1 week of therapy.[48] The chronic use of corticosteroids does not induce a state of corticosteroid dependence, there is no evidence of tolerance produced by chronic administration.

The corticosteroids used in asthma are compared in **Table 26-8**.[48,49] Besides acute severe asthma, systemic corticosteroids are also recommended for the treatment of impending episodes of severe asthma unresponsive to bronchodilator therapy.[2,3] The effects of corticosteroids in asthma are dose and duration dependent. This pattern is true for the adverse effects as well (**Table 26-9**). The clinician must continually balance the toxicity of chronic systemic corticosteroid therapy with control of asthma symptoms. Because short-term (1-2 weeks) high-dose corticosteroids (1-2 mg/kg/day of prednisone) do not produce serious toxicities, the ideal use is to administer the systemic corticosteroids in a short "burst" and then to maintain the patient on appropriate long-term control therapy with ICSs (discussed below).[2] In general, therapy for more than 5 days at doses that exceed the usual physiologic endogenous cortisol production will cause temporary aberration in adrenal cortisol release.[48] However, this hypothalamic–pituitary–adrenal (HPA) axis suppression is short-lived (1-3 days) and readily reversible following short bursts (less than or equal to 10 days) of pharmacologic doses.[48] A maximum number of short bursts that a patient can receive probably exists, after which chronic corticosteroid side effects occur. Adult patients receiving at least eight bursts (more than or equal to 10 days each) have a similar decrease in trabecular bone density as patients on daily or alternate-day corticosteroids over 1 year.[47] Children who received four or more bursts per year of prednisone exhibited a subnormal response to hypoglycemic stress or adrenocorticotropic hormone (ACTH) administration.[48] Very short courses (3-5 days) have been effective in reducing hospitalization from acute exacerbations.[2,3] Use of the shorter-acting corticosteroids such as prednisone will produce less adrenal suppression than the longer-acting dexamethasone.[48]

TABLE 26-8 Pharmacodynamic/Pharmacokinetic Comparison of the Corticosteroids

Systemic	Antiinflammatory Potency	Mineralocorticoid Potency	Duration of Biologic Activity (hours)	Elimination Half-Life (hours)
Hydrocortisone	1	1	8-12	1.5-2
Prednisone	4	0.8	12-36	2.5-3.5
Methylprednisolone	5	0.5	12-36	3.3
Dexamethasone	25	0	36-72	3.4-4
ICS	**Receptor Binding Affinity**	**Oral Bioavailability (%)**	**Systemic Clearance (L/h)**	**Half-Life (hours) (IV/Inhaled)**
BDP/BMP[a]	0.4/13.5	20/40	150/120	(0.5/2.7)/(UK/2.7)
BUD	9.4	11	84	2.8/2
CIC/des-CIC[a]	0.12/12	<1/<1	152/228	(0.36/3.4)/(0.5/4.8)
FLU	1.8	20	58	1.6/1.6
FP	18	≤1	66	7.8/14.4
MF	23[b]	<1	53	5.8/UK

Note: Receptor binding affinities are relative to dexamethasone equal to 1. BDP, beclomethasone dipropionate; BMP, beclomethasone 17-monopropionate; BUD, budesonide; CIC, ciclesonide; des-CIC, des-ciclesonide; FLU, flunisolide; FP, fluticasone propionate; MF, mometasone furoate; UK, unknown.

[a]BDP and CIC are prodrugs that are activated in the lung to their active metabolites BMP and des-CIC, respectively.

[b]MF studied in a different receptor system. Value estimated from relative values of BDP and FP in that system.

TABLE 26-9 Adverse Effects of Chronic Systemic Glucocorticoid Administration

Hypothalamic–pituitary–adrenal suppression	Hypertension
Growth retardation	Skin striae
Skeletal muscle myopathy	Impaired wound healing
Osteoporosis/fractures	Inhibition of leukocyte and monocyte function
Aseptic necrosis of bone	Subcutaneous tissue atrophy
Pancreatitis	Glaucoma
Pseudotumor cerebri	Posterior subcapsular cataracts
Psychiatric disturbances	Moon facies
Sodium and water retention	Central redistribution of fat

Hypokalemia/hyperglycemia

Anticholinergics

The anticholinergic agents have a long history of use for asthma, with an evolving role in the management of asthma.[2,3,50] Anticholinergics are competitive inhibitors of muscarinic receptors.[50] Unlike β_2-agonists, they are not functional antagonists; they only reverse cholinergic-mediated bronchoconstriction. Normal bronchial tone is maintained through parasympathetic innervation of the airways via the vagus nerve.[50] A number of the triggers and mediators of asthma (ie, histamine, prostaglandins, sulfur dioxide, exercise, and allergens) produce bronchoconstriction in part through vagal reflex mechanisms.[50] Studies consistently demonstrate that anticholinergics are effective bronchodilators in asthma. Anticholinergics attenuate but do not block allergen-induced asthma in a dose-dependent fashion and have no effect on BHR.[50] Anticholinergics attenuate but do not block EIB.[14] Five muscarinic receptor subtypes (M_1 through M_5), all inhibited by atropine, have been identified; M_1, M_2, and M_3 are the principal receptors in the airway.[50]

Ipratropium bromide is a nonselective antagonist of M_1, M_2, and M_3 receptors. Although ipratropium produces net bronchodilation, blockade of M_2 receptors allows further release of presynaptic acetylcholine, and may antagonize the bronchodilatory effect of blocking M_3, a possible basis of paradoxical bronchoconstriction.[50] Only the quaternary ammonium derivatives such as ipratropium bromide and tiotropium should be used because they have the advantage of little absorption across respiratory mucosa and do not penetrate the blood–brain barrier. This attribute contributes to negligible systemic effects with a prolonged local effect (ie, bronchodilation). In addition, the quaternary compounds do not appear to significantly alter mucociliary clearance or respiratory secretions.[50] Ipratropium bromide has duration of action of 4 to 8 hours. Both intensity and duration of action are dose dependent. Tiotropium bromide, a long-acting inhaled anticholinergic with duration of 24 hours, has a higher affinity for muscarinic receptors than ipratropium; it dissociates from muscarinic receptors more slowly than ipratropium.[50] Time to reach maximum bronchodilation for ipratropium is considerably slower than for aerosolized short-acting β_2-agonists (30-60 minutes vs 5-10 minutes). However, this difference is of little clinical consequence because some bronchodilation is seen within 30 seconds; 50% of maximum response occurs within 3 minutes.[50] Ipratropium bromide is only indicated as adjunctive therapy in acute severe asthma not completely responsive to β_2-agonists alone.[2,3] Recent trials of tiotropium bromide in chronic asthma suggest that it may be as effective as LABAs added to ICSs and add additional control in severe asthma when added to ICS/LABA combinations.[50,51,52]

EVALUATION OF THERAPEUTIC OUTCOMES

General Principles, Long-Term Management Goals, and Treatment of Chronic Asthma

Whereas, the NAEPP[2] and GINA[3] have outlined sound strategies for management and treatment of chronic asthma, the following chapter sections rely on the GINA document.[3] GINA is more current (updated in 2015), and describes levels of evidence used in their report.[3] Evidence level A provides a rich body of data consisting of randomized controlled trials (RCTs) and meta-analyses; Evidence level B has a more limited body of data, but still relies on RCTs and meta-analyses. Evidence C includes outcomes of nonrandomized trials or observational studies, and evidence D relies on panel consensus judgment.

Global Initiative for Asthma's long-term goals of asthma management are: (1) to achieve good control of symptoms and maintain normal activity levels and (2) to minimize future risk of exacerbations, fixed airflow limitation, and side effects.[3] The importance of eliciting the patient's own goals is emphasized, as is the development of a patient-healthcare provider partnership. Key components are strategies to both facilitate good communication and reduce the impact of impaired health literacy.[3] Self-management education reduces asthma morbidity in both adults and children (Evidence A).[3] GINA recommends control-based asthma management, adjusting pharmacological and non-pharmacological treatment in a continuous cycle of assessment, treatment, and review. Assessment includes symptom control, risk factors, inhaler technique and adherence, and patient preferences. Response review includes symptoms, exacerbations, medication side effects, patient satisfaction, and lung function.[3] GINA does not recommend neither sputum-guided treatment nor FeNO-guided treatment for the general asthma population.[3]

Global Initiative for Asthma discriminates between preferred treatment options at a population level (based on efficacy, effectiveness, safety, and availability/cost at this level) versus choosing between asthma controller options for individual patients. A shared-decision making approach is recommended for the latter, to include preferred treatment, patient characteristics or phenotype,[3] patient/parent preference, and practical issues (inhaler technique, adherence, and cost).[3]

Non-pharmacologic Therapy

Although the mainstay of the management of asthma is pharmacologic therapy, it is likely to fail without concurrent attention to relevant

environmental control and management of comorbidities that may contribute to respiratory symptoms and poor quality of life. Non-pharmacologic therapies are incorporated into GINA's recommendations for initiation of regular daily controller treatment, as well as the stepwise approach for adjusting treatment in adults, adolescents, and children.[3] The guidelines were designed to give healthcare providers a framework with which to develop the proper approach to the individualized therapy of patients. The heterogeneity of asthma demands an individualized approach to therapy with the basic goals of therapy as primary outcome measures.[3] The focus of controller therapy is the reduction of airway inflammation, control of symptoms, and reduction of future risks. Thus, current therapeutic options in asthma consist of acute reliever (rescue) medications for as-needed relief of breakthrough symptoms and exacerbations, and long-term control medications used for the prevention of symptoms and exacerbations and the suppression of inflammation and reduction of BHR.[3] GINA emphasizes the importance of concurrently identifying and treating modifiable risk factors, such as active smoking and exposure to tobacco smoke, obesity, major psychological problems, major socioeconomic problems, confirmed food allergy, and allergen exposure if sensitized.[3] Avoidance of occupational exposures, indoor allergens, and medications that may make asthma worse should be considered when relevant.

7 The development of a patient-healthcare provider partnership in care through patient education and the teaching of patient self-management skills should be the cornerstone of any treatment program.[3] There are a number of published self-management programs for children and adults available through local American Lung Association chapters, as well as asthma treatment centers, and nationally through the NAEPP, GINA, and the Asthma and Allergy Foundation of America.[2,3] Asthma self-management programs have been shown to improve patient adherence to medication regimens, improve self-management skills, and improve use of healthcare services.[53,54]

Self-management programs instruct patients in the pathogenesis of asthma and the appropriate use of their medications but focus principally on teaching patients to recognize triggers for their asthma, how to recognize early signs of deterioration and how to keep track of symptoms (with or without a diary), and take action.[2,3,53] Home PEF monitoring is part of some programs, however, routine PEF monitoring in and of itself does not improve patient outcomes.[2] Short-term PEF monitoring may be useful: following an exacerbation, to monitor recovery; following a change in treatment to assess response; if symptoms appear excessive; and to assist in trigger identification. Long-term PEF monitoring may be useful for earlier detection of exacerbations, especially in patients with poor perception of airflow limitation; for patients with a history of sudden severe exacerbations; and for patients with difficult-to-control or severe asthma.[3]

The NAEPP has recommended a PEF monitoring system based on a traffic light scenario (based on percentage of normal predicted values or personal best values): the green zone is equal to 80% to 100%, the yellow zone is equal to 50% to 79%, and the red zone is less than 50%. The yellow zone is cautionary and requires increasing as-needed bronchodilator use and possibly beginning prednisone if not improved, whereas the red zone warrants contacting the patient's healthcare provider.[2]

Patient education is essential before monitoring can be effective. It proved successful regardless of the healthcare provider who provides it. The NAEPP and GINA advocate significant involvement of all points of patient care in the educational process.[2,3] The provision of written action plans enhances the success of education and is considered an essential component of care.[2,3] Samples of clinically tested written action plans are available from NAEPP and GINA guidelines and other sources.[2,3]

In patients with known allergic triggers for their asthma, allergen avoidance has resulted in an improvement in symptoms, a reduction in medication use, and a decrease in BHR.[2] A comprehensive approach to environmental control is advocated. For example, for patients with house dust mite allergy removing carpeting from bedrooms, washing sheets in hot water (greater than 54.4°C [greater than 130°F]) and using special dust-proof pillow and mattress covers can reduce symptoms and need for medications.[2] Obvious environmental triggers (eg, animal dander and cockroaches), if the patient is sensitive, should be avoided. Evidence for home air-filtering systems and chemicals for killing house dust mites is limited.[2] Immunotherapy (allergy shots) with single antigens particularly has been beneficial and may be considered in patients with persistent asthma with documented sensitivity.[2] Immunotherapy with multiple antigens has been less effective.

Pharmacologic Therapy

The current GINA recommendations for initial controller treatment in adults and adolescents with persistent asthma are summarized in **Table 26-10**.[3] Regardless of the long-term therapy, all patients need to have quick-relief medication in the form of short-acting inhaled β_2-agonists available for acute symptoms. Ensure that the patient can use both the reliever and controller delivery devices correctly. Schedule an appointment for a healthcare provider visit after 2 to 3 months, or earlier depending on clinical urgency. Step down treatment once good control is maintained for 3 months.[3]

TABLE 26-10 GINA Recommendations for Initial Controller Treatment in Adults and Adolescents

Symptom Presentation	Preferred Treatment (Evidence Level)

Symptom Presentation	Preferred Treatment (Evidence Level)
Symptoms or need for SABA lt; 2×/mo; no waking due to asthma in last month; and no risk factors for exacerbations, including in prior year	No controller (D)
Infrequent symptoms, but patient has ≥ risk factor for exacerbation, eg, low lung function, use of OCS in prior year, intensive care treatment for asthma ever	Low dose ICS (D)
Symptoms or need for SABA between 2×/mo and 2×/week, or patient wakes due to asthma ≥ (×) mo.	Low dose ICS (B)
Symptoms or need for SABA > 2×/week	Low dose ICS* (A)
Troublesome symptoms most days or waking ≥ 1×/week, esp. if any risk factors exist	Medium/high dose ICS(A) or Low dose ICS/LABA** (A)
Symptoms consistent with severely uncontrolled asthma, or with an acute exacerbation	OCS short course AND start of high-dose ICS(A) or moderate-dose ICS/LABA** (D)

*Less effective options are LTRA or theophylline.

**Not recommended for initial controller treatment in children 6-11 years.

ICS, inhaled corticosteroids; LABA, long-acting beta$_2$-agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroids; SABA, short-acting beta$_2$-agonist.

The GINA stepwise approach for control-based management is outlined in **Table 26-11**.[3] This GINA approach emphasizes three components[3]:

- ASSESS—documentation of symptom control and risk factors, and if these are uncontrolled, check inhaler technique and adherence, and consider whether symptoms are due to a co-morbid condition such as allergic rhinitis, GERD, or obesity rather than asthma.
- ADJUST therapy (up or down)—both drug therapy and non-pharmacological strategies; treat modifiable risk factors.
- REVIEW RESPONSE—assess and optimize asthma control about every 3 months.

TABLE 26-11 GINA Stepwise Approach to Control Symptoms and Minimize Future Risk[7]

Step	Preferred Option (Evidence Level)	Other Recommended Options (Evidence Level)
1	As-needed SABA (A)	Consider low dose ICS, in addition to as-needed SABA, for patients at risk for exacerbations (B) LTRA (A)
2	Low dose ICS, plus as-needed SABA (A)	Low-dose ICS/LABA (A) ICS started with symptoms of allergic asthma, for seasonal treatment only (D)
3	Low dose ICS/LABA, plus as-needed SABA for adults/adolescents (A) OR low dose ICS/formoterol as both maintenance and reliever (A) For children 6-11 years, mod. dose ICS, plus as-needed SABA Medium dose ICS/LABA, plus as-needed SABA for adults/adolescents (B)	Medium dose ICS, for adults/adolescents (A) Low dose ICS plus LTRA (A) or low dose, sustained release theophylline (B)
4	OR medium dose ICS/formoterol as both maintenance and reliever (A) For children 6-11 years, refer child to asthma specialist	Add-on therapy with tiotropium for adults with exacerbation history (B)
5	Referral to specialist and consideration of add-on treatment	Tiotropium if < 18 years (B) Omalizumab for moderate-severe allergic asthma (A)

Step	Preferred Option (Evidence Level)	Other Recommended Options (Evidence Level)
		Sputum-guided treatment adjusted by eosinophilia >3% (A)
		Bronchial thermoplasty in some adults with severe asthma (B)
		Add-on low dose OCS (≤7.5 mg/day prednisone equivalent) (B)

ICS, inhaled corticosteroids; LABA, long-acting beta$_2$-agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroids; SABA, short-acting beta$_2$-agonist.

Global Initiative for Asthma provides general principles for step-down of controller treatment.[3] Consideration is warranted if symptoms have been well controlled and lung function stable for more than or equal to 3 months (D). An appropriate time should be chosen (no respiratory infection, not travelling, not pregnant). Engage the patient in this therapeutic trial, monitor with symptoms and/or PEF, and schedule follow-up (D). Stepping down ICS doses by 25% to 50% at 3 month intervals is considered feasible and safe for most patients (B).

The ICSs are considered the preferred long-term control therapy for persistent asthma in all patients due to their potency and consistent effectiveness.[3] Low- to medium-dose ICSs reduce BHR, improve lung function, and reduce severe exacerbations leading to ED visits and hospitalizations. They are more effective than theophylline or the LTRAs.[3,55] In addition, the ICS is the only therapy that reduces the risk of dying from asthma.[2,3] In the low to medium doses recommended by GINA (**Table 26-12**), ICSs are safe for long-term administration (see below).[3,55] They do not appear to reduce airway remodeling and loss of lung function found in some patients with persistent asthma. The ICSs do not enhance lung growth in children with asthma, prevent the development of asthma in high-risk infants, or induce remission of asthma as BHR and other measures of inflammation return to pretreatment levels on discontinuation of therapy.[57] The sensitivity and consequent clinical response to ICSs can vary among patients.[2,3]

TABLE 26-12 Available Inhaled Corticosteroid Products, Lung Delivery, and Comparative Daily Dosages

ICS	Product	Lung Delivery[a]
Beclomethasone dipropionate (BDP)	40 and 80 mcg/actuation HFA MDI	50%-60%
Budesonide (BUD)	90 or 180 mcg/dose DPI, Flexhaler	15%-30%
	200 and 500 mcg ampules, 1 mg	5%-8%
Ciclesonide (CIC)	80 or 160 mcg/actuation HFA MDI	50%
Flunisolide (FLU)	80 mcg/actuation HFA MDI	68%
Fluticasone furoate (FF)	100, 200 mcg/actuation DPI, Ellipta	80%-85%
Fluticasone propionate (FP)	44, 110, and 220 mcg/actuation HFA MDI	20%
	50, 100, and 250 mcg/dose DPI, Diskus	15%
Mometasone furoate (MF)	110 and 220 mcg/dose DPI, Twisthaler; 100 mcg and 200 mcg/actuation HFA MDI	11%

	Comparative Daily Dosages (mcg) of Inhaled Corticosteroids		
	Low Daily Dose Child[a]/Adult	**Medium Daily Dose Child[a]/Adult**	**High Daily Dose Child[a]/Adult**

[a]5-11 years of age, except for BUD Nebules, which is 2-11 years of age.

Although studies of the alternative long-term control therapies (eg, LTRAs and theophylline) demonstrate improvement in symptoms, lung function, and as-needed, short-acting inhaled β_2-agonist use, they do not reduce BHR, suggesting minimal anti-inflammatory activity.[2,3] The evidence suggests minimal to no differences in efficacy between these alternatives.

For those patients inadequately controlled on low-dose ICSs either an increased dose of the ICS or the combination of ICS and LABA is recommended Step 3 to gain control of more moderate persistent asthma.[3] Alternatives could be the addition of LTRAs or theophylline to ICSs.[3] The addition of theophylline or LTRAs to ICSs is no more effective than doubling the dose of the ICS.[2] The combination of ICS/LABA is more effective at reducing severe asthma exacerbations than doubling the dose of ICS in moderate persistent asthma; increasing the dose of ICSs fourfold also will result in a significant reduction in exacerbations.[58,59] However, doses of ICSs in the high range significantly enhance the risk of toxicity.[56] Thus, high doses of ICSs plus LABA are reserved for patients with severe persistent asthma.[2,3]

Although the addition of a third controller medication is often used clinically in patients with severe persistent asthma uncontrolled on high-dose ICS/LABA, there are limited studies evaluating this practice.[3] LTRAs or theophylline added to high-dose combination ICS/LABA do not improve outcomes.[3] Omalizumab, a recombinant anti-IgE, has demonstrated significant activity in these severe uncontrolled atopic patients.[60] More recently tiotropium bromide has shown promise as add-on to ICS or ICS/LABA combination for use in asthma.[61,62,63] Studies also point to a beneficial role of tiotropium in the treatment of difficult-to-control asthma and a potential function in ACOS treatment.[64]

Special Populations

6 The management of asthma in children younger than 5 years of age follows the same stepwise approach as in older children and adults but many treatments have not been studied adequately. Thus, many of the recommendations in this age group are extrapolated from older children and adults.[3] The primary differences in management are that no controller treatment is necessarily indicated for Step 1 and the recommended treatment in Step 3 is doubling the dose of ICS rather than adding LABA as is recommended for older children and adults; LABA are not recommended for this age group at any step unless there is evaluation and a clear indication from a specialist.[3] Due to the risk of LABA contributing to asthma exacerbation risk, the FDA required manufacturers of LABA containing products to conduct safety studies in children and adults and there is an ongoing study specifically in children 4 to 11 years of age. Most of the available ICS have been studied in young children but not all have marketing approval from the FDA in this age group. Lack of an approved indication in children under 5 years of age could affect insurance coverage for specific products. ICSs are available as MDI, DPI, and nebulized formulations but the preferred method of delivery is by MDI with a valved spacer and facemask, if needed.[3] Smaller spacers (less than 350 mL) are preferred because 5 to 10 breaths after actuation are required to inhale the complete dose. It is also recommended to not change the spacer type once a child is stable on a specific dose of ICS due to large differences in delivery between devices.[3] ICS use, even with low doses, causes reductions in growth velocity in children that are clinically important.[65,66] Thus, the lowest effective should be used and height should be regularly measured during treatment.[65,66] Treatment of moderate to severe asthma exacerbations may require use of oral corticosteroids but high-dose nebulized budesonide administered intermittently (1 mg twice a day for 7 days) at early signs of upper respiratory tract infections was as effective at preventing severe episodes of wheezing in infants 12 to 53 months of age with recurrent wheezing as low-dose (0.5 mg daily) continuous therapy.[67]

The FDA approval for montelukast (a leukotriene receptor antagonist) in children younger than age 6 was based on safety and pharmacokinetic studies establishing doses but not on efficacy, although improvement in symptoms and as-needed bronchodilators was noted.[2] Based on data from older children, a small minority of children may respond better to montelukast than ICS.[2] ICSs are recommended as first line therapy but the initial choice between a trial of ICS or montelukast should be based on shared decision making between the provider and caregiver.

The elderly are at highest risk from dying of asthma and there are multiple contributing factors.[3] As in very young children, there have been few prospective studies evaluating drug therapies.[3] In addition, the elderly have a high co-morbidity burden which may impact response to therapies differently than with younger patients, and which contributes to the difficultly with adherence when multiple medications for different diseases are given daily. Control of co-morbid conditions (obesity, smoking, depression, and rhinosinusitis) may be required to improve treatment outcomes.[68] Arthritis, vision impairment, and muscle weakness which may affect inspiratory flow, should be considered when selecting inhaler devices.[3] In addition, the elderly may have difficulty distinguishing breathlessness due to ageing or cardiovascular disease from symptoms of asthma.[3] Owing to the increased risk of osteoporosis and cataracts in the elderly, patients requiring high doses of ICSs should have routine height measurements, bone mineral density determinations, and ophthalmic examinations.[2,69] Appropriate therapies for prevention of osteoporosis should be instituted.[2,69] ICS use may contribute to skin bruising which is already common in the elderly.

Asthma affects 8% of pregnant women, making it potentially the most common serious medical condition to complicate pregnancy.[70] Maternal asthma has been reported to increase the risk of perinatal mortality, preeclampsia, preterm birth, and low-birth-weight infants.[70] More severe asthma is associated with increased risks, whereas better-controlled asthma is associated with decreased risks. A systematic review of the evidence on the safety of asthma medications has concluded that it is safer for pregnant women with asthma to be treated with effective medications than for them to have exacerbations.[70] Proper monitoring and control of asthma should enable a woman with asthma to maintain a normal pregnancy with little or no risk to mother or her fetus. Patients should be monitored monthly as exacerbations are more common in the second trimester and should include objective assessment of lung function and validated assessment of symptoms.[3,70]

A stepwise approach to managing asthma during pregnancy and lactation has been published, with low-dose ICSs recommended as preferred treatment for mild persistent asthma with the addition of a LABA if not adequately controlled.[22,70] Budesonide is considered the preferred ICS to initiate because it has the greatest amount of safety data, and the data are reassuring; however, patients who are well-controlled on a particular ICS should remain on current treatment as changing doses could jeopardize asthma control.[22,70] Stepping down treatment should not be initiated during pregnancy due to a risk of perturbations in asthma control.[3] Albuterol is considered the preferred rescue therapy.[70] Conditions that may aggravate asthma such as allergic rhinitis, sinusitis, and GERD should be aggressively treated.[71] Pregnant women are particularly susceptible to viral infections which may lead to exacerbations and worsening asthma symptoms, and should be aggressively treated to avoid fetal hypoxia.[3] Moderate to severe exacerbations should be treated per usual treatment guidelines with a target oxygen saturation of 95%.[3] Hyperventilation during labor may induce bronchoconstriction and should be treated with short-acting inhaled β_2-agonist.[3] Fentanyl, rather than morphine, should be used for pain control as morphine may induce histamine release and respiratory depression.[71]

Drug Class Information for Management of Chronic Asthma

Inhaled Corticosteroids

The mechanism of action of the corticosteroids has been reviewed (see above). The principal advantage of the ICSs is their high topical potency to reduce inflammation in the lung and low systemic activity.[49] The ICSs have high anti-inflammatory potency, approximately 1,000-fold greater than endogenous cortisol, and differ from each other by as much as fourfold to sixfold.[49] However, potency differences, which are simply a measure of binding affinity to the receptor, can be overcome simply by giving different microgram dosages of drug. Aerosol delivery of the preparations is remarkably variable, ranging from 10% to 60% of the nominal dose (ie, that dose which leaves an actuator for an MDI or, in the case of a DPI, that which is released on actuation of the inhaler).[49] Different devices for the same chemical entity may result in twofold differences in delivery, so that delivery method can make a significant difference in the relative comparable dose or therapeutic index.[2,49]

The ICSs, beclomethasone dipropionate, budesonide, ciclesonide, flunisolide, fluticasone propionate, fluticasone furoate, and mometasone furoate, that are currently available for use are compared and listed in Table 26-12. The ICSs have pharmacokinetic differences that result in different topical/systemic activity.[49] Most evidence is consistent with log-linear dose–response curves for both indirect and direct responses. The log-linear nature of the dose–response curve for ICS activity raises the issue of how much of a difference in dose (or lung delivery) or potency is detectable. The measures used to assess efficacy (lung function, BHR, symptoms, and as-needed short-acting inhaled β_2-agonist use) are downstream events from the anti-inflammatory activity. It takes a fourfold difference in potency or dose to detect clinically significant differences in efficacy.[59] The table of comparable ICS doses (see Table 26-12) is based on extensive clinical trial data.[3,49] Clinically comparable doses take into consideration drug potency differences as well as device delivery differences but not the potential for systemic activity.

Since the glucocorticoid receptors within the various tissues are the same, differences in the pharmacokinetic profile are required to produce differences in the topical/systemic effect ratio (therapeutic index).[49] Pharmacokinetic properties that enhance topical selectivity include rapid systemic clearance, poor oral bioavailability, and prolonged residence time in the lung.[49] Owing to their high lipophilicity, systemic clearance of the available ICSs is very rapid, approaching the rate of liver blood flow with the exception of ciclesonide, which is inactivated by blood esterases as well.[49] However, the ICSs differ markedly in their oral bioavailability, although they all undergo rather extensive first-pass metabolism to less active substances when absorbed[49] (see Table 26-8). The ICSs produce dose-dependent systemic effects, contributed by the orally absorbed fraction and the fraction absorbed from the lung[2,49] (**Table 26-13**). Essentially all the drug that reaches the lung is absorbed systemically; thus, a slow absorption from the lung results in an apparent long elimination half-life and enhances topical selectivity by lowering the systemic concentration.[49] Ciclesonide and beclomethasone dipropionate differ from the other ICSs in that the parent compounds are prodrugs that are metabolized in the lung to the active compounds des-ciclesonide and beclomethasone monopropionate.[49] The potential advantage of the drugs with low oral bioavailability is obviated by using a spacer device with the MDI for the drugs with higher oral bioavailability because appropriate spacers reduce the oral amount delivered by

80%.[49] The use of VHCs also can increase systemic activity by increasing lung delivery of drugs not absorbed significantly orally.[49] If this increase in lung deposition is twofold or less, it will increase systemic activity without producing a clinically important increase in efficacy, thus decreasing the therapeutic index.[49] Mouth rinsing and spitting will also reduce the oral availability and are particularly useful for DPI devices.[2,49] Although ciclesonide and its active metabolite have rapid systemic clearance suggesting an improved therapeutic index, it has not yet been clearly established in clinical trials.[49]

TABLE 26-13 Effects of Inhaled Corticosteroids

Beneficial Effects	Potential Adverse Effects
Decrease eosinophil numbers	Hoarseness, dysphonia, thrush
Decrease mast cell numbers	Growth retardation, skeletal muscle myopathy
Decrease T-lymphocyte cytokine production	Osteoporosis, fractures and aseptic necrosis of hip
Inhibit transcription of inflammatory genes in airway epithelium	Posterior subcapsular cataract formation and glaucoma
Reduce endothelial cell leak	Adrenal axis suppression, immunosuppression
Upregulate β_2-receptor production	Impaired wound healing, easy bruising, skin striaeHyperglycemia/hypokalemia, hypertension
Reduce airway epithelial subbasement membrane thickening	Psychiatric disturbances

The response to ICSs is somewhat delayed. Most patients' symptoms will improve in the first 1 to 2 weeks of therapy and will reach maximum improvement in 4 to 8 weeks.[2] Improvement in baseline FEV_1 and PEF may require 3 to 6 weeks for maximum improvement, whereas improvement in BHR requires 2 to 3 weeks and approaches maximum in 1 to 3 months but may continue to improve over 1 year.[2] Most of the improvement in these parameters occurs at low to medium doses, and there is a large variability in response, with 10% of patients not demonstrating an improvement in either parameter.[2] Whether these nonresponders also show no improvement in rates of exacerbations is unknown. Significant decreases in FeNO occur within 1 to 2 days with maximum effect in 2 to 3 weeks. Sensitivity to exercise challenge decreases after 4 weeks of therapy.[14] Although single doses do not inhibit the immediate asthmatic response to antigen challenge or exercise, continued therapy for 1 week partially suppresses the response. The two latter effects are likely due to a reduction in mucosal mast cells.[2]

Local adverse effects from ICSs include oropharyngeal candidiasis and dysphonia that are dose dependent. The dysphonia (reported in 5%-20% of patients) appears to be due to a local corticosteroid-induced myopathy of the vocal cords.[2] The use of a spacer device with MDIs can decrease oropharyngeal deposition and thus decrease the incidence and severity of local side effects.[2] In infants who require ICS delivery through a face mask, the parent should clean the nasal–perioral area with a damp cloth following each treatment to prevent topical candidiasis.

Systemic adverse effects can occur with any of the ICSs given in a sufficiently high dose.[2,3] Long-term adverse effects of greatest concern include growth suppression in children, osteoporosis, cataracts, dermal thinning, and adrenal insufficiency and crisis.[2,49] Of these, only growth retardation occurs in low to medium doses. However, the growth reduction appears to be transient in that growth velocity is reduced in the first 6 months to 2 years of therapy and then returns to normal.[2,49] The effect is small (1-2 cm total) and not cumulative, but does persist into adulthood.[72] The suppression of the HPA axis and decreased bone mineralization are dose dependent and do not appear to be significant clinically except at high doses.[56] The risks therefore depend on the therapeutic index of each ICS and its delivery device. The effect of delivery device is illustrated by fluticasone propionate, which has both the greatest therapeutic index when administered by DPI and the lowest therapeutic index when administered by MDI plus VHC.[49] Many of the ICSs, including fluticasone propionate, budesonide, ciclesonide, and mometasone furoate, are metabolized in the GI tract and liver by CYP3A4 isoenzymes. Potent inhibitors of CYP3A4 such as ritonavir and ketoconazole have the potential for increasing systemic concentrations of these ICSs by increasing oral availability and decreasing systemic clearance.[49] Some cases of clinically significant Cushing's syndrome and secondary adrenal insufficiency have been reported.[49]

Most patients with moderate disease can be controlled with twice-daily dosing of most ICSs.[2,3,49] Twice-daily dosing produces less thrush than three- to four-times-daily dosing regimens. In milder asthma, once-daily dosing is often sufficient to maintain control.[49] Some of the newer products have gained once-daily dosing indications, particularly in mild asthma once initial control is established.[49] There is no specific pharmacologic or pharmacokinetic aspect of the current ICSs that allows for once-daily dosing because all the agents studied (both the older low-potency ICSs and newer high-potency ICSs) have been effective, provided that patients had relatively mild-to-moderate asthma.[49] More severe patients require multiple daily dosing. The inflammatory response of asthma has been shown

to inhibit corticosteroid-receptor binding.[49] Once asthma is controlled, many patients are able to reduce the ICS dose and maintain control.[49] There has been interest in using ICSs as needed or intermittently in patients with mild persistent asthma; however, the as-needed use has shown inconsistent results with better overall control from regular use.[73,74]

Long-Acting Inhaled β_2-Agonists

The two LABAs, formoterol and salmeterol, provide long-lasting bronchodilation (greater than or equal to 12 hours)[75] (see Table 26-7). Unlike the more water-soluble short-acting β_2-agonists, the long-acting agents are lipid soluble, readily partitioning into the outer phospholipid layer of the cell membrane.[75] In addition, ultra-LABA (indacaterol, vilanterol, and olodaterol), are now available and have a 24-hour bronchodilator duration of effect. Vilanterol in combination with fluticasone furoate is available for once daily dosing for asthma in adults aged 18 and older in the United States and for children and adults aged 12 and older in European countries. Currently, products containing indacterol and olodaterol are only indicated for COPD, but are being evaluated for asthma.

The LABAs and ultra-LABAs are more β_2-selective than albuterol and more bronchoselective by virtue of their property of remaining in the lung tissue cell membrane, which produces its longer duration.[75] The LABAs have a duration of bronchodilator effect of about 12 hours and are dosed twice daily whereas the ultra-LABAs have extended bronchodilator characteristics and last up to 24 hours permitting once daily dosing.[75] The onset of action (time required to increase FEV_1 by 12% over baseline) is similar to that of albuterol for LABAs and ultra-LABAs with the exception of salmeterol which has an onset of approximately 10 minutes. However, this difference is of little consequence as salmeterol, formoterol, and vilanterol are recommended for chronic therapy only in combination with ICSs in the United States (in European countries combination ICS with formoterol are also used on-demand for acute relief of symptoms).[3] LABAs are available as single entity and as fixed-dose combinations with ICSs (see below) though single entity LABA products are FDA approved for use only with ICS. Patients need to be counseled to continue to use their short-acting inhaled β_2-agonists for acute exacerbations while receiving the LABA/ICS combination products.

The LABAs are preferred adjunctive therapy to ICSs in children 12 years and older and adults for step 3 and children 6 to 11 years of age for steps 4 and 5.[3] Combination treatment with ICS/LABA provides greater asthma control than increasing the dose of ICS alone, while at the same time reducing the frequency of mild and severe exacerbations.[3]

As with short-acting β_2-agonists, tolerance can occur with chronic administration of LABAs and seems to plateau after about 1 week of regular therapy but response recovers rapidly after only 3 days of non-use.[75] Long-term trials have shown no diminution in bronchodilator response but a partial loss of the bronchoprotective effect against methacholine, histamine, and exercise challenge.[75] These effects do not seem to have a significant impact on the quality of asthma control with chronic daily use.

Concern for risks with long-acting β_2-agonist use began shortly after approval of the first available LABA, salmeterol, with reports of respiratory deaths in salmeterol users.[76] Two large studies of over 25,000 adult patients found an increased risk of death in patients using salmeterol which was observed to be greater in African Americans than whites in one study.[77,78] An FDA review of data revealed similar increases in exacerbation rates with both salmeterol and formoterol including effects in children.[79] However, whether concomitant use of ICS mitigated the risk was unclear. Therefore, FDA has required manufacturers of long-acting β_2-agonists to conduct large (over 40,000 participants) clinical trials separately in adults and children (4-11 years) to evaluate effects on asthma control.[80] The results of the first large study in adults found no increased risk for serious asthma-related events nor asthma-related deaths with LABA/ICS treatment compared to ICS treatment alone; other studies are ongoing.

Methylxanthines

Methylxanthines have been used for asthma therapy for more than 50 years, but their use has declined markedly owing to the high risk of severe life-threatening toxicity and numerous drug interactions, as well as decreased efficacy compared with ICSs and LABAs. Theophylline, the primary methylxanthine of interest, is a moderately potent bronchodilator with mild anti-inflammatory properties.[2] Like the β_2-agonists, the methylxanthines are functional antagonists of bronchospasm; however, their clinical utility is limited by their low therapeutic index.[2] Theophylline as a sustained-release product is the preferred oral preparation, whereas its complex with ethylenediamine (aminophylline) is the preferred injectable product owing to increased solubility.[2]

The mechanism by which theophylline produces bronchodilation appears to be through nonselective phosphodiesterase (PDE) inhibition —producing increased cAMP and cyclic guanosine monophosphate (cGMP) concentrations.[2] The PDE isoenzymes currently thought to be important for theophylline's clinical effects are isoenzymes III, predominant in airway smooth muscle, and IV, important in inflammatory cell regulation such as mast cells, neutrophils, eosinophils, and T lymphocytes.[2] Selective PDE isoenzyme IV inhibitors, however, have no significant effects in clinical asthma. Theophylline also activates histone deacetylase that is involved in the corticosteroid-induced decrease in pro-inflammatory gene expression.[81] It is a competitive antagonist of adenosine and stimulates

endogenous catecholamine release, which are important determinants of toxic symptoms of excess theophylline.[2]

Theophylline has a log-linear dose–response curve.[82] Most chronic stable patients with asthma will obtain significant bronchodilation when the serum theophylline concentration reaches 5 mcg/mL (28 µmol/L), and most patients will have no toxic symptoms with serum concentrations of less than 15 mcg/mL (83 µmol/L).[2,82] The percentage of patients experiencing adverse effects increases sharply as concentrations exceed 15 mcg/mL (83 µmol/L). As with the β_2-agonists, the dose–response curves for smooth muscle relaxation by theophylline are dynamic and shifted to the right in the face of increasing contractile stimuli.[82] This property probably explains theophylline's relative lack of bronchodilatory effect in acute severe asthma.[2,82] The severity of theophylline's toxicity precludes even doubling the usual dosage. Toxicities include caffeine-like effects of nausea, vomiting, tachycardia, jitteriness, and difficulty sleeping to more severe toxicities such as cardiac tachyarrhythmias and seizures. Death has occurred in children receiving their usual doses of theophylline during acute systemic viral illnesses due to a reduction in clearance.[82]

Routine monitoring of serum concentrations is essential for the safe and effective use of theophylline.[2] Theophylline is eliminated primarily by metabolism via the hepatic cytochrome P450 (CYP) mixed-function oxidase microsomal enzymes (primarily the CYP1A2 and CYP3A3 isozymes), with 10% or less excreted unchanged in the kidney.[2] Theophylline clearance is age dependent, with 1- to 9-year-olds having the highest systemic clearances and therefore requiring the largest dosages (on a weight basis). However, even within the same age groups, theophylline clearance can vary twofold to threefold.[2] **Figure 26-8** outlines a dosing and monitoring schedule for theophylline. Factors affecting theophylline's hepatic metabolism are listed in **Table 26-14**.[2] Only drugs or diseases that produce a greater than or equal to 20% inhibition or a greater than or equal to 50% induction of theophylline metabolism are likely to result in clinically significant interactions.[82]

FIGURE 26-8

Algorithm for slow titration of theophylline dosage and guide for final dosage adjustment based on serum theophylline concentration measurement. For infants younger than 1 year of age, the initial daily dosage can be calculated by the following regression equation: Dose (mg/kg) = (0.2) (age in weeks) + 5. Whenever side effects occur, dosage should be reduced to a previously tolerated lower dose.

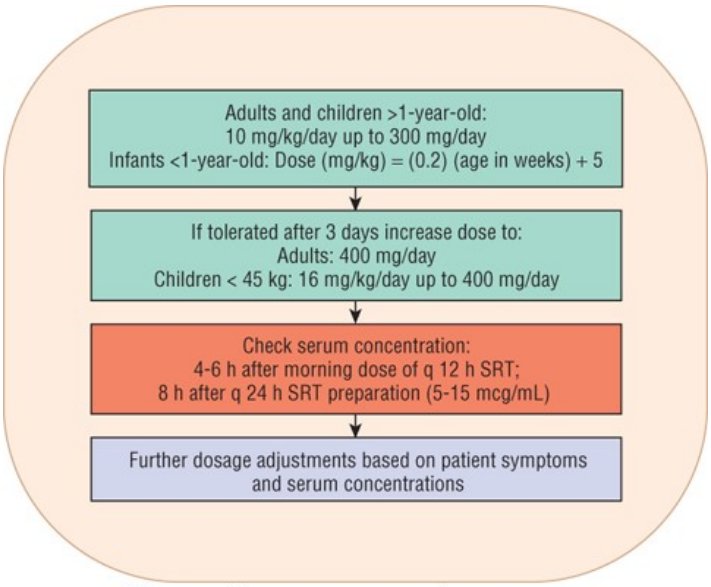

TABLE 26-14 Factors Affecting Theophylline Clearance

Decreased Clearance	% Decrease	Increased Clearance	% Increase
Cimetidine	–25 to –60	Rifampin	+53
		Carbamazepine	+50
Macrolides: erythromycin, TAO, clarithromycin	–25 to –50	Phenobarbital	+34
		Phenytoin	+70
Allopurinol	–20	Charcoal-broiled meat	+30
Propranolol	–30		

Decreased Clearance	% Decrease	Increased Clearance	% Increase
		High-protein diet	+25
Quinolones ciprofloxacin, enoxacin, perfloxacin	–20 to –50		
		Smoking	+40
Interferon	–50	Sulfinpyrazone	+22
Thiabendazole	–65	Moricizine	+50
Ticlopidine	–25	Aminoglutethimide	+50
Zileuton	–35		
Systemic viral illness	–10 to –50		

Sustained-release theophylline is less effective than ICSs and no more effective than oral sustained-release β_2-agonists or LT antagonists.[2,3] The addition of theophylline to ICSs is similar to doubling the dose of the ICS and is overall less effective than the LABAs as adjunctive therapy.[2] The addition of theophylline to patients with poorly controlled asthma receiving ICS/LABA combination does not improve outcomes.[83]

Leukotriene Modifiers

Two cysteinyl LT receptor antagonists (zafirlukast and montelukast) and one 5-lipoxygenase inhibitor (zileuton) are available in the United States.[84] In challenge studies, they reduce allergen-, exercise-, cold-air hyperventilation-, irritant-, and aspirin-induced asthma.[84] Clinical use of zileuton is limited due to the potential for elevated liver enzymes (especially in the first 3 months of therapy), and the potential inhibition of drugs metabolized by the CYP3A4 isoenzymes.[84] They are not preferred alternatives in mild persistent asthma nor as alternative add-on therapy for moderate persistent asthma (see Tables 26-10 and 26-11).[3]

These drugs improve pulmonary function tests (FEV_1 and PEF), decrease nocturnal awakenings and β_2-agonist use, and improve asthma symptoms.[84] A major advantage is that they are effective orally, and can be administered once or twice a day.[84] However, they are less effective in asthma than low doses of ICSs.[2,3,55] Although montelukast is approved for EIB in adults, it is significantly less effective than short-acting inhaled β_2-agonists.[14] In adults with severe uncontrolled asthma they do not improve outcomes.[84] They are not as effective as LABAs when added to ICSs for moderate persistent asthma.[84] It is not yet possible to predict which patients respond best to LT modifiers, although there is some evidence that patients with aspirin-sensitive asthma do well, as predicted by studies showing increased cysteinyl LT production in these patients.[84] It is possible that genetic polymorphisms in the 5-lipoxygenase or LTC_4 synthase pathways or in cys-LT_1 receptors might predict better responders in the future.[84] LTRAs also have modest efficacy in allergic rhinitis.

In general, the LTD_4 receptor antagonists are well tolerated and do not appear to have serious class-specific effects.[2] An idiosyncratic syndrome similar to the Churg-Strauss syndrome, with marked circulating eosinophilia, heart failure, and associated eosinophilic vasculitis, has been reported in a small number of patients treated with zafirlukast and montelukast.[82] The majority of these patients had been receiving high-dose ICS or oral corticosteroids and were able to reduce the dose as a consequence of the LTD_4 receptor antagonists. It is unclear whether the increased reports are due to increased case findings among patients with asthma prescribed a new drug or whether the syndrome is related to corticosteroid dose reduction or an idiosyncratic effect of LTRAs in general. Whatever the cause, it appears to be a rare syndrome, with an estimated incidence of less than 1 case per 15,000 to 20,000 patient-years of treatment.[82]

Reports of adverse neuropsychiatric events have caused the manufacturers of the LT inhibitors to revise their labeling. However, evidence for causality of suicidal thoughts and suicide is lacking.[85] Reports of fatal hepatic failure associated with zafirlukast have prompted a warning for patients to be made aware of signs and symptoms of hepatic dysfunction.[2]

Zileuton can be administered twice daily as controlled-release tablets.[2] Efficacy data are more limited, liver function monitoring is recommended, and drug interactions are reported with warfarin and theophylline.

Anti-IgE (Omalizumab)

Omalizumab is a recombinant anti-IgE antibody approved for the treatment of allergic asthma not well controlled on oral corticosteroids or ICSs.[86] It is a composite of 95% human and 5% antihuman murine IgE sequences. Omalizumab binds to the Fc portion of the IgE antibody preventing the binding of IgE to its high-affinity receptor (FcεRI) on mast cells and basophils. The decreased binding of IgE on the surface of mast cells leads to a decrease in the release of mediators in response to allergen exposure. Omalizumab also decreases FcεRI expression on basophils and airway submucosal mast cells over 8 to 12 weeks.[86]

Omalizumab is administered subcutaneously and has a slow absorption rate; peak serum concentration is achieved in 3 to 14 days.[86]

Omalizumab is eliminated primarily through the reticuloendothelial system and has an elimination half-life of 17 to 22 days; serum free IgE levels return to previous level in about 3 weeks.[86] Omalizumab should be administered under medical observation with drugs for treating anaphylaxis available.

The dosage of omalizumab is determined by the patient's baseline total serum IgE level (international units per milliliter) and body weight (kilograms).[86] Doses range from 150 to 375 mg and are given at either 2- or 4-week intervals. No further adjustments for variations in total serum IgE are required, and patients receive a consistent dose for the duration of treatment.[86] Omalizumab is approved for patients greater than 6 years with allergic asthma.[86] Due to its significant cost, it is only indicated as step 5 or 6 care for patients who have allergies and severe persistent asthma that are inadequately controlled with the combination of high-dose ICS/LABA and at risk for severe exacerbations.[2,3] It is the only adjunctive therapy that has demonstrated improved outcomes in patients uncontrolled on ICS/LABA and has allowed oral corticosteroid reduction in a number of studies.[2,3,86] Omalizumab therapy is associated with a 0.2% rate of anaphylaxis prompting an FDA warning that patients should remain in the healthcare provider's office for a reasonable period of time past the injection as 70% of reactions occur within 2 hours. In addition, patients should be counseled on the signs and symptoms of anaphylaxis because some reactions have occurred up to 24 hours following an injection.[2,86]

EVALUATION OF ASTHMA CONTROL

The two domains of asthma control are "symptom control" and "future risk of adverse outcomes."[3] Symptom control is assessed from the frequency of daytime and night-time asthma symptoms, reliever medication use, and activity limitations; poor symptom control is an indicator of future risk for exacerbations.[3] However, even when perceived symptom control is good, assessments of future risk of exacerbations, airflow limitation (which may be under-perceived by patients), and medication adverse effects need to be assessed.[3] Factors contributing to asthma severity and future risk of exacerbations and are discussed previously in this chapter.

Future risk of adverse outcomes includes assessment of risks for: future exacerbations, fixed airflow limitation (and thus diminished response to therapy), and medication adverse effects.[3] To assess the risk for future exacerbations (with exacerbation defined as a worsening of asthma requiring the use of systemic corticosteroids or an increase in the use of systemic corticosteroids for patients on a stable maintenance dose to prevent a serious outcome), lung function should be measured before the start of treatment and then 2 months later when maximum response to controller medications is likely attained.[3,87,88] This benchmark of "personal best" can then be used for ongoing risk assessment. Other factors that affect future risk of exacerbations and are to be evaluated include exacerbation history in the previous year (one or more exacerbations requiring systemic corticosteroids is a risk factor) or intubation or intensive care unit stay for asthma as well as ED visits for urgent care.[3,88] Fixed airflow limitation can be affected by lack of ICS treatment, smoking exposure, and low lung function. During ongoing care, spirometry should be measured yearly but long-term PEF monitoring is typically reserved for those with severe asthma.[3] Adverse effect risks are influenced by oral and ICS dose and potential drug interactions with cytochrome P450 inhibitors.[3] In addition, poor inhaler technique (such as not rinsing and spitting after ICS use) can lead to oral candidiasis or an increase in the swallowed fraction of the dose that could influence linear growth in children.

There are several simple screening questionnaires that can be used to assess asthma symptom control quickly in a clinic setting. The Asthma Control Test is a validated simple 5-question survey for patients 12 years and older that yields a numerical score; a score of 19 or less indicates poor asthma control and several institutions have incorporated the survey into the electronic health record in order to evaluate changes over time.[89,90] There is a companion Childhood Asthma Control Test survey for children 4 to 11 years.[89,90] A number of other validated questionnaires exist such as the Asthma Therapy Assessment Questionnaire (ATAQ) and the Asthma Control Questionnaire (ACQ).[89,90]

Patients should also be asked about exercise tolerance as perceived good exercise tolerance may be biased by a sedentary lifestyle adapted to the frequency of bothersome symptoms. All patients on inhaled drugs should have their inhalation delivery technique evaluated periodically—monthly initially and then every 3 to 6 months. Before stepping up therapy, adherence, environmental control, and comorbid conditions should be reviewed.[3]

Following initiation of anti-inflammatory therapy or an increase in dosage, most patients should begin experiencing a decrease in symptoms in 1 to 2 weeks and achieve maximum symptomatic improvement within 4 to 8 weeks. The use of higher ICS doses or more potent agents may accelerate the process. Improvement in FEV_1 and PEF should follow a similar time frame; however, a decrease in BHR, as measured by morning PEF, PEF variability, and exercise tolerance, may take longer and improve over 1 to 3 months.[3] Patients should be informed that following a viral respiratory infection, they may experience decreased exercise tolerance for up to 4 weeks.

Initial visits with the patient should focus on the patient's concerns, expectations, and goals of treatment. Basic education should focus on asthma as a chronic lung disease, the types of medications, and how they are to be used. Inhaler technique is taught, as is when to seek medical advice. Written action plans should be provided. Both peak flow-based or symptom-based self-monitoring can be effective, if taught and followed correctly.[3] The first follow-up visit should include repetition of the educational messages from the first visit, as well

as review of the patient's current medications, adherence, and any difficulties related to the therapy.

FUTURE THERAPIES: BIOLOGIC AGENTS IN ASTHMA

Since asthma represents a heterogeneous disease with multiple phenotypes and different pathobiologies, natural histories, symptom burden, and therapeutic responses, approaches to management can no longer be "one-size-fits all." Whereas, the investigation of long-acting muscarinic antagonists (LAMAs) as alternatives to LABAs is a first step, the development of targeted biologic agents is close behind, especially for patients defined as severe asthma.[91]

The World Health Organization (WHO) includes 3 groups of patients who would meet criteria for the diagnosis of severe asthma:[92] (1) untreated severe asthma; (2) difficult-to-treat severe asthma; and (3) treatment-resistant severe asthma. This latter group includes both those individuals for whom control is not achieved despite the highest level of recommended treatment (refractory asthma and corticosteroid-resistant asthma) *and* those individuals for which control can be maintained only with the highest level of recommended treatment.

Alternative definitions of severe asthma have been provided by the American Thoracic Society (ATS).[93] The ATS defines refractory or severe asthma on the basis of 2 major and 7 minor criteria.[93] To meet the ATS definition, patients must have 1 of the 2 major criteria (OCS for greater than 50% of past year or continuous high-dose ICS) and 2 of the 7 minor criteria (concurrent use of greater than or equal to 1 other controller, daily symptoms requiring SABA, FEV_1 less than 80% predicted, greater than or equal to 1 urgent care visits in past year, greater than or equal to 3 OCS bursts in past year, deterioration with decrease in corticosteroid dose of 25%, and history of near-fatal event). This definition of severe asthma may include patients with good disease control and focuses on the need of high doses of corticosteroids; the NLHBI Severe Asthma Research Program uses these criteria as do many of the pharmaceutical manufacturers developing drugs to meet the unmet need of the severe disease phenotype.[91] Gaps still remain about the determinants of severe asthma in children, and trials of novel therapeutic strategies for severe asthma in childhood populations are essential to guide therapy rather than reliance of extrapolation of results from trials conducted in adults.[94]

Table 26-15 outlines the current biologic agents either FDA approved or in trials, as well as the biomarkers predicting therapeutic responses and the biomarkers modulated by therapy.[91,95,96] These agents are targeting the IgE pathway (relevant to allergic asthma) or IL-4, IL-13, and IL-5 pathways (relevant to eosinophilic disorders).

TABLE 26-15 Targeted Biologic Therapies for Asthma and Potential Biomarkers

Pathway	Biologic Agents Approved/in Trials	Biomarkers Predicting Therapeutic Response	Biomarkers Modulated by Therapy
IgE	Omalizumab (Xolair®)	FeNO Blood eosinophils Periostin	FeNO Sputum eosinophils
IL-4/IL-13	Pitrakinra (competitive antagonist) Dupilumab (receptor antibody)	FeNO Sputum eosinophils Blood eosinophils Periostin	FeNO
IL-13	Tralokinomab	FeNO Eosinophils Sputum IL-13 (periostin surrogate)	
IL-15	Mepolizumab (Nucala®) Reslizumab (Cinqair) (blocks IL-5 alpha receptor) Benralizumab	Sputum eosinophils Blood eosinophils	Sputum eosinophils Blood eosinophils

FeNO, functional exhaled nitric oxide.

Omalizumab (described earlier) is currently recommended for the treatment of patients greater than 6 years of age with moderate-to-severe asthma, which is not adequately controlled by ICS, ICS/LABA, and is some cases, OCS. Clinical trials that have included children less than 12 years with allergic asthma and poor disease control demonstrate nearly complete elimination of the spring and fall exacerbations.[97]

Eosinophils drive asthmatic inflammation and contribute to airway dysfunction secondary to release of their pro-inflammatory cytokines, chemokines, lipid mediators, and cytotoxic granules from these cells.[96] Reduced sputum eosinophils by ICS reduced asthma exacerbations and contributes to disease control. IL-5 (produced by lymphocytes, mast cells, and maybe eosinophils) contributes to terminal differential, survival, migration, and activation of eosinophils.[96] Thus, this cytokine has been a primary target in asthma treatment.

Mepolizumab (Nucala®) is the first anti-IL5 agent approved in the U.S. for use in combination with other medications for maintenance treatment of severe asthma in patients aged 12 years or older with an eosinophic phenotype.[91] It is administered as a 100 mg fixed dose subcutaneous injection every 4 weeks. Those individuals who were shown to benefit from mepolizumab in the Phase III clinical trials had blood eosinophil levels of 150 cells/mcl or greater just prior to treatment. Patients treated with mepolizumab experienced fewer exacerbations; the medication was well-tolerated. Adverse effects most commonly reported included headache, injection-site reactions, back pain, and fatigue.[91]

CONCLUSION

Asthma is a complex disease with a multitude of clinical presentations. The exact defect in asthma has not been defined, and it may be that asthma is a common presentation of a heterogeneous group of diseases. Asthma is defined and characterized by excessive reactivity of the bronchial tree to a wide variety of noxious stimuli. The reaction is characterized by bronchospasm, excessive mucus production, and inflammation. The central role of inflammation in inducing and maintaining BHR is now becoming widely appreciated. The goal of asthma therapy is to normalize, as much as possible, the patient's life and prevent chronic irreversible lung changes. Drugs are the mainstay of asthma management. The goal of drug therapy is to use the minimum amount of medications possible to completely control the disease. In persistent asthma, therapy should be aimed at both bronchospasm and inflammation in order to produce the best results. Patients should be followed and monitored diligently for toxicities. Although death from asthma is an uncommon event, the most common cause of death is underassessment of the severity of obstruction either by the patient or by the clinician; the next common cause is under-treatment. A cornerstone of any therapy is education and the realization that most asthma deaths are avoidable.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACOS	Asthma COPD Overlap Syndrome
ACQ	Asthma Control Questionnaire
ACT	Asthma Control Test
ACTH	adrenocorticotropic hormone
Arg	arginine
ATAQ	Asthma Therapy Assessment Questionnaire
BHR	bronchial hyperresponsiveness
cAMP	cyclic adenosine monophosphate
CFC	chlorofluorocarbon
cGMP	cyclic guanosine monophosphate
COPD	chronic obstructive pulmonary disease
CYP	cytochrome P450
DPI	dry powder inhaler
ED	emergency department
EIB	exercise-induced bronchospasm
EPR3	Expert Panel Report 3
FeNO	fraction of exhaled nitric oxide
FEV_1	forced expiratory volume in 1 second
FVC	forced vital capacity

GERD	gastroesophageal reflux disease
GINA	Global Initiative for Asthma
Gln	glutamine
Glu	glutamic acid
Gly	glycine
GM-CSF	granulocyte-macrophage colony-stimulating factor
HFA	hydrofluoroalkane
HPA	hypothalamic–pituitary–adrenal
ICAM-1	intercellular adhesion molecule 1
ICS	inhaled corticosteroid
IFN-γ	interferon-γ
IgE	immunoglobulin E
IL	interleukin
iNOS	inducible nitric oxide synthase
LABA	long-acting inhaled β_2-agonist
LAMA	long-acting muscarinic antagonist
LT	leukotriene
MDI	metered-dose inhaler
MMAD	mass median aerodynamic diameter
NAEPP	National Asthma Education and Prevention Program
NANC	nonadrenergic, noncholinergic
NO	nitric oxide
O_2	oxygen
PAF	platelet-activating factor
PDE	phosphodiesterase
PEF	peak expiratory flow
PKA	protein kinase A
RCT	randomized controlled trial
RSV	respiratory syncytial virus
SABA	short-acting beta-agonist
T cells	thymically derived lymphocytes
Th_1	type 1 T-helper
Th_2	T-helper cell type 2
VCAM-1	vascular cell adhesion molecule 1
VHC	valved holding chamber
VIP	vasoactive intestinal peptide
WHO	World Health Organization

Chapter 27: Chronic Obstructive Pulmonary Disease

Sharya V. Bourdet; Dennis M. Williams

INTRODUCTION

KEY CONCEPTS

- 1 Chronic obstructive pulmonary disease (COPD) is a treatable and preventable disease characterized by progressive airflow limitation that is not fully reversible and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.
- 2 Chronic obstructive pulmonary disease is historically described as either *chronic bronchitis* or *emphysema*. Chronic bronchitis is defined in clinical terms, whereas emphysema is defined in terms of anatomic pathology. Because most patients exhibit some features of each phenotype, the appropriate emphasis of COPD pathophysiology is on small airway disease and parenchymal damage that contributes to chronic airflow limitation.
- 3 Mortality from COPD has increased steadily over the past 3 decades; it currently is the third leading cause of death in the United States.
- 4 The primary cause of COPD is cigarette smoking, implicated in 85% of diagnosed cases. Other risks include a genetic predisposition, environmental exposures (including occupational dusts and chemicals), and air pollution.
- 5 Smoking cessation and avoidance of other known toxins are the only management strategies proven to slow the progression of COPD.
- 6 Oxygen therapy has been shown to reduce mortality in selected patients with COPD. Oxygen therapy is indicated for patients with a resting PaO_2 of less than 55 mm Hg or a PaO_2 of less than 60 mm Hg and evidence of right-sided heart failure, polycythemia, or impaired neurologic function.
- 7 Bronchodilators represent the mainstay of drug therapy for COPD. Pharmacotherapy is used to relieve patient symptoms, improve quality of life, and reduce exacerbation risks. Guidelines recommend short-acting bronchodilators as initial therapy for patients with mild or intermittent symptoms.
- 8 For the patient who experiences chronic symptoms, long-acting bronchodilators are appropriate. Either a β_2-agonist or an anticholinergic offers significant benefits. Combining long-acting

bronchodilators is recommended if necessary.

- 9 The role of inhaled corticosteroid (IC) therapy in COPD is controversial. International guidelines suggest that patients with severe COPD and frequent exacerbations may benefit from ICs.
- 10 Acute exacerbations of COPD have a significant impact on disease progression and mortality. Treatment of acute exacerbations includes intensification of bronchodilator therapy and a short course of systemic corticosteroids.
- 11 Antimicrobial therapy should be used during acute exacerbations of COPD if the patient exhibits at least two of the following: increased dyspnea, increased sputum volume, and increased sputum purulence.

1 Chronic obstructive pulmonary disease (COPD) is a common lung disease characterized by airflow limitation that is not fully reversible and is both chronic and progressive.[1] COPD is preventable and treatable and causes significant extrapulmonary effects that contribute to disease severity in a subset of patients. The prevalence and mortality of COPD have increased substantially over the past 2 decades. In the United States, approximately 24 million Americans are estimated to have COPD, and it accounts for 120,000 deaths annually which is the 3rd leading cause of death.[2] Among the top 5 leading causes of death, only COPD increased in incidence between 2007 and 2010.[3]

In order to standardize the care of patients with COPD and present evidence-based recommendations, the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO) launched the Global Initiative for Chronic Obstructive Lung Disease (GOLD) in 2001. This report was most recently revised in January 2016.[1] The goals of the GOLD organization are to increase awareness of COPD and reduce morbidity and mortality associated with the disease. International guidelines have also been developed through a collaborative effort of the American College of Physicians (ACP), the American College of Chest Physicians (ACCP), the American Thoracic Society (ATS), and the European Respiratory Society (ERS) and are widely available.[4] In addition, the British guidelines were updated in 2010.[5] All of these guidelines are generally concordant in their recommendations. Finally, ACCP and the Canadian Thoracic Society collaborated on a guideline focusing on the prevention of COPD exacerbations which was published in 2015.[6]

Chronic obstructive pulmonary disease is differentiated from asthma in that the airflow limitation present is not fully reversible. Within a patient, the degree of reversibility is typically small; however, between patients, there can be substantial differences in the extent of variability. For some patients airflow obstruction is fixed with minimal improvement in response to a bronchodilator or with optimal treatment. Other patients can demonstrate a significant improvement with pharmacotherapy. The chronic and progressive nature of COPD is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.[1,4,5] Nonetheless, COPD is preventable and treatable. In recent years, there has been an increased appreciation for the impact of the systemic consequences of chronic inflammatory diseases, including COPD, and for the impact of comorbidities in individual patients that can complicate COPD management.

Historically, clinicians and researchers have exhibited a nihilistic attitude toward the value of treatments for COPD. This was based on the paucity of effective therapies, the destructive nature of the condition, and the fact that the common etiology is cigarette smoking, a modifiable health risk. There is now a renewed interest in evaluating the value of treatments and prevention based on the availability of new therapeutic options for

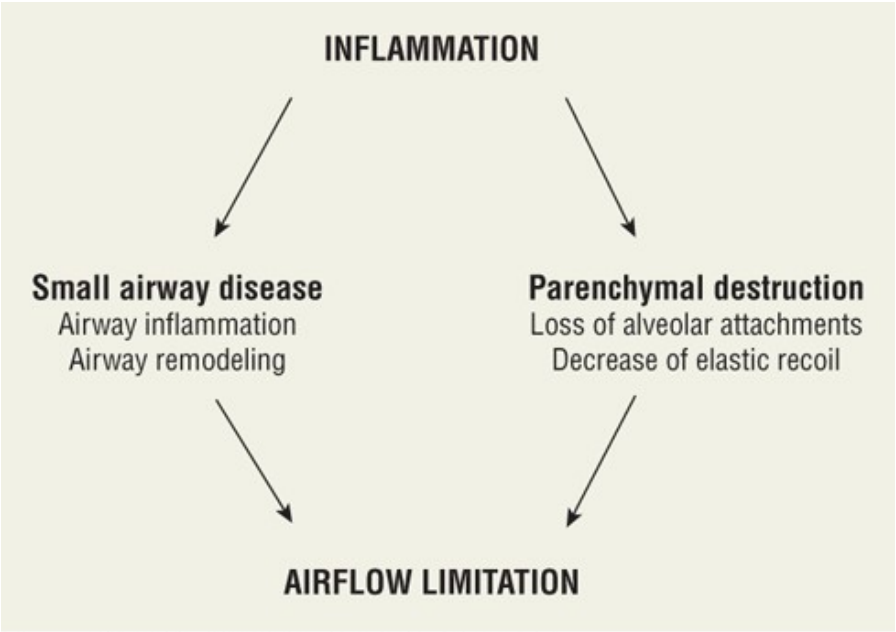
pharmacotherapy and guidelines based on evidence. Additionally, a variety of new agents are available for treatment. The international guidelines emphasize the terms *preventable* and *treatable* to support a positive approach to managing the patient with COPD. Support is also reflected in the availability of research funding to improve understanding about this disease and its management. This includes NHLBI funding of Specialized Centers of Clinically Oriented Research (SCCOR) programs in COPD that have an objective to promote multidisciplinary research on clinically relevant questions enabling basic science findings to be more rapidly applied to clinical problems.[7]

2 The term *COPD* has historically been used to describe various pulmonary diseases with a fixed component of airflow limitation. The two principal conditions are chronic bronchitis and emphysema, which are referred to as phenotypes. Chronic bronchitis is associated with chronic or recurrent excessive mucus secretion into the bronchial tree with cough that is present on most days for at least 3 months of the year for at least 2 consecutive years in a patient in whom other causes of chronic cough have been excluded.[1,5] While chronic bronchitis is defined in clinical terms, emphysema is defined in terms of anatomic pathology. Emphysema historically was defined on histologic examination at autopsy. Because this histologic definition is of limited clinical value, emphysema also has been defined as abnormal permanent enlargement of the airspaces distal to the terminal bronchioles accompanied by destruction of their walls, yet without obvious fibrosis.[1]

Differentiating COPD as either chronic bronchitis or emphysema as descriptive subsets of COPD is no longer considered relevant. This is based on the observation that the majority of COPD is caused by a common risk factor (cigarette smoking) and most patients exhibit features of both chronic bronchitis and emphysema. Currently, emphasis is placed on the pathophysiologic features of small airways disease and parenchymal destruction as contributors to chronic airflow limitation. Chronic inflammation affects the integrity of the airways and causes damage and promotes destruction of the parenchymal structures. The underlying problem is persistent exposure to noxious particles or gases that sustain the inflammatory response. The airways of both the lung and the parenchyma are susceptible to inflammation, and the result is the chronic airflow limitation that characterizes COPD (**Fig. 27-1**).

FIGURE 27-1

Mechanisms for developing chronic airflow limitation in COPD. *Data from reference 1*.



EPIDEMIOLOGY

The true prevalence of COPD is likely underreported in the United States. According to national surveys, the true prevalence of people with chronic airflow obstruction as measured by spirometry may exceed 28 million, although more than half are not diagnosed.[8] Surveys indicate that women are twice as likely to be diagnosed with COPD compared to men.[8]

3 Chronic obstructive pulmonary disease is the third leading cause of death in the United States, exceeded only by cancer and heart disease.[2,9] Overall, the mortality rate is six times higher in males; however, the female death rate has doubled over the past 25 years, and the number of female deaths exceeded male deaths in each year since 2000. The mortality rate is higher in whites compared with that in blacks.[9]

Cigarette smoking is the primary cause of COPD and, although the prevalence of cigarette smoking has declined compared with 1965, approximately 23% of individuals in the United States currently smoke.[1] The trend of increasing COPD mortality likely reflects the long latency period between smoking exposure and complications associated with COPD.

The mortality of COPD is significant; however, morbidity associated with the disease also has a significant impact on patients, their families, and the healthcare system. Patients with COPD accounted for over 15 million physician office visits and over 700,000 hospitalizations. A survey by the American Lung Association revealed that among COPD patients, 51% reported that their condition limits their ability to work, 70% were limited in normal physical activity, 56% were limited in performing household chores, and 50% reported that sleep was affected adversely.[9]

The economic impact of COPD continues to increase as well. In the United States, the direct costs of COPD are $29.5 billion with indirect costs of $20.4 billion.[1] These costs are nearly twice that for patients without the disease, and are directly related to the severity of COPD and exacerbation frequency.[2]

ETIOLOGY

4 Cigarette smoking is the most common risk factor and accounts for 85% to 90% of cases of COPD.[1,4,5] Components of tobacco smoke activate inflammatory cells, which produce and release the inflammatory mediators characteristic of COPD. Smokers are 12 to 13 times more likely to die from COPD than nonsmokers.[10] Although the risk is lower in pipe and cigar smokers, it is still higher than in nonsmokers. Age of starting, total pack-years, and current smoking status are predictive of COPD mortality.

However, only 15% to 20% of all smokers go on to develop COPD, and not all smokers who have equivalent smoking histories develop the same degree of pulmonary impairment, suggesting that other host and environmental factors contribute to the degree of lung dysfunction. Nevertheless, the rate of loss of lung function is determined primarily by smoking status and history.[1,5] Children and spouses of smokers have increased risk of developing significant pulmonary dysfunction through passive smoking, also known as *environmental tobacco smoke* or *secondhand smoke*.

In addition to cigarette smoking, COPD is attributed to a combination of risk factors that results in lung injury and tissue destruction. Risk factors can be divided into host factors and environmental factors (**Table 27-1**), and, commonly, the interaction between these risks leads to expression of the disease. Host factors, such as genetic predisposition, may not be modifiable but are important for identifying patients at high risk of developing the disease.

TABLE 27-1 Risk Factors for Development of Chronic Obstructive Pulmonary Disease (COPD)

Exposures	Host Factors
Environmental tobacco smoke	Genetic predisposition (AAT deficiency)
Occupational dusts and chemicals	Airway hyperresponsiveness
Air pollution	Impaired lung growth

Environmental factors, such as tobacco smoke, occupational dust, and chemicals are modifiable factors that, if avoided, may reduce the risk of disease development. Environmental exposures associated with COPD are particles that are inhaled by the individual, which result in inflammation and cell injury. Exposure to multiple environmental toxins increases the risk of COPD. Thus, the total burden of inhaled particles (eg, cigarette smoke as well as occupational and environmental particles and pollutants) can play a significant role in the development of COPD. In such cases, it is helpful to assess an individual's total burden of inhaled particles. For example, an individual who smokes and works in a textile factory has a higher total burden of inhaled particles than an individual who smokes and has no occupational exposure.

In nonindustrialized countries, occupational exposures may be a more common risk than cigarette smoking. These exposures include dust and chemicals such as vapors, irritants, and fumes. Reduced lung function and deaths from COPD are higher for individuals who work in gold and coal mining, in the glass or ceramic industries with exposure to silica dust, and in jobs that expose them to cotton dust or grain dust, toluene diisocyanate, or asbestos. Other occupational risk factors include chronic exposure to open cooking or heating fires.

It is unclear whether air pollution alone is a significant risk factor for the development of COPD in smokers and nonsmokers with normal lung function. However, in individuals with existing pulmonary dysfunction, significant air pollution worsens symptoms. As evidence for this, emergency department visits are increased during higher-intensity periods of air pollution.

Individuals exposed to the same environmental risk factors do not have the same chance of developing COPD, suggesting that host factors play an important role in pathogenesis.[1,5] While many not-yet-identified genes may influence the risk of developing COPD, the best documented genetic factor is a hereditary deficiency of α_1-antitrypsin (AAT). AAT-associated emphysema is an example of a pure genetic disorder inherited in an autosomal recessive pattern. Inheritance is sometimes described as autosomal codominant by some researchers, because heterozygotes can also have decreased concentrations of AAT enzyme.[1,4] The consequences of AAT deficiency are discussed in the following section as the protease–antiprotease imbalance. True AAT deficiency accounts for less than 1% of COPD cases.[4]

AAT is a 42 kDa plasma protein that is synthesized in hepatocytes. A primary role of AAT is to protect cells, especially those in the lung, from destruction by elastase released by neutrophils. In fact, AAT may be responsible for 90% of the inhibition of this destructive enzyme.[11] In individuals with the most common allele (M), plasma levels of AAT are approximately 20 to 50 µmol (100-350 mg/dL). The protective effect of AAT in the lungs is significantly diminished when plasma levels are less than 11 µmol (80 mg/dL).[1] AAT is an acute-phase reactant, and the serum concentration can be quite variable.

Several types of AAT deficiency have been identified and are due to mutations in the AAT gene. Two main gene variants, S and Z, have been identified. For patients who are homozygous with the S variant, AAT levels are at least 60% of those of normal individuals. These patients usually do not have an increased risk of COPD compared with normal individuals. Patients with homozygous Z deficiency (ZZ) represent 95% of clinical cases[11] and have AAT levels that are 10% of those of normal individuals, while patients with heterozygous Z variant (SZ) have levels closer to 40% of those of normal individuals. Homozygous Z patients have a higher risk of developing COPD compared with heterozygous Z patients. A history of cigarette smoking increases this risk. A small number of patients have a null phenotype and are at high risk for developing emphysema because they produce virtually no AAT.

Patients with AAT deficiency develop COPD at an early age (20-50 years) primarily owing to an accelerated decline in lung function. Compared with an average annual decline in forced expiratory volume in 1 second (FEV_1) of 25 mL/y in healthy nonsmokers, patients with homozygous Z deficiency have been reported to have declines of 54 mL/y for nonsmokers and 108 mL/y for current smokers. Effective diagnosis is dependent on clinical suspicion, diagnostic testing of serum concentrations, and genotype confirmation.[11] Patients developing COPD at an early age or those with a strong family history of COPD should be screened for AAT deficiency. If the concentration is low, genotype testing (DNA) should be performed.

Other genes have been implicated with increased risk of developing COPD, including chromosome 2q, transforming growth factor β_1, microsomal epoxide hydrolase 1, and tumor necrosis factor-α (TNF-α). However, there are no definite conclusions about an association other than AAT. One genetic factor that may reduce the risk of developing COPD is a polymorphism in the gene encoding for matrix metalloproteinase 12 (MMP12). A cohort of smokers with the polymorphism exhibited a lower risk for developing COPD (relative risk of 0.63).[12]

Two additional host factors that may influence the risk of COPD include airway hyperresponsiveness and lung growth. Individuals with airway hyperresponsiveness to various inhaled particles may have an accelerated decline in lung function compared with those without airway hyperresponsiveness. Additionally, individuals who do not attain maximal lung growth owing to low-birth-weight, prematurity at birth, or childhood illnesses may be at risk for COPD in the future.[1]

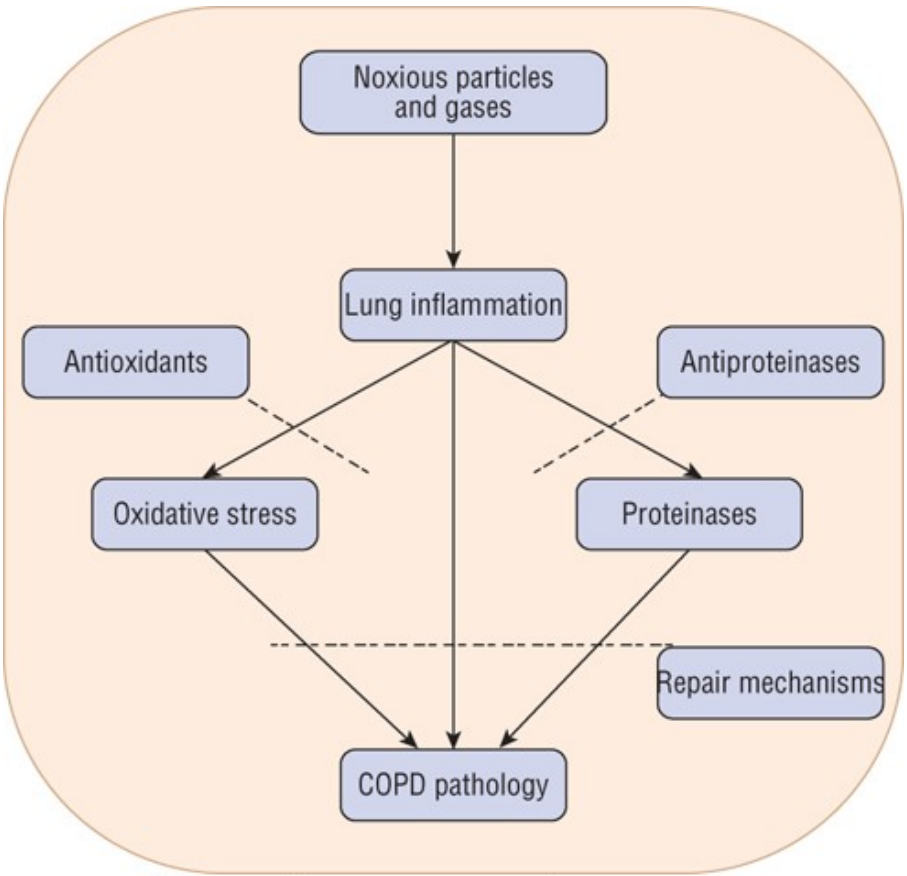
PATHOPHYSIOLOGY

Chronic obstructive pulmonary disease is characterized by chronic inflammatory changes that lead to destructive changes and the development of chronic airflow limitation. The inflammatory process is widespread and not only involves the airways but also extends to the pulmonary vasculature and lung parenchyma. The inflammation of COPD is often referred to as *neutrophilic* in nature, but macrophages and CD8+ lymphocytes also play major roles.[1,4,13] The inflammatory cells release a variety of chemical mediators, of which TNF-α, interleukin 8 (IL-8), and leukotriene B_4 (LTB_4) play major roles.[1,13] The actions of these cells and mediators are complementary and redundant, leading to the widespread destructive changes. The stimulus for activation of inflammatory cells and mediators is an exposure to noxious particles and gas through inhalation. The most common etiologic factor is exposure to environmental tobacco smoke, although other chronic inhalational exposures can lead to similar inflammatory changes.

Other processes that have been proposed to play a major role in the pathogenesis of COPD include oxidative stress and an imbalance between aggressive and protective defense systems in the lungs (proteases and antiproteases).[1,13] These processes may be the result of ongoing inflammation or occur as a result of environmental pressures and exposures (**Fig. 27-2**).

FIGURE 27-2

Pathogenesis of COPD.



An altered interaction between oxidants and antioxidants present in the airways is responsible for the increased oxidative stress present in COPD. Increases in markers (eg, hydrogen peroxide and nitric oxide) of oxidants are seen in the epithelial lining fluid.[1] The increased oxidants generated by cigarette smoke react with and damage various proteins and lipids, leading to cell and tissue damage. Oxidants also promote inflammation directly and exacerbate the protease–antiprotease imbalance by inhibiting antiprotease activity.[13]

The consequences of an imbalance between proteases and antiproteases in the lungs were described over 40 years ago when the hereditary deficiency of the protective antiprotease AAT was discovered to result in an increased risk of developing emphysema prematurely. As discussed earlier, the enzyme (AAT) is responsible for inhibiting several protease enzymes, including neutrophil elastase. In the presence of unopposed activity, elastase attacks elastin, a major component of alveolar walls.[1]

In the inherited form of emphysema, there is an absolute deficiency of AAT. In cigarette smoking-associated emphysema, the imbalance is likely associated with increased protease activity or reduced activity of antiproteases. Activated inflammatory cells release several proteases other than AAT, including cathepsins and metalloproteinases (MMPs). In addition, oxidative stress reduces antiprotease (or protective) activity.

It is helpful to differentiate inflammation occurring in COPD from that present in asthma because the response to antiinflammatory therapy differs. The inflammatory cells that predominate differ between the two conditions, with neutrophils playing a major role in COPD and eosinophils and mast cells in asthma. Mediators of inflammation also differ leukotriene B_4 (LTB_4), interleukin 8 (IL-8), and tumor necrosis factor alpha (TNF-α) predominating in COPD, compared with leukotriene D_4 (LTD_4), interleukin 4 (IL-4), and interleukin 5 (IL-5) among the numerous mediators modulating inflammation in asthma.[1,13] Characteristics of inflammation for the two diseases are summarized in **Table 27-2**.

TABLE 27-2 Features of Inflammation in COPD Compared with Asthma

	COPD	Asthma
Cells	Neutrophils	Eosinophils
	Large increase in macrophages	Small increase in macrophages
	Increase in CD8+ T lymphocytes	Increase in CD4+ Th2 lymphocytes
		Activation of mast cells
Mediators	LTB_4	LTD_4
	IL-8	IL-4, IL-5
	TNF-α	(Plus many others)
Consequences	Squamous metaplasia of epithelium	Fragile epithelium
	Parenchymal destruction	Thickening of basement membrane
	Mucus metaplasia	Mucus metaplasia
	Glandular enlargement	Glandular enlargement
Response to treatment	Glucocorticosteroids have variable effect	Glucocorticosteroids inhibit inflammation

Pathologic changes of COPD are widespread, affecting large and small airways, lung parenchyma, and the pulmonary vasculature.[1] An inflammatory exudate is often present that leads to an increase in the number and size of goblet cells and mucus glands. Mucus secretion is increased, and ciliary motility is impaired. There is also a thickening of smooth muscle and connective tissue in the airways. Inflammation is present in central and peripheral airways. The chronic inflammation results in a repeated injury and repair process that leads to scarring and fibrosis. Diffuse airway narrowing is present and is more prominent in smaller peripheral airways. The decrease in FEV_1 is attributed to the presence of inflammation in the airways, while the blood gas abnormalities result from impaired gas transfer due to parenchymal damage and loss of alveolar-capillary networks.

Parenchymal changes affect the gas-exchanging units of the lungs, including the alveoli and pulmonary capillaries. The distribution of destructive changes varies depending on the etiology. Most commonly, smoking-related disease results in centrilobular emphysema that primarily affects respiratory bronchioles. Panlobular emphysema is seen in AAT deficiency and extends to the alveolar ducts and sacs.

The vascular changes of COPD include a thickening of pulmonary vessels and often are present early in the disease.[1,13] Increased pulmonary pressures early in the disease are due to hypoxic vasoconstriction of pulmonary arteries. If persistent, the presence of chronic inflammation may lead to endothelial dysfunction of the pulmonary arteries. Later, structural changes lead to an increase in pulmonary pressures, especially during exercise. In severe COPD, secondary pulmonary hypertension leads to the development of right-sided heart failure.

Mucus hypersecretion is present early in the course of the disease and is associated with an increased number and size of mucus-producing cells. The presence of chronic inflammation perpetuates the process, although the resulting airflow obstruction and chronic airflow limitation may be reversible or irreversible. The various causes of airflow obstruction are summarized in **Table 27-3**.

TABLE 27-3 Etiology of Airflow Limitation in COPD

Reversible
Presence of mucus and inflammatory cells and mediators in bronchial secretions
Bronchial smooth muscle contraction in peripheral and central airways
Dynamic hyperinflation during exercise
Irreversible
Fibrosis and narrowing of airways
Reduced elastic recoil with loss of alveolar surface area
Destruction of alveolar support with reduced patency of small airways

Thoracic overinflation is a relevant feature in the pathophysiology of COPD, because it is a central factor in causing dyspnea. Chronic airflow obstruction leads to air trapping, resulting in thoracic hyperinflation that can be detected on chest radiograph. This problem results in several dynamic changes in the chest, including flattening of diaphragmatic muscles. Under normal circumstances, the diaphragms are dome-shaped muscles tethered at the base of the lungs. When the diaphragm contracts, the muscle becomes shorter and flatter, which creates the negative inspiratory force through which air flows into the lung during inspiration. In the

presence of thoracic hyperinflation, the diaphragmatic muscle is placed at a disadvantage and is a less efficient muscle of ventilation. The increased work required by diaphragmatic contractions predisposes the patient to muscle fatigue, especially during periods of exacerbations.

The other consequence of thoracic hyperinflation is a change in lung volumes. For patients with COPD who exhibit thoracic hyperinflation, there is an increase in the functional residual capacity (FRC), which is the amount of air left in the lung after exhalation at rest. Therefore, these patients are breathing at higher lung volumes that perturb gas exchange. In addition, the increased FRC limits the inspiratory reserve capacity, which is the amount of air that the patient can inhale to fill the lungs. The increased FRC also limits the duration of inhalation time, and this has been associated with an increase in dyspnea complaints by patients.[1,2,5] Drug therapy for COPD, especially bronchodilators, can reduce thoracic hyperinflation by reducing airflow obstruction and air trapping. This explains the improvement in symptoms reported by patients with COPD despite minimal improvements in expiratory lung function with drug therapy.

Airflow limitation is assessed through spirometry, which represents the "gold standard" for diagnosing and monitoring COPD. The hallmark of COPD is a reduction in the ratio of FEV_1 to forced vital capacity (FVC) to less than 70%.[1,5] The FEV_1 generally is reduced, except in very mild disease, and the rate of FEV_1 decline is greater in COPD patients compared with that in normal subjects.

The impact of the numerous pathologic changes in the lung perturbs the normal gas-exchange and protective functions of the lung. Ultimately, these are exhibited through the common symptoms of COPD, including dyspnea and a chronic cough productive of sputum. As the disease progresses, abnormalities in gas exchange lead to hypoxemia and/or hypercapnia, although there often is not a strong relationship between pulmonary function and arterial blood gas (ABG) results.

Significant changes in ABGs usually are not present until the FEV_1 is less than 1 L.[1] In these patients, hypoxemia and hypercapnia can become chronic problems. Initially, when hypoxemia is present, it usually is associated with exertion. However, as the disease progresses, hypoxemia at rest develops. Patients with severe COPD can have a low arterial oxygen tension (pressure exerted by oxygen gas in arterial blood [PaO_2] = 45-60 mm Hg) and an elevated arterial carbon dioxide tension (pressure exerted by carbon dioxide gas in arterial blood [$PaCO_2$] = 50-60 mm Hg). The hypoxemia is attributed to hypoventilation ($\dot{V}$) of lung tissue relative to perfusion ($\dot{Q}$) of the area. This low ($\dot{V}/\dot{Q}$) ratio will progress over a period of several years, resulting in a consistent decline in the PaO_2. Some COPD patients lose the ability to increase the rate or depth of respiration in response to persistent hypoxemia. In addition as COPD progresses and lung function and gas exchange worsens, some patients exhibit chronic hypercapnia, and are referred to as carbon dioxide retainers. In these patients, the central respiratory response to a chronically increased $PaCO_2$ can be blunted. These changes in PaO_2 and $PaCO_2$ are subtle and progress over a period of many years. As a result, the pH usually is nearly normal because the kidneys compensate by retaining bicarbonate. If acute respiratory distress develops, such as might be seen in pneumonia or a COPD exacerbation with impending respiratory failure, the $PaCO_2$ may rise sharply, and the patient presents with a worsening respiratory acidosis.

The consequences of long-standing COPD and chronic hypoxemia include the development of secondary pulmonary hypertension that progresses slowly if appropriate treatment of COPD is not initiated. Pulmonary hypertension is the most common cardiovascular complication of COPD and can result in cor pulmonale, or right-sided heart failure.[14]

The elevated pulmonary artery pressures are attributed to vasoconstriction (in response to chronic hypoxemia), vascular remodeling, and loss of pulmonary capillary beds. When elevated pulmonary pressures

are sustained, cor pulmonale develops, characterized by hypertrophy of the right ventricle in response to increases in pulmonary vascular resistance. The risks of cor pulmonale include venous stasis with the potential for thrombosis and pulmonary embolism.

Another important systemic consequence of COPD is a loss of skeletal muscle mass and general decline in the overall health status. These changes are partially attributed to systemic inflammation which is a characteristic of COPD.[15] A consequence is widespread skeletal muscle dysfunction, especially in the leg muscles involved with ambulation.[15] The systemic manifestations can have devastating effects on overall health status and comorbidities. These include cardiovascular events associated with ischemia, cachexia, osteoporosis, anemia, and muscle wasting. There is some interest in the role of measuring C-reactive protein as a parameter to assess systemic inflammation and its impact on COPD severity; however, it is premature to recommend this strategy currently.[16]

CLINICAL PRESENTATION Symptoms

- Chronic cough
- Sputum production
- Dyspnea

Exposure to Risk Factors

- Tobacco smoke
- α_1-Antitrypsin deficiency
- Occupational hazards

Physical Examination

- Cyanosis of mucosal membranes
- Barrel chest
- Increased resting respiratory rate
- Shallow breathing
- Pursed lips during expiration
- Use of accessory respiratory muscles

Diagnostic Tests

- Spirometry with reversibility testing
- Radiograph of chest
- Arterial blood gas (not routinely assessed in chronic management; has utility in acute decompensation)

PATHOPHYSIOLOGY OF EXACERBATION

The natural history of COPD is characterized by recurrent exacerbations associated with increased symptoms and a decline in overall health status. An exacerbation is defined as a change in the patient's baseline symptoms (dyspnea, cough, or sputum production) beyond day-to-day variability sufficient to warrant a change in management.[1,6,17] Exacerbations have a significant impact on the natural course of COPD and occur more frequently for patients with more severe chronic disease. Because many patients experience chronic symptoms, the diagnosis of an exacerbation is based, in part, on subjective measures and clinical judgment; thus, it can be considered a syndrome. Exacerbations are significant events in that if they hasten disease progress. Additionally, exacerbations, especially those requiring hospitalization, are associated with an increased mortality risk.[17]

There are limited data about pathology during exacerbations owing to the nature of the disease and the condition of patients. However, inflammatory mediators including neutrophils and eosinophils are increased in the sputum. Chronic airflow limitation is a feature of COPD and may not change remarkably even during an exacerbation.[1] The lung hyperinflation present in chronic COPD is worsened during an exacerbation, which contributes to worsening dyspnea and poor gas exchange.

The primary physiologic change is often a worsening of ABG results due to poor gas exchange and increased muscle fatigue. For a patient experiencing a severe exacerbation, profound hypoxemia and hypercapnia can be accompanied by respiratory acidosis and respiratory failure.

CLINICAL PRESENTATION

The diagnosis of COPD is made based on the patient's symptoms, including cough, sputum production, and dyspnea, and a history of exposure to risk factors such as tobacco smoke and occupational exposures. Patients may experience cough for several years before dyspnea develops and often will not seek medical attention until dyspnea is significant. A diagnosis of COPD should be considered for any patient, age 40 years or older, with persistent or progressive dyspnea, with chronic cough productive of sputum, and who exhibits an unusual or abnormal decline in activity, especially in the presence of exposure to environmental tobacco smoke. In addition, the presence of genetic factors, including AAT deficiency, and occupational exposures should be evaluated because approximately 15% of patients with COPD do not have a history of cigarette smoking.

The presence of airflow limitation should be confirmed with spirometry. Spirometry represents a comprehensive assessment of lung volumes and capacities. The hallmark of COPD is an FEV_1:FVC ratio of less than 70%, which indicates airway obstruction.[1] A fixed ratio of less than 70% may be problematic because normal aging may affect this result; however, it continues to be the current standard. Previous criteria for the diagnosis of COPD included measuring the degree of airflow limitation before and after inhaled bronchodilator challenge. It is no longer recommended to obtain pre-bronchodilator values or to calculate the degree of reversibility in order to diagnose COPD (**Table 27-4**).[1] Post-bronchodilator spirometry results should be used in assessing lung function in patients with COPD. The use of peak expiratory flow measurements as a diagnostic tool is not adequate for COPD due to low specificity and the high degree of effort dependence; however, a low peak expiratory flow is consistent with the clinical presentation of COPD. A comprehensive discussion about spirometry can be found in Chapter 26.

TABLE 27-4 Procedures for Postbronchodilator Testing

Preparation

Tests should be performed when patients are clinically stable and free from respiratory infection.

Patient must be able to participate with maximal effort during test.

Spirometry

Bronchodilators can be given by either metered-dose inhaler or nebulization.

Usual doses are 400 mcg of β-agonist, 160 mcg of anticholinergic, or the two combined.

FEV_1 should be measured 10-15 minutes after a short-acting β-agonist or 30-45 minutes after a short-acting anticholinergic or combination.

Results

Airflow limitation is confirmed by a postbronchodilator $FEV_1/FVC < 0.70$.

Data from reference 1.

Spirometry combined with a physical examination improves the diagnostic accuracy of COPD.[1,4] Spirometry also is useful to determine the severity of airflow limitation. Patients with all levels of severity of COPD exhibit the hallmark finding of airflow obstruction, specifically, a reduction in the FEV_1/FVC ratio to less than 70%. FVC is the total amount of air exhaled after a maximal inhalation. Currently, the GOLD consensus guidelines suggest a four-grade classification of airflow limitation (**Table 27-5**). Patients in GOLD 3 or 4 have the most significant airflow limitation and are at the highest risk for future exacerbations, while patients in GOLD 1 and 2 have less airflow limitation and are at lower risk for exacerbations.

TABLE 27-5 Classification of Severity of Airflow Obstruction (Based on Postbronchodilator FEV_1)

GOLD 1: mild

$FEV_1/FVC < 70\%$

$FEV_1 \geq 80\%$

With or without symptoms

GOLD 2: moderate

$FEV_1/FVC < 70\%$

$50\% \leq FEV_1 < 80\%$

With or without symptoms

GOLD 3: severe

$FEV_1/FVC < 70\%$

$30\% \leq FEV_1 < 50\%$

With or without symptoms

GOLD 4: very severe

$FEV_1/FVC < 70\%$

FEV_1 <30%

Data from reference 1.

Dyspnea is typically the most troublesome complaint for the patient with COPD and often is the stimulus for the patient seeking medical attention. It can impair exercise performance and functional capacity and is frequently associated with depression and anxiety. Together, these have a significant effect on health-related quality of life.[1,4,5] As a subjective symptom, dyspnea is often difficult for the clinician to assess. Various tools are available to evaluate the severity of dyspnea. The modified Medical Research Council (mMRC) scale is commonly employed and categorizes dyspnea grades from 0 to 4.[1,3] In recent years, the impact of COPD on other measures of health status has been recognized and newer patient assessment tools, such as COPD assessment Test (CAT) and Clinical COPD Questionnaire (CCQ), include more items related to overall symptoms and activities.[18,19] Currently, there are three patient assessment questionnaires that are amenable to use in routine clinical practice and are recommended by international guidelines (**Table 27-6**).[1]

TABLE 27-6 Comparison of Patient Assessment Questionnaires Used in COPD

Name	Description of Scoring System	Link to Assessment Tool
COPD Assessment Test (CAT)	• Includes 8 items related to health status and impact of COPD on daily activities • Each item scored 0-5 with additive total score of 40 • Score of <10 means less symptoms • Score of ≥10 means more symptoms	**http://catestonline.org**
Modified Medical Research Council Dyspnea Questionnaire (mMRC)	• Includes 5 descriptive statements related to dyspnea only • Patient chooses most appropriate statement • Each statement corresponds to score of 0-4 • Score of <2 means less symptoms • Score of ≥2 means more symptoms	**http://www.goldcopd.org**
Clinical COPD Questionnaire (CCQ)	• Includes 10 items in 3 domains related to symptoms, functional state, mental state • Assesses clinical control of disease in past week	**http://www.ccq.nl**

Name	Description of Scoring System	Link to Assessment Tool
	• Score weighted for each domain • Score <1 means less symptoms[a] • Score ≥1 means more symptoms[a]	

[a]Exact cut point values have not yet been established for this assessment questionnaire.

Previously, guidelines have defined disease severity solely by spirometry. Observations that patients with similar spirometric parameters exhibit variations in symptom severity and risk of adverse health events, such as exacerbations, have led to a revision in severity classification. In order to incorporate multiple factors that contribute to disease risk, the revised GOLD consensus guidelines recommend that three separate parameters be assessed when classifying disease severity. Parameters include an assessment of airflow limitation by spirometry, measurement of symptom severity, and an assessment of exacerbation frequency. Symptom assessment should be measured at baseline and then during routine visits using CAT, mMRC or CCQ. Defined cut points for patients exhibiting "more symptoms" and "less symptoms" have been established for CAT and mMRC but are not as well defined for CCQ. Until further evaluated, it is reasonable to define "more symptoms" as a CCQ score greater than 1 to 1.5.[1] Frequency of exacerbations can be assessed either by predicted risk of future exacerbations based on classification of airflow limitation or through a review of exacerbation history for the past 12 months. Patients with at least two exacerbations in the last 12 months, or one exacerbation requiring hospitalization, would be considered high risk for future exacerbations. If both methods of exacerbation risk are assessed, the method with the highest risk result should be used to classify the patient (**Table 27-7**).

TABLE 27-7 Combined Assessment of COPD Severity

Patient Category	Description	Spirometry	Exacerbations in Last Year[a]	CAT	mMRC	CCQ
A	Less symptoms; low risk	FEV_1 ≥ 50% of predicted	0-1	<10	0-1	0-1
B	More symptoms; low risk	FEV_1 ≥ 50% of predicted	0-1	≥10	≥2	≥1
C	Less symptoms; high risk	FEV_1 < 50% of predicted	≥2	<10	0-1	0-1
D	More symptoms; high risk	FEV_1 < 50% of predicted	≥2	≥10	≥2	≥1

[a]> exacerbation, or one requiring hospitalization equals high risk (e.g. Patient Category C or D)

Data from reference 1.

While a physical examination is appropriate in the diagnosis and assessment of COPD, most patients who present in the milder stages of COPD will have a normal physical examination. In later stages of the disease, when airflow limitation is severe, patients may have cyanosis of mucosal membranes, development of "barrel chest" due to hyperinflation of the lungs, an increased respiratory rate and shallow breathing, and changes in breathing mechanics such as pursing of the lips to help with expiration or use of accessory respiratory

muscles.

Classification Based on Severity

In 2011, the GOLD guidelines included a modified system for classifying COPD based on severity. As discussed above, the new system is based on numerous factors that have a significant impact on the patient, including the degree of airflow obstruction, the frequency and severity of symptoms, and the frequency of exacerbations (see Table 27-7). A patient can first be classified according to the severity of airflow obstruction into grades ranging from 1 to 4 (see Table 27-5). Then the patient is placed into a group (Patient Category A, B, C, or D) based on the impact of symptoms and the risk for future exacerbations. The extent of symptoms is assessed using a validated symptom assessment tool (eg, mMRC, CAT or CCQ). Finally, the risk for an exacerbation is based on previous exacerbations. A patient is categorized based on a history of less than two annual exacerbations, or two or more. A history of at least one exacerbation requiring hospitalization in the past 12 months automatically places the patient in Patient Category C or D. This new classification system by group provides an appropriate emphasis for each of the parameters included (see Table 27-7). Another advantage is that classifying patients according to these groups informs treatment decisions.

Prognosis

For the patient with COPD, the combination of impaired lung function and recurrent exacerbations promotes a clinical scenario characterized by dyspnea, reduced exercise tolerance and physical activity, and deconditioning. These factors lead to disease progression, poor quality of life, possible disability, and premature mortality. COPD is ultimately a fatal disease if it progresses and advanced directives and end-of-life care options are appropriate to consider. The primary causes of death of patients with COPD include respiratory failure, cardiovascular events or diseases, and lung cancer.[1]

Patients with COPD are a heterogeneous group and multiple factors, such as airflow limitation, age, frequency and severity of exacerbations, and comorbidities, have been implicated in rate of disease progression and prognosis.[20] The mortality rate of patients with COPD increases with worsening airflow limitation. In the Towards a Revolution in COPD Health (TORCH) and Understanding Potential Long-Term Impacts on Function with Tiotropium (UPLIFT) trials, 3-year mortality in patients with COPD was reported to be 11% for GOLD 2 (moderate airflow limitation), 15% for GOLD 3 (severe airflow limitation), and 24% for GOLD 4 (very severe airflow limitation).[21,22]

The average rate of decline of FEV_1 is a useful objective measure to assess the course of COPD over time. However, patients with similar FEV_1 values may differ in the frequency and severity of symptoms and exacerbation history, thus emphasizing the need for a combined assessment for all patients. The average rate of decline in FEV_1 for healthy, nonsmoking patients owing to age alone is 25-30 mL/y. The rate of decline for smokers is steeper, especially for heavy smokers compared with light smokers. The decline in pulmonary function is a steady curvilinear path. The more severely diminished the FEV_1 at diagnosis, the steeper is the rate of decline. Greater numbers of years of smoking and number of cigarettes smoked also correlate with a steeper decline in pulmonary function.[1,5,13] Patients with COPD should have spirometry performed at least annually to assess disease progression. At each clinic visit, patients should be assessed for smoking cessation readiness, if applicable, symptoms and impact on daily activities, and exacerbation history.[1]

Pulmonary gas exchange, affecting both oxygenation and expiration of carbon dioxide, can be impaired in severe disease. Pulse oximetry measures oxygen saturation in the blood and is useful to assess need for

supplemental oxygen therapy. It is recommended for all stable patients with FEV_1 less than 35% of predicted and for unstable patients who have signs of respiratory failure, severe exacerbation, or right heart failure.[1] For patients with an oxygen saturation less than 92%, an ABG should be obtained to assess the pO_2 more precisely and to evaluate for hypercapnia.

Asthma is usually differentiated from COPD based on the patient's medical history, risk factors, and improvements on postbronchodilator spirometry; however, in some cases, asthma patients exhibit COPD-like features and COPD patients exhibit asthma-like features. It is also possible for the two conditions to coexist. This coexistence of conditions has been termed "asthma and COPD overlap syndrome" (ACOS) and has been included in the most recent update of the international COPD guidelines.[1] Phenotypes of patients who may meet the ACOS features include those with partially reversible airflow obstruction, an atopic symptoms, and minimal smoking history. Optimal management strategies for a patient with ACOS is not clear; however, there is evidence that this condition is associated with substantially greater treatment costs compared to asthma alone.[2,3]

CLINICAL PRESENTATION OF COPD EXACERBATION

Because of the subjective nature of defining an exacerbation of COPD, the criteria used among clinicians vary widely; however, most rely on a change in one or more of the following clinical findings: worsening symptoms of dyspnea, increase in sputum volume, or increase in sputum purulence. Acute exacerbations have a significant impact of the economics of treating COPD as well, estimated at 35% to 45% of the total costs of the disease in some settings.[2,13,17]

A widely accepted definition of an exacerbation is that it is an event in the natural course of COPD that is characterized by a worsening in baseline dyspnea, cough, and/or sputum that is beyond the normal day-to-day variation, is acute in onset, and may warrant a change in regular medication. With an exacerbation, patients using rapid-acting bronchodilators may report an increase in the frequency of use. Exacerbations are commonly staged as mild, moderate, or severe according to the criteria summarized in **Table 27-8**.[1]

TABLE 27-8 Staging Acute Exacerbations of COPD[a]

Mild (type 1)	One cardinal symptom[a] plus at least one of the following: URTI[b] within 5 days, fever without other explanation, increased wheezing, increased cough, increase in respiratory or heart rate >20% above baseline
Moderate (type 2)	Two cardinal symptoms[a]
Severe (type 3)	Three cardinal symptoms[a]

[a]Cardinal symptoms include worsening of dyspnea, increase in sputum volume, and increase in sputum purulence.

[b]URTI, upper respiratory tract infection.

An important complication of a severe exacerbation is acute respiratory failure. In the emergency department or hospital, an ABG usually is obtained to assess the severity of an exacerbation. The diagnosis of acute respiratory failure in COPD is made based on an acute change in the ABGs. Defining acute respiratory failure

as a PaO_2 of less than 50 mm Hg or a $PaCO_2$ of greater than 50 mm Hg often may be incorrect and inadequate because these values may not represent a significant change from a patient's baseline values. A more precise definition is an acute drop in PaO_2 of 10 to 15 mm Hg or any acute increase in $PaCO_2$ that decreases the serum pH to 7.3 or less. Additional acute clinical manifestations of respiratory failure include restlessness, confusion, tachycardia, diaphoresis, cyanosis, hypotension, irregular breathing, miosis, and unconsciousness.

Prognosis

Chronic obstructive pulmonary disease exacerbations are associated with significant morbidity and mortality. While mild exacerbations may be managed at home, mortality rates are higher for patients admitted to the hospital. COPD exacerbations contribute to in hospital mortality and deaths after discharge, in addition to hastening the decline of lung function. Many patients experiencing an exacerbation do not have a return to their baseline clinical status for several weeks, significantly affecting their quality of life. Additionally, as many as half the patients originally hospitalized for an exacerbation are readmitted within 6 months.[2,6,17]

There is good evidence that acute exacerbations of COPD have a tremendous impact on disease progression and ultimate mortality. For exacerbations requiring hospitalizations, mortality rates range from 22% to 43% after 1 year, and 36% to 49% in 2 years.[24,25]

TREATMENT

Chronic Obstructive Pulmonary Disease

Desired Outcome

Given the nature of COPD, a major focus in healthcare should be on prevention. However, for patients with a diagnosis of COPD, the primary goal is to prevent or minimize progression. Specific goals of management are listed in **Table 27-9**. The primary goal of pharmacotherapy has been relief of symptoms, including dyspnea. However, more recently there has been increased interest in the value of therapeutic interventions that reduce exacerbation frequency and severity, as well as reduce mortality. In fact, a reduction in exacerbation frequency is an important outcome measure to consider when evaluating the role and benefit of individual chronic therapies used in COPD management.

TABLE 27-9 Goals of COPD Management

Prevent disease progression
Relieve symptoms
Improve exercise tolerance
Improve overall health status
Prevent and treat exacerbations
Prevent and treat complications
Reduce morbidity and mortality

CLINICAL PRESENTATION Features of COPD Exacerbation Symptoms

- Increased sputum volume
- Acutely worsening dyspnea
- Chest tightness
- Presence of purulent sputum
- Increased need for bronchodilators
- Malaise, fatigue
- Decreased exercise tolerance

Physical Examination

- Fever
- Wheezing, decreased breath sounds

Diagnostic Tests

- Sputum sample for Gram stain and culture
- Chest radiograph to evaluate for new infiltrates

Optimally, these goals can be accomplished with minimal risks or side effects. The therapy of the patient with COPD is multifaceted and includes pharmacologic and nonpharmacologic strategies. Appropriate measures of effectiveness of the management plan include continued smoking cessation, symptom improvement, reduction in FEV_1 decline, reduction in the number of exacerbations, improvements in physical and psychological well-being, and reduction in mortality, hospitalizations, and days lost from work.

Unfortunately, most treatments for COPD have not been shown to improve survival or to slow the progressive decline in lung function. However, many therapies do improve pulmonary function and quality of life and reduce exacerbations and duration of hospitalization. Several disease-specific quality-of-life measures are available to assess the overall efficacies of therapies for COPD, including the CAT, CCQ, Chronic Respiratory Questionnaire (CRQ), and the St. George's Respiratory Questionnaire (SGRQ). These questionnaires measure the impact of various therapies on such disease variables as severity of dyspnea and level of activity. They do not measure impact of therapies on survival. While earlier studies of COPD therapies focused primarily on improvements in pulmonary function measurements such as FEV_1, there is a trend towards greater use of these disease-specific quality-of-life measures to evaluate the benefits of therapy on larger clinical outcomes.

General Approach to Treatment

To be effective, the clinician should address four primary components of management: assess and monitor the condition, avoid or reduce exposure to risk factors, manage stable disease, and treat exacerbations. These components are addressed through a variety of nonpharmacologic and pharmacologic approaches.

Nonpharmacologic Therapy

Patients with COPD should receive education about their disease, treatment plans, and strategies to slow progression and prevent complications.[1,5] Advice and counseling about smoking cessation are essential, if applicable, and should be addressed for patients in all stages of the disease. Because the natural course of the disease leads to respiratory failure, the clinician should address end-of-life decisions and advanced directives prospectively with the patient and family. Increasingly, palliative care services, which include both end-of-life and hospice care for patients with all types of life-threatening acute and chronic illnesses, have been utilized for patients with severe COPD.[26]

Smoking Cessation

5 Smoking cessation represents the single most important intervention in preventing the development, as well as the progression, of COPD. A primary component of COPD management is avoidance of or reduced exposure to risk factors. Exposure to environmental tobacco smoke is a major risk factor, and smoking cessation is the most effective strategy to reduce the risk of developing COPD and to slow or stop disease progression. The cost-effectiveness of smoking-cessation interventions compares favorably with interventions made for other major chronic diseases.[1,4,5] The importance of smoking cessation cannot be overemphasized. Smoking cessation leads to decreased symptomatology and slows the rate of decline of pulmonary function even after significant abnormalities in pulmonary function tests have been detected. As confirmed by the Lung Health Study, smoking cessation is the only intervention proven to affect long-term decline in FEV_1 and slow the progression of COPD.[27] In this 5-year prospective trial, smokers with early COPD were randomly assigned to one of the following three groups: smoking-cessation intervention plus inhaled ipratropium three times a day, smoking-cessation intervention alone, or no intervention. During an 11-year followup, the rate of decline in FEV_1 among subjects who continued to smoke was more than twice the rate in sustained quitters. Smokers who underwent smoking-cessation intervention had fewer respiratory symptoms and a smaller annual decline in FEV_1 compared with smokers who had no intervention. However, this study also demonstrated the difficulty in achieving and sustaining successful smoking cessation.

Tobacco cessation has mortality benefits beyond those related to COPD. A follow-up analysis of the Lung Health Study data conducted more than 14 years later demonstrated an 18% reduction in all-cause mortality in patients who received the intervention compared with usual care.[47] Intervention patients had lower death rates due to coronary artery disease (the leading cause of mortality), cardiovascular diseases, and lung cancer, although all categories did not reach clinical significance.

Every clinician has a responsibility to assist smokers in smoking-cessation efforts. A clinical practice guideline for treating tobacco dependence from the US Public Health Service (PHS) was last updated in 2008.[28] The major findings and recommendations of that report are summarized in **Table 27-10**. A more recent review of tobacco cessation strategies, including the potential role of electronic nicotine dispensing systems (eg, e-cigarettes), was published in 2015.[29] Since 2004, reports from the Surgeon General on the health consequences of smoking have emphasized the detrimental effects of cigarette smoking on the general health of smokers and individuals exposed to secondhand smoke. It is estimated that over 20 million Americans have died prematurely from exposure to cigarette smoking since 1964.

TABLE 27-10 Key Guideline Recommendations Regarding Tobacco Use and Dependence

Tobacco dependence is a chronic disease that often requires repeated intervention and multiple attempts to quit. Effective treatments are available that can significantly improve rates of long-term abstinence.
Clinicians and healthcare delivery systems should consistently identify and document tobacco use status and

treat every tobacco user.

Tobacco-dependence treatments are effective over a broad range of populations. Clinicians should encourage every patient willing to make a quit attempt to use counseling treatments and medications recommended in the guideline.

Brief tobacco-dependence treatments are effective. Clinicians should offer every patient who uses tobacco at least these brief treatments.

Individual, group, and telephone counseling are effective, and their effectiveness increases with treatment intensity. Practical counseling (problem-solving and/or skills training) and social support are especially effective and should be employed as a part of treatment.

There are numerous effective medications for tobacco dependence, and clinicians should encourage their use by patients during a quit attempt, except when medically contraindicated or with populations in which the evidence of effectiveness is insufficient (pregnancy, smokeless tobacco users, light smokers, and adolescents). Seven first-line medications (5 nicotine and 2 non-nicotine) consistently increase long-term abstinence rates. Clinicians should also consider the use of combinations as identified in the guideline.

Counseling and medication are effective when used by themselves for treating tobacco dependence. The combination of the two is more effective than either alone. Patients should be encouraged to use both counseling and medication.

Telephone quitline counseling is effective for diverse populations and offers the advantage of broad reach. Clinicians should ensure patient access to quitlines and promote quitline use.

For a tobacco user who is currently unwilling to make a quit attempt, clinicians should use motivational treatments that have been shown to be effective in increasing future quit attempts.

Tobacco-dependence treatments are both clinically effective and highly cost-effective relative to interventions for other clinical disorders. Providing coverage for these treatments increases quit rates. Insurers and purchasers should ensure that all insurance plans include the counseling and medications identified as effective in the guideline as covered benefits.

Data from reference 28.

All clinicians should take an active role in assisting patients with tobacco dependence in order to reduce the burden on the individual, his or her family, and the healthcare system. It is estimated that over 75% of smokers want to quit and that one-third have made a serious effort. Yet complete and permanent tobacco cessation is difficult.[28,29] Counseling that is provided by clinicians is associated with greater success rates than self-initiated efforts.

The PHS guidelines recommend that clinicians take a comprehensive approach to smoking-cessation counseling. Advice should be given to smokers even if they have no symptoms of smoking-related disease or if they are receiving care for reasons unrelated to smoking. Clinicians should be persistent in their efforts because relapse is common among smokers owing to the chronic nature of dependence. Brief interventions (3 minutes) of counseling are proven effective. However, it must be recognized that the patient must be ready to stop smoking because there are several stages of decision making. Based on this, a five-step intervention program is proposed (**Table 27-11**).

TABLE 27-11 Five-Step Strategy for Smoking-Cessation Program (5 A's)

Ask	Use systematic approach to identify all tobacco users.
Advise	Urge all tobacco users to quit.
Assess	Determine willingness to make a cessation attempt.
Assist	Provide support for the patient to quit smoking.
Arrange	Schedule follow-up and monitor for continued abstinence.

There is strong evidence to support the use of pharmacotherapy to assist in smoking cessation. In fact, it should be offered to most patients as part of a cessation attempt. In general, available therapies will double the effectiveness of a cessation effort. Agents that are considered first line are listed in **Table 27-12**. The usual duration of therapy is 8 to 12 weeks, although some individuals may require longer courses of treatment. Precautions to consider before using bupropion include a history of seizures or an eating disorder. Nicotine replacement therapies are contraindicated for patients with unstable coronary artery disease, active peptic ulcers, or recent myocardial infarction or stroke. Nicotine patch, bupropion, and the combination of bupropion and the nicotine patch were compared with placebo in a controlled trial.[30] The treatment groups that received bupropion had higher rates of smoking cessation than the groups that received placebo or the nicotine patch. The addition of the nicotine patch to bupropion slightly improved the smoking-cessation rate compared with bupropion monotherapy. Varenicline, a nicotine acetylcholine receptor partial agonist, relieves physical withdrawal symptoms and reduces the rewarding properties of nicotine. Nausea and headache are the most frequent complaints associated with varenicline. Currently, varenicline has not been studied in combination with other tobacco cessation therapies. Second-line agents are less effective or associated with greater side effects; however, they may be useful in selected clinical situations. These therapies include clonidine and nortriptyline, a tricyclic antidepressant. Given the significant increase in use of e-cigarettes and other electronic nicotine delivery systems (ENDS), there is interest in the potential role of these agents as a smoking cessation strategy. It is not clear that substituting ENDS for traditional smoking aids with tobacco cessation.[29] These agents should not be recommended as part of a smoking related strategy until additional evidence is available.

TABLE 27-12 First-Line Pharmacotherapies for Smoking Cessation

Agent	Usual Dose	Duration	Common Complaints
Bupropion SR	150 mg orally daily for 3 days, then twice daily	12 weeks, up to 6 months	Insomnia, dry mouth
Nicotine gum	2-4 mg gum prn, up to 24 pieces daily	12 weeks	Sore mouth, dyspepsia
Nicotine inhaler	6-16 cartridges daily	Up to 6 months	Sore mouth and throat
Nicotine nasal spray	8-40 doses daily	3-6 months	Nasal irritation
Nicotine patches	Various, 7-21 mg every 24 hours	Up to 8 weeks	Skin reaction, insomnia
Varenicline	0.5 mg daily orally for 3 days, then 0.5 mg twice daily for 4 days, then 1 mg twice daily	12 weeks	Nausea, sleep disturbances

Behavioral modification techniques or other forms of psychotherapy also may be helpful in assisting in

smoking cessation. Programs that address the many issues associated with smoking (ie, learned behaviors, environmental influences, and chemical dependence) using a team approach are more likely to be successful. The role of alternative medicine therapies in smoking cessation is controversial. Hypnosis may aid in improving abstinence rates when added to a smoking-cessation program but appears to give little benefit when used alone.

Other Environmental Triggers

Although cigarette smoke represents the overwhelming majority of risk for developing COPD, exposure to other environmental toxins also confers risks.[1] Exposures to occupational dusts and fumes have been implicated as a cause of COPD in 19% of smokers and 31% of nonsmokers with COPD in the United States. In the case of known environmental hazards, primary prevention is appropriate. Policies to limit airborne exposures in the workplace and outdoors, as well as education efforts of workers and policy makers, are recommended.

Pulmonary Rehabilitation

Exercise training is beneficial in the treatment of COPD to improve exercise tolerance and to reduce symptoms of dyspnea and fatigue.[1,3,5] Pulmonary rehabilitation programs are an integral component in the management of COPD and should include exercise training along with smoking cessation, breathing exercises, optimal medical treatment, psychosocial support, and health education. Pulmonary rehabilitation has no direct effect on lung function or gas exchange. Instead, it optimizes other body systems so that the impact of poor lung function is minimized. Exercise training reduces the CNS response to dyspnea, ameliorates anxiety and depression, reduces thoracic hyperinflation, and improves skeletal muscle function.[15] High-intensity training (70% maximal workload) is possible even in advanced COPD patients, and the level of intensity improves peripheral muscle and ventilatory function. Studies have demonstrated that pulmonary rehabilitation with exercise three to seven times per week can produce long-term improvement in activities of daily living, quality of life, exercise tolerance, and dyspnea for patients with moderate-to-severe COPD.[31] Improvements in dyspnea can be achieved without concomitant improvements in spirometry. While rehabilitation programs vary based on length of program, and exercise frequency and intensity, those with longer length and more frequent sessions have demonstrated the best clinical benefit.

Immunizations

Vaccines can be considered as pharmacologic agents; however, their role is described here in reducing risk factors for COPD exacerbations. Because influenza is a common complication in COPD that can lead to exacerbations and respiratory failure, an annual vaccination with the inactivated intramuscular influenza vaccine is recommended. Immunization against influenza can reduce serious illness and death by 50% in COPD patients.[32] Influenza vaccine should be administered annually during each influenza season. Vaccination against influenza can begin as early as August, with most patients being vaccinated during regular medical visits or at vaccination clinics in October and November. COPD patients should receive an inactivated form of the influenza virus vaccine. An oral antiinfluenza agent (oseltamivir) can be considered for patients with COPD during an outbreak for patients who have not been immunized; however, this therapy is less effective and causes more side effects.[33]

The Centers for Disease Control and Prevention (CDC) and the American Lung Association recommend the 23-valent pneumococcal polysaccharide vaccine (PPSV23) for people from 2 to 64 years of age who have

chronic lung disease and for all people older than 65 years.[33] In 2009, the CDC added smokers over the age of 18 years to the recommendations. Although evidence for the benefit of the polysaccharide pneumococcal vaccine in COPD is not strong, the argument for continued use is that the current vaccine provides coverage for 85% of pneumococcal strains causing invasive disease and the increasing rate of resistance of pneumococcus to selected antibiotics.[34] Currently, administering the vaccine remains the standard of practice and is recommended by the CDC and the American Lung Association. The GOLD guidelines recommend immunization with pneumococcal polysaccharide vaccine for all COPD patients who are 65 years and older and for patients less than 65 years only if the FEV_1 is less than 40% predicted.[1] Repeated vaccination with the 23-valent product is not recommended for patients aged 2 to 64 years with chronic lung disease; however, revaccination is recommended for patients over 65 years of age if the first vaccination was more than 5 years earlier and the patient was younger than age 65. In 2014, the Advisory Committee on Immunization Practices (ACIP) recommended vaccination with the 13-valent pneumococcal conjugate vaccine (PCV13) for all adults aged 65 years or older. This recommendation will impact the immunization strategies for patients with COPD. At age 65, it is recommended to administer PCV13 followed in 1 year with PPSV23, as long as at least 5 years have passed since the previous PPSV23.

Long-Term Oxygen Therapy

6 The use of supplemental oxygen therapy increases survival in COPD patients with chronic hypoxemia. Although long-term oxygen has been used for many years for patients with advanced COPD, it was not until 1980 that data became available documenting its benefits. At that time, the Nocturnal Oxygen Therapy Trial Group published its data comparing nocturnal oxygen therapy (NOT), 12 h/day, with continuous oxygen therapy (COT), average of 20 h/day.[35] Among patients who were followed for at least 12 months, the results revealed a mortality rate in the NOT group that was nearly double that of the COT group (51% vs 26%). Statistical estimates of the COT group suggest that COT may have added 3.25 years to a COPD patient's life. Additional data from the Nocturnal Oxygen Therapy Trial Group revealed that COT patients had fewer (but statistically insignificant) hospitalizations, improved quality of life and neuropsychological function, reduced hematocrit, and decreased pulmonary vascular resistance.[35]

The decline in mortality with oxygen therapy is proven with 15 h/day of oxygen versus no supplemental oxygen in COPD patients. Patients receiving oxygen therapy for at least part of the day have lower rates of mortality than those not receiving oxygen. Long-term oxygen therapy provides even more benefit in terms of survival after at least 5 years of use, and it improves the quality of life of these patients by increasing walking distance and neuropsychological condition and reducing time spent in the hospital.[1,4,5] Before patients are considered for long-term oxygen therapy, they should be stabilized in the outpatient setting, and pharmacotherapy should be optimized. Once this is accomplished, long-term oxygen therapy should be instituted if either of the following two conditions is observed and documented twice in a 3-week period:

1. A resting PaO_2 of less than 55 mm Hg or SaO_2 less than 88% with or without hypercapnia.
2. A resting PaO_2 between 55 and 60 mm Hg or SaO_2 less than 88% with evidence of right-sided heart failure, polycythemia, or pulmonary hypertension.

The most practical means of administering long-term oxygen is with the nasal cannula, at 1 to 2 L/min, which provides 24% to 28% oxygen. The goal is to raise the PaO_2 above 60 mm Hg. Patient education about flow rates and avoidance of flames (ie, smoking) is of the utmost importance.

There are three different ways to deliver oxygen, including (a) in liquid reservoirs, (b) compressed into a cylinder, and (c) via an oxygen concentrator. Although conventional liquid oxygen and compressed oxygen are quite bulky, smaller, portable tanks are available to permit greater patient mobility. Oxygen concentrator devices separate nitrogen from room air and concentrate oxygen. These are the most convenient and the least expensive method of oxygen delivery. Oxygen-conservation devices are available that allow oxygen to flow only during inspiration, making the supply last longer. These may be particularly useful to prolong the oxygen supply for mobile patients using portable cylinders. However, the devices are bulky and subject to failure.

Adjunctive Therapies

In addition to supplemental oxygen, adjunctive therapies to consider as part of a pulmonary rehabilitation program are psychoeducational care and nutritional support. Psychoeducational care (such as relaxation) has been associated with improvement in the functioning and well-being of adults with COPD.[1,4] The role of nutritional support for patients with COPD is controversial. Several studies have shown an association among malnutrition, low body mass index (BMI), and impaired pulmonary status among patients with COPD. However, results from multiple studies suggest that the effect of nutritional support on physical and functional outcomes in COPD is small and may be most beneficial for malnourished patients.[36]

Pharmacologic Therapy

Results from numerous clinical trials have improved insight and understanding about the respective roles of various medications used in chronic COPD management. Yet, some controversies still exist related to both effectiveness and safety. In contrast to the survival benefit conferred by supplemental oxygen therapy, there is no medication available for the treatment of COPD that has been conclusively shown to modify the progressive decline in lung function or prolong survival.[1,4,5] There is limited evidence that chronic treatment with pharmacotherapy can reduce the rate of decline in spirometry in a subset of patients with more severe disease. Currently, the primary goal of pharmacotherapy is to control patient symptoms and reduce complications, including the frequency and severity of exacerbations, and improving the overall health status and exercise tolerance of the patient.

Currently available inhalational therapies for COPD are summarized in **Tables 27-13** and **27-14**. International guidelines recommend a stepwise approach to the use of pharmacotherapy based on disease severity, which is determined by the results of spirometry, nature of symptoms, and exacerbation rates.[1,5] The impact of recurrent exacerbations on accelerating disease progression is increasingly recognized as an important factor to be considered. The primary goals of pharmacotherapy are to control symptoms (including dyspnea), reduce exacerbations, and improve exercise tolerance and health status. Currently, there is inadequate evidence to support the use of more aggressive pharmacotherapy early in the course of disease because of the lack of a disease-modifying benefit. Because of the progressive nature of COPD, pharmacotherapy tends to be chronic and cumulative and step-down approaches in stable patients are not successful, although recent evidence suggests that this practice requires further evaluation. Patients exhibit variable responses to available therapies and the treatment approach should be individualized.

TABLE 27-13 Recommended Pharmacologic Therapy for Stable COPD

Patient Category	First Choice	Second Choice	Alternate Therapy
A (less symptoms, less risk)	SABA prn or SAMA prn	LAMA or LABA or SAMA and SABA	Theophylline

Patient Category	First Choice	Second Choice	Alternate Therapy
B (more symptoms, less risk)	LAMA or LABA	LAMA and LABA	SABA and/or SAMA theophylline
C (less symptoms, more risk)	ICS and LABA or LAMA	LAMA and LABA or LAMA and PDE4I or LABA and PDE4I	SABA and/or SAMA theophylline
D (more symptoms, more risk)	ICS and LABA and/or LAMA	ICS and LABA and LAMA or ICS and LABA and PDE4I or LAMA and LABA or LAMA and PDE4I	SABA and/*or* SAMA Theophylline

ICS, inhaled corticosteroids; LABA, long acting beta agonist; LAMA, long-acting muscarinic antagonists; PDE4I, phosphodiesterase type 4 inhibitor (roflumilast); SABA, short acting beta-agonist; SAMA, short-acting muscarinic antagonists.

TABLE 27-14 COPD Medication Chart

Brand Name	Device	SABA	SAMA	ICS	LABA	LAMA	Other	Dosing
Proair, Ventolin, Proventil		Albuterol						
	MDI	90 mcg						1-2 puffs q4-6h prn
Xopenex		Levalbuterol						
	MDI	45 mcg						1-2 puffs q4-6h prn
Combivent		Albuterol	Ipratropium					
	Respimat	100 mcg	20 mcg					1 puff q6h
Atrovent			Ipratropium					
	MDI		17 mcg					2 puffs q6h
Advair				Fluticasone	Salmeterol			
	MDI			45, 115, 230 mcg	21 mcg			2 puffs BID
	Diskus			100 mcg	50 mcg			1 puff BID
				250 mcg	50 mcg			1 puff BID

Brand Name	Device	SABA	SAMA	ICS	LABA	LAMA	Other	Dosing
				500 mcg	50 mcg			1 puff BID
Symbicort				Budesonide	Formoterol			
	MDI			80 mcg	4.5 mcg			2 puffs BID
				160 mcg	4.5 mcg			2 puffs BID
Breo	Ellipta			Fluticasone	Vilanterol			
				100 mcg	25 mcg			1 puff once daily
				200 mcg	25 mcg			1 puff once daily
Serevent	Diskus				Salmeterol			
					50 mcg			1 puff BID
Foradil	Aerolizer				Formoterol			
					12 mcg			1 puff BID
Striverdi	Respimat				Olodaterol			
					2.5 mcg			2 puffs once daily
Arcapta	Neohaler				Indacaterol			
					75 mcg			1 puff once daily
Anoro	Ellipta				Vilanterol	Umeclidinium		
					25 mcg	62.5 mcg		1 puff once daily
Stiolto	Respimat				Olodaterol	Tiotropium		
					2.5 mcg	2.5 mcg		2 puffs once daily
Spiriva	Handihaler					Tiotropium		
	Respimat					18 mcg		1 puff once daily

Brand Name	Device	SABA	SAMA	ICS	LABA	LAMA	Other	Dosing
						2.5 mcg		2 puffs once daily
Tudorza	Pressair					Aclidinium 400 mcg		1 puff BID
Incruse	Ellipta					Umeclidinium 62.5 mcg		1 puff once daily
Utibron	Neohaler				Indacaterol 27.5 mcg	Glycopyrrolate 15.6 mcg		1 puff twice daily
Seebri	Neohaler					Glycopyrrolate 15.6 mcg		1 puff twice daily
Daliresp	(Oral)						Roflumilast (PDE-4 Inhibitor)	500 mcg orally daily
Theophylline	Oral						PDE inhibitor; Adenosine Antagonist	Variable dosing in Patients

Pharmacotherapy of COPD typically involves the use of inhaled medications, requiring patient knowledge, understanding, and skills using the various inhalation devices. Several delivery devices are available (eg, metered-dose inhalers [MDIs], dry powder inhalers [DPIs], soft-mist inhalers [SMIs], nebulizers, and ancillary devices such as holding chambers), and the instructions about proper use vary. Comorbidities that are common for patients with COPD, including physical and mental conditions, can have a significant effect on the patient's ability to use the devices. Periodic and frequent reinforcement and observation by the clinician is required for the patient's benefit.

7 Pharmacotherapy focuses on the use of bronchodilators to control symptoms. Bronchodilators relax bronchial smooth muscle, improve lung emptying, reduce thoracic hyperinflation at rest and during exercise, and improve exercise tolerance.[1] These effects can be seen in the absence of objective improvements on spirometry. There are several classes of bronchodilators to choose from, and classes differ with respect to onset and duration of action, and adverse events. The initial and subsequent choice of medications should be based on the specific clinical situation and patient characteristics. Short-acting medications can be used as needed or on a scheduled basis depending on the clinical situation, and additional therapies should be added in a stepwise manner depending on the response and severity of disease. Considerations should be

given to individual patient response, tolerability, adherence, and economic factors. Recommendations for management of COPD have been proposed based on a combined assessment of airflow limitation, symptoms, and risk of exacerbations, according to the new classification system for disease severity (see Table 27-13). This schema provides clearer guidance on management compared with previous recommendations, and also allows for the individualization of pharmacotherapy based on patient-specific factors of lung function, symptom frequency and severity, and exacerbation risk.

According to the guidelines, patients with intermittent symptoms and low risk for exacerbations (Group A) should be treated with short-acting bronchodilators as needed. When symptoms become more persistent (Group B), long-acting bronchodilators should be initiated. For patients at high risk for exacerbations (Groups C and D), ICS combined with long-acting bronchodilators should be considered. Short-acting bronchodilators relieve symptoms and increase exercise tolerance. Long-acting bronchodilators relieve symptoms, reduce exacerbation frequency, and improve quality of life and health status. Patients have a variety of choices in using inhalational therapies, including MDIs, DPIs, SMIs or nebulizers. There is no clear advantage of one delivery method over another, and it is recommended that patient-specific factors and preferences should be considered in selecting the device.[1]

The benefit of individual therapies in reducing the severity and frequency of exacerbations has been a major focus for the past several years. With the exception of short-acting bronchodilators, each of the agents typically used in the long-term treatment of COPD has been shown to reduce exacerbation frequency, and each does so to a similar degree. In a meta-analysis that included many clinical trials, it was reported that exacerbations were reduced by long-acting inhaled β_2-agonists (LABAs) (23%), tiotropium (29%), ICs (22%), and ICs plus LABAs (28%).[37] There were no significant differences between the agents, with regards to exacerbation frequency. These exacerbation reduction rates are consistent with those seen in the large clinical trials for tiotropium (UPLIFT and TORCH [ICs plus LABAs]).[21,22]

Bronchodilators

Bronchodilator classes available for the treatment of COPD include β_2-agonists, anticholinergics, and methylxanthines. Bronchodilators generally work by reducing the tone of airway smooth muscle (relaxation), thus minimizing airflow limitation. For patients with COPD, the clinical benefits of bronchodilators include increased exercise capacity, decreased air trapping in the lungs, and relief of symptoms such as dyspnea. However, use of bronchodilators may not be associated with significant improvements in pulmonary function measurements of expiratory airflow such as FEV_1. In general, side effects of bronchodilator medications are related to their pharmacologic effects and are dose dependent. Because COPD patients are older and more likely to have comorbid conditions, the risk for side effects and drug interactions is higher compared with patients with asthma.

There is no clear benefit to one bronchodilator agent or class over others, although inhaled therapy generally is preferred. In general, it can be more difficult for patients with COPD to use inhalation devices effectively compared with other populations owing to advanced age and the presence of other comorbidities. Clinicians should advise, counsel, and observe patient technique with the devices frequently and consistently.

Short-Acting Bronchodilators

The initial therapy for COPD patients who experience symptoms intermittently is short-acting bronchodilators. Among these agents, the choices are a short-acting β_2-agonist or an anticholinergic. Either

class of agents has a relatively rapid onset of action, relieves symptoms, and improves exercise tolerance and lung function. In general, both classes are equally effective.

Short-Acting Sympathomimetics (β_2-Agonists)

β_2-agonists cause bronchodilation by stimulating the enzyme adenyl cyclase to increase the formation of cyclic adenosine monophosphate (cAMP). cAMP is responsible for mediating relaxation of bronchial smooth muscle, leading to bronchodilation. In addition, β_2-agonists may improve mucociliary clearance. Older agents with less selectivity are no longer available and the choices for short-acting, selective β_2-agonists are albuterol and levalbuterol. Racemic epinephrine is available as an over the counter therapy but is not appropriate for chronic treatment.

The preferred route of administration for short-acting, selective β_2-agonists is by inhalation. The use of oral and parenteral β-agonists in COPD is discouraged because they are no more effective than a properly used inhalation device, and the incidence of systemic adverse effects such as tachycardia and hand tremor is greater. Administration of β_2-agonists in the outpatient and emergency room settings via inhalers (MDIs or DPIs) is at least as effective as nebulization therapy and usually favored for reasons of cost and convenience.[1,3,5] Chapter 26 includes a complete description of the devices used for delivering aerosolized medication and a comparison of β_2-agonist therapies.

Albuterol is the most frequently used β_2-agonist. It is available as an oral and inhaled preparation. Albuterol is a racemic mixture of (*R*)-albuterol, which is responsible for the bronchodilator effect, and (*S*)-albuterol, which has no therapeutic effect. (*S*)-Albuterol is considered by some clinicians to be inert, whereas others believe that it may be implicated in worsening airway inflammation and antagonizing the response to (*R*)-albuterol. Levalbuterol is a single-isomer formulation of (*R*)-albuterol. Despite years of clinical use, there is not compelling evidence to suggest that levalbuterol offers consistent advantages in terms of clinical effectiveness or safety, and it is more expensive than albuterol.[38]

In COPD patients, β_2-agonists exert a rapid onset of effect, although the response generally is less than that seen in asthma. Short-acting inhaled β_2-agonists cause only a small improvement in FEV_1 acutely but may improve respiratory symptoms and exercise tolerance despite the small improvement in spirometric measurements.[1,13] Patients with COPD can use quick-onset β_2-agonists as needed for relief of symptoms or on a scheduled basis to prevent or reduce symptoms. The duration of action of short-acting β_2-agonists is 4 to 6 hours.

Inhaled β_2-agonists are generally well tolerated. They can cause sinus tachycardia and rhythm disturbances in predisposed patients, but these are rarely reported. Skeletal muscle tremors can occur initially but subside as tolerance develops.

Short-Acting Anticholinergics

When given by inhalation, anticholinergics produce bronchodilation by competitively inhibiting cholinergic receptors in bronchial smooth muscle. This activity blocks acetylcholine, with the net effect being a reduction in cyclic guanosine monophosphate (cGMP), which normally acts to constrict bronchial smooth muscle. Muscarinic receptors on airway smooth muscle include M_1, M_2, and M_3 subtypes. Activation of M_1 and M_3 receptors by acetylcholine results in bronchoconstriction; however, activation of M_2 receptors inhibits further acetylcholine release.

Ipratropium is the primary short-acting anticholinergic agent used for COPD in the United States. The lack of systemic absorption of ipratropium greatly diminishes the anticholinergic side effects such as blurred vision, urinary retention, nausea, and tachycardia associated with atropine. Ipratropium is also available as a MDI and SMI in combination with albuterol and as a solution for nebulization at 200 mcg/mL. The soft-mist inhaler (available as Respimat®) is a new type of inhalation device and requires specific patient education to ensure proper use. Ipratropium has a peak effect in 1.5 to 2 hours and has a duration of effect of up to 8 hours. Compared with standard β_2-agonists, ipratropium has a slower onset of action and a more prolonged bronchodilator effect. Because of the slower onset of effect (15-20 minutes compared with 5 minutes for albuterol), it may be less suitable for as-needed use; however, it is often prescribed in that manner.

The role of inhaled anticholinergics in COPD is well established.[1,3,4] However, results from the Lung Health Study showed that treatment with ipratropium did not affect the progressive decline in lung function.[27] Studies comparing ipratropium with inhaled β_2-agonists have generally reported similar improvements in pulmonary function. Others report a modest benefit with ipratropium, including a lower incidence of side effects such as tachycardia.[1,4] Although the recommended dose of ipratropium is 2 puffs four times a day, there is evidence for a dose–response, so the dose can be titrated upward often to 24 puffs a day. Ipratropium has been shown to increase maximum exercise performance in stable COPD patients with doses of 8 to 12 puffs prior to exercise but not with doses of 4 puffs or less.[39] Ipratropium is well tolerated. The most frequent patient complaints are dry mouth, nausea, and an occasional metallic taste.

Clinicians differ about preference in choosing the initial short-acting bronchodilator therapy for the patient with COPD. Both a short-acting β_2-agonist and ipratropium represent reasonable choices for initial therapy. When a patient does not achieve adequate control of symptoms with one agent, the combination of a short-acting β_2-agonist and ipratropium is a reasonable alternative.

Long-Acting Bronchodilators

For patients with moderate-to-severe COPD who experience symptoms on a regular and consistent basis, or in whom short-acting therapies do not provide adequate relief (category B and D), long-acting bronchodilator therapies are the recommended treatment. Long-acting agents are also recommended for patients at high risk for exacerbation (category C and D). Long-acting inhaled bronchodilator therapy can be administered as an inhaled β_2-agonist (LABA) or an anticholinergic (LAMA). Long-acting, inhaled bronchodilator therapy is more convenient and effective, compared with short-acting agents, for patients with chronic symptoms. There are superior outcomes in lung function as measured by spirometry, symptoms including dyspnea, and, importantly, reductions in exacerbation frequency and improved quality of life.

Long-Acting Inhaled β_2-Agonists

LABAs offer the convenience and benefit of a long duration of action for patients with persistent symptoms. Some LABAs (eg, salmeterol, formoterol, and arformoterol) are dosed every 12 hours and provide sustained bronchodilation. Two ultra-long-acting agents, indacaterol (approved 2011) and olodaterol (approved 2014), require only once-daily dosing. Another ultra-long-acting agent, vilanterol, is also administered once daily but is currently available in the United States only as a combination product with an inhaled corticosteroid (IC) (fluticasone) or long-acting anticholinergic (umeclidinium). Arformoterol, formoterol, indacaterol and olodaterol have an onset of action similar to albuterol (less than 5 minutes), whereas salmeterol has a slower onset (15-20 minutes); however, none of these agents are recommended for acute relief of symptoms. There is no dose titration for any of these agents; the starting dose is the effective and recommended dose for all

patients. The clinical benefits of LABAs compared with short-acting therapies include similar or superior improvements in lung function and symptoms, as well as reduced exacerbation rates and need for hospitalization.[40] The use of the long-acting agents should be considered for patients with frequent and persistent symptoms and those at higher risk for exacerbation (see Table 27-13). When patients require short-acting β_2-agonists on a scheduled basis, LABAs are more convenient based on dosing frequency but may be more expensive. Salmeterol and indacaterol are available in dry powder inhalation devices. Formoterol and arformoterol are available as solutions for nebulization, and olodaterol is formulated as a soft-mist inhaler (Respimat). In addition to decreasing frequency of exacerbations, LABAs are also useful to reduce nocturnal symptoms and improve quality of life. When compared with short-acting bronchodilators or theophylline, both salmeterol and formoterol improve lung function, symptoms, exacerbation frequency, and quality of life.[3,13,17] These benefits are apparent even for patients with poorly reversible lung function and are related to improvements in inspiratory capacity. Similar to salmeterol and formoterol, indacaterol has been shown to have beneficial effects on health care status, frequency of exacerbations and bronchodilation.[41] In direct comparison trials, indacaterol has greater effect on bronchodilation than salmeterol and formoterol. Comparative data for olodaterol and other bronchodilators are limited. Available studies have demonstrated similar effects with olodaterol on FEV_1 and symptoms compared with other long-acting bronchodilators; however, the effect on other outcomes such as exacerbation frequency has not been evaluated.

Long-Acting Anticholinergics

Tiotropium bromide, a long-acting quaternary anticholinergic agent, has been available in the United States since 2004. Additional long-acting anticholinergic agents, aclidinium and umeclidinium, were approved in 2012 and 2014. Inhaled anticholinergics block the effects of acetylcholine by binding to muscarinic receptors in airway smooth muscle and mucus glands, inhibiting the cholinergic effects of bronchoconstriction and mucus secretion. Long-acting anticholinergic agents, such as tiotropium, are more selective than ipratropium at blocking important muscarinic receptors. They dissociate slowly from M_3 receptors, resulting in prolonged bronchodilation with once or twice a day dosing.[42] There is no dose titration for any of these agents. Aclidinium has a faster onset of action (30 minutes) compared to tiotropium (80 minutes); however, none of these agents are recommended for acute relief of symptoms. In the United States, tiotropium, is available as a dry-powder and soft-mist inhaler. Aclindium and umeclidinium are available as dry-powder inhalers. Because it acts locally, tiotropium is well tolerated, with the most common complaint being a dry mouth. Other anticholinergic side effects that are reported include constipation, urinary retention, tachycardia, blurred vision, and precipitation of narrow-angle glaucoma symptoms.

The benefits of tiotropium have been evaluated in numerous trials of patients with COPD. Compared to placebo and ipratropium, treatment with tiotropium results in significantly greater improvements in lung function, quality of life and reduces the frequency of exacerbation and need for hospitalization.[43] For outcomes such as bronchodilation, quality of life and frequency of exacerbations, tiotropium therapy has equal or superior efficacy compared with LABAs in various studies.[44,45]

The most notable study involving the use of tiotropium in recent years for patients with COPD was the UPLIFT trial.[22] This was a randomized, double-blind study over 4 years. A total of 5,993 subjects received either tiotropium 18 mcg daily inhaled via a handihaler dry-powder device or a matching placebo. All other COPD therapies were allowed except for other anticholinergic therapies (eg, ipratropium). The mean postbronchodilator FEV_1 among subjects was 1.32 L, and the primary outcome was the rate of decline in FEV_1

on spirometry. The results showed that tiotropium treatment resulted in a significant improvement in FEV_1 from baseline. However, the rate of decline in the mean FEV_1 result was not statistically significant between the groups. Tiotropium-treated subjects benefited from treatment as reflected in improved quality-of-life scores, reduced exacerbation rates, fewer hospitalizations, and instances of respiratory failure. Tiotropium was associated with a lower overall risk of mortality, including deaths from respiratory and cardiac causes.

Previously, retrospective analyses have reported an increased risk of cardiovascular events associated with ipratropium and tiotropium use.[46] However, the UPLIFT study, which was a prospective trial over 4 years, did not report an increased cardiovascular risk associated with tiotropium use when administered from both devices.[22] Additionally, a prospective, noninferiority trial (TIOSPIR) was published in 2013 which compared the effects of tiotropium delivered via Handihaler or Respimat devices among 17,000 patients with COPD over a median 2.3 year period.[47] The primary outcomes in this trial were risk of death and risk of first COPD exacerbation. Secondary outcomes included cardiovascular safety. No significant differences were seen in any of the primary or secondary outcomes when comparing tiotropium delivery devices. Further studies are needed to evaluate the cardiovascular safety of ipratropium.

In clinical trials, aclidinium has been shown to have similar improvements in spirometry and symptom scores compared to tiotropium.[48] However, reduction in exacerbation frequency has not been observed in trials to date. While available as both a single-drug and combination inhaler (with vilanterol), umeclidinium has primarily been evaluated as part of a combination bronchodilator regimen.

Combination Anticholinergics and β-Agonists

Combination regimens of bronchodilators are used often in the treatment of COPD, especially as the disease progresses and symptoms worsen over time. Combining bronchodilators with different mechanisms of action allows the lowest possible effective doses to be used and reduces potential adverse effects from individual agents.[1] Combinations of both short- and long-acting β_2-agonists with ipratropium provide added symptomatic relief and improvements in pulmonary function. A combination of albuterol and ipratropium (Combivent Respimat) is available as a soft-mist inhaler in the United States for chronic maintenance therapy of COPD. This product offers the obvious convenience of two classes of bronchodilators in a single inhaler.

Although clinical practice guidelines have recommended that combinations of long-acting bronchodilators are appropriate for patients who do not receive adequate benefit from a single agent, data to support the use of these combinations have been lacking. These approaches have been the focus of more recent research. A recent Cochrane review evaluated five trials comparing combination long-acting bronchodilators (LABA plus tiotropium) versus tiotropium alone. Combination therapy resulted in significant improvement in FEV_1 and quality-of-life measures compared with tiotropium alone, although no difference was shown for frequency of exacerbations or symptom scores.[49]

In 2013, the first LABA-LAMA combination inhaler (umeclidinium/vilanterol—DPI) was approved in the United States and another combination inhaler was approved in 2015 (tiotropium/olodaterol—SMI). As a result of this drug development process, there is now more evidence for the efficacy and safety of using long-acting bronchodilators in combination.[50,51,52] To date, efficacy has been demonstrated for improvements in lung function and symptoms scores with combination long-acting bronchodilators compared to single-therapy; however, additional benefit in exacerbation reduction needs to be evaluated.

Methylxanthines

Methylxanthines, including theophylline and aminophylline, have been available for the treatment of COPD for at least 5 decades and at one time were considered first-line therapy. However, with the availability of LABAs and inhaled anticholinergics, the role of methylxanthine therapy is significantly limited. Inhaled bronchodilator therapy is preferred for COPD. Because of the risk for drug interactions and the significant intrapatient and interpatient variability in dosage requirements, theophylline therapy generally is considered for patients who are intolerant or unable to use an inhaled bronchodilator. Theophylline is still an alternative to commonly used inhaled therapies partially due to the potential for multiple mechanisms (bronchodilation and antiinflammatory) and the possible benefit that systemic administration may exert on peripheral airways.[1,5]

The methylxanthines may produce bronchodilation through numerous mechanisms, including (a) inhibition of phosphodiesterase, thereby increasing cAMP levels, (b) inhibition of calcium ion influx into smooth muscle, (c) prostaglandin antagonism, (d) stimulation of endogenous catecholamines, (e) adenosine receptor antagonism, and (f) inhibition of release of mediators from mast cells and leukocytes.[1]

Chronic theophylline use for patients with COPD may offer improvements in lung function, including vital capacity (VC), FEV_1, minute ventilation, and gas exchange. Subjectively, theophylline has been shown to reduce dyspnea, increase exercise tolerance, and improve respiratory drive in COPD patients.[1] Other nonpulmonary effects of theophylline that may contribute to improved overall functional capacity for patients with COPD include improved cardiac function and decreased pulmonary artery pressure.

Regular use of methylxanthines has not been shown to have either a beneficial or a detrimental effect on the progression of COPD. However, methylxanthines may be added to the treatment plan of patients who have not achieved an optimal clinical response to inhaled bronchodilators. The efficacy of combination therapy with salmeterol and theophylline for patients with COPD can improve pulmonary function and reduce dyspnea better than either treatment alone.[1] Combination treatment has also been associated with a reduced number of exacerbations only when compared with the theophylline group, suggesting that the salmeterol component was responsible for this beneficial effect.

As is the case with other bronchodilator therapy, parameters other than objective measurements, such as FEV_1, should be monitored to assess efficacy of theophylline in COPD. Subjective parameters, such as perceived improvements in symptoms of dyspnea and exercise tolerance, become increasingly important in assessing the acceptability of methylxanthines for COPD patients. Although objective improvement may be minimal, patients may experience an improvement in clinical symptoms, and thus benefit to the individual may be meaningful.

Although theophylline is available in a variety of oral dosage forms, sustained-release preparations are most appropriate for the long-term management of COPD. These products have the advantages of improving patient compliance and achieving more consistent serum concentrations over rapid-release theophylline and aminophylline preparations. However, caution must be used in switching from one sustained-release preparation to another because there are considerable variations in sustained-release characteristics.[53] Aside from IV aminophylline, there is no need to use any of the various salt forms of theophylline.

Therapy can be initiated at 200 mg twice daily and titrated upward every 3 to 5 days to the target dose. Most patients require daily doses of 400 to 900 mg. Dosage adjustments generally should be made based on serum concentration results. Traditionally, the therapeutic range of theophylline was identified as 10 to 20 mcg/mL; however, because of the frequency of dose-related side effects and the relatively minor benefit of higher concentrations, a more conservative therapeutic range of 8 to 15 mcg/mL often is targeted. This is

especially preferable for the elderly. When concentrations are measured, trough measurements are most appropriate.

Once a dose is established, serum concentrations should be monitored once or twice a year unless the patient's disease worsens, medications that interfere with theophylline metabolism are added to therapy, or toxicity is suspected. The most common side effects of theophylline therapy are related to the GI system, the cardiovascular system, and the CNS. Side effects are dose related; however, there is overlap in side effects between the therapeutic and toxic ranges. Minor side effects include dyspepsia, nausea, vomiting, diarrhea, headache, dizziness, and tachycardia. More serious toxicities, especially at toxic concentrations, include arrhythmias and seizures.

Factors that decrease theophylline clearance and lead to reduced maintenance dose requirements include advanced age, bacterial or viral pneumonia, left or right ventricular failure, liver dysfunction, hypoxemia from acute decompensation, and use of drugs such as cimetidine, macrolides, and fluoroquinolone antibiotics. Factors that may enhance theophylline clearance and result in the need for higher maintenance doses include tobacco and marijuana smoking, hyperthyroidism, and the use of such drugs as phenytoin, phenobarbital, and rifampin.

In summary, there are decades of experience with theophylline and other methylxanthine products in the management of patients with COPD. However, inhalation therapy is currently preferred based on superior efficacy and safety, as well as ease of use by the clinician. Theophylline is a challenging medication to dose, monitor, and manage due to the significant intrapatient and interpatient variability in pharmacokinetics and the potential for drug interactions and toxicities.

Corticosteroids

9 Corticosteroid therapy has been studied and debated in COPD therapy for half a century; however, owing to the poor risk-to-benefit ratio, chronic systemic corticosteroid therapy should be avoided if possible.[1] Because of the potential role of inflammation in the pathogenesis of the disease, clinicians hoped that corticosteroids would be promising agents in COPD management. However, their use continues to be debated, especially in the management of stable COPD.

The antiinflammatory mechanisms whereby corticosteroids exert their beneficial effect in COPD include (a) reduction in capillary permeability to decrease mucus, (b) inhibition of release of proteolytic enzymes from leukocytes, and (c) inhibition of prostaglandins. Unfortunately, the clinical benefits of systemic corticosteroid therapy in the chronic management of COPD are often not evident, and the risk of toxicity is extensive and far-reaching. Currently, the appropriate situations to consider corticosteroids in COPD include (a) short-term systemic use for acute exacerbations and (b) inhalation therapy for chronic stable COPD in selected patients.

Chronic therapy with oral steroids is not warranted. Only a small fraction (10%) of COPD patients treated with steroids show clinically significant improvement in baseline FEV_1 (increase of 20%) compared with those treated with placebo. While a small number of COPD patients are considered responders to oral steroids, many of these patients actually may have an asthmatic, or reversible, component to their disease. Previously, a common clinical practice was to administer a short course (2 weeks) of oral corticosteroids as a trial to predict which patients would benefit from chronic oral or ICS. There is now sufficient evidence suggesting that this practice is not effective in predicting a long-term response to ICS and should not be recommended.

Long-term adverse effects associated with systemic corticosteroid therapy include osteoporosis, muscular atrophy, thinning of the skin, development of cataracts, and adrenal suppression and insufficiency. The risks

associated with long-term steroid therapy are much greater than the clinical benefits. If a decision to treat with long-term systemic corticosteroids is made, the lowest possible effective dose should be given once per day in the morning to minimize the risk of adrenal suppression. If therapy with oral agents is required, an alternate-day schedule should be used.

Initially, it was postulated that ICS might be beneficial in COPD to slow disease progression. Unfortunately, the results of major clinical trials have failed to demonstrate any benefit from chronic treatment with ICS in modifying long-term decline in lung function that is characteristic of COPD.[1,4,5,13,17] However, ICS have been associated with other important benefits in some patients, including a decrease in exacerbation frequency and improvements in overall health status.[1,54] Patients with severe to very severe COPD (FEV_1 less than 60% predicted) and those at high risk of exacerbation receive the most benefit from ICS.

Although a dose–response relationship for ICS has not been demonstrated in COPD, the major clinical trials employed moderate to high doses for treatment. At these doses, adverse effects are a consideration with long-term therapy. Recent trials have reported that treatment with ICS increases the risk of pneumonia for patients with COPD.[21,54,55] Other adverse effects include hoarseness, sore throat, oral candidiasis, and skin bruising. Severe adverse effects, such as adrenal suppression, osteoporosis, and cataract formation, have been reported less frequently than with systemic corticosteroids, but clinicians should monitor patients who are receiving high-dose chronic therapy.

There is conflicting evidence supporting a dose relationship between ICS use and the risk of fractures. In a cohort of over 1,600 subjects with a diagnosis of asthma or COPD (mean age 80 years), the risk of a fracture was 2.53 times higher (CI, 1.65-3.89) in those receiving a mean daily dose of ICS of 601 mcg or greater.[56] A meta-analysis found no evidence supporting an increased risk of fractures or decreased bone mineral density with chronic ICS use.[57] It appears prudent to suggest that, to minimize the risk of fracture, patients should be treated with the lowest effective dose of ICS. It may also be helpful to recommend adequate intake of calcium and vitamin D and possibly periodic bone mineral density testing.

Currently, the recommended role of ICS therapy is for patients with severe or very severe COPD and at high risk of exacerbation (Groups C and D) who are not controlled with inhaled bronchodilators. Given the risks associated with long-term ICS therapy, clinicians should appropriately identify patients who will receive the best benefit, such as reduction in exacerbations. Evaluations of current practice has shown that many patients with COPD may be inappropriately prescribed an IC (eg, not high risk for exacerbations); thus, exposing them to unnecessary adverse effects.[58]

Two recent trials have evaluated the effects of withdrawing ICS from therapy in patients with moderate and severe COPD.[59,60] In the INSTEAD trial, patients with moderate COPD and low risk of exacerbations (eg, no exacerbation in the previous 12 months) were transitioned from salmeterol/fluticasone combination therapy to indacaterol alone. At 12 weeks, there was no difference in lung function, symptoms or health status between treatment groups. Effect of therapy change on long-term risk of exacerbation was not evaluated.[59] In another trial, patients with severe COPD receiving “triple therapy” (eg, LAMA-LABA-ICS) had their ICS tapered over 12 weeks and then discontinued. Discontinuation of ICS therapy did not result in a significant increase in exacerbations. However, some patients experienced a decrease in FEV_1 or return of symptoms with ICS withdrawal.[60] These trials provide more information to clinicians who may wish to scale back ICS therapy due to observed adverse effects, such as recurrent pneumonia, or in patients who are not at high risk for exacerbations and can be maintained on long-acting bronchodilators alone.

Combination Therapy: Bronchodilators and Inhaled Corticosteroids

Following the disappointing results of chronic ICS studies and the progressive decline in lung function, investigators became interested in the combination of potent antiinflammatory therapies and long-acting bronchodilators. In various studies, combination therapy with LABA and ICS was associated with greater improvements in clinical outcomes such as FEV_1, health status, and frequency of exacerbations compared with ICS or long-acting bronchodilators alone.[61] The availability of combination inhalers (eg, salmeterol plus fluticasone, budesonide plus formoterol, and mometasone plus formoterol) makes administration of both ICS and long-acting bronchodilators more convenient for patients and decreases the total number of inhalations needed daily.

One of the largest prospective studies evaluating combination therapy to date is referred to as the TORCH study.[21] This trial included 6,112 patients who received one of four treatments for 3 years. Treatment groups were placebo, salmeterol 50 mcg twice daily, fluticasone 500 mcg twice daily, or the combination of salmeterol and fluticasone in a single inhaler. The primary outcome was death from any cause and secondary outcomes were exacerbation rates, lung function, and health status. None of the active treatments differed significantly from placebo, although the combination of salmeterol and fluticasone trended toward fewer deaths (P = 0.052). The combination also reduced exacerbation rates, and improved lung function and health status compared with the other treatments. Exacerbation rates were also significantly reduced with combination therapy compared with either single agent alone. Both treatment groups that included fluticasone had higher rates of pneumonia. Although this study did not reflect a mortality benefit, the authors indicated that the relative risk of death was reduced by 17.5% with the combination therapy.

In a posthoc analysis of this trial, both individual agents and the combination decreased the rate of spirometry decline in patients with an FEV_1 of less than 60% predicted.[62] While this observation is interesting, it is in contrast to previous randomized controlled studies that have not demonstrated an effect of pharmacotherapy on rate of disease progression.

In a head-to-head trial, a large study comparing a combination of salmeterol and fluticasone with tiotropium alone showed no difference in the exacerbation rates between the groups, although the combination therapy was associated with a higher study completion rate.[63]

Combinations of Long-Acting Bronchodilators Compared with Long-Acting Bronchodilators Plus Inhaled Corticosteroids

Given that COPD is a progressive disease, common practice is to add therapies over time to achieve symptom control and prevent exacerbations. Ultimately, many patients may receive combination therapy with multiple agents, despite a lack of strong evidence for efficacy. For patients with more symptoms and at high risk of exacerbation (category D), triple therapy (LABA-LAMA-IC) may be considered as a first or second choice.

The benefit of triple therapy was evaluated in a 1-year randomized, double-blind, placebo-controlled study involving 449 subjects with moderate-to-severe COPD. Treatment consisted of tiotropium, tiotropium plus salmeterol, or tiotropium, salmeterol, and fluticasone.[64] There was no difference between treatments for the primary outcome of percentage of patients experiencing an exacerbation requiring systemic corticosteroids or antibiotics. The triple-drug regimen improved lung function, quality of life, and reduced hospitalization compared with tiotropium alone, while two-drug therapy did not offer any benefit in lung function improvement or hospitalization rates compared with the single agent.

These data involving combinations of long-acting bronchodilators and ICS are limited and preliminary.[65,66] More research is required and should include other outcome parameters including relief of symptoms, exacerbation rates, and quality of life. Larger sample sizes and longer durations will provide insight into the value of combinations.

Phosphodiesterase Inhibitors

Phosphodiesterase 4 (PDE4) is the major phosphodiesterase found in airway smooth muscle cells and inflammatory cells and is responsible for degrading cAMP. Inhibition of PDE4 results in relaxation of airway smooth muscle cells and decreased activity of inflammatory cells and mediators such as TNF-α and IL-8. One PDE4 inhibitor, roflumilast, was approved in 2011 to reduce the risk of exacerbations in patients with severe COPD. When either used as monotherapy or added to a maintenance regimen with other inhaled bronchodilators, roflumilast was associated with a modest increase in FEV_1 and reduction in rate of exacerbation by approximately 15%.[67] Of note, patients in phase III trials evaluating roflumilast were not allowed to receive ICS as part of their maintenance regimen.

A more recent study evaluated the addition of roflumilast to combination therapy with IC and LABA.[68] Patients with severe COPD were randomized to receive placebo or roflumilast in addition to an IC and LABA for 1 year. Open-label LAMA was also allowed, and approximately 70% of patients in both groups were receiving a LAMA as part of their therapy prior to randomization. The primary outcome was frequency of moderate to severe exacerbations, and secondary outcomes of lung function, symptoms and health status were also measured. Treatment with roflumilast was associated with a significant decrease in exacerbation rate and need for hospitalization compared to placebo. No significant improvements were seen in symptom scores or health status with roflumilast therapy.

Roflumilast is dosed at 500 mcg orally once a day. Major adverse effects include weight loss and neuropsychiatric effects such as suicidal thoughts, insomnia, anxiety, and new or worsened depression. Weight loss may be of concern in patients with low BMI and drug discontinuation may be necessary if significant weight loss is observed. Both patients and family members should be counseled regarding the potential for mood and behavior changes and to alert healthcare providers if they occur.

Roflumilast is metabolized by CYP3A4 and 1A2 and coadministration with strong inducers of cytochrome P450 is not recommended due to potential for subtherapeutic plasma concentrations. Although there are no recommended dose adjustments, caution should also be used when administering roflumilast with strong inhibitors of cytochrome P450 due to potential for adverse effects.

Given the limited evidence demonstrating long-term clinical benefit, the role of roflumilast in the management of COPD is not entirely clear. Current consensus guidelines recommend roflumilast for patients with severe or very severe COPD who are at high risk of exacerbation (Groups C and D) and are not controlled by inhaled bronchodilators (see Table 27-13). Roflumilast may also be considered for patients who are intolerant or unable to use inhaled bronchodilators or corticosteroids. Given that both theophylline and roflumilast have similar mechanisms of action through inhibition of phosphodiesterases, it is not recommended to use both together for the management of COPD.

α_1-Antitrypsin Replacement Therapy

For patients with inherited AAT deficiency-associated emphysema, treatment focuses on reduction of risk factors such as smoking, symptomatic treatment with bronchodilators, and augmentation therapy with

replacement AAT. Based on knowledge about the relationship between serum concentrations of AAT and the risk of developing emphysema, the rationale for augmentation therapy is to maintain serum concentrations above the protective threshold throughout the dosing interval.[1,5] Indirect evidence of AAT activity in the interstitium of the lung has been demonstrated by measuring concentrations of the enzyme in epithelial lining fluid obtained during bronchoalveolar lavage. Augmentation therapy consists of weekly infusions of pooled human AAT to maintain AAT plasma levels over 10 µmol/L. Much of the data supporting the use of AAT replacement are based on evidence of biochemical efficacy (eg, administering the product and demonstrating protective serum concentrations of AAT).

Clinical evidence for slowing lung function decline or improving outcomes with augmentation therapy is sparse. Stated challenges to performing randomized clinical trials include the large sample size and long duration of follow-up required, and the expense of conducting such a trial. One observational study followed patients in the National Registry of Severe AAT Deficiency over a period of several years and documented clinical outcomes. In this study, patients who received weekly augmentation therapy with purified AAT had slower declines in FEV_1 and decreased mortality compared with patients who never received augmentation therapy.[69] However, this was an observational study of patients, not a randomized, placebo-controlled trial, and so direct cause-and-effect relationships cannot be concluded. One randomized, placebo-controlled study of patients with severe AAT deficiency (ZZ phenotype) did show a significant reduction in lung tissue loss and destruction as measured by computed tomographic (CT) scan for patients receiving augmentation therapy.[70] Other measures of lung function and mortality were not recorded.

The recommended dosing regimen for replacement AAT is 60 mg/kg administered IV once a week at a rate of 0.08 mL/kg/min, adjusted to patient tolerance. This form of augmentation therapy will cost over $54,000 annually. In the absence of alternative treatments, it is difficult to assess the cost-effectiveness using conventional criteria. There have been repeated problems with supply of this biologic replacement therapy (derived from pooled blood donors) related to production difficulty and contamination issues. Currently, there are four products available (Prolastin-C [Talecris], Aralast and Aralast-NP [Baxter], Zemaira [CSL Behring]), that should minimize this problem in the future. Drug development research continues in the area of recombinant products and inhalational therapy.

TREATMENT

COPD Exacerbation

Desired Outcomes

10 The goals of therapy for patients experiencing exacerbations of COPD are (a) prevention of hospitalization or reduction in hospital stay, (b) prevention of acute respiratory failure and death, and (c) resolution of exacerbation symptoms and a return to baseline clinical status and quality of life.[1,6,17] Acute exacerbations can range from mild to severe. Factors that influence the severity, and subsequently the level of care required, include the severity of airflow limitation, presence of comorbidities, and the history of previous exacerbations. **Table 27-15** includes factors that warrant treatment in the hospital.

TABLE 27-15 Factors Favoring Hospitalization for Treatment of COPD Exacerbation

Presence of high risk comorbidity (eg, pneumonia, arrhythmia, CHF, diabetes, renal or hepatic failure)
Suboptimal response to outpatient management

Marked worsening of dyspnea

Inability to eat or sleep due to symptoms

Worsening hypoxemia or hypercapnia

Mental status changes

Lack of home support for care

Uncertain diagnosis

Various therapeutic options for exacerbation management are summarized in **Table 27-16**. Pharmacotherapy consists of intensification of bronchodilator therapy and a short course of systemic corticosteroids. Antimicrobial therapy is indicated in the presence of selected symptoms. Since the frequency and severity of exacerbations are closely related to each patient's overall health status, all patients should receive optimal chronic treatment, including smoking cessation, appropriate pharmacologic therapy, and preventative therapy such as vaccinations.

TABLE 27-16 Therapeutic Options for Acute Exacerbations of COPD

Therapy	Comments
Antibiotics	Recommended if two or more of the following are present: • Increased dyspnea • Increased sputum production • Increased sputum purulence
Corticosteroids	Oral or IV therapy may be used. If IV is used, it should be changed to oral after improvement in pulmonary status. If continued longer than 14 days, then the dose should be tapered to avoid HPA Axis suppression.
Bronchodilators	MDIs and DPIs equal in efficacy to nebulization. β-Agonists also may increase mucociliary clearance. Long-acting β-agonists or long-acting antimuscarinics should not be used for quick relief of symptoms or on an as-needed basis.
Controlled oxygen therapy	Titrate oxygen to desired oxygen saturation (>90%). Monitor arterial blood gas for development of hypercapnia.
Noninvasive mechanical ventilation	Consider for patients with acute respiratory failure. Not appropriate for patients with altered mental status, severe acidosis, respiratory arrest, or cardiovascular instability.

Nonpharmacologic Therapy

Controlled Oxygen Therapy

Oxygen therapy should be provided for patients with significant hypoxemia during an exacerbation (eg, oxygen saturation less than 90%). Caution must be used, however, because many patients with COPD rely on mild hypoxemia to trigger their drive to breathe. In normal, healthy individuals, the drive to breathe is triggered by carbon dioxide accumulation. For patients with COPD who retain carbon dioxide as a result of their disease progression, hypoxemia rather than hypercapnia becomes the main trigger for their respiratory drive. Overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. Oxygen therapy should be used to achieve a PaO_2 of greater than 60 mm Hg or oxygen saturation of greater than 90%. However, an ABG should be obtained after oxygen initiation to monitor carbon dioxide retention owing to hypoventilation.

Noninvasive Mechanical Ventilation

Noninvasive positive-pressure ventilation (NPPV) provides ventilatory support with oxygen and pressurized airflow using a face or nasal mask with a tight seal but without endotracheal intubation. There have been numerous trials reporting the benefits of NPPV for patients with acute respiratory failure due to COPD exacerbations. NPPV has been associated with lower mortality, lower intubation rates, and shorter hospital stays for COPD exacerbations. A recent analysis regarding NPPV in patients with respiratory failure in general included a subset of patients with COPD and reported that the risk of hospital-based mortality and long-term mortality was reduced by 56%.[71] The benefits seen with NPPV generally can be attributed to a reduction in the complications that often arise with invasive mechanical ventilation. Not all patients with COPD exacerbations are appropriate candidates for NPPV. Patients with altered mental status may not be able to protect their airway and thus may be at increased risk for aspiration. Patients with severe acidosis (pH <7.25), respiratory arrest, or cardiovascular instability should be not considered for NPPV. Patients failing a trial of NPPV or those considered poor candidates might be considered for intubation and mechanical ventilation.

Pharmacologic Therapy

Bronchodilators

During exacerbations, intensification of bronchodilator regimens is used commonly. The doses and frequency of bronchodilators are increased to provide symptomatic relief. Short-acting β_2-agonists are preferred owing to rapid onset of action. Anticholinergic agents may be added if symptoms persist despite increased doses of β_2-agonists. In fact, combinations of these agents are employed often, although data are lacking about the benefit versus higher doses of one agent. Bronchodilators may be administered via MDIs or nebulization with equal efficacy. Nebulization may be considered for patients with severe dyspnea who are unable to hold their breath after actuation of an MDI. Clinical evidence supporting the use of theophylline during exacerbations is lacking, and thus theophylline generally should be avoided. However, addition of theophylline may be considered for patients not responding to other therapies. The risk of adverse effects such as cardiac arrhythmias should be considered and serum levels monitored closely.

Corticosteroids

The role of systemic corticosteroids for COPD exacerbations is well established based on several studies that document the value of systemic corticosteroids in exacerbations of COPD.[17,72,73,74] The Systemic Corticosteroids in COPD Exacerbations (SCCOPE) trial evaluated three groups of patients hospitalized for

exacerbations of COPD.[72] The first group received an 8-week course of corticosteroids given as methylprednisolone 125 mg IV every 6 hours for 72 hours, followed by once-daily oral prednisone (60 mg on days 4-7, 40 mg on days 8-11, 20 mg on days 12-43, 10 mg on days 44-50, and 5 mg on days 51-57). The second group received a 2-week course given as methylprednisolone 125 mg IV every 6 hours for 72 hours, followed by oral prednisone (60 mg on days 5-7, 40 mg on days 8-11, and 20 mg on days 12-15) and placebo on days 16 to 57. The third group received placebo for all 57 days of study. Rates of treatment failure and hospital stay were significantly higher in the placebo group than in either treatment group at 30 and 90 days. Groups randomized to corticosteroid treatment also had a significantly shorter length of hospital stay compared with the placebo group. The 8-week regimen was not found to be superior to the 2-week regimen. Significant treatment benefits were no longer evident at 6 months.

Davies et al.[73] evaluated the oral use of corticosteroids in hospitalized patients with acute exacerbations of COPD. Patients received either 30 mg/day oral prednisolone or placebo for 14 days. Patients who were treated with corticosteroids had a significantly more rapid improvement in FEV_1 and a shorter hospital stay than did patients who received placebo. There was no significant difference between groups at 6-week follow-up.

In total, results from these trials suggest that patients with acute exacerbations of COPD should receive a short course of IV or oral corticosteroids. However, because of the large variability in dosage ranges, the optimal dose and duration of corticosteroid treatment are not known. Several trials used high initial doses of steroids before tapering to a lower maintenance dose. Adverse effects such as hyperglycemia, insomnia, and hallucinations may occur at higher doses. Depending on the clinical status of the patient, treatment may be initiated at a lower dose or tapered more quickly if these effects occur. It appears that a regimen of prednisone 40 mg orally daily (or equivalent) for 10 to 14 days can be effective for most patients. If steroid treatment is continued for greater than 2 weeks, a tapering oral schedule should be employed to avoid hypothalamic–pituitary–adrenal (HPA) axis suppression.

A recent systematic review reported benefits from either oral or parenteral corticosteroids in reducing treatment failures (OR 0.48 with CI of 0.35-0.67), risk of relapse (HR 0.78 with CI of 0.63-0.97), but no beneficial effect on mortality.[75] There was also an increase in the risk for adverse effects with the use of corticosteroids (OR 2.33 with CI of 1.59-3.43).

It may be possible to limit adverse effects without compromising the effectiveness of systemic corticosteroids.[76] The REDUCE trial evaluated a 5 day course of prednisone 40 mg versus 14 days in a non-inferiority study.[76] For the primary outcome which was time to the next exacerbation in 6 months, the shorter treatment duration was non-inferior with a hazard ratio of 0.95%. Shorter courses of corticosteroids may be as effective as longer courses and have a lower risk of associated adverse effects owing to less time of exposure.

Antimicrobial Therapy

11 It is thought that most acute exacerbations of COPD are caused by viral or bacterial infections. However, as many as 30% of exacerbations are caused by unknown factors.[1] The data supporting the need and the efficacy of antibiotics for COPD exacerbations are remarkably sparse. It is suggested that antibiotics are of most benefit and should be initiated if at least two of the following three symptoms are present: increased dyspnea, increased sputum volume, and increased sputum purulence.[77] The utility of sputum Gram stain and culture is questionable because some patients have chronic bacterial colonization of the bronchial tree

between exacerbations.

The emergence of drug-resistant organisms has mandated that antibiotic regimens be chosen judiciously. Selection of empirical antimicrobial therapy should be based on the most likely organism(s) thought to be responsible for the infection based on the individual patient profile and site-specific sensitivities. The most common organisms for any acute exacerbation of COPD are *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae*, and *Haemophilus parainfluenzae*. More virulent bacteria may be present for patients with more complicated acute exacerbations of COPD, including drug-resistant pneumococci, *β*-lactamase–producing *H. influenzae* and *M. catarrhalis*, and enteric gram-negative organisms, including *Pseudomonas aeruginosa*. **Table 27-17** summarizes recommended antimicrobial therapy for exacerbations of COPD and the most common organisms based on patient presentation.[78]

TABLE 27-17 Recommended Antimicrobial Therapy in Acute Exacerbations of COPD

Patient Characteristics	Likely Pathogens	Recommended Therapy
Uncomplicated exacerbations <4 exacerbations per year No comorbid illness FEV_1 >50% of predicted	*S. pneumoniae* *H. influenzae* *M. catarrhalis* *H. parainfluenzae* Resistance uncommon	Macrolide (azithromycin, clarithromycin) Second- or third-generation cephalosporin Doxycycline Therapies not recommended[a]: TMP/SMX, amoxicillin, first-generation cephalosporins, and erythromycin
Complicated exacerbations: Age ≥65 and >4 exacerbations per year FEV_1 <50% but >35% of predicted	As above plus drug-resistant pneumococci, *β*-lactamase–producing *H. influenzae* and *M. catarrhalis*	Amoxicillin/clavulanate Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gemifloxacin, and moxifloxacin)
Complicated exacerbations with risk of *P. aeruginosa* Chronic bronchial sepsis[b] Need for chronic corticosteroid therapy Resident of nursing home with <4 exacerbations per year FEV_1 <35% of predicted	Some enteric gram-negatives As above plus *P. aeruginosa*	Fluoroquinolone with enhanced pneumococcal and *P. aeruginosa* activity (levofloxacin) IV therapy if required: *β*-lactamase resistant penicillin with antipseudomonal activity 3rd- or 4th-generation cephalosporin with antipseudomonal activity

[a]TMP/SMX should not be used due to increasing pneumococcal resistance; amoxicillin and first-generation cephalosporins are not recommended due to *β*-lactamase susceptibility; and erythromycin is not recommended due to insufficient activity against *H. influenzae*.

[b]In sepsis, double antipseudomonal coverage should be considered (eg, addition of aminoglycoside).

The benefits of antimicrobial therapy are unclear; however, they continue to be recommended as part of standard therapy, especially in more severe exacerbations. Therapy with antibiotics generally should be continued for at least 7 to 10 days. Studies evaluating shorter treatment courses (usually 5 days) with the fluoroquinolones, second- and third-generation cephalosporins, and macrolide antimicrobials have demonstrated comparable efficacy with the longer treatment regimens.[79] If the patient deteriorates or does not improve as anticipated, hospitalization may be necessary, and more aggressive attempts should be made to identify potential pathogens responsible for the exacerbation.

Other Management Considerations

Chronic obstructive pulmonary disease patients are at increased risk for pulmonary embolism during severe exacerbations requiring hospitalizations. An increased awareness of this risk and appropriate preventative measures are warranted.[80]

Complications

Cor Pulmonale

Cor pulmonale is right-sided heart failure secondary to pulmonary hypertension. Long-term oxygen therapy and diuretics have been the mainstays of therapy for cor pulmonale. Increasing the PaO_2 above 60 mm Hg with supplemental oxygen therapy decreases pulmonary hypertension and thus decreases the force against which the right ventricle has to work. While diuretics may help decrease fluid overload, caution should be used because patients with significant right-sided heart failure are highly dependent on preload for cardiac output. Therefore, the decision to use diuretics must be based on a risk-to-benefit ratio. Digitalis glycosides have no role in the treatment of cor pulmonale.

Beta blocker therapy is indicated to treat systolic heart failure including patients who have experienced a myocardial infarction. Beta blocker therapy can present unique challenges for patients with airway disease but are generally well tolerated by patients with COPD who do not exhibit bronchial hyperreactivity. Patients with COPD should be treated with $beta_1$ selective agents when appropriate. The use of beta blocker therapy for patients with COPD and cardiac disease has been associated with improved overall survival.[81,82]

Polycythemia

Polycythemia secondary to chronic hypoxemia in COPD patients can be improved by either oxygen therapy or periodic phlebotomy if oxygen therapy alone is not sufficient. COT was shown by the Nocturnal Oxygen Therapy Trial Group to reduce hematocrit values in treated patients. Acute phlebotomy is indicated if the hematocrit is above 55% to 60% and the patient is experiencing CNS effects suggestive of sludging from high blood viscosity. Long-term oxygen then can be used to maintain a lower hematocrit.

Other Pharmacologic Considerations

A number of other treatments have been explored over the years. Among these therapies, either there is insufficient evidence to warrant recommending their use or they have been proven to not be beneficial in the management of COPD. A brief summary is provided because the clinician likely will encounter patients who are receiving or inquire about these treatments.

Suppressive Antimicrobial Agents

Because COPD patients often are colonized with bacteria and experience recurrent exacerbations of their condition, a common practice employed in the past has been the use of low-dose antimicrobial therapy as preventative or prophylaxis against these acute exacerbations. However, clinical studies over the past 40 years have failed to demonstrate any significant benefit from this practice.[1]

In certain pulmonary conditions such as cystic fibrosis and bronchiectasis, chronic therapy with macrolide antibiotics, specifically azithromycin, has shown clinical benefit based on its proposed antiinflammatory properties and is used in clinical practice. In a study evaluating chronic azithromycin in patients with COPD, patients were randomized to azithromycin (250 mg orally daily) or placebo in addition to maintenance therapy for COPD and were followed for 1 year.[83] Chronic azithromycin was associated with a lower rate of exacerbations and improved quality-of-life scores; however, more patients in the azithromycin group reported hearing deficits (25% vs 20% in the placebo group). Therapy with azithromycin was also associated with a higher rate of colonization with macrolide-resistant bacteria during the study period. Of note, patients were carefully screened for hearing impairment and risk factors for QT prolongation prior to entering the study and were excluded if either was present.

In 2012, a retrospective, observational study reported an increase in cardiac events with short courses of azithromycin and the FDA has since updated the product labeling to include a precaution about QT prolongation.[84] Given the limited evidence for long-term treatment (beyond 1 year) with azithromycin, it would be prudent to wait for more long-term safety data before routinely recommending this therapy for patients with COPD who are at risk for exacerbations. Other therapies that reduce exacerbation risk (IC, LABA, LAMA, and roflumilast) should be considered first. Clinicians may choose to consider azithromycin for individual patients at high risk for exacerbations after weighing the risks and benefits of therapy.

Expectorants and Mucolytics

Adequate water intake generally is acceptable to maintain hydration and assist in the removal of airway sections. Mucolytics and expectorants such as compounded saturated solutions of potassium iodide, ammonium chloride, N-acetylcysteine, and guaifenesin have been evaluated as adjunctive therapy for patients with COPD. In one recent trial, patients with moderate to severe COPD were randomized to either placebo or oral N-acetylcysteine 600 mg twice daily for 1 year. Patients were not required to be on ICs prior to randomization. N-acetylcysteine was associated with a significant decrease in exacerbation rate among patients with moderate disease only (GOLD 2).[85] Strong evidence of clinical benefit is lacking for the routine use of mucolytics in the treatment of COPD.[86]

In 2011, the FDA announced its intention to remove various unapproved cough and cold preparations (including several containing guaifenesin) from the market due to safety and efficacy concerns. Two extended release tablet formulations are currently approved by the FDA. Other approved formulations of guaifenesin contain dextromethorphan or pseudoephedrine and should not be used for COPD maintenance therapy.

Opioids

Systemic (oral and parenteral) opioids, especially morphine, can relieve dyspnea for patients with end-stage COPD. Nebulized therapy is sometimes used in clinical practice, although data about clinical benefit are lacking. Opioids should be used carefully, if at all, to avoid adverse effects on ventilatory drive.

Respiratory Stimulants

There is no role for respiratory stimulants in the long-term management of COPD.[1] Agents that have shown some utility in the acute setting include almitrine and doxapram. However, almitrine is available only in Europe, and its usefulness is limited by neurotoxicity. Doxapram is available for IV use only and may be no better than intermittent NPPV.

Targeted Therapy for Pulmonary Hypertension

Secondary pulmonary hypertension is a feature of severe COPD. This has prompted interest about the potential role of agents used to treat pulmonary arterial hypertension. However, the use of an endothelin receptor antagonist (bosentan) failed to improve exercise tolerance and worsened hypoxemia in one trial.[87] Investigations with sildenafil, a phosphodiesterase type 5 (PDE5) inhibitor, have been conflicting in uncontrolled clinical trials. Due to concerns that PDE5 inhibitors may worsen gas exchange in patients with COPD, they are not recommended outside of clinical trials.[88]

Surgical Intervention

Various surgical options have been employed in the management of COPD. These include bullectomy, lung volume reduction surgery (LVRS), and lung transplantation. Bullectomy has been performed for many years and may be useful when large bullae (more than 1 cm) are noted on computerized axial tomography (CT or CAT) scan. The presence of bullae may contribute to complaints of dyspnea, and their removal can improve lung function and reduce symptoms, although there is no evidence of a mortality benefit.

Because of the prevalence of COPD, it is the most frequent indication for lung transplantation. Transplantation is considered when predicted survival is less than 2 years, FEV_1 is less than 25% predicted, and hypoxemia, hypercapnia, and pulmonary hypertension exist despite medical management.[5] Experience to date shows 2-year survival of 65% to 90%, and 5-year survival of 41% to 53%.

Short-term trials comparing the effects of pulmonary rehabilitation plus LVRS with pulmonary rehabilitation alone reported that the combination of treatments resulted in greater improvements in lung function, gas exchange, and quality of life at 3 months. The National Emphysema Treatment Trial (NETT), a prospective, randomized trial evaluating the long-term effects of LVRS plus pulmonary rehabilitation compared with pulmonary rehabilitation alone, followed 1,218 patients for 3 years.[89] The primary end points for the study were mortality and maximal exercise capacity 2 years after randomization. Secondary end points included pulmonary function, distance walked in 6 minutes, and quality-of-life measurements. At an interim analysis, patients with an FEV_1 of less than 20% of predicted or a carbon monoxide diffusing capacity of less than 20% of predicted were noted to be at high risk of death after surgery and subsequently were excluded from the study. Results of the study showed no mortality benefit with LVRS compared with pulmonary rehabilitation alone. Patients undergoing surgery had improved exercise capacity, lung function, and quality of life at 2 years, but these patients also had a higher risk of short-term morbidity and mortality associated with the surgery. A subgroup analysis of the study noted that patients with predominately upper-lobe emphysema and low exercise capacity undergoing surgery had lower mortality rates at 2 years compared with patients treated with medical therapy alone. Because of the costs and risks associated with LVRS, more studies are needed to better determine the ideal surgical candidates and identify subgroups of patients that would benefit most from surgery. The long-term benefits of LVRS are exhibited as improved oxygenation and decreased requirements for supplemental oxygen during treadmill walking as well as self-reported oxygen

requirements for up to 24 months after the procedure.[90]

Dietary Supplements

There has been increasing interest in the role of antioxidants, including vitamins E and C and β-carotene, in reducing the frequency of exacerbations. It is postulated that they may be beneficial in COPD as a result of an imbalance between oxidants and antioxidants that has been considered in the pathogenesis of smoking-induced lung disease. However, there is no good evidence that antioxidant therapies improve COPD symptoms or slow disease progression. Nutritional supplements, including creatine, have not proven beneficial to improve the benefit of pulmonary rehabilitation programs.[91]

Investigational Therapies

Much of the recent progress concerning pharmacotherapies has focused on long-acting bronchodilators and corticosteroid agents. In addition, based on the knowledge about the importance of neutrophilic inflammation in COPD and potential therapeutic benefit of inhibition of neutrophil activity, a number of antiinflammatory compounds are being explored. Specifically, agents inhibiting LTB_4, neutrophil elastase, and phosphodiesterases have being evaluated. Studies of these strategies have been disappointing. As noted above, therapies targeting oxidative stress have not borne promising results, although vitamin D continues to be an area of exploration.[92]

Manipulation of various cytokines have been evaluated despite earlier studies involving infliximab, a TNFα-blocker, which failed to demonstrate any benefits on quality of life or secondary end points including lung function, exercise capacity, or exacerbation rates. The discontinuation rate due to adverse events was high (20%-27%) in the active treatment group.[93] Other current areas of investigation include p38 mitogen activated protein kinase inhibitors (MAPK), inhibitors of interleukin 1 and interleukin 5, epithelial growth factor receptor inhibitors, and neutrophil elasatase inhibitors.[92,94]

The role of HMG-CoA reductase inhibitors for patients with COPD has continued to garner interest because of the systemic inflammation that is present. A recent meta-analysis reported a hazard ratio of 0.62 for all-cause mortality, 0.48 for COPD mortality, and 0.93 for cardiovascular mortality.[95] The risk for COPD exacerbations was also reduced (HR 0.64). These results suggest the need for a prospective trial. In the meantime, patients receiving statin therapy for other reasons likely derive benefits related to their COPD.

PHARMACOECONOMIC CONSIDERATIONS

The overall cost of therapy is an important consideration in contemporary medical practice. Meaningful cost analysis goes beyond the cost of the medication itself and incorporates the impact of a given therapeutic agent on overall healthcare cost. Because of the relative lack of benefit among objective outcome measures in COPD clinical trials, pharmacoeconomic studies can be useful in decision making about pharmacotherapy options. Although there appears to be substantial interest in describing the pharmacoeconomic impact of COPD, much of the current literature appears to address modeling and predicting costs.[96,97]

A recent database study evaluating 8,554 patients with a mean age of 70.1 years reported the economic impact of exacerbations.[98] The population was predominantly insured by Medicare and, during a 2 year period, 49.8% of the patients had experienced an exacerbation. The COPD-related mean annual costs were $4,069 overall and $6,381 for patients with two or more exacerbations. All-cause health care costs were

$18,976 overall and $23,901 for patients with two or more exacerbations. The authors concluded that exacerbations add significantly to the annual costs.

Another systematic review reported that direct health costs increased 38% between 1987 and 2007, and continued to rise 5% annually through 2009.[99] The annual healthcare costs were 10 fold higher in patients who experienced an exacerbation and two studies suggested that long-acting bronchodilator therapy reduced the risk of exacerbations by 16% to 17%, with a resultant lowering in costs.

Few data are available about the cost-effectiveness of educational programs for patients with COPD. In an outpatient clinic, patients attending one 4-hour group session, followed by one to two individual sessions with a clinician, reported improved outcomes, and costs were reduced in an evaluation 12 months later.[100] Additional research is needed regarding the best model for education and also the specific self-management strategies to teach. One modeling study evaluated the cost effectiveness of improving adherence to therapy and inhalation technique among patients.[101] The study reported a 10% reduction in annual costs mostly related to a reduced risk of hospitalization.

One literature review focused on the cost-effectiveness of pharmacotherapy in ambulatory care settings.[102] The author concluded (without providing quantitative assessments) that pharmacotherapeutic strategies for managing ambulatory COPD patients are cost effective, with particular benefit for more severe patients.

Clinical Controversy…

In the United States, all products containing a LABA agent, either alone or in combination with ICs, include a black box warning about an increased risk of severe asthma attacks or death associated with their use. This caution applies to patients with asthma, and it is strongly recommended that LABAs use should always be in conjunction with another controller therapy (eg, ICs) and that use should be limited in duration. This concern only applies to patients with asthma and is not relevant concerning the use of LABA therapy for COPD patients.

Combination products of a long-acting inhaled β-agonist and an IC agent are the most commonly prescribed medications for lung disease, including COPD. However, in expert guidelines, ICs are indicated only for patients with more severe disease who experience frequent exacerbations. Many patients now receiving therapy with the combination inhaler may be candidates for bronchodilator therapy alone, although the benefit of ICs continues to be a focus of clinical research, including the potential for a mortality benefit.

The role of systemic corticosteroids for acute exacerbations of COPD has been clarified in recent years. However, the appropriate dosage regimen is not well established. Regimens range from initial high doses (methylprednisolone 125 mg every 6 hours) to more conservative dosing (prednisone 40-60 mg/day). Consensus guidelines indicate that bronchodilator therapy is the focus of pharmacotherapy for COPD. However, there is no clear choice for the initial agent. For patients with daily but not persistent symptoms, either ipratropium or albuterol offers advantages as initial therapy. Both also have limitations if chosen as the initial therapy.

International guidelines recommend long-acting bronchodilator therapy for patients with moderate to very severe disease or when symptoms are not adequately managed with short-acting agents or as-needed therapy. When response to a single long-acting bronchodilator is not optimal, guidelines recommend the use of combinations. However, data are lacking presently about the therapeutic benefit of combinations of long-acting bronchodilators, and this approach is associated with substantial costs.

EVALUATION OF THERAPEUTIC OUTCOMES

To evaluate therapeutic outcomes of COPD effectively, the practitioner must first delineate between chronic stable COPD and acute exacerbations. In chronic stable COPD, pulmonary function tests should be assessed periodically and with any therapy addition, change in dose, or deletion of therapy. Because objective improvements often are minimal, subjective assessments are important. Other outcome parameters are commonly evaluated, including dyspnea score, quality-of-life assessments, and exacerbation rates, including visits to the emergency department or hospitalization. In acute exacerbations of COPD, white blood cell count, vital signs, chest x-ray, and changes in frequency of dyspnea, sputum volume, and sputum purulence should be assessed at the onset and throughout treatment of an exacerbation. In more severe exacerbations, ABGs and oxygen saturation also should be monitored. As with any drug therapy, patient adherence to therapeutic regimens, side effects, potential drug interactions, and subjective measures of quality of life also must be evaluated.

To date, there is no evidence that any of the available pharmacotherapies for COPD impact disease progression. Removal of the primary causative factor for COPD (eg, cessation of cigarette smoking) does improve survival, as does supplemental oxygen therapy in a subset of patients with COPD. The most pertinent clinical outcomes that have emerged from clinical trials over the past decade are symptom improvement and reductions in exacerbation frequency. While it is important to continue to explore strategies to improve survival, consideration should be given to these two relevant and important outcome measures when initiating, continuing, and monitoring therapy. Because of the tremendous impact of exacerbations on disease progression, a reduction in exacerbation frequency may be predicted to show a benefit; however, this has not been proven.

END-OF-LIFE CARE

Based on the natural course of COPD, characterized by the progressive decline in lung function and development of complications, consideration should be given to end-of-life decisions and advanced directives.[1] Factors associated with expected mortality within 1 year have been identified. These include older age, diagnosis of depression, declining overall health status, hypercapnia, an FEV_1 of less than 30% predicted, ability to walk only a few steps without resting, more than one emergent hospitalization in the past year, and the presence of comorbidities, including congestive heart failure. An effective strategy to discuss end-of-life care involves the patient's participation in identifying advanced directives. Patients should be assured that symptoms, including pain, will be managed and their dignity will be preserved. Specific issues that should be addressed include location and provider for terminal care, desires to use or withhold mechanical ventilation, and involvement of other family members in decisions on behalf of the patient.

Chapter 28: Pulmonary Arterial Hypertension

Rebecca Moote; Rebecca L. Attridge; Deborah J. Levine

INTRODUCTION

KEY CONCEPTS

- 1 Pulmonary arterial hypertension (PAH) is defined as a mean pulmonary artery pressure (mPAP) more than or equal to 25 mm Hg at rest with a pulmonary wedge pressure or left ventricular end-diastolic pressure (LVEDP) less than or equal to 15 mm Hg and a pulmonary vascular resistance (PVR) more than 3 Wood units (WU) measured by right cardiac catheterization.
- 2 Diagnosis of PAH is growing because of increased awareness and knowledge of the disease state, leading to earlier and improved evaluation and identification.
- 3 Regardless of the etiology, be it unknown or related to an associated medical condition, subgroups of PAH are based on similar clinical and pathologic physiology.
- 4 The underlying cause of PAH is a complicated amalgam of endothelial cell dysfunction, a procoagulant state, platelet activation, vasoconstriction, loss of relaxing factors, cellular proliferation, hypertrophy, fibrosis, and inflammation.
- 5 Patients with PAH present with exertional dyspnea, fatigue, weakness, and exertion intolerance. As the disease progresses, symptoms of right heart dysfunction and failure, such as dyspnea at rest, lower extremity edema, chest pain, and syncope, are seen.
- 6 The only way to make a definitive diagnosis of PAH is by right heart catheterization. The right heart catheterization provides important prognostic information and can be used to assess pulmonary vasoreactivity prior to initiating therapy.
- 7 The goals of treatment are to alleviate symptoms, improve the quality of life, slow the progression of the disease, and improve survival.
- 8 A general goal of PAH treatment is to correct the imbalance between vasoconstriction and

vasodilation and prevent adverse thrombotic events to improve oxygenation, functional class, exercise capacity, and quality of life.

- 9 Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH.
- 10 Conventional therapy of PAH includes oral anticoagulants, diuretics, oxygen, and digoxin.
- 11 Prostacyclin analogs such as epoprostenol, treprostinil, and iloprost induce potent vasodilation of pulmonary vascular beds. Only epoprostenol has demonstrated improved survival.
- 12 Endothelin receptor antagonists, bosentan, ambrisentan and macitentan, improve exercise capacity, hemodynamics, and functional class in PAH. Macitentan also significantly decreases the composite end point of events related to PAH or death.
- 13 Phosphodiesterase-5 inhibitors, including sildenafil and tadalafil, are potent and highly specific drugs that have been shown to reduce mPAP and improve functional class.
- 14 Riociguat is a novel soluble guanylate cyclase stimulator shown to improve exercise capacity, hemodynamic parameters, and functional class.
- 15 Calcium channel blockers may be considered in a small number of patients who have a positive response on acute vasoreactivity testing.
- 16 Combination therapy in PAH may address more than one mechanism causing this disease. Combination therapy may be initiated sequentially or as the initial regimen in patients with worse functional classes. Recent evidence demonstrated that initial combination therapy was associated with a significant reduction in time to clinical failure and PAH hospitalizations.

Pulmonary hypertension is a term describing a group of conditions relating to elevated blood pressure measured within the pulmonary artery. Pulmonary hypertension is not a specific diagnosis; rather it is a complex group of disorders relating to the pulmonary circulation. Pulmonary hypertension is classified into five groups according to the World Health Organization (WHO; **Table 28-1**).[1] Pulmonary arterial hypertension (PAH) or Group 1 pulmonary hypertension is a progressive disease characterized by an elevation in pulmonary arterial pressure and pulmonary vascular resistance (PVR). 1 PAH may be defined as a mean pulmonary artery pressure (mPAP) more than or equal to 25 mm Hg at rest, with a pulmonary capillary wedge pressure or left ventricular end-diastolic pressure (LVEDP) less than or equal to 15 mm Hg and a PVR more than 3 Wood units (WU) measured by cardiac catheterization.[2,3,4]

TABLE 28-1 World Health Organization Classification of Pulmonary Hypertension

Group 1—PAH

Group 1—PAH

- 1.1. IPAH
- 1.2. Heritable
    - 1.2.1. BMPR2
    - 1.2.2. Other mutations: ALK-1, ENG, SMAD9, CAV1, KCNK3
- 1.3. Drugs and toxins induced
- 1.4. APAH
    - 1.4.1. Connective tissue diseases
    - 1.4.2. HIV infection
    - 1.4.3. Portal hypertension
    - 1.4.4. Congenital heart diseases
    - 1.4.5. Schistosomiasis
- 1.5. Pulmonary venoocclusive disease and/or pulmonary capillary hemoangiomatosis
    - 1.5.1. Idiopathic
    - 1.5.2. Heritable
        - 1.5.2.1. EIF2AK4 mutation
        - 1.5.2.2. Other mutations
    - 1.5.3. Drugs, toxins, and radiation induced
    - 1.5.4. Associated with:
        - 1.5.4.1. Connective tissue disease
        - 1.5.4.2. HIV infection
- 1.6. Persistent pulmonary hypertension of the newborn

Group 2—Pulmonary Hypertension due to Left Heart Disease

- 2.1. Left ventricular systolic dysfunction
- 2.2. Left ventricular diastolic dysfunction

- 2.3. Valvular disease
- 2.4. Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
- 2.5. Congenital/acquired pulmonary veins stenosis

Group 3—Pulmonary Hypertension due to Lung Diseases and/or Hypoxia

- 3.1. Chronic obstructive pulmonary disease
- 3.2. Interstitial lung disease
- 3.3. Other pulmonary diseases with mixed restrictive and obstructive pattern
- 3.4. Sleep-disordered breathing
- 3.5. Alveolar hypoventilation disorders
- 3.6. Chronic exposure to high altitude
- 3.7. Developmental abnormalities

Group 4—CTEPH

- 4.1. Chronic thromboembolic pulmonary hypertension
- 4.2. Other pulmonary artery obstructions
    - 4.2.1. Angiosarcoma
    - 4.2.2. Other intravascular tumors
    - 4.2.3. Arteritis
    - 4.2.4. Congenital pulmonary arteries stenosis
    - 4.2.5. Parasites (hydatidosis)

Group 5—Pulmonary Hypertension with Unclear and/or Multifactorial Mechanisms

- 5.1. Hematological disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
- 5.2. Systemic disorders: sarcoidosis, pulmonary Langerhans' cell histiocytosis, lymphangioleiomyomatosis

Group 1—PAH

- 5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
- 5.4. Others: pulmonary tumoral thrombotic microangiopathy, fibrosing mediastinitis, chronic renal failure (with/without dialysis), segmental pulmonary hypertension

ALK-1, activin receptor-like kinase type-1; APAH, associated pulmonary hypertension; BMPR2, bone morphogenetic protein receptor 2; CAV1, caveolin-1; CTPH, chronic thromboembolic pulmonary hypertension; EIF2AK4, eukaryotic translation initiation factor 2 alpha kinase 4; ENG, endoglin; HIV, human immunodeficiency virus; IPAH, idiopathic pulmonary arterial hypertension; PAH, pulmonary arterial hypertension.

Data from Galiè N, Humbert M, Vachiery J-L, et al. 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Heart J. *August 2015:ehv317*.

PAH may occur in the setting of underlying medical conditions or as an idiopathic disease (idiopathic PAH [IPAH]). Historically, medical treatment of PAH has been limited because of lack of effective, targeted therapy. Without medical therapy, IPAH portends a poor prognosis (median survival 2.8 years) after diagnosis.[5] Prior to the availability of disease-specific therapy for IPAH, survival rates for 1, 3, and 5 years were 68%, 48%, and 34%, respectively.[6] Since the approval of epoprostenol in 1995, a number of new therapeutic options have been developed. A recent epidemiologic study demonstrated survival rates at 1 and 3 years were 85% and 68%, respectively, in patients with PAH, and 91% and 74%, respectively, in patients with IPAH.[7]

EPIDEMIOLOGY

The prevalence of PAH is estimated to be 15 to 26 patients per million individuals.[8] Unfortunately, only 15,000 to 20,000 of the afflicted patients worldwide have an established diagnosis of PAH and are currently receiving treatment. In a French registry study of more than 600 patients with PAH, Humbert found that the most common cause of PAH was IPAH (approximately 40%), followed by PAH associated with connective tissue diseases (15.3%), congenital heart disease (11.3%), portal hypertension (10.4%), and familial PAH (FPAH) (3.9%).[9] The US based REVEAL registry (Registry to Evaluate Early and Long-Term Pulmonary Arterial Hypertension Disease Management) also provides helpful insight in to the epidemiology of PAH. The registry includes over 3,500 patients and found that 46% of PAH was idiopathic while 25% was associated with connective tissue diseases and 10% was associated with congenital heart diseases.[10] 2 However, diagnosis of PAH is growing because of increased awareness and knowledge of the disease state, leading to earlier and improved evaluation and identification.

ETIOLOGY

PAH most often originates with a predisposing state and one or more inciting factors that could be

genetic or environmental exposures.[11] Once a permissive environment exists, multiple mechanisms can be activated leading to vascular constriction, cellular proliferation, and a prothrombotic state resulting in PAH and its sequelae.[12] PAH can be associated with numerous conditions as well as being an idiopathic condition (IPAH). The incidence of IPAH is estimated to be 2.0 to 7.6 per 1 million in North America and Europe, with a marked female predominance (male-to-female ratio, 1:1.7), and mean age at time of recognition is approximately 37 years, although there is considerable variation.[1,2,3] Based on recent registry data, PAH overall is now being diagnosed more commonly in older patients, with a mean age at diagnosis ranging from 50 to 65 years.[1,2,4] Although uncommon in the United States, the most common form of PAH worldwide is schistosomiasis followed by congenital heart disease and pulmonary hypertension of early childhood.[3] Rheumatologic diseases such as scleroderma, systemic lupus erythematosus, rheumatoid arthritis, and myositis are also associated with development of PAH. Patients with scleroderma who develop PAH, estimated between 7% and 12% of patients, have markedly worse outcomes in comparison to other PAH subgroups. Patients with human immunodeficiency virus (HIV) infection can develop PAH with a prevalence of 0.5%. In patients with liver disease, portal hypertension may cause concurrent pulmonary hypertension in an estimated 2% to 6% of patients.[3] Multiple drugs and toxins have been associated with PAH but those that definitively precipitate PAH include anorexigens such as aminorex, fenfluramine, benfluorex, and dexfenfluramine.[1,3,4] Other definite precipitants include toxic rapeseed oil and selective serotonin reuptake inhibitors (SSRIs), specifically in pregnant patients exposed to SSRIs after 20 weeks of gestation.[3,4] Other drugs considered to be likely or possible causative agents for PAH include amphetamines, L-tryptophan, cocaine, interferon α and β, dasatinib and certain chemotherapeutic agents (mitomycin C, carmustine, etoposide, cyclophosphamide, bleomycin).[3,4] Heritable PAH (HPAH) includes both IPAH with germline mutations and familial cases without an identified mutation. Germline mutations seen in PAH include bone morphogenetic protein receptor 2 (BMPR2) and activin receptor-like kinase 1 (ALK-1). About 75% of patients with HPAH have BMPR2 mutations.[2] Genetic testing for these mutations may be offered and professional genetic counseling should be provided at expert centers.[3]

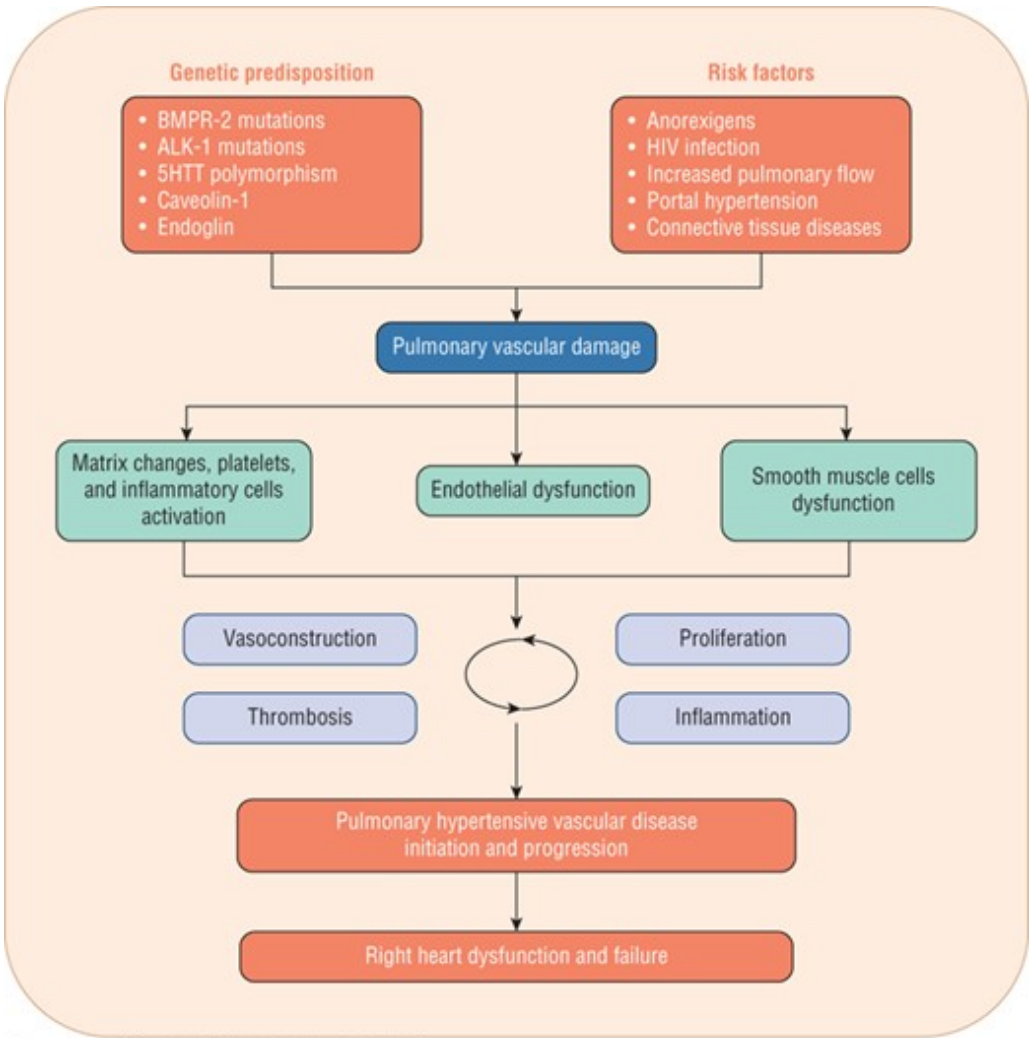
PATHOPHYSIOLOGY

PAH is a disease progressive vasoconstriction of the small pulmonary arteries that eventually leads to right ventricular hypertrophy and failure. The right ventricle is thin-walled and used to the much lower pressures of the pulmonary system and therefore does not have the reserve that the LV does.[14] 3 Regardless of etiology, all subgroups of PAH are based on similar clinical and pathologic physiology. 4 The pathobiology of PAH involves several key biologic events, including endothelial cell dysfunction, thrombotic lesions, platelet activation, gain of constricting factors, loss of relaxing factors, intimal proliferation, medial hypertrophy, fibrosis, and inflammation—all combining to produce progressive and deleterious vascular remodeling (**Fig. 28-1**).[15,16] Multiple genetic mutations are known to contribute to the pathophysiology of PAH, including BMPR2, ALK-1, Caveolin-1, KCNK3, nitric oxide synthase (ec-NOS), 5-hydroxytryptamine (serotonin [5-HT]) transporter (5-HTT), and others.[3,15,17] A mutation of BMPR2 receptor is an aberration of signal transduction in the pulmonary

vascular smooth muscle cell that is postulated to alter apoptosis favoring cellular proliferation. ALK-1 is part of the transforming growth factor-β superfamily and is seen in hereditary hemorrhagic telangiectasia and PAH.[18] 5-HTT is associated with pulmonary artery smooth muscle proliferation and is present in IPAH in the homozygous form in 65% of patients.[19] Dysregulation of 5-HT synthesis mediated via tryptophan hydroxylases is closely linked to the hypoxic PAH phenotype in mice and may contribute to PAH development.[20]

FIGURE 28-1

Pulmonary arterial hypertension; potential pathogenetic and pathobiologic mechanisms. (5-HTT, serotonin transporter gene; ALK-1, activin receptor-like kinase 1 gene; BMPR-2, bone morphogenetic receptor 2 gene; HIV, human immunodeficiency virus.) *(Reproduced with permission from Galie N, Torbicki A, Barst R. Guidelines on diagnosis and treatment of pulmonary arterial hypertension.* Eur Heart J *2004;25:2243-2278.)*



Molecular, cellular, and genetic mechanisms are mediated by a variety of biologically active compounds, including prostacyclin (PGI_2), endothelin-1 (ET-1), nitric oxide (NO), and 5-HT. PGI_2 is a

vasodilatory and antiproliferative substance that is produced by the endothelial cells, and the synthesis of PGI_2 and its circulating levels are reduced in PAH. Furthermore, thromboxane, a vasoconstrictor, is increased in PAH. ET-1 is produced in the endothelium, and it possesses potent vasoconstrictor and mitogenic effects. ET-1 levels are increased in PAH and clearance is reduced. ET-1 acts via the endothelin receptors (ET_A and ET_B) to promote vascular smooth muscle proliferation and vasoconstriction.[16,21] Plasma levels of ET-1 are correlated with severity of PAH and prognosis.[22] NO is produced in the endothelium via NO synthase and leads to vasodilation and opening of cell membrane potassium channels to allow potassium ion efflux, membrane depolarization, and calcium channel inhibition. Voltage-dependent potassium channels are inhibited by a number of stimuli that promote PAH, including hypoxia and fenfluramine, resulting in downregulated potassium channels in patients with PAH. Entering calcium is a signal for release of sarcoplasmic calcium and activation of the contractile apparatus. NO promotes vasodilation through calcium channel inhibition. In PAH there is evidence of decreased NO synthase expression, leading to vasoconstriction and cellular proliferation.[23] Elevated 5-HT has been observed and vasoconstriction mediated via the increased expression of the $5\text{-}HT_{1B}$ receptor is seen in PAH.[3]

Autoantibodies, proinflammatory cytokines, and inflammatory infiltrates may also participate in the pathogenesis of PAH. Coagulation is disordered in PAH as evidenced by increased levels of von Willebrand factor, plasma fibrinopeptide A, plasminogen activator inhibitor-1, 5-HT, and thromboxane. Furthermore, tissue plasminogen activator, thrombomodulin, NO, and PGI_2 are decreased, leading to an imbalance favoring thrombosis. Endothelial dysfunction is the common denominator of mechanisms for PAH, and a variety of injuries, such as shear stress, inflammation, toxins, and hypoxia, are thought to be involved.[3,15]

5 The signs and symptoms of PAH are highly variable depending on the stage of the disease and comorbidities. The impact of these signs and symptoms on functional capacity can be generally described using the World Health Organization functional classification (**Table 28-2**). Symptoms are often related to right ventricular dysfunction and may include exertional dyspnea, fatigue, and weakness.[4] As the disease progresses, patients may experience dyspnea at rest, chest pain, presyncope, syncope, lower extremity edema, and abdominal bloating and distension. On physical examination, patients with PAH may have an accentuated component of S_2 audible at the apex of the heart, midsystolic ejection murmur, palpable left parasternal lift, right ventricular S_4 gallop, and a prominent "a" wave.[3] Hepatojugular reflux, a diastolic murmur of pulmonary regurgitation, and a systolic murmur of tricuspid regurgitation may be present in advanced disease.[3] Patients with an increased risk of mortality are more likely to have a higher WHO functional class, older age, male gender, higher brain natriuretic peptide (BNP), higher right atrial pressure and lower cardiac output. In contrast, patients with a decreased risk of mortality are more likely to have a lower WHO functional class, higher 6-minute walk distance, lower BNP, and higher cardiac output.[24]

TABLE 28-2 World Health Organization Functional Classification of PAH

Class	Description
I	Patients with PAH in whom there is no limitation of usual physical activity; ordinary physical

Class	Description
	activity does not cause increased dyspnea, fatigue, chest pain, or presyncope.
II	Patients with PAH who have mild limitation of physical activity. There is no discomfort at rest, but normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope.
III	Patients with PAH who have marked limitation of physical activity. There is no discomfort at rest, but less than normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope.
IV	Patients with PAH who are unable to perform any physical activity at rest and who may have signs of right ventricular failure. Dyspnea and/or fatigue may be present at rest, and symptoms are increased by almost any physical activity.

PAH, pulmonary arterial hypertension.

Data from Badesch DB, Abman SH, Simonneau G, Rubin LJ, McLaughlin VV. Medical therapy for pulmonary arterial hypertension: Updated ACCP evidence-based clinical practice guidelines. Chest *2007;131:1917-1928.*

Several comorbidities and environmental factors play a role in the development of PAH and must be evaluated when establishing an initial diagnosis of PAH (**Fig. 28.2**). In patients with a clinical suspicion of PAH, Doppler echocardiography should be performed as a noninvasive screening test that can detect increased pulmonary pressures, although this study cannot be used to definitively diagnose PAH.[25] Echocardiography is also useful in evaluating specific causes of pulmonary hypertension, such as a cardiac shunt or left-sided heart disease. Echocardiography can also be used to assess treatment interventions and to follow disease progression.[3] However, right heart catheterization is the definitive study to use in diagnosis of PAH and when patients are worsening clinically.[17] Right heart catheterization can be used to assess pulmonary vasoreactivity in patients with idiopathic, heritable, or drug-induced PAH with the administration of fast-acting, short-duration vasodilators to determine the extent of vascular smooth muscle constriction and vasodilator response to calcium channel blockers (CCBs; I-C for IPAH; IIIb-C for associated pulmonary arterial hypertension [APAH]).[1] **Table 28-3** lists the classes of recommendations and levels of evidence, and **Table 28-4** lists commonly used agents and their dosages. The consensus definition of a positive response is defined as a reduction of mPAP by at least 10 mm Hg to a value of 40 mm Hg or less.[26] Patients with an acute response (approximately 13% of patients on initial testing) are most likely to have a beneficial hemodynamic and clinical response. These patients may be able to be treated with CCBs. However, about half of these patients lose an acute vasodilator response when tested 1 year later.[27] Therefore, even this small group of patients who may be treated with CCBs must be followed closely for safety and efficacy. If the patient loses the acute vasodilator response, the patient needs to be switched to different PAH therapy. Patients who have a negative response on initial vasodilator testing are not candidates for treatment with CCBs.[3,28]

FIGURE 28-2

Diagnostic algorithm of PAH. (CTEPH, chronic thromboembolic pulmonary hypertension; HIV, human

immunodeficiency virus; PVOD/PCH, pulmonary venoocclusive disease or pulmonary capillary hemangiomatosis; RHC, right heart catheterization.) *(Data from Galie N, Humbert M, Vachiery JL, et al. 2015 ESC/ERA Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Respir J 2015.)*

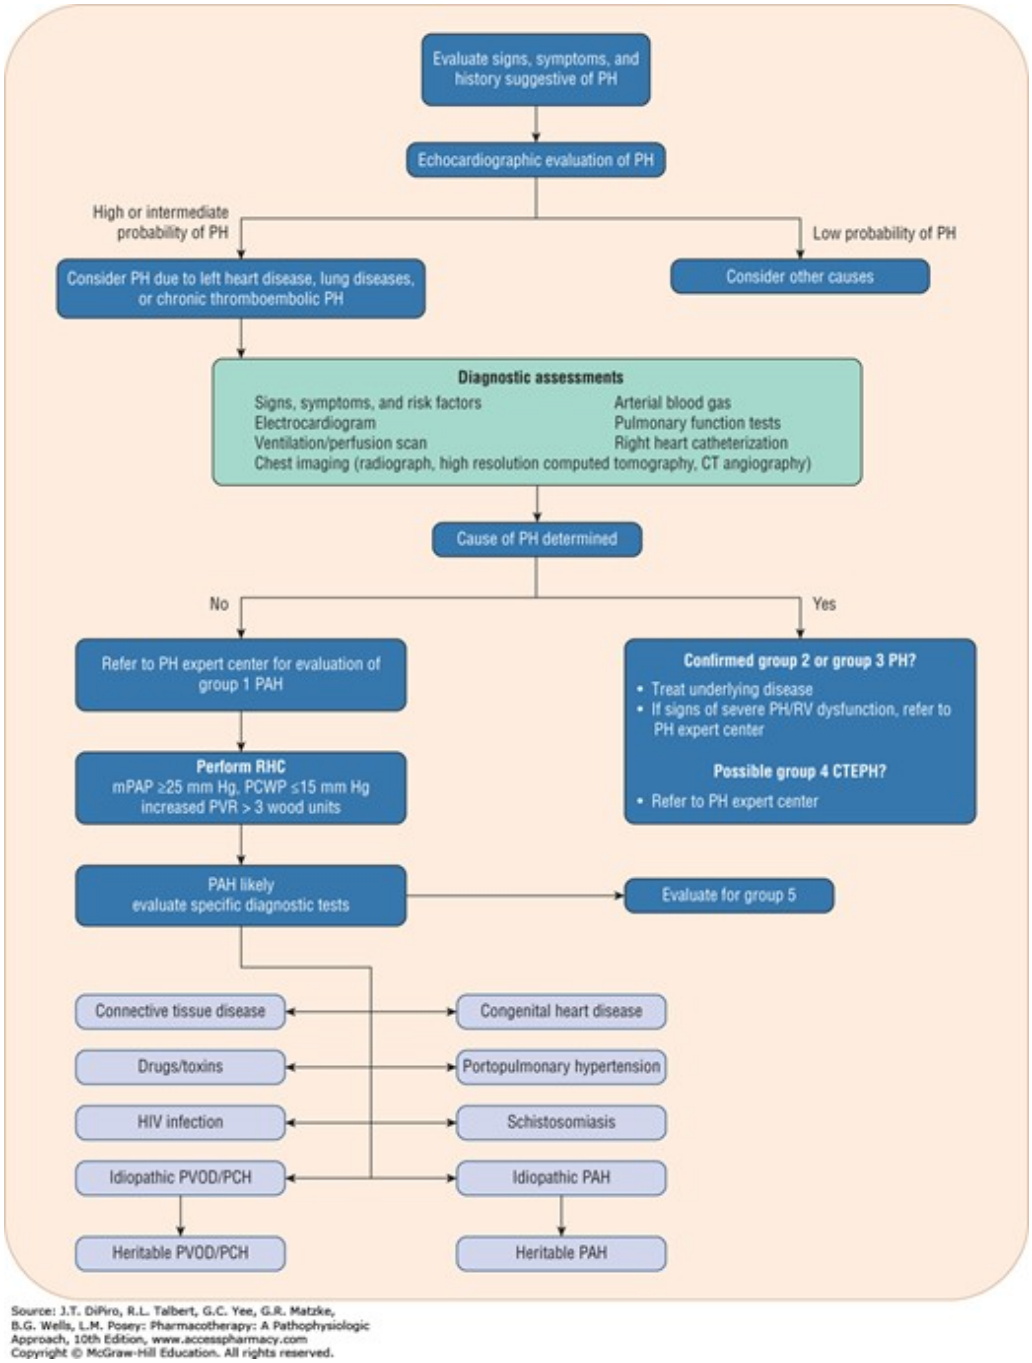


TABLE 28-3 Classes of Recommendations and Levels of Evidence[a]

Classes of Recommendations	Definition	Suggested Wording to Use
Class I	Evidence and/or general agreement that a given treatment or procedure is beneficial, useful, effective.	Is recommended/Is indicated.

Classes of Recommendations	Definition	Suggested Wording to Use
Class II	Conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of the given treatment or procedure.	
Class IIa	Weight of evidence/opinion is in favor of usefulness/efficacy.	Should be considered.
Class IIb	Usefulness/efficacy is less well established by evidence/opinion.	May be considered.
Class III	Evidence or general agreement that a given treatment or procedures is not useful/effective, and in some cases may be harmful.	Is not recommended.
Levels of Evidence	**Definition**	
Level of evidence A	Data derived from multiple randomized clinical trials or meta-analyses.	
Level of evidence B	Data derived from a single randomized clinical trial or large nonrandomized studies.	
Level of evidence C	Consensus of opinion of the experts and/or small studies, retrospective studies, registries.	

[a]Classes of Recommendations and Levels of Evidence are consistent between the ESC/ERS Guidelines and the WHO Guidelines.

TABLE 28-4 Agents for Vasodilator Testing in PAH

	NO	Epoprostenol	Adenosine
Route	Inhaled	IV	IV
Dose range	10-80 ppm	2-10 ng/kg/min	50-250 mcg/kg/min
Dosing increments	10-80 ppm for 5 min	2 ng/kg/min every 15 min	50 mcg/kg/min every 2 min
Common side effects	None	Headache, flushing, nausea	Chest tightness, dyspnea

NO, nitric oxide; PAH, pulmonary arterial hypertension.

Data from reference 33.

CLINICAL PRESENTATION Pulmonary Arterial Hypertension Symptoms

- Exertional dyspnea
- Fatigue
- Weakness

- Exertional chest pain
- Complaints of general exertion intolerance
- Dyspnea at rest as disease progresses
- Syncope
- Lower extremity edema

Symptoms of Related Conditions

- Paroxysmal nocturnal dyspnea as a result of left-sided heart disease
- Raynaud phenomenon, arthralgia, or swollen hands and other symptoms of connective tissue disease
- Orthopnea

Symptoms of Disease Progression

- Leg swelling
- Abdominal bloating and distension
- Anorexia
- Profound fatigue
- May develop as right ventricular dysfunction and tricuspid valve regurgitation evolve

Signs

- Accentuated component of S_2 audible at the apex of the heart
- Early systolic ejection click
- Midsystolic ejection murmur
- Palpable left parasternal lift
- Right ventricular S_4 gallop
- Prominent “a” wave due to increased right ventricular stiffness

Signs of Advanced Disease

- Diastolic murmur of pulmonary regurgitation
- Pansystolic murmur of tricuspid regurgitation

- Hepatojugular reflux
- A pulsatile liver
- Right ventricular S_3 gallop
- Marked distension of jugular veins
- Peripheral edema
- Hypotension
- Cool extremities suggesting markedly reduced cardiac output and peripheral vasoconstriction
- Diminished pulse pressure
- Cyanosis (suggests right-to-left shunting)
- Digital clubbing
- Rales
- Dullness
- Decreased breath sounds
- Accessory muscle use
- Prolonged exhalation
- Peripheral venous insufficiency (suggests venous thrombosis or pulmonary thrombotic disease)

Because PAH commonly occurs in the setting of connective tissue disease, serologic markers should be obtained to confirm or exclude these diagnoses.[3,29] Liver function tests (LFTs) should also be evaluated due to the increased risk for PAH in patients with cirrhosis and portal hypertension and as a baseline for certain PAH therapies. HIV is associated with an increased prevalence of PAH, and HIV testing should be done as part of the initial PAH workup.[3] Chronic thromboembolic pulmonary hypertension (CTEPH) should be evaluated with ventilation–perfusion lung scans and/or pulmonary angiography. Pulmonary function testing and arterial blood oxygenation should be evaluated. The diffusing capacity of carbon monoxide may be particularly helpful in systemic sclerosis and PAH.[3] In patients with PAH, serial determinations of functional class, exercise capacity (assessed by the 6-minute walk distance), and serial biomarkers provide benchmarks for disease severity, response to therapy, and progression.[3,29] These variables can be used to determine risk level in patients and may aid in prognosis. **Table 28-5** outlines calculation of low, intermediate, and high-risk patients based on these factors. **Table 28-6** also provides guidelines for initial assessment and timing and when each assessment is indicated.

TABLE 28-5 Risk Assessment in PAH

Determinants of Prognosis[a] (Estimated 1-year Mortality)	Low Risk <5%	Intermediate Risk 5%-10%	High Risk >10%
Clinical signs of right heart failure	Absent	Absent	Present
Progression of symptoms	No	Slow	Rapid
Syncope	No	Occasional syncope[b]	Repeated syncope[c]
WHO functional class	I, II	III	IV
6MWD	>440 m	165-440 m	<165 m
Cardiopulmonary exercise testing	Peak VO_2 >15 mL/min/kg (>65% pred.)	Peak VO_2 11-15 mL/min/kg (35%-65% pred.)	Peak VO_2 <11 mL/min/kg (<35% pred.)
	Ve/VCO_2 slope <36	Ve/VCO_2 slope 36-44.9	Ve/VCO_2 slope ≥45
NT-proBNP plasma levels	BNP <50 ng/L	BNP 50-300 ng/L	BNP >300 ng/L
	NT-proBNP <300 ng/mL	NT-proBNP 300-1400 ng/mL	NT-proBNP >1400 ng/mL
Imaging (echocardiography, CMR imaging)	RA area <18 cm^2	RA area 18-26 cm^2	RA area >26 cm^2
	No pericardial effusion	No or minimal, pericardial effusion	Pericardial effusion
	RAP <8 mm Hg	RAP 8-14 mm Hg	RAP >14 mm Hg
Hemodynamics	CI ≥2.5 L/min/m^2	CI 2.0-2.4 L/min/m^2	CI ≤2.0 L/min/m^2
	SvO_2 >65%	SvO_2 60%-65%	SvO_2 <60%

6MWD, 6-minute walking distance; NT-proBNP, N-terminal pro-brain natriuretic peptide; RA, right atrium; RAP, right atrial pressure; SvO2, mixed venous oxygen saturation; VCO2, ventilatory equivalents for carbon dioxide; VO2, oxygen consumption.

[a]Most of the proposed variables and cut-off values are based on expert opinion. They may provide prognostic information and may be used to guide therapeutic decisions, but applications to individual patients must be done carefully. One must also note that most of these variables have been validated mostly for IPAH and the cut-off values used above may not necessarily apply to other forms of PAH. Futhermore, the use of approved therapies and their influence on the variables should be considered in the evaluation of the risk.

[b]Occasional syncope during brisk or heavy exercise, or occasional orthostatic syncope in the otherwise stable patient.

[c]Repeated episodes of syncope, even with little or regular physical activity.

hypertension. Eur Respir J *2015*.

TABLE 28-6 Suggested Assessment and Timing for the follow-up of Patients with PAH

	At Baseline	Every 3-6 Months[a]	Every 6-12 Months[a]	3-6 Months after Changes in Therapy[a]	In Case of Clinical Worsening
Medical assessment and determination of functional class	+	+	+	+	+
ECG	+	+	+	+	+
6MWT/Borg dyspnea score	+	+	+	+	+
CPET	+		+		+[a]
Echo	+		+	+	+
Basic laboratories[b]	+	+	+	+	+
Extended lab[c]	+		+		+
Blood gas analysis[d]	+		+	+	+
Right heart catheterization	+		+[e]	+[f]	+[f]

6MWT, 6-minute walking test; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BGA, blood gas analysis; BNP, brain natriuretic peptide; CPET, cardiopulmonary exercise testing; ECG, electrocardiogram; Echo, echocardiography; ERAs, endothelin receptor antagonists; FC, functional class; INR, international normalized ratio; lab, laboratory assessment; NT-proBNP, N-terminal pro-brain natriuretic peptide; PAH, pulmonary arterial hypertension; RHC, right heart catheterization; TSH, thyroid stimulating hormone.

[a]Intervals to be adjusted according to patient needs.

[b]Basic lab includes blood count, INR (in patients receiving vitamin K antagonists), serum creatinine, sodium, potassium, AST/ALT (in patients receiving ERAs), bilirubin and BNP/NT-proBNP.

[c]Extended lab includes TSH, troponin, uric acid, iron status (iron, ferritin, soluble transferrin receptor) and other variables according to individual patient need.

[d]From arterial or arterialized capillary blood; may be replaced by peripheral oxygen saturation in stable patients or if BGA is not available.

[e]Some centers perform RHCs at regular intervals during follow-up.

[f]Should be considered.

TREATMENT

Desired Outcomes

7 The goals of treatment are alleviation of symptoms, improvement in the quality of life, prevention of disease progression, and improvement in survival.[13] While the first two outcomes are obtainable based on data from randomized trials, controversy exists over improvement in survival with current treatment regimens. Meta-analyses are conflicting; a 2007 meta-analysis of 16 trials demonstrated no mortality benefit in functional classes III/IV while a later 2009 study of 21 trials (6 of which were not included in the 2007 study) in predominately functional class III patients showed a 43% reduction in mortality.[30] Unfortunately, overall mortality remained high.[31] In addition, individual trials also show survival benefit, at least in the short term (ie, 3 years).[32]

General Approach to Treatment

Treatment of PAH may be categorized into nonpharmacologic, pharmacologic, and surgical interventions. 8 The principal endothelial abnormalities that are current pharmacologic therapeutic targets include (a) supplementing endogenous vasodilators, (b) inhibiting endogenous vasoconstrictors, and (c) reducing endothelial platelet interaction and limiting thrombosis. Nonpharmacologic therapy can be quite broad and should be used when clinically appropriate. Surgical therapy is indicated in certain situations and includes atrial septostomy, pulmonary thromboendarterectomy for CTEPH, and lung or heart–lung transplantation (for disease that is not responsive to medical therapy). Bilateral lung and lung-heart transplantation has been shown to improve survival rates in patients with PAH.[1]

Nonpharmacologic Therapy

9 Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH. Patients with PAH should be counseled on several important points. Pregnancy should be avoided due to high morbidity and mortality rates in females with PAH during pregnancy and in the postpartum course (I-C).[5] Immunization against influenza and pneumococcal disease should be provided (I-C).[3] Hypoxemia may aggravate vasoconstriction in patients with PAH; therefore, PAH patients may require supplemental oxygen (I-C), particularly when using air travel due to a reduction in ambient air concentration of oxygen.[33] Patients should adhere to a low-sodium diet to avoid fluid retention predisposing to right heart failure.[34] Cardiopulmonary rehabilitation improves functional status, exercise capacity, and quality of life in patients with PAH (I-A).[1]

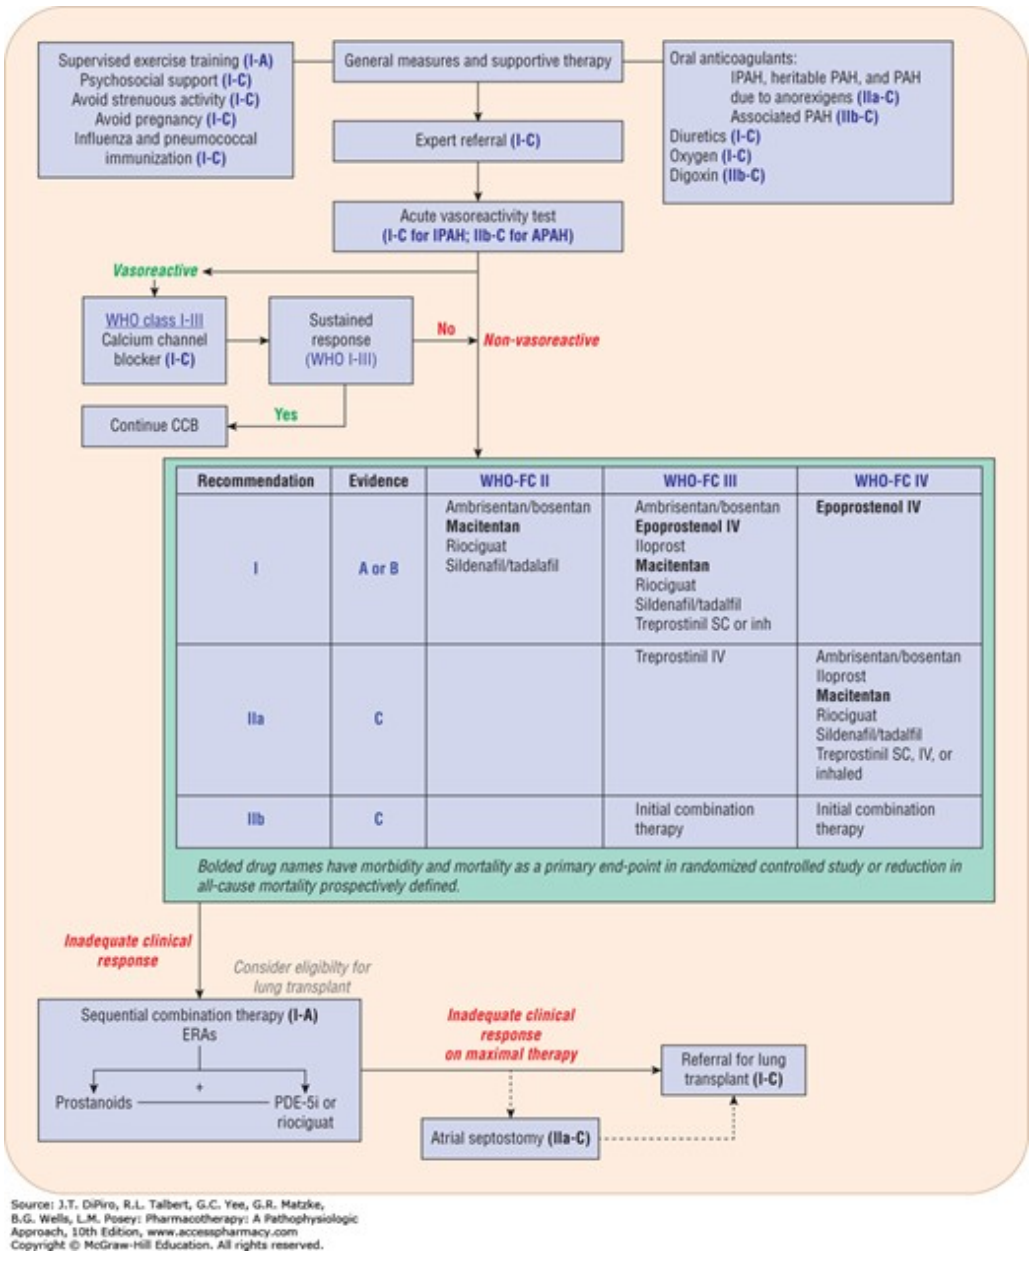
Pharmacologic Therapy

The number of potential therapies for PAH has expanded dramatically in the last decade. In addition to adjunctive background therapy, multiple drugs have been developed specifically for treatment of PAH. **Figure 28-3** illustrates the current recommended treatment algorithm based on the most recent

guidelines.[15]

FIGURE 28-3

Treatment algorithm for pulmonary arterial hypertension (PAH). Levels of evidence and strength of recommendation are defined in Table 28-3. (APAH, associated pulmonary arterial hypertension; CCBs, calcium channel blocker; ERA, endothelin receptor antagonist; IPAH, idiopathic pulmonary arterial hypertension; PDE-5i, phosphodiesterase type-5 inhibitor, WHO-FC, World Health Organization functional class.) *(Adapted from Galie N, Corris PA, Frost A, et al. Updated treatment algorithm of pulmonary arterial hypertension.* J Am Coll Cardiol *2013;62:D60-72.)*



Conventional Pharmacologic Treatment

10 Conventional therapy includes oral anticoagulants, diuretics, oxygen, and digoxin.[29]

Anticoagulation with warfarin may be considered in patients with PAH, particularly if they have IPAH. The rationale for oral anticoagulants is based on the presence of traditional risk factors for venous thromboembolism, such as heart failure and sedentary lifestyle, as well as on the demonstration of thrombotic predisposition and thrombotic changes in the pulmonary microcirculation. Small retrospective and prospective studies support a survival benefit with anticoagulation.[35,36,37,38] The target international normalized ratio (INR) in most centers is 1.5 to 2.5.[3,26] Anticoagulation is recommended for patients with IPAH, HPAH, and PAH due to anorexigens (IIb-C) as well as in associated PAH (IIb-C).[1] It may also be recommended in patients on long-term intravenous prostaglandin therapy as these patients are at risk for catheter-associated thrombosis.[4]

Loop diuretics such as furosemide are helpful adjunctive therapy in patients with decompensated right heart failure and associated findings of increased central venous pressure, abdominal organ congestion, peripheral edema, and ascites.[3] Appropriate diuretic therapy in right heart failure provides symptomatic and clinical benefits in patients with PAH (I-C).[1] Patients should be maintained at as close to a euvolemic state as possible.

Oxygen therapy with a goal oxygen saturation greater than 90% (0.90) may be beneficial in some patients, although there are no data regarding the long-term effects of oxygen treatment in PAH (I-C).[1] Oxygen treatment is controversial in patients with PAH associated with shunts (ie, Eisenmenger syndrome).

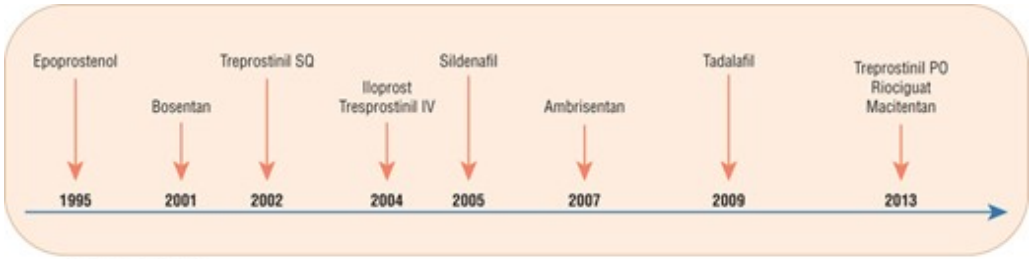
Digoxin may be used for patients with PAH with right heart failure as adjunctive therapy along with diuretics to control symptoms as well as in patients with atrial arrhythmias (I-C).[1] There are no long-term trials and benefit is uncertain. Optimal plasma concentrations are unknown; however, in light of recent trials of digoxin in left systolic dysfunction, the typical target concentration is between 0.5 and 0.8 ng/mL (0.64 and 1 nmol/L). Patients on digoxin should receive periodic monitoring of potassium.

Specific Pharmacologic Therapy

In recent years, there has been a surge in availability of drug therapy for the treatment of PAH. **Figure 28-4** illustrates the timeline of drug approval over the past few decades.

FIGURE 28-4

Timeline of pulmonary arterial hypertension (PAH) medication approvals.



Epoprostenol: 1995
Treprostnil: SQ 2002, IV 2004, PO 2013
Iloprost: 2004
Bosentan: 2001
Ambrisentan: 2007
Sildenafil: 2005
Tadalafil: 2009
Riociguat: 2013
Macitentan: 2013

Synthetic Prostacyclin and Prostacyclin Analogs

11 PGI_2 is produced predominantly by endothelial cells, and it induces potent vasodilation of all vascular beds. It is also a potent inhibitor of platelet aggregation and possesses cytoprotective and antiproliferative activities. PGI_2 synthase expression is reduced in pulmonary arteries, and urinary excretion of PGI_2 metabolites is reduced in PAH. Epoprostenol is a synthetic analog of PGI_2 and has a short half-life of 3 to 5 minutes; consequently, it must be given by continuous IV infusion. Initiation of epoprostenol should be done in a hospital setting at low doses ranging from 2 to 4 ng/kg/min and increased at a rate limited by side effects (flushing, headache, diarrhea, jaw pain, backache, abdominal cramping, extremity pain, and hypotension). The two available products, Flolan® (now available generic) and Veletri®, have unique stability and reconstitution parameters; both pharmacists and patients should be aware of the differences and follow the manufacturer recommendations. Due to the short half-life of the drug, it is recommended that the patient have a backup supply of the drug and infusion pump as interruption of epoprostenol may lead to life-threatening pulmonary vasoconstriction.[39] Because the drug must be administered by continuous infusion with a central venous catheter and pump, infection, catheter obstruction, and sepsis are potential complications. A Centers for Disease Control and Prevention study found that bloodstream infections occurred with epoprostenol and treprostinil in the range of 0.3 to 2.1 per 1,000 medicine days (approximately 1 infection every 3 years) when these drugs are given by the IV route.[40] The target dose for the first 2 to 4 weeks is around 10 to 15 ng/kg/min, and periodic dose increases are then required to maximize efficacy. Optimal doses are variable but are in the range of 25 to 40 ng/kg/min.[33,41] Multiple observational series have documented an improvement in survival in patients with IPAH compared with either historical control or predicted survival based on the National Institutes of Health Registry equation.[41,42,43] Based on current guidelines, epoprostenol is indicated for WHO functional class III and IV (I-A).[1]

Treprostinil (Remodulin) is a stable analog of PGI_2 given for subcutaneous (SC) or IV infusion approved for functional classes II, III, and IV.[41] The major advantages of treprostinil over epoprostenol include ease of use and increased safety due to a longer half-life, lowering the risk of rebound effects that may happen with drug interruption.[21] Treprostinil has been shown to improve 6-minute walk distance and hemodynamics with outcomes that are similar to epoprostenol.[44,45] In

clinical trials, the greatest exercise improvement was observed in patients who were more compromised at baseline and in patients who could tolerate doses in the upper quartile (≥13.8 ng/kg/min). The initial dose for treprostinil is 1.25 ng/kg/min by either the SC or the IV route. If not tolerated, the dose should be reduced to 0.625 ng/kg/min and retitration attempted at 4 weeks. Infusion site pain is common with the SC route and can occur in up to 85% of patients, leading to discontinuation of treatment in 8% of patients and limiting upward dose titration.[33] Patients unable to tolerate SC can be transitioned to IV treprostinil.[26] Transitions between prostacyclin agents or routes should be performed in an inpatient setting at an expert referral center. Bloodstream infections, primarily due to gram-negative pathogens, are more likely with IV treprostinil than with IV epoprostenol.[46] Recent data demonstrate that use of the diluent used for epoprostenol, which has a more basic pH, to reconstitute IV treprostinil may decrease rates of bloodstream infections to a rate similar to that seen with epoprostenol.[47] Other side effects are similar to epoprostenol. Based on international guidelines, treprostinil is recommended for functional class III (SC administration—I-A/B; IV administration—IIa-C), and functional class IV (SC and IV administration—IIa-C).[1]

In an effort to prevent complications and use of pumps and central venous catheters for PGI_2 analog administration, aerosolized formulations were developed. The first approved formulation, iloprost (Ventavis), is a PGI_2 analog that is given by inhalation using a dosing system provided by the manufacturer (ADD system) with the initial inhaled dose being 2.5 mcg six to nine times per day up to every 2 hours during waking hours. The dose should be titrated and maintained at 5 mcg/dose if tolerated. In a 3-month, randomized, double-blind, placebo-controlled trial, iloprost via inhalation provided at least a 10% improvement in 6-minute walking distance and improvement in functional class.[48] Inhaled iloprost can be cumbersome to use as each inhalation dose can take 4 to 10 minutes to administer and multiple inhalations are required for a full dose. Patients should also be instructed to have a backup supply as iloprost has a short half-life, similar to epoprostenol.[26] Adverse effects are similar to other PGI_2 analogs, including cough, headache, flushing, and jaw pain. Inhaled iloprost is indicated for functional class III (I-A/B) and functional class IV (IIa-C), although many clinicians prefer using the IV or SC route in patients with more severe disease.[1]

The second aerosolized formulation, inhaled treprostinil (Tyvaso), was approved by the FDA in July 2009 to improve exercise capacity in functional class III patients. In a randomized, double-blind, 12-week trial, patients receiving inhaled treprostinil experienced a 20-m improvement in 6-minute walk distance compared with those on placebo ($P < 0.0006$). All patients included in the trial were concurrently receiving bosentan or sildenafil for at least 3 months.[49] An open-label extension of the trial found that inhaled treprostinil provided sustained benefit and was safe and efficacious over a 2-year period.[50] The approved dosing of inhaled treprostinil is three breaths (18 mcg each) four times daily during waking hours. The dose may be titrated based on patient tolerance at 1- to 2-week intervals to maximum dose of nine breaths four times daily. Inhaled treprostinil requires less time to administer, but the formulation is more complicated to prepare than inhaled iloprost.[26] While inhaled treprostinil avoids the infusion-related complications of the other PGI_2 analogs, use is cautioned in patients with acute pulmonary infections or underlying lung disease. The most common adverse effects seen in clinical trials include throat irritation, cough, headache, nausea, dizziness, and flushing. Inhaled treprostinil may also cause systemic hypotension, and patients should be monitored carefully

if they are concurrently on diuretics, antihypertensives, or other vasodilators. Inhaled treprostinil is indicated for patients with functional class III (I-A/B) and IV (IIa-C).[1]

Finally, the first oral prostacyclin analog, sustained-release trepostinil (Orenitram), was approved by the FDA in December 2013 for patients with functional class II and III PAH. Oral treprostinil was studied as monotherapy in a 12-week study of 349 patients with PAH and was associated with a significant increase of 23 meters in 6-minute walk distance.[51] No differences were observed between treprostinil and placebo in time to clinical worsening or WHO functional class. Two randomized controlled trials followed evaluating use of oral treprostinil in addition to endothelin receptor antagonists and/or phosphodiesterase-5 inhibitors. Both studies used change in 6-minute walk distance as the primary endpoint and neither study demonstrated a significant improvement with oral treprostinil therapy.[52,53] The average increase in 6-minute walk distance did correspond to treprostinil dose, with patients receiving higher doses demonstrating more improvement in exercise capacity as measured by 6-minute walk distance. Adverse events in studies included headache, nausea, diarrhea, and jaw pain. Like other prostacyclin analogs, oral treprostinil inhibits platelet aggregation and may increase risk of bleeding, especially in patients treated with anticoagulants. Of note, oral trepostinil must be taken with food to improve absorption and cannot be crushed due to the osmotic release formulation. Oral treprostinil was not available at the time of recent guidelines publication and current data do not support use of oral treprostinil in combinations with endothelin receptor antagonists or PDE-5 inhibitors therefore.

Endothelin Receptor Antagonists (ERAs)

12 ET-1, a peptide produced primarily by the vascular endothelial cells, is characterized as a powerful vasoconstrictor and mitogen for smooth muscle. Activation of the ET-1 system has been shown in both plasma and lung tissue of PAH patients. Bosentan (Tracleer) is an orally active dual ET_A and ET_B receptor antagonist that improves exercise capacity, functional class, hemodynamics, echocardiographic and Doppler variables, and time to clinical worsening.[54,55] In one of the larger studies with bosentan, patients were started on 62.5 mg twice daily for 4 weeks followed by 125 or 250 mg twice daily for a minimum of 12 weeks. Both doses were better than placebo, and the higher dose provided greater improvement in 6-minute walking distance. Increases in hepatic aminotransferases occurred in 11% of patients and were dose-dependent.[55] The mechanism of increased liver enzymes is thought to be competition by bosentan and its metabolites with the biliary excretion of bile salts, resulting in retention of bile salts that can be cytotoxic to hepatocytes. Because of this toxicity, bosentan is only available through a distribution program, the Tracleer Access Program.[26] Bosentan should be started at 62.5 mg twice daily in adults and adolescents for 4 weeks. After 4 weeks of therapy, the dose should be increased to 125 mg twice daily. If LFTs are confirmed to be in the range of three to five times the upper limit of normal, reduce the daily dose or interrupt treatment. If LFTs return to pretreatment levels, bosentan may be continued or reintroduced if indicated. LFTs should be monitored at baseline and monthly thereafter, and monthly pregnancy testing is required in females (category X). Complete blood count should be monitored every 3 months as bosentan has been associated with anemia. Bosentan is indicated for WHO functional class II and III (I-A/B) as well as functional class IV (IIa-C).[1]

Ambrisentan (Letairis) is a once-daily selective ET_A receptor antagonist that improves exercise capacity and hemodynamics and delays clinical worsening in PAH.[56,57] Two large (*n* = 202 and 192) trials recently evaluated the efficacy of ambrisentan compared with placebo. In 12 weeks, both studies demonstrated a significant improvement in functional capacity at doses of 2.5, 5, and 10 mg daily (range of 31-59 m). However, greater response was seen with increased doses. All doses were well tolerated, with no patients on therapy experiencing an increase in LFTs >3 times the upper limit of normal. Similar to bosentan, ambrisentan is category X for pregnancy; the distribution program for ambrisentan is referred to as Letairis Education and Access Program (LEAP).[26] Unlike bosentan, liver toxicity occurs very rarely with ambrisentan (0.8% in 12-week trials and 2.8% for up to 1 year).[42] Common side effects include peripheral edema, nasal congestion, flushing, anemia, and palpitations. Treatment should be initiated with 5 mg once daily and increased to 10 mg once daily if required. Ambrisentan is recommended for WHO functional class II and III (I-A/B) as well as functional class IV (IIa-C).[3]

Macitentan (Opsumit) was FDA approved in 2013 as a once-daily dual ERA. Macitentan was approved based on the results of the Study with an Endothelin Receptor Antagonist in Pulmonary Arterial Hypertension to Improve Clinical Outcome (SERAPHIN) trial.[58] In this phase 3 multicenter, placebo-controlled study, patients (*n* = 742) were randomized to placebo, macitentan 3 mg orally daily, or macitentan 10 mg orally daily. Patients from WHO functional class II, III, and IV were included. Patients could be on concomitant therapy, if at stable doses for 3 months, with oral or inhaled prostanoids, calcium channel blockers, or oral phosphodiesterase inhibitors. Patients on intravenous or subcutaneous prostacyclins were excluded. The majority of patients (more than 80%) were functional class II or III. The most common diagnosis was IPAH. Over a treatment period of about 3 months, both doses demonstrated statistically significant decreases in the composite end point of events related to PAH or death compared to placebo. Worsening of PAH was the most common event (defined as a decrease in 6-minute walk distance, worsening symptoms, and need for additional treatment). Increase in LFTs was similar across all groups, about 3.5% to 4.5%. More patients in the macitentan groups experienced nasopharyngitis, headache, and anemia than with placebo. The FDA-approved dose is 10 mg by mouth daily. Macitentan is considered category X for pregnancy and female patients must go through a Risk Evaluation and Mitigation Strategy (REMS) program to receive the drug. Macitentan is recommended for WHO functional class II and III (I-A/B) as well as functional class IV (IIa-C).[1]

Phosphodiesterase Inhibitors

There are two phosphodiesterase-5 inhibitors available for the treatment of PAH—sildenafil (Revatio) and tadalafil (Adcirca). 13 Sildenafil is a potent and highly specific phosphodiesterase-5 inhibitor that is approved for erectile dysfunction but also has been shown to reduce mPAP and improve functional class. Sildenafil exerts its pharmacologic effect by increasing the intracellular concentration of cyclic guanosine monophosphate, leading to vasorelaxation and antiproliferative effects on vascular smooth muscle cells. In a double-blind, placebo-controlled trial, sildenafil with conventional therapy significantly improved 6MWD and hemodynamic parameters at 12 weeks compared with placebo. A 1-year extension study showed a continued improvement in 6MWD of 51 m (95% CI 41-60).[59] The

FDA-approved dose is 20 mg by mouth three times (TID) per day; however, much higher doses are routinely used clinically. Common adverse effects include headaches, flushing, epistaxis, dyspepsia, and diarrhea. Sildenafil may also cause systemic hypotension. Changes in vision have been reported, including blue-tinted vision and sudden loss of vision. In the event of sudden loss of vision, the drug should be stopped. Concurrent administration of sildenafil and bosentan leads to a 50% decrease in sildenafil concentrations through cytochrome P450 3A4 induction, requiring dose adjustment of sildenafil. Nitrate therapy may lead to excessive blood pressure reduction should be avoided with sildenafil. Based on the current guidelines, sildenafil is recommended for functional class II and III patients with PAH (I-A/B) in addition to functional class IV patients (IIa-C).[1]

Another phosphodiesterase-5 inhibitor, tadalafil (Adcirca), was approved by the FDA in 2009 for the treatment of PAH. In a 16-week study, tadalafil 40 mg daily significantly improved exercise capacity (an average of +33 m; $P < 0.01$) and quality of life measures. Tadalafil 40 mg also improved the time to clinical worsening ($P = 0.041$), which has not been demonstrated with sildenafil. Fifty-three percent of patients in this study were also on background bosentan therapy. Treatment-naïve patients demonstrated not only greater improvement in exercise capacity than those on bosentan therapy (+44 m vs 23 m) but also greater improvement on all secondary outcomes. One possible explanation is decreased tadalafil levels as bosentan is a potent CYP450 3A4 inducer. Higher doses of tadalafil may be required in patients on concurrent bosentan therapy.[60] The most commonly reported adverse events were headache, myalgia, and flushing. The recommended dose is 40 mg by mouth once a day.[61] Concurrent use with nitrate therapy should also be avoided with tadalafil. Current guidelines indicate tadalafil for functional class II and III (I-A/B) and functional class IV (IIa-C).[1]

Guanylate Cyclase Stimulator

14 A new class of medication recently became available in the treatment of PAH, soluble guanylate cyclase stimulators. Riociguat (Adempas®) was approved by the FDA in 2013. Riociguat works synergistically with nitric oxide and directly stimulates soluble guanylate cyclase. In the phase 3 study Pulmonary Arterial Hypertension Soluble Guanylate Cyclase-Stimulator Trial 1 (PATENT-1), riociguat 2.5 mg by mouth TID daily improved 6MWD over 12 weeks compared to placebo ($P < 0.001$).[62] Hemodynamic parameters and WHO functional class were also statistically significantly improved. Syncope occurred in 1% of riociguat patients compared to 4% in the placebo group. Of note, patients were continued on baseline therapy of endothelin-receptor antagonists or nonintravenous prostacyclin analogs. However, use of riociguat with phosphodiesterase-5 inhibitors is contraindicated due to the additive risk of hypotension. The recommended starting dose is 1 mg by mouth TID daily, titrated by 0.5 mg TID every 2 weeks to a maximum dose of 2.5 mg by mouth TID. Riociguat is considered category X for pregnancy and female patients must go through a REMS program to receive the drug. Riociguat is recommended for WHO functional class II and III (I-A/B) as well as functional class IV (IIa-C).

Calcium Channel Blockers

15 Since such a small number of patients with IPAH, HPAH, or PAH induced by drugs or toxins have a positive response to acute vasodilator testing, CCBs are infrequently used in the management of PAH

in these subgroups. Approximately 13% of patients with IPAH will demonstrate an acute vasodilator response and may be initiated on CCB therapy; however, the number responding to long-term therapy is low (7%).[27] CCBs should not be used in the absence of demonstrated acute vasoreactivity.[1] If used in patients without acute vasoreactivity, CCBs are associated with systemic hypotension leading to reflex tachycardia, sympathetic stimulation, and right ventricular ischemia, ultimately increasing patient morbidity.[5] The preferred drugs are dihydropyridine CCBs as they lack the negative inotropic effects seen with verapamil. Diltiazem may be used in patients with tachycardia to slow heart rate through atrioventricular node blockade. If left ventricular systolic dysfunction is present, diltiazem and verapamil should not be used because of their negative inotropic effects. Assessment of CCB therapy should occur soon after initiation, and if improvement in functional class to class I or II is not seen, additional or alternative PAH therapy must be initiated. In acute responders, CCBs may be used in WHO functional classes I to IV (I-C).[1] The doses of these drugs are relatively high—that is, up to 20 to 30 mg/day for amlodipine, 120 to 240 mg/day for nifedipine, and 240 to 720 mg/day for diltiazem—however, initial doses should be much lower and titrated upward to response.[5] The most common adverse effect is peripheral edema. More specific information concerning individual drugs used for PAH is shown in **Tables 28-7, 28-8, 28-9**.

TABLE 28-7 Drug Dosing Table

Drug	Brand Name	Initial Dose	Usual Range	Other
Epoprostenol	Flolan®	Starting dose 2-4 ng/kg/min IV	Titrate up to 20-40 ng/kg/min Decrease to 0.625 ng/kg/min if not tolerated	
Treprostinil (IV or SC)	Remodulin®	Initially 1.25 ng/kg/min continuous subcutaneous or IV infusion	Increase by no more than 1.25 ng/kg/min weekly for the first 4 wk of therapy and no more than 2.5 ng/kg/min weekly for the duration of therapy	
Treprostinil (inhaled)	Tyvaso®	Initially three breaths (18 mcg) via oral inhalation four times daily during waking hours (approximately 4 h apart)	Reduce to one to two breaths if three breaths not tolerated; increase to three breaths when tolerance improves Goal maintenance dose is nine breaths (54 mcg) per treatment four times daily; titrate by	

Drug	Brand Name	Initial Dose	Usual Range	Other
			increasing three breaths at 1- to 2-wk intervals as tolerated	
Treprostinil (Oral)	Orenitram®	0.25 mg every 12 hours or 0.125 mg every 8 hours	Titrate dose in increments of 0.25-0.5 mg every 12 h or 0.125 mg every 8 h every 3-4 days Maximum dose is determined by tolerability Avoid abrupt discontinuation; if not tolerated, decrease dose stepwise in 0.25-0.5 mg increments	If unable to continue oral therapy temporarily while inpatient, consider initiation of IV or SC treprostinil; 1/5 of total daily dose is estimate of total daily parenteral dose
Iloprost	Ventavis®	Initially 2.5 mcg inhaled six to nine times daily (dosing at ≥2-h intervals while awake)	Titrate to 5 mcg per dose with a maximum daily dose of 45 mcg	
Bosentan	Tracleer®	Initially 62.5 mg orally twice daily for 4 wk	Increase to 125 mg orally twice daily	Available through Tracleer Access Program
Ambrisentan	Letairis®	Initial dose 5 mg orally daily	Titrate to maximum dose of 10 mg daily	Available through Letairis Education and Access Program
Macitentan	Opsumit®	Initial dose 10 mg orally daily	Maximum dose of 10 mg orally daily	Available through Opsumit Risk Evaluation and Mitigation Strategy Program
Sildenafil	Revatio®	Initial dose 20 mg orally three times daily, taken at least 4-6 h apart	Maximum FDA-approved dose is 20 mg orally three times a day; higher doses frequently used clinically	
Tadalafil	Adcirca®	40 mg orally once daily, with or without food	40 mg orally once daily	Not recommended to divide the dose

Drug	Brand Name	Initial Dose	Usual Range	Other
Riociguat	Adempas®	Initial dose 0.5-1 mg orally three times daily	Maximum dose is 2.5 mg orally three times daily Titrate every 2 wk to maximum tolerated dose; dose limited by hypotension	Use is contraindicated with PDE-5 inhibitors due to additive risk of hypotension Available through Adempas Risk Evaluation and Mitigation Program

TABLE 28-8 Drug Monitoring Information

Drug	ADR	Monitoring Parameter	Comments
Synthetic Prostacyclin and Prostacyclin Analogs			
Epoprostenol	Pain (chest and jaw), flushing, headache	Titrate to balance efficacy and adverse effect	Occurs with dose titration
	GI (nausea, vomiting, diarrhea, anorexia)		
	Hypotension	Blood pressure	Occurs with dose titration; additive hypotensive effects with other anithypertensives, vasodilators, and diuretics
	Thrombocytopenia	Platelets; signs and symptoms of bleeding	Monitor with concurrent anticoagulant and antiplatelet agents
Treprostinil (IV or SC)	SC site pain	Local pain at SC administration site	Frequent site rotation may improve; may also use cool compresses, lidocaine-based creams or patches, or PLO to relieve pain
	See epoprostenol		
Treprostinil (inhaled)	Cough and throat irritation		
Treprostinil (oral)			
Iloprost	Throat irritation		
	Cough		
Endothelin Receptor Antagonists			
Bosentan	Hepatotoxicity	Baseline and monthly liver function tests required	Black box warning for liver injury

Drug	ADR	Monitoring Parameter	Comments
	Anemia	Hemoglobin	Usually resolves after the first 3 mo of therapy
	Edema	Edema on physical examination	May require dose increase of diuretic therapy
Ambrisentan and Macitentan	Anemia	Hemoglobin	Usually resolves after the first 3 mo of therapy
	Edema	Edema on physical examination	May require dose increase of diuretic therapy
Phosphodiesterase-5 Inhibitors			
Sildenafil and Tadalafil	Headache	Self-report by patient; occurs due to vasodilation	
	Nasal congestion		
	Hypotension	Blood pressure	Concurrent use with nitrates potentiates effects
	Visual changes	Consider baseline examination; repeat examination if visual changes occur	
Soluble Guanylate Cyclase Stimulator			
Riociguat	Headache		
	Hypotension	Blood pressure	
	Peripheral edema	Edema on physical examination	
	Major bleeding	Hemoglobin and hematocrit	
		Signs and symptoms of bleeding	
	GERD		

GERD, gastroesophageal reflux disease; IV, intravenous; PLO, pluronic lecithin organogel; SC, subcutaneous.

TABLE 28-9 Potentially Signficant Drug Interactions with Pulmonary Arterial Hypertension Drugs

PAH drug	Mechanism of interaction	Interacting drug	Interaction
Ambrisentan ?		Cydosporine Ketoconazole	Caution is required in the co-administration of ambrisentan with ketoconazole and cyclosporine.

PAH drug	Mechanism of interaction	Interacting drug	Interaction
Bosentan	CYP3A4 inducer	Sildenafil	Sildenafil levels fall 50%; bosentan levels increase 50%. May not require dose adjustments of either drug.
	CYP3A4 substrate	Cydosporine	Cyclosporine levels fall 50%; bosentan levels 4-fold. Combination contraindicated.
	CYP3A4 substrate	Erythromycin	Bosentan levels increase. May not require dose adjustement of bosentan during a short course.
	CYP3A4 substrate	Ketoconazole	Bosentan levels increase twofold.
	CYP3A4 substrate + bile salt pump inhibitor	Glibenclamide	Increase incidence of elevated aminotransferases. Potential decrease of hypoglycaemic effect of glibendamide. Combination contraindicated.
	CYP2C9 and CYP3A4 substrate	Fluconazole, amlodarone	Bosentan levels increase considerably. Combination contraindicated.
	CYP2C9 and CYP3A4 inducers	Rifampicin, phenytoin	Bosentan levels decrease by 58%. Need for dose adjustment uncertain.
	CYP2C9 inducer	HMG CoA reductase inhibitors	Simvastatin levels reduce 50%; similar effects likely with atorvastatin. Cholesterol level should be monitored.
	CYP2C9 inducer	Warfarin	Increases warfarin metabolism, may need to adjust warfarin dose. Intensified monitoring of warfarin recommended following initiation but dose adjustment usually unnecessary.
	CYP2C9 and CYP3A4 inducers	Hormonal contraceptives	Hormone levels decrease. Contraception unreliable.
Macitentan			To be determined.
Selexipag			To be determined.
Sildenafil[43]	CYP3A4 substrate	Bosentan	Sildenafil levels fall 50%; bosentan levels increase 50%. May not require dose adjustments of either drug.
	CYP3A4 substrate	HMG CoA reductase inhibitors	May increase simvastatin/atorvastatin levels through competition for metabolism. Sildenafil levels may increase. Possible increased risk or rhabdomyolysis.
	CYP3A4 substrate	HIV protease inhibitors	Ritonavir and saquinovir increase sildenafil levels markedly.
	CYP3A4 Inducer	Phenytoin	Sildenafil level may fall.
	CYP3A4 substrate	Erythromycin	Sildenafil levels increase. May not require dose adjustment for a short course.

PAH drug	Mechanism of interaction	Interacting drug	Interaction
	CYP3A4 substrate	Ketoconaczole	Sildenafil levels increase. May not require dose adjustment.
	CYP3A4 substrate	Cimetidine	Sildenafil levels increase. May not require dose adjustment.
	cGMP	Nitrates, Nicorandil Molsidomine	Profound systemic hypotension, combination contraindicated.
Tadalafil(44)	CYP3A4 substrate	Bosentan	Tadalafil exposure decreases by 42%, no significant changes in bosentan levels.(44) May not require dose adjustment.
	cGMP	Nitrates, Nicorandil	Profound systemic hypotension, combination contraindicated.
Rioclguat(18)	cGMP	Sildenafil, other PDE-5 inhibitors	Hypotension, servere side effects, combination contraindicated.
	cGMP	Nitrates, Nicorandil	Profound systemic hypotension, combination contraindicated.

cGMP, cyclic guanosine monophosphate; HMG CoA, 3-hydroxy-3-methylglutaryl-CoA reductase; PDE-5, phosphodiesterase type 5.

Data from N. Galie et al. 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. Eur Respir J 2015.

Combination Therapy

16 Combination therapy is an attractive option to address the multiple pathophysiologic mechanisms in PAH, resulting in improvement in hemodynamics, symptoms, and exercise capacity. Combination therapy can be pursued by the simultaneous initiation of two (or more) treatments or by the addition of a second (or third) agent if previous treatment has been insufficient. The goal with combination therapy is for the patient to achieve WHO functional class I or II along with normalization of the cardiac index and BNP.[1] Combination therapy may be started as initial therapy or added sequentially throughout treatment. **Table 28-10** and **Table 28-11** show current treatment recommendations for initial combination and sequential combination therapy, respectively.

TABLE 28-10 Recommendations for Efficacy of Initial Drug Combination Therapy for PAH (Group 1) according to World Health Organization Functional Class. Sequence Is by Rating

Measure/Treatment	Class[a]-Level[b]					
	WHO-FC II		WHO-FC III		WHO-FC IV	
Ambrisentan + tadalafil[d]	I	B	I	B	IIb	C
Other ERA + PDE-5i	IIa	C	IIa	C	IIb	C

Measure/Treatment	Class[a]-Level[b]					
	WHO-FC II		WHO-FC III		WHO-FC IV	
Bosentan + sildenafil + IV epoprostenol	-	-	IIa	C	IIa	C
Bosentan + IV epoprostenol	-	-	IIa	C	IIa	C
Other ERA or PDE-5i + SC treprostinil			IIb	C	IIb	C
Other ERA or PDE-5i + other IV prostacyclin analogues			IIb	C	IIb	C

ERA, endothelin receptor antagonist; IV, intravenous; PAH, pulmonary arterial hypertension; PDE-5i, phosphodiesterase type 5 inhibitor; RCT, randomized controlled trial; SC, subcutaneous; WHO-FC, World Health Organization functional class.

[a]Class of recommendation.

[b]Level of evidence.

[c]Reference(s) supporting recommendations.

[d]Time to clinical failure as primary endpoint in RCTs or drugs with demonstrated reduction in all-cause mortality (prospectively defined).

TABLE 28-11 Recommendations for Efficacy of Sequential Drug Combination Therapy for PAH (Group 1) according to World Health Organization Functional Class. Sequence Is by Rating and by Alphabetical Order

Measure/Treatment	Class[a]-Level[b]					
	WHO-FC II		WHO-FC III		WHO-FC IV	
Macitentan added to sildenafil[d]	I	B	I	B	IIa	C
Riociguat added to bosentan	I	B	I	B	IIa	C
Selexipag[e] added to ERA and/or PDE-5i[d]	I	B	I	B	IIa	C
Sildenafil added to epoprostenol	-	-	I	B	IIa	B
Treprostinil inhaled added to sildenafil or bosentan	IIa	B	IIa	B	IIa	C
Iloprost inhaled added to bosentan	IIb	B	IIb	B	IIb	C
Tadalafil added to bosentan	IIa	C	IIa	C	IIa	C
Ambrisentan added to sildenafil	IIb	C	IIb	C	IIb	C
Bosentan added to epoprostenol	-	-	IIb	C	IIb	C
Bosentan added to sildenafil	IIb	C	IIb	C	IIb	C
Sildenafil added to bosentan	IIb	C	IIb	C	IIb	C
Other double combinations	IIb	C	IIb	C	IIb	C
Other triple combinations	IIb	C	IIb	C	IIb	C
Riociguat added to sildenafil or other PDE-5i	III	B	III	B	III	B

EMA, European Medicines Agendy; ERA, endothelin receptor antagonist; PAH, pulmonary arterial

hypertension; PDE-5i, phosphodiesterase type 5 inhibitor; RCT, randomized controlled trial; WHO-FC, World Health Organization functional class.

[a]Class of recommendation.

[b]Level of evidence.

[c]Reference(s) supporting recommendations.

[d]Time to clinical failure as primary endpoint in RCTs or drugs with demonstrated reduction in all-cause mortality (prospectively defined).

[e]This drug was not approved by the EMA at the time of publication of these guidelines.

ERAs plus PDE-5 inhibitors, PDE-5 inhibitors with PGI_2 analogs, ERAs with PGI_2 analogs, and all three classes used in combination have all shown improved functional outcomes.[54,55,60,63,64] Sequential combination therapy is recommended for patients with inadequate clinical response to monotherapy; combinations of prostanoids, phosphodiesterase-5 inhibitors, and endothelin antagonists may be used (I-A).[1] Certain combinations, such as riociguat and phosphodiesterase-5 inhibitors, should be avoided due to unsafe adverse effects.

Recent results of the AMBITION trial comparing ambrisentan and tadalafil together versus either alone suggest that initial combination therapy was associated with a significant reduction in time to clinical failure and PAH hospitalizations. Adverse effects such as peripheral edema, headache, nasal congestion, and anemia were more common in the combination group than either monotherapy group. However, there was no difference in drug discontinuation due to adverse events.[65] Based on the results of this trial, the FDA approved combination use of ambrisentan and tadalafil as first line therapy for patients with WHO Class II or II PAH in October 2015.

Evaluation of Therapeutic Outcomes

Response to treatment in PAH can be objectively measured by the 6-minute walk distance, echocardiography to assess pulmonary pressures, and right heart catheterization as the gold standard to assess ventricular function and pulmonary pressures (see Table 28-6). The WHO functional classification system is clinically useful, but correlations to hemodynamics may be imprecise. Other outcomes that are useful in clinical trials include hospitalization for exacerbations of PAH and the development of complications and death. Table 28-6 provides recommendations regarding specific baseline and follow-up assessments and when they are indicated.

CONCLUSION

Significant advances have been made in elucidating the pathogenesis of PAH as well as in the evaluation and treatment of these patients over the past 3 decades. With approved targeted therapies such as ERAs, phosphodiesterase-5 inhibitors, and PGI_2 analogs, clinical improvement is

possible in most patients, leading to a better quality of life and delay of disease progression. Patient education is important to improve acceptance of this disease and referral to specialty care centers may provide the best outcomes.

Chapter 29: Cystic Fibrosis

Chanin C. Wright; Yolanda Y. Vera

INTRODUCTION

KEY CONCEPTS

- 1 Good nutrition with appropriate pancreatic enzyme and vitamin supplementation are essential in the management of cystic fibrosis (CF).
- 2 Airway clearance and anti-inflammatory therapies are key components to improve pulmonary health in CF patients.
- 3 Antipseudomonal agents are the cornerstone of antibiotic therapy for chronic lung infections in the CF patient.
- 4 Altered pharmacokinetics of CF patients can impact the dosing and clearance of pharmacologic therapy.

"Woe to that child which when kissed on the forehead tastes salty. He is bewitched and soon must die." This European adage accurately describes the fate of an individual diagnosed with cystic fibrosis (CF) during ancient times.[1]

CF is a disease state resulting from a dysfunction in the cystic fibrosis transmembrane conductance regulator (CFTR). It is the most common life-limiting genetic disorder in the Caucasian population, with an incidence of 1 in 2,000 to 4,000 live births and a prevalence of 30,000 affected individuals in the United States.[2,3,4,5,6,7]

Currently with care, affected individuals have an expected life span of 41 years. Multiple organ systems are affected in CF individuals, especially, the lungs, the digestive system, and the reproductive organs. Mortality is most commonly due to chronic organ damage or resistant pulmonary infections.[8]

The pharmacist plays an essential role in the development and management of a pharmacotherapeutic care plan for the CF patient.

EPIDEMIOLOGY

CF occurs in approximately 1 in 3,500 Caucasian newborns. In the 1970s, patients only survived into their teen years. By 2013, progress in care had extended survival to 41 years. Institution of care at a young age impacts long-term survival; hence, timing of diagnosis and recognition of signs and symptoms are crucial.[2,3,4,5,6,7]

Although CF occurs in all ethnicities, other ethnicities besides the Caucasian population display lower frequencies: 1 in 13,500 Hispanic-Americans, 1 in 15,000 African Americans, and 1 in 31,000 to 100,000 Asians, Native Hawaiian, and Pacific Islanders. The carrier frequency is 1 in 28 North American white populations, 1 in 29 Ashkenazi Jews, and 1 in 84 African Americans.[6]

Etiology

The cause of CF is due to a mutation of the *CFTR* gene. Extensive genetic studies have increased awareness regarding the large spectrum of mutations in the CF population. Over 1,800 mutations have been identified due to the extensive collaboration of the CF Foundation with international researchers. The most common mutation identified in CF patients is *ΔF508*.[3]

CF is an autosomal recessive disease, in which one mutation present on each allele of the *CFTR* gene results in presentation of the disease. The presentation of a mutation on only one allele of the *CFTR* gene will prevent the full expression of CF. Genetic studies have increased the understanding of genotype–phenotype relationships. Various mutations on the *CFTR* gene can result in various pathologies such as primary lung disease to minor gastrointestinal (GI) involvement.[3]

PATHOPHYSIOLOGY

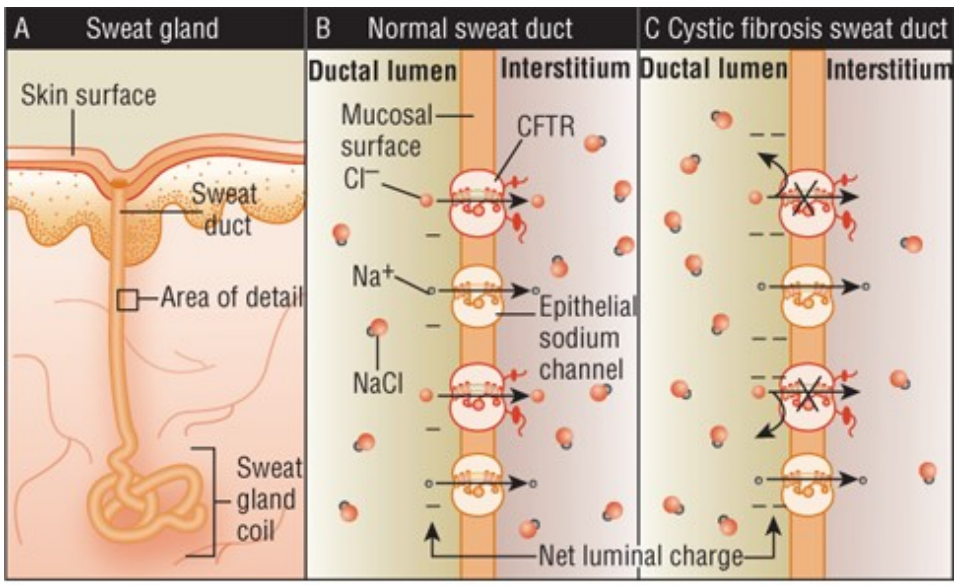
In order to successfully treat CF, a good understanding of the disease's underlying mechanism of action is crucial. It is well established that gene mutations cause an abnormality in the CFTR. This initiates the sequence of events responsible for the manifestations of CF. Mucosal obstruction occurs in the distal airways of the lung and submucosal glands, which express the CFTR. The CFTR also performs numerous cellular functions, including the regulation of chloride transport across the cell membrane. Studies in genotype–phenotype relationships have shown that an abnormality on the CFTR contributes to the expression of other gene proteins involved with inflammatory responses, ion transport, and cell signaling. These various expressions result in differences in clinical severity among patients with the same mutations on the CFTR.[3,9,10,11]

Under normal conditions, the CFTR helps regulate ion transport and salt homeostasis in the sweat glands. Typically, the sodium ion is followed by the chloride ion, and is reabsorbed from the lumen by the CFTR and apical sodium channels. As a result of the CFTR's malfunction in CF patients, chloride fails to be reabsorbed, which impacts the sodium ion reabsorption as well. This failed process produces sweat that contains high levels of salt. The endpoint of this process is a highly negatively charged lumen, which leads to an increased salt content in the sweat gland. This is known as the

transepithelial potential difference, which is two to three times greater in CF patients than in patients without CF. These processes can lead to organ damage in the CF patient (**Fig. 29-1**).

FIGURE 29-1

Mechanism of underlying elevated sodium chloride levels in the sweat of patients with cystic fibrosis (CF). Sweat ducts (Panel *A*) in patients with CF differ from those in people without the disease in the ability to reabsorb chloride before the emergence of sweat on the surface of the skin. A major pathway for Cl^- absorption is through CFTR, situated within luminal plasma membranes of cells lining the duct (ie, on the apical, or mucosal, cell surface) (Panel *B*). Diminished chloride reabsorption in the setting of continued sodium uptake leads to an elevated transepithelial potential difference across the wall of the sweat duct, and the lumen becomes more negatively charged because of a failure to reabsorb chloride (Panel *C*). The result is that total sodium chloride flux is markedly decreased, leading to increased salt content. The thickness of the arrows corresponds to the degree of movement of ions. *(Used with permission from Rowe SM, Miller S, Sorscher EJ. Cystic fibrosis.* N Engl J Med *2005;352[19]:1992-2001.)*



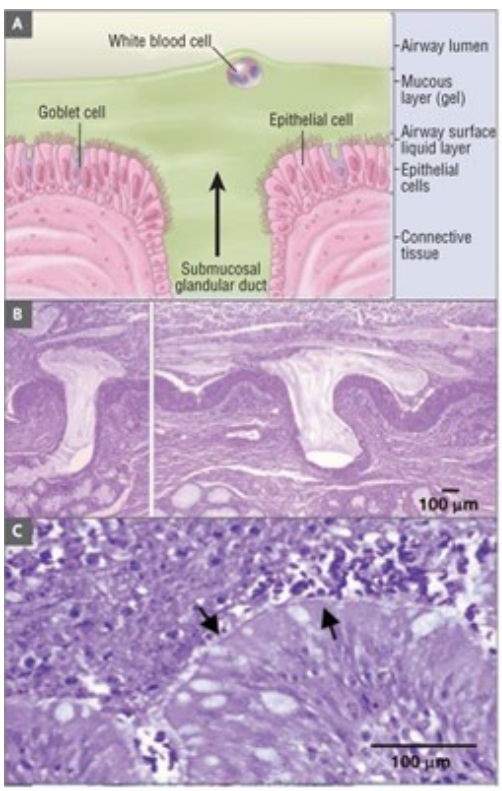
There are several theories as to how mucosal obstruction occurs in the airways. One of these theories, known as the "low-volume model," explains that the pulmonary surface epithelium behaves the opposite of a sweat gland in CF patients. There is an increased absorption of sodium, chloride, and fluid, which causes dehydration of the airway surfaces and defective mucociliary transport. An alternative theory known as the "high-salt model" indicates that the pulmonary surface epithelium behaves similarly to the sweat gland. A high salt content predisposes the CF patient to bacterial infections. Both theories agree that CF airways lack the ability to transport chloride through the CFTR.[9,12,13]

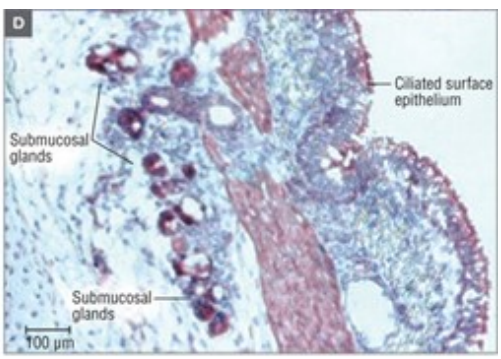
One of the common causes of morbidity and mortality in CF patients is mucosal obstruction of the

exocrine glands. Mucosal obstruction causes the ducts to dilate, which results in the coating of lung surfaces by thick, viscous, neutrophil-dominated debris. These secretions initiate a cascade of events that lead to inflammation and formation of scar tissue in the lungs[14] (**Fig. 29-2**).

FIGURE 29-2

Extrusion of mucus secretion onto the epithelial surface of airways in cystic fibrosis (CF). Panel *A* shows a schematic of the surface epithelium and supporting glandular structure of the human airway. In Panel *B*, the submucosal glands of a patient with CF are filled with mucus, and mucopurulent debris overlies the airway surfaces, essentially burying the epithelium. Panel *C* is a higher-magnification view of a mucus plug tightly adhering to the airway surface, with arrows indicating the interface between infected and inflamed secretions and the underlying epithelium to which the secretions adhere. (Both Panels *B* and *C* were stained with hematoxylin and eosin, with the colors modified to highlight structures.) Infected secretions obstruct airways and, over time, dramatically disrupt the normal architecture of the lung. In Panel *D*, CFTR is expressed in surface epithelium and serous cells at the base of submucosal glands in a porcine lung sample, as shown by the dark staining, signifying binding by CFTR antibodies to epithelial structures (aminoethylcarbazole detection of horseradish peroxidase with hematoxylin counterstain). *(Used with permission from Rowe SM, Miller S, Sorscher EJ. Cystic fibrosis.* N Engl J Med *2005;352(19):1992-2001.)*





Other organ systems are impacted by the absence of CFTR activity as well. Ten percent of CF patients are born with meconium ileus, which is an intestinal obstruction that may be fatal if left untreated. Blockage of the pancreatic duct leads to complications such as chronic fibrosis and fatty replacement of the pancreatic gland. Bile duct obstruction causes cirrhosis of the liver, and male CF patients can

experience infertility due to obstruction of the vas deferens in utero.[9]

Sinus and Pulmonary Presentation

CF patients will usually experience chronic infections and frequently develop polyps in the sinus cavity. Daily symptomatology includes shortness of breath and cough, with sputum production. A common finding in radiology chest films is a flat diaphragm with an increased chest diameter and air trapping. Pulmonary function tests will reflect a decrease in forced expiratory volume at 1 second (FEV_1). Older patients will experience digital clubbing, a deformity of the fingers and fingernails often associated with chronic hypoxia.

Bacterial growth in the lungs will often drive CF patients to a state of exacerbation, resulting in increased cough, a reduction in pulmonary function, and increased sputum production with a change in color.

Gastrointestinal System Presentation

Most patients with nonclassic CF will maintain adequate pancreatic function. However in classic CF patients, steatorrhea, or greasy stools, is typically present that can lead to a failure to thrive, resulting in malnutrition. Infants and small children will show an increase in frequency of small stools. Newborns may present with meconium ileus, which is considered diagnostic of CF. Older patients may experience constipation, abdominal cramping, and flatulence. This presentation is due to the obstruction of the pancreatic ducts and intestinal tract and their inability to digest essential nutrients.

Pancreatic malfunction can also lead to an insulin deficiency, which is often a later finding detected by a loss in weight, an increase in blood glucose levels, and a failed oral glucose tolerance test (OGTT).

Reproductive Presentation

As patients reach adolescent and adult ages, tests may show azoospermia due to blockage of or the congenital bilateral absence of the vas deferens. Females may experience reduced fertility as cervical fluids have lower water content and decreased thinning during ovulation.[9,15,16]

CLINICAL PRESENTATION

In the classic presentation of CF, there are two mutations present (**Table 29-1**). The patients show signs and symptoms of chronic sinus and pulmonary infections, pancreatic insufficiency, and elevated sweat chloride levels. Patients with nonclassic CF have one mutation present, therefore retaining partial function of the CFTR and maintaining appropriate pancreatic function (**Fig. 29-3**).

TABLE 29-1 Cystic Fibrosis Foundation Diagnosis Criteria and Clinical Presentation

A. Meets one or more of the following clinical features associated with the CF phenotype plus:

a. Two CF mutations

b. Two positive QPIT results

c. An abnormal transepithelial potential difference value

B. The following are typical phenotypes associated with CF:

a. Chronic sinopulmonary disease

i. Persistent colonization/infection with pathogens typical of CF lung disease

ii. Endobronchial disease manifested by

1. Cough and sputum production

2. Wheeze and air trapping

3. Radiographic abnormalities

4. Evidence of obstruction on pulmonary function test

5. Digital clubbing

iii. Chronic sinus disease

1. Nasal polyps

2. Radiographic changes

b. GI/nutritional abnormalities

i. Intestinal abnormalities

1. Meconium ileus

2. Exocrine pancreatic insufficiency

3. Distal intestinal obstruction syndrome

4. Rectal prolapse

5. Recurrent pancreatitis

ii. Chronic hepatobiliary disease manifested by clinical and/or laboratory evidence of

1. Focal biliary cirrhosis

2. Multilobar cirrhosis

iii. Failure to thrive

iv. Hypoproteinemia–edema

v. Fat-soluble vitamin deficiencies

c. Obstructive azoospermia in males

d. Salt-loss syndromes

i. Acute salt depletion

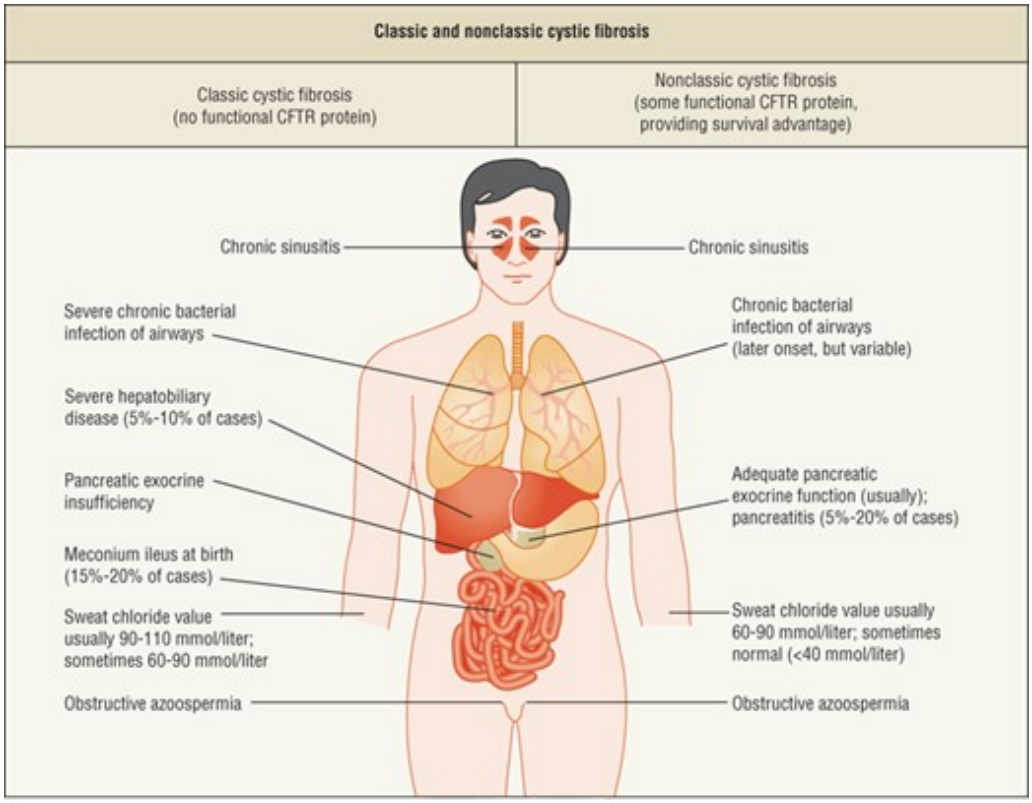
ii. Chronic metabolic alkalosis

e. CF in a first-degree relative

CF, cystic fibrosis; GI, gastrointestinal; QPIT, quantitative pilocarpine iontophoresis test.

FIGURE 29-3

Classic and nonclassic cystic fibrosis (CF). The findings in classic CF are shown on the left-hand side, and those of nonclassic CF on the right-hand side. Patients with nonclassic CF have better nutritional status and better overall survival. Although the lung disease is variable, patients with nonclassic CF usually have late-onset or more slowly progressive lung disease. Sweat-gland function, as evidenced by the sweat chloride test, is abnormal but not to the extent noted in classic CF. Pancreatitis may occur in patients with nonclassic disease. However, chronic sinusitis and obstructive azoospermia occur in both groups of patients. On the basis of these findings, one can infer that mutations in *CTFR,* perhaps coupled with other genetic or environmental factors, may confer a predisposition to sinusitis, pancreatitis, or congenital bilateral absence of the vas deferens (azoospermia) in the general population. *(Used with permission from Knowles MR, Durie PR. What is cystic fibrosis?* N Engl J Med *2002;347(6):439-442.)*



DIAGNOSIS

All states are required to perform CF newborn screening.[17] The screening test checks for immunoreactive trypsinogen (IRT), a chemical produced by the pancreas. The IRT tends to be high in babies with CF. A second test may be done with a follow-up IRT test or a DNA test to look for a genetic mutation that causes CF. The CF newborn screening consists of a test called the quantitative pilocarpine iontophoresis sweat test (QPIT). The QPIT came about due to the risk of hyperpyrexia associated with older methods that utilized plastic body bags to make patients sweat. QPIT uses only a small area on the forearm, which is then stimulated to secrete sweat through the skin by iontophoresis of pilocarpine. Sweat from the stimulated area is then collected and analyzed for chloride content. Chloride concentrations are quantified as: normal: ≤39 mmol/L; intermediate: 40 to 59 mmol/L; and abnormal: ≥60 mmol/L. Values more than or equal to 60 mmol/L are consistently diagnostic of CF. It is suggested that samples from two sites will increase the reliability of the diagnosis[3,4,5] (**Fig. 29-4**).

FIGURE 29-4

The cystic fibrosis (CF) diagnostic process for screened newborns. *(Used with permission from Farrell PM, Rosenstein BJ, White TB, et al. Guidelines for the diagnosis of cystic fibrosis in newborns through older adults: Cystic Fibrosis Foundation Consensus Report.* J Pediatr *2008;153(2):S4-S14.)*

Desired Outcomes

Pharmacists play a vital role in assisting patients to reach the following long- and short-term goals. Since CF affects multiple organ systems, there are several therapeutic goals that must be addressed for each system.[8]

Sinopulmonary

1. Prevent and treat sinusitis.
2. Increase FEV_1 and promote optimal pulmonary function tests and prevent pulmonary exacerbations.
    a. Promote effective airway clearance by providing counseling on the use of appropriate medications and chest physiotherapy.
    b. Prevent and treat colonization of the lungs with pathogens.
    c. Prevent and treat acute exacerbations.

Gastrointestinal

1. Control pancreatic insufficiency by providing adequate enzyme supplementation.
2. Optimize growth and nutritional status.
3. Promote healthy bowel habits.
4. Maintain normal fat-soluble vitamin levels.

Reproduction

1. Provide mutation analysis with appropriate genetic counseling at the time of diagnosis and periodically thereafter.

Psychosocial

1. Keep these patients living essentially normal lives by being active in school and the workplace.
2. Encourage adherence with pharmacological and nonpharmacological therapies in order to help prolong CF patient's lives.

NUTRITION

[1] In healthy individuals, the pancreas is vital to the absorption and digestion of essential nutrients for the body's growth and function. In pancreatic-insufficient CF individuals, the resulting inability to absorb these nutrients may lead to malnourishment. The focus of treatment lies in achieving and maintaining normal weight for adults and normal growth patterns for children. This is mostly achieved by managing GI and pulmonary symptoms, monitoring nutrient and energy intakes, and addressing psychosocial and financial issues. The CF Foundation recommends that both children and adults optimize nutritional status, due to its association with healthy pulmonary function, including better FEV_1, and an increase in survival.

To help meet this desired outcome, the CF Foundation recommends energy intakes greater than the standard for the general population to support weight gain and maintenance in children over 2 years and in adults. Trial evidence gathered from population-based studies has shown that energy intakes of 110% to 200% compared to the general health population intakes yield improved nutritional status in CF individuals. The CF Foundation has also established consensus-based assessment parameters to monitor nutritional status in CF individuals. These parameters and goals are listed in **Table 29-2**. In order to achieve these goals, pancreatic enzyme replacement therapy (PERT) is used to improve fat absorption due to pancreatic insufficiency. For patients who consistently fail to meet weight requirements, the clinician must consider the use of nutritional supplements that may be given orally or enterally via a percutaneous endoscopic gastrostomy (PEG) tube.

TABLE 29-2 Cystic Fibrosis Foundation Nutritional Assessment Parameters and Recommendations

- Age-appropriate BMI method should be utilized to assess weight and height.

- Better FEV_1 status at about 80% (0.80) predicted or above was associated with BMI % at 50th percentile or higher.
- For children and adolescents aged 2-20 years, the CF Foundation recommends that weight-for-stature assessment uses the BMI percentile method and those children and adolescents maintain a BMI at or above the 50th percentile.
- For children diagnosed <2 years, the CF Foundation recommends that children reach a weight-for-length status of 50th percentile by 2 years.
- For adults 20 years and older, the CF Foundation recommends that weight-for-stature assessment use the BMI method and that women maintain a BMI ≥22, and men maintain a BMI ≥23.
- For adults 20 years and older, the CF Foundation recommends that unintentional weight loss be avoided. When encountered in patient care, unintentional weight loss should be evaluated in the context of the patient's usual weight and health status.

BMI, body mass index; CF, cystic fibrosis; FEV_1, forced expiratory volume at 1 second.

PERT has been proven both safe and efficacious in improving nutritional status in CF patients and is recommended in addition to adequate dietary intake. Consensus-based guidelines have established a dose of 500 to 2,500 lipase units per kilogram (kg) of body weight per meal; or 10,000 units per kg per day; or 4,000 units per gram of dietary fat per day. Generic enzyme supplements are not bioequivalent; therefore, the CF Foundation does not recommend their use.

Historically, pancreatic enzymes were considered nutritional supplements, and were not under the Food and Drug Administration (FDA) jurisdiction. New regulations now require all pancreatic enzyme supplements to obtain FDA approval. **Table 29-3** shows currently used enzyme preparations.[18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,38,39]

TABLE 29-3 Pancreatic Enzyme Supplements

Trade Name	Manufacturer	Lipase Units	Protease Units	Amylase Units	Dosage Form	FDA Approval
Creon®	Abbott Laboratories	3,000	9,500	15,000	Delayed release capsule, enteric-coated microspheres	Approved
		6,000	19,000	30,000		
		12,000	38,000	60,000		
		24,000	76,000	120,000		
		36,000	114,000	180,000		
Pancreaze®	Janssen Pharmaceuticals,	4,200	10,000	17,500	Delayed release capsule, enteric-coated	Approved

Trade Name	Manufacturer	Lipase Units	Protease Units	Amylase Units	Dosage Form	FDA Approval
		10,500	25,000	43,750		
	Inc.	16,800	40,000	70,000	microtablets	
		21,000	37,000	61,000		
Pertzye®	Digestive Care, Inc.	8,000	28,750	30,250	Delayed-release capsule, bicarbonate-buffered enteric-coated microspheres	Approved
		16,000	57,500	60,500		
		13,800	27,600	27,600		
Ultresa®	Aptalis Pharma US, Inc.	20,700	41,400	41,400	Delayed-release capsule, enteric-coated minitablets	Approved
		23,000	46,000	46,000		
Viokace	Aptalis Pharma US, Inc.	10,440	39,150	39,150	Tablet	Approved
		20,880	78,300	78,300		
		3,000	10,000	16,000		
		5,000	17,000	27,000		
		10,000	34,000	55,000		
Zenpep®	Aptalis Pharma US, Inc.	15,000	51,000	82,000	Delayed-release capsule, enteric-coated beads	Approved
		20,000	68,000	109,000		
		25,000	85,000	136,000		
		40,000	136,000	218,000		

Most preparations are capsules containing enteric-coated microspheres or enteric-coated tablets designed to withstand the acidic environment in the stomach allowing for absorption in the small intestine. Frequently CF patients require the addition of histamine receptor antagonists or proton-pump inhibitors in order to create an alkaline environment in the intestine. Enteric-coated capsules should not be crushed but may be opened and mixed with nonalkaline food. However, if allowed to sit in food for a prolonged amount of time, the enteric coating will be lost and enzymes inactivated. Enzymes are administered prior to meals, snacks, and fat-soluble vitamins.[40]

Patients dosed beyond the recommended guidelines may develop fibrosing colonopathy, which leads to colonic strictures. This condition should be considered in individuals who have evidence of obstruction, bloody diarrhea, or ascites, as well as in patients who have a combination of abdominal pain, ongoing diarrhea, and/or poor weight gain. Risk factors for fibrosing colonopathy include: age less than 12 years; enzyme dosages more than 6,000 lipase units/kg/meal for more than 6 months;

history of meconium ileus or distal intestinal obstruction syndrome (DIOS); history of any intestinal surgery; and inflammatory bowel disease.

Patients who experience fibrosing colonopathy are treated by reducing the dose of enzyme supplements, or with oral laxatives and/or enemas, all of which have been proven effective. More severe cases may require surgical intervention.[41]

BONE HEALTH AND VITAMIN SUPPLEMENTATION

Increased longevity in CF patients has revealed bone disease as an emerging complication. Many studies have observed that 50% to 75% of CF adults have low bone density and increased rates of fractures. CF patients are especially at risk as a result of several contributing factors: malabsorption of vitamin D, poor nutritional status, physical inactivity, glucocorticoid therapy, delayed pubertal maturation, and early hypogonadism. Increased bone resorption and decreased bone formation are likely stimulated by elevated serum cytokine levels triggered by chronic pulmonary inflammation. Additionally, chronic infections lead to bone loss in patients regardless of pancreatic sufficiency. Pancreatic-insufficient CF patients lack the ability to absorb fat-soluble vitamins A, D, E, and K (ADEK). Decreased calcium absorption and intake can also compound this problem. As bone disease progresses, this can lead to exclusion from lung transplantation, which is often a life-saving operation for individuals with CF.

Appropriate bone density monitoring for CF patients requires obtaining levels of fat-soluble vitamins yearly, as well as treatment with daily supplementation. Special multivitamin formulations contain high amounts of fat-soluble vitamins designed to deliver the appropriate doses required. Recommended vitamin D levels are a minimum of 30 ng/mL (75 nmol/L). Even with these precautions, adequate vitamin D levels may be difficult to maintain due to altered absorption, reduced fat mass, and minimal exposure to sun light. Medical management of CF patients can also contribute to bone disease by the administration of glucocorticoids, posttransplant immunosuppressant therapies, and antibiotic therapies that require protection from sunlight exposure.[42,43,44,45,46,47,48,49,50,51]

PULMONARY HEALTH AND TREATMENT

2 One of the fundamentals of pulmonary care in CF patients is airway clearance. CF patients, in general, have impaired mucociliary clearance that results in thick sputum, predisposing them to chronic infections and inflammation. Effective airway clearance involves the use of a bronchodilator, a mucolytic medication, and chest percussion. It is recommended that airway clearance therapy (ACT) be initiated within the first few months of life. **Table 29-4** shows typical medications used in airway clearance.

TABLE 29-4 Airway Clearance Therapies

	Dose
Albuterol	2 puffs prior to therapy 2-4 times a day

	Dose
HyperSal® (hypertonic saline)	4 mL delivered via a nebulizer 2-4 times a day
Pulmozyme® (dornase alfa)	2.5 mg delivered via a nebulizer 1-2 times a day

Choosing a particular ACT routine for a patient is based on the patient's needs. There is no consensus on the optimal method of ACT. The regimen including duration or number of treatments per day may be changed in response to acute illness or exacerbations.

Chest percussion was originally performed with a cupped hand pounding on the chest that generated percussion or vibration. Currently, the most convenient method is the use of a percussion vest. Aerobic exercise is also effective and recommended for improved airway clearance.[52]

The recommended sequence of clearance therapy or "pulmonary toilet" regimen is as follows (note that these therapies are recommended for individuals ≥6 years and are administered concurrently with percussion therapy):

1. Bronchodilator: Albuterol is commonly used for this indication. It helps open up the airways and prevents bronchospasm.

2. Hypertonic saline (HyperSal®): It hydrates the airway mucus secretions and facilitates mucociliary function.

3. Dornase alfa (Pulmozyme®): Enzyme that cleaves extracellular DNA, which results in decreased viscosity of mucus.

4. Aerosolized antibiotics (ie, Aztreonam [Cayston], tobramycin [TOBI®]): If this therapy is indicated based on severity of lung disease and sputum cultures, it is administered after the CF patient completes percussion therapy.

Bronchodilator therapy is recommended for patients 6 years or older who demonstrate bronchiole hyperresponsiveness or a bronchodilator response. Chronic use of bronchodilator therapy is recommended to improve lung function by enhancing mucociliary action.[53,54]

Inhaled hypertonic saline is a novel agent used for the treatment of CF. Based on the "low-volume model" theory, the use of hypertonic saline would restore airway hydration and enhance mucociliary function.[55] Hypertonic saline is recommended for patients 6 years or older. A study conducted in Australia showed that CF patients who surfed had better pulmonary outcomes than other patients who did not surf.[56] Researchers believed that the inhalation of ocean water helped improve FEV_1 in CF patients who surfed. In this study, 24 patients were randomly assigned to receive a daily treatment of 7% hypertonic saline with or without pretreatment of a control. Clearance and pulmonary function were measured during a 14-day period. Results showed significant improvement in FEV_1 and forced vital capacity (FVC), as well as improvement of respiratory symptoms in hypertonic saline patients. The study also demonstrated that these patients were able to sustain mucus clearance for more than 8 hours. Other studies assessing the use of hypertonic saline have supported this study, showing an

improvement in lung function and a 56% reduction in exacerbations. Known side effects during administration include irritation to the airways, which may lead to a drop in FEV_1, increased cough, sore throat, and chest tightness. In an attempt to ameliorate these symptoms, providers may use a lower concentration of 3% hypertonic saline.[53,54,55,56,57]

Dornase alfa (Pulmozyme®) is also recommended in all patients 6 years or older, and is strongly recommended in patients with moderate-to-severe lung disease, to improve lung function and reduce exacerbations. Three randomized controlled trials and a crossover trial involving 520 patients were conducted. Study results showed improvement in FEV_1 by 3.2% and a reduction in exacerbations.[53,58,59]

Anti-inflammatory Therapies

Pulmonary inflammation begins early in life, as shown by the predominance of proinflammatory mediators that can be seen on bronchiolar lavage. A normal inflammatory response to bacteria becomes pathologic in CF patients who have both a prolonged and exaggerated reaction. Treatment of this inflammatory response is crucial to treating the CF patient.

Anti-inflammatory therapies must address the neutrophil response and inhaled therapies will target the endobronchial location, which is the site of inflammation. Using medications that terminate the inflammatory process may be effective. Airway clearance and antibiotics will help control the inflammatory stimulation. Steroids and nonsteroidal anti-inflammatory drugs (NSAIDs) are not widely used because of long-term safety concerns. High-dose ibuprofen (20-30 mg/kg of body weight twice daily) has proven efficacious in a study where patients showed less decline in pulmonary function when compared with patients given placebo. Patients on high dose ibuprofen were able to maintain weight and had less hospital admissions. The benefits of this regimen exceed the risks of GI complications and nephrotoxicity. Despite these outcomes, less than 5% of CF patients in the United States are on this regimen. The low number of patients using this proven therapy may be related to the requirement to obtain a specific therapeutic level of ibuprofen, which in turn requires frequent blood draws for pharmacokinetic monitoring.[7,53,60,61,62,63]

Studies with macrolides have shown an inhibition of the neutrophil migration and a decrease in production of proinflammatory mediators. It is unclear at this point if the anti-inflammatory effects of macrolides are a combination of antimicrobial and/or immunomodulatory mechanisms of action. A study conducted in Japan first demonstrated the benefit of macrolides against *Pseudomonas aeruginosa*. Four randomized controlled trials have since demonstrated this effect with azithromycin (250-500 mg) given three times weekly, which has led to increased nutritional status and decreased pulmonary infections. Other treatments are under investigation, but larger studies are needed before they become recommended therapies.[53,60,64,65]

Infectious Disease

3 Antibiotic therapy plays two integral roles in the treatment of CF patients: improving pulmonary function and preventing pulmonary failure. Oral, IV, and aerosolized antibiotic formulations are

indicated and used in patients who experience acute pulmonary exacerbations, are chronically infected with *P. aeruginosa*, or require prevention of chronic *P. aeruginosa* infection. A major disadvantage of treatment in CF patients is that pathogens are not fully eradicated from the airways and will often develop resistance. Unfortunately, this limits antimicrobial selection, and can contribute to deterioration of pulmonary function (**Table 29-5**).

TABLE 29-5 Antimicrobial Agents Used in Cystic Fibrosis

Antibiotic Oral	Pediatric Dose (mg/kg/day)	Adult Dose	Frequency Range	Pathogens
Ciprofloxacin	40	750 mg	Q 12 H	*Pseudomonas, Alcaligenes*
Sulfamethoxazole/Trimethoprim	15-20 mg of TMP	15-20 mg of TMP/kg/day	Q 6-8 H	*Staphylococcus* (MRSA, MSSA), *Burkholderia* *Stenotrophomonas, Alcaligenes*
Doxycycline	2-4	Max 200 mg/day	Q 12-24 H	*Stenotrophomonas, Staphylococcus*
IV				
Amikacin	30	15 mg/kg/day	Q 8 H	*Pseudomonas*
Aztreonam	200-300	2 g	Q 6-8 H	*Pseudomonas*
Cefepime	150-200	2 g	Q 8 H	*Pseudomonas*
Ceftazidime	150-200	2 g	Q 8 H	*Pseudomonas, Burkholderia, Alcaligenes*
Ciprofloxacin	30	400 mg	Q 8 H	*Pseudomonas, Alcaligenes*
Colistimethate	5-8	5-8 mg/kg/day	Q 8 H	*Pseudomonas*
Doxycycline	4	Max 200 mg/day	Q 12-24 H	*Stenotrophomonas, Staphylococcus*
Gentamicin	10-12	7.5-10 mg/kg/day	Q 6-8 H	*Pseudomonas*
Imipenem	60-100	2-4 g	Q 6 H	*Pseudomonas, Burkholderia, Alcaligenes*
Meropenem	120	1-2 g	Q 8 H	*Pseudomonas, Burkholderia, Alcaligenes*
Piperacillin–Tazobactam	300-400 (piperacillin	4.5 g	Q 4-6 H	*Pseudomonas, Alcaligenes,*

Antibiotic Oral	Pediatric Dose (mg/kg/day)	Adult Dose	Frequency Range	Pathogens
	component)			*Staphylococcus MSSA*
Ticarcillin–Clavulanate	300-400 (ticarcillin component)	3.1 g	Q 4 H	*Pseudomonas, Alcaligenes* *Staphylococcus* (MSSA)
Tobramycin	10-12	7.5-10 mg/kg/day	Q 6-8H	*Pseudomonas*
Vancomycin	60	15 mg/kg	Q 6-12 H	*Staphylococcus* (MRSA, MSSA)
Inhalation				
Tobramycin (Tobi®, Bethkis®)	60-600 mg/day	60-600 mg/day	Q 12 H	*Pseudomonas*
Tobramycin (TOBI Podhaler®)	224 mg/day	224 mg/day	Q 12 H	
Colistimethate	75 mg/day	75 mg/day	Q 12 H	*Pseudomonas*
Aztreonam (Cayston®)	225 mg/day	225 mg/day	Q 8 H	*Pseudomonas*

Early in life, patients will routinely be colonized with *Staphylococcus aureus* and then later with *P. aeruginosa*. A 5- to 7-year study of cephalexin prophylaxis in young CF children showed decreased *S. aureus* colonization; however, there was an increase in frequency of *P. aeruginosa* infections. Ultimately, this study showed no significant improvement in health outcomes, therefore, prophylaxis for *S. aureus* colonization is not recommended.[66,67]

The finding of *P. aeruginosa* on sputum culture is a predictor of morbidity and mortality. There are relatively few antibiotics available for the treatment of *P. aeruginosa*. Antibiotics available include extended-spectrum penicillins, select cephalosporins, select carbapenems, aztreonam, quinolones, colistimethate, and aminoglycosides. The only two mechanisms of action represented in this group are cell wall destruction and inhibited cell wall synthesis by ribosomal attachment. Standard practice is to combine these two mechanisms for the best bactericidal results. It is not unusual for patients to have multiple organisms growing in their sputum. The clinician can review the quantitative sputum culture for both the organisms present and the amount or colony forming units grown. By targeting the organisms with the most numerous organisms present and reviewing the susceptibility panels, the clinician can choose the most appropriate regimen. After years of drug exposure, older CF patients will exhibit multidrug-resistant *P. aeruginosa*. At this point, sputum cultures can be sent to specialized laboratories that will test combinations of antibiotics and report out any synergy results. Aerosolized antibiotics are directly deposited into the lung, providing concentrations that may overcome the standard measures of resistance.[68]

Other organisms that may be seen are *Alcaligenes*, *Stenotrophomonas*, *Mycobacteria*, *Aspergillus*, and *Burkholderia*. The importance of *Alcaligenes* as a pathogen is not well described. Originally only thought to have a prevalence of 2.7%, better lab testing and more studies have found infection rates

closer to 8% in CF patients older than 6 years.[69,70,71,72] *Stenotrophomonas* is intrinsically multidrug resistant and pathogenic. A risk factor for acquiring this organism may be broad-spectrum antibiotic use (carbapenems and cephalosporins).[73,74] Quite often this bacteria is misidentified and confirmatory testing may show *Burkholderia*. Prevalence in American CF patients is reported to be 8.4%; however, some centers report incidence to be as high as 25%.[75,76,77] Treatment choice is trimethoprim–sulfamethoxazole or doxycycline. *Mycobacteria* have been reported with more frequency in the past 10 years. Species include *M. tuberculosis*, nontuberculosis *M. chelonei, M. fortuitum*, and *M. avium-intracellulare* (MAI). The impact of *Mycobacteria* in the CF patient is unclear. Caseating granulomas have been found in some patients with clinical disease while other patients with nontuberculous mycobacteria (NTM) have shown no adverse consequences.[78,79,80,81] *Aspergillus* species has a prevalence of 10% to 25% in American CF patients. During the TOBI® trials, patients treated with aerosolized tobramycin appeared to be more at risk for colonization with *Aspergillus* than the placebo group. Although *Aspergillus* does not directly inhibit lung function, it may cause allergic bronchopulmonary aspergillosis which is an immunologic-mediated response to the presence of *Aspergillus* in the lungs.[82,83] *B. cepacia* is now known to be a bacterial species called "genomovars." Currently, up to nine species have been identified.

The two typical antimicrobial choices to treat *B. cepacia* are ceftazidime and trimethoprim-sulfamethoxazole®. It is important to recognize the transmission of *B. cepacia* from patient to patient has been shown via droplet route and therefore proper infection control precautions should be taken.[84,85,86]

Although CF patients are not more susceptible to respiratory viral infections, the outcome of such illnesses may be more severe. Decline in pulmonary function can be directly related to the number of annual viral infections. Newborns diagnosed with CF should be evaluated to receive respiratory syncytial virus (RSV) prevention with Synagis® (palivizumab), a monoclonal antibody for the first 2 years of life. Synagis® is usually dosed at 15 mg/kg intramuscularly once a month during the RSV season. All CF patients who are 6 months of age or older should receive the annual influenza vaccine.[87,88,89,90,91,92,93]

The CF Foundation recommends inhaled tobramycin (TOBI®) to CF patients 6 years or older, with mild to severe lung disease with persistent *Pseudomonas* present in sputum cultures. Aerosolized antibiotics deliver drug locally to the lung while decreasing the risk of systemic side effects. In 1998, the FDA approved TOBI® for treating bacterial lung infections in patients with CF. Routine monitoring of serum aminoglycoside levels is unnecessary in patients with normal renal function using approved doses. It is recommended that CF patients use a preservative-free formulation of aerosolized antibiotics to prevent occurrence of bronchospasm.[94]

Geller et al. describes the pharmacokinetics of inhaled TOBI®, specifically looking at sputum concentrations in CF patients receiving three cycles of routine TOBI® (ie, 28 days on, 28 days off), 300 mg twice daily. The study followed 258 patients for 24 weeks, and showed that approximately 95% of patients achieved sputum concentrations of more than 25 times the minimum inhibitory concentration (MIC) of *Pseudomonas* isolates. This confirmed that inhaled TOBI® can be efficacious in

helping prevent the progression of lung disease. At 25 times the MIC, tobramycin has a bactericidal effect.[95]

In 2010, the FDA approved an inhaled formulation of aztreonam, known as, Cayston®, for the treatment of *Pseudomonas*. Cayston® is approved for CF patients older than 6 years with mild to severe lung disease and persistent *Pseudomonas* present in sputum cultures. This inhaled formulation of aztreonam has demonstrated improvement in respiratory symptoms and lung function in patients older than 6 years. Cayston® has been compared with TOBI® in a head-to-head trial and met noninferiority and superiority endpoints. It requires an Altera nebulizer that can deliver the medication in 3 minutes. This in itself increases compliance and has a positive impact on the quality of life in CF patients.[96]

Pharmacokinetics

4 CF patients are unique in respect to a larger volume of distribution and a faster rate of clearance. With a larger volume of distribution, patients may require larger antibiotic doses. Dosing intervals become shorter because drugs are eliminated faster. Critically ill patients may vary from their baseline function and require closer monitoring. However, as patients age, they tend to approach normal population parameters. Therapeutic drug monitoring and necessary dosage and regimen adjustments are critical to the successful treatment of CF patients.

Once daily dosing of intravenous aminoglycosides is preferred for ease of home care administration, and may actually work well in this setting. However, given the possibility of a shortened half-life, each patient's unique pharmacokinetic parameters must be calculated to determine if once daily dosing is appropriate.[97,98]

Reproduction

Fertility discussions with older CF patients may arise during clinic visits, and these conversations should include genetic counseling and options for contraception. Drug–drug interactions between oral contraceptive pills (OCPs) and antibiotics should be monitored. Studies have shown that OCP use in CF patients is safe and effective in comparison to other contraception methods. Patches may not reliably adhere to the skin as a result of increased sweat on the surface of the skin.

The issues surrounding the use of contraception among CF men are similar to those among the normal population. CF men should not assume they are infertile, and should adhere to using protective measures in order to prevent unwanted pregnancy and the spread of sexually transmitted diseases. Should a CF male with a nonfunctioning vas deferens desire to become a biological parent, microsurgical epididymal aspiration of spermatozoa with intracytoplasmic sperm injection into the oocyte can be performed.[16]

Diabetes

As CF patients live longer, glucose intolerance and cystic fibrosis related diabetes (CFRD) are

common complications. Even though it shares features of type 1 and type 2 diabetes, CFRD is unique because it is influenced by factors specific to CF, including insulin deficiency, undernutrition, chronic and acute infection, elevated energy expenditure, glucagon deficiency, malabsorption, abnormal intestinal transit time, and liver dysfunction.[99] In comparison to the general CF population, patients with CFRD show a higher mortality rate. In a study of 448 patients, 60% of non-CFRD population and 25% of the CFRD were alive at age 30. The average onset of CFRD is between 18 and 21 years, with a slight female predominance and is more commonly seen in CF gene mutation *ΔF508*.[99,100,101,102,103,104]

It is recommended that at age 10 years and every year thereafter, CF patients be screened for CFRD. The OGTT should be used as the HbA1c is not a reliable indicator of diabetes in this population. In stable outpatients, fasting glucose levels of more than or equal to 126 mg/dL (7.0 mmol/L) are diagnostic of CFRD. A 2-hour OGTT plasma glucose level of more than or equal to 200 mg/dL (greater than 11.1 mmol/L) repeated on two separate days may also be diagnostic of CFRD.[105]

A desired goal in this population is to control hyperglycemia and prevent hypoglycemia in order to reduce acute and chronic diabetes complications. Because insulin deficiency is the hallmark of CFRD, insulin is the recommended medical treatment. Insulin regimens are individualized based on the patient's lifestyle and circumstances. Exercise is encouraged because it can improve peripheral insulin sensitivity and have beneficial effects in overall health, pulmonary function, and well-being.[100,101,102,103]

Oral antidiabetic agents have inconsistent results in the literature; therefore, support for their use in therapy for CFRD patients is not recommended. Medications that help improve insulin sensitivity do not address the primary problem of insulin deficiency in CF. Metformin's mechanism of action is to improve hepatic and peripheral insulin sensitivity; however, it is contraindicated in patients with hypoxia due to the risk of fatal lactic acidosis. Additionally, metformin's multiple GI effects include anorexia, diarrhea, flatulence, and abdominal discomfort. Thiazolidinediones help enhance peripheral insulin sensitivity, but there is serious potential for hepatic toxicity due to the underlying liver problems in CF patients. The use of acarbose is also discouraged due to its mechanism of action, which reduces postprandial glucose and insulin excursion by limiting intestinal absorption of glucose. This inhibits the energy absorption in malnourished individuals while causing diarrhea, anorexia, and abdominal discomfort. Sulfonylureas are being considered due to their ability to enhance insulin secretion by acting on a specific islet beta-cell receptor; however, evidence has also shown that these agents bind and inhibit the CFTR. Use of sulfonylureas is not recommended at this time.[100,104] Newer antidiabetic agents effective for treatment of Type 1 and Type 2 diabetes are currently being studied for treatment of CFRD. One current focus is in glucagon-like-peptide (GLP)1, which is an incretin hormone the body releases in response to eating. At least one study has found that CF patients may have a deficiency of this hormone. This deficiency was found in both CF patients with diagnosed diabetes and those without diabetes. It is not yet known how this plays into the future determination of diabetes in CF patients. There are ongoing studies evaluating the results of supplementation with GLP-1 in CF patients. A disadvantage of utilizing these new agents in CFRD is that these therapies target weight loss as well as glycemic control. Weight loss in CF patients may be detrimental to overall health, as the goal is to optimize nutrition status which contributes to optimal pulmonary

health and survival.[100,101,102,103,104]

SPECIAL POPULATIONS

Pregnancy

As women with CF live longer, more choose to become pregnant. CF women considering pregnancy and their partners should both undergo genetic counseling. CF women who become pregnant are considered a high-risk pregnancy; therefore, several considerations should be addressed at the onset of and during pregnancy. At the beginning, both current medications and medications that might be used to treat exacerbations need to be considered. Several of these medications are classified as category C and may pose a potential harm to the fetus. These patients should also be screened and treated accordingly for CFRD.

Several complications that will arise during CF pregnancy include increases in minute ventilation, increased oxygen uptake, increased blood volume, and cardiac output. In a woman with severe lung disease, these changes can cause right-sided heart failure.

Other pharmacotherapy issues that are seen in this population are altered pharmacokinetics and increased maintenance of nutritional and pulmonary health.

The addition of the fetus impacts the CF woman's health by placing a strain on a precariously balanced state of being. The CF woman who chooses to breastfeed must take into account the additional nutritional requirement of approximately 500 kcal/day (2,093 kJ/day).[16]

Pediatrics

Education of the parents is emphasized in this population, concerning administration of pancreatic enzymes and infant formula. Parents are also counseled to encourage their child to adhere with pulmonary health and nutritional health practices. As the child grows into adolescence, compliance becomes an issue. Peer pressure and social restraints may interfere with CF compliance and may influence the patients to disregard their personal well-being.

Transplant Patients

Lung transplantation has become an option with a 5-year survival rate of approximately 50%. Criteria for selection of transplant candidates include not only an FEV_1 of less than 30% (less than 0.30), but also gender, nutritional status, diabetic status, sputum microbiology, and number of pulmonary exacerbations. Factors affecting compliance to CF care and to immunosuppressant therapy may also be taken under consideration for candidacy.[16]

NEW THERAPIES

Bronchitol, an inhaled dry powder form of mannitol, is a new agent to help restore normal airway

hydration by drawing water to the airway surface, which hydrates secretions to help improve airway clearance. Bronchitol completed two large multinational phase 3 trials, has been approved for CF treatment in Australia, and was submitted to the FDA in 2012. The FDA rejected the new drug application (NDA), due to failure to prove safety and efficacy.[111]

An exciting breakthrough in CF treatment focuses on treating the basic defect of the disease: CFTR dysfunction. Kalydeco® (ivacaftor) was approved on January 31, 2012, for patients 6 years or older with the *G551D* mutation. Ivacaftor works by potentiating the activity of the CFTR protein so that the channels stay open longer on the cell surface. As a result, mucus is thinned by fluid movement into the airways making airway clearance easier for the patient.

In a randomized, double-blind, placebo-controlled trial evaluating ivacaftor in patients 12 years or older, ivacaftor met effectiveness endpoints. Researchers saw significant improvements in lung function, risk of pulmonary exacerbations, respiratory symptoms, and weight and sweat chloride concentrations. The change in baseline FEV_1 was greater than 10.6 percentage points (0.106) in comparison with placebo (*P* less than 0.001) with an improvement in pulmonary function noted by 2 weeks and sustained through week 48. An average weight increase of 2.7 kg was seen in the ivacaftor group versus placebo at the end of 48 weeks. No significant safety issues were noted in the study. Currently, 87.5% of eligible patients are taking ivacaftor.[112,113]

Orkambi® is a combination of ivacaftor and lumacaftor, a CFTR potentiator and CFTR corrector. It was approved by FDA in 2015 for patients 12 years or older with the *ΔF508* mutation. In 2 phase 3 placebo controlled, randomized control trials, Orkambi® showed improvement in percentage of predicted FEV_1, as well as reduction in pulmonary exacerbations in comparison to placebo.[112,113]

Clinical Controversy…

CF is a worldwide problem, with a variety of approaches toward treatment. Discussions regarding controversial methods are constantly being held while new therapies are tried. Due to the relatively small population of CF patients, any studies that are conducted are frequently small in number or do not accurately reflect this population. This makes it difficult to extrapolate and come to a consensus regarding therapy. Some of these controversies will be discussed.

Contraceptive use in CF women continues to be a difficult issue to manage due to limited studies and recommendations. According to these studies, majority of CF women are sexually active, and use a variety of contraceptive methods. The most common method reported was the OCP. Although without further research, providers must consider several compounding factors regarding the use of OCPs. Several pharmacokinetic factors are altered in this population, including decreased absorption, increased rate of metabolism, and increased clearance. Drug interactions should also be considered, as CF women will be on antibiotics that may compromise the efficacy of the pill. Emerging therapy modalities such as the CFTR modulators (ie, ivacaftor) need more studies to confirm lack of drug interactions that may compromise contraception. Other risks associated with OCP use include thromboembolic events that may be potentiated in the CF patient with an indwelling central vascular device.

Other contraceptive methods should be considered, such as estrogen patches, intrauterine devices, vaginal rings, and hormone implants. These methods may be beneficial by avoiding first pass metabolism, reducing the risk of drug interactions. Medroxyprogesterone acetate may be beneficial in improving nutritional status, however, contributes to bone mineral density (BMD) loss, leading to early osteoporosis.

In light of this interesting, but sparse data, there is an encouraging possibility that exogenous hormone therapy has a potential benefit to prolong the life span of CF women. In comparison to CF men, women have a worsened disease severity and shorter life span. It is possible that fluctuating estradiol levels are associated with increased pulmonary exacerbations. However, studies in this area are limited and need to be substantiated as hormone therapy is not without risk.

SOCIAL

The social worker is an integral part of the CF team, due to the complex social issues that surround CF patients. Maintaining health insurance is a lifelong problem for CF patients. The inability to pay for CF medications may often influence compliance. Employment is difficult to maintain because some employers may penalize for frequent hospitalizations. Thus, many CF patients have low-paying jobs without insurance coverage.

Building relationships and confiding in others about personal health issues can be intimidating and difficult for CF patients. Due to infection control guidelines, group settings are limited. The use of new technology now allows support groups via video conferencing and online discussion. The decision to marry and/or have children is complicated by an awareness of their abbreviated life span.[16]

SUMMARY

Multidisciplinary care for CF patients should involve pulmonologists, gastroenterologists, pharmacists, social workers, respiratory therapists, and dieticians. Complexity of care requires good communication within the CF team. Although intravenous (IV) antibiotics have historically been a mainstay of therapy, recent focus has shifted to optimizing nutrition status and promoting effective pulmonary clearance. New treatment modalities such as CFTR modulators will necessitate greater involvement by pharmacists. As patients live longer, more social issues arise and medical issues become more complex.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACT	airway clearance therapy
ADEK	fat-soluble vitamins A, D, E, K
BMD	bone mineral density
CF	cystic fibrosis

CFRD	cystic fibrosis related diabetes
CFTR	cystic fibrosis transmembrane conductance regulator
DIOS	distal intestinal obstruction syndrome
FDA	Food and Drug Administration
FEV_1	forced expiratory volume at 1 second
FVC	forced vital capacity
GI	gastrointestinal
IRT	immunoreactive trypsinogen
IV	intravenous
MAI	*Mycobacterium avium-intracellulare*
MIC	minimum inhibitory concentration
NDA	new drug application
NSAIDs	nonsteroidal anti-inflammatory drugs
NTM	nontuberculous mycobacteria
OGTT	oral glucose tolerance test
OCPs	oral contraceptive pills
PEG	percutaneous endoscopic gastrostomy
PERT	pancreatic enzyme replacement therapy
QPIT	quantitative pilocarpine iontophoresis test
RSV	respiratory syncytial virus

Chapter e30: Drug-Induced Pulmonary Diseases

FIGURE e30-1

Hengameh H. Raissy; Michelle Harkins

INTRODUCTION

KEY CONCEPTS

- 1 Select populations may be more susceptible to toxicities associated with specific agents.
- 2 Primary treatment is discontinuation of the offending agent and supportive care.

The manifestations of drug-induced pulmonary diseases span the entire spectrum of pathophysiologic conditions of the respiratory tract. As with most drug-induced diseases, the pathological changes are nonspecific. Therefore, the diagnosis is often difficult and, in most cases, is based on exclusion of all other possible causes. In addition, the true incidence of drug-induced pulmonary disease is difficult to assess as a result of the pathological nonspecificity and the interaction between the underlying disease state and the drugs.

Considering the physiologic and metabolic capacity of the lung, it is surprising that drug-induced pulmonary disease is not more common. The lung is the only organ of the body that receives the entire circulation. In addition, the lung contains a heterogeneous population of cells capable of various metabolic functions, including *N*-alkylation, *N*-dealkylation, *N*-oxidation, reduction of *N*-oxides, and *C*-hydroxylation.

In Unites States, more than 2 million cases of adverse drug reactions occur every year with 100,000 reported deaths;[1] 0.3% of hospital deaths are drug-related.[2] Evaluation of epidemiologic studies on adverse drug reactions provides a perspective on the importance of drug-induced pulmonary disease. In a 2-year prospective survey of a community-based general practice, 41% of 817 patients experienced adverse drug reactions.[3] Four patients, or 0.5% of the total respondents, experienced adverse respiratory symptoms. Respiratory symptoms occurred in 1.2% of patients experiencing adverse drug reactions. In a recent retrospective analysis of clinical case series in France, 898 patients

had reported drug allergy, with a bronchospasm incidence of 6.9%. When these patients were rechallenged with the suspected drug, only 241 (17.6%) tested positive. The incidence of bronchospasm in patients with positive provocation test was 7.9%.[4]

Adverse pulmonary reactions are uncommon in the general population but are among the most serious reactions, often requiring intervention. In a study of 270 adverse reactions leading to hospitalization from two populations, 3.0% were respiratory in nature.[5] Of the reactions considered to be life threatening, 12.3% were respiratory. An early report on death caused by drug reactions from the Boston Collaborative Drug Surveillance Program indicated that 7 of 27 drug-induced deaths were respiratory in nature.[6] This was confirmed in a follow-up study in which 6 of 24 drug-induced deaths were respiratory in nature.[7]

DRUG-INDUCED APNEA

Apnea may be induced by central nervous system depression or respiratory neuromuscular blockade (**Table e30-1**). Patients with chronic obstructive airway disease, alveolar hypoventilation, and chronic carbon dioxide retention have an exaggerated respiratory depressant response to narcotic analgesics and sedatives. In addition, the injudicious administration of oxygen in patients with carbon dioxide retention can worsen ventilation-perfusion mismatching, further elevating pCO_2 and thus producing apnea.[8] Although the benzodiazepines are touted as causing less respiratory depression than barbiturates, they may produce a profound additive or synergistic effect when taken in combination with other respiratory depressants. Combining intravenous diazepam with phenobarbital to stop seizures in an emergency department frequently results in admissions to an intensive care unit for a short period of assisted mechanical ventilation, regardless of the drug administration rate. Too rapid intravenous administration of any of the benzodiazepines, even without coadministration of other respiratory depressants, will result in apnea. The risk appears to be the same for the various available agents (diazepam, lorazepam, and midazolam). Respiratory depression and arrests resulting in death and hypoxic encephalopathy have occurred following rapid intravenous administration of midazolam for conscious sedation prior to medical procedures. This has been reported more commonly in the elderly and the chronically debilitated or in combination with opioid analgesics. Concurrent use of inhibitors of cytochrome P450 3A4 with benzodiazepines is likely to lead to greater risk of respiratory depression.

TABLE e30-1 Drugs That Induce Apnea

	Relative Frequency of Reactions
Central nervous system depression	
Narcotic analgesics	F
Barbiturates	F
Benzodiazepines	F
Other sedatives and hypnotics	I
Tricyclic antidepressants	R
Phenothiazines	R

	Relative Frequency of Reactions
Ketamine	R
Promazine	R
Anesthetics	R
Antihistamines	R
Alcohol	R
Fenfluramine	I
L-Dopa	R
Oxygen	R
Respiratory muscle dysfunction	
Aminoglycoside antibiotics	I

1 Prolonged apnea may follow administration of any of the neuromuscular blocking agents used for surgery, particularly in patients with hepatic or renal dysfunction. In addition, persistent neuromuscular blockade and muscle weakness have been reported in critically ill patients who are receiving neuromuscular blockers continuously for more than 2 days to facilitate mechanical ventilation.[9,10] This has resulted in delayed weaning from mechanical ventilation and prolonged intensive care unit stays. The prolonged neuromuscular blockade has been confined principally to pancuronium and vecuronium in patients with renal disease. Both agents have pharmacologic active metabolites that are excreted renally. The persistent muscular weakness is less well defined but appears to represent an acute myopathy.[9,11,12,13] High-dose corticosteroids appear to produce a synergistic effect, supported by animal studies showing that corticosteroids at dosages greater than or equal to 2 mg/kg per day of prednisone produce atrophy in denervated muscle.[14] The fluorinated corticosteroids (eg, triamcinolone) appear to be more myopathic.[15] Dose-dependent respiratory muscle weakness has been reported in chronic obstructive pulmonary disease (COPD) and asthma patients receiving repeated short courses of oral prednisone in the previous 6 months,[16,17] as well as patients with steroid-dependent asthma.

Respiratory failure has been known to occur following local spinal anesthesia. Apnea from respiratory

paralysis and rapid respiratory muscle fatigue has followed the administration of polymyxin and aminoglycoside antibiotics.[8] The mechanism appears to be related to the complexation of calcium and its depletion at the myoneural junction. Intravenous calcium chloride has been variably effective in reversing the paralysis.[8] The aminoglycosides competitively block neuromuscular junctions. This has resulted in life-threatening apnea when neomycin, gentamicin, streptomycin, or bacitracin has been 1 administered into the peritoneal and pleural cavities.[8] The aminoglycosides will produce an additive blockade and ventilatory paralysis with curare or succinylcholine and in patients with myasthenia gravis or myasthenic syndromes.[8] Intravenous administration of aminoglycosides has resulted in respiratory failure in babies with infantile 2 botulism. Treatment consists of ventilatory support and administration of an anticholinesterase agent (neostigmine or edrophonium).[8]

DRUG-INDUCED ASTHMA

Epidemiologic studies demonstrate an increase in the prevalence of asthma and COPD with increased use of acetaminophen. The use of aspirin or ibuprofen is not associated with asthma or COPD.[18] A relationship with acetaminophen in the etiology of asthma, COPD or allergic diseases has been reported from in utero, infant, childhood, and adulthood exposures. A weak association between use of acetaminophen during pregnancy and asthma in children between ages 28 months and 7 years was reported using The Danish National Birth Cohort.[19,20,21] The association between use of acetaminophen in infancy and childhood and risk of childhood asthma was reported by the International Study of Asthma and Allergies in Childhood, including data from 31 countries.[22] Administration of acetaminophen in the first year of life was associated with a 46% increase in risk of asthma symptoms at the age of 6 to 7 years.[22,23] Furthermore, The European Respiratory Health Survey reported an increase in prevalence of wheezing in adults by 0.26% for each gram increase in per capita acetaminophen sales.[24] In a prospective birth cohort study, the association between frequency of acetaminophen use and risk of childhood asthma at age 7 disappeared when adjusted for frequency of respiratory infections.[25] The acetaminophen—asthma/COPD associations may be explained by reduction of glutathione, an endogenous antioxidant enzyme in the airway epithelium resulting in oxidant damage in the lung.[18] However, these findings should be interpreted with caution since confounding by indication may play a part in this association.

DRUG-INDUCED BRONCHOSPASM

Bronchoconstriction is the most common drug-induced respiratory problem. Bronchospasm can be induced by a wide variety of drugs through a number of disparate pathophysiologic mechanisms (**Table e30-2**). Regardless of the pathophysiologic mechanism, drug-induced bronchospasm is almost exclusively a problem of patients with preexisting bronchial hyperreactivity (eg, asthma, COPD).[26] By definition, all patients with nonspecific bronchial hyperreactivity will experience bronchospasm if given sufficiently high doses of cholinergic or anticholinesterase agents. Severe asthmatics with a high degree of bronchial reactivity may wheeze following the inhalation of a number of particulate substances, such as the lactose in dry-powder inhalers and inhaled

corticosteroids, presumably through direct stimulation of the central airway irritant receptors. Other pharmacologic mechanisms for inducing bronchospasm include β_2-receptor blockade and nonimmunologic histamine release from mast cells and basophils.[26] A large number of agents are capable of producing bronchospasm through immunoglobulin (Ig) E-mediated reactions.[26] These drugs can become a significant occupational hazard for pharmacists, nurses, and pharmaceutical industry workers.[26]

ASPIRIN-INDUCED BRONCHOSPASM

Overall prevalence of aspirin sensitivity or intolerance in the general population ranges from 0.6% to 2.5% which increases prevalence that range from 2% to 25% in patients with asthma.[27,28,29] The frequency of aspirin-induced bronchospasm increases with age, on average at 30 years. Women

predominate over men, and there is no evidence for a genetic or familial predisposition.[30,31] The classic description of the aspirin-intolerant asthmatic includes the triad of severe asthma, nasal polyps, and aspirin intolerance. The typical patient experiences rhinorrhea and nasal congestion as early symptoms followed by nasal polyps. Asthma and aspirin hypersensitivity will develop over the next 2 to 15 years. Bronchospasm typically begins within minutes to hours following ingestion of aspirin and is associated with rhinorrhea, flushing of the head and neck, and conjunctivitis. The reactions are severe and often life-threatening and once developed, aspirin hypersensitivity remains throughout life.[27,32]

All aspirin-sensitive asthmatics do not fit the classic "aspirin triad" picture, and not all patients with asthma and nasal polyps develop sensitivity to aspirin.[31] In most cases, aspirin-sensitive asthmatics are clinically indistinguishable from the general population of asthmatics except for their intolerance to aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs). Aspirin-induced asthmatics are not at higher risk of having fatal asthma if aspirin and other NSAIDs are avoided.[33]

Diagnosis of aspirin-induced asthma requires a detailed medical history. The definitive diagnosis is made by aspirin provocation tests, which may be done via different routes.[27,30,31,34] An oral provocation test is used commonly where threshold doses of aspirin induce a positive reaction measured by a drop in forced expiratory volume in the first second of expiration (FEV_1) and/or the presence of symptoms.[34,35] Both nasal and bronchial provocation tests are done by the application of one dose of lysine-aspirin, and aspirin sensitivity is manifested with clinical symptoms of watery discharge and a significant fall in inspiratory nasal flow or mild bronchospasm.[27,30,34,35] The oral provocation test remains the most sensitive in comparison with other routes.[27,30]

Pathogenesis

Aspirin-induced asthma is correctly classified as an idiosyncratic reaction in that the pathogenesis is still unknown. Patients with aspirin intolerance have increased plasma histamine concentrations after ingestion of aspirin and elevated peripheral eosinophil counts.[27,30] All attempts to define an immunologic mechanism have been unsuccessful. Chemically similar drugs such as salicylamide and choline salicylate do not cross-react, whereas a large number of chemically dissimilar NSAIDs do produce reactions.[27,30] **Table e30-3** lists the analgesics that do and do not cross-react with aspirin.

TABLE e30-3 Tolerance of Anti-Inflammatory and Analgesic Drugs in Aspirin-Induced Asthma

Cross-Reactive Drugs	Drugs with No Cross-Reactivity
Diclofenac	Acetaminophen[a]

Sulindac	
Sulfinpyrazone	
Tartrazine	
Tolmetin	

[a]A very small percentage (5%) of aspirin-sensitive patients react to acetaminophen and phenacetin.

The currently accepted hypothesis of aspirin-induced asthma is that aspirin intolerance is integrally related to inhibition of cyclooxygenase (COX). There are at least two COX enzymes coded by different genes and only COX-I is sensitive to inhibition by NSAID.[27,30] This is supported by the following evidence: (a) All NSAIDs that inhibit COX produce reactions, (b) the degree of cross-reactivity is proportional to the potency of COX inhibition, and (c) each patient with aspirin sensitivity has a threshold dose for precipitating bronchospasm that is specific for the degree of COX inhibition produced, and once established, the dose of another COX inhibitor needed to induce bronchospasm can be estimated.[30,36]

The mechanism by which COX inhibition produces bronchospasm in susceptible individuals is unknown. Arachidonic acid metabolism through the 5-lipoxygenase pathway may lead to the excess production of leukotrienes C_4 and D_4.[31,33] Leukotrienes C_4, D_4, and E_4 produce bronchospasm and promote histamine release from mast cells.[27,30] The precise mechanism by which augmented leukotriene production occurs is unknown, and available hypotheses do not explain why only a small number of asthmatic patients react to aspirin and NSAIDs.

Desensitization

Patients with aspirin sensitivity can be desensitized. The ease of desensitization correlates with the sensitivity of the patient.[36] Highly sensitive patients who react initially to less than 100 mg aspirin require multiple rechallenges to produce desensitization.[36] Desensitization usually persists for 2 to 5 days following discontinuance, with full sensitivity reestablished within 7 days.[36] Cross-desensitization has been established between aspirin and all NSAIDs tested to date. Because patients may experience life-threatening reactions, desensitization should be attempted only in a controlled environment by personnel with expertise in handling these patients. In addition, there are reports of

patients who have failed to maintain a desensitized state despite continued aspirin administration.[31,36] In one open follow-up trial in 172 aspirin-sensitive asthmatics who had undergone desensitization and continued daily aspirin treatment (1,300 mg/day) an improvement in nasal-sinus and asthma symptoms occurred after 6 months of treatment, which persisted up to 5 years.[37]

Cross-Sensitivity with Food, Drug Additives, and Other Agents

1 The yellow azo dye tartrazine (FD&C Yellow No. 5) is used widely for coloring foods, drinks, drugs, and cosmetics, has occasionally been reported to trigger asthma.[38] However, adequately controlled trials have not confirmed a cause-and-effect role for tartrazine and asthma even among aspirin-sensitive asthmatics who were thought to be at higher risk.[39] Reactions to other azo dyes, monosodium glutamate, parabens, and nonazo dyes have been reported much less frequently than reactions to tartrazine, and have been equally difficult to confirm with controlled challenges. Acetaminophen is a weak inhibitor of COX and may be used as an alternative for analgesia in patient with aspirin-sensitive asthma; however, acetaminophen at high doses (1,000 mg) will produce reactions in sensitive patients.[40] Studies have shown that less than 2% of patients with asthma are sensitive to both aspirin and acetaminophen. Well-designed studies have shown that selective COX 2 inhibitors are well tolerated at therapeutic doses and may be used safely in aspirin-sensitive patients.[31,41,42,43,44,45] A systemic review of databases in patients with aspirin-induced asthma included placebo-controlled and blinded clinical trials, No significant difference in respiratory symptoms with COX 2 was reported compared to placebo.[29](ref F) At this point, the package inserts of these agents state that they are contraindicated for aspirin-sensitive asthmatics[31,42,43,44,45] as there are reports of cross-reactivity in extremely sensitive patients.[46,47,48,49,50] Sporadic cases of worsening bronchospasm and anaphylaxis have been reported in aspirin-sensitive asthmatics receiving intravenous hydrocortisone succinate; however, such reactions have not been reported with use of other corticosteroids.[36] It is not known whether it is the hydrocortisone or the succinate that aggravates the problem.

TREATMENT

Aspirin-Sensitive Asthma

2 Therapy of aspirin-sensitive asthmatics takes one of two general approaches: desensitization or avoidance. Avoidance of triggering substances seldom alters the clinical course of patients' asthma. The therapy of asthma has been nonspecific; however, in theory, 5-lipoxygenase inhibitors such as zileuton or leukotriene antagonists should provide specific therapy. A few studies have investigated use of leukotriene modifiers to prevent aspirin-induced bronchospasm in aspirin-sensitive asthmatics.[51,52,53,54,55] Pretreatment with zileuton in eight aspirin-sensitive asthma patients protected them from the same threshold-provoking doses of aspirin.[51] However, larger, escalating doses of aspirin above the threshold challenge doses were not examined in this study. Furthermore, when doses of aspirin were escalated above the threshold provocative doses, zileuton did not

prevent formation of leukotrienes.[52] In a similar study, pretreatment with montelukast 10 mg/day did not protect patients when aspirin doses were increased above their threshold doses.[46] In another study, the mean provoking dose of aspirin did not differ in the asthmatics who were taking leukotriene modifiers and the control group (60.4 mg vs 70.3 mg, respectively).[56] Although initial studies suggested that leukotriene modifiers blocked aspirin-induced reactions, it is now apparent that they merely shift the dose—response curve to the right, leaving the patient at risk at higher doses.[57] Thus even patients who might benefit from leukotriene modifiers should avoid aspirin and all NSAIDs. A case of ibuprofen 400-mg-induced asthma was reported in an asthmatic patient on zafirlukast 20 mg twice daily.[58] Furthermore, most of the challenge studies are based on incremental doses of aspirin or NSAIDs, and exposure of patients to full clinical doses of aspirin or NSAIDs can overcome the antagonistic effect of leukotriene modifiers. The respiratory symptoms can be decreased but not prevented by pretreatment with antihistamines and cromolyn.[59] The long-term asthma control of patients with aspirin sensitivity does not differ from that for other asthmatics. There is no evidence to support that aspirin-sensitive asthmatics respond better to leukotriene modifiers. In a double-blind, randomized, placebo-controlled study, aspirin-sensitive asthmatic patients on montelukast showed a 10% improvement in FEV_1 compared with the placebo group.[60] Similar results were reported when montelukast was compared with placebo in patients with intermittent or persistent asthma.[61]

β-Blockers

1 β-Adrenergic receptor blockers comprise the other large class of drugs that can be hazardous to a person with asthma. Even the more cardioselective agents such as acebutolol, atenolol, and metoprolol have been reported to cause asthma attacks.[26] Patients with asthma may take nonselective and β_1-selective blockers without incident for long periods; however, the occasional report of fatal asthma attacks resistant to therapy with β-agonists should provide ample warning of the dangers inherent in β-blocker therapy.[26]

If a patient with bronchial hyperreactivity requires β-blocker therapy, one of the selective β_1-blockers (eg, acebutolol, atenolol, or metoprolol) should be used at the lowest possible dose. In a meta-analysis of 29 clinical trials in patients with mild to moderate airway obstruction, cardioselective β-blockers did not produce any clinically significant respiratory effects in short-term.[62] Similar results were reported in patients with chronic obstructive pulmonary disease (COPD).[63] In a large cohort study in United Kingdom, more than 53,000 patients with asthma were identified who were issued oral β-blocker therapy and followed for at least 84 days. The authors did not find a significant difference in asthma exacerbation, defined as use of oral corticosteroid, after prescribing a new oral β-blocker therapy compared to baseline. There was no difference in stratification for β-blocker selectivity in the cohort.[64] Celiprolol and betaxolol appear to possess greater cardioselectivity than currently marketed drugs.[65,66] Timolol is metabolized by CYP2D6 and patients who are poor metabolizers CYP26 may have higher systemic concentration of timolol resulting in respiratory adverse events.[67] Fatal status asthmaticus[68] and interstitial lung diseases[69] have occurred with the topical administration of the nonselective timolol maleate ophthalmic solution for the treatment of

open-angle glaucoma.[68] Although ophthalmic betaxolol suggests that it is well tolerated even in timolol-sensitive asthmatics, long-term betaxolol therapy in glaucoma patients with history of pulmonary diseases has been associated with pulmonary obstruction.[70,71,72] Airway obstruction following topical β-blockers for glaucoma has also been reported in patients with no history of airway obstruction and close monitoring is warranted.[73]

Sulfites

Severe, life-threatening asthmatic reactions following consumption of restaurant meals and wine have occurred secondary to ingestion of the food preservative potassium metabisulfite.[74,75] Sulfites have been used for centuries as preservatives in wine and food. As antioxidants, they prevent fermentation of wine and discoloration of fruits and vegetables caused by contaminating bacteria.[76] Previously, sulfites had been given "generally recognized as safe" status by the Food and Drug Administration (FDA). Sensitive patients react to concentrations ranging from 5 to 100 mg, amounts that are consumed routinely by anyone eating in restaurants. Consumption of sulfites in US diets is estimated to be 2 to 3 mg/day in the home with 5 to 10 mg per 30 mL of beer or wine consumed.[75] Anaphylactic or anaphylactoid reactions to sulfites in nonasthmatics are extremely rare. In the general asthmatic population, the overall presence of reactions to sulfites are about 3.9% with more persistent asthma patients at a higher rate.[77] Approximately 5% of steroid-dependent asthmatics demonstrate sensitivity to sulfiting agents.[76]

Mechanism

Three different mechanisms have been proposed to explain the reaction to sulfites in asthmatic patients.[76,78] The first is explained by the inhalation of sulfur dioxide, which produces bronchoconstriction in all asthmatics through direct stimulation of afferent parasympathetic irritant receptors. Furthermore, inhalation of atropine or the ingestion of doxepin protects sulfite-sensitive patients from reacting to the ingestion of sulfites. The second theory, IgE-mediated reaction, is supported by reported cases of sulfite-sensitive anaphylaxis reaction in patients with positive sulfite skin test. Finally, a reduced concentration of sulfite oxidase enzyme (the enzyme that catalyzes oxidation of sulfites to sulfates) compared with normal individuals has been demonstrated in a group of sulfite-sensitive asthmatics.

A number of pharmacologic agents contain sulfites as preservatives and antioxidants. The FDA now requires warning labels on drugs containing sulfites. Most manufacturers of drugs for the treatment of asthma have discontinued the use of sulfites. In addition, labeling is required on packaged foods that contain sulfites at 10 parts per million or more, and sulfiting agents are no longer allowed on fresh fruits and vegetables (excluding potatoes) intended for sale.

Pretreatment with cromolyn, anticholinergics, and cyanocobalamin have protected sulfite-sensitive patients.[76,79] Presumably, pharmacologic doses of vitamin B_{12} catalyze the nonenzymatic oxidation of sulfite to sulfate.

Other Preservatives

Both ethylenediamine tetraacetic acid (EDTA) and benzalkonium chloride, used as stabilizing and bacteriostatic agents, respectively, can produce bronchoconstriction.[51] In addition to producing bronchoconstriction, EDTA potentiates the bronchial responsiveness to histamine.[80] These effects presumably are mediated through calcium chelation by EDTA. Benzalkonium chloride is more potent than EDTA, and its mechanism appears to be a result of mast cell degranulation and stimulation of irritant C fibers in the airways.[80]

The bronchoconstriction from benzalkonium chloride can be blocked by cromolyn but not the anticholinergic ipratropium bromide.[81] Benzalkonium chloride is found in the commercial multiple-dose nebulizer preparations of ipratropium bromide and beclomethasone dipropionate marketed in the United Kingdom and Europe and is presumed to be in part responsible for paradoxical wheezing following administration of these agents.[80,81,82] Benzalkonium chloride is also found in albuterol nebulizer solutions marketed in the United States and has been implicated as a possible cause of paradoxical wheezing in infants receiving this preparation.[80] The effect of these agents on FEV_1 when used in the amount administered for treatment of acute asthma was evaluated in subjects with stable asthma.[83] Patients were assigned randomly to inhale up to four 600-mcg nebulized doses of EDTA and benzalkonium chloride and normal saline. The change in FEV_1 was not different between EDTA and the placebo group; however, benzalkonium chloride was associated with a statistically significant decrease in FEV_1 compared with placebo. It is important to consider that these agents are always used in combination with bronchodilators and β_2-agonists, which are potent mast cell stabilizers, and the anecdotal reports have not yet been confirmed with controlled investigations.[70,71,72,73,74,75,76,77,78,79,80,81]

Contrast Media

Iodinated radiocontrast materials are the most common cause of anaphylactoid reactions producing bronchospasm.[84] This is discussed in more detail in Chapter 22.

Natural Rubber Latex Allergy

Allergy to natural rubber latex, first reported in 1989 in the United States, is a common cause of occupational allergy for healthcare workers.[85] Natural rubber is a processed plant product from the commercial rubber tree, *Hevea brasiliensis*.[86] Latex allergens are proteins found in both raw latex and the extracts used in finished rubber products. Latex gloves are the largest single source of exposure to the protein allergens.[86]

1 The reported prevalence of latex allergy depends on the sample population. In the general population, latex allergy is between 5% and 10%; however, the prevalence increases in healthcare workers to 0.5% to 17%.[86,87] Risk factors for latex allergy include frequent exposure to rubber gloves, history of atopic disease, and presence or history of hand dermatitis. Patients with spina bifida are at an increased risk of latex allergy, with an incidence of 18% to 64% as a result of early and repeated

exposure to rubber devices during the surgical procedures.[86,88,89]

Clinical manifestations of latex allergy range from contact dermatitis and urticaria, rhinitis and asthma, and reported cases of anaphylaxis.[85,86] The early manifestation of rubber allergy is contact urticaria, which is an IgE-mediated reaction to rubber proteins following direct contact with the medical devices: mainly rubber gloves.[86] Contact dermatitis may occur within 1 to 2 days. Contact dermatitis is a cell-mediated delayed-type hypersensitivity reaction to the additive chemical component of rubber products.[86] Rhinitis and asthma may follow inhalation of allergens carried by cornstarch powder used to coat the latex gloves. Asthma caused by occupational exposure is seen mostly in atopic patients with histories of seasonal and perennial allergies and asthma.[86] Isolated cases of wheezing secondary to latex exposure in patients without a history of asthma have also been reported.[86]

The diagnosis of latex allergy is based on the presence of latex-specific IgE, as well as symptoms consistent with IgE-mediated 2 reactions.[90] The mainstay of therapy for latex allergy is avoidance. Substitution of powdered latex gloves with low protein natural rubber latex has reduced the rate of latex allergy and sensitivity in healthcare workers.[91] The FDA requires appropriate labeling for all medical devices containing natural rubber latex to ensure avoidance and a latex-free environment. The role of pretreatment with antihistamines, corticosteroids, and allergen immunotherapy remains to be determined.[86,90] Specific immunotherapy for latex allergy (either subcutaneous or sublingual immunotherapy) has been evaluated and sublingual immunotherapy seems more tolerable than the subcutaneous injection; however, systemic reactions have been reported during the build-up phase of immunotherapy[92] and it may not be the best option for patients with moderate to severe asthma.[87,93]

Angiotensin-Converting Enzyme Inhibitor-Induced Cough

1 Cough has become a well-recognized side effect of angiotensin-converting enzyme (ACE) inhibitor therapy. According to spontaneous reporting by patients, cough occurs in 1% to 10% of patients receiving ACE inhibitors, with a preponderance of females. In a retrospective analysis, 14.6% of women had cough compared with 6.0% of the men on ACE inhibitors. It is suggested that women have a lower cough threshold, resulting in their reporting this adverse effect more commonly than men.[94] Studies specifically evaluating cough caused by ACE inhibitors report a prevalence of 19% to 25%.[94,95] Patients receiving ACE inhibitors had a 2.3 times greater likelihood of developing cough than a similar group of patients receiving diuretics.[94] Patients with hyperreactive airways do not appear to be at greater risk.[94,96] African Americans and Chinese have a higher incidence of cough.[97] When different disease states were compared, 26% of patients with heart failure had ACE inhibitor-induced cough compared with 14% of those with hypertension.[97] Cough can occur with all ACE inhibitors.[98]

The cough is typically dry and nonproductive, persistent, and not paroxysmal.[98] The severity of cough varies from a “tickle” to a debilitating cough with insomnia and vomiting. The cough can begin within

3 days or have a delayed onset of up to 12 months following initiation of ACE inhibitor therapy.[98] The cough remits within 1 to 4 days of discontinuing therapy but (rarely) can last up to 4 weeks and recur with rechallenge.[98] Patients should be given a 4-day withdrawal to determine if the cough is induced by ACE inhibitors. The chest radiograph is normal, as are pulmonary function tests (spirometry and diffusing capacity). Bronchial hyperreactivity, as measured by histamine and methacholine provocation, may be worsened in patients with underlying bronchial hyperreactivity such as asthma and chronic bronchitis. However, bronchial hyperreactivity is not induced in others.[98,99] The cough reflex to capsaicin is enhanced but not to nebulized distilled water or citric acid.[98]

The mechanism of ACE inhibitor-induced cough is still unknown. ACE is a nonspecific enzyme that also catalyzes the hydrolysis of bradykinin and substance P (see Chapter 13 for more detail) that produce or facilitate inflammation and stimulate lung irritant receptors.[98] ACE inhibitors may also induce COX to cause the production of prostaglandins. NSAIDs, benzonatate, inhaled bupivacaine, theophylline, baclofen, thromboxane A_2 synthase inhibitor,[97,100] and cromolyn sodium all have been used to suppress or inhibit ACE inhibitor-induced cough.[98,101] The cough is generally unresponsive to cough suppressants or bronchodilator therapy. No long-term trials evaluating different treatment options for ACE inhibitor-induced cough exist. Cromolyn sodium may be considered first because it is the 2 most studied agent and has minimal toxicity.[97] The preferred therapy is withdrawal of the ACE inhibitor and replacement with an alternative antihypertensive agent. Owing to their decrease in ACE inhibitor-induced side effects, angiotensin II receptor antagonists are often recommended in place of an ACE inhibitor; however, there are rare reports of this agent inducing bronchospasm.[96,102] The clinical trials suggest that angiotensin II receptor antagonists have the same incidence of cough as placebo. Furthermore, when angiotensin II receptor antagonists were compared with ACE inhibitors, cough occurred much less frequently. Reduction in the incidence of cough with angiotensin II receptor antagonists is likely caused by the lack of effect on clearance of bradykinin and substance P.[103] The use of alternative therapies to treat ACE inhibitor-induced cough is generally not recommended.[103]

Pulmonary Edema

Pulmonary edema may result from the failure of any of a number of homeostatic mechanisms. The most common cause of pulmonary edema is an increase in capillary hydrostatic pressure because of left ventricular failure. Excessive fluid administration in compensated and decompensated heart failure patients is the most frequent cause of iatrogenic pulmonary edema. Besides hydrostatic forces, other homeostatic mechanisms that may be disrupted include the osmotic and oncotic pressures in the vasculature, the integrity of the alveolar epithelium, the interstitial pulmonary pressure, and the interstitial lymph flow.[8] The edema fluid in cardiogenic pulmonary edema contains a low amount of protein, whereas noncardiogenic pulmonary edema fluid has a high protein concentration.[8] This indicates that noncardiogenic pulmonary edema results primarily from disruption of the alveolar epithelium.

The clinical presentation of pulmonary edema includes persistent cough, tachypnea, dyspnea, tachycardia, rales on auscultation, hypoxemia from ventilation—perfusion imbalance and

intrapulmonary shunting, widespread fluffy infiltrates on chest roentgenogram, and decreased lung compliance (stiff lungs). Noncardiogenic pulmonary edema may progress to hemorrhage; cellular debris collects in the alveoli, followed by hyperplasia and fibrosis with a residual restrictive mechanical defect.[8,104]

Narcotic-Induced Pulmonary Edema

The most common drug-induced noncardiogenic pulmonary edema is produced by the narcotic analgesics (**Table e30-4**).[8] Narcotic-induced pulmonary edema is associated most commonly with intravenous heroin use, but also has occurred with morphine, methadone, meperidine, and propoxyphene use.[8,104,105] There have also been a few reported cases associated with the use of the opiate antagonist naloxone and nalmefene, a long-acting opioid antagonist.[104,106,107] The mechanism is unknown but may be related to hypoxemia similar to the neurogenic pulmonary edema associated with cerebral tumors or trauma or a direct toxic effect on the alveolar capillary membrane.[105] Initially thought to occur only with overdoses, most evidence now supports the theory that narcotic-induced pulmonary edema is an idiosyncratic reaction to moderate as well as high narcotic doses.[104,105]

Patients with pulmonary edema may be comatose with depressed respirations or dyspnea and tachypnea. They may or may not have other signs of narcotic overdose. Symptomatology varies from cough and mild crepitations on auscultation with characteristic radiologic findings to severe cyanosis and hypoxemia, even with supplemental oxygen. Symptoms may appear within minutes of intravenous administration but may take up to 2 hours to occur, particularly following oral methadone.[105] Hemodynamic studies in the first 24 hours have demonstrated normal pulmonary capillary wedge pressures in the presence of pulmonary edema.

Clinical symptoms generally improve within 24 to 48 hours, and radiologic clearing occurs in 2 to 5 days, but abnormalities in pulmonary function tests may persist for 10 to 12 weeks. Therapy consists of naloxone administration, supplemental oxygen, and ventilatory support if required. Mortality is less than 1%.[105]

Cough has been reported with intravenous administration of fentanyl in adult and pediatric population.[108,109] A cohort of 1,311 adult patients undergoing elective surgery had 120 patients with vigorous cough within 20 seconds after administration of fentanyl. The cough was associated with young age and absence of cigarette smoking.[108] Among anesthetic factors, it was associated with the absence of epidurally administered lidocaine and the absence of a priming dose of vecuronium. A history of asthma or COPD had no predictive effect.[108] Further clinical trials are required to understand the mechanism of paradoxical cough with fentanyl and to identify the means to prevent it.

Other Drugs That Cause Pulmonary Edema

A paradoxical pulmonary edema has been reported in a few patients following hydrochlorothiazide ingestion but not any other thiazide diuretic.[8,110] Acute pulmonary edema rarely has followed the injection of high concentrations of contrast medium into the pulmonary circulation during angiocardiography.[8,110] Rare occurrences of pulmonary edema have followed the intravenous administration of bleomycin, cyclophosphamide, and vinblastine.[8]

The selective β_2-adrenergic agonists terbutaline and ritodrine have been reported to induce pulmonary edema when used as tocolytics.[8,110] This disorder commonly occurs 48 to 72 hours after tocolytic therapy.[107] This has never occurred with their use in asthma patients, even in inadvertent overdosage. This reaction may result from excess fluid administration used to prevent the hypotension from β_2-mediated vasodilation or the particular hemodynamics of pregnancy. In a review of 330 patients who received tocolytic therapy and were monitored closely for their fluid status, no episode of pulmonary edema was reported.[107]

Interleukin-2, a cytokine used alone or in combination with cytotoxic drugs, has been reported to induce pulmonary edema. Although other cytokines have been associated with pulmonary edema, the problem is most significant with interleukin-2. A weight gain of 2 kg has been reported after treatment with interleukin-2.[107]

Pulmonary edema has occurred occasionally with salicylate overdoses. The serum salicylate concentrations are often greater than 45 mg/dL, and the patients have other signs of toxicity, although some cases have been associated with concentrations in the usual therapeutic range.[104,105]

Pulmonary Eosinophilia

Pulmonary infiltrates with eosinophilia (Löffler syndrome) are associated with nitrofurantoin, *para*-aminosalicylic acid, methotrexate, sulfonamides, tetracycline, chlorpropamide, phenytoin, NSAIDs, and imipramine (**Table e30-5**).[8,110,111,112] The disorder is characterized by fever, nonproductive cough, dyspnea, cyanosis, bilateral pulmonary infiltrates, and eosinophilia in the blood.[8] Lung biopsy has revealed perivasculitis with infiltration of eosinophils, macrophages, and proteinaceous edema fluid in the alveoli. The symptoms and eosinophilia generally respond rapidly to withdrawal of the offending drug.

TABLE e30-5 Drugs That Induce Pulmonary Infiltrates with Eosinophilia (Löffler Syndrome)

Drug	Relative Frequency of Reactions
Nitrofurantoin	F
para-Aminosalicylic acid	F
Amiodarone	F
Iodine	F
Captopril	F

Drug	Relative Frequency of Reactions
Bleomycin	F
L-tryptophan	F
Methotrexate	F
Phenytoin	F
Gold salts	F
Sulfonamides	I
Penicillins	I
Carbamazepine	I
Granulocyte-macrophage colony stimulating factor	I
Imipramine	I
Minocycline	I
Nilutamide	I
Propylthiouracil	I
Sulfazalazine	I
Tetracycline	R
Procarbazine	R
Cromolyn	R
Niridazole	R
Chlorpromazine	R
Naproxen	R
Sulindac	R
Ibuprofen	R
Chlorpropamide	R
Mephenesin	R

F, frequent; I, infrequent; R, rare.

Sulfonamides were first reported as causative agents in users of sulfanilamide vaginal cream.[8] *para*-Aminosalicylic acid frequently produced the syndrome in tuberculosis patients being treated with this agent.[8] There are nine reported cases associated with sulfasalazine use in inflammatory bowel disease.[111] The drug associated most frequently with this syndrome is nitrofurantoin.[8,105] Nitrofurantoin-induced lung disorders appear to be more common in postmenopausal women.[105] Lung reactions made up 43% of 921 adverse reactions to nitrofurantoin reported to the Swedish Adverse Drug Reaction Committee between 1966 and 1976.[111] No apparent correlation exists between duration of drug exposure and severity or reversibility of the reaction.[111] Most cases occur within 1 month of therapy. Typical symptoms include fever, tachypnea, dyspnea, dry cough, and, less commonly, pleuritic chest pain. Radiographic findings include bilateral interstitial infiltrates, predominant in the bases and pleural effusions 25% of the time. Although there are anecdotal

reports that steroids are beneficial, the usual rapid improvement following discontinuation of the drugs brings the usefulness of steroids into question. Complete recovery usually occurs within 15 days of withdrawal.

A few cases of pulmonary eosinophilia have been reported in asthmatics treated with cromolyn.[8,111] The significance of this is unknown in light of the occasional spontaneous occurrence of pulmonary eosinophilia in asthmatic patients. Cases of acute pneumonitis and eosinophilia have been reported to occur with phenytoin and carbamazepine therapy.[111] Patients have had other symptoms of hypersensitivity, including fever and rashes. The symptoms of dyspnea and cough subside following discontinuation of the drug.

Oxygen Toxicity

Because of the similarity to pulmonary fibrosis, oxygen-induced lung toxicity is reviewed briefly. More extensive reviews on this topic have been published.[113,114]

The earliest manifestation of oxygen toxicity is substernal pleuritic pain from tracheobronchitis.[114] The onset of toxicity follows an asymptomatic period and presents as cough, chest pain, and dyspnea. Early symptoms are usually masked in ventilator-dependent patients. The first noted physiologic change is a decrease in pulmonary compliance caused by reversible atelectasis. Then decreases in vital capacity occur, followed by progressive abnormalities in carbon monoxide diffusing capacity.[114] Decreased inspiratory flow rates, reflected in the need for high inspiratory pressures in ventilator-dependent patients, occur as the fractional concentration of inspired oxygen requirement increases. The lungs become progressively stiffer as the ability to oxygenate becomes more compromised.

The fraction of inspired oxygen and duration of exposure are both important determinants of the severity of lung damage. Normal human volunteers can tolerate 100% oxygen at sea level for 24 to 48 hours with minimal to no damage.[113] Oxygen concentrations of less than 50% are well tolerated even for extended periods. Inspired oxygen concentrations between 50% and 100% carry a substantial risk of lung damage, and the duration required is inversely proportional to the fraction of inspired oxygen.[113] Underlying disease states may alter this relationship. Lung damage may not be lasting and may improve months to years after the exposure.[115,116]

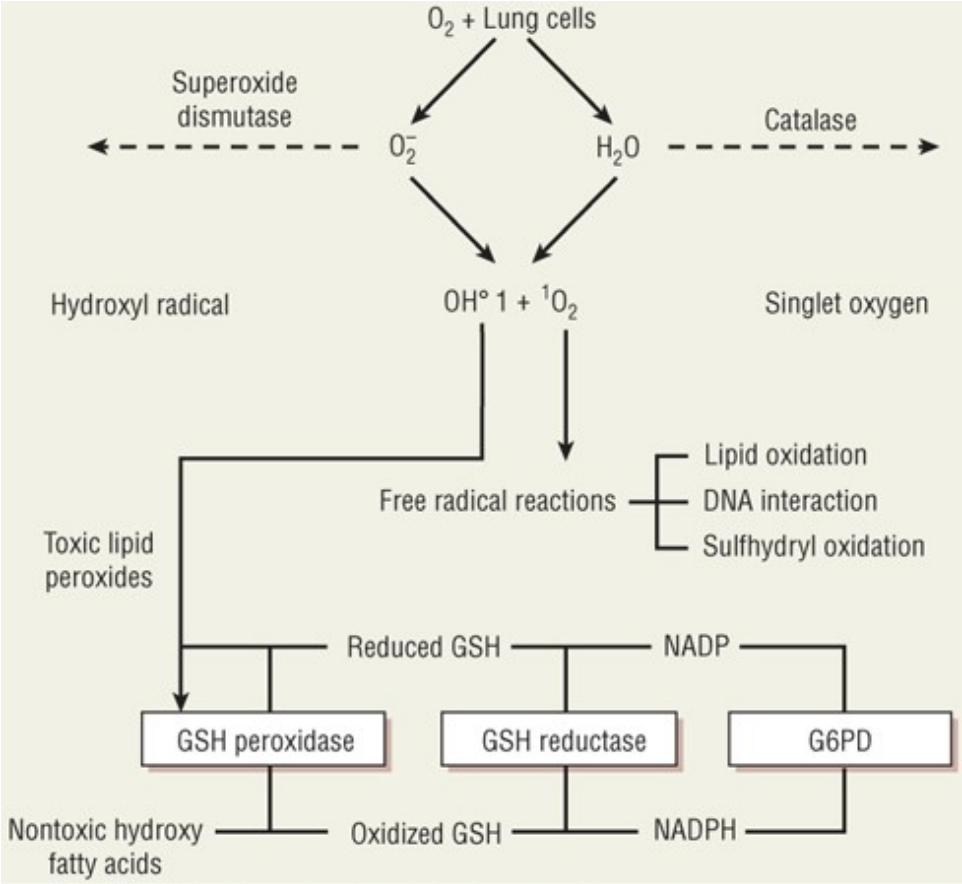
Oxygen-induced lung damage is generally separated into the acute exudative phase and the subacute or chronic proliferative phase. The acute phase consists of perivascular, peribronchiolar, interstitial, and alveolar edema with alveolar hemorrhage and necrosis of pulmonary endothelium and type I epithelial cells.[113] The proliferative phase consists of resorption of the exudates and hyperplasia of interstitial and type II alveolar lining cells. Collagen and elastin deposition in the interstitium of alveolar walls then leads to thickening of the gas-exchange area and the fibrosis.[113]

The biochemical mechanism of the tissue damage during hyperoxia is the increased production of highly reactive, partially reduced oxygen metabolites (**Fig. e30-1**).[114] These oxidants are normally produced in small quantities during cellular respiration and include the superoxide anion, hydrogen

peroxide, the hydroxyl radical, singlet oxygen, and hypochlorous acid.[114] Oxygen free radicals are normally formed in phagocytic cells to kill invading microorganisms, but they are also toxic to normal cell components. The oxidants produce toxicity through destructive redox reactions with protein sulfhydryl groups, membrane lipids, and nucleic acids.[114]

FIGURE e30-1

Schematic of the interaction of oxygen radicals and the antioxidant system. (GSH, glutathione; G6PD, glucose-6-phosphate dehydrogenase; NADP, nicotinamide-adenine dinucleotide phosphate; NADPH, reduced NADP.)



The oxidants are products of normal cellular respiration that are normally counterbalanced by an antioxidant defense system that prevents tissue destruction. The antioxidants include superoxide dismutase, catalase, glutathione peroxidase, ceruloplasmin, and α-tocopherol (vitamin E).[117] Antioxidants are ubiquitous in the body. Hyperoxia produces toxicity by overwhelming the antioxidant system. There is experimental evidence that a number of drugs and chemicals produce lung toxicity through increasing production of oxidants (eg, bleomycin, cyclophosphamide, nitrofurantoin, and paraquat) and/or by inhibiting the antioxidant system (eg, carmustine, cyclophosphamide, and nitrofurantoin).[118,119]

Pulmonary Fibrosis

A large number of drugs are associated with chronic pulmonary fibrosis with or without a preceding acute pneumonitis (**Table e30-6**). The cancer chemotherapeutic agents and hematopoietic stem cell transplantation make up the largest group and have been the subject of numerous reviews.[118,119,120] Although the mechanisms by which all the drugs produce pneumonitis and fibrosis are not known, the clinical syndrome, pulmonary function abnormalities, and histopathology present a relatively homogeneous pattern.[118] The histopathological picture closely resembles oxidant lung damage, and in some experimental cases, oxygen enhances the pulmonary injury.[105] Although the terms *pulmonary fibrosis* or *interstitial pneumonitis* have been used widely to describe pneumonia after bone marrow transplantation, in 1991, a National Institutes of Health workshop recommended that the term *idiopathic pneumonia syndrome* (IPS) should be used to avoid histopathological terms and to define the inherent heterogeneity of this disorder.[121] IPS accounts for more than 40% of deaths related to bone marrow transplantation.[85] Suggested causes of IPS include radiation or chemotherapy regimens prior to transplantation, graft-versus-host disease, unrecognized infections, and other inflammation-related lung injuries.[120,122,123] IPS is characterized by dyspnea, hypoxemia, nonproductive cough, diffuse alveolar damage, and interstitial pneumonitis in the absence of lower respiratory infection. IPS has been reported early and late, up to 24 months after bone marrow transplantation.[120,123]

TABLE e30-6 Drugs That Induce Pneumonitis and/or Fibrosis

Drug	Relative Frequency of Reactions
Oxygen	F
Radiation	F
Bleomycin	F
Busulfan	F
Carmustine	F
Hexamethonium	F
Paraquat	F
Amiodarone	F
Mecamylamine	I
Pentolinium	I
Cyclophosphamide	I
Practolol	I
Methotrexate	I
Mitomycin	I
Nitrofurantoin	I
Methysergide	I
Sirolimus	I
Azathioprine, 6-mercaptopurine	R

Drug	Relative Frequency of Reactions
Chlorambucil	R
Melphalan	R
Lomustine and semustine	R
Zinostatin	R
Procarbazine	R
Teniposide	R
Sulfasalazine	R
Phenytoin	R
Gold salts	R
Pindolol	R

The lung damage following ingestion of the contact herbicide paraquat classically resembles hyperoxic lung damage. Hyperoxia accelerates the lung damage induced by paraquat. Lung toxicity from paraquat occurs following oral administration in humans and aerosol administration and inhalation in experimental animals.[119] The pulmonary specificity of paraquat results in part from its active uptake into lung tissue. Paraquat readily accepts an electron from reduced nicotinamide-adenine dinucleotide phosphate and then is reoxidized rapidly, forming superoxide and other oxygen radicals.[119] The toxicity may be a result of nicotinamide-adenine dinucleotide phosphate depletion (see eFig. 30-1) and/or excess oxygen free radical generation with lipid peroxidation. Treatment with exogenous superoxide dismutase has had limited and conflicting results.[119]

A number of furans have been shown to produce oxidant injury to lungs.[119] Occasionally, patients with acute nitrofurantoin lung toxicity will progress to a chronic reaction leading to fibrosis, and rarely, a patient may develop chronic toxicity without an antecedent acute reaction. Like paraquat, nitrofurantoin undergoes cyclic reduction and reoxidation that may produce superoxide radicals or deplete nicotinamide-adenine dinucleotide phosphate. In addition, nitrofurantoin inhibits glutathione reductase, an enzyme involved in the glutathione antioxidant system (see Fig. e30-1). **Table e30-7** lists possible nondrug causes of pulmonary fibrosis.

TABLE e30-7 Possible Causes of Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (fibrosing alveolitis)

Pneumoconiosis (asbestosis, silicosis, coal dust, talc berylliosis)

Hypersensitivity pneumonitis (molds, bacteria, animal proteins, toluene diisocyanate, epoxy resins)

Smoking

Sarcoidosis

Tuberculosis

Lipoid pneumonia

Systemic lupus erythematosus

Rheumatoid arthritis

Systemic sclerosis

Polymyositis/dermatomyositis

Sjögren syndrome

Polyarteritis nodosa

Wegener granuloma

Byssinosis (cotton workers)

Siderosis (arc welders' lung)

Radiation

Oxygen

Chemicals (thioureas, trialkylphosphorothioates, furans)

Drugs (see Tables e30-5, e30-6 and e30-8)

Drugs Associated with Pulmonary Fibrosis

Antineoplastics

A number of cancer chemotherapeutic agents produce pulmonary fibrosis.[124] In an excellent review,[118] six predisposing factors for the development of cytotoxic drug-induced pulmonary disease were described: (a) cumulative dose, (b) increased age, (c) concurrent or previous radiotherapy, (d) oxygen therapy, (e) other cytotoxic drug therapy, and (f) preexisting pulmonary disease. Drugs that are directly toxic to the lung would be expected to show a dose–response relationship.

Dose–response relationships have been established for bleomycin, busulfan, and carmustine (BCNU).[118] Bleomycin and busulfan exhibit threshold cumulative doses below which a very small percentage of patients exhibit toxicity, but carmustine shows a more linear relationship.[113] Older patients appear to be more susceptible, possibly as a result of a decrease in the antioxidant defense system. The Childhood Cancer Survivor Study (CCSS), a retrospective cohort of over 14,000 survivors of cancer over 5 years reported a cumulative incidence of pulmonary fibrosis, chronic cough, and shortness of breath with cyclophosphamide, bleomycin, busulfan, BCNU and lomustine (CCNU). The incidence will continue to rise up to 25 years from the time of diagnosis.[125] About 1% to 10% of the patients taking bleomycin, carmustine, busulfan, or cyclophosphamide develop lung toxicity.[1]

Excessive irradiation produces a pneumonitis and fibrosis thought to be caused by oxygen free radical formation.[118,120] Evidence for synergistic toxicity with radiation exists for bleomycin, busulfan, and mitomycin. Hyperoxia has shown synergistic toxicity with bleomycin, cyclophosphamide, and mitomycin.[118] Carmustine, mitomycin, cyclophosphamide, bleomycin, and methotrexate all appear to show increased lung toxicity when they are part of multiple-drug regimens.

Nitrosoureas

BCNU is associated with the highest incidence of pulmonary toxicity (20%-30%).[118] The lung pathology generally resembles that produced by bleomycin and busulfan. Unique to BCNU is the finding of fibrosis in the absence of inflammatory infiltrates. BCNU preferentially inhibits glutathione reductase, the enzyme required to regenerate glutathione, thus reducing glutathione tissue stores.[118,119] The patients present with dyspnea, tachypnea, and nonproductive cough that may begin within a month of initiation of therapy but may not develop for as long as 3 years.[118] Most patients receiving BCNU develop fibrosis that may remain asymptomatic or become symptomatic any time up to 17 years after therapy.[126] The cumulative dose has ranged from 580 to 2,100 mg/m^2.[119] The disease is usually slowly progressive with a mortality rate from 15% to greater than 90% depending on the study and period of follow-up. In a retrospective study, the risk factors for development of IPS and prognostic factors for outcomes were evaluated in 94 patients with relapsed Hodgkin disease treated with BCNU containing high-dose chemotherapy and hematopoietic support. The risk factors for pulmonary fibrosis and mortality were female sex and dose of BCNU, with all deaths reported in those who received BCNU at doses of more than 475 mg/m^2.[127] Rapid progression and death within a few days occur in a small percentage of patients.[112] Corticosteroids do not appear to be effective in reducing damage.[118] Other nitrosoureas, lomustine, and semustine have also been reported to produce lung damage in patients receiving unusually high doses.[118]

Bleomycin

Bleomycin is the best-studied cytotoxic pulmonary toxin. Because of its lack of bone marrow suppression, pulmonary toxicity is the dose-limiting toxicity of bleomycin therapy. The incidence of bleomycin lung toxicity is approximately 4%, which may be affected by the following risk factors: bleomycin cumulative dose, age, high concentration of inspired oxygen, radiation therapy, and

multidrug regimens, particularly those with cyclophosphamide.[107] Age at the time of treatment with bleomycin may also be a risk factor; patients younger than 7 years at the time of receiving bleomycin therapy are more likely to develop pulmonary toxicity compared with older subjects.[107] The cumulative dose above which the incidence of toxicity significantly increases is 450 to 500 units.[118] However, rapidly fatal pulmonary toxicity has occurred with doses as low as 100 units.[118]

Experimentally, bleomycin generates superoxide anions, and the lung toxicity is increased by radiation and hyperoxia.[118] Pretreatment with superoxide dismutase and catalase reduces toxicity in experimental animals.[118] Bleomycin also oxidizes arachidonic acid, which may account for the marked inflammation. Bleomycin may also affect collagen deposition by its stimulation of fibroblast growth.[118] Combination of bleomycin with other cytotoxic agents, particularly regimens containing cyclophosphamide, may predispose patients to pulmonary damage.
