The automated reporting of eGFR in the clinical setting has led some practitioners to consider substituting eGFR in place of eCL_{cr} for renal dose adjustments. Others argue that use of the MDRD and CKD-EPI equations for drug dosing are not appropriate given that the pharmacokinetic studies were performed using estimated creatinine clearance via the CG equation.[74,75] Furthermore, many studies have highlighted discordance between drug dosing recommendations based on these equations.[76,77,78,79,80,81] These studies have compared dosing recommendations based on the three different equations for commonly used drugs in CKD patients. Average discordance rates for the MDRD Study and CG equations were between 20% and 30%.[76,77,78,79,80] Another study which evaluated eight antimicrobial dosing regimens based on CKD-EPI, MDRD, and CG demonstrated overall discordance rates were 15% to 25% between CG and CKD-EPI and 7% to 12% between MDRD and CKD-EPI.[81] Major limitations with these studies include, equations were not compared to gold standard such as measured GFR and the studies did not assess drug levels or clinical outcomes. Although Stevens et al described average concordance rates for the MDRD study and CG equations to measured GFR to be 88% and 85%, respectively; this was a simulation study and they did not evaluate drug levels or patient outcomes.[82]

Serum cystatin C has also been proposed as an alternative marker to estimate GFR, either alone or in combination with serum creatinine. Multiple equations have been proposed to estimate GFR from age, gender, race, and muscle mass based on cystatin C measurements (Table 42-6)[82,83,84,85,86], however, their use in drug dosing is limited to a few studies with carboplatin, topotecan, and cefuroxime.[87,88,89,90]

Therefore, none of these equations for estimating GFR should be used as the sole determinant for drug dosing decision making. Potential discrepancies in kidney function estimates and corresponding drug dosing regimens necessitate careful consideration of the risk: benefit ratio of each approach

within the context of the complete clinical picture of the patient. Since most drug dosage regimen recommendations are based on broad categorical ranges of kidney function, the impact of an eGFR of 40 mL/min/1.73 m^2 versus 50 mL/min/1.73 m^2 is likely of no clinical significance. Furthermore these estimating equations for GFR are based on a standard 1.73 m^2 body surface area (BSA); thus for an individual patient, the BSA must be determined separately so that the eGFR can be expressed in milliliters per minute (mL/min).[74] Nevertheless, regardless of the kidney function estimating equation that was used and published dosing recommendation guidelines that were consulted, clinical judgment will ultimately prevail in the determination of which regimen is best for the patient and feasible to administer given the available dosage forms.

Drug Dosing Information Resources

Prior to 1998, there were no official guidelines regarding when and how to conduct pharmacokinetic and pharmacodynamic studies of a new drug in patients with impaired kidney function. The 1998 FDA guidance on pharmacokinetic studies in patients with impaired kidney function recommended use of renal dosage adjustment categories derived from creatinine clearance (CL_{cr}).[91] This was based on the rationale that CL_{cr} was widely used in patient care settings as a measure of renal function, and thus more practical than most other alternatives as a criterion for adjusting drug dosage. Since then both the FDA and the European Medicine Agency (EMA) have issued updated guidance documents on the conduct of pharmacokinetic studies in patients with impaired kidney function.[92,93] The adoption of the 1998 FDA guidance has resulted in improved availability of pharmacokinetic and drug dosing recommendations for drugs which have high (greater than 30%) fraction of the drug eliminated renally unchanged.[7] It appears that there have been significant improvements over the past 15 years in the frequency and rigor with which pharmacokinetic studies have been conducted in the setting of kidney dysfunction.

The 2010 proposed revision to the 1998 FDA guidance recommended: (a) conducting studies for nonrenally as well as renally eliminated drugs, (b) conducting studies in patients receiving HD, (c) conducting studies to evaluate pharmacokinetics of therapeutic proteins in patients with renal insufficiency, (d) categorizing renal function based on eGFR (using the MDRD equation) or CL_{cr} (using the CG equation), and (e) modifications to how the results of renal impairment studies are presented in the official drug label.[93] Furthermore, several recent publications have offered suggestions to pharmaceutical industry and regulatory agencies regarding assessment of kidney function and which populations of patients should be included in the pharmacokinetic studies of new chemical entities during the drug development process.[94,95] These papers present population pharmacokinetics and physiologically based pharmacokinetic models that will assist in providing optimal dosing recommendations for new chemical entities in development in subjects with kidney dysfunction. Finally, the Kidney Disease: Improving Global Outcomes (KDIGO) held a conference to investigate these issues and propose recommendations for practitioners, researchers, and those involved in drug development and regulatory affairs. The conference generated 37 recommendations for clinical practice, 32 recommendations for future research, and 24 recommendations for regulatory agencies to enhance the quality of pharmacokinetic and pharmacodynamic information available to clinicians.[96]

Drug Dosing Regimens for CKD Patients

4 The initial or "loading" dose for CKD patients should be the same as the dose recommended for those with normal renal function unless the drug's V_D is known to be altered in the presence of CKD or a concomitant disease then the dose should be increased proportionally (see Table 48-1). Rapid achievement of therapeutic drug concentrations is important in many patient care situations and thus it is better to start therapy aggressively rather than conservatively. Maintenance dosage regimen guidelines for CKD patients in FDA- or EMA-approved product labeling should be the foundation for ongoing therapy.[96] However, if such information is not available or if there is marked variance between these two agencies' recommendations, the approach depicted in **Table 48-4** for designing a dosage regimen for a patient with CKD can be used. In either case, the design of the optimal dosage regimen is dependent on the availability of an accurate characterization of the relationship between the pharmacokinetic parameters of the drug and renal function and an accurate assessment of the patient's renal function.

TABLE 48-4 Stepwise Approach to Adjust Drug Dosage Regimens for Patients with Renal Insufficiency

Step 1	Obtain history and relevant demographic/clinical information	Ask/obtain patient medical history including: Prescription medication Over-the-counter medication Recreational drugs Tobacco and alcohol use History of renal disease Height Weight Measure serum creatinine and/or cystatin C
Step 2	Determine the degree of renal insufficiency	Determine eGFR or CL_{cr} for drug dosing based best available methodology Order 24-hour urine collection for measured CL_{cr} if necessary
Step 3	Review the medication list	Ensure medications are all indicated Evaluate for potential drug interactions Identify drugs which need to dosage regimen adjusted Ascertain best initial dosage regimen from FDA- or EMA-approved product labelling
Step 4	Individualize treatment regimen for identified medications	For narrow therapeutic range drugs—calculate dosage regimen based on pharmacokinetic characteristics of the drug and the patient's renal function Titrate the dose of drugs to patient effect, if applicable
Step 5	Avoid nephrotoxic drugs	Discontinue or avoid prescription of nephrotoxic medications if possible

		Monitor drug serum concentrations (if available) to guide further therapy
Step 6	Monitor	Monitor parameters of drug response and toxicity
		Monitor renal function every 3-5 days for acute therapies and monthly or quarterly for chronic medications
		Reassess the patient to evaluate drug efficacy and safety
Step 7	Reassess	Revise regimen based on drug response or change in patient condition (including renal function)

CL_{cr}, creatinine clearance; eGFR, estimated glomerular filtration rate; EMA, European Medicine Agency; FDA, Food and Drug Administration.

Most dosage adjustment guidelines have proposed the use of a fixed dose or interval for patients with broad ranges of renal function that are different from those that are the foundation of the CKD staging scheme (see Chapter 44).[9,17,28,74,97,98,99,100,101,102,103] Indeed, normal renal function has often been ascribed to anyone who has a CL_{cr} greater than 80 to 90 mL/min/1.73 m^2 (greater than 0.77-0.87 mL/s/m^2), even though the population normal CL_{cr} values range from 115 to 125 mL/min per 1.73 m^2 (greater than 1.11-1.20 mL/s/m^2) (see Chapter e42). The approved product labeling dosage adjustment recommendations and secondary references often use different ranges to represent mild, moderate, and severe renal insufficiency.[74] The predominant ranges for mild, moderate, and severe renal insufficiency can be defined as a CL_{cr} of 60 to 89 mL/min (1-1.48 mL/s), CL_{cr} of 30 to 59 mL/min (0.5-0.99 mL/s), and CL_{cr} of 10 to 29 mL/min (0.17-0.49 mL/s), respectively (**Table 48-5**). ESRD is usually defined as a CL_{cr} of less than 10 mL/min (0.17 mL/s). Each of these categories encompasses a broad range in renal function, and thus the recommended drug regimen may not be optimal for all patients whose renal function lies within the given category of renal function.

TABLE 48-5 GFR Categories Based on KDIGO Classification

GFR Category[a]	GFR (mL/min/1.73 m^2 [mL/s/m^2])	Terms
1	>90 (>0.87)	Normal or high
2	60-89 (0.58-0.86)	Mildly decreased
3a	45-59 (0.43-0.57)	Mildly to moderately decreased
3b	30-44 (0.29-0.42)	Moderately to severely decreased
4	15-29 (0.14-0.28)	Severely decreased
5	<15 (<0.14)	Kidney failure

GFR, glomerular filtration rate; KDIGO, Kidney Disease: Improving Global Outcomes.

[a]To meet criteria for CKD there must be a significant reduction in GFR (categories 3a-5) or there must also be evidence of kidney damage (categories 1 & 2) for 3 months or greater. Adapted from reference 96.

5 FDA-approved drug labels, and commonly used drug information sources such as American Hospital Formulary Service Drug Information,[97] Goodman and Gilman's the Pharmacological Basis of Therapeutics,[17,103] the British National Formulary,[98] and Drug Prescribing in Renal Failure,[99] are excellent sources of information about a drugs' pharmacokinetic characteristics. In some cases, however, they yield marked variation in recommendations and the paucity of details of the methods used to generate the dosing advice have resulted in some clinicians cautioning against their routine clinical use[104,105] (**Table 48-6**)**.** In addition, none of these sources consistently provide the explicit relationships of the kinetic parameters of interest (total body clearance [CL], elimination rate constant [k], and V_D) with a continuous index of renal function, such as eCL_{cr} or eGFR. To find this information, one may need to identify the original research study that assessed the drug's disposition or a comprehensive review article on the class of drugs of interest. This is a time-consuming process that may be difficult to carry out for each drug and patient combination in real time.

TABLE 48-6 Comparison of Secondary References Used for Drug Dosing in CKD

Resource	Pros	Cons
Aronoff's Drug Prescribing in Renal Failure[99]	• - Exclusive focus on drug dosing in renal dysfunction • - Information provided for IHD, PD, CRRT • - Tables include drug PK and dosage adjustment based on CrCl (>50, 10-50, <10 mL/min [>0.83, 0.17-0.83, <0.17 mL/s]) • - Tables for both adult and pediatric dosing provided • - Concise, easy to use • - References to primary literature provided	• - Hard copy only • - Updated every few years; information may not be most current, newer drugs may not be included • - Some dosage recommendations are not feasible for dialysis patients (ie, q 36 hours dosing interval)
The Renal Drug Handbook[100]	• - Contains information on clinical use of drugs, drug PK, dose in normal renal function, dose adjustment in CKD, drug interactions and administration • - Specific to CKD patients	• - Updated every few years information may not be most current, newer drugs may not be included • - References not provided

Resource	Pros	Cons
Lexicomp[101]	- Easy to access with a subscription - Accessible via mobile device - Easy to navigate - Concise information - Dose adjustment in CKD provided (HD and PD)	- Difficult to navigate at first - No specific focus on CKD patients - References to primary literature for dosing not provided
Micromedex[102]	- Easy to access with a subscription - Accessible via mobile device - Comprehensive, detailed information (both "in-depth" and "quick") - Dose adjustment in CKD provided (both HD and PD)	- Difficult to navigate - Can be slow - No specific focus on CKD patients - References to primary literature for dosing not provided
American Hospital Formulary Service (AHFS)[97]	- Detailed drug monographs - "Dosage in Renal and Hepatic Impairment/Special Populations" section for each drug listed - Available online with a subscription - Online version updated regularly, print version updated yearly	- Hard copy version can be difficult to navigate, cumbersome - Information on dose adjustment in CKD is minimal - No specific focus on CKD patients - References to primary literature for dosing not provided

CKD, chronic kidney disease; CrCl, creatinine clearance; CRRT, continuous renal replacement therapy; HD, hemodialysis; IHD, intermittent hemodialysis; PD, peritoneal dialysis; PK, pharmacokinetics.

Data from references [97,99,100,101,102,103,104,105].

Dr. Luzius Dettli is often credited for being the first to systematically approach the issue of drug dosing for those with impaired kidney function.[106] The "Dettli Method" is a graphic means to

generate drug dosing recommendations based on the linear relationship between the elimination rate constant of a given renally cleared drug and a patient's creatinine clearance:

$k = k_{NR} + (\alpha \times CL_{cr})$

where k is the elimination rate constant of the drug based on a first-order one compartment model, k_{NR} is the nonrenal elimination rate constant, and α is a constant relating the renal drug elimination rate constant to the patient's creatinine clearance (CL_{cr}). This approach assumes that the overall elimination rate constant (or clearance) declines linearly with CL_{cr}, and that the nonrenal elimination rate constant (or CL_{NR}) remains constant as kidney function declines. While the first assumption generally holds true for drugs that are mainly renally cleared, the second assumption is flawed, as the functional expression of many drug metabolizing enzymes and drug transporters is reduced in patients with kidney disease.[36,37]

Ideally, one should be able to identify a relationship between CL or k with an estimated GFR or CL_{cr}, such as those depicted in **Table 48-7**. This information, along with the patient's estimated CL_{cr} or GFR, is the foundation upon which one can formulate a therapeutic regimen to attain the desired drug concentration time profile and ultimately the therapeutic outcome when approved product labeling information is not available.

TABLE 48-7 Relationship Between CL_{cr} and CL of Selected Drugs

Drug	Total Body Clearance[a]
Acyclovir	CL = 3.37 (CL_{cr}) + 0.41
Amikacin	CL = 0.6 (CL_{cr}) + 9.6
Aztreonam	CL = 0.8 (CL_{cr}) + 26.6
Cefazolin	CL = 0.34 (CL_{cr}) + 6.6
Ceftazidime	CL = 1.15 (CL_{cr}) + 10.6
Ciprofloxacin	CL = 2.83 (CL_{cr}) + 363
Digoxin	CL = 0.88 (CL_{cr}) + 23
Ganciclovir	CL = 1.24 (CL_{cr}) + 8.57
Gentamicin	CL = 0.983 (CL_{cr})
Imipenem	CL = 1.42 (CL_{cr}) + 54
Lithium	CL = 0.20 (CL_{cr})
Ofloxacin	CL = 1.04 (CL_{cr}) + 38.7
Piperacillin	CL = 1.36 (CL_{cr}) + 1.50
Tobramycin	CL = 0.801 (CL_{cr})
Vancomycin	CL = 0.69 (CL_{cr}) + 3.7

CL, total body clearance; CL_{cr}, creatinine clearance.

[a]Clearance in mL/min can be converted to mL/s through multiplication by 0.0167.

If specific literature recommendations and/or the relationship of kinetic parameters to estimated GFR or CL_{cr} are not available, then one can estimate the CL or *k* of the CKD patient with the method of Rowland and Tozer,[8] provided the fraction of the drug that is eliminated renally unchanged (f_e) in subjects with normal renal function is known.[107] This approach assumes that the change in CL and *k* are proportional to ${}_eCL_{cr}$, that the renal disease does not alter the drug's metabolism, that the metabolites, if formed, are inactive and nontoxic, that the drug obeys first-order (linear) kinetic principles, and that it is adequately described by a one-compartment model. If these assumptions are true, which is rarely the case, then the kinetic parameter/dosage-adjustment factor (*Q*) can be calculated as:

$$Q = 1 - [f_e\ (1 - KF)]$$

where KF is the ratio of the patient's eCL_{cr} or eGFR to the assumed normal value of 120 mL/min (equivalent to 2 mL/s). Thus for a drug that is 85% eliminated renally unchanged in a patient who has an eCL_{cr} of 10 mL/min (0.17 mL/s), the *Q* factor would be:

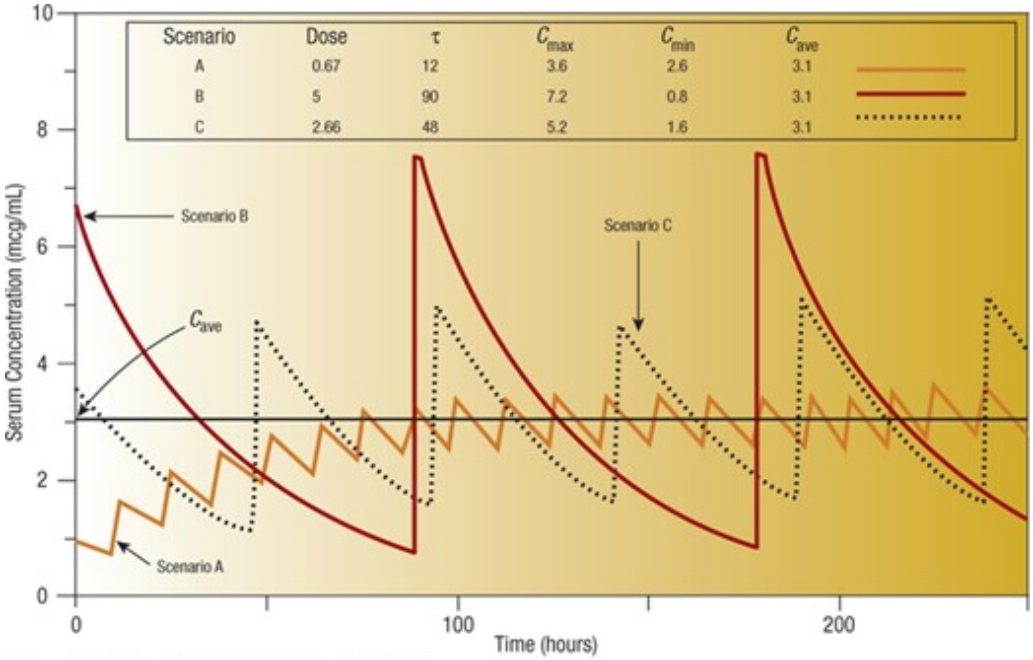
$$\begin{aligned} Q &= 1 - [0.85[1 - (10/120)]] \\ &= 1 - [0.85(0.85(0.92)] \\ &= 1 - 0.78 \\ &= 0.22 \end{aligned}$$

The best method for dosage regimen adjustment must then be selected. Specifically, one must determine whether the desired goal is the maintenance of a similar peak, trough, or average steady-state drug concentration or if there is a clearly defined pharmacodynamic endpoint such as the time above the MIC (eg, cephalosporins) or the ratio of the AUC relative to the MIC (eg, fluoroquinolones).[108] If there is a significant relationship between peak concentration and clinical response (eg, aminoglycosides)[109] or toxicity[107] (eg, phenobarbital and phenytoin), then attainment of the specific target values is critical. If, however, no specific target values for peak or trough concentrations have been reported (eg, antihypertensive agents and benzodiazepines), then a regimen goal of attaining the same average steady-state concentration is likely to be appropriate.

The principal choices to attain the desired average steady-state concentration profile are to decrease the dose or prolong the dosing interval. If the size of the dose is reduced while the dosing interval remains unchanged, the desired average steady-state concentration will be similar; however, the peak will be lower and the trough higher (**Fig. 48-1**). Alternatively, if the dosing interval is increased and the dose size remains unchanged, the peak and trough concentrations in the patient with reduced renal function will be similar to those in the patient with normal renal function. This dosage adjustment method is often recommended because it is likely to yield cost savings as a result of a reduction in nursing and pharmacy time, as well as a reduction in the supplies associated with frequent drug administration. Finally, the dose and dosing interval may both need to be changed to allow the administration of a clinically feasible dose (500 mg vs a calculated value of 487 mg) or a practical dosing interval, for example, 12 hours instead of 17 hours.

FIGURE 48-1

Although the average steady-state concentrations (C_{ave}) are identical regardless of which dosage-adjustment strategy one decides to implement, the concentration–time profile will be markedly different if one changes the dose and maintains the dosing interval (τ) constant (*Scenario A*), versus changing the dosing interval and maintaining the dose constant (*Scenario B*) or changing both (*Scenario C*).



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

If the relationship between the pharmacokinetic parameters of the drug and renal function are known, the first step in the process is to estimate the drug disposition parameters in the patient with renal insufficiency. The dosage-adjustment factor (*Q*) calculated as the ratio of the estimated *k* or CL of the patient relative to subjects with normal renal function is then used to determine the dose or dosing interval alterations necessary for the patient.

First, the relationship between drug clearance and CL_{cr} (expressed in conventional units of mL/min) is required; these relationship equations have been reported for several drugs (Table 48-7). How one can apply the relationship between a patient's renal function and pharmacokinetic characteristics of ciprofloxacin, a commonly used antibiotic for the treatment of infections in CKD and dialysis patients to develop and individualized dosage recommendation are illustrated in **Table 48-8** and briefly highlighted here. The first step is to calculate the CL of ciprofloxacin for a subject with normal renal function (CL_{norm}) and CL for the patient with CKD (CL_{CKD}) to obtain the ratio of the predicted clearance values (*Q*) which can be used to calculate the new dosing regimen.

TABLE 48-8 Stepwise Approach to Calculating a Dosage Regimen Based on Drug's Pharmacokinetic Characteristics and Patient's Renal Function

Steps	Calculation Examples with Ciprofloxacin

	Steps	Calculation Examples with Ciprofloxacin
		$CL_{norm} = [2.83 (CL_{cr})] + 363$
Step 1	Calculate total body clearance of drug in a subject with normal renal function (CL_{norm}); CL_{cr} = 120 mL/min	$CL_{norm} = [2.83(120)] + 363$ CL_{norm} = 702.6 mL/min per 1.73 m^2 In patient with CL_{cr} = 15 mL/min
Step 2	Calculate total body clearance of drug in a subject with renal insufficiency (CL_{fail})	$CL_{fail} = [2.83(CL_{cr})] + 363$ $CL_{fail} = [2.83(15)] + 363$ CL_{fail} = 405.5 mL/min per 1.73 m^2
Step 3	Calculate the quotient (Q) for a subject with renal insufficiency	$Q = CL_{fail}/CL_{norm}$ $Q = 702.6/405.5$ $Q = 0.58$
Step 4	Calculate the maintenance dose (D_f) or adjusted dosing interval (τ_f) in a subject with renal insufficiency; D_n = normal dose; τ_n = normal dosing interval	D_n = 500 mg; τ_n = 12 h $D_f = D_n \times Q$ D_f = 500 mg × 0.58 D_f = 290 mg $\tau_f = \tau_n/Q$ $\tau_f = 12/0.58$ τ_f = 20.7 h
Step 5	Choose dosing adjustment: 1. Maintain D_n and use τ_f 2. Maintain τ_n and use D_f	Dosing adjustments: 1. 500 mg every 21 h 2. 290 mg every 12 h
Step 6	Calculate D_f based on practical dosing interval (τ_p), which is selected	D_n = 500 mg; τ_f = 21 h; τ = 24 h (selected to limit missed doses) $D_f = (D_n \times Q \times \tau_p)/\tau_n$

	Steps	Calculation Examples with Ciprofloxacin
		D_f = (500 mg × 0.58 × 24)/12
		D_f = 580 mg
Step 7	Recommend dosing regimen (dependent on product availability and limited risk of missed doses)	500 mg every 24 h

CL_{cr}, creatinine clearance.

Creatinine clearance in mL/min can be converted to mL/s through multiplication by 0.0167. Clearance in mL/min per 1.73 m^2 can be converted to mL/s/m^2 through multiplication by 0.00963.

It is also important to consider other characteristics of antibiotics, such as the most relevant MICs and concentrations associated with toxicities and adverse events, before modifying a dosage regimen.[110] Ciprofloxacin, a concentration-dependent antibiotic has an associated concentration-dependent post antibiotic effect, in which bactericidal action continues for a period of time after the antibiotic concentration falls below the MIC. The peak concentration and AUC determine efficacy of these antibiotics. Therefore extending the interval but keeping the same dose allows for this pharmacodynamic action. Furthermore, extending the interval without increasing the dose will achieve high concentrations of ciprofloxacin without an accumulation of drug that could cause dose-dependent toxicities such as seizures.[110]

If the V_D of a drug is significantly altered in CKD patients or if one desires to attain a specific maximum or minimum concentration, the estimation of a dosage regimen becomes more complex. If the relationship between V_D and CL_{cr} has been characterized, then V_D may be estimated. If one assumes that a one-compartment linear model can describe the drug, the predicted V_D may then be used with the predicted k of the drug to yield an adjusted-dosing interval and IV dose.

For orally administered drugs, the τ_f can be calculated and the dose can be approximated from the following equations as:

$$\tau_f = [(-1/k_f)[\ln(C_{min}/C_{max})]] + t_{peak}$$

$$\text{Dose } p_o = [F\, C^t_p\, V_D\, (ka - k)] \,/\, [ka\, (e^{-kt}/1 - e^{-k\tau})(e^{-kat}/1 - e^{-ka\tau})]$$

where F equals bioavailability, C^t_p equals the desired plasma concentration at time t, and k_a is the absorption rate constant. Although, this approach allows for the individualization of an oral dosage regimen for attainment of specific peak and trough serum concentrations it is rarely used in clinical practice. This is in part due to the paucity of data on the absorption rate constant of individual drug formulations. Thus many assume that the drug is absorbed extremely rapidly, in which case one can approximate the τ_f and the dose using equations originally proposed for IV dosing as:

$$\tau_f = (-1/k_f)[\ln (C_{min}/C_{max})]$$

$$\text{Dose } p_o = V_D \times (C_{max} - C_{min})$$

These principles have been used by several investigators to derive dosage recommendations for many commonly used drugs for CKD patients (**Tables 48-9** and **48-10**).[99,100,101,102,111,112,113,114]

TABLE 48-9 Drug Dosing Guidelines for Nonantibiotics Commonly Used by CKD Patients

Drug	Regimen for Normal Renal Function	Glomerular Filtration Rate (mL/min)[a]			
		30-50	10-30	<10	IHD Dosing
Amlodipine	5 mg daily	No Adjustment Necessary			
Apixaban	Indication dependent; 2.5-10 mg BID	50-25 mL/min: 100%	<25 mL/min: Not Recommended	Not Recommended	5 mg BID 2.5 mg BID if age >79 years or body weight <61 kg[3]
Aripiprazole	2-5 mg daily	No Adjustment Necessary			
Atenolol	50-100 mg daily	100%	50 mg q 24 h	25 mg q 24 h	25-50 mg three times weekly
Atorvastatin	10 mg daily	No Adjustment Necessary

Rivaroxaban	Treatment dependent; 10-20 mg daily	15-50 mL/min: 15 mg daily <15 mL/min: Avoid		Avoid	Avoid
Rosuvastatin	5-40 mg daily	100%	5–10 mg daily[d]	5-10 mg daily[d]	5-10 mg daily[d]
Simvastatin	10-40 mg daily	100%	100%	5 mg q 24 h	5 mg q 24
Sitagliptin	100 mg daily	50%	25%	25%	25%
Spironolactone	50-100 mg/daily	Usual dose, q 12-24 h	Usual dose, q 12-24 h	Not Recommended	Not Recommended
Venlafaxine	75 mg daily	25%-50%	25%-50%	25%-50%	50%
Zopiclone	5-7.5 mg daily	3.75-5 mg daily	3.75-5 mg daily	3.75-5 mg daily	3.75-5 mg daily

IHD, intermittent hemodialysis; LD, loading dose; MD, maintenance dosing.

% = percentage of usual dose.

[a]The range following glomerular filtration rate (GFR) indicates the use of the dose that corresponds to that range of GFR in patients not on dialysis. GFR in mL/min can be converted to mL/s through multiplication by 0.0167.

[b]Caution should be used when initiating or escalating dose.

[c]Should not be used with CL_{cr} <30 mL/min (<0.5 mL/s), but are effective with loop diuretics.

[d]Initial dose should be 5 mg daily and titrate as needed to a maximum dose of 10 mg daily.

Voriconazole[h]	Weight <40 kg: 100 mg PO q 12 h Weight >40	100%	100%	100%	100%

Drug	Regimen for Normal Renal Function	Glomerular Filtration Rate (mL/min)[a]			
		30-50	10-30	<10	IHD Dosing
	kg: 200 mg PO q 12 h				

IND, individualize based on concentration monitoring; IHD, intermittent hemodialysis; LD, loading dose; MD, maintenance dosing; MU, million units; NC, no change.

[a]The range following glomerular filtration rate (GFR) indicates the use of the dose that corresponds to that range of GFR in patients not on dialysis. GFR in mL/min can be converted to mL/s through multiplication by 0.0167.

[b]Extended release and 875 mg tablets are not recommended.

[c]For infection caused by *Pseudomonas aeruginosa*, should be dosed 500 mg IV q 12 h on day 1, then 500 mg IV q 24 h.

[d]First dosage modification should be made at a GFR of ≤40 mL/min (≤0.67 mL/s). Second dosage modification should be made at a GFR of <20 mL/min (<0.33 mL/s).

[e]Dosing in critically ill patients should be individualized based on pharmacokinetic monitoring.

[f]Dosed based on trimethoprim component.

[g]A vancomycin loading dose of 25-30 mg/kg (based on actual body weight) should be considered for all patients. In patients with a GFR ≤ 30 mL/min (≤0.5 mL/s), subsequent doses of 15 to 20 mg/kg should be given when the serum concentration falls below 10 mg/L or 20 mg/L (6.9 or 14 µmol/L) (depending on the site of infection and MIC of organism).

[h]Intravenous formulation of voriconazole not recommended, as the vehicle it is prepared in can be nephrotoxic.

Data from references 9,97,99,100,101,102,107,108,114,120,121,122,123.

It should be noted, however, that in most dosing guidelines, the "usual" dose or dose for "normal renal function" represents eGFR greater than 50 mL/min/1.73 m^2. This assumption, however, could lead to dosing errors for patients with eGFRs of 60 mL/min/1.73 m^2 versus 90 mL/min/1.73 m^2 versus 130 mL/min/1.73 m^2. In fact, augmented renal clearance (ARC) defined as CL_{cr} greater than 130 mL/min/1.73 m^2 has been associated with subtherapeutic antibiotic concentrations and patient outcomes when standard doses of antibiotics were administered.[115,116,117] Although more research has been performed in the past 10 years in the critically ill, clinicians need to be aware of the potential to under dose these patients because of their augmented renal function and thus need to consider the use of higher doses especially for antibiotics and antivirals.

DRUG DOSAGE REGIMEN DESIGN FOR PATIENTS RECEIVING RENAL REPLACEMENT THERAPY

Continuous renal replacement therapies are used for the management of fluid overload and the removal of uremic toxins in patients with AKI and other conditions. Several forms of continuous renal replacement therapy in clinical use today are extensively described in Chapter 43 and several dosage regimen individualization approaches are also presented in that chapter. Which of these therapies will be optimal for a given patient is dependent on several factors, including bleeding risk, degree of hypercatabolism, acid–base balance, and experience of the healthcare provider team. The rationale and approaches for delivery of renal replacement therapy for those with ESRD are described in Chapter 45.

This next section will describe drug dosing regimens for patients on peritoneal dialysis and HD, including short-daily hemodialysis (SDHD) and nocturnal hemodialysis (NHD).

Peritoneal Dialysis

Peritoneal dialysis, like other dialysis modalities, has the potential to affect drug disposition; however, drug therapy individualization is often less complicated in these patients as a result of the limited drug clearances achieved with the variants of this procedure (see Chapter 45). In general, HD is more effective in removing drugs than peritoneal dialysis such that if a drug is not removed by HD, it is unlikely to be significantly removed by peritoneal dialysis. Many of the factors that are important in determining drug dialyzability for other treatment modalities pertain to peritoneal dialysis as well.[118,119] Factors that influence drug dialyzability by peritoneal dialysis include drug-specific characteristics such as molecular weight, solubility, degree of ionization, protein binding, and V_D. The intrinsic properties of the peritoneal membrane that affect drug removal include blood flow and peritoneal membrane surface area, which is approximately equal to the body surface area. There is an inverse relationship between peritoneal drug clearance and molecular weight, protein binding, and V_D. In addition, drug compounds that are ionized at physiologic pH will diffuse across the membrane more slowly than unionized compounds. Detailed reviews of the disposition of several drugs in chronic peritoneal dialysis patients are reported elsewhere.[120,121] Anti-infective agents are the most commonly studied drugs because of their primary role in the treatment of peritonitis.[120,122] The treatment priorities for peritoneal dialysis peritonitis and the recommended drug regimens are presented in detail in Chapter 45.

Peritoneal dialysis, in current practice, is often prescribed to attain a urea clearance of approximately 10 mL/min (0.17 mL/s), so it is unlikely to significantly impact the CL of any drug.[96] In addition, since most medications have a larger molecular size than urea, their resultant CL will likely be even lower: probably between 5 and 7.5 mL/min (0.08-0.13 mL/s). Therefore, drug dosing recommendations for the management of conditions other than peritonitis, reported for patients with estimated CL_{cr} or GFR of 10 to 15 mL/min (0.17-0.25 mL/s), are likely suitable for patients receiving peritoneal dialysis.[99]

Hemodialysis

Although many hemodialyzers have been introduced in the past 20 years and more than 100 different ones were available in North America in 2015, the effect of HD on drug disposition is rarely reevaluated after it is initially reported. Thus, most of the literature, especially for older medications, probably represents an underestimation of the impact of HD on a drug's disposition.[123]

6 The impact of HD on a patient's drug therapy is dependent on several factors, including the physicochemical characteristics of the drug, the dialysis conditions, and the clinical situation for which dialysis is performed. Drug-related factors that affect dialyzability include the molecular weight or size, degree of protein binding, and V_D.[6] The vast majority of dialysis filters in use in North America up until the mid-1990s were composed of cellulose, cellulose acetate, or regenerated cellulose (cuprophane), and they were generally impermeable to drugs with a molecular weight greater than 1,000 Da.[123] Dialysis membranes in the 21st century are predominantly composed of semisynthetic or synthetic materials (eg, polysulfone, polymethylmethacrylate, or polyacrylonitrile). These high-flux dialysis membranes have larger pore sizes and more closely mimic the filtration characteristics of the human kidney. This allows the passage of most solutes, including drugs (eg, vancomycin) that have a molecular weight of 20,000 Da or less.[123,124] Therefore drugs such as vancomycin (1,450 Da) will be more easily removed with high flux dialyzers. An increase in removal has also been reported with several other drugs that have lower molecular weights such as ceftzadine.[123] Some drugs that are cleared in high-flux dialysis but not through conventional dialysis include: carbamazepine, cisplatin, enoxaparin, ranitidine, valproic acid, sorafenib, and tramadol.[96] Therefore, it is likely that many dosing recommendations for HD patients made prior to this change underestimate the impact of HD on drug removal. If this is the case some have suggested that the dosage of many of these older drugs may need to be increased by as much as 25% to 50% due to enhanced dialytic clearance.[96] Therefore therapeutic drug monitoring for drugs such as aminoglycosides and vancomycin should be performed to ensure adequate dosing for patients on HD.

Drugs that are small but highly protein bound (ie, greater than 90%) are not well dialyzed because both of the principal binding proteins, α_1-acid glycoprotein and albumin, have a very high molecular weight. For example, the molecular weight of albumin is 60,000 Da; thus a drug such as apixaban which is 90% bound to plasma proteins would not be removed by HD. Finally, those drugs that are widely distributed, with V_D greater than 2 L/kg such as ciprofloxacin, are poorly removed by HD.

The HD procedure, be it acute for the management of AKI, intermittent three times a week or daily for an extended period or some combination thereof for the management of category G5 CKD patients can dramatically affect the total body clearance of a medication.[123] The primary factors that vary between patients are the composition of the dialysis filter, the filter surface area, the blood, dialysate and ultrafiltration flow rates, and whether or not the dialysis unit reuses the dialysis filter.

Overall, the impact of HD on drug therapy is highly variable and thus one cannot assume that a certain percentage of a drug is removed with each dialysis session; neither should a "yes" or "no" answer regarding the dialyzability of a drug be considered sufficient information to make therapeutic

decisions, since this provides no quantification of the impact of HD. Characteristics of the dialysis procedure that was utilized in the drug study, such as membrane composition and surface area and blood and dialysis flow rates, are thus critical data that should be known before one uses the published HD clearance data to prospectively design a drug dosing regimen for a HD patient.

If drug concentrations can be measured in the clinical setting the quantitative impact of HD on drug disposition can be calculated in one of several ways.[6] The most commonly utilized means for assessing the effect of HD is to calculate the dialyzer clearance (CL_D) of the drug. The CL^p_D from blood can be calculated as $CL^p_D = Q_p\,[(A_p - V_p)/A_p]$, where Q_b is the blood flow through the dialyzer and Q_p is the plasma flow, which equals Q_b (1 – hematocrit) and, A_p is the plasma concentration of drug entering the dialyzer, and V_p is the plasma concentration of the drug leaving the dialyzer. This clearance calculation most accurately reflects dialysis drug clearance as most drugs do not significantly penetrate red blood cells or bind to formed blood elements. However, for drugs that readily partition into and out of erythrocytes, this equation would likely underestimate HD clearance. Furthermore, one must keep in mind that venous plasma concentrations may be artificially high and CL^p_D will be low if plasma water is removed from the blood at a faster rate than the drug. This tends to occur when extensive ultrafiltration is performed simultaneously with diffusion during dialysis.[96]

The following principles may be used to generate a drug dosage regimen recommendation for HD patients, if none is available in FDA or EMA product labeling, by using a value of CL_D that is reported in the literature.[6,17,123] Because clearance terms are additive, the total clearance during dialysis can be calculated as the sum of the patient's residual renal and nonrenal clearance during the interdialytic period (CL_{RES}) and dialyzer clearance (CL_D):

$$CL_T = CL_{RES} + CL_D$$

The half-life during the period between dialysis treatments and during dialysis can then be calculated from the following relationships using an estimate of the drug's V_D, which can be obtained from the literature:[6,107]

$$t_{1/2,\text{off HD}} = 0.693(V_D/CL_{RES})$$

$$t_{1/2,\text{on HD}} = 0.693(V_D/CL_{RES} + CL_D)$$

Once the key pharmacokinetic parameters have been estimated/calculated, they may be used to simulate the plasma concentration–time profile of the drug for the individual patient and then one can ascertain how much drug to administer and when. This approach to drug therapy individualization can be accomplished in a stepwise fashion assuming first-order elimination of the drug and a one-compartment model.

CLINICAL CASE EXAMPLE Dosage Regimen Calculation for a Hemodialysis patient

A 54-year-old critically ill woman with ESRD was transferred to a medical intensive care unit from the general medical unit, where she was febrile with a temperature of 39°C (102.2°F). Her weight was 64 kg (141 lb) and her height was 65 in (165 cm). She had a residual CL_{cr} of 5 mL/min (0.083 mL/s), and

was receiving high-flux dialysis (F80 polysulfone dialyzer) for 4 hours on Mondays, Wednesdays, and Fridays. She was started on vancomycin for a methicillin-resistant *Staphylococcus aureus* (MRSA) catheter-associated bacteremia and her first dose of 1,000 mg was administered at the end of her HD treatment. The first step is to estimate this patient's pharmacokinetic parameters of vancomycin on the basis of published population data.[125] The V_D in this patient can be estimated to be 54.4 L (0.85 L/kg × 64 kg), and her residual total body clearance (CL_{RES}) estimated from the relationship between CL and CL_{cr} [CL_{RES} = (0.69 × CL_{cr}) +3.7] is 7.15 mL/min (0.12 mL/s) or 0.43 L/h. The *k* can be approximated as:

$$k = CL_{RES}/V_D$$
$$= 0.43\ L/h/54.4\ L$$
$$= 0.0079\ h^{-1}$$

The HD clearance of vancomycin (CL_D) is dependent on the dialyzer and a value of 120 mL/min (2 mL/s; 7.2 L/h) is a reasonable estimate for this dialyzer.[125,126]

One now can predict what the plasma concentrations of vancomycin will be over the next 24 to 48 hours, assuming the infusion time for the drug (*t*′) was 1 hour. The concentration at the end of the 1-hour infusion (C_{max}) would be:

$$C_{max} = \frac{(Dose/t')(1-e^{-kt'})}{CL_{RES}}$$
$$= \frac{(1{,}000\ mg/h)(1-e^{-(0.0079)1})}{0.43\ L/h}$$
$$= (2{,}325.58\ mg/L)(0.0078)$$
$$= 18.1\ mg/L$$

The plasma concentration prior to the next dialysis session (C_{bD}), which is 44 hours away can be calculated as:

$$C_{bD} = C_{max} \times e{-}(CL_{RES}/V_D) \times t$$
$$= 18.1 \times e{-}0.0079 \times 44$$
$$= 12.8\ mg/L$$

and the concentration 4 hours later after dialysis (C_{aD}) can be calculated as:

$$C_{aD} = C_{bD} \times e^{-[(CL_{RES}+CL_D)/V_D]\times t}$$
$$= 12.8 \times e^{-[(0.43+7.2)/54.4]\times 4}$$
$$= 12.8 \times e^{-0.14\times 4}$$
$$= 7.3\ mg/L$$

On the basis of these data, the second dose which should be administered after the second dialysis session should be increased as one generally desires to maintain vancomycin trough concentrations

between 15 and 20 mg/L (10-14 µmol/L) for a MRSA catheter-associated bacteremia.[111,127] The patient received a vancomycin dose of 1,500 mg 4 hours after the end of the second dialysis session. The increase in serum concentration at the end of this 1-hour infusion (C_{change}) can thus be estimated:

$$C_{change} = \frac{(Dose/t')(1-e^{-kt'})}{CL_{RES}}$$
$$= \frac{(1{,}500\ mg/h)\left(1-e^{-(0.0079)1}\right)}{0.43\ L/h}$$
$$= (3{,}488.4\ mg/L)(0.0078) = 27.2\ mg/L$$

Thus the C_{max} would be approximately 34 mg/L (24 µmol/L), the sum of the residual concentration from the first dose of approximately 7 mg/L (5 µmol/L) and the C_{change}. The plasma concentration prior to the third dialysis session (C_{bD}), which is 40 hours away can be estimated as:

$$C_{bD} = C_{max} \times e^{-(CL_{RES}/V_D)\times t}$$
$$= 34\ mg/L \times e^{-0.0079 \times 40}$$
$$= 24.8\ mg/L$$

and the concentration 4 hours later after the third dialysis (C_{aD}) can be estimated as:

$$C_{aD} = C_{bD} \times e^{-[(CL_{RES}+CL_D)/V_D]\times t}$$
$$= 24.8 \times e^{-[(0.43+7.2)/54.4]\times 4}$$
$$= 24.8 \times e^{-0.14\times 4}$$
$$= 14.2\ mg/L$$

This higher dose would be considered by many to have achieved too high of concentrations since the lowest value during the majority of the dosing interval exceeded 24.8 mg/L (17.1 µmol/L).

For medications with a narrow therapeutic index (eg, vancomycin, phenytoin, and gentamicin), therapeutic drug monitoring (eg, plasma concentration measurements and dialyzer clearance estimation) should be utilized to guide drug dosing.[6] The ultimate reason for measuring the plasma concentrations of antibacterial agents is to individualize the patient's dosage regimen to achieve a bacteriologic cure while preventing adverse effects and preserving residual renal function. Thus there remains one important step in the case above: the calculation of the dose the patient should receive after the second dialysis session. Vancomycin dosing is primarily based on attaining desired trough concentrations, usually between 15 and 20 mg/L (10-14 µmol/L). Peak concentrations are rarely used and not recommended to derive dosing recommendations and adjustments; however, for this patient example, a desired peak concentration of 30 mg/L (21 µmol/L), the midpoint of the recommended range of 20 to 40 mg/L (14-28 µmol/L) could be utilized to calculate a dose.[111]

Assuming the desired peak concentration of 30 mg/L (21 µmol/L) and trough concentration was 15 mg/L (10 µmol/L), the postdialysis dose this patient would need can then be calculated using the simplified approach below, because the $t_{1/2}$ is extremely prolonged relative to the infusion time, and

thus minimal drug is eliminated during the post HD infusion period:

$$\text{Dose} = V_D \times (C_{max} - C_{min})$$
$$= 40\ \text{L} \times (30 - 15)$$
$$= 600\ \text{mg}$$

7 It is common practice in most HD units to administer drugs after the patient has received dialysis on the premise that it is desirable to minimize the loss of drug that would result from the additional clearance during HD. Certainly, administration of antihypertensive agents and vasoactive drugs should be avoided in the hours prior to a HD session to minimize the likelihood of hypotension. In some cases, medications for pain are given on a precise schedule and thus the medication would be given to the patient irrespective of the time on dialysis. The administration of traditional doses of tobramycin (1.5 mg/kg) or vancomycin (1,000 mg) during dialysis has been associated with markedly lower AUCs than those observed when the same dose was administered postdialysis; consequently, higher dosage regimens are usually necessary to compensate for the additional loss of drug during the dialysis procedure. Furthermore, emerging pharmacokinetic and pharmacodynamic considerations suggest that it may be optimal approach to administer some drugs, such as aminoglycosides[128,129] and vancomycin during or immediately prior to the start of a dialysis treatment.[130,131] Two evaluations of predialysis and one of intradialytic dosing of aminoglycosides indicate that similar peak concentrations, a prime indicator of efficacy, can be obtained in these scenarios relative to those observed with postdialysis dosing.[128] The AUC during the dosing interval and the subsequent predialysis concentrations were noted to be significantly reduced and thus the risk of ototoxicity and further renal injury may be minimized. The best dosing schedule, a dose roughly twice that traditionally employed for postdialysis administration, in the 26 patients evaluated by Teigen et al, resulted in the achievement of the desired peak and AUC in approximately 90% of patients.[128]

Performing HD immediately after dosing might also be a good option for several anticancer drugs. The predialysis administration of a normal dose makes sense when the patient undergoes HD 2 to 12 hours later. This strategy delivers the desired maximum plasma concentration effect while minimizing patient exposure to the toxic drug or metabolite effects.[132,133,134,135]

Alternative Hemodialysis Modalities

Short-daily and nocturnal HD are two alternative HD techniques. Both modalities are administered 6 to 7 days a week but differ primarily in the duration of the treatment and blood-flow rate. SDHD is typically for 2 hours per session; nocturnal HD occurs overnight for 6 to 8 hours but at lower blood and dialysate flow rates.[136]

Nocturnal Hemodialysis

NHD use is increasing since there is increased evidence of benefits over conventional thrice-weekly HD[137,138,139] (Chapter 45). NHD has demonstrated improvements in hypertension, left ventricular

hypertrophy, quality of life related to burden and effects of kidney disease, and malnutrition compared to conventional HD.[137,138] In addition, North American studies suggest that survival is significantly better in NHD than conventional HD and possibly similar to survival after kidney transplantation.[140,141]

NHD is performed over 5 to 8 hours on 3 to 7 nights per week thus receive between 24 and 45 hours of dialysis per week, versus 12 hours with conventional HD.[136] The longer dialysis duration removes a higher quantity of solute and fluid, more closely mimicking the human physiological state when compared with conventional HD.[136] There is a paucity of data when it comes to drug dosing with this modality; however, the principles of drug dosing discussed above with intermittent HD can also be applied here. Although there is an increase in dialysis hours, which would suggest an increase in drug removal, the blood and dialysate flow rates are slower and thus drug clearance per unit of time will be less. This has been shown in a study with cefazolin where the cefazolin clearance during NHD was slightly lower (CL = 1.65 L/h) than during high-flux intermittent HD (CL = 1.85 L/h);[141] however, a greater percentage of cefazolin was removed in 8 hours of NHD (80%) than conventional 4-hour high-flux HD (60%). The investigators concluded that a dosing regimen of a 2-g loading dose followed by 1g IV after each NHD was sufficient to achieve concentrations 6 × MIC for *Staphylococcus* species for at least 70% of the dosing interval.[141]

Short-Daily Hemodialysis

SDHD involves 2 hours of dialysis, 6 days of the week, and has been associated with improved control of blood pressure and phosphorus, decreased medication requirements, decrease in left ventricular mass, and improved quality of life.[142,143] It has also shown a trend toward prolonged survival because of these improvements in clinical outcomes. As in the case with NHD, there is also limited data on drug dosing with this modality; however, the general principles of drug dosing for HD also apply here. In SDHD, the number of dialysis sessions per week and blood and dialysate flow rates are similar to intermittent HD, which may suggest similar drug removal. However, for certain medications (smaller size and decreased V_D, and protein binding) drug removal may be increased.

This has been shown in a study with cefazolin where the cefazolin clearance rate in SDHD was slightly higher than the value observed during high-flux intermittent HD; in fact the amount of cefazolin removed in 2 hours of SDHD was similar to that after 4 hours of high-flux HD.[144] The investigators concluded that a dosing regimen of 1 g after each SDHD was sufficient to achieve concentrations 8 × MIC for *Staphylococcus* species for at least 90% of the dosing interval.[144] Therefore, it appears that the same amount of medication given over the entire week for patients on intermittent HD could also be given to patients on SDHD but in smaller amounts administered more frequently. For instance, in intermittent HD, the cefazolin dose is typically 2 g IV after each HD for a total of 6 g per week; whereas in SDHD, the dose would be 1 g IV daily (ie, for 6 days) after each HD.

Overall small solute removal is more efficient if the frequency of HD is increased. Therefore, SDHD and NHD therapies yield different clearance values compared to intermittent three times per week HD. Furthermore, prolonged HD such as in the case of NHD, results in less rebound of drug concentrations after the termination of dialysis. This likely occurs because the rate of transfer from

the peripheral to central compartment relative to the rate of diffusive removal is lower. Therefore, careful monitoring of drug therapy is necessary when these newer modalities are used to avoid potential errors in designing drug dosing regimens.

CONCLUSION

Subtherapeutic responses to drugs in patients with renal insufficiency are often misinterpreted and not recognized. The adverse outcomes associated with inappropriate drug dosing have rarely been quantified but warrant future investigations. The utilization of FDA or EMA drug dosage recommendations in official prescribing information should be used for the initiation of therapy in most clinical situations. However, critically ill individuals especially those with preexisting CKD likely have marked pharmacokinetic variability and may require the use of pharmacokinetic principles in conjunction with reliable population pharmacokinetic estimates to determine the optimal drug dosage regimen design. Individualization of all drugs with a narrow therapeutic index for AKI and CKD patients should be undertaken whenever clinical therapeutic monitoring tools are available. The key action step is to use the knowledge we have to improve patient outcomes. The lack of dosage adjustment for CKD patients in ambulatory and hospital environments is an unfortunate reminder of how far we still have to go to optimize the therapy of CKD patients.[10,11,12,13,14,145]

Clinicians should therefore be aware of all the possible alternations in pharmacokinetics of drug, what processes are likely to be altered in renal failure and tailor pharmacotherapy accordingly to ensure that CKD patients receive maximal benefits from their drug therapy while minimizing potential adverse outcomes.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

A_b	concentration of drug in blood going into the dialyzer (arterial side)
AKI	acute kidney injury
A_p	concentration of drug in plasma going into the dialyzer (arterial side)
AUC_{0-t}	the area under the predialyzer plasma concentration–time curve during hemodialysis
ARC	augmented renal clearance
BSA	body surface area
C_{aD}	plasma concentration after dialysis
C_{bD}	plasma concentration prior to the next dialysis session
CG	Cockcroft–Gault
CKD	chronic kidney disease
CKD-EPI	Chronic Kidney Disease Epidemiology Collaboration Equation
CL	total body clearance
CL^b_D	dialyzer clearance from blood

CL_{cr}	creatinine clearance
CL_D	dialyzer clearance
CL_{fail}	clearance of a drug in patients with impaired renal function
CL_{norm}	clearance of a drug in patients with normal renal function
CL_{NR}	clearance nonrenal
CL^p_D	dialyzer clearance from plasma
CL_R	net renal excretion
CL^r_D	recovery clearance of dialyzer
$CL_{reabsorption}$	tubular reabsorption
CL_{RES}	residual drug clearance in a dialysis patient
$CL_{secretion}$	tubular secretion
CL_T	total clearance during dialysis
C_{max}	peak drug concentration
C_{min}	trough drug concentration
C_{ss}	average steady-state plasma concentration
CYP	cytochrome P450
D_f	maintenance dose for a patient with renal insufficiency
D_n	dose for a patient with normal renal function
EBT	erythromycin breath test
eCLcr	estimated creatinine clearance
eGFR	estimated glomerular filtration rate
EMA	European Medicine Agency
ESRD	end-stage renal disease
f_e	fraction of drug eliminated unchanged in the urine
f_u	fraction of drug unbound to plasma proteins
GFR	glomerular filtration rate
HD	hemodialysis
INR	international normalized ratio
k	elimination rate constant
k_{DD}	elimination rate constant during dialysis
KDIGO	Kidney Disease: Improving Global Outcomes
KF	ratio of the patient's CL_{cr} to the assumed normal value of 120 mL/min (2 mL/s)
k_{ID}	elimination rate constant between dialysis sessions (interdialytic)
MDRD	modification of diet in renal disease equation
MIC	minimum inhibitory concentration

MRSA	methicillin-resistant *Staphylococcus aureus*
NHD	nocturnal hemodialysis
Q	kinetic parameter/dosage-adjustment factor
Q_b	blood flow through the dialyzer
Q_p	plasma flow through the dialyzer = Q_b (1 – hematocrit)
R	the total amount of drug recovered unchanged in the dialysate
SSRIs	selective serotonin reuptake inhibitors
t'	infusion time of drug
Δt	time in hours between two measured concentrations
$t_{1/2}$	half-life
$t_{1/2,\text{on HD}}$	half-life during dialysis
$t_{1/2,\text{off HD}}$	half-life off dialysis
τ_f	dosing interval in a patient with renal failure
τ_p	practical dosing interval for a patient with renal failure
τ_n	dosing interval in a patient with normal renal function
t_{max}	time-to-peak drug concentration
TTR	time in therapeutic range
V_{area}	volume of distribution area
V_b	blood concentration of drug leaving the dialyzer
V_β	volume of terminal phase (serum protein)
V_c	volume of the central compartment
V_D	volume of distribution
V_{ss}	volume of distribution at steady state

Chapter 49: Disorders of Sodium and Water Homeostasis

Katherine H. Chessman; Jason Haney

INTRODUCTION

KEY CONCEPTS

- 1 Blood volume and serum osmolality which are essential for normal cellular function are tightly regulated in the human body. Water balance determines the serum sodium concentration, and sodium balance determines water status.
- 2 Hypovolemic hypotonic hyponatremia is relatively common in patients taking thiazide diuretics; however, thiazide-induced hyponatremia is usually mild and relatively asymptomatic.
- 3 Euvolemic (isovolemic) hyponatremia is most often caused by the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Common causes of SIADH include certain cancers, central nervous system (CNS) and pulmonary disorders, and some drugs.
- 4 Symptoms of hypo- or hypernatremia are usually neurologic and range from weakness, lethargy, restlessness, irritability, twitching, and confusion to seizures, coma, and death. Symptom severity depends on both the magnitude of the change in the serum sodium concentration and the rate at which it changes.
- 5 Treatment goals in patients with either hypo- or hypernatremia should include cautious correction of the serum sodium concentration and, when appropriate, restoration of a normal extracellular fluid (ECF) volume. Too rapid correction of the serum sodium can result in cerebral edema, seizures, neurologic damage, osmotic demyelination syndrome, and possibly death. To minimize the risk of these complications, the serum sodium concentration should be corrected at a rate not to exceed 6 to 12 mEq/L (mmol/L) in 24 hours, depending on the rate of change in the serum sodium concentration.
- 6 Asymptomatic or mildly symptomatic hyponatremia should be managed conservatively with treatment directed at the underlying cause. Intravenous (IV) infusion of 0.9% sodium chloride

(NaCl) is most often used to correct the serum sodium concentration in patients with hypovolemic hypotonic hyponatremia and moderate to severe symptoms. A 3% NaCl infusion may be used cautiously in patients with moderate to severe symptoms and euvolemic or hypervolemic hypotonic hyponatremia (along with a loop diuretic).

- 7 Hypernatremia is always hypertonic and most commonly occurs when increased water or hypotonic fluid losses are not offset by increased water intake.
- 8 Hypovolemic hypernatremia is relatively common in patients taking loop diuretics. After symptoms of hypovolemia are corrected with 0.9% NaCl, the free water deficit should be replaced.
- 9 Patients with central diabetes insipidus (DI) can be treated with desmopressin acetate, with a goal to decrease urine volume to less than 2 L per day while maintaining a normal or near normal serum sodium concentration. Patients with nephrogenic DI should be treated by correcting the underlying cause, when possible, and sodium restriction in conjunction with a thiazide diuretic to decrease the ECF volume by approximately 1 to 1.5 L.
- 10 Edema develops as a primary defect in the kidney's ability to adjust sodium reabsorption or as a response to a decreased effective circulating volume. It is usually first detected in the feet or pretibial areas of ambulatory patients. Pulmonary edema, evidenced by auscultatory crackles, can be life-threatening.
- 11 Diuretics are the primary pharmacologic means for minimizing edema. Diuretic resistance often can be overcome by using an increased dose or by using a combination of a loop diuretic and a thiazide or thiazide-like diuretic.

1 Blood volume and serum osmolality which are essential for normal cellular function are tightly regulated. Blood volume is a determinant of effective tissue perfusion which is required to deliver oxygen and nutrients to and remove metabolic waste products from tissues. Serum osmolality, the primary determinant of which is sodium concentration, is an important determinant of intracellular fluid (ICF) volume. Maintenance of normal ICF volume is particularly critical in the brain, which is 80% water, and where alterations, especially rapid changes, can result in significant dysfunction and potentially death.

Simply put, water balance determines the serum sodium concentration, and sodium balance determines the volume status. Thus, the homeostatic mechanisms for controlling blood volume are focused on controlling sodium balance, and, in contrast, the homeostatic mechanisms for controlling serum osmolality are focused on controlling water balance. Disorders of sodium and water homeostasis are common, caused by a variety of diseases, conditions, and drugs, and potentially serious. This chapter reviews the etiology, classification, clinical presentation, and therapy for disorders of sodium and water homeostasis.

SODIUM AND WATER HOMEOSTASIS

The average daily sodium intake of those consuming western diets far exceeds the usual requirement of 1.5 g per day.[1] Appropriately functioning kidneys excrete the excess to maintain the serum sodium concentration and osmolality within a very tight range. The kidney can also conserve sodium during periods of low sodium intake or in the presence of excessive losses. Both hypo- and hypernatremia are syndromes of altered serum tonicity and cell volume that reflect a change in the ratio of total exchangeable body sodium to total body water (TBW). TBW comprises 45% to 60% of body weight and is distributed primarily into two compartments: the intracellular compartment or intracellular fluid (ICF; two-thirds [67%] of TBW) and the extracellular compartment or extracellular fluid (ECF; one-third [33%] of TBW). Serum (plasma) volume is approximately 17% of the ECF volume. Sodium and its accompanying anions (chloride and bicarbonate) comprise more than 90% of the ECF osmolality; whereas ICF osmolality is primarily determined by the concentration of potassium and its accompanying anions (mostly organic and inorganic phosphates). The intra- and extracellular sodium and potassium concentrations are maintained by the sodium–potassium–adenosine triphosphatase (Na^+-K^+-ATPase) pump. Most cell membranes are freely permeable to water, allowing the free flow of water between compartments, keeping the ICF and ECF osmolalities equal.

Effective osmoles are solutes that cannot freely cross cell membranes, such as sodium and potassium. The ECF concentration of effective osmoles determines its tonicity, which directly affects water distribution between the ECF and ICF. Addition of an isotonic solution (eg, 0.9% NaCl) to the ECF will result in no change in intracellular volume because there will be no change in the effective ECF osmolality. However, addition of a hypertonic solution (eg, 3% NaCl) to the ECF will result in a decrease in ICF (cell) volume. Conversely, addition of a hypotonic solution (eg, 0.45% NaCl) to the ECF will result in an increase in ICF (cell) volume. **Table 49-1** summarizes the composition of commonly used IV solutions and their respective distribution into the ICF and ECF compartments following administration.

TABLE 49-1 Composition of Common IV Solutions

Solution	Dextrose	$[Na^+]$ (mEq/L or mmol/L)	$[Cl^-]$ (mEq/L or mmol/L)	Osmolality (mOsm/kg or mmol/kg)	Tonicity	Distribution		Free water (mL/1,000 mL)
						% ECF	% ICF	
Dextrose 5% in water	5 g/dL (50 g/L)	0	0	253	Hypotonic	33	67	1,000 mL
0.45% NaCl[a]	0	77	77	154	Hypotonic	67	33	500 mL
Lactated Ringer's	0	130	105	273	Isotonic	97	3	0 mL
0.9% NaCl[b]	0	154	154	308	Isotonic	100	0	0 mL
3% NaCl[c]	0	513	513	1,026	Hypertonic	100	0	–2,331 mL

Cl^-, chloride; ECF, extracellular fluid; ICF, intracellular fluid; IV, intravenous; Na^+, sodium; NaCl, sodium chloride.

[a]Also referred to as “half normal saline.”

[b]Also referred to as “normal saline.”

[c]This hypertonic solution will result in osmotic removal of water from the intracellular space.

Edelman’s equation (simplified) defines serum sodium (Na_S) as a function of the total exchangeable sodium and potassium in the body and the TBW: $Na_S = Na_{total\ body} + K_{total\ body}/TBW$, where $Na_{total\ body}$ is the total body sodium content; $K_{total\ body}$ is the total body potassium content; and TBW is the total body water in liters.[2,3] The serum sodium concentration is tightly regulated and thus usually varies by no more than 3%. Regulation of serum sodium occurs via mechanisms that control its determinants: serum osmolality and blood volume. The kidney regulates water excretion through a hypothalamic feedback mechanism, such that the serum osmolality remains relatively constant (275-290 mOsm/kg [mmol/kg]) despite day-to-day variations in water intake. While serum osmolality is primarily determined by the sodium concentration, glucose and blood urea nitrogen (BUN) may contribute significantly at times. Serum osmolality can be estimated as:

$$Osm_S = (2 \times Na_S) + (glucose_S/18) + (BUN/2.8)$$

where Osm_S is the serum osmolality in mOsm/kg; Na_S is the serum sodium concentration in mEq/L; $glucose_S$ is the serum glucose concentration in mg/dL; BUN is the blood urea nitrogen concentration in mg/dL; and 18 and 2.8 are the factors needed to convert from a weight measurement (mg/dL) to a concentration (mmol/L) for glucose and BUN, respectively. Thus, when using SI units the equation becomes:

$$Osm_S = (2 \times Na_S) + glucose_S + BUN$$

where Osm_S is the serum osmolality in mmol/kg; and Na_S, $glucose_S$, and BUN are their respective concentrations in mmol/L.

Arginine vasopressin (AVP), commonly known as antidiuretic hormone (ADH), is synthesized in the hypothalamus and secreted by the posterior pituitary in response to both osmotic and nonosmotic regulators. When the serum osmolality increases by as little as 1% to 2%, AVP is released and binds to vasopressin 2 (V2) receptors on the basolateral surface of renal tubular epithelial cells, resulting in the insertion of water channels (aquaporin 2) into the apical tubular lumen surface of the cell.[4] Water can then pass through the cell into the peritubular capillary space where it is reabsorbed into the systemic circulation. The increase in AVP release also stimulates thirst as an additional means to return serum osmolality toward normal. The combined effect of increased water intake and decreased water excretion (kidney’s response to AVP) results in a decrease in the serum osmolality and inhibition of further AVP secretion, once the serum osmolality is restored to normal.

Nonosmotic AVP release occurs when osmoreceptors in the brain detect a 6% to 10% reduction in the effective circulating blood volume or arterial blood pressure. The effective circulating volume is that part of the ECF responsible for organ perfusion. A decrease in the effective circulating volume (more accurately, the blood pressure associated with that volume) activates arterial baroreceptors in

the carotid sinus and glomerular afferent arterioles, resulting in stimulation of the renin–angiotensin system and increased angiotensin II synthesis. Angiotensin II stimulates both nonosmotic AVP release and thirst. This volume stimulus can override osmotic inhibition of AVP release. Water conservation then restores the effective circulating volume and blood pressure at the expense of producing a decreased serum osmolality and hyponatremia.[4] While hyponatremia and hypernatremia can be associated with conditions of high, low, or normal ECF sodium and volume, both conditions most commonly result from abnormalities of water homeostasis. To understand treatment options, it is important to note the distinction between *dehydration* (hypertonicity) and *hypovolemia*. Dehydration refers to a loss of TBW producing hypertonicity while hypovolemia (volume depletion) is a deficit in ECF volume.[5,6] Although these terms are often used interchangeably, they are reflective of different processes.

HYPONATREMIA

Epidemiology and Etiology

Hyponatremia, generally defined as a serum sodium concentration less than 135 mEq/L (mmol/L), is the most common electrolyte abnormality encountered in clinical practice in both adults and children.[2,6,7,8,9] Although the prevalence is not well established and varies with the patient population studied, it has been estimated to be as high as 28% at the time of admission to an acute care hospital. The prevalence of mild hyponatremia (serum sodium concentration less than 136 mEq/L [mmol/L]) was 42% (28% on admission, 14% during admission); 6.2% of patients evaluated (2.5% on admission, 3.7% during admission) had values less than 126 mEq/L (mmol/L); and only 1.2% (0.5% on admission, 0.7% during admission) had values less than 116 mEq/L (mmol/L). The incidence of hyponatremia (serum sodium concentration less than 136 mEq/L [mmol/L]) was reported to be 21% in patients seen in ambulatory hospital clinics and 7% in community clinics.[10] Drug-induced hyponatremia, especially that associated with thiazide diuretics[11,12] and psychotropic medications,[13,14] is common. Advancing age (older than 30 years) also appears to be a risk factor for hyponatremia, independent of sex.[10]

Residents in nursing homes have a twofold higher incidence of hyponatremia than that observed in age-matched, community-dwelling individuals.[6] More than 75% of these hyponatremic episodes were precipitated by increased intake of hypotonic oral or IV fluids. Similarly, ingestion of excessive volumes of hypotonic fluids (water, sports drinks) has been identified as a key risk factor in the development of exercise-associated hyponatremia in athletes.[15] In one study, women runners had a threefold higher rate of hyponatremia; however, smaller body size and longer racing time, not sex, were the principal factors accounting for the increased incidence.[16]

Recognition of the high prevalence of hyponatremia is essential because this condition is associated with significant morbidity and mortality.[4,17,18,19,20] Transient or permanent brain dysfunction in patients with hyponatremia can result from either the acute effects of hypoosmolality or too rapid correction of hypoosmolality. Hyponatremia is predominantly the result of an excess of extracellular water relative to sodium because of impaired water excretion. The kidney normally has the capacity

to excrete large volumes of dilute urine after ingestion of a water load. Nonosmotic AVP release, however, can lead to water retention and a decrease in the serum sodium concentration, despite a decrease in both serum and intracellular osmolality. Causes of nonosmotic AVP release include hypovolemia and decreased effective circulating volume as seen in patients with chronic heart failure (HF), nephrosis, and cirrhosis. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH), a common cause of hyponatremia, is associated with some cancers, especially small cell lung cancer, and central nervous system (CNS) damage (eg, traumatic brain injury, meningitis). The pathophysiology, clinical features, and management of hyponatremia are discussed further.

Pathophysiology

Hyponatremia can be associated with normal, increased, or decreased serum osmolality, depending on its cause. **Figure 49-1** provides an algorithm for evaluating patients with hyponatremia.[2,21] Hyponatremia in a patient with a normal measured serum osmolality can be seen in those with markedly elevated serum lipids or proteins (hyperproteinemia, multiple myeloma) when flame photometry is the method used to measure the sodium concentration. This *pseudohyponatremia* is an artifact because the elevated lipids or proteins account for a larger than usual proportion of the total sample volume, reducing the percentage of water in the serum (**Fig. 49-2**). Because sodium is distributed in the water component only, the measured serum sodium concentration will be falsely decreased. The measurement of serum osmolality is not affected, leading to a discrepancy between the calculated and measured serum osmolality. When sodium concentration is measured via ion-selective electrodes, pseudohyponatremia has not been noted because all serum samples are diluted and a constant distribution between water and the solid phase of serum is assumed when the serum sodium concentration is calculated. If the measurement of serum osmolality is not available, direct potentiometery using a blood gas analyzer will yield the true sodium concentration.[21]

FIGURE 49-1

Diagnostic algorithm for the evaluation of hyponatremia. (HF, heart failure; EABV, effective arterial blood volume; GI, gastrointestinal; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; UNa, urine sodium concentration [values in mEq/L are numerically equivalent to mmol/L]; UOsm, urine osmolality [values in mOsm/kg are numerically equivalent to mmol/kg].)

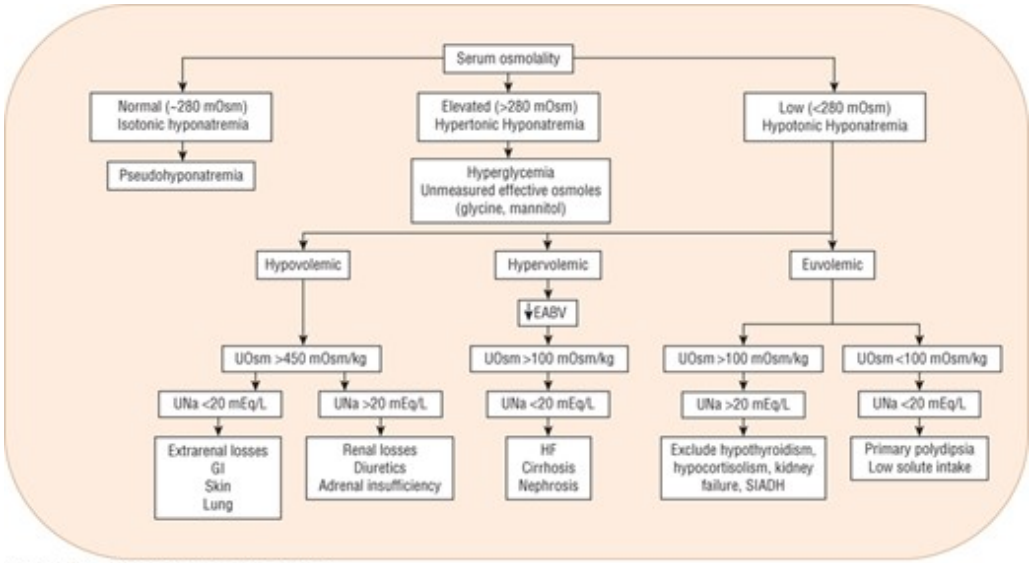

FIGURE 49-2

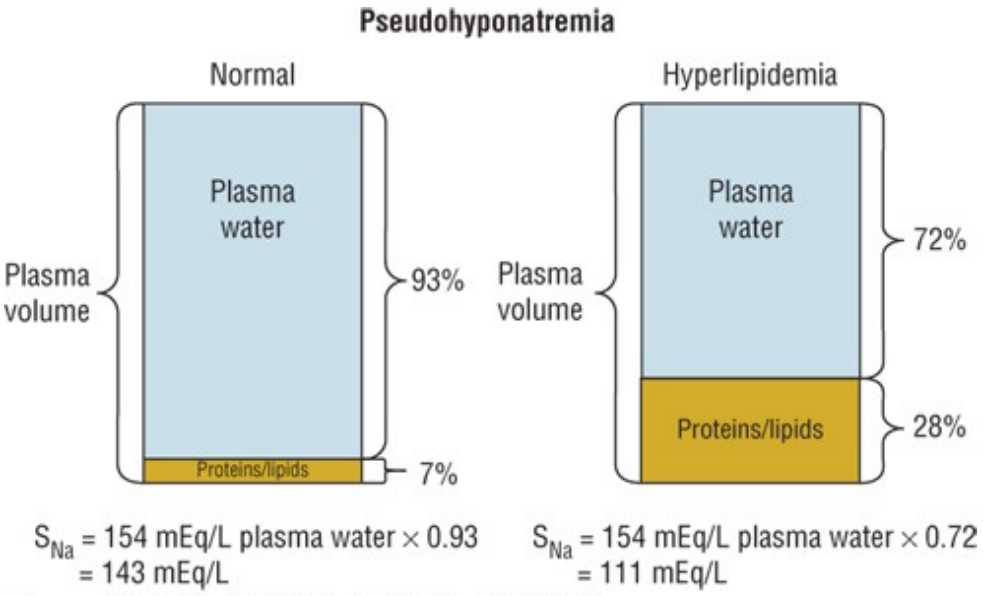
Elevated lipids or proteins result in a larger discrepancy between the volume of the sample and serum water, leading to a falsely low measurement of the serum sodium concentration when using the method of flame photometry. (S_{Na}, serum sodium concentration [values in mEq/L are numerically equivalent to mmol/L].)



Hyponatremia associated with an increased serum osmolality, hypertonic hyponatremia, is due to the presence of excess, effective osmoles (other than sodium) in the ECF. This type of hyponatremia is most frequently encountered in patients with hyperglycemia. The elevated serum glucose concentration causes diffusion of water from the cells (ICF) into the ECF, thereby decreasing the ICF volume, expanding the ECF volume, and diluting the existing sodium resulting in a decreased serum

sodium concentration. The volume of distribution (V_d) of glucose is a complex function of insulin activity, glucose distribution time, ECF volume, and glucose concentration. Using a clinically relevant glucose V_d of 0.3 to 0.5 L/kg, one would predict a 1.5 to 1.9 mEq/L (mmol/L; mean, 1.7 mEq/L [mmol/L]) decrease in the serum sodium concentration for every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration above 100 mg/dL (5.6 mmol/L) or 0.29 mmol/L for every 1 mmol/L decrease, and the serum osmolality will increase by 2 mOsm/kg (mmol/kg).[5,22] It is important to remember that this correction is only a rough estimate because of the variability in the V_d of glucose. The presence of other effective osmoles (eg, mannitol, glycine, sorbitol) can also cause hypertonic hyponatremia. The presence of one of these unmeasured osmoles should be suspected in patients with hypertonic hyponatremia when there is a significant osmolal gap, defined as the difference between the measured and calculated serum osmolality.

Hyponatremia associated with decreased serum osmolality, hypotonic hyponatremia, is the most common form of hyponatremia and has many potential causes (**Table 49-2**). Clinical assessment of ECF volume is an important step in the diagnostic evaluation of a patient with hypotonic hyponatremia. Categorization of these patients into one of three groups (decreased, increased, or clinically normal ECF volume) is the essential first step in identifying the pathophysiologic mechanisms responsible for the hyponatremia and developing an appropriate treatment plan.

TABLE 49-2 Characteristics of Hypotonic Hyponatremic States

Characteristics	Hypovolemic Hyponatremia	Euvolemic (Isovolemic) Hyponatremia	Hypervolemic Hyponatremia
Water and sodium	Sodium loss >> water loss	Water gain only	Water gain >sodium gain
Causes	Renal: thiazide diuretics Nonrenal: diarrhea, cerebral salt-wasting	SIADH	Heart Failure Liver cirrhosis Kidney failure
Effect on TBW	↓↓	↑	↑↑
Effect on TBNa	↓	↔	↑↑
Additional laboratory findings	Renal: UOsm high, UNa high Nonrenal: UOsm high, UNa low	Renal: UOsm low, UNa variable Nonrenal: UOsm high, UNa variable	UOsm high, UNa high
Clinical presentation	Orthostasis, hypotension, tachycardia, dry mucous membranes, CNS changes	Depends on severity of hyponatremia: seizures, lethargy	Peripheral and pulmonary edema, variable blood pressure
Treatment	0.9% NaCl until vital signs stable; then maintenance fluid replacement	Water restriction; demeclocycline; loop	Sodium restriction; water restriction; loop

Characteristics	Hypovolemic Hyponatremia	Euvolemic (Isovolemic) Hyponatremia	Hypervolemic Hyponatremia
	(D5/0.45% NaCl); sodium replacement if cerebral salt wasting; vaptan contraindicated	diuretics; vaptan	diuretics; vaptan

CNS, central nervous system; a SIADH, syndrome of inappropriate antidiuretic hormone; TBW, total body weight.

Hypovolemic Hypotonic Hyponatremia

Most patients with ECF volume contraction lose fluids that are hypotonic relative to serum and thus can become "transiently" hypernatremic. This scenario includes patients with fluid losses caused by diarrhea, excessive sweating, and diuretics. This transient hypernatremic hyperosmolality results in osmotic AVP release and thirst. If sodium and water losses continue, the resultant hypovolemia results in more AVP release. Patients who then drink water (a hypotonic fluid) or who are given hypotonic IV fluids retain water, and hyponatremia develops. These patients will typically have a urine osmolality greater than 450 mOsm/kg (mmol/kg), reflecting AVP action leading to formation of concentrated urine. The urine sodium concentration will be less than 20 mEq/L (mmol/L) when sodium losses are extrarenal (eg, diarrhea), and greater than 20 mEq/L (mmol/L) in patients with renal sodium losses (eg, thiazide diuretic use or adrenal insufficiency).[23]

2 Hypotonic hyponatremia is relatively common in patients taking thiazide diuretics.[12,21,24] Thiazide diuretic-induced hyponatremia is usually mild and relatively asymptomatic, but occasionally it can be severe and symptomatic.[24] Hyponatremia typically develops within 2 weeks of diuretic initiation, but can occur at any time during therapy, particularly after dosage increases or if other causes of hyponatremia are present.[20,24] Elderly women are at the greatest risk for thiazide diuretic-induced hyponatremia.[21,24]

The mechanism of thiazide diuretic-induced hyponatremia is likely related to the balance of their direct and indirect effects. Thiazide diuretics block sodium reabsorption in the distal tubules of the renal cortex, thereby increasing sodium and water removal from the body. The resulting decrease in effective circulating volume stimulates AVP release, resulting in increased free water reabsorption in the collecting duct, as well as increased water intake because of stimulation of thirst. Hyponatremia develops when the net result of these effects is the loss of more sodium than water.

Conversely, hyponatremia occurs infrequently with loop diuretics due to their different site of action. Loop diuretics block sodium reabsorption in the ascending limb of the loop of Henle. This action decreases medullary osmolality; thus, when loop diuretic use decreases effective circulating volume and stimulates AVP release, less water reabsorption occurs in the collecting ducts than would occur if the osmolality of the renal medulla were normal. Thiazide diuretics do not alter medullary osmolality because they act in the renal cortex. In addition, most loop diuretics have a shorter half-life than thiazides, and patients can usually replete the urinary sodium and water losses prior to taking the

next dose, thereby minimizing AVP stimulation.[25]

Cerebral/renal salt wasting syndrome is a rare condition observed in patients with intracranial disorders such as subarachnoid bleeding and traumatic brain injury, but it can occur in patients without CNS pathology. It results in decreased ECF volume due to profound natriureis. A very high urine sodium concentration, high serum urea, orthostatic hypotension, low central venous pressure, and high urine output suggests cerebral salt wasting rather than SIADH.[21,26]

Euvolemic Hypotonic Hyponatremia

3 Euvolemic (isovolemic) hypotonic hyponatremia is associated with a normal or slightly decreased ECF sodium content and increased TBW and ECF volume. The ECF volume increase is usually not sufficient to cause peripheral or pulmonary edema or other signs of volume overload, and thus patients appear euvolemic upon physical examination. Euvolemic hyponatremia is most often caused by SIADH.

In SIADH, water intake exceeds the kidney's capacity to excrete water, either because of increased AVP release via nonosmotic and/or nonphysiologic processes or enhanced sensitivity of the kidney to AVP. In most patients with SIADH, the urine osmolality will be greater than 100 mOsm/kg (mmol/kg), and the urine sodium concentration will be greater than 20 mEq/L (mmol/L) due to ECF volume expansion (see Table 49-2).

The most common causes of SIADH include tumors such as small cell lung or pancreatic cancer, CNS disorders (eg, head trauma, stroke, meningitis, pituitary surgery), and pulmonary disease (eg, tuberculosis, pneumonia, acute respiratory distress syndrome). Patients with kidney and adrenal insufficiency or hypothyroidism can also present with euvolemic hyponatremia, and the evaluation of patients with suspected SIADH should always include consideration of these disorders. A number of drugs can cause SIADH by enhancing AVP release or its effect on the kidney, or by other mechanisms[13,17,27] (**Table 49-3**). The differential diagnosis of euvolemic hypotonic hyponatremia also includes primary or psychogenic polydipsia. Patients with this disorder drink more water (usually more than 20 L/day) than the kidneys can excrete as solute-free water. However, unlike in SIADH, AVP secretion is suppressed, resulting in a urine osmolality that is less than 100 mOsm/kg (mmol/kg). The urine sodium is typically low (less than 15 mEq/L [mmol/L]) as a result of dilution.[4,14] Hyponatremia can develop even with more modest water intakes in patients who ingest very low-solute diets.

TABLE 49-3 Potential Causes of SIADH

Drug-Induced		Nondrug-Induced
Barbiturates	Nicotine	Malignancy (lung, pancreatic, duodenal)
Bromocriptine	Opioids	CNS (trauma, tumor, meningitis, hemorrhage, stroke)
Carboplatin	Phenothiazines	Pulmonary (pneumonia, ARDS, TB)
Cisplatin	Thioridazine	Postoperative state

Drug-Induced		Nondrug-Induced
Clofibrate	Thiothixene	Nausea
Haloperidol	Tricyclic antidepressants	Anxiety
Monoamine oxidase inhibitors		
Increased sensitivity to ADH		
Acetaminophen	NSAIDs	
AVP analogs (desmopressin)	Oxytocin	
Lamotrigine	Tolbutamide	
Mixed or uncertain mechanism		
ACE inhibitors	Moxifloxacin	
Carbamazepine	Omeprazole	
Chlorpropamide	SSRIs	
Cyclophosphamide	Vinca alkaloids	
Ecstasy		

ACE, angiotensin-converting enzyme; ARDS, acute respiratory distress syndrome; AVP, arginine vasopressin; CNS, central nervous system; NSAIDs, nonsteroidal anti-inflammatory drugs; SIADH, syndrome of inappropriate antidiuretic hormone; SSRIs, selective serotonin receptor inhibitors; TB, tuberculosis.

Hypervolemic Hypotonic Hyponatremia

Hyponatremia associated with ECF volume expansion occurs in conditions in which both the kidney's sodium and water excretion are impaired. Patients with cirrhosis, HF, or nephrotic syndrome have an expanded ECF volume and edema, but a decreased effective arterial blood volume. This decreased volume results in renal sodium retention, and eventually ECF volume expansion and edema. At the same time, there is nonosmotic stimulation of AVP release and water retention in excess of sodium retention, which perpetuates the hyponatremic state.

Clinical Controversy…

Traditional maintenance fluids for children provide dextrose and potassium in a hypotonic solution such as 0.45% NaCl or 0.2% NaCl. Concern for the development of hyponatremia has led some clinicians to advocate for the use of isotonic solutions such as 0.9% NaCl for "maintenance" fluids to reduce the incidence of hyponatremia. Isotonic fluids may, in fact, be appropriate for some hospitalized children, but it is important to remember that 'maintenance' fluids are appropriate when used as intended for children who are euvolemic, with no excess ongoing fluid losses and normal

kidney function. Excess administration of isotonic fluids can result in sodium overload and metabolic acidosis.

Clinical Presentation

4 Patients with chronic (lasting longer than 48 hours) mild hyponatremia (serum sodium concentration 125-134 mEq/L [mmol/L]) are usually asymptomatic, with hyponatremia often being discovered incidentally when serum electrolytes are measured for other purposes.[28] Mild symptoms of hyponatremia frequently go unnoticed by both clinicians and patients.[18,29] Chronic, mild hyponatremia however has been associated with impairment of attention, posture, and gait, all of which contribute to a substantially increased fall risk. Even "asymptomatic" patients, when formally tested, have impaired attention and gait to a degree that is comparable to symptoms seen with a blood alcohol level of 0.06% (13 mmol/L).[18,30,31]

Patients with moderate (serum sodium concentration 115-124 mEq/L [mmol/L]), severe (serum sodium concentration 110-114 mEq/L [mmol/L]), or rapidly developing hypotonic hyponatremia often present with a range of neurologic symptoms resulting from hypoosmolality-induced brain cell swelling. Classic neurologic symptoms include nausea, malaise, headache, lethargy, restlessness, and disorientation. In severe cases, seizures, coma, respiratory arrest, brainstem herniation, and death can occur.

CLINICAL PRESENTATION Hyponatremia General

- Patients are usually asymptomatic.
- Symptoms are primarily neurologic.
- Presence and severity of symptoms depend on the magnitude and rapidity of onset of hyponatremia.
- Other symptoms may be present depending on the etiology of the hyponatremia (eg, dry mucous membranes, tachycardia, and hypotension with hypovolemia).

Symptoms

- Mild: Nausea and malaise
- Moderate: Headache, lethargy, restlessness, disorientation
- Severe: Seizures, coma, respiratory arrest, brainstem herniation, death

Laboratory Tests

- Serum sodium concentration less than 135 mEq/L (mmol/L)
- Plasma osmolality and urine sodium concentration can be helpful

- Other tests: Serum glucose and lipids and kidney and thyroid function tests

The presence and severity of these symptoms depend on both the degree of the hyponatremia and the rate at which it develops. The magnitude of the hyponatremia is important because serum osmolality decreases in direct proportion to the serum sodium concentration, and water movement into brain cells increases as serum osmolality decreases. The rate of change of the serum osmolality is important because brain cells are not able to rapidly adjust intracellular osmolality to minimize cellular volume changes.[3,32] When a decline in serum osmolality causes water movement into brain cells, inorganic Cl^- and K^+, and organic osmolytes, such as taurine, glutamate, and myoinositol, move out of the cells to decrease intracellular osmolality and minimize intracellular water shifts.[31] The components of this adaptive mechanism occur over different time frames, with sodium and potassium efflux occurring within minutes to hours and organic osmolyte efflux occurring within hours to days.[32,33] Maximal compensation for decreased serum osmolality typically requires up to 48 hours. Thus, acute changes in serum osmolality are more likely to be associated with symptoms. Concurrent respiratory failure and hypoxemia increase the risk of adverse neurologic outcomes because hypoxemia diminishes the brain's capacity to actively transport solute out of cells, leading to a higher incidence of cerebral edema.[32,33] Children and women have poorer clinical outcomes than adults and men, respectively. For example, post menopausal women with acute hypervolemic hypotonic hyponatremia have a 25-fold higher risk of death or permanent neurological damage than men.[34] Hyponatremia is a severe risk factor for morbidity and mortality in patients with HF and cirrhosis.[4]

In addition to neurologic symptoms, patients with hypovolemic hyponatremia present with signs and symptoms of hypovolemia, including dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, hypotension, and orthostatic hypotension. These findings are often helpful in identifying the type of hyponatremia present.

5 The brain's adaptation to a chronic change in the serum osmolality leads to development of neurologic symptoms if hyponatremia (hypoosmolality) is corrected too rapidly. The combination of the adaptive decrease in intracellular osmolality and rapid increase in serum osmolality results in rapid and excessive water movement out of the brain cells and ICF volume depletion. Thus, too rapid correction of the serum sodium concentration can lead to an acute decrease in brain cell volume, which contributes to the pathogenesis of *osmotic demyelination syndrome* (ODS), or central pontine myelinolysis.[4,35] Demyelinated lesions seen on magnetic resonance imaging most often occur in the central pons, but ODS can extend to extrapontine structures.[23] Patients with ODS may develop hyperreflexia, para- or quadriparesis, parkinsonism, pseudobulbar palsy, *locked-in syndrome* (a condition in which a patient is aware and awake but cannot move or communicate verbally due to complete paralysis of nearly all voluntary muscles in the body except for the eyes), or death in approximately 1 to 7 days.[2,16,36] Patients with a significant degree of cerebral adaptation (eg, chronic serum sodium concentration less than 110 mEq/L [mmol/L]) to hypotonic hyponatremia are at highest risk of developing ODS because as these patients have lower intracellular osmolalities at the initiation of therapy, there is a greater decrease in intracellular volume in brain cells when the serum osmolality is raised too rapidly.[35] Other concomitant conditions that increase the risk of ODS include

alcoholism, liver failure, orthotopic liver transplantation, potassium depletion, and malnutrition. Thus, if duration of hyponatremia is unknown, then it is generally safer to treat as if it is chronic when developing an initial treatment plan.

TREATMENT

6 General guidelines for the treatment of patients with hyponatremia are shown in **Table 49-4**.[2,22,24,27,37] Application of these principles to the treatment of various forms of hypotonic hyponatremia is discussed in the following sections.

TABLE 49-4 General Guidelines for Treatment of Hyponatremia

- For both short- and long-term management, treat the underlying cause of hyponatremia.
- Appropriate treatment of hypotonic hyponatremia requires balancing the risks of hyponatremia vs the risk of ODS.
- Patients who acutely develop moderate to severe hyponatremia and/or patients who have severe symptoms are at greatest risk and potentially benefit most from more rapid correction of hyponatremia.
- Correction of hypovolemic hypotonic hyponatremia is usually best accomplished with 0.9% NaCl, as these patients have both sodium and water deficits.
- Active correction of euvolemic and hypervolemic hypotonic hyponatremia in patients who do not require rapid correction is usually best accomplished by water restriction. Demeclocycline, AVP vasopressin 2-receptor antagonists (*vaptans*), or 0.9% NaCl plus a loop diuretic (furosemide, bumetanide) can be used if the initial response to water restriction is not adequate.
- In patients with severe symptoms, 3% NaCl (possibly combined with a loop diuretic) should initially be used to more rapidly correct the hyponatremia. A loop diuretic can be administered concurrently with 3% NaCl to enhance the serum sodium correction by increasing free water excretion.
- Long-term management will be required for patients in whom the underlying cause of hyponatremia cannot be corrected. Depending on the cause, water restriction, increasing sodium intake, and/or an AVP antagonist (vaptan) may be used.

AVP, arginine vasopressin; ODS, osmotic demyelination syndrome.

Desired Outcome

Regardless of the type or cause of hyponatremia, treatment goals for all patients are to resolve the underlying cause of the sodium and ECF volume imbalance, if possible, and to safely correct the sodium and water derangements. The treatment plan for a patient with hyponatremia depends on

the underlying cause and the severity of symptoms. Patients with an acute onset of hyponatremia or severe symptoms require more aggressive therapy to correct the hypotonicity. The initial goal for these patients is to increase serum tonicity just enough to control severe symptoms; this typically requires only a small increase (5%) in serum sodium concentration. Once severe symptoms have abated, then continued serum sodium correction should be achieved at a controlled rate. Patients who are asymptomatic or who have only mild to moderate symptoms do not require rapid correction of the serum sodium concentration. Treatment is dictated by the underlying etiology. In all cases, the goal is to avoid an increase in the serum sodium concentration of more than 12 mEq/L (mmol/L) in 24 hours or 0.5 mEq/L (mmol/L) per hour.[2,4,21,28,37] However, when duration of hyponatremia is unknown, a correction rate of no more than 6 to 8 mEq/L (mmol/L) or 0.33 mEq/L/h (mmol/L/h) is prudent to avoid ODS.[2]

ACUTE OR SEVERELY SYMPTOMATIC HYPOTONIC HYPONATREMIA

A patient who has or is at high risk of experiencing severe symptoms caused by hyponatremia should receive either 3% NaCl (513 mEq/L [mmol/L]) or 0.9% NaCl (154 mEq/L [mmol/L]) until severe symptoms resolve.[2,6,24,29,38] Resolution of severe symptoms frequently requires only a small (approximately 5%) increase in serum sodium concentration; although, some clinicians suggest that the initial safe target should be a serum sodium concentration of approximately 120 mEq/L (mmol/L).[6,39] The relative concentrations of urine sodium and potassium (osmotically effective urine cations) must be compared with those of the infusate in planning a treatment regimen for patients with hypotonic hyponatremia. For the serum sodium concentration to increase after a NaCl infusion, the sodium concentration of the infusate must exceed the sum of the urinary sodium and potassium concentrations to produce an effective net free-water excretion.

Patients with SIADH often have urinary concentrations of osmotically effective cations that exceed the sodium concentration of 0.9% NaCl. In this case, use of isotonic NaCl can actually worsen hyponatremia.[40] These patients should be preferentially treated with 3% NaCl. The relatively high urinary sodium concentration in patients with SIADH is due to ECF expansion, which minimizes sodium reabsorption along the nephron. When the urine osmolality exceeds 300 mOsm/kg (mmol/kg), it is generally advisable to administer an IV loop diuretic, not only to increase solute-free water excretion but also to prevent volume overload, which can result from hypertonic sodium chloride. Intravenous furosemide 20 to 40 mg every 6 hours or bumetanide 0.5 to 1 mg every 2 to 3 hours for several doses is generally sufficient to prevent volume overload and to decrease the urinary concentration of osmotically active cations to less than 150 mEq/L (mmol/L). If intermittent loop diuretic doses are not sufficient to manage edema, then continuous infusions have been used. Either furosemide 20 to 40 mg given intravenously followed by a 10 to 40 mg/h infusion or bumetanide 1 mg given intravenously followed by a 0.5 to 2 mg/h infusion can be used.

Patients with hypovolemic hypotonic hyponatremia can be treated with 0.9% NaCl. In contrast to patients with SIADH, patients with this condition avidly reabsorb sodium throughout the nephron because the effective circulating blood volume is decreased. Thus, the urine sodium concentration is

often less than 20 mEq/L (mmol/L), substantially less than the sodium content of 0.9% NaCl. While the use of 3% NaCl will correct hyponatremia in these patients, it will not correct the hypovolemia; thus, its use should be reserved for patients with severe symptoms requiring very rapid correction of the serum sodium concentration.

Acute hypervolemic hypotonic hyponatremia is particularly problematic to manage because the sodium and volume needed to minimize the risk of cerebral edema or seizures can worsen already compromised liver, heart, or kidney function. These patients generally should be treated with 3% NaCl and initiation of fluid (water) restriction. Loop diuretic therapy will also likely be required to facilitate urinary free water excretion.

Determination of a Sodium Chloride Infusion Regimen

Multiple methods for determining the correct NaCl infusion regimen for a patient with hyponatremia can be used.[2,4,21,24,36,38,39] These empiric approaches provide an initial estimate of the correct infusion regimen. Several complex equations have been derived, but improved outcomes using these equations have not been demonstrated.[24,36]

One common approach is to estimate the change in serum sodium concentration resulting from the infusion of 1 L of 3% or 0.9% NaCl. An example of this approach is shown in **Table 49-5**. Another method involves calculating the sodium deficit, then replacing one-third of the deficit in the first 6 hours and the remaining two-thirds over the following 24 to 48 hours or longer depending on the acuity of the decrease in the serum sodium concentration. Sodium deficit can be calculated using the following equation: Na deficit (mEq or mmol) = $[(Na_D - Na_S) \times TBW]$

TABLE 49-5 Assessment and Treatment of Euvolemic Hyponatremia

Change in serum sodium concentration after an IV fluid bolus

$$\Delta Na_S = (Na_{IV} - Na_S) / (TBW + volume_{IV})$$

ΔNa_S, change in serum sodium concentration; Na_{IV}, sodium concentration of infusate (eg, 154 mEq/L [mmol/L] for 0.9% NaCl; 513 mEq/L [mmol/L] for 3% NaCl); Na_S, initial serum sodium concentration; TBW, total body water (L); and $volume_{IV}$, volume of infused fluid (L)

TBW can be estimated as:

Children and men younger than 70 years: 0.6 L/kg × wt (kg)

Men older than 70 years and women younger than 70 years: 0.5 L/kg × wt (kg)

Women older than 70 years: 0.45 L/kg × wt (kg)

Dehydrated, older patients: 0.4 L/kg × wt (kg)

where wt is the current body weight

Clinical Example

A 66-year-old man (weight, 70 kg [154 lb]; height, 178 cm [5 ft 10 in]) presents with nausea, headache, and confusion which developed over the past 3 days. Ten days ago, he began taking carbamazepine for trigeminal neuralgia. His serum sodium concentration on admission to the emergency department was 109 mEq/L (mmol/L). He is diagnosed with SIADH.

Plan of Care

1. Discontinue carbamazepine (the likely etiology of his SIADH).

2. Admit to the hospital for correction of hyponatremia.

3. Increase the serum sodium concentration by no more than 6 to 12 mEq/L (mmol/L) during first 24 hours and no higher than 120 mEq/L (mmol/L); thus, the goal is to increase the sodium concentration by 11 mEq/L (mmol/L).

4. Due to degree of hyponatremia (less than 110 mEq/L [mmol/L]) and the presence of moderate to severe symptoms, give 3% NaCl.

Calculate the change in serum sodium after 1 L infusion of 3% NaCl:

ΔNa_S = (513 mEq/L – 109 mEq/L)/[(0.5 L/kg × 70 kg) + 1 L] = 11.2 mEq/L or 1.12 mEq/100 mL

(Note: In SI units, the calculation is the same using mmol/L rather than mEq/L.)

Infusion of 1 L of 3% NaCl will result in a 11.2 mEq/L (mmol/L) rise in the serum sodium concentration. An 11 mEq/L (mmol/L) increase is desired; thus, the appropriate infusion volume is 982 mL [(11 mEq/L/11.2 mEq/L) × 1,000 mL] or [(11 mmol/L/11.2 mmol/L) × 1,000 mL].

(Note: The approach to this calculation would be similar if 0.9% NaCl was used, except that for each 1 L infusion, the expected increase in serum sodium concentration would be only 1.25 mEq/L (mmol/L), and an infusion volume of approximately 8.8 L would be required to achieve the targeted serum sodium concentration.)

5. Moderate to severe symptoms: serum sodium concentration should be increased by approximately 1.5 mEq/L/h (mmol/L/h) over the first 2 to 4 hours of treatment for a total of 3 to 6 mEq/L [mmol/L] or until the symptoms have resolved. An initial infusion rate of 114 mL/h for the first 2 to 4 hours is needed.

6. Check serum sodium concentration every 1 to 3 hours.

7. Once symptoms subside, continue infusion rate at approximately 23 to 31 mL/h for the next 20 to 22 hours, to slowly correct hyponatremia. Monitor serum sodium concentration every 4 hours or more often if serum sodium is rapidly changing.

where Na_D is the goal or desired serum sodium (usually 120-125 mEq/L [mmol/L] to avoid too rapid or over correction); Na_S is the patient's current serum sodium concentration; and, TBW is the patient's current TBW calculated as shown in Table 49-5.

Using these methods, the appropriate infusion volume for a given patient can be estimated using the desired proportion of the estimated change that would result from a 1-L infusion or the amount of fluid needed to provide the calculated sodium deficit, respectively. The final step is to calculate an appropriate infusion rate for the calculated volume that will increase the serum sodium concentration by 6 to 12 mEq/L (mmol/L) in 24 hours (see table 49-5). Using desmopressin in combination with 3% NaCl to minimize the risk of treating hyponatremia has been suggested but is generally not recommended.[2]

Clinical Controversy…

Clinicians often disagree whether or not to administer 3% NaCl to patients with symptomatic hypotonicity. An Advantage of 3% NaCl is more rapid correction of serum sodium concentration with a smaller infusion volume. The disadvantage of 3% NaCl is a higher risk of too rapid correction of serum sodium concentration causing ODS. The clinician must carefully consider the cause and the rapidity of development of the patient's hyponatremia as well as the relative risk of slower correction of the hyponatremia versus the development of ODS.

Evaluation of Therapeutic Outcomes

Patients with severely symptomatic hypotonic hyponatremia should be admitted to the intensive care unit (ICU) or other setting where frequent monitoring of neurologic symptoms and volume status is feasible. Examination of the heart, lungs, and neurologic status should be performed frequently during the initial 12 hours of therapy. The serum sodium concentration should be measured at least every 2 to 4 hours, and the urine osmolality, sodium, and potassium should be measured every 4 to 6 hours over the first day of therapy so that the infusion rate can be adjusted to avoid increasing the serum sodium too rapidly.[2]

NONEMERGENT HYPOVOLEMIC HYPOTONIC HYPONATREMIA

Most patients with hypovolemic hypotonic hyponatremia are either asymptomatic or have only mild-to-moderate symptoms so they do not require rapid correction of their hyponatremia. Many of these patients are at higher risk of developing ODS if serum sodium correction occurs too rapidly because they have chronic hyponatremia that has been maximally compensated for by the brain's osmotic adaptation. Treatment of these patients should include correction of the underlying condition, if possible, and administration of 0.9% NaCl to correct the hypovolemia. This solution will replace the existing sodium and water deficits, and its use carries a lower risk of too rapid correction

than using 3% NaCl.

The ECF deficit can be estimated based on sex, change in body weight, and age. One method to estimate the ECF deficit and an example of its use is shown in **Table 49-6**. If the patient's previous weight is not known, the ECF deficit can be roughly estimated based on clinical signs and symptoms. The presence of hyponatremia suggests an ECF deficit of 5% or more, whereas the presence of orthostatic hypotension suggests an ECF deficit of at least 10% to 15%. An isotonic solution (0.9% NaCl or Lactated Ringer's) would be optimal to correct the patient's volume deficit because essentially 100% of it will remain in the ECF space (see Table 49-1). The overriding initial treatment goal is to restore effective circulating volume; thus, it might be necessary to infuse 0.9% NaCl at 200 to 400 mL/h until symptoms of hypovolemia improve. The infusion rate can then be decreased to 100 to 150 mL/h so that the serum sodium concentration increases by no more than 6 to 12 mEq/L (mmol/L) or 0.5 to 1 mEq/L/h (mmol/L/h) over the initial 24 hours. Fluids should be given rapidly enough and in sufficient quantity to restore and maintain adequate tissue perfusion without overloading the cardiovascular system. The patient's underlying heart and kidney function will determine how well fluid replacement is tolerated. For example, infusion of 0.9% NaCl at a rate greater than 250 mL/h should be used cautiously in patients with left ventricular dysfunction or severe kidney dysfunction.

TABLE 49-6 Assessment and Treatment of Hypotonic Hypovolemic Hyponatremia

Calculating ECF Deficit

ECF deficit (mL) = $ECF_{normal} - ECF_{current}$

where ECF volume = 0.33 × TBW

Clinical Example

A 75-year-old woman (height, 168 cm [5 ft 6 in]; usual weight, 50 kg [110 lb]) was started on hydrochlorothiazide 25 mg once daily 10 days ago for hypertension. She presents with complaints of mild nausea and dizziness when she stands up. Her current weight is 45 kg (99 lb). Upon physical examination she has dry mucous membranes and orthostatic hypotension. Her serum sodium concentration is 126 mEq/L (mmol/L).

Calculate the ECF deficit

ECF deficit = (50 kg × 0.4 L/kg × 0.33) – (45 kg × 0.4 L/kg × 0.33) = 660 mL

(Note: TBW = 0.4 L/kg used because she is a dehydrated older patient; see Box 49-1)

Calculate the expected increase in the serum sodium after infusion of 1 L of 0.9% NaCl (see Box 49-1):

ΔNa_S with 1 L of infusate = [154 mEq/L – 126 mEq/L]/ [(0.4 L/kg × 45 kg) + 1 L] = 1.47 mEq/L (mmol/L)

The patient's serum sodium concentration will be 127.5 mEq/L (mmol/L) following the infusion of 1 L 0.9% NaCl

Treatment goals: Restore effective circulating volume and correct serum sodium concentration

Treatment plan:

1. Infuse 0.9% NaCl at 200 to 250 mL/h until symptoms of hypovolemia improve; then decrease infusion to 150 to 200 mL/h so that the serum sodium concentration increases by no more than 6 to 12 mEq/L (mmol/L) or 0.5 to 1 mEq/L/h (mmol/L/h) over the initial 24 hours. Rate depends on patient status.
2. Hold thiazide diuretic until volume status is restored.
3. Consider restarting diuretic at lower dose, for example, 12.5 mg once daily, if needed.

It is important to recognize that the rate of increase in the serum sodium concentration can substantially increase once hypovolemia has been corrected if infusion rates are not adjusted appropriately.[2] When the ECF volume is restored, AVP secretion will stop, and a rapid water diuresis can ensue, which can potentially result in an increase in the serum sodium concentration at a rate greater than desired. Estimation of the patient's ECF deficit at the start of therapy can be helpful. If the serum sodium concentration is observed to be increasing at a rate greater than 0.5 mEq/L/h (mmol/L/h), the infusate can be changed to 0.45% NaCl, and the infusion rate set to one that slows the rate of increase in the serum sodium concentration. In general, 0.45% NaCl should not be infused alone as this solution is hypo-osmolar (osmolality is 154 mOsm/L), and its infusion may result in red blood cell hemolysis. Most often, Dextrose 5%/0.45% NaCl is infused to provide an isotonic solution. Potassium depletion or repletion can also affect hyponatremia and its correction. One mEq (mmol) of retained potassium equals 1 mEq (mmol) retained sodium; thus, if concomitant hypokalemia is corrected at the same time as the hyponatremia, too rapid correction of hyponatremia can occur.[2]

Evaluation of Therapeutic Outcomes

Patients presenting with evidence of volume depletion should be reexamined frequently during the initial few hours of therapy. The serum sodium concentration should be measured every 2 to 4 hours to allow timely adjustment of the rate and composition of IV fluids to avoid too rapid increase in the serum sodium concentration. In patients with a history of HF or kidney insufficiency, 0.9% NaCl should be administered judiciously with frequent cardiopulmonary assessments so that the infusion rate can be appropriately decreased at the earliest sign of pulmonary congestion.

NONEMERGENT EUVOLEMIC HYPOTONIC HYPONATREMIA

The fact that an individual's neurological performance is restored to normal with correction of hyponatremia provides a rationale for therapeutic management of all patients to maintain their serum sodium concentration at or above 130 mEq/L (mmol/L), if possible. Long-term management is thus required for patients in whom the underlying cause of hyponatremia is not readily correctable.

The treatment of SIADH always involves restricting water and correcting the underlying cause (see Table 49-2). Drugs that could be contributing should be identified and discontinued. The goal of treatment is to induce negative water balance by restricting water intake to less than 1,000 to 1,200 mL/day, such that water losses from insensible sources (skin and lung) and from obligate urine and stool losses exceed intake. Daily insensible water losses via skin and lungs are approximately 900 mL/day; whereas approximately 200 mL and a minimum of 500 mL/day is lost in stool and urine, respectively. Because approximately 850 mL of water per day is ingested in food, and an additional 350 mL are generated from oxidative processes, this degree of water restriction should result in a negative water balance of several hundred milliliters per day. Other therapy goals include keeping the serum sodium concentration between 125 and 130 mEq/L (mmol/L) to prevent symptoms of hypotonicity and avoiding iatrogenic hypo- or hypervolemia.

Patients with chronic SIADH who are unable to restrict water sufficiently to maintain the serum sodium between 120 and 125 mEq/L (mmol/L) can be treated by increasing solute intake with NaCl and/or administration of a loop diuretic. NaCl tablets increase the obligatory daily solute excretion, which augments the kidney's capacity for water excretion. The goal is to increase the daily solute intake and excretion to approximately 900 mOsm (mmol) per day. Because an average diet contains approximately 600 mOsm (mmol), 9 g of NaCl would be required to increase the osmolar excretion to 900 mOsm/day (mmol/day) (each 1 g NaCl tablet contains 17 mmol of sodium and 17 mmol of chloride). Because ECF volume expansion is an expected adverse effect, a loop diuretic should be administered concurrently to avoid pulmonary and peripheral edema. Loop diuretics will also enhance water excretion by limiting the formation of the medullary concentration gradient.

Demeclocycline is a treatment option in patients with SIADH whose serum sodium concentration is not adequately controlled by water restriction alone or as an alternative to water restriction. Demeclocycline, a semisynthetic tetracycline antibiotic, essentially causes nephrogenic diabetes insipidus by inhibiting tubular AVP activity, resulting in increased free water excretion. The use of demeclocycline in SIADH is largely based on clinical experience rather than data from clinical trials.[41] The usual demeclocycline dosage is 300 mg given orally two to four times daily. Because of its delayed onset of action (3-6 days), this agent has no role in the acute management of severe hyponatremia, and dosage adjustments should be made no more frequently than every 3 to 4 days.[42] Demeclocycline should not be used in patients with liver disease or compromised fluid intake, who are at high risk for demeclocycline-induced renal tubular toxicity and acute kidney failure,[42,43] in children younger than 8 years because it can interfere with tooth and bone development, and in pregnant women.

The usual therapeutic options of water restriction, loop diuretic, and increased sodium intake have

recently been augmented with the introduction of the vaptans. These agents can be used to treat SIADH, as well as other causes of euvolemic and hypervolemic hypotonic hyponatremia.[42,44,45,46,47,48,49]

Blockade of AVP binding can occur at one or more of its three distinct receptors: V1, predominantly found in the liver, CNS, and cardiomyocytes; V2, located in the distal nephron; and V3, located in the anterior pituitary and pancreas. Selective V2-receptor antagonism prevents aquaporin-2 water channel transport to the apical surface, thereby decreasing AVP-dependent water reabsorption in the collecting duct. The inhibition of AVP activity leads to excretion of large volumes of water, decreased urine osmolality, and thus an increase in the serum sodium concentration.[4] These positive outcomes are achieved without significantly increasing electrolyte excretion; thus, these agents also have been called "aquaretics." Vaptans are not effective in patients with stage 4 or 5 chronic kidney disease.[49] New compounds are being investigated, but only two vaptans are currently marketed in the United States.

Conivaptan (Vaprisol®, Astellas Pharma US, Inc., North Brook, IL), a mixed vasopressin V1- and V2-receptor antagonist, is FDA-labeled for use in the treatment of acute euvolemic and hypervolemic hyponatremia in hospitalized patients. Its utility in the treatment of chronic hyponatremia is limited because it is only available as an IV formulation, is a moderate CYP3A4 inhibitor, and is not FDA-labeled for use in patients with HF.

Tolvaptan (Samsca®, Otsuka Pharmaceutical Co, Ltd, Tokyo, Japan) is an oral, nonpeptide selective AVP V2-receptor blocker with a greater affinity for the V2 receptor than endogenous AVP. It is FDA-labeled for use in the treatment of clinically significant (serum sodium concentration less than 125 mEq/L [mmol/L]) euvolemic or hypervolemic hyponatremia or less marked symptomatic hyponatremia that is unresponsive to other therapeutic interventions in patients with HF, cirrhosis, and SIADH. It appears to be safe and effective when given alone at promoting aquaresis and raising serum sodium concentration by 3.6 mEq/L (mmol/L) at 4 days and 4.4 mEq/L (mmol/L) at 30 days in both short- and intermediate-term studies (SALT-1 and SALT-2), respectively.[46,50] However, the average fluid intake was approximately 2 L per day for patients in these studies which may have limited tolvaptan's efficacy. The percent of patients with normal serum sodium concentrations (greater than 135 mEq/L [mmol/L]) at one month was 53% (SALT-1) and 58% (SALT-2) for tolvaptan versus 25% (both studies) for placebo. When used alone, tolvaptan appears to be superior to furosemide or water restriction, and when given in combination with furosemide, synergistic effects have been noted.[51] Approximately 15% of patients do not significantly respond to vaptan therapy.[52] Therapeutic resistance or failure with vaptan therapy could be due to high circulating AVP concentrations, AVP-independent impaired urinary dilution, excessive water intake, or an activating V2-receptor mutation causing nephrogenic SIADH.[49] There are currently no pharmacogenomic data for the G protein-coupled receptor family of AVP receptors or any of the available vaptans that can be used to individualize therapy.[53]

Tolvaptan is primarily metabolized to inactive metabolites by CYP3A4 and less than 1% is eliminated unchanged in the urine; thus clinicians should avoid its use in those receiving potent CYP3A4 inhibitors (eg, ketaconazole, clarithromycin, itraconazole, ritonivir). Concomitant therapy with

P-glycoprotein inhibitors and grapefruit juice has also been noted to result in increased serum tolvaptan concentrations. For example, digoxin steady-state concentrations increased 20%, peak concentrations increased approximately 30%, and renal clearance decreased 59% when given concomitantly with tolvaptan (60 mg/day).[54] Conversely, the optimal benefits of tolvaptan therapy may not be realized and the dosage may need to be increased in patients who are receiving potent CYP3A4 inducers (eg, phenytoin, phenobarbital, St. John's Wort). Dose linearity has been observed within the therapeutic range, and based on its terminal half-life (5-12 hours after 7 days or more of therapy), minimal accumulation occurs.[55,56] The usual starting tolvaptan dosage is 15 mg given orally once daily. Tolvaptan has an oral bioavailabilty of about 56%, and its activity peaks at 2 to 4 hours after the dose. For patients who can not take tolvaptan tablets orally, the tablets can be crushed, suspended in water and administered via a nasogastric tube, but a 25% mean decrease in the tolvaptan area under the concentration-time curve has been demonstrated in healthy adults with this administration method.[57] If, after 24 hours, a greater increase in serum sodium concentration is needed, the dosage may be increased to 30 mg once daily, and after another 24 hours, to a maximum of 60 mg once daily. Tolvaptan therapy is contraindicated in those patients needing rapid correction of their serum sodium concentration, those unable to sense or respond appropriately to thirst, patients with hypovolemic hyponatremia, patients taking strong CYP3A4 inhibitors, and patients who are anuric. Vaptan use should be avoided with hypertonic saline (eg, 3% NaCl) due to the risk of too rapid and/or overcorrection of the serum sodium concentration. Among clinical trial participants who had a serum sodium concentration less than 125 mEq/L (mmol/L) at the start of tolvaptan therapy, the most common adverse events were thirst, dry mouth, weakness, constipation, hyperglycemia, and urinary frequency; although, these adverse events have rarely necessitated therapy discontinuation. Reversible hepatic transaminase elevations have also been reported. However, irreversible liver damage was reported in three patients in a large clinical trial evaluating the use of tolvaptan in patients with autosomal dominant polycystic kidney disease.[58] The dosages in this trial were two to four times higher than those used for hyponatremia and the length of therapy was longer than 30 days. As a result, the FDA issued a warning that tolvaptan should not be used for more than 30 days; should not be used by anyone with liver disease, including cirrhosis; and if any sign of liver injury occurs during therapy, it should be stopped. To reduce the ODS risk, the FDA-approved labeling includes a boxed warning stating that tolvaptan therapy should begin or resume only in a hospital where the patient's serum sodium concentration can be closely monitored. A medication guide is included in the package insert given to all patients with each prescription.

The vaptans have dramatic effects on water excretion, and the marketing of tolvaptan represented the first significant breakthrough in the therapy of hyponatremia and disorders of fluid homeostasis since the introduction of loop diuretics. However, the role of vaptans in the clinical management of patients with SIADH and HF is still unclear, especially given their high cost.[49] It is still unknown if vaptans decrease length of hospitalization, rehospitalization rates, morbidity, or increase quality of life. The association between copeptin peptide concentrations and tolvaptan response was recently investigated in patients with HF and may help determine the most appropriate patients for vaptan use.[59,60]

Evaluation of Therapeutic Outcomes

The serum sodium concentration should be measured every 24 to 48 hours after water restriction is initiated until it stabilizes at a concentration at or above 125 mEq/L (mmol/L). A continued decline in the serum sodium concentration would indicate either nonadherence to the prescribed water restriction or the need for stricter restriction. Serum sodium concentration should be monitored every 4 hours after tolvaptan administration. When the serum sodium has increased by 6 to 8 mEq/L (mmol/L), oral water or IV Dextrose 5% in water (D_5W) should be given to replace urine output to minimize the risk of overcorrecting the serum sodium concentration and development of ODS. In the SALT trials, only 1.8% of patients exceeded the daily limit for changes in serum sodium; however, most of the patients had serum sodium concentrations greater than 130 mEq/L (mmol/L) and were protected from overcorrection by thirst, so the risk of sodium overcorrection in clinical practice may be greater.[46] Once the serum sodium concentration is stable at 125 mEq/L (mmol/L) or higher, the patient should be evaluated every 2 to 4 weeks to assess neurologic status and to obtain serum and urine sodium, potassium, and osmolality. Volume status assessments (eg, blood pressure, mucous membranes, skin turgor, and heart and lung examination) should also be done, particularly in patients who are being treated with NaCl tablets and/or loop diuretics.

NONEMERGENT HYPERVOLEMIC HYPOTONIC HYPONATREMIA

The initial treatment goals for patients with asymptomatic or minimally symptomatic hypotonic hyponatremia and an expanded ECF volume include achieving a negative water balance while minimizing rapid changes in cell volume until the serum sodium concentration is at or above 125 mEq/L (mmol/L). Management involves correction of the underlying cause, when possible, as well as water restriction to an intake of less than 1,000 to 1,200 mL/day. Additionally, dietary sodium intake should be restricted to 1,000 to 2,000 mg/day, depending on the degree of ECF volume expansion and edema.

The severity of hypervolemic hypotonic hyponatremia is directly related to the severity of HF and is associated with poorer short- and long-term prognoses once serum sodium concentrations fall below 137 mEq/L (mmol/L).[61,62] Patients with hypervolemic hypotonic hyponatremia caused by HF should be treated with measures that can potentially improve cardiac contractility and effective circulating volume, thereby limiting nonosmotic AVP release. Therapeutic options include digitalis or afterload reduction with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs). Of these, only ACEIs have been shown in clinical trials to be of benefit in partially correcting hyponatremia in patients with HF[63]; however, correction of sodium with ACEIs has not been shown to lead to better outcomes.[64] No specific ACEI offers any particular advantage for this indication, and the dosage should be titrated to keep the systolic blood pressure between 100 and 130 mm Hg. Dose-limiting adverse effects of ACEIs include hyperkalemia (serum potassium concentration greater than 5.5 mEq/L [mmol/L]) and impaired kidney function. The benefits and risks of continuing ACEI use must be weighed carefully in each case, but a decrease in glomerular filtration rate (GFR) of less than 30% that stabilizes within 2 months of beginning ACEI therapy generally does not require ACEI dosage reduction or discontinuation.[61]

Other potentially treatable causes of asymptomatic hyponatremia associated with an expanded ECF

volume include nephrotic syndrome and cirrhosis. ACEIs can be used to decrease proteinuria in patients with nephrotic syndrome, leading to partial correction of hypoalbuminemia and to a decrease in nonosmotic AVP release. Patients with advanced cirrhosis can benefit from placement of a transjugular intrahepatic portosystemic shunt, which can increase the effective circulating volume and thus reduce nonosmotic AVP release. This procedure can potentially exacerbate or precipitate hepatic encephalopathy and should be avoided in patients with a history of encephalopathy.

Vaptans have also been used for the treatment of hypervolemic hypotonic hyponatremia in patients with HF or cirrhosis.[44,46,65,68] As previously mentioned, an FDA warning was issued regarding the use of tolvaptan in patients with liver dysfunction due to the potential for further liver injury.[58] Conivaptan would not be an ideal choice for patients with cirrhosis due to its mixed antagonism of the V1 and V2 receptors. Blockade of the V1 receptor in such patients may worsen hypotension, increase bleeding risk, and compromise kidney function.[68] The effectiveness of tolvaptan in the short-term management of HF patients with hypervolemic hyponatremia has been evidenced by decreased body weight, increased urine output, decreased pulmonary capillary wedge pressure, and decreased urine osmolality.[69,70,71,72,73,74] Long-standing beneficial effects, reduction in hospitalization or death, or slowed progression of HF have not been observed in several pivotal trials, and the recommended duration of tolvaptan use is only 30 days.[71,73,74,75] Prolonged tolvaptan use leads to increased endogenous AVP concentration, and this overstimulation of V1A receptors could lead to increased afterload and HF progression.[76] However, no worsening of left ventricular dilatation has been observed after 52 weeks of tolvaptan therapy (30 mg daily).[75] The 2013 American College of Cardiology Foundation/American Heart Association (ACCF/AHA) guidelines recommend short-term use of vaptans in hospitalized patients who have volume overload and persistent severe hyponatremia and who are at risk for or having cognitive symptoms despite fluid restriction and optimization of guideline-directed medical therapy.[77]

Clinical Controversy…

Despite FDA labeling, tolvaptan may be considered in patients with end stage liver disease who are awaiting liver transplantation in order to normalize serum sodium concentrations. The benefit of avoiding rapid perioperative correction of hyponatremia outweighs the likely negligible effect of tolvaptan-related hepatotoxicity in such patients. Additonally, it is reasonable to continue treatment until liver transplantation even if beyond 30 days.

Evaluation of Therapeutic Outcomes

Patients being treated for hypervolemic hypotonic hyponatremia should initially be evaluated on a daily basis for lung congestion, ascites, peripheral edema, and signs or symptoms of hyponatremia. The serum sodium concentration should be measured daily until it stabilizes at or above 125 mEq/L (mmol/L) following initiation of water restriction. If vaptan therapy is initiated, serum sodium concentrations should be monitored every 4 hours to minimize sodium overcorrection and the development of ODS. Patients should be assessed 1 week following discharge, and then every 2 to 4 weeks to assess compliance with water restriction and other treatment measures, volume status, and hyponatremia-related symptoms.

HYPERNATREMIA

Epidemiology and Etiology

Hypernatremia, defined as a serum sodium concentration greater than 145 mEq/L (mmol/L), is always associated with hypertonicity and cellular dehydration, resulting from a deficit of water relative to ECF sodium content. This hypertonic state is a potent stimulus for AVP secretion and activation of the thirst mechanism. Therefore, hypernatremia is most commonly observed in patients with an impaired thirst response or in those who can not access water. Young infants and children, intubated mechanically ventilated patients or comatose patients, the elderly, and disabled patients with an impaired sensorium or functional status are therefore at highest risk for this disorder.[78] Hypernatremia generally occurs in sicker patients and has a higher mortality.[79] The incidence of hypernatremia in general medical–surgical hospitalized patients and patients in ICUs has been estimated to be at least 1% and as high as 26%, respectively.[10,80,81,82,83] In 92% of 130 ICU cases in a matched case–control study, hypernatremia was iatrogenic: the result of too little free water and too much hypertonic solution along with increased renal water loss.[84]

Clinical outcomes in patients with hypernatremia, as in hyponatremia, depend on the severity of the increase and the rapidity with which it developed. In children, mortality from acute hypernatremia developing in less than 72 hours ranges from 10% to 70%. In contrast, chronic hypernatremia, defined as that which develops over 3 or more days, has a mortality rate of only 10%.[85] In adults, an acute increase in serum sodium concentration to greater than 160 mEq/L (mmol/L) is associated with a 75% mortality rate. In contrast to children, adults in whom hypernatremia develops at a slower rate still have a high mortality rate of approximately 60%.[38] Hypernatremia in adults is often associated with a serious underlying illness, which likely contributes to the higher mortality rate.

Pathophysiology

Hypernatremia most often results from water loss by either renal or extrarenal mechanisms. Hypernatremia can also result from administration of hypertonic or isotonic fluids or excess sodium ingestion. Patients develop hypovolemic, hypervolemic, or isovolemic hypernatremia depending on the relative magnitude of sodium and water loss or gain caused by the underlying condition (**Table 49-7**).

TABLE 49-7 Characteristics of Hypernatremic States

Characteristics	Hypovolemic Hypernatremia	Euvolemic (Isovolemic) Hypernatremia	Hypervolemic Hypernatremia
Water and sodium	Water loss >> sodium loss	Water loss only	Sodium gain > water gain
Causes	Renal: osmotic diuresis, diuretic use,	Congenital or acquired DI	Sodium overload (eg, 3% NaCl, sodium bicarbonate, salt tablets,

Characteristics	Hypovolemic Hypernatremia	Euvolemic (Isovolemic) Hypernatremia	Hypervolemic Hypernatremia
	postoperative diuresis, high-output acute tubular necrosis	Nephrogenic DI Primary polydipsia	concentrated tube feedings, hypertonic dialysate, sodium-containing medications)
Effect on TBW	↓↓	↓	↑
Effect on TBNa	↓	↔	↑↑
Laboratory findings in addition to hypernatremia	Renal: UOsm high, UNa high Non-renal: UOsm high, UNa low	Renal: UOsm low, UNa variable Non-renal: UOsm high, UNa variable	UOsm high, UNa high
Clinical presentation	Orthostasis, hypotension, tachycardia, dry mucous membranes	Depends on severity of hypernatremia; seizures, lethargy	Peripheral and pulmonary edema, variable blood pressure
Treatment	0.9% NaCl until vital signs stable, then free water replacement	Free water replacement, AVP, AVP analogue	Free water replacement with loop diuretic; may require hemodialysis to remove volume

DI, diabetes insipidus; TBW, total body weight;

Water loss commonly occurs as a result of insensible losses (evaporative water loss through the skin and lungs) in patients deprived of water. Hospitalized patients who are febrile or receiving mechanical ventilation are often treated with IV fluids containing insufficient free water to replace insensible losses. Hypernatremia can be observed in patients with hypotonic GI losses (diarrhea, vomiting, gastric suctioning) or in patients who have been exposed to high temperatures who suffer large water losses from both sweat and insensible losses.

A water diuresis can also be caused by diabetes insipidus (DI), which can be classified as either central DI (decreased AVP secretion) or nephrogenic DI (decreased kidney response to AVP). Patients with untreated DI excrete large volumes (3-20 L/day) of dilute urine, resulting in hypernatremia. Possible causes of DI are listed in **Table 49-8**.

TABLE 49-8 Causes of DI

Central	Nephrogenic
Familial[a]	Familial
Unreplaced insensible losses • Skin • Lung	• Inherited aquaporin-2 defect • Inherited vasopressin V2-receptor defect Hypercalcemia (chronic)

Central	Nephrogenic
Hypodipsia Neurogenic • Neurosurgery • Tuberculosis • Head trauma • CNS malignancy/cyst • Hypoxic encephalopathy • Ethanol ingestion (transient) • Sarcoidosis • Sheehan syndrome[b]	Hypokalemia Kidney disease Drug-induced • Cidofovir • Lithium toxicity • Amphotericin B • Demeclocycline • Foscarnet • Ifosfamide • Vaptans • Methoxyflurane

AVP, arginine vasopressin; CNS, central nervous system; DI, diabetes insipidus.

[b]Postpartum hypopituitarism caused by severe bleeding during childbirth.

Hypertonic NaCl administration can result in hypernatremia and an expanded ECF volume. This type of hypernatremia is typically iatrogenic and can follow excess sodium bicarbonate administration, use of hypertonic NaCl enemas, or intrauterine injection of hypertonic sodium chloride. Normal ECF osmolality is 275 to 290 mOsm/kg (mmol/kg); whereas these *isotonic* solutions, Lactated Ringer's and 0.9% NaCl, are 273 mOsm/kg (mmol/kg) and 308 mOsm/kg (mmol/kg), respectively (see Table 49-1). Excessive 0.9% NaCl infusions may lead to sodium accumulation, particularly if a dilute urine is excreted.[86] Patients with hyperaldosteronism rarely present with an expanded ECF and mild hypernatremia. A common cause of hypernatremia in the ICU patient is sodium intake from IV and enteral fluids and medications.[79,87] Sodium balance should be carefully monitored in critically ill patients to avoid iatrogenic hypernatremia.

Clinical Presentation

Hypernatremia results in movement of water from the ICF to the ECF. Patients with central DI often present with sudden onset of polyuria, whereas patients with nephrogenic DI develop polyuria more gradually. Symptoms seen in patients with hypernatremia are similar to those seen with

hyponatremia and primarily due to decreased neuronal (brain) cell volume. Symptoms of mild to moderate hypernatremia (hypertonicity) include weakness, lethargy, restlessness, irritability, twitching, and confusion. More severe or rapidly developing hypernatremia can lead to seizures, coma, and/or death. As discussed in the hyponatremia section, neurons adapt to ECF tonicity changes by decreasing or increasing the concentration of inorganic (potassium, chloride) and organic (glutamate, taurine, and myoinositol).[3,33] ECF hypertonicity results in generation of intracellular organic osmolytes within 24 hours of onset leading to an increase in ICF tonicity that then draws water into brain cells, limiting the decrease in cell volume. Patients with chronic hypernatremia are therefore less likely to present with symptoms compared to patients with acute hypernatremia.

CLINICAL PRESENTATION Hypernatremia General

- Increase in serum sodium concentration and osmolality causes acute water movement from the ICF to the ECF.
- Decreased volume in the brain can cause cerebral vein rupture, leading to focal intracerebral and subarachnoid hemorrhages and possible irreversible neurologic damage.

Symptoms

- Mild: Lethargy, weakness, confusion, restlessness, irritability
- Moderate: Twitching
- Severe: Seizures, coma, death; usually requires an acute elevation in the plasma sodium concentration to 160 mEq/L (mmol/L) or higher
- Serum sodium concentrations greater than 180 mEq/L (mmol/L) are associated with a high mortality rate
- Other symptoms depend on etiology of hypernatremia: postural hypotension, tachycardia, dry mucous membranes, diminished skin turgor, reduced or increased urine output
- Signs and symptoms may be difficult to detect because many patients with this condition have underlying neurologic disease

Laboratory tests

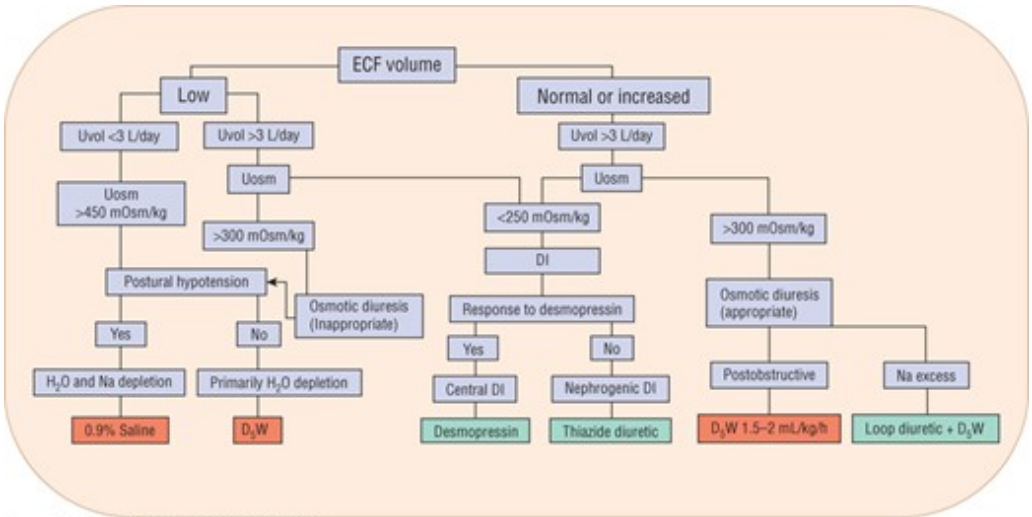
- Serum sodium concentration greater than 145 mEq/L (mmol/L)
- Urine osmolality may be helpful in diagnosing the cause

Hypernatremia is often associated with serious underlying illness, and signs and symptoms related to the illness are often present. Patients with a history of severe diarrhea or vomiting can present with ECF volume depletion. Elderly patients deprived of water after sustaining a stroke or hip fracture often present with mental status changes and other signs of ECF volume depletion. Clinically detectable ECF volume depletion, however, might not be evident until the serum sodium concentration exceeds 160 mEq/L (mmol/L) because these patients primarily have water loss,

two-thirds of which is derived from the ICF. The urine is concentrated, osmolality often exceeds 450 mOsm/kg (mmol/kg), as a result of both osmotic and nonosmotic AVP release. The first step in evaluating patients with hypernatremia is the clinical assessment of the ECF and urine volume and the serum and urine osmolality (**Fig. 49-3**). Assessment of the ECF volume status is commonly imprecise. It is important to note that volume status is not defined by just one value or number, such as blood pressure.

FIGURE 49-3

Diagnostic and treatment algorithm for hypernatremia. (D_5W, Dextrose 5% in water; DI, diabetes insipidus; ECF, extracellular fluid; H_2O, water; Na, sodium; Uosm, urine osmolality [values in mOsm/kg are numerically equivalent to mmol/kg]; Uvol, daily urine volume.) See the text for guidelines regarding calculations of infusion rates for IV solutions.



Patients with a contracted ECF volume and a low urine output include those who have sustained insensible water losses that exceed intake, as well as those with extrarenal losses of hypotonic fluids. On physical examination, the patient will have postural hypotension, diminished skin turgor, and delayed capillary refill. Lactic acidosis and low mixed venous oxygen saturation, indicating decreased tissue perfusion, may be present. The daily urine output is typically less than 1 L.

A multicenter, case–control study examined the clinical presentation of hypernatremia in 150 elderly patients in geriatric care facilities.[88] Low blood pressure, tachycardia, dry oral mucosa, decreased skin turgor, and recent changes in consciousness were all more common in patients with hypernatremia than in controls. In this patient population, the presence of signs of dehydration was variable, with orthostatic hypotension and decreased subclavicular and forearm skin turgor present in at least 60% of patients. Abnormal subclavicular and thigh skin turgor, dry oral mucosa, and recent change in consciousness were significantly and independently associated with hypernatremia.

Osmotic Diuresis

In the presence of an ongoing osmotic diuresis, patients will have a urine volume greater than 3 L/day. Excessive urinary excretion of glucose, sodium, urea, or an exogenously administered solute (eg, mannitol) can be identified either by history or by direct measurement of serum and urinary concentrations of the suspected solute. Patients with postobstructive diuresis, such as those with bladder outlet obstruction caused by prostatic hypertrophy, are usually volume expanded as a result of retained excess solute because of a decline in the GFR. The osmotic diuresis that follows obstruction resolution is appropriate in that it promotes excretion of the excess retained solute.

Patients with severe hyperglycemia may have a measured low sodium concentration (hyponatremia) but a high corrected sodium concentration (hypernatremia). Patients with severe hyperglycemia present with signs of volume depletion, and the diuresis is inappropriate as it further exacerbates the degree of ECF volume contraction associated with hyperglycemia. The estimated (or corrected) serum sodium concentration can be calculated by adding 1.7 mEq/L (mmol/L) for every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration before estimating the water deficit (see Box 49-1).[6]

Diabetes Insipidus

Patients with DI tend to maintain a normal ECF volume as long as they are conscious and have free access to water. Patients typically have only a slight increase in the serum sodium concentration (usually 141-145 mEq/L [mmol/L]), and a daily urine volume greater than 3 L.

A water deprivation test is sometimes recommended to aid in the differential diagnosis.[38,83] This diagnostic test consists of depriving a patient of water for 8 to 12 hours in a supervised setting to avoid severe hypernatremia and volume depletion in patients with marked polyuria. Body weight and urine osmolality and volume are measured before and after administration of desmopressin acetate (4 mcg subcutaneously or intravenously or 10 mcg intranasally).[86] After desmopressin administration, patients with central DI will have a prompt increase in urine osmolality to approximately 600 mOsm/kg (mmol/kg) and a decrease in urine volume. In patients with nephrogenic DI, the urine osmolality will not increase above 300 mOsm/kg (mmol/kg).

The value of performing a water deprivation test in patients with polyuria and hypernatremia has been questioned.[87] Because hypernatremia provides a maximal stimulus for AVP secretion, discriminating between nephrogenic and central DI can be based on the serum AVP concentration and urinary response to desmopressin without the need for water deprivation. The water deprivation test is likely to be of diagnostic value only in patients with polyuria and a normal serum sodium concentration.

Sodium Overload

Patients who have ingested large amounts of sodium (more than 4 tablespoons table salt [1,400 mEq or mmol sodium]) or who have received more than 5 L of hypertonic fluids are volume expanded; although, this volume may not always be clinically evident as edema. Volume expansion results in an osmotic diuresis, polyuria, and a urine osmolality greater than 300 mOsm/kg (mmol/kg). The excess

sodium will be excreted in the urine in patients with normal perfusion and kidney function; with organ dysfunction, volume expansion will occur.

Clinical Controversy…

The relative merits of the various drug treatment options, including thiazides and nonsteroidal anti-inflammatory drugs (NSAID), for nephrogenic DI have not been well studied. The choice of agent is therefore subject to clinician preference. It is unclear if there is a significant difference among these agents in the risk of clinically important decreases in GFR when they are used to produce a mild ECF volume deficit.

TREATMENT

Desired Outcomes

Treatment goals for patients with hypernatremia include correcting the serum sodium concentration to 145 to 150 mEq/L (mmol/L) at a rate that restores and maintains brain cell volume as close to normal as possible and normalizing the ECF volume, if indicated. Adequate treatment should result in the resolution of symptoms associated with hypovolemia, but hypernatremia is often undertreated in adults. Although inadvertent overcorrection is more common with hyponatremia, careful titration of fluids and medications should minimize the adverse effects from too rapid correction of the serum sodium concentration. Rapid correction can result in movement of excessive water into brain cells, resulting in cerebral edema, seizures, neurologic damage, and potentially death. However, these complications have almost exclusively been reported in young children with chronic hypernatremia of at least 48 hours duration and serum sodium concentrations greater than 150 mEq/L (mmol/L).[3] Water replacement and dietary sodium restriction can be necessary to prevent recurrence of hypernatremia.

Physical examination with attention to volume status and measurement of serum and urine sodium concentrations and osmolalities should be completed every 2 to 3 months during chronic therapy. A 24-hour urine collection to measure urine volume and sodium excretion will help guide therapy with diuretics and determine adherence to sodium restriction.

Pharmacologic Therapy

Hypovolemic Hypernatremia

8 Patients with hypovolemic hypernatremia should be treated initially with 0.9% NaCl until hemodynamic stability is restored. An initial infusion rate of 200 to 300 mL/h will likely be appropriate for most adults; children generally receive 10 to 20 mL/kg/h. Once intravascular volume is restored, 0.45% NaCl, D_5W, or another hypotonic fluid, can be infused to correct the water deficit. In patients with hypernatremia from water loss, the ECF volume deficit can be estimated as:

$$\text{ECF (water) deficit} = TBW_{current} \times [1 - (140/Na_{S1})]$$

where Na_{S1} is the initial serum sodium concentration (in mEq/L [mmol/L]); and 140 is the normal or goal serum sodium concentration in mEq/L (mmol/L). Although this formula provides an estimate of the water deficit caused by pure free water loss, it underestimates the deficit in patients with hypotonic fluid loss.[2]

The appropriate correction rate depends on the rapidity with which the hypernatremia developed. Hypernatremia developing in only a few hours can be initially corrected at a rate of approximately 1 mEq/L (mmol/L) per hour, whereas a rate of 0.5 mEq/L (mmol/L) per hour or less should be used when hypernatremia has developed more slowly.[2,3,28] The correction should generally be limited to no more than 10 to 12 mEq/L (mmol/L) per day.[2,3,37] Renal replacement therapy may be initiated for severe cases in patients with kidney failure. NaCl should be added to the replacement fluid/dialysate to achieve the same sodium content as the goal serum sodium concentration in order to avoid rapid overcorrection and cerebral edema.[79]

The serum sodium concentration and fluid status should be monitored every 2 to 3 hours during the first 24 hours of treatment in patients with symptomatic hypernatremia to permit appropriate adjustment of the hypotonic fluid infusion rate. After symptoms resolve and the serum sodium concentration is less than 148 mEq/L (mmol/L), assessing serum sodium concentrations every 6 to 12 hours and fluid status every 8 to 24 hours is generally adequate.

Recurrent iatrogenic hypernatremia can be prevented by avoiding infusing too much hypertonic solution, providing adequate amounts of maintenance fluids, and replacing ongoing abnormal losses. The standard maintenance fluid for adults and children weighing 40 kg or more is Dextrose 5%/0.45% NaCl with 20 mEq (mmol) KCl/L. Children weighing less than 40 kg typically receive Dextrose 5%/0.2% NaCl with 20 mEq (mmol) KCl/L, except infants younger than 3 months who may receive Dextrose 10%/0.2% NaCl with 20 mEq (mmol) KCl/L. Estimating daily fluid requirements and calculation of an appropriate maintenance fluid rate is discussed in Chapter 141.

Treatment of hyperglycemia-induced osmotic diuresis consists of correcting the hyperglycemia with insulin, as well as administering 0.9% NaCl until signs of ECF volume depletion resolve. Once hemodynamic stability is restored, the free water deficit should be corrected as described above.

Hypernatremia in patients undergoing a postobstructive diuresis should be treated with infusion of hypotonic fluids (eg, 0.45% NaCl) at a rate of approximately 1.5 mL/kg per hour. Because this solution is hypotonic, care should be taken to avoid infusing it alone to prevent hemolysis. The common practice of administering IV or oral fluids to replace urine output on a 1:1 volume basis tends to perpetuate the diuresis and generally should be avoided. Some clinicians use a 0.5:1 volume replacement for this reason.

Central Diabetes Insipidus

9 Patients with central DI should generally receive AVP replacement therapy with desmopressin, an AVP analog.[2,28] Because of variable absorption of orally administered desmopressin, central DI is best treated with the intranasal formulation, 1-desamino-8-D-arginine vasopressin (DDAVP); however, oral

tablets are available and are useful in some patients. The initial intranasal DDAVP dosage should be 10 mcg once daily, titrated to 20 mcg twice daily based on serum sodium concentration. Each insufflation of intranasal DDAVP (100 mcg/mL) delivers 10 mcg of desmopressin acetate.[89] A rhinal tube delivery system is preferred in patients requiring doses that are not in increments of 10 mcg. Patients commonly prefer oral tablets due to the ease of administration, but not all patients adequately respond to the oral formulation. The bioavailability of DDAVP is approximately 5%. A 0.1 mg tablet is equivalent to 2.5 to 5 mcg of nasal spray but retitration is often required when transitioning between dosage forms due to the unpredictable response. Subcutaenous or IV desmopressin may be administered in cases when the intranasal and oral routes are not feasible.

The desmopressin dose should be adjusted to achieve adequate urinary concentration during sleep to prevent nocturia, a daily urine volume of approximately 1.5 to 2 L, and a normal or near normal serum sodium concentration. The mean duration of action of intranasal DDAVP is 7 to 9 hours. The serum sodium concentration should be measured at 24 hours and every 3 to 4 days during the initial dose titration period, and then every 2 to 4 months. Desmopressin administration results in nonsuppressible AVP activity and presents a risk of water intoxication with excess water retention. Patients using desmopressin should be aware of signs and symptoms of both hyponatremia and hypervolemia. Patients who experience water intoxication may minimize the risk of a second episode by delaying one desmopressin dose each week until polyuria and thirst develop, thus demonstrating the continued need for desmopressin therapy.[28]

Additionally, several medications with antidiuretic properties have been used successfully in the management of central and nephrogenic DI (**Table 49-9**). They can be used as adjunctive therapy or as an alternative to DDAVP.

TABLE 49-9 Drugs Used to Manage Central and Nephrogenic DI

Drug	Indication	Dose
Desmopressin acetate	Central and nephrogenic	5-20 mcg intranasally q 12-24 h
Chlorpropamide	Central	125-250 mg orally daily
Carbamazepine	Central	100-300 mg orally twice daily
Clofibrate	Central	500 mg orally four times daily
Hydrochlorothiazide	Central and nephrogenic	25 mg orally q 12-24 h
Amiloride	Lithium-related nephrogenic	5-10 mg orally daily
Indomethacin	Central and nephrogenic	50 mg orally q 8-12 h

DI, diabetes insipidus.

Nephrogenic Diabetes Insipidus

In patients with nephrogenic DI, concomitant hypercalcemia and hypokalemia, if present, should be corrected, and any medications that potentially contribute to the pathogenesis should be discontinued, if possible.[91,92] Because the ongoing urinary losses are essentially free water, patients with nephrogenic DI should receive hypotonic fluids to avoid excess NaCl intake and worsening

hypernatremia. Water or milk should be given enterally or, if necessary, intravenous D_5W can be given intravenously at a rate that slightly exceeds the urine output with a goal to normalize the serum sodium concentration at a rate of less than 0.5 mEq/L/h (mmol/L/h).[93] One key goal in treating nephrogenic DI is to induce a mild ECF deficit (1-1.5 L) with a thiazide diuretic and dietary sodium restriction (85 mEq [mmol] Na^+ or 2,000 mg NaCl per day), which can decrease urine volume by as much as 50% (see Table 49-9). This ECF deficit will increase proximal tubule water reabsorption, decrease the filtrate volume delivered to the distal nephron, and decrease urine volume. In a patient with a maximally dilute urine osmolality (100 mOsm/kg [mmol/kg]), each gram of salt that is avoided will reduce the obligatory urine output by 360 mL because 1 g of table salt provides an osmolar load of approximately 36 mOsm.[93] Indomethacin, 50 mg given orally three times daily, potentiates AVP activity and can be used as adjunctive therapy in patients able to tolerate the GI side effects.

Sodium Overload

Treatment of sodium overload consists of administration of D_5W and a loop diuretic to facilitate excretion of the excess sodium. The infusate volume needed to correct the water deficit and hypernatremia at an appropriate rate can be estimated as described previously. Furosemide, 20 to 40 mg given intravenously every 6 hours, should also be administered.

The serum sodium concentration should initially be measured at least every 2 to 4 hours, and the diuretic continued until signs of ECF volume overload (pulmonary congestion and edema) resolve. The serum sodium concentration can be determined every 6 to 12 hours once the serum sodium concentration is less than 148 mEq/L (mmol/L) and symptoms of hypertonicity have resolved.

EDEMA

10 The development of edema is usually due to heart, kidney, or liver failure, or a combination of these conditions; although, it can develop secondary to a rapid decrease in serum albumin concentration along with excess fluid intake such as seen in the setting of burns or trauma.[94,95] Blood volume is constantly monitored to ensure adequate tissue perfusion. A decline in the effective circulating volume (actually the blood pressure resulting from that volume) results in decreased kidney sodium and water excretion. Under these conditions, the kidneys retain all the water and sodium ingested until the effective circulating volume is restored to near normal. An increase in dietary sodium is accompanied by an increase in water intake caused by the initial increase in serum osmolality and stimulation of thirst. The resultant increase in ECF volume augments kidney perfusion, resulting in a transient increase in GFR which leads to enhanced sodium filtration and excretion. These homeostatic mechanisms are crucial for maintaining sodium balance, as retention of just a few milliequivalents (millimoles) of sodium per day can eventually lead to an expanded ECF volume and edema formation.

Pathophysiology

Edema can be defined as a clinically detectable increase in interstitial fluid volume. In adults, edema

formation is indicative of an interstitial volume increase of at least 2.5 to 3 L. Edema develops when excess sodium is retained either as a primary defect in renal sodium excretion or as a response to a decrease in the effective circulating volume despite a normal or expanded ECF volume. An increase in the capillary hydrostatic pressure because of ECF volume expansion or an increase in central venous pressure can lead to edema formation. Edema may also occur when there is an alteration in Starling forces within the capillary.[94] The Starling equation denotes the relationship between factors affecting fluid movement between the capillary and interstitium and is discussed in detail in Chapters 23 and 24.

Edema may develop rapidly in those with an acute decompensation in myocardial contractility, which leads to an elevation in pulmonary venous pressure that is transmitted back to the pulmonary capillaries and ultimately results in acute pulmonary edema. Edema may also develop insidiously as in the case of renal sodium and water retention due to diminished effective circulating volume, which leads to increased ECF volume and edema formation in both peripheral and pulmonary interstitial tissues.

Edema is the classical presentation in patients with nephrotic syndrome. There are two theories posited to explain edema in nephrotic syndrome: the *underfill* and the *overfill* hypothesis.[94] The underfill hypothesis states that decreased oncotic pressure from hypoalbuminemia (most pronounced with a serum albumin concentration <2 g/dL [20 g/L]) leads to excess filtration of fluid from the intravascular space to the interstitial space (*third spacing*) causing hypovolemia, kidney hypoperfusion, activation of the renin–angiotensin–aldosterone system, and secondary renal sodium retention. The overfill hypothesis is simply that primary renal sodium retention leads to edema. Both of these mechanisms contribute to edema formation. Distinguishing the predominant mechanism in individual patients with nephrotic syndrome is clinically important, as patients that are primarily underfilled will likely have worsening hypovolemia and an elevated serum creatinine after initially tolerating diuresis.

Patients with cirrhosis initially develop ascites as a result of splanchnic vasodilation resulting in an increase in the pressure in the portal circulation (portal hypertension). The combination of portal hypertension and splanchnic vasodilation increases capillary pressure and permeability and facilitates the accumulation of ascites (fluid in the abdominal cavity; third spacing). Ascites can cause a decrease in effective circulating ECF volume and activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system, leading to secondary hyperaldosteronism. The subsequent renal sodium retention leads to worsened ascites and edema.[94]

Clinical Presentation

Edema is usually first detected in the feet or pretibial area of ambulatory patients and in the presacral area of bed-bound individuals. Edema is described as “pitting” when a depression created by exerting pressure for several seconds over a bony prominence, such as the tibia, does not rapidly refill. Edema severity should be rated on a semi-quantitative scale of 1+ to 4+ depending on the depth of the pit: 1+ = 2 mm; 2+ = 4 mm; 3+ = 6 mm; and 4+ = 8 mm.

The extent of the edema should also be quantified according to the areas involved. Pretibial edema,

for example, should be quantified according to how far it extends up the lower leg (eg, one-third up the lower leg). Pulmonary edema, an increase in lung interstitial and alveolar water, is often evidenced by crackles (rales) upon auscultation. Rales should be quantified according to how far the crackles extend from the dependent portion of the lung(s). So, for example, edema limited to the ankles and feet would indicate less severe edema than edema that extends halfway up the lower legs, and crackles limited to the base of both lungs in an upright person would indicate less severe pulmonary edema than crackles throughout both lung fields. *Anasarca* is a term used to refer to a massive amount of edema that is generalized throughout the body.

TREATMENT

General Approach

Treatment goals for hypervolemic hypernatremia are to minimize edema and to improve organ function, as well as to relieve accompanying symptoms (eg, dyspnea, abdominal distention). Importantly, the presence of edema does not always dictate the need for pharmacologic (diuretic) therapy. Severe pulmonary edema however requires immediate pharmacologic treatment because it is life-threatening. Other forms of edema may be treated gradually, with a comprehensive approach that includes not only diuretics but also sodium and water restriction and treatment of the underlying disease. Sodium intake should generally be restricted to 1,000 to 2,000 mg/day. A slow, more judicious approach in non-life-threatening situations will help minimize complications of diuretic therapy and excessive diuresis, including impaired perfusion, azotemia, and impaired cardiac output due to a fall in the left ventricular end-diastolic filling pressure. Fluid should be removed cautiously in patients with cirrhosis and ascites but no peripheral edema. A maximum of 300 to 500 mL/day can be safely mobilized in patients with isolated ascites before the resultant decreased serum volume leads to elevated BUN and possibly hepatorenal syndrome.[96]

Pharmacologic Therapy

11 Diuretics are the primary pharmacologic therapy for edema when treatment of the underlying disease and sodium and water restriction are insufficient. Diuretics can be categorized according to the site in the nephron where sodium reabsorption is inhibited. Loop diuretics (furosemide, bumetanide, torsemide and ethacrynic acid) inhibit the sodium–potassium–chloride (Na^+–K^+–$2Cl^-$) carrier in the loop of Henle, while thiazide diuretics (hydrochlorothiazide, chlorothiazide, chlorthalidone, and metolazone) inhibit the Na^+–Cl^- carrier in the distal tubule. Potassium-sparing diuretics inhibit the sodium channel in the cortical collecting duct either directly (triamterene and amiloride) or by interfering with aldosterone activity (spironolactone and eplerenone). A diuretic's efficacy in edema therapy depends on: the amount of filtered sodium normally reabsorbed at its site of action; the amount of sodium reabsorbed distal to its site of action; adequate drug delivery to the site of action; and the amount of sodium reaching the site of action.

All diuretics act by inhibiting sodium reabsorption in the renal tubules; thus they increase fractional excretion of sodium (FeNa). Loop diuretics are the most potent diuretics, as evidenced by the fact that they increase peak FeNa from normal (1% [0.01] or less) to 20% to 25% (0.20-0.25). Thiazide- and

potassium-sparing diuretics are less potent and increase peak FeNa only to 3% to 5% (0.03-0.05) and 1% to 2% (0.01-0.02), respectively.[25] Although a large portion of the filtered sodium is reabsorbed in the proximal nephron, the efficacy of proximal-acting diuretics (eg, acetazolamide) is limited by excess fluid and sodium reabsorption in the loop of Henle. Furthermore, sodium reabsorption by the distal tubule can compensate for reduced reabsorption in the loop of Henle when sodium intake is high.

The pharmacogenomics of diuretic therapy, particularly the thiazides, have been studied extensively in the area of hypertension therapy.[97,98] Multiple variants involving the different diuretic sites of action have been identified, but no clinically significant differences in outcomes have been demonstrated in large randomized studies.[99] Perhaps a more complex predictive model utilizing pharmacodynamic as well as pharmacokinetic and pharmacogenomic information will be necessary to predict significantly different responses and outcomes due to the potential for compensatory mechanisms in other parts of the nephron.[94] Genetic testing is currently not a practical option to guide diuretic treatment because there are no commercially available tests that identify these gene variants.

The effectiveness of thiazide and loop diuretics is dependent on drug concentrations in the tubular lumen. These diuretics are delivered to the tubular lumen via active transport by the proximal tubular cells. Osmotic diuretics are freely filtered into the tubular lumen in the proximal tubule; whereas, spironolactone gains access to mineralocorticoid receptors in the cortical collecting duct through diffusion from the systemic circulation.

A threshold concentration of loop or thiazide diuretic must be delivered to the respective site of action to achieve a natriuresis.[25] Once this threshold concentration is achieved, a further diuretic dose increase will not elicit an increase in diuretic response. Thus, a "ceiling dose" for these diuretics is recognized. Administration of 40 mg of furosemide intravenously to a normal subject will result in excretion of 200 to 250 mEq (mmol) of sodium in 3 to 4 L of urine over a 3- to 4-hour period.[25]

Loop diuretics, except torsemide, have a rapid action but short half-life requiring administration every 2 to 3 hours while thiazide diuretics have a longer half-life allowing for less frequent (once daily) dosing (**Table 49-10**). **Table 49-11** lists the maximal effective doses and dosing intervals for loop diuretics in patients with cirrhosis, HF, nephrotic syndrome, and those with reduced kidney function.

TABLE 49-10 Characteristics of Thiazide Diuretics

Diuretic	Duration of Action	Initial Daily Dose(s)	Sequential Nephron Blockade	Maximum Total Daily Dose
Chlorothiazide	6-12 h	250-500 mg once or twice	500-1,000 mg once plus loop diuretic	1,000 mg
Chlorthalidone	24-72 h	12.5-25 mg once		100 mg
Hydrochlorothiazide	6-12 h	25 mg once or twice	25-100 mg once or twice plus loop diuretic	200 mg
Indapamide	36 h	2.5 mg once		5 mg

Diuretic	Duration of Action	Initial Daily Dose(s)	Sequential Nephron Blockade	Maximum Total Daily Dose
Metolazone	12-24 h	2.5 mg once	2.5-10 mg plus loop diuretic	20 mg

TABLE 49-11 Characteristics of Loop Diuretics

Diuretic	Dosing Interval	Normal	Cirrhosis	HF	Nephrotic Syndrome	GFR 10-50 mL/min [0.17-0.83 mL/s]	GFR <10 mL/min (<0.17 mL/s)	Maximum Total Daily Dose
Furosemide								
IV	6-8 h	10-40 mg	40 mg	40-80 mg	120 mg	80 mg	200 mg	200 mg or 160 mg/h
Oral	6-8 h	20-80 mg	80 mg	80-160 mg	240 mg	160 mg	320-400 mg	600 mg
Bumetanide								
IV/oral	6-8 h	1 mg	1 mg	2-3 mg	3 mg	2-3 mg	8-10 mg	10 mg
Torsemide								
IV/oral	24 h	15-20 mg	10-20 mg	20-50 mg	50 mg	20-50 mg	50-100 mg	200 mg

HF, heart failure; GFR, glomerular filtration rate.

[a]Although these doses are considered maximal doses, higher doses may be required due to insufficient quantities in the renal tubular fluid.[73]

Patients with kidney insufficiency often require larger diuretic doses to achieve adequate drug concentrations at the site of action. The natriuretic response is decreased in patients with kidney insufficiency because the filtered sodium load falls proportionately as GFR declines. This decrease in the GFR can be partially overcome by administering diuretics more frequently or by using a continuous infusion, a method commonly used in critically ill patients. The latter will limit the effect of postdiuretic sodium retention in the distal nephron. **Table 49-12** lists initial continuous infusion rates based on creatinine clearance and maximum infusion rates.

TABLE 49-12 Continuous Infusion Rates for Loop Diuretics

Drug	Initial Infusion Rate based on Creatinine Clearance			Maximum Infusion Rate	
	<25 mL/min (<0.42 mL/s)	25-75 mL/min (0.42-1.25 mL/s)	>75 mL/min (>1.25 mL/s)	Undiluted Bolus	Continuous Infusion
Bumetanide	1-2 mg/h	0.5-1 mg/h	0.5 mg/h	5 mg/min	0.17 mg/min[a] (up to 5 mg)
Furosemide	20-40 mg/h	10-20 mg/h	10 mg/h	40 mg/min	4 mg/min

Drug	Initial Infusion Rate based on Creatinine Clearance			Maximum Infusion Rate	
Torsemide	10-20 mg/h	5-10 mg/h	5 mg/h	100 mg/min	3.1 mg/h[b]

[a]Doses of 2 to 5 mg may be given over 30 to 60 minutes in 500 mL of a suitable infusion fluid.

[b]Studies used a 100-mg total daily dose as a 25-mg injection over 2 minutes (25% of total daily dose) followed by an infusion of 3.1 mg/h over 24 hours (75% of total daily dose).

Loop diuretic resistance can be caused by pronounced sodium reabsorption in the distal nephron when sodium absorption in the loop of Henle is blocked. If sodium intake is not restricted, this distal sodium reabsorption can compensate entirely for loop-diuretic induced sodium loss. Patients with diuretic-resistant edema can be treated with both a loop diuretic and metolazone, a thiazide-type diuretic. Metolazone should be given first and allowed sufficient time to start blocking distal sodium reabsorption in order to maximize the loop diuretic's efficacy. Another mechanism of diuretic resistance is impaired diuretic delivery to the site of action. Patients with HF and a normal GFR may have impaired oral furosemide absorption. An adequate diuresis is most readily sustained by increasing the frequency of diuretic administration, but a higher dose may also be effective (**Fig. 49-4**). Absorption of orally administered loop diuretics can be compromised by GI edema and delayed gastric emptying, conditions often seen in critically ill patients. Inadequate drug concentrations at the site of action can also be caused by decreased perfusion as might be seen in patients with decompensated HF or those with decreased kidney perfusion. Due to extensive albumin binding (more than 95%), very little of these agents reach the tubule lumen by filtration, and they are almost exclusively transported into the proximal tubule lumen by active secretion via the organic acid secretory pathway.[25] Human studies, however, have demonstrated that when albumin binding is inhibited by concurrent sulfasoxazole administration, diuretic resistance persists, suggesting a decrease in intrinsic tubular sensitivity to loop diuretics.[100] This impaired natriuretic response can be overcome by using higher diuretic doses to increase unbound drug delivery to the secretory site in the nephron.[101] Decreased intrinsic diuretic activity with repeated dosing may also play a role in the development of diuretic resistance. Whether this is mediated by the first two mechanisms or as a mechanism to prevent hypovolemia is not well understood. Combinations of loop diuretics with distally acting diuretics are generally necessary to promote a natriuresis that exceeds distal tubular sodium reabsorption for those with nephrotic syndrome (**Fig. 49-5**).

FIGURE 49-4

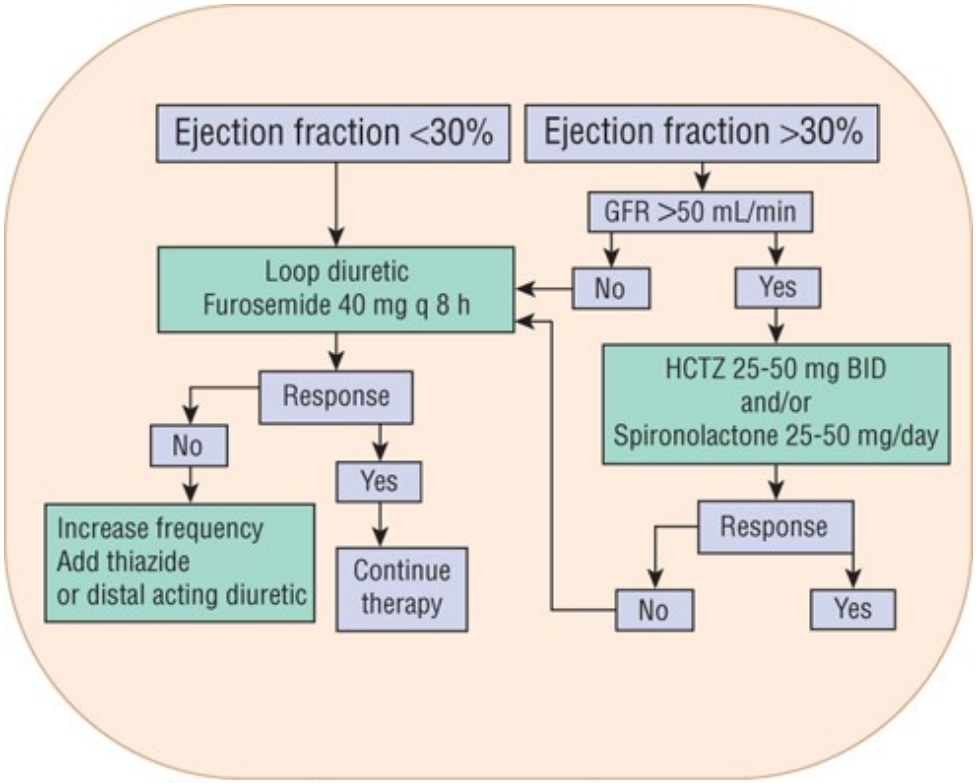

FIGURE 49-5

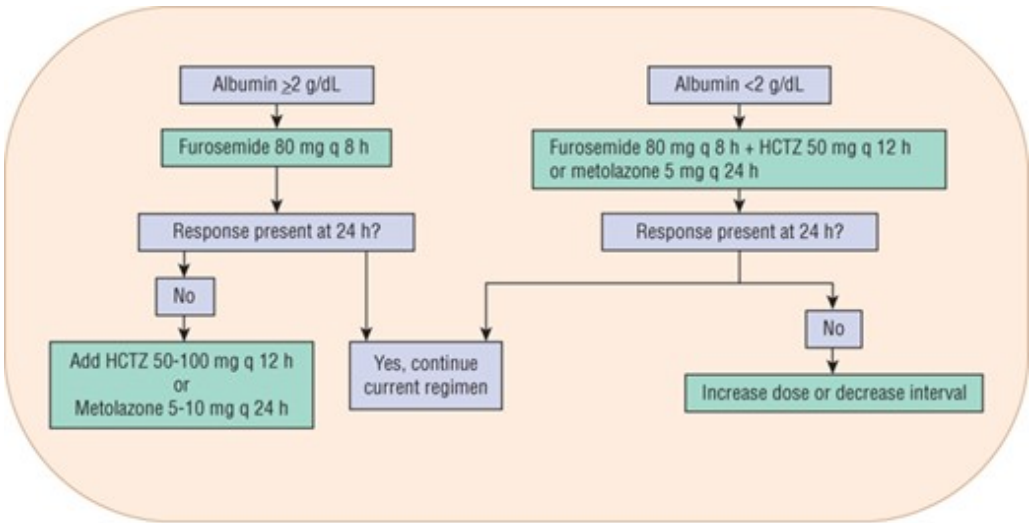
Therapeutic algorithm for diuretic therapy in patients with nephrotic syndrome. Albumin concentration of 2 g/dL is equivalent to 20 g/L. (HCTZ, hydrochlorothiazide.)

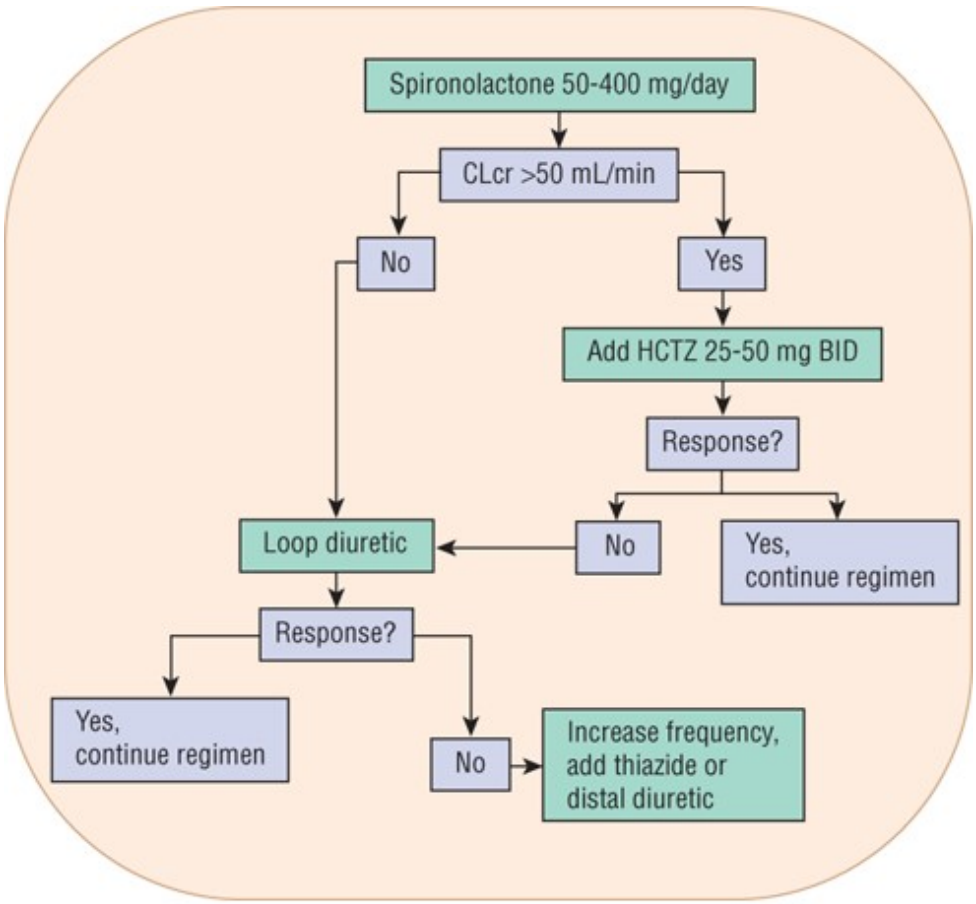


Secondary hyperaldosteronism from activation of the renin–angiotensin–aldosterone system plays a major role in the pathogenesis of edema in patients with cirrhosis. Therefore, these patients should initially be treated with an aldosterone antagonist (eg, spironolactone) in the absence of impaired

GFR and hyperkalemia (**Fig. 49-6**). Thiazides can then be added for patients with a creatinine clearance greater than 50 mL/min (0.83 mL/s). For those whose edema remains diuretic resistant, a loop diuretic can be used instead of the thiazide. Patients with impaired GFR (creatinine clearance less than 40 mL/min [0.67 mL/s]) can require a loop diuretic, with addition of a thiazide in those who do not achieve adequate diuresis.[95,100]

FIGURE 49-6

Therapeutic algorithm for diuretic use in patients with cirrhosis. (CLcr, creatinine clearance [50 mL/min is equivalent to 0.83 mL/s]; HCTZ, hydrochlorothiazide.)



Complications of loop and thiazide diuretic therapy include hypokalemia, excess ECF volume loss (hypovolemia), calcium imbalance (hypocalcemia with loop, hypercalcemia with thiazide), hypo- or hypernatremia (hyponatremia with thiazides, hypernatremia with loop), hypomagnesemia, metabolic alkalosis, and hyperuricemia. Patients with refractory edema treated with high-dose synergistic combinations are at highest risk for developing hypokalemia.[11] Thiazide-induced hypercalcemia can occur, particularly in patients with mild subclinical hyperparathyroidism. Loop diuretics cause hypercalciuria and can lead to bone disorders when used chronically. Chronic therapy with potassium-sparing diuretics can cause a mild metabolic acidosis and hyperkalemia. Patients with moderate to severe kidney dysfunction or those receiving NSAIDs, ACEIs, or angiotensin receptor

blockers are at highest risk for hyperkalemia. In addition, spironolactone can cause reversible gynecomastia in about 10% of men receiving it, and in about 50% of men receiving 150 mg/day or more. This side effect, however, has not been associated with eplerenone, another aldosterone antagonist.[102]

Evaluation of Therapeutic Outcomes

Patients should be monitored by careful history and intermittent physical examinations to detect signs and symptoms of edema as well as adverse effects. Physical examination should include measurement of blood pressure and pulse in either supine or seated positions and after standing for 2 to 3 minutes. ECF volume can be estimated based on the height of the jugular venous pressure, extent of edema, heart and lung auscultation, and skin turgor. Follow-up monitoring (10-14 days after therapy initiation) should include determinations of serum sodium, potassium, chloride, bicarbonate, magnesium, calcium, BUN, serum creatinine, and uric acid. A new steady state will have developed over that time period and further fluctuations in ECF volume and electrolyte balance generally do not occur in the absence of a change in clinical status, diuretic dosage, or dietary intake. Repeated blood tests are not necessary at every visit unless there is a change in the patient's clinical status.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACEI	angiotensin-converting enzyme inhibitor
AVP	arginine vasopressin, also known as vasopressin, antidiuretic hormone, or ADH
ATPase	adenosine triphosphatase
BUN	blood urea nitrogen
D_5W	Dextrose 5% in water
DDAVP	1-desamino-8-D-arginine vasopressin
DI	diabetes insipidus
ECF	extracellular fluid
FeNa	fractional excretion of sodium
GFR	glomerular filtration rate
HF	heart failure
ICU	intensive care unit
IV	intravenous
NSAID	nonsteroidal anti-inflammatory drug
ODS	osmotic demyelination syndrome
SIADH	syndrome of inappropriate secretion of antidiuretic hormone
TBW	total body water
Vaptan	vasopression 2 receptor antagonist

V_d volume of distribution

Chapter 50: Disorders of Calcium and Phosphorus Homeostasis

Amy Barton Pai

INTRODUCTION

KEY CONCEPTS

- 1 Severe acute hypercalcemia can result in cardiac arrhythmias, whereas chronic hypercalcemia can lead to calcium deposition in soft tissues including blood vessels and the kidney.
- 2 The correction of hypercalcemia can include multiple pharmacotherapeutic modalities such as hydration, diuretics, bisphosphonates, and steroids, depending on the etiology and acuity of the hypercalcemia.
- 3 Hypocalcemia is typically associated with an insidious onset; however, some drugs such as cinacalcet are associated with rapid decreases in serum calcium.
- 4 Acute treatment of hypocalcemia requires calcium supplementation whereas chronic management may require other therapies such as vitamin D to maintain serum calcium values.
- 5 Hyperphosphatemia occurs most frequently in patients with chronic kidney disease (CKD).
- 6 Treatment of nonemergent hyperphosphatemia includes the use of phosphate binders to decrease absorption of phosphorus from the gastrointestinal (GI) tract.
- 7 Hypophosphatemia is a relatively common complication among critically ill patients.
- 8 Treatment of acute hypophosphatemia usually requires IV supplementation of phosphorous salts.

Disorders of calcium and phosphorus are common complications of multiple acute and chronic diseases. These disorders are frequently seen in the acute care setting; however, they are also often present in ambulatory patients, usually in a less severe state. The consequences of electrolyte

disorders can range from asymptomatic to life-threatening, requiring hospitalization and emergent treatment. The maintenance of fluid and electrolyte homeostasis requires adequate functioning and modulation by multiple hormones on tissues of multiple organ systems.

There are many common drug therapies that can disturb the normal homeostatic mechanisms that maintain calcium and phosphorous balance. In addition, with some drug therapies, toxicity is enhanced when underlying electrolyte disorders are present. Drug-induced disorders typically respond well to discontinuation of the offending agent(s); however, additional therapies are sometimes required to correct the disorder. This chapter reviews the etiology, classification, clinical presentation, and therapy for the most common disorders of calcium and phosphorus homeostasis.

DISORDERS OF CALCIUM HOMEOSTASIS

The maintenance of physiologic calcium concentrations in the intracellular and extracellular spaces is vital for the preservation and function of cell membranes; propagation of neuromuscular activity; regulation of endocrine and exocrine secretory functions; blood coagulation cascade; platelet adhesion process; bone metabolism; muscle cell excitation/contraction coupling; and mediation of the electrophysiologic slow-channel response in cardiac and smooth-muscle tissue.

The disorders of calcium homeostasis are related to the calcium content of the extracellular fluid (ECF), which is tightly regulated and comprises less than 0.5% of the total body stores of calcium. Skeletal bone contains more than 99% of total body stores of calcium.[1] ECF calcium is moderately bound to plasma proteins (40%), primarily albumin.[2] Ionized or free calcium is the physiologically active form and is the fraction that is homeostatically regulated.[3] Extracellular calcium, however, is most commonly measured as the total serum calcium level, which includes both bound and unbound calcium.[2] The normal total calcium serum concentration range is 8.5 to 10.5 mg/dL (2.13-2.63 mmol/L).[3]

Proper assessment of total serum calcium concentrations includes measurement of the patient's serum albumin concentration. Hypoalbuminemia, which can be associated with many chronic disease states, is probably the most common cause of "laboratory hypocalcemia." Patients remain asymptomatic because the unbound or ionized fraction of serum calcium remains normal (normal range, 4.4-5.4 mg/dL [1.10-1.35 mmol/L]). A corrected total serum calcium (S_{ca}) concentration can be calculated based on the measured total serum calcium and the difference between a patient's measured albumin concentration and the normative value of 4 g/dL (40 g/L) by the following equations:

$$\text{Corrected } S_{ca}\ (\text{mg/dL}) = \text{Measured } S_{ca}\ (\text{mg/dL}) + (0.8 \times [4\ \text{g/dL} - \text{measured albumin (g/dL)}])$$

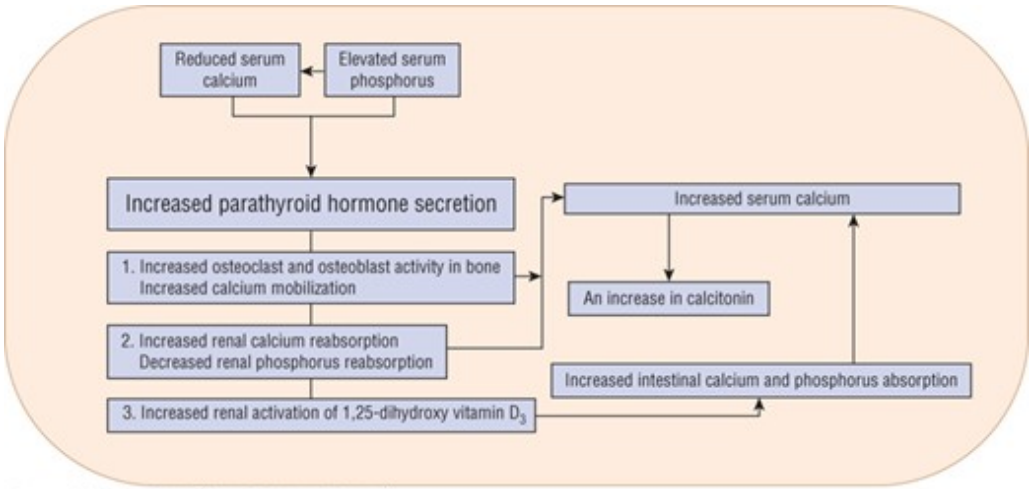
or

$$\text{Corrected } S_{ca}\ (\text{mmol/L}) = \text{Measured } S_{ca}\ (\text{mmol/L}) + (0.02 \times [40\ \text{g/L} - \text{measured albumin (g/L)}])$$

The concentration of ionized calcium is closely regulated by the interactions of parathyroid hormone (PTH), phosphorus, vitamin D, and calcitonin (**Fig. 50-1**). PTH increases serum calcium concentrations by stimulating calcium release from bone, increasing renal tubular reabsorption, and enhancing absorption in the gastrointestinal (GI) tract secondary to increased renal production of 1,25-dihydroxy vitamin D_3. Vitamin D directly increases serum calcium, as well as phosphorus concentrations, by increasing GI absorption. Indirectly, it can also lead to calcium release from bone and reduced renal excretion. Calcitonin inhibits osteoclastic bone resorption. Its plasma concentrations are increased when ionized calcium concentrations are high as the body attempts to return the calcium level to the normal range. Disruption of these homeostatic mechanisms results in the clinical manifestations of hypercalcemia or hypocalcemia.

FIGURE 50-1

Homeostatic mechanisms to maintain serum calcium concentrations.



Alteration of the concentration of albumin or its binding of calcium can be expected to change the unbound fraction of total serum calcium. The most significant cause of changes in calcium binding to albumin is a change in ECF pH. In the presence of acute metabolic alkalosis the fraction of calcium bound to albumin is increased, thus reducing the plasma concentration of ionized calcium. This can result in symptomatic hypocalcemia; that is, paresthesia, muscle cramping and spasms, memory loss, and seizures.[1] Conversely, metabolic acidosis decreases calcium binding to albumin and results in increased ionized calcium. Hypoalbuminemic states are probably the most common cause of "laboratory hypocalcemia." When the albumin level is decreased, the ionized calcium concentration can be normal, although total serum calcium concentration is low. Each 1 g/dL (10 g/L) drop in the serum albumin concentration below 4 g/dL (40 g/L) will result in a decrease of total serum calcium concentration by 0.8 mg/dL (0.20 mmol/L).[2] This approach of calculating an albumin-adjusted calcium concentration has been found to overestimate the degree of hypercalcemia and usually fails to identify hypocalcemia in critically ill patients; therefore, ionized calcium values should be used to assess calcium status in these patients.[3,4,5]

HYPERCALCEMIA

There are multiple and diverse causes of hypercalcemia (total serum calcium more than 10.5 mg/dL [more than 2.63 mmol/L]) (**Table 50-1**). The most common causes of hypercalcemia are cancer and primary hyperparathyroidism.

TABLE 50-1 Etiologies of Hypercalcemia

Neoplasms	**Medications**
Bone metastasis	Thiazides
Breast	Lithium
Multiple myeloma	Vitamin D
Lymphoma	Vitamin A
Leukemia	Calcium
Humoral induced	Aluminum/magnesium antacids
Ovary	Theophylline
Kidney	Tamoxifen
Pheochromocytoma	Ganciclovir
Multiple endocrine neoplasia	**Granulomatous disease**
Lung	Sarcoidosis
Head and neck	Tuberculosis
Esophagus	Cryptococcus
Cervix	Berylliosis
Lymphoproliferative disease	Histoplasmosis
Hyperparathyroidism	Coccidioidomycosis
Primary	Leprosy
Tertiary	**Endocrine disease**
Miscellaneous	Adrenal insufficiency
Immobilization	Hyperthyroidism

Paget's disease

Familial hypocalciuric hypercalcemia

Acromegaly

Adolescence

Rhabdomyolysis

Epidemiology and Etiology

The reported incidence of primary hyperparathyroidism in the United States ranges from 10 to 30 cases per 100,000 people.[6] Hypercalcemia of cancer occurs in approximately 15% to 70% of cancer patients at some time during the course of their disease and is dependent on tumor type.[7] Cancer-associated hypercalcemia is predominantly encountered in hospitalized patients, whereas primary hyperparathyroidism accounts for the vast majority of cases in the outpatient setting.[8,9]

Pathophysiology

Hypercalcemia is the result of one or a combination of three primary mechanisms: increased bone resorption, increased GI absorption, or increased tubular reabsorption by the kidneys (see Fig. 50-1).

Many tumors secrete PTH-related protein (PTHrP), which binds to the PTH receptors in bone and renal tissues, leading to increased bone resorption and renal tubular reabsorption.[10] Tumors can also secrete substances such as vitamin D, transforming growth factor, interleukins, prostaglandins, interferon, tumor necrosis factor, and granulocyte-macrophage colony-stimulating factor, which are associated with the development of hypercalcemia.[7] Hypercalcemia of malignancy is a common complication of squamous cell carcinomas of the lung, head, and neck, hematologic malignancies such as multiple myeloma and T-cell lymphomas, and carcinomas of ovary, kidney, bladder, and breast. The most frequent types of malignancy associated with hypercalcemia are carcinomas of the lung and breast.[7] Breast and squamous cell lung carcinomas secrete PTHrP which binds to the type I PTH receptor (PTHR1) and enhances bone resorption.[10,11] In contrast, up to 40% of patients with multiple myeloma develop hypercalcemia principally as the result of osteoclast-mediated bone destruction.[7]

Primary hyperparathyroidism is the most common cause of chronic hypercalcemia in the general population. Benign parathyroid adenomas account for 80% to 85% of these cases of hyperparathyroidism, parathyroid hyperplasia accounts for 15%, and parathyroid carcinoma is the cause in less than 1% of cases.[8]

Other causes of chronic hypercalcemia include medications, endocrine and granulomatous disorders, physical immobilization, high bone-turnover states (adolescence and Paget disease), and rhabdomyolysis. Increased GI absorption can be the result of excessive ingestion of vitamin D analogs, calcium supplements, and lithium. Lithium and vitamin A therapy can increase bone resorption, whereas increased renal tubular reabsorption of calcium can occur with thiazide and

lithium therapy. The exact mechanism of lithium-induced hypercalcemia is not known but may include competitive inhibition of calcium influx into cells, increasing the threshold sensitivity of the calcium-sensing receptor (CaSr) and subsequent inhibition of PTH gene transcription.[11] Addison disease, acromegaly, and thyrotoxicosis are endocrine disorders that can lead to hypercalcemia because of increased renal tubular reabsorption and increased bone resorption. Milk-alkali syndrome is the term applied to those situations where an individual develops hypercalcemia following the ingestion of calcium and absorbable alkali (eg, calcium carbonate) and is a frequent cause of hypercalcemia in patients who are not on dialysis.[12,13] Finally, the granulomatous disorders (sarcoidosis, tuberculosis, histoplasmosis, and leprosy) are associated with hypercalcemia secondary to an increase in GI and renal tubular absorption as the result of granuloma production of 1,25-dihydroxy vitamin D_2.[14]

Clinical Controversy...

Prevalent use of calcium and vitamin D supplementation has increased the frequency of hypercalcemia. This risk ultimately needs to be balanced with evidence of improved outcomes associated with supplementation of calcium and vitamin D.

Clinical Presentation

Patients with mild-to-moderate hypercalcemia, that is, total serum calcium concentrations above the upper threshold of normal but less than 13 mg/dL (3.25 mmol/L) or ionized calcium concentrations less than 6 mg/dL (1.50 mmol/L) can often be asymptomatic. This is typically the case for the vast majority of patients who have drug-induced hypercalcemia or primary hyperparathyroidism.[14,15] In fact, one study noted normocalcemia in approximately 20% of patients with a diagnosis of primary hyperparathyroidism, suggesting target tissue resistance to PTH.[15]

1 The presenting signs and symptoms of severe hypercalcemia that occur if the total serum calcium concentration is more than 13 mg/dL (more than 3.25 mmol/L) may differ depending on the acuity of onset.[2] Hypercalcemia of malignancy usually develops quickly and is accompanied by a classic symptom complex of anorexia, nausea and vomiting, constipation, polyuria, polydipsia, and nocturia.[7] Polyuria and nocturia secondary to a urinary-concentrating defect constitute some of the most frequent renal effects of hypercalcemia.[14] Hypercalcemic crisis is characterized by an acute elevation of total serum calcium to a value more than 15 mg/dL (more than 3.75 mmol/L), acute renal insufficiency, and obtundation (inability to arouse).[15,16] If untreated, hypercalcemic crisis can progress to oliguric renal failure, coma, and life-threatening ventricular arrhythmias.[14] The primary complications associated with chronic hypercalcemia (hyperparathyroidism) include metastatic calcification, hypercalciuria, and chronic renal insufficiency secondary to interstitial nephrocalcinosis.[14]

Calcium and/or calcium–phosphorus complex deposition in blood vessels and multiple organs is a complication of chronic hypercalcemia and/or concomitant hyperphosphatemia and hyperparathyroidism. Calcium deposits in atherosclerotic lesions contribute to cardiac disease.[17]

Intracardiac and arterial calcifications have been found in patients with Paget disease who have normal renal function. It is hypothesized that similar calcification processes occur in both bone and vascular tissue, leading to cardiovascular diseases including heart failure, systolic hypertension, and ischemic heart disease.[18]

The electrocardiographic changes associated with hypercalcemia include shortening of the QT interval and coving of the ST-T wave.[14] Very high serum calcium concentrations can cause T-wave widening, indicating a repolarization defect that may be associated with spontaneous ventricular tachyarrhythmias.[14] Hypertension and arrhythmias have occurred in the setting of hypercalcemia. The effects of digoxin on cardiac conduction including lowering of the excitation threshold, shortening of the effective refractory period, and increased atrioventricular refractoriness can be potentiated by hypercalcemia.[19]

CLINICAL PRESENTATION Hypercalcemia General

- The signs and symptoms of hypercalcemia depend on the severity and on the rapidity of onset.

Symptoms

- Symptoms include fatigue, weakness, anorexia, depression, anxiety, cognitive dysfunction, vague abdominal pain, and constipation. Renal symptoms can include polyuria, polydipsia, and nocturia. Rarely, severe hypercalcemia leads to acute pancreatitis.

Signs

- Renal: Nephrolithiasis; renal tubular dysfunction, particularly decreased concentrating ability; and acute and chronic renal insufficiency
- Cardiovascular: Hypercalcemia also directly shortens the myocardial action potential, which is reflected in a shortened QT interval and coving of the ST-T wave. Spontaneous ventricular tachyarrhythmias and elevations in blood pressure have also been reported. Chronic hypercalcemia can lead to cardiac calcification
- Musculoskeletal: Rheumatologic complaints related to hyperparathyroidism include gout, pseudogout, and chondrocalcinosis

Laboratory Tests

- Serum calcium concentrations of more than 10.5 mg/dL (more than 2.63 mmol/L) are considered to represent hypercalcemia. Patients with values up to 13 mg/dL (3.25 mmol/L) are generally considered to have mild or moderate hypercalcemia, whereas those with values greater than this indicate the presence of severe hypercalcemia.

Nephrolithiasis

Nephrolithiasis (kidney stones) and nephrocalcinosis (calcium deposits in the kidney) are the primary

renal complications arising from long-standing hypercalcemia, as the result of primary hyperparathyroidism. Stone formation is dependent on a favorable milieu within the kidney or urinary tract, such as oversaturation of the urine and/or reduced concentrations of endogenous inhibitors of crystal formation (eg, citrate or pyrophosphate). It is estimated that hyperparathyroidism accounts for 2% to 8% of all patients with calcium stones.[20,21] Of note, in those patients with low glomerular filtration rates (GFRs), the 24-hour urinary calcium will actually diminish secondary to decreased production of 1,25-dihydroxy vitamin D_2. However, the fractional excretion of calcium might increase.[21] Sarcoidosis is the other hypercalcemic condition frequently associated with calcium stones.[14] Other causes of nephrolithiasis with calcium-containing stones include hypocitraturia, renal tubular acidosis, hyperoxaluria, and hyperuricosuria, which are conditions that are prevalent among bariatric surgery patients.[22,23] Stone formers who have primary hyperparathyroidism are more likely to be women, older than 50 years, and have a family history of multiple endocrine disorders.[20] High dietary sodium intake can also raise urinary calcium concentrations, perhaps due to a reduction in calcium reabsorption in the kidney, thus predisposing patients to calcium stones. Although chronic renal failure can be the ultimate result of persistent stones, it is the primary cause of renal disease in less than 2% of the end-stage renal disease population.

TREATMENT

Desired Outcome

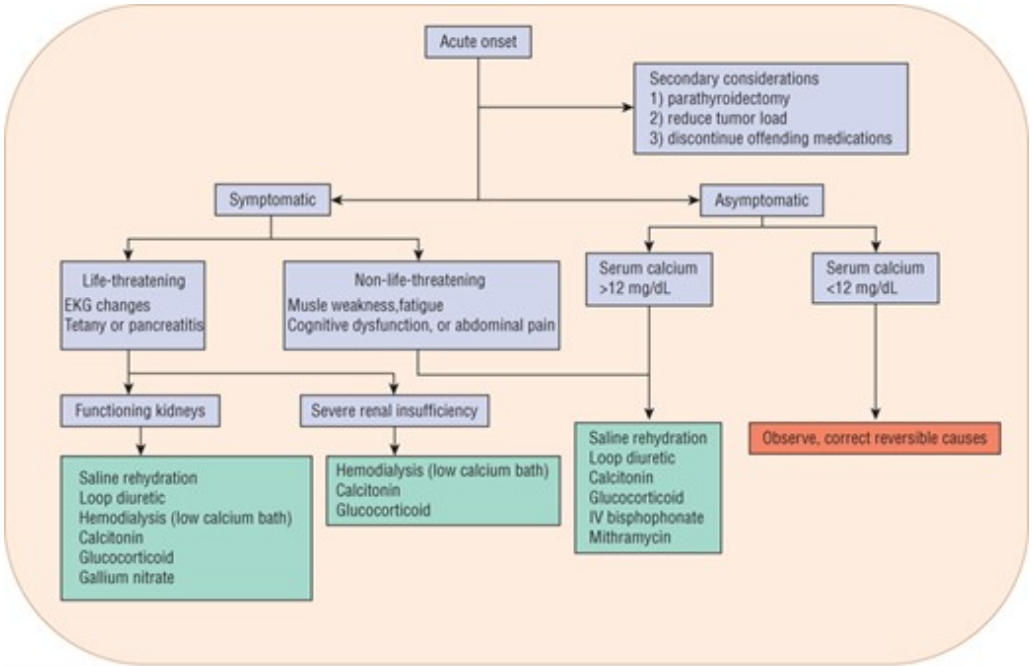
The indications for the treatment of acute hypercalcemia are dependent on the severity of hypercalcemia, acuity of its development, and presence or absence of symptoms requiring emergent treatment (eg, necrotizing pancreatitis). The therapeutic intervention plan should be crafted to reverse signs and symptoms, restore normocalcemia within hours to days depending on acuity, and correct or manage the underlying cause of hypercalcemia.

General Approach

Chronic hypercalcemia is usually caused by an underlying medical condition or prescribed pharmacotherapies that can be resolved by successful treatment of the condition or withdrawal of the offending agent resulting in a decrease in serum calcium within days or weeks. Acute hypercalcemic episodes induced by malignancies may be mitigated by chemotherapy and/or radiation treatment. Effective surgical or drug treatment of primary hyperparathyroidism should reduce serum calcium concentrations as well as reduce the development of long-term complications such as vascular complications, chronic kidney disease (CKD), and kidney stones. For treatment of nephrolithiasis the goal in management of serum calcium is prevention of stone formation and diameter. The reduction of serum calcium should be targeted at the underlying disease state causing hypercalcemia (eg, using cinacalcet for primary hyperparathyroidism). Hypercalcemic crisis and acute symptomatic severe hypercalcemia should be considered medical emergencies and treated immediately (**Fig. 50-2**).

FIGURE 50-2

Pharmacotherapeutic options for the acutely hypercalcemic patient. Serum calcium of 12 mg/dL is equivalent to 3 mmol/L.



These patients may require immediate-acting interventions to promptly reduce the serum calcium concentration if electrocardiographic (ECG) changes, neurologic manifestations, or pancreatitis are present. Pharmacologic therapy consisting of volume expansion and enhancement of urinary calcium excretion with loop diuretics is usually the initial management strategy. Hemodialysis against a zero- or low-calcium dialysate solution should be considered for patients with severely impaired renal function (CKD stage 4 or 5) who cannot tolerate large fluid loads and in whom diuretics have limited efficacy.[14]

Effective treatment of moderate to severe hypercalcemia in the absence of life-threatening symptoms begins with attention to the underlying disorder and correction of associated fluid and electrolyte abnormalities. Patients with primary hyperparathyroidism may require surgery, particularly if they have systemic manifestations.

Patients with malignancy often require surgical or chemotherapeutic reduction of tumor load to control the exogenous supply of cytokines and hormones (eg, PTHrP) that cause hypercalcemia. In contrast, patients with drug-induced hypercalcemia generally respond to discontinuation of the offending agent.

Pharmacologic Therapy

Sympotomatic Patient Management

2 For those patients with normal to moderately impaired renal function (CKD stages 3a, 3b, and 4), the cornerstone of initial first-line treatment of severe, acute hypercalcemia or hypercalcemic crisis is

volume expansion with normal saline to increase natriuresis and ultimately urinary calcium excretion (**Table 50-2**). Patients with symptomatic hypercalcemia are often extracellular volume depleted secondary to vomiting and polyuria; thus rehydration with saline-containing fluids is necessary to interrupt the stimulus for sodium and calcium reabsorption in the renal tubule.[24] Rehydration can be accomplished by the rapid infusion of 1 to 2 L of normal saline followed by a maintenance infusion at 250 to 300 mL/h, until the patient is fluid resuscitated and serum calcium approaches the upper limit of the normal range.[24] The precise rate depends on concomitant conditions (primarily cardiovascular and renal) and magnitude of hypercalcemia. The saline infusion rate can be decreased to a rate that approximates the patient's intake of oral or IV fluids. See Chapter 49 for a thorough discussion of how to calculate water deficit and monitor patient's response to saline infusion. Loop diuretics such as furosemide (40-80 mg IV every 1-4 hours) can also be instituted to increase urinary calcium excretion.[24] Loop diuretics block calcium (and sodium) reabsorption in the thick ascending limb of the loop of Henle and augment the calciuric effect of saline alone. Rehydration prior to loop diuretic use is critical because if dehydration persists or becomes worse, the serum calcium can actually increase because of enhanced proximal tubule calcium reabsorption.[25] The primary role for loop diuretics is to minimize the development of volume overload from the administration of saline. (Fig. 50-2 and Table 50-2). Despite its common use there is little evidence that supports the efficacy of furosemide in tratement of hypercalcemia.[25] Potassium chloride, 10 to 20 mEq/L (10-20 mmol/L), should be considered for addition to the saline infusion after rehydration is accomplished to prevent the development of hypokalemia that is a common adverse effect of aggressive diuretic therapy. Serum magnesium levels should also be monitored, and magnesium replacement instituted if magnesium concentrations fall below 1.8 mg/dL (0.74 mmol/L). Rehydration with saline and administration of furosemide may result in normalization total serum calcium within 24 to 48 hours, however, rebound hypercalcemia can occur.[25] Hemodialysis with low or zero calcium dialysate is a treatment option in the case of failure or when calcium concentrations are life threatening. It should be noted that preparing a patient for hemodialysis takes time to achieve vascular access, thus, this approach is best suited for patients already receiving hemodialysis chronically.

TABLE 50-2 Drug Dosing Table for Hypercalcemia

Drug/Brand Name	Starting Dosage	Time Frame to Initial Response	Monitoring and Special Population Considerations
0.9% saline ± electrolytes	200-300 mL/h	24-48 hours	Electrolyte abnormalities; fluid overload CI in renal insufficiency; congestive heart failure
Loop diuretics			
Furosemide/Lasix® Bumetandide/Bumex® Torsemide/Demadex®	40-80 mg IV q 1-4 h of furosemide or equivalent	N/A	Electrolyte abnormalities (potassium and magnesium) CI in patients with allergy to sulfas (use ethacrynic acid)

Drug/Brand Name	Starting Dosage	Time Frame to Initial Response	Monitoring and Special Population Considerations
Calcitonin/Miacalcin®	4 units/kg q 12 h SC/IM 10-12 units/h IV	1-2 hours	Facial flushing, nausea/vomiting, allergic reaction, CI in patients with allergy to calcitonin
Pamidronate/Aredia®	30-90 mg IV over 2-24 hours	2 days	Fever, fatigue, skeletal pain, CI in renal insufficiency
Zoledronate/Zometa®	4-8 mg IV over 15 minutes	1-2 days	Fever, fatigue, skeletal pain, CI in renal insufficiency
Glucocorticoids	40-60 mg oral prednisone equivalents daily	3-5 days	Diabetes; osteoporosis; infection, CI in patients with serious infections; hypersensitivity

CI, contraindicated; SC, subcutaneous.

Asymptomatic Patient Managment

Calcitonin

In those patients in whom saline hydration therapy is contraindicated (eg, those with severe chronic heart failure [CHF] or moderate-to-severe renal dysfunction), short-term therapy with calcitonin is a viable alternative agent to initiate reduction of serum calcium levels within 24 to 48 hours. Calcitonin has a rapid onset of action (within 1-2 hours); however, the degree and extent of serum calcium level reduction are often unpredictable.[2]

Subcutaneous administration of salmon calcitonin, 50 to 100 international units daily or three times weekly, has been used to manage mild hypercalcemia in patients with Paget disease.[26] The intranasal formulation of calcitonin has been used in doses of 200 to 400 international units daily; unfortunately, this has resulted in only mild decreases in serum calcium. The lack of significant efficacy of the synthetic intranasal formulation is the result of the lower potency and shorter duration of action as compared to salmon calcitonin.

Pharmacology

Calcitonin decreases serum calcium concentrations, primarily by inhibiting bone resorption. It can also reduce renal tubular reabsorption of calcium, thus promoting calciuresis.[26] Calcitonin from salmon sources is most commonly administered subcutaneously or intramuscularly (for larger volumes) in a starting dose of 4 units/kg every 12 hours.

Adverse Effects

The side effects from IV administered calcitonin (facial flushing, nausea, and vomiting) limit patient acceptability. Allergic reactions, although rare, do occur; therefore, a test dose (intradermal injection

of 0.1 mL of a 10 units/mL solution) is recommended prior to starting therapy. If marked erythema and/or wheal formation does not occur within 15 minutes after administration, therapy can begin. Salmon calcitonin therapy is associated with tachyphylaxis caused by antibody formation to foreign proteins or molecules resembling the calcitonin polypeptide.[27] Tachyphylaxis has been primarily documented in patients receiving therapy for more than 4 months and thus might not be clinically significant in the acute care setting. The addition of corticosteroid therapy or conversion to human calcitonin increases effectiveness.[2]

Bisphosphonates

Bisphosphonates block bone resorption very efficiently, render the hydroxyapatite crystal of bone mineral resistant to hydrolysis by phosphatases, and also inhibit osteoclast precursors from attaching to the mineralized matrix, thus blocking their transformation into mature functioning osteoclasts.[14,28] The antiresorptive properties of this class of agents can provide long-term control of serum calcium and are the first-line therapy for cancer-associated hypercalcemia.

Pharmacology

The first line bisphosphonates to treat hypercalcemia are pamidronate and zoledronic acid.[29] The usual dose of pamidronate is 30 to 90 mg as an IV infusion given over 2 to 24 hours. Pamidronate also has the advantage of single-day therapy.[29] Zoledronic acid is a high-potency bisphosphonate with demonstrated effectiveness in the treatment of hypercalcemia of malignancy. Complete response has been reported in 88.4% to 86.7% of zoledronate- versus 69.7% of pamidronate-treated patients.[30,31] Zoledronic acid IV doses of 4 to 8 mg given over 15 minutes have resulted in normalization of serum calcium concentrations.[30] IV infusions of 0.02 or 0.04 mg/kg diluted in 5% dextrose (given over 20-50 minutes) have also been effective.[32] The onset of serum calcium concentration decline is slower with bisphosphonate therapy (concentrations begin to decline in 2 days and reach a nadir in 7 days); thus calcitonin therapy or other interventions may be necessary if rapid serum level reduction is required.[29] Duration of normocalcemia varies, but usually does not exceed 2 to 3 weeks. It appears to be dependent on the severity and treatment response of the underlying malignancy.[7] The duration of response has been suggested to be longer with zoledronate (4-5 weeks), although the data are sparse.[32]

Adverse Effects

Fever is a common side effect of IV bisphosphonate therapy. Although oral bisphosphonates are useful for the treatment of bone turnover in Paget disease, there are insufficient data to suggest their use for the initial treatment of hypercalcemia. The use of oral bisphosphonates for maintenance therapy in patients predisposed to hypercalcemia (malignancy) has been successful in some cases.[33] The safety of continuous bisphosphonate therapy in patients with moderate-to-severe renal insufficiency is currently unknown. Renal function monitoring (serum creatinine) is advised with the use of bisphosphonates, as cases of renal function decline and acute tubular necrosis have been reported.[34,35] Although there are no published guidelines for frequency of serum creatinine

monitoring, it is advisable to evaluate serum creatinine within a week after the infusion and just prior to the next scheduled dose. Osteonecrosis of the jaw is evidenced by an area of exposed bone in the maxillofacial or mandibular region that does not heal within 8 weeks after diagnosis.[29] Higher potency bisphosphonates and longer durations of therapy are associated with increased risk.[36]

Denosumab

Pharmacology

Denosumab is a monoclonal antibody that inhibits the receptor activator of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) ligand (RANKL), a principal mediator of osteoclast survival. Denosumab is FDA-approved for the treatment hypercalcemia of malignancy.[37] An open-label, trial evaluated the value of denosumab in patients with hypercalcemia of malignancy (with or without bone metastases) who were refractory to intravenous bisphosphonate therapy, that is, their corrected serum calcium remained above 12.5 mg/dL (3.13 mmol/L) after more than 7 days of therapy.[37] Sixty-four percent of patients who received 120 mg of denosumab subcutaneously on days 1, 8, achieved a corrected serum calcium less than or equal to 11.5 mg/dL (less than or equal to 2.88 mmol/L) within 10 days which is considered an appropriate duration for time to clinical response. Denosumab has also been reported to successfully treat hypercalcemia after successful stem cell transplantation and restitution of osteoclast function in patients with osteopetrosis, a heritable disorder associated with defective osteoclast function.[38]

Adverse Effects

Denosomab has been associated with osteonecrosis of the jaw.[39] Athough the renal impairment has not been shown to affect the pharmacodynamics and pharmacokinetics of denosumab, severe, symptomatic hypocalcemia has been reported in CKD patients receiving the drug.[40] This may be due to induction of a hungry bone-like syndrome and warrants careful monitoring.[41]

Corticosteroids

Prednisone or an equivalent agent is usually effective in the treatment of hypercalcemia resulting from multiple myeloma, leukemia, lymphoma, sarcoidosis, and hypervitaminoses A and D.[14,28,42] Steriods are effective because they reduce GI calcium absorption.[42] Corticosteroids may also prevent tachyphylaxis to salmon calcitonin.[26] Daily doses of 40 to 60 mg of prednisone or the equivalent have effectively normalized serum calcium values within 3 to 5 days followed by a reduction in urinary calcium excretion within 7 to 10 days. The disadvantages of corticosteroid therapy are its relatively slow onset of action and the potential for diabetes mellitus, osteoporosis, and increased susceptibility to infection.[43]

Cinacalcet

The calcimimetic agent cinacalcet is approved for management of parathyroid carcinoma and

primary hyperparathyroidism.[44,45] It binds to the CaSr, and increases the sensitivity for receptor activation by extracellular calcium. This results in reduced PTH and serum calcium concentrations.[44,45] Cinacalcet administered at a starting dose of 30 mg orally twice daily has been used for the treatment of hypercalcemia secondary to parathyroid carcinoma. The dosage is titrated every 2 to 4 weeks in 30-mg increments until the desired serum calcium level is achieved. The maximum approved dosage is 90 mg three to four times daily. Patients should have serum calcium measured within 1 week after starting or increasing the dose of this agent.[46] The role of cinacalcet in the management of nephrolithiasis is still controversial. Patients were randomly assigned to receive potassium citrate alone, allopurinol or allopurinol with cinacalet. Stone number and diameter was reduced compared to baseline in patients who received the combination regimen with cinacalcet in both hypercalcemic and normocalcemic patients.[47]

Pharmacoeconomic Considerations

For treatment of asymptomatic hypercalcemia from a pharmacoeconomic standpoint corticosteroids are very inexpensive, however, the low cost of the drug may be offset by the multitude of long-term side effects and potential need for additional treatment. Calcitonin is only suitable for very short-term therapy and thus long-term pharmacoeconimic analyses have not been done. The introduction of denosomab and it's demonstrated efficacy in preventing and delaying skeletal related adverse events while reducing hypocalcemia has stimulated cost-effectiveness analyses.[48] Denosumab and zoledronic acid in hormone refractory prostate cancer with bone metastatses showed that the incremental total costs per skeletal-related adverse event avoided for denosomab were $71,027 over a 1-year period and $51,319 over a 3-year period.[48] This suggests that denosomab may be a costly alternative to zoledronic acid and formulary restrictions with specific patient criteria may be judicious. Additional considerations for choice of therapy evaluated in a survey of more than 200 physicians included co-pay costs and patient assistance program availablity for these agents.[49]

Nephrolithiasis Chronic Hypercalcuria and Hypercalemia

Patients who develop nephrolithiasis from hypercalciuria are most often treated with sodium citrate to prevent stone formation, thiazide diuretics to decrease urinary calcium excretion, or shock wave lithotripsy (**Table 50-3**). There are multiple approaches to treating and preventing future nephrolithiasis issues which include stone removal or disintegration, using medications to dissolve or prevent stone formation as well as dietary interventions to prevent stone formation.[23] Procedures such as shockwave lithotripsy are effective in disintegrating stones and subsequently allowing for their urinary removal, however, the procedure is painful and expensive. Urinary alkalinizing agents such as potassium or sodium citrate prevent growth of stone diameter, increasing the likelihood of spontaneous passage. These agents can also be used for prevention but are available in liquid form and must be taken consistently multiple times per day to maintain an alkaline urine.[20] Thiazide diuretics decrease urinary calcium excretion and reduce the potential for crystal formation and are commonly used for prevention.[23] Other agents such as calcium binding resins, natural plant extracts (*Phyllanthus niruri)* and reduction of dietary calcium have limited evidence that they offer a successful prevention strategy.

TABLE 50-3 Treatment of Nephrolithiasis Associated with Chronic Hypercalcemia and Hypercalciuria

Intervention	Indications	Comments
Extracorporeal Shock Wave Lithotripsy		
Uses sound waves to break up stones, which then can pass spontaneously	Obstruction of the urinary tract, especially with stones >5 mm	Consider adjunctive use of potassium citrate to inhibit aggregation of residual fragments
Prevention of Stone Formation		
Alkalinizing agents Potassium citrate PO 20 mEq twice daily Sodium citrate PO 20-30 mEq twice daily	Treatment for nonemergent active stones. Can also be used for prevention	Potassium citrate preferred over sodium citrate as it decreases urinary calcium, inhibits calcium oxalate precipitation, and increases urinary citrate more
Decrease Urinary Calcium Excretion		
Thiazide diuretics Hydrochlorothiazide (Hydrodiuril®) PO 50 mg every day Indapamide (Lozol®) PO 25 mg every day Chlorthalidone (Hygroton®) PO 25 mg every day	Prevention	Drug of choice in patients with low bone density
Binding Intestinal Calcium		
Cellulose sodium phosphate (Calcibind) Calcium binding ion-exchange resin that decreases GI absorption of calcium: PO 5 g twice daily with oxalate restriction	Prevention for those with absorptive hypercalciuria	Alternative to thiazides if intolerant or ineffective, monitor bone density
Inhibition of Crystal Formation		
Phyllanthus niruri plant extract Inhibits calcium oxalate stone formation by incorporating glycosaminoglycans into the calculi: PO 2 g daily	Prevention, after shock wave lithotripsy	Commercial preparations with *P. niruri* as the sole ingredient can be difficult to obtain

Intervention	Indications	Comments
Low-Calcium Diet		
Less than 400 mg/day	Prevention	Monitor bone density prior to and periodically during treatment, limit oxalate restriction, can increase hyperoxaluria, data suggest that high calcium intake may actually be more beneficial

HYPOCALCEMIA

3 Hypocalcemia occurs infrequently in the outpatient setting and is most common in elderly, malnourished patients and those who have received sodium phosphate as a bowel preparation agent.

Epidemiology

The incidence of hypocalcemia in intensive care unit patients ranges from 70% to 90% based on total serum calcium values less than 8.5 mg/dL (2.13 mmol/L) to 15% to 50% based on the observation of ionized calcium concentrations less than 4.4 mg/dL (1.10 mmol/L).[4] Emergent treatment of hypocalcemia is rarely warranted unless life-threatening symptoms are present (eg, frank tetany or seizures).

Pathophysiology

Hypocalcemia is the result of alterations in the effect of PTH and vitamin D on the bone, gut, and kidney (see Fig. 50-1). The primary causes of hypocalcemia are postoperative hypoparathyroidism and vitamin D deficiency. Other causes include magnesium deficiency, thyroid surgery, medications, hypoalbuminemia, blood transfusions, peripheral blood progenitor cell harvesting, tumor lysis syndrome, and mutations in the CaSr.[50,51,52,53,54,55] PTH concentrations are elevated in conditions of hypocalcemia, with the exception of hypoparathyroidism and hypomagnesemia.[56]

Vitamin D Deficiency

Vitamin D and its metabolites play an important role in the maintenance of extracellular calcium concentrations and in normal skeletal structure and mineralization. Vitamin D is necessary for the optimal absorption of calcium and phosphorus. On a worldwide basis, the most common cause of chronic hypocalcemia is nutritional vitamin D deficiency. In malnourished populations, manifestations include rickets and osteomalacia. Nutritional vitamin D deficiency is uncommon in Western societies because of the fortification of milk with ergocalciferol. The most common cause of vitamin D deficiency in Western societies is GI disease.[14] Gastric surgery, chronic pancreatitis, small-bowel disease, intestinal resection, and bypass surgery are associated with decreased concentrations of

vitamin D and its metabolites.[14] Vitamin D replacement therapy might need to be administered by the IV route if poor oral bioavailability is noted. Decreased production of 1,25-dihydroxyvitamin D_3 can occur as a result of a hereditary defect resulting in vitamin D-dependent rickets.[56] Recently, polymorphisms of the vitamin D receptor have been identified, and these genetic variations can contribute to increased risk of rickets associated with vitamin D and calcium deficient diets, especially in certain African and East Asian populations.[57] It also can occur secondary to CKD if there is insufficient production of the 1-α-hydroxylase enzyme for the production of the 1,25-dihydroxy vitamin D_3. Treatment of hypocalcemia associated with CKD is reviewed in Chapter 44.

Hypomagnesemia

Hypomagnesemia of any cause can be associated with severe symptomatic hypocalcemia that is unresponsive to calcium replacement therapy (see Chapter 51). Reduced serum magnesium concentrations can impair PTH secretion and induce resistance of target organs to the actions of PTH.[14] Normalization of serum calcium concentrations in these patients is thus dependent on appropriate replacement of magnesium.

Hungry Bone Syndrome

An acute, symptomatic rapid fall in total serum calcium concentration (to values less than 7 mg/dL [less than 1.75 mmol/L]) is common in patients who have recently had a parathyroidectomy or thyroidectomy. Hypocalcemia in these postsurgical patients is generally transient in nature.[56] The "hungry bone syndrome" is a condition of profound hypocalcemia whereby the bone avidly incorporates calcium and phosphorus from the blood in an attempt to recalcify bone.[58] Serum calcium concentrations should be monitored every 6 hours during the 24 to 48 hours following such surgeries, and pharmacologic doses of calcium can be necessary to prevent or minimize the drop in serum calcium. Additionally, mild-to-moderate hypocalcemia can be a long-term consequence of parathyroidectomy in hemodialysis patients.[56]

Drug-Induced Hypocalcemia

Drug-induced hypocalcemia has been reported in patients receiving furosemide, calcitonin, bisphosphonates, denosomab, oral sodium phosphate solutions, polyethylene glycol bowel preparation solutions, cinacalcet, fluoride, ketoconazole, and pentamidine.[40,46,59,60]

Oral phosphorus therapy, commonly used to treat patients with malabsorption syndromes caused by GI diseases, can also result in hypocalcemia. The anticonvulsants phenobarbital and phenytoin cause hypocalcemia by increasing catabolism of vitamin D and thereby impairing calcium release from bone and reducing intestinal calcium absorption.[50] Drugs that cause hypomagnesemia (aminoglycosides, amphotericin B, cyclosporine, diuretics, foscarnet, and cisplatin) are also associated with an increased risk of hypocalcemia.[61] Chelating agents in blood (citrate) and in radiographic contrast media (ethylenediaminetetraacetate) can also cause transient hypocalcemia.[50,51,62] Concentrated citrate is increasingly being used in hemodialysis catheter locks and to anticoagulate

the dialysis circuit during continuous renal replacement therapy.[63] Symptomatic hypocalcemia (ionized calcium less than 2.4 mg/dL [less than 0.60 mmol/L]) has been reported in patients exposed to citrate solutions, which appears to be related to the concentration of the citrate solution.[64] Injection of citrate solutions greater than the volume of the dead space of the catheter lumen or accidental injection of citrate catheter lock solutions that are not intended for systemic administration have been associated with serious cardiovascular problems such as hypotension or cardiac arrest.[65]

CLINICAL PRESENTATION Hypocalcemia General

- Acute hypocalcemia may result in rapid decreases in serum ionized calcium. Parathyroidectomy and thyroidectomy are also associated with a rapid reduction in serum calcium. In chronic hypocalcemia vitamin D deficiency should be considered.

Symptoms

- The symptoms of hypocalcemia include tetany, paresthesia, muscle cramps, and laryngeal spasms. Chronic hypocalcemia is usually associated with depression, anxiety, memory loss, and confusion.

Signs

- Neurologic: The hallmark of acute hypocalcemia is tetany, which is characterized by neuromuscular irritability including seizure potential. Extrapyramidal disorders, mainly parkinsonism but also dystonia, hemiballismus, choreoathetosis, and oculogyric crises occur in 5% to 10% of patients with idiopathic hypoparathyroidism. Chvostek and/or Trousseau signs can be elicited during physical examination.
- Dermatologic: The skin can be dry, puffy, and coarse. Other dermatologic manifestations can include hyperpigmentation, dermatitis, eczema, and psoriasis. Hair and skin signs including coarse, brittle, and sparse hair with patchy alopecia and brittle nails can also appear.
- Ophthalmologic: Cataract development has been reported to occur with hypocalcemia.
- Dental manifestations: These are usually associated with the presence of chronic hypocalcemia in early development. Signs include dental hypoplasia, failure of tooth eruption, defective enamel and root formation, and abraded carious teeth.
- Cardiovascular: Hypotension, decreased myocardial performance, and CHF have been reported. A prolonged QT interval, arrhythmias, and bradycardia can also occur but are more common with acute or very severe hypocalcemia.
- GI: Steatorrhea can be associated with chronic hypocalcemia.
- Musculoskeletal: Myopathy has been reported.
- Endocrine: Hypocalcemia alone can impair insulin release. In addition, idiopathic hypoparathyroidism can be associated with polyglandular autoimmune syndromes.

Laboratory Tests

- Serum calcium levels of less than 8.5 mg/dL (2.13 mmol/L) are considered to represent hypocalcemia if ionized calcium values are also less than 4.4 mg/dL (1.1 mmol/L).

Hypoparathyroidism

Hypoparathyroidism can be caused by autoimmune disease, congenital defects, or iatrogenically by inadvertent removal of some or all of the parathyroid glands during thyroidectomy or from damage with radiation therapy. Chronic hypoparathyroidism produces an insidious development of hypocalcemia and thus most patients remain asympotomatic. The chronic hypocalcemia may ultimately present as visual impairment secondary to cataracts.[66]

Clinical Presentation

The clinical manifestations of hypocalcemia are quite variable. The more acute the drop in ionized calcium concentration, the more likely the patient will develop symptoms.[3] Increases in plasma pH enhance the binding of calcium to albumin and thus alkalosis can result in rapid decreases in ionized calcium. Concomitant hypomagnesemia, hypokalemia, hyponatremia, and additive side effects from prescribed medications also increase the likelihood of symptomatic presentation.

Hypocalcemia can manifest as neuromuscular, central nervous system (CNS), dermatologic, and cardiac sequelae.[14] Acute hypocalcemia is more likely to manifest as neuromuscular (paresthesia, muscle cramps, tetany, and laryngeal spasm) and cardiovascular symptoms, whereas chronic hypocalcemia often presents as CNS (eg, depression, anxiety, memory loss, confusion, hallucinations, and tonic–clonic seizures) and dermatologic symptoms (hair loss, grooved and brittle nails, and eczema).[50] The hallmark sign of acute hypocalcemia is tetany caused by enhanced peripheral neuromuscular irritability.[14] Tetany manifests as paresthesia around the mouth and in the extremities, muscle spasms and cramps, carpopedal (hands and feet) spasms, and rarely as laryngospasm and bronchospasm.[14] Chvostek and/or Trousseau signs can be elicited during physical examination.[50] Chvostek sign is elicited by tapping the facial nerve anterior to the ear and eliciting twitching of facial muscles. Trousseau sign is elicited by inflating a blood pressure cuff above systolic blood pressure for 3 minutes and observing whether a carpal spasm is induced.

The cardiovascular manifestations of hypocalcemia result in ECG changes characterized by a prolonged QT interval and symptoms of decreased myocardial contractility often associated with congestive heart failure (CHF).[50] Both acute and chronic hypocalcemia can result in a reversible syndrome characterized by acute myocardial failure or refractory CHF. Other cardiovascular manifestations include arrhythmias, bradycardia, and hypotension that are unresponsive to fluid and pressor administration.[50]

Clinical Controversy...

Bariatric surgery is associated with malabsorption of calcium. There are limited data regarding the

differential impact the various bariatric procedures have on calcium absorption and what if any adverse consequences develop.[23]

TREATMENT

Desired Outcome

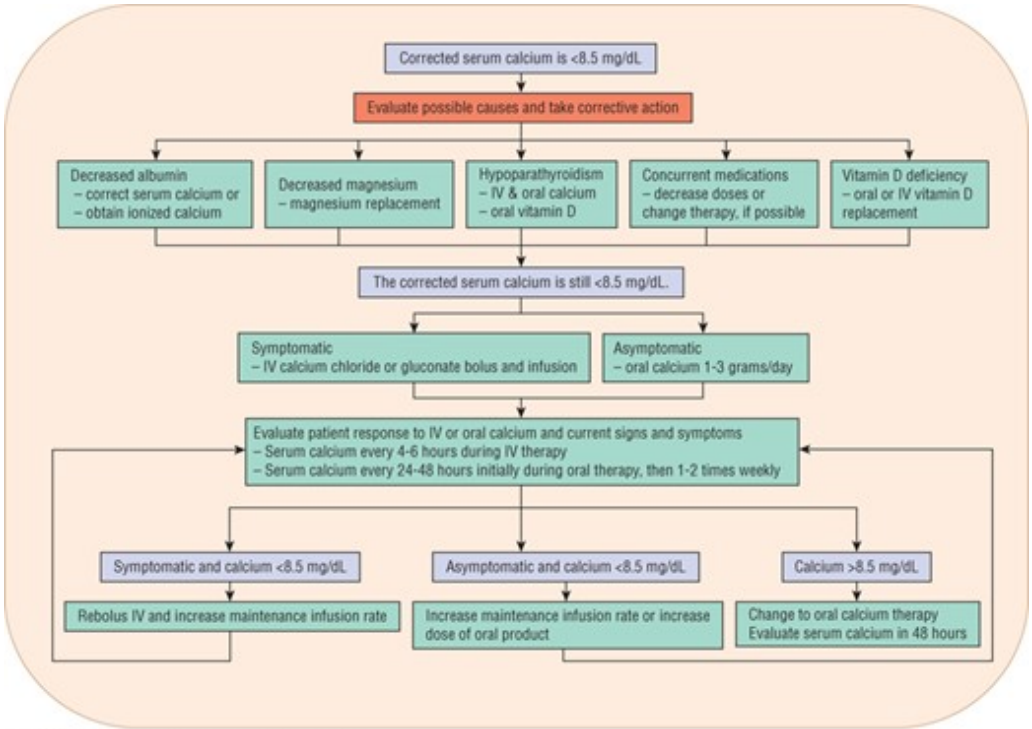
4 The goals of therapy for patients with normal renal function are the resolution of signs and symptoms of hypocalcemia, restoration of normocalcemia, management of associated electrolyte abnormalities, and treatment of the underlying cause of hypocalcemia. The goals for patients with CKD are different and are discussed in detail in Chapter 44. Asymptomatic hypocalcemia associated with hypoalbuminemia requires no treatment because ionized (physiologically active) plasma calcium concentrations are normal. Treatment of hypocalcemia is dependent on identification of the pathogenesis of the underlying disorder, acuteness of onset, and presence and severity of symptoms.

Pharmacologic Therapy

Treatment of hypocalcemia is driven by acuity of onset and how significant the ionized calcium is below the normal range. The first approach to treatment is to evaluate causes that will dictate corrective action. Acute symptomatic hypocalcemia will nearly always require parenteral administration of soluble calcium salts (**Fig. 50-3**).

FIGURE 50-3

Hypocalcemia diagnostic and treatment algorithm. Serum calcium of 8.5 mg/dL is equivalent to 2.13 mmol/L.



Acute Treatment

The initial therapeutic intervention for patients with acute symptomatic hypocalcemia is to administer 100 to 300 mg of elemental calcium IV slowly over 10 to 30 minutes.[66] This can be accomplished by the administration of 1 g of calcium chloride (27% elemental calcium) or 2 to 3 g of calcium gluconate (9% elemental calcium). Calcium gluconate is generally preferred over calcium chloride for peripheral venous administration because calcium gluconate is less irritating to veins. Calcium should not be infused at a rate greater than 60 mg of elemental calcium per minute because severe cardiac dysfunction, including ventricular fibrillation, can result, thus electrocardiogram monitoring is recommended.[61] IV calcium administration should be used with caution in patients receiving digitalis glycosides because of the possibility of bradycardia or atrioventricular (A–V) block.[66] The bolus dose of calcium is only effective for 1 to 2 hours and should be followed by a continuous infusion of elemental calcium at a rate of 0.5 to 2 mg/kg per hour.[61] Serum calcium should rise by approximately 1.2 to 2 mg/dL (0.30-0.50 mmol/L).[66] The calcium concentrations should be monitored every 4 to 6 hours during IV infusions. The ionized calcium concentration usually normalizes within 4 hours, and the maintenance infusion rate of elemental calcium can then be decreased to 0.3 to 0.5 mg/kg per hour to maintain the desired calcium concentration.[66] Calcium should not be added to bicarbonate- or phosphate-containing solutions because of the possibility of precipitation.[61] Treatment of chronic hypoparathyroidism with parathyroid hormone formulations such as teriparatide has been shown to better maintain serum calcium concentrations and normalize urinary calcium.[67]

Chronic Treatment

Once acute hypocalcemia is corrected by parenteral administration, further treatment modalities

should be individualized according to the cause of hypocalcemia. If hypomagnesemia is present, magnesium supplementation is indicated until concentrations normalize which will promote successful calcium supplementation regardless of route. (see Chapter 51). Hypocalcemia secondary to hungry bone syndrome following parathyroidectomy has been attenuated by pretreatment with bisphosphonates.[68] Asymptomatic and chronic hypocalcemia associated with hypoparathyroidism and vitamin D-deficient states can be managed by oral calcium and vitamin D supplementation (see Chapter 44). Therapy is begun with 1 to 3 g/day of elemental calcium.[61] Average maintenance doses range from 2 to 8 g of elemental calcium per day in divided doses. If serum calcium does not normalize, a vitamin D preparation may need to be added. In patients with achlorhydria a solution of 10% (1-30 mL) calcium chloride orally every 8 hours can raise serum calcium.[61]

Treatment of chronic asymptomatic hypocalcemia associated with vitamin D-deficient states should be individualized. In patients with malabsorption, vitamin D requirements vary markedly, and large doses can be required. In contrast, vitamin D deficiency associated with anticonvulsant medication can be corrected with smaller doses of vitamin D. Oral doses of 1,25-dihydroxy vitamin D_3 usually range from 0.5 to 3 mcg daily.[61] The usual initial oral dose of ergocalciferol is 50,000 international units daily.[61] Vitamin D doses are usually adjusted approximately every 4 weeks. Vitamin D deficiency is highly prevalent especially in areas of low sun exposure and limited dietary sources of vitamin D.[69] New data suggest that current dietary recommendations are not sufficient to maintain 25-hydroxy vitamin D_3 concentrations at or above 32 mcg/L (80 nmol/L).[69] The treatment of vitamin D deficiency associated with CKD generally requires the administration of 1,25-dihydroxy vitamin D_3 or another synthetic vitamin D_2 analog such as paricalcitol or doxercalciferol. Patients who have reduced 25-hydroxylase activity (eg, hepatic disease) can also require treatment with calcitriol (1,25-dihydroxy vitamin D_3). In selected cases, increasing calcium ingestion can be required if vitamin D replacement alone is ineffective in returning calcium concentrations to normal.

Clinical Controversy…

Some data have shown that animal source vitamin D_3 (cholecalciferol) is more efficacious at raising serum 25(OH)D concentrations compared with plant source vitamin D_2 (ergocalciferol). However, higher loading and maintenance doses of cholecalciferol are required to maintain serum 25, OH vitamin D concentrations.

Adverse Effects

Adverse effects of oral calcium and vitamin D supplementation include hypercalcemia and hypercalciuria, especially in the hypoparathyroid patient, in whom the renal calcium-sparing effect of PTH is absent. Hypercalciuria can increase the risk of calcium stone formation and nephrolithiasis in susceptible patients. One maneuver to help prevent calcium stones is to maintain the urine calcium excretion below 300 mg per day. Intermittently monitoring of 24-hour urine collections for total calcium excretion can help minimize the occurrence of hypercalciuria. The addition of thiazide diuretics for patients at risk for stone formation can result in an increase in tubular calcium reabsorption and reduction of vitamin D requirements.[61] (see Table 50-3)

DISORDERS OF PHOSPHORUS HOMEOSTASIS

Inorganic phosphorus in the form of phosphate is an essential element in phospholipid cell membranes, nucleic acids, and phosphoproteins, which are required for mitochondrial function.[1] Phosphorus regulates the intermediary metabolism of carbohydrates, fats, and proteins. Phosphorus also regulates enzymatic reactions including glycolysis, ammoniagenesis, and the 1-hydroxylation of 25-hydroxyvitamin D_3.[1,70] In addition, phosphorus is required for the generation of 2,3-diphosphoglycerate (2,3-DPG) in red blood cells, which is required for normal oxygen–hemoglobin dissociation and delivery of oxygen to the tissues.[1] Phosphorus is the source of the high-energy bonds of adenosine triphosphate (ATP), thus fueling a wide variety of physiologic processes, including muscle contractility, electrolyte transport, neurologic function, and other important biochemical reactions.[1] Considering its diverse biologic importance, it is not difficult to appreciate the clinical implications of disorders of phosphorus homeostasis.

Phosphate, the major intracellular anion, is present in living organisms mainly as organic phosphate esters such as 2,3-DPG, adenosine, guanosine triphosphate, and fructose 1,6-diphosphate.[1] Only a small fraction of intracellular phosphorus exists as inorganic phosphate; however, this fraction is critical because it is the source from which ATP is resynthesized.[1] The majority of inorganic phosphate is located in the extracellular space where it is the prime determinant of intracellular phosphate; thus, small increments in the organic phosphate levels can profoundly alter both the extracellular and intracellular phosphate levels. Metabolic disturbances (acidosis, alkalosis, and ketoacidosis), hydrogen ion shifts, and hormones (PTH, calcitonin, cortisol, and vitamin D) all can cause transcellular shifts in phosphorus concentrations. Because of these phenomena, the serum phosphorus level does not accurately reflect total body stores.[71]

The typical Western diet provides a daily intake of 800 to 1,600 mg of phosphorus. Approximately 60% to 80% of this is absorbed in the GI tract by passive and active transport (vitamin D-mediated). PTH, 1,25-dihydroxy vitamin D_3, and low-phosphate diets mediate increased absorption. Decreased absorption occurs under conditions of increased dietary intake of phosphorus and magnesium, glucocorticoid therapy, and hypothyroidism. The normal serum phosphorus concentration in adults is 2.5 to 4.5 mg/dL (0.81-1.45 mmol/L) and for children younger than 12 years it is 4 to 5.6 mg/dL (1.29-1.81 mmol/L). Influx via the GI tract and bone and tubular reabsorption by the kidney are the most important regulators of steady-state serum phosphorus concentrations. Renal excretion of phosphorus is a two-step process: glomerular filtration and proximal tubular reabsorption by passive transport coupled to sodium. Under normal conditions, 85% to 90% of filtered phosphate is reabsorbed, the majority in the early proximal tubule. Renal tubular reabsorption of phosphate is inhibited by PTH and 1,25-dihydroxy vitamin D_3.[71] There are increasing data in the literature that indicate fibroblast growth factor 23 (FGF23) is a key regulator of phosphate homeostasis.[72] FGF23 acts principally to decrease tubular reabsorption of phosphate and inhibit 1-α-hydroxylase, thereby reducing the concentration of active vitamin D. FGF23-mediated receptor activation requires klotho, a transmembrane protein. The tissue specificity for FGF23 effects appears to be defined by klotho–FGF23 coexpression. Conversely, phosphate reabsorption in the renal tubule is increased by

growth hormone, insulin, and insulin-like growth factor 1.[1] Internal phosphorus balance (transcellular phosphate distribution) is also of importance in the maintenance of normal serum phosphate. The serum phosphate concentration can vary by as much as 2 mg/dL (0.65 mmol/L) throughout the day, primarily as the result of changes in carbohydrate intake, insulin secretion, and diurnal variation.[1]

Hyperphosphatemia

Hyperphosphatemia typically results from either CKD, acute kidney injury (AKI), or endogenous intracellular phosphate release. Hyperphosphatemia occurs frequently in patients with AKI and is a nearly universal finding in those with advanced CKD (eg, stages 4 and 5). Tumor lysis syndrome, a complication of chemotherapy associated with massive lysis of cells and release of intracellular contents is also associated with hyperphoshatemia. The incidence of tumor lysis syndrome is highest among patients treated for acute lymphoblastic leukemia, acute myeloid leukemia and Burkitt's lymphoma[53] (see Chapter 134). Other causes of hyperphosphatemia include hemolysis and rhabdomyolysis.

Pathophysiology

5 The most common cause of hyperphosphatemia is a reduction in renal tubular reabsorption of phosphate when GFR is markedly inpaired (eg, GFR less than 25 mL/min/1.73 m^2 [less than 0.24 mL/s/m^2]).[70,71] Retention of phosphate decreases vitamin D synthesis and induces hypocalcemia, which leads to an increase in PTH, a finding that can be seen in those with stage 2 to 3 CKD. This physiologic response inhibits further tubular reabsorption of phosphorus as the kidney attempts to correct hyperphosphatemia and normalize serum calcium concentrations. Patients with excessive exogenous phosphate administration or who experience massive tissue breakdown or cell lysis in the setting of acute renal failure can rapidly develop moderate-to-severe hyperphosphatemia (serum phosphate more than 6.5 mg/dL [more than 2.10 mmol/L]).[71] Severe hyperphosphatemia (serum phosphate more than 7 mg/dL [more than 2.26 mmol/L]) is commonly encountered in patients with CKD, especially those with GFRs less than 15 mL/min per 1.73 m^2 (0.14 mL/s/m^2) (see Chapter 44).

Hyperphosphatemia caused by an increase in renal tubular reabsorption associated with hypoparathyroidism and associated decreases in PTH, is usually less severe than that observed in patients with severe renal failure or excessive exogenous or endogenous introduction of phosphate into the ECF. Acromegaly (mediated by growth hormone) and thyrotoxicosis (mediated by catecholamines) can also cause hyperphosphatemia by increasing tubular phosphate reabsorption.

Exogenous Phosphate Loads

Iatrogenic causes of hyperphosphatemia have been widely reported, and clinicians should be aware of the phosphorus content of IV, oral, and rectally administered products.[73] Although less-well recognized, oral and rectal administration of phosphate-containing solutions such as sodium phosphate (Fleet Phospho-Soda) can also result in severe and life-threatening hyperphosphatemia, especially in patients with moderate and severe CKD.[60,73] The risk of mortality is dependent on the

amount of phosphorus absorbed from the administered product; however, fatalities have occurred at low phosphate concentrations.[73] Acute phosphate nephropathy and renal failure have also been reported with the use of oral sodium phosphate bowel preparations. In 2008, the FDA issued a safety warning regarding the use of these products in patients at risk (the elderly, those with CKD) or on medications known to effect renal hemodynamics (eg, diuretics, nonsteroidal anti-inflammatory drugs [NSAIDs], or renin–angiotensin–aldosterone system inhibitors).[74] Acute phosphorus poisoning as a result of ingestion of laundry detergents is a rare and often unrecognized cause of elevated phosphate concentrations.

Rapid Tissue Catabolism

Any disorder that results in necrosis of skeletal muscle (ie, rhabdomyolysis) can generate the release of large amounts of intracellular phosphate into the systemic circulation. This condition is frequently associated with AKI (see Chapter 43) and thus severe hyperphosphatemia can develop because of increased endogenous phosphate release coupled with the impaired proximal tubule reabsorption such that phosphaturic hormones (eg, PTH, FGF23) become ineffective. Bowel infarction, malignant hyperthermia, and severe hemolysis are also conditions that can increase endogenous release of phosphate.

Moderate hyperphosphatemia is also commonly observed in patients undergoing treatment for acute leukemia and lymphomas.[53] Chemotherapeutic treatment of acute lymphoblastic leukemia can result in the release of large amounts of phosphate into the systemic circulation secondary to lysis of lymphoblasts. Initiation of chemotherapy for Burkitt lymphoma results in tumor lysis syndrome, a rapid lysis of malignant cells that results in hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia.[53]

Acid–Base Disorders

Lactic acidosis and diabetic ketoacidosis can trigger the transcellular shift of endogenous intracellular phosphate into the extracellular space and thereby dramatically increases serum phosphorous concentrations.[75] After the institution of treatment, serum phosphate levels should be checked hourly as they can decrease rapidly, and patients can ultimately develop hypophosphatemia.

Clinical Presentation

The severe acute onset of hyperphosphatemia can result in calcium and phosphate complexation and lead to the precipitation of calcium phosphate crystals in soft tissues, and within the kidney tht can result in nephrolithiasis or obstructive uropathy. Extravascular calcification can result in band keratopathy, “red eye,” pruritus, and periarticular calcification, especially in CKD patients. In addition, soft-tissue calcifications in the conjunctiva, skin, heart, cornea, lung, gastric mucosa, and kidney have been observed, primarily in CKD patients with chronic disordered mineral metabolism.[71] Extracellular phosphate can form insoluble nanoparticles with both calcium and fetuin-A which are referred to as calciprotein particles.[1] Calcium-phosphate crystals are likely to form in vivo when the product of the

serum calcium and phosphate concentrations exceeds 50 to 60 mg^2/dL^2 (4-4.8 $mmol^2/L^2$). Serum phosphate concentrations greater than 6.5 mg/dL (2.10 mmol/L) have been independently associated with increased morbidity and mortality in patients on maintenance hemodialysis.[76] Other symptoms associated with moderate-to-severe hyperphosphatemia include nausea, vomiting, diarrhea, lethargy, and seizures. The major effects of long-term hyperphosphatemia are related to the development of hypocalcemia (caused by phosphate inhibition of renal 1-α-hydroxylase) and its related consequences, as well as vascular and organ damage resulting from the deposition of calcium-phosphate crystals. Hyperphosphatemia associated with CKD can result in renal osteodystrophy because of overproduction of PTH. This condition is discussed in detail in Chapter 44.

TREATMENT

Desired Outcome

Management of patients with acutely elevated serum phosphate concentrations should be directed at avoiding GI and neurologic symptoms and preventing deposition in the urinary tract to avoid the development of AKI. The treatment of hyperphosphatemia is focused on returning serum phosphate concentrations to the normal or near normal (for those with CKD) range, with the hope that one can minimize the long-term cardiovascular consequences of calcium-phosphate deposition in the vasculature. The Kidney Disease Improving Global Outcomes (KDIGO) clinical practice guidelines suggest that for patients with CKD stages 3 to 5, serum phosphorus should be maintained in the normal range. In dialysis-dependent patients with stage 5 CKD, KDIGO suggests lowering elevated phosphorus levels toward the normal range.[77] (See Table 44-10.)

Pharmacologic Therapy

Severe symptomatic hyperphosphatemia manifesting as hypocalcemia and tetany may be treated by the IV administration of calcium. Although this can seem counterintuitive and many consider it controversial for a patient with a phosphate of 16 mg/dL (5.17 mmol/L) and a calcium of 7 mg/dL (1.75 mmol/L) (the calcium–phosphorus product is 112 mg^2/dL^2 [9 $mmol^2/L^2$]), correction of severe hypocalcemia is of primary importance because of the critical nature of this disorder. If calcium concentrations are not critically low, the initial management strategy should include limitation of all exogenous sources of phosphate and efforts to block further absorption should be initiated. Hemodialysis can be initiated if the patient remains symptomatic despite these interventions.[61]

6 In general, the most effective way to treat nonemergent hyperphosphatemia is to decrease phosphate absorption from the GI tract by implementing phosphate-binding therapy and altering the dietary content of phosphorous.[71] Antacids containing divalent and trivalent cations (calcium, lanthanum, magnesium, iron, and aluminum), or sevelamer are the agents most frequently used in the prevention and treatment of hyperphosphatemia (see Table 44-11).[78] Long-term treatment with aluminum hydroxide and aluminum carbonate should be discouraged because the use of these agents has been associated with anemia, CNS disorders, and bone disease.[78] Short-term therapy with these agents is effective and safe. Aluminum, calcium, and magnesium agents are available in oral

suspension formulations, which can aid administration in acutely ill patients who are receiving enteral nutrituion. The most frequent adverse effect from phosphate-binding agents (especially calcium) is constipation. Calcium salts are the preferred phosphate-binding agents except when there is concomitant hypercalcemia. Therapy with the polymer agent (sevelamer) or lanthanum carbonate might avoid the detrimental effects associated with the other agents. The iron-based binder offers the potential advantage of enhancing iron absorption (ferric citrate coordination complex) and reduced pilled burden (sucroferric oxyhydroxide).[79]

Hypophosphatemia

Mild-to-moderate hypophosphatemia is usually asymptomatic and associated with serum phosphate concentrations of 1 to 2 mg/dL (0.32-0.65 mmol/L), whereas severe hypophosphatemia that is frequently symptomatic is correlated with serum phosphorus concentrations of less than 1 mg/dL (0.32 mmol/L).[80]

Incidence

Hypophosphatemia has been observed in approximately 1% to 3% of the laboratory screening panels of patients who have been admitted to a hospital.[80] The incidence in hospitalized critically ill patients is 18% to 28%.[80] Unlike its severe form, mild or moderate hypophosphatemia seldom causes recognizable signs and symptoms.[78]

CLINICAL PRESENTATION Hyperphosphatemia General

- Serum phosphate concentration is primarily determined by the ability of the kidneys to reabsorb phosphate; therefore, hyperphosphatemia is uncommon in patients with normal kidney function.

Symptoms

- Acute symptoms include GI disturbances, lethargy, obstruction of the urinary tract, and rarely seizures. Symptoms associated with chronic hyperphosphatemia include “red eye” and pruritus.

Signs

- The elevated calcium-phosphate product results in precipitation in arteries, joints, soft tissues, and the viscera. This can result in tissue necrosis, termed calciphylaxis or calcemic uremic arteriopathy.

Laboratory Tests

- Serum phosphate levels more than 4.5 mg/dL (more than 1.45 mmol/L) represent hyperphosphatemia.

Pathophysiology

7 Hypophosphatemia can be the result of decreased GI absorption, reduced tubular reabsorption, or extracellular to intracellular redistribution.[1] Although mild-to-moderate hypophosphatemia is common and can occur in inpatients and outpatients, severe hypophosphatemia is predominantly encountered in the acute care setting and can be associated with life-threatening symptoms, including seizures, coma, and rhabdomyolysis (**Table 50-4**).

TABLE 50-4 Conditions Associated with the Development of Hypophosphatemia

Decreased GI absorption
Phosphate-binding drugs
Sucralfate
Calcium carbonate
Aluminum/magnesium antacids
Sevelamer
Lanthanum carbonate
Decreased dietary phosphorus intake
Glucocorticoids
Vitamin D deficiency/resistance
Hypoparathyroidism
Chronic diarrhea
Steatorrhea
Reduced tubular reabsorption
Hyperparathyroidism (primary and secondary)
Elevated FGF23
Recovery from burns
Rickets
Malignant neoplasms
Fanconi syndrome
Acute volume expansion
Metabolic acidosis
Renal transplantation
Vitamin D deficiency and/or resistance
Diuretics
Acetazolamide
Osmotic agents
Glucocorticoids
Sodium bicarbonate
Internal redistribution
Refeeding syndrome

Parenteral nutrition

Parathyroidectomy (hungry bone syndrome)

Alcoholism

Respiratory alkalosis

Diabetic ketoacidosis (correction)

Dextrose solutions

Insulin

Catecholamines

Anabolic steroids

Glucagon

Calcitonin

Erythropoietin

Decreased GI Absorption

Phosphate-binding substances such as sucralfate, calcium carbonate, sevelamer, lanthanum carbonate, sucroferric oxyhydroxide, ferric citrate coordination complex, and aluminum- or magnesium-containing antacids have the potential to bind large amounts of phosphorus in the gut, thereby preventing absorption. If phosphate-binding agents are ingested on a chronic basis in conjunction with a dietary phosphorus deficiency, hypophosphatemia can result.[81] Patients who are receiving long-term phosphate-binding agents, those with peptic ulcer disease or CKD, and those who may be predisposed to moderate hypophosphatemia (alcoholics) are at highest risk for the development of severe hypophosphatemia. Hyperparathyroidism can cause hypophosphatemia as a result of decreased GI absorption of dietary phosphorus.

Decreased Tubular Reabsorption

Reduced tubular reabsorption of phosphate can occur in hyperparathyroid (primary and secondary) patients with normal renal function and those with vitamin D deficiency or elevated FGF23 concentrations. Elevated PTH levels lead to an increase in serum calcium concentrations and decreased serum phosphate concentrations. Serum phosphorus is decreased as the result of a reduction in renal tubular reabsorption.[75] Recovery from extensive third-degree burns is associated with development of an anabolic state as stress levels decrease and nutritional therapies take effect as well as a marked diuretic phase associated with an impressive renal loss of phosphate.[82] Because phosphate is rapidly incorporated into the new cells, this can contribute to the severity of the hypophosphatemia. Drugs that cause increased renal elimination of phosphate include diuretics (acetazolamide and osmotic diuretics), glucocorticoids, and sodium bicarbonate.[81] In a recent analysis, the IV iron formulation ferric carboxymaltose was associated with the development of hypophosphatemia (in 51% of patients treated, and 13% of cases were severe (serum phosphorus less than 1 mg/dL [less than 0.32 mmol/L]) and prolonged.[83] The mechanism is unclear, however, iron deficiency itself is associated with elevated FGF-23.[84]

Cellular Redistribution

Rapid refeeding of malnourished patients with high-carbohydrate, high-calorie diets with inadequate amounts of supplemental phosphate can result in severe symptomatic hypophosphatemia. This phenomenon is especially prevalent in patients with other underlying risk factors for the development of hypophosphatemia, such as alcoholism.[82] The etiology of severe hypophosphatemia associated with hyperalimentation and nutritional recovery can be separated into two phases: acute, rapid hypophosphatemia secondary to intracellular shifts of phosphate resulting from glucose-induced insulin secretion; and the gradual decrease in serum phosphate concentration over 5 to 10 days secondary to tissue repair in the presence of phosphate deprivation.[85] The development of severe hypophosphatemia secondary to hyperalimentation can be prevented by the administration of 12 to 15 mmol of phosphate per liter of hyperalimentation solution or 15 mmol per 1,000 calories (4.2 kJ) of dextrose.[85] Transcellular shifts in phosphate also occur after parathyroidectomy, causing severe hypocalcemia and hypophosphatemia because of hungry bone syndrome (deposition of phosphate and calcium in the bone).

Severe and prolonged respiratory alkalosis (a result of hyperventilation, pain, anxiety, and sepsis) can cause hypophosphatemia.[80] Respiratory alkalosis is thought to contribute significantly to the hypophosphatemia observed during alcohol withdrawal.[71] Although patients with diabetic ketoacidosis may present with hyperphosphatemia, the institution of therapy to correct it can cause serum phosphate concentrations to decrease rapidly as phosphate shifts back into the intracellular compartment. In addition, the acidosis associated with the diabetic ketoacidotic state can cause a decomposition of organic compounds inside the cell and a release of inorganic phosphate into the plasma and subsequently into the urine.[86] The combination of intracellular phosphate breakdown and the shift of phosphate into cells on initiation of treatment can lead to severe hypophosphatemia. Drugs associated with transcellular shifts in phosphate include dextrose solutions, glucagon, insulin, catecholamines, calcitonin, erythropoietic agents, and anabolic steroids.

Chronic ethanol abusers are prone to a variety of serum electrolyte disorders including hypocalcemia, hypomagnesemia, hypokalemia, and hypophosphatemia. The etiology of hypophosphatemia in the alcoholic patient is multifactorial. Malnutrition, poor dietary intake, diarrhea, vomiting, and the use of phosphate-binding antacids can all contribute to the hypophosphatemia of alcoholism.[87] In addition, serum phosphate concentrations may decrease after hospitalization in the alcoholic patient with the institution of dextrose-containing IV fluids as a result of an intracellular shift of phosphate.[85,87] Hyperventilation associated with the alcohol withdrawal syndrome can also contribute to the development of hypophosphatemia.[85] Alcoholic patients are particularly susceptible to the complications of hypophosphatemia such as rhabdomyolysis, which is often seen during withdrawal or refeeding.[85] Thus, serum phosphate concentrations should be routinely monitored in alcoholic patients.

Clinical Presentation

The clinical manifestations of severe hypophosphatemia are diverse and many organ systems can be

affected. It is likely that two primary biochemical abnormalities are responsible for most of the clinical manifestations of severe hypophosphatemia.[80] First, intracellular energy stores may be decreased secondary to depletion of intracellular ATP. This can result in disruptions in cellular function. Second, reduced red blood cell 2,3-DPG concentrations are associated with a shift to the left of the oxyhemoglobin saturation curve. This shift is associated with a decrease in the release of oxygen to peripheral tissues (secondary to increased oxygen affinity for hemoglobin) and may result in tissue hypoxia.[80] These metabolic disorders can be seen in a wide variety of organ systems.

Neurologic manifestations of severe hypophosphatemia can result in a metabolic encephalopathy syndromecharacterized by irritability, apprehension, weakness, numbness, paresthesia, dysarthria, confusion, obtundation, seizures, and coma has been described in patients with severe hypophosphatemia.[82,85] Neuropsychiatric disturbances include apathy, delirium, hallucinations, and paranoia. Peripheral neuropathy and symptoms resembling Guillain–Barré syndrome have also been reported.[85]

Severe hypophosphatemia can result in significant dysfunction of skeletal muscle ranging from myalgia, bone pain, and weakness, with chronic hypophosphatemia, to potentially fatal rhabdomyolysis with severe acute hypophosphatemia.[82] Laboratory evaluations can help distinguish between chronic and acute on chronic hypophosphatemia. Elevated alkaline phosphatase, normal creatine phosphokinase, and normal to low phosphate and calcium are present in cases of chronic hypophosphatemia. In contrast, hyperkalemia, hyperuricemia, elevated blood urea nitrogen and creatinine, hypercalcemia, and myoglobinuria are often present in cases in which rhabdomyolysis complicates the acute or chronic hypophosphatemia.[76] Hypophosphatemia can result in acute respiratory failure secondary to respiratory muscle weakness and diaphragmatic contractile dysfunction. Thus, frequent assessment of serum phosphate concentration is indicated in patients at risk for respiratory failure.[80] Likewise, adequate treatment of hypophosphatemia in respiratory failure can aid in successful weaning from the ventilator.[80] Dysphagia and ileus have also been attributed to hypophosphatemia.[80]

Myocardial dysfunction has been reported to be impaired in the setting of hypophosphatemia and has resulted in congestive cardiomyopathy. This has been reported in alcoholics, and postoperative and intensive care patients. Depletion of cardiac ATP stores has been hypothesized as the cause of this syndrome[88] Arrhythmias have also been reported in patients with hypophosphatemia. Because hypophosphatemia is a potentially reversible cause of heart failure, it should be considered in patients who experience an acute deterioration in ventricular function.

Hematologic manifestations of hypophosphatemia include decreased levels of 2,3-DPG, decreased red blood cell ATP, and membrane rigidity.[88] When red blood cell ATP decreases cells become spherocytic and rigid, and are trapped and destroyed in the spleen.[88] Therefore, hemolysis can be a manifestation of severe hypophosphatemia. Reduction in ATP content of white blood cells can result in mobility, chemotaxis, phagocytosis, and bactericidal dysfunction.[88,85] These changes can contribute to an increased risk of infection in hypophosphatemic patients.

CLINICAL PRESENTATION Hypophosphatemia General

- Major conditions associated with symptomatic hypophosphatemia are chronic alcoholism, IV hyperalimentation without adequate phosphate supplementation, and the chronic ingestion of antacids. Severe hypophosphatemia can also be seen during treatment of diabetic ketoacidosis and with prolonged hyperventilation.

Symptoms

- Except for the effects on mineral metabolism, the symptoms of hypophosphatemia are caused by two consequences (reduction of red cell 2,3-DPG and reduction of intracellular ATP levels), and can impact virtually all organ systems. The symptoms are predominantly neurological and can include irritability, apprehension, weakness, numbness, paresthesia, and confusion. Severe acute development of hypophosphatemia can result in seizures or coma.

Signs

- The initial response of bone to hypophosphatemia contributes to hypercalcemia and hypercalciuria. Prolonged hypophosphatemia can also result in rickets and osteomalacia.
- Neurologic: Severe hypophosphatemia can lead to a metabolic encephalopathy.
- Cardiopulmonary: Impaired myocardial contractility, respiratory failure secondary to ATP depletion, CHF, new onset or worsening of an existing condition.
- Musculoskeletal: Proximal myopathy, dysphagia, and ileus have been reported. Acute hypophosphatemia superimposed on preexisting severe phosphate depletion can lead to rhabdomyolysis.
- Hematologic: Alterations in the hematopoietic system can also occur, resulting in hemolysis, reduction in phagocytotic and granulocyte chemotactic ability, as well as defective clot retraction and thrombocytopenia.

Laboratory Tests

- Serum phosphate levels less than 2.4 mg/dL (less than 0.78 mmol/L) are indicative of hypophosphatemia; however, symptomatic hypophosphatemia typically is not evident until serum phosphate less than 1 mg/dL (less than 0.32 mmol/L).

Finally, prolonged hypophosphatemia may result in osteopenia and osteomalacia because of enhanced osteoclastic resorption of bone and limited crystallization constituents (phosphate), respectively.[87]

TREATMENT

Desired Outcomes

The goals of therapy are the reversal of signs and symptoms of hypophosphatemia, normalization of serum phosphate concentrations, and management of underlying conditions. Awareness of the

clinical situations in which hypophosphatemia is anticipated (alcoholism, diabetic ketoacidosis, and parenteral nutrition) is of vital importance in preventing iatrogenic hyperphosphatemia due to overly aggressive therapy. The routine addition of phosphate (12-15 mmol/L) to IV parenteral nutrition solutions is important for the prevention of severe hypophosphatemia in hospitalized patients.

Pharmacologic Therapy

Pharmacologic treatment for hypophosphatemia will typically involve phosphorus salt supplementation. The acuity and other electrolyte conditions dictate the salt, formulation, and route of administration (**Table 50-5**).

TABLE 50-5 Phosphorus Replacement Therapy

Product (Salt)	Phosphate Content	Initial Dosing Based on Serum K
Oral Therapy (Potassium Phosphate + Sodium Phosphate)		
Neutra-Phos® (7 mEq/packet each of Na and K)	250 mg (8 mmol)/packet	Serum K >5.5 mEq/L (mmol/L) one packet three times daily
Neutra-Phos-K® (14.25 mEq/packet of K)	250 mg (8 mmol)/packet	Serum K >5.5 mEq/L (mmol/L); not recommended
K-Phos Neutral® (13 mEq/tablet Na and 1.1 mEq/tablet K)	250 mg (8 mmol)/tablet	Serum K >5.5 mEq/L (mmol/L) one tablet three times daily
Uro-KP-Neutral® (10.9 mEq/tablet Na and 1.27 mEq/tablet K)	250 mg (8 mmol)/tablet	Serum K >5.5 mEq/L (mmol/L) one tablet three times daily
Fleets Phospho-soda® (sodium phosphate solution)	4 mmol/mL	Serum K >5.5 mEq/L (mmol/L) 2 mL three times daily
IV Therapy		
Sodium PO_4 (4 mEq/mL Na)	3 mmol/mL	Serum K >3.5 mEq/L (mmol/L) 15-30 mmol IVPB
Potassium PO_4 (4.4 mEq/mL K)	3 mmol/mL	Serum K <3.5 mEq/L (mmol/L) 15-30 mmol IVPB

IVPB, IV piggy back; K, potassium; Na, sodium; PO_4, phosphate.

Severe Hypophosphatemia

8 Patients with severe (less than 1 mg/dL [less than 0.32 mmol/L]) or symptomatic hypophosphatemia should be treated with parenteral phosphate replacement. Thus, dosage and infusion recommendations, as well as response to parenteral phosphate replacement, are highly variable.[89] The infusion of 15 mmol of phosphate in 250 mL of 5% dextrose or 0.9% sodium chloride over 3 hours is a safe and effective treatment for severe hypophosphatemia.[87] Mean increases in serum phosphate of 0.5 to 0.8 mg/dL (0.16-0.26 mmol/L) have been reported. Doses of 0.2 to 0.6 mmol/kg of phosphate can be given over 1 to 3 hours in patients without hypercalcemia (serum

calcium more than 10.5 mg/dL [more than 2.63 mmol/L]).[89] Other authors recommend a wider dosage range of 0.08 to 0.64 mmol/kg body weight (5-45 mmol in a 70-kg [154 lb] patient) given over 4 to 12 hours.[90] IV phosphate therapy produces the desired increase in serum phosphate at 24 hours in 20% to 80% of patients. Response is dependent on the degree of phosphate depletion and replacement dose administered.[87] The initial success is often followed in 48 to 72 hours by recurrent hypophosphatemia, necessitating close monitoring of serum phosphate and repeated administration of phosphate products as warranted.

Adverse Effects of Parenteral Phosphate

Parenteral phosphate supplementation is associated with risks of hyperphosphatemia, metastatic soft tissue deposition of calcium-phosphate product, hypomagnesemia, hypocalcemia, and hyperkalemia or hypernatremia (dependent on which IV phosphate formulation is administered). Inappropriate administration of large doses of parenteral phosphate over relatively short time periods has resulted in symptomatic hypocalcemia and soft-tissue calcification.[1] The rate of infusion and choice of initial dosage should therefore be based on severity of hypophosphatemia, presence of symptoms, and coexistent medical conditions. Patients should be closely monitored with frequent (every 6 hours) serum phosphate determinations for 48 to 72 hours after starting IV therapy. It can be necessary to continue administration of IV phosphate for several days in some patients, although other patients may be able to tolerate an oral maintenance regimen. Monitoring should also include assessment of serum potassium, calcium, and magnesium concentrations. Hypomagnesemia secondary to intracellular shifts occurs frequently (27%-80%) in severely hypophosphatemic patients.[78] Therapy with parenteral phosphate should be undertaken with great caution and at reduced dosage for patients with hypercalcemia or renal dysfunction.[85]

Mild-to-Moderate Hypophosphatemia

Mild-to-moderate or asymptomatic hypophosphatemia can be treated by the administration of oral phosphate salts in doses of 1.5 to 2 g (50-60 mmol) daily in divided doses (see Table 50-5). Phosphate concentrations should be monitored daily, with the goal of correcting the reduced phosphate concentration in approximately 7 to 10 days. The primary dose-limiting adverse effect associated with oral phosphate replacement is the development of osmotic diarrhea. Patients with mild-to-moderate hypophosphatemia and moderate-to-severe renal insufficiency should receive reduced daily oral doses (ie, 1 g or approximately 30 mmol of phosphate) with careful monitoring of serum phosphate concentration because they are predisposed to phosphate retention. In addition to phosphate supplementation for hypophosphatemia, dipyridamole can decrease renal phosphate leaking and increase serum phosphate. Doses of 75 mg four times daily have resulted in increases in serum 1,25-dihydroxy vitamin D_3 and decreases in serum calcium and urolithiasis events.[81]

CLINICAL BOTTOM LINE

Initial treatment strategy should be based on acuity of onset and severity of symptoms. Because the etiologies of calcium and phosphate disorders are diverse, it is important to integrate the known or

anticipated consequences of concomitant diseases into the treatment strategy. The patient's medication history should be comprehensively assessed to determine whether the electrolyte abnormality may be drug induced. After resolution or treatment of the acute calcium or phosphate disorder, the medication regimen should be evaluated periodically. This proactive interventional approach will facilitate the management of mild disorders in the community and can reduce the need for hospitalization.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ATP	adenosine triphosphate
CHF	congestive heart failure
CKD	chronic kidney disease
FGF23	fibroblast growth factor 23
2,3-DPG	2,3-diphosphoglycerate
NSAID	nonsteroidal anti-inflammatory drug
PTH	parathyroid hormone
PTHrP	PTH-related protein
S_{ca}	serum calcium

Chapter 51: Disorders of Potassium and Magnesium Homeostasis

Rachel W. Flurie; Donald F. Brophy

INTRODUCTION

KEY CONCEPTS

- 1 Potassium regulates many biochemical processes in the body and is a key cation for electrical action potentials across cellular membranes.
- 2 In patients with concomitant hypokalemia and hypomagnesemia, it is imperative to correct the hypomagnesemia before the hypokalemia.
- 3 Potassium chloride is the preferred potassium supplement for the most common causes of hypokalemia.
- 4 Hyperkalemia is a common occurrence in patients with acute kidney injury or chronic kidney disease.
- 5 Hypomagnesemia is commonly caused by excessive gastrointestinal (GI) or renal magnesium wasting.
- 6 Hypermagnesemia is predominantly observed in patients with acute or chronic kidney disease.
- 7 Severe hypermagnesemia may affect the neuromuscular and cardiovascular systems.

Potassium and magnesium are electrolytes that are responsible for numerous metabolic activities. Disorders of these electrolytes are frequently seen in both the acute care and community ambulatory care settings. Therefore, clinicians need a firm understanding of the etiology, pathophysiology, symptoms, pharmacotherapy, and monitoring of these disorders. This chapter describes the homeostatic mechanisms that are responsible for the maintenance of normal potassium and magnesium serum concentrations. The clinical disorders responsible for the development of hyperkalemia, hypermagnesemia, hypokalemia, and hypomagnesemia are also reviewed.

POTASSIUM

Potassium is the most abundant cation in the body, with estimated total-body stores of 3,000 to 4,000 mEq (mmol).[1] Ninety-eight percent of this amount is contained within the intracellular compartment, and the remaining 2% is distributed within the extracellular compartment. The sodium-potassium adenosine triphosphatase (Na^+-K^+-ATPase) pump located in the cell membrane is responsible for the compartmentalization of potassium. This pump is an active transport system that maintains increased intracellular stores of potassium by transporting sodium out of the cell and potassium into the cell at a ratio of 3:2. Consequently, the pump maintains a higher concentration of potassium inside the cell.

The normal serum concentration range for potassium is 3.5 to 5 mEq/L (mmol/L), whereas the intracellular potassium concentration is approximately 150 mEq/L (mmol/L).[2] Approximately 75% of the intracellular potassium is located in skeletal muscle; the remaining 25% is located in the liver and red blood cells. Extracellular potassium is distributed throughout the serum and interstitial space. Potassium is dynamic in that it is constantly moving between the intracellular and extracellular compartments according to the body's needs. Thus, the serum potassium concentration alone does not accurately reflect the total-body potassium content.

1 Potassium has many physiologic functions within cells, including protein and glycogen synthesis and cellular metabolism and growth. It is also a determinant of the electrical action potential across the cell membrane.[1] The ratio of the intracellular-to-extracellular potassium concentration is the major determinant of the resting membrane potential across the cell membrane. Thus, the resting membrane potential is greatly affected by variations in extracellular potassium concentration. Serum potassium concentrations outside the normal range can have disastrous effects on neuromuscular activity, in particular cardiac conduction. Hypo- and hyperkalemia are both associated with potentially fatal cardiac arrhythmias, along with other neuromuscular disturbances. Finally, potassium is integral to maintaining blood pressure, prevention of stroke, and potentially other cardiovascular diseases.[3] Both the National High Blood Pressure Education Program and the Institute of Medicine recommend potassium supplementation as a strategy for preventing and treating hypertension.[4-5]

Control of Potassium Homeostasis

Potassium homeostasis, the maintenance of serum potassium within the normal range, is affected by dietary intake, GI and urinary excretion, hepatic and muscular sequestration, hormones, acid–base balance, body fluid tonicity, central and peripheral circadian clocks, and a highly integrated feedback mechanism.[6,7] Together, these mechansisms usually maintain total-body potassium content within a narrow window without appreciable changes in the serum potassium concentration.[6] Deviations in serum potassium concentrations outside of the normal range are a result of nonhomeostatic processes that are not sensitive to changes in potassium balance.[6] The recommended adequate intake of dietary potassium in the United States is approximately 120 mEq/day (mmol/day); yet the typical American adult only consumes 56% of this recommended amount.[8] Potassium is considered to be a nutrient of concern, because of its beneficial effects on blood pressure, reduction in the risk of kidney stones, and decrease of bone loss.[9] Potassium is abundant in fruits, vegetables, meats, whole grains, and milk

products. Most dietary potassium is absorbed, with only 10 to 20 mEq/day (mmol/day) eliminated in feces. The amount eliminated in the feces increases, however, in patients with diarrhea and in those with chronic kidney disease (CKD).[7]

The kidney is the primary route of potassium elimination. Potassium is freely filtered, but almost all of it is reabsorbed passively in the proximal tubule and the thick ascending limb of the loop of Henle.[9] Therefore, urinary potassium excretion is primarily determined by potassium secretion from the luminal cells of the distal tubule and collecting duct. Although the amount of potassium filtered by the glomerulus approaches 700 mEq (mmol) per day, only approximately 10% to 20% is actually excreted in the urine.[9] However, this amount can vary based on dietary intake, serum potassium concentration, and aldosterone activity. For example, more potassium is renally excreted in conditions that result in high aldosterone activity (eg, dehydration) when the body is attempting to conserve sodium or when there is an increase in dietary potassium intake.

Hormones such as insulin, catecholamines, and aldosterone dramatically affect potassium homeostasis. Insulin is the most important hormonal mediator of potassium balance because it stimulates the cellular Na^+-K^+-ATPase pump to increase transport of potassium into liver, muscle, and adipose tissue.[6] There is a complex negative feedback loop in which insulin secretion tightly regulates serum potassium concentrations: an increase of only a few tenths of a milliequivalent (mmol) of potassium stimulates pancreatic insulin secretion in an attempt to prevent hyperkalemia from developing.[1] If hyperkalemia does occur, glucagon is released from the liver to protect against insulin-induced hypoglycemia. Conversely, hypokalemia inhibits insulin secretion, a finding that explains why some patients receiving diuretics develop hyperglycemia.

An elevation in circulating catecholamines such as epinephrine usually results in the intracellular movement of potassium by two mechanisms.[9] Stimulation of the β-receptor, which directly activates the Na^+-K^+-ATPase pump and glycogenolysis, which raises blood glucose concentrations, thereby increasing insulin secretion. This dual mechanism is often used therapeutically in patients with hyperkalemia to normalize serum potassium concentrations.

Aldosterone, a mineralocorticoid that is secreted from the adrenal glands in response to high serum potassium concentrations, promotes urinary potassium excretion. Aldosterone acts on the distal tubule and collecting duct to promote the reabsorption of sodium and water in exchange for potassium. It also increases potassium permeability and transport across the luminal membrane of the nephron by stimulating cellular Na^+-K^+-ATPase pump activity.[7]

Changes in acid–base status significantly affect the serum potassium concentration. For example, the infusion of metabolic inorganic acids, such as hydrochloric acid, results in an increase in serum potassium. The body compensates for excessive hydrogen ions by moving them from the serum into the cell in exchange for intracellular potassium, to maintain electroneutrality. The processes by which this occurs are highly complex and involve cellular H^+-K^+-ATPase pumps and both Na^+-HCO_3^- and K^+-HCO_3^- cotransporters.[10] The efflux of potassium into the serum can result in hyperkalemia. A commonly quoted approximation of the pH effect is that for every 0.1 unit decrease in pH, serum potassium concentration increases by 0.6 to 0.8 mEq/L (mmol/L) (with a wide range of 0.2 to 1.7).[11] This

is often referred to as *false hyperkalemia* because there is not a true excess of total-body potassium. Metabolic acidosis associated with lactic acidosis and ketoacidosis does not result in hyperkalemia, because both cations and anions enter the cell, thus maintaining electroneutrality.[1] Respiratory acidosis also does not significantly affect the serum potassium concentration.

Conversely, metabolic alkalosis has been associated with hypokalemia. As a result of a net loss of hydrogen ion from the serum, intracellular hydrogen ions enter the serum to increase the acidity of the blood. To maintain electroneutrality, extracellular potassium ions are shifted intracellularly. This creates a relative deficiency of potassium in the serum. Serum potassium decreases approximately 0.6 mEq/L (mmol/L) for each 0.1 unit increase in blood pH. This is frequently termed *false hypokalemia* because there is not a true deficiency in total-body potassium.

Finally, hyperosmolality can result in enhanced movement of potassium from the cell into the extracellular fluid. This occurs most likely because of the associated cell shrinkage and water loss, which increases the intracellular-to-extracellular potassium gradient.[4] This is seen in conditions such as diabetic ketoacidosis. Conversely, hypoosmolality does not seem to affect potassium distribution.

HYPOKALEMIA

Epidemiology

Hypokalemia (defined as a serum potassium concentration less than 3.5 mEq/L [mmol/L]) is a commonly encountered electrolyte abnormality in clinical practice. Hypokalemia is often categorized as mild (serum potassium 3.1-3.5 mEq/L [mmol/L]), moderate (serum potassium 2.5-3 mEq/L [mmol/L]), or severe (less than 2.5 mEq/L [mmol/L]).[2] When hypokalemia is detected, the diagnostic workup should evaluate the patient's comorbid disease states and concomitant medications. Hypokalemia is virtually nonexistent in healthy adults. This is due in part to the relatively high potassium content in the typical Western diet as well as the body's effective potassium-sparing mechanisms, which tightly regulate the serum potassium concentration. However, as many as 20% of hospitalized patients and up to 40% of patients taking thiazide diuretics will develop hypokalemia.[2]

While transient hypokalemia may be thought of as merely a laboratory abnormality, there are serious potential consequences associated with persistent hypokalemia. Recent data suggest that hypokalemia increases mortality in patients with chronic heart failure or CKD, populations typically thought to be more sensitive to the effects of hyperkalemia.[12] In fact, even mild hypokalemia in patients with CKD appears to confer a greater risk of death compared with those with mild to moderate hyperkalemia.[13]

Etiology and Pathophysiology

Hypokalemia results when there is a total-body potassium deficit, or when serum potassium is shifted into the intracellular compartment. Total-body deficits occur in the setting of poor dietary intake of potassium, or when there are excessive renal and GI losses of potassium. Maintaining a consistent dietary intake of potassium is important because the body has no effective method for storing potassium. At steady state, potassium excretion matches potassium intake; approximately 90% of

ingested potassium is renally excreted, whereas 10% is excreted in feces.[9] This underscores the importance of eating a well-balanced diet. Elderly patients with chronic diseases and those undergoing surgery are at increased risk for developing hypokalemia because of insufficient intake or losses resulting from surgery.

Many drugs can cause hypokalemia by a variety of mechanisms including intracellular potassium shifting and increased renal or stool losses (**Table 51-1**). The most common cause of drug-induced hypokalemia is loop and thiazide diuretic administration as these agents inhibit renal sodium reabsorption, which results in increased sodium delivery to the distal tubule. Consequently, hypokalemia develops because the distal tubule selectively reabsorbs sodium, and excretes potassium. Second, because diuretics result in vascular volume contraction, aldosterone is secreted that further promotes the renal excretion of potassium. If concomitant potassium supplements are not provided to patients receiving loop and thiazide diuretics, mild to moderate hypokalemia is inevitable.

TABLE 51-1 Mechanism of Drug-Induced Hypokalemia

Transcellular Shift	Enhanced Renal Excretion	Enhanced Fecal Elimination
β_2-Receptor agonists	Diuretics	
Epinephrine	Acetazolamide	
Albuterol	Thiazides	
Terbutaline	Indapamide	
Fomoterol	Metolazone	
Salmeterol	Furosemide	
Isoproterenol	Torsemide	Laxatives
Ephedrine	Bumetanide	Sodium polystyrene sulfonate
Pseudoephedrine	Ethacrynic acid	Phenolphthalein
Tocolytic agents	High-dose penicillins	Sorbitol
Ritodrine	Nafcillin	Patiromer
Nylidrin	Ampicillin	
Theophylline	Penicillin	
Levothyroxine	Mineralocorticoids	
Decongestants	Miscellaneous	
Caffeine	Aminoglycosides	
Insulin overdose	Amphotericin B	

Transcellular Shift	Enhanced Renal Excretion	Enhanced Fecal Elimination
Verapamil overdose	Cisplatin	
Barium overdose		

The second most common etiology of hypokalemia is excessive loss of potassium-rich GI fluid as a result of diarrhea and/or vomiting. The typical potassium loss in feces is approximately 10 mEq (mmol) per day.[7] In diarrheal states, this amount increases proportionally with the volume of stool output. A case report of a patient with secretory diarrhea reported fecal potassium losses of 130 to 170 mEq/L (mmol/L).[14] Vomiting also accounts for substantial potassium losses, which have been estimated to be as high as 30 to 50 mEq (mmol) per liter of vomitus.[15] Metabolic alkalosis which often develops in those with severe diarrhea and vomiting as a result of loss of these bicarbonate-rich fluids causes an intracellular shift of potassium, which lowers the serum concentration of potassium even further. Prolonged diarrhea and vomiting tend to affect children and elderly patients profoundly because their kidneys are unable to effectively maintain adequate fluid status.

2 Hypomagnesemia, which is present in more than 50% of cases of clinically significant hypokalemia, contributes to the development of hypokalemia because it reduces the intracellular potassium concentration and promotes renal potassium wasting.[16] While the precise mechanism of the accelerated renal loss is unknown, many believe that the intracellular potassium concentration may decrease because hypomagnesemia impairs the function of the Na^+-K^+-ATPase pump thereby promoting potassium wasting. Alternatively, the combination of increased sodium delivery to the distal tubule, elevated aldosterone concentrations, and hypomagnesemia may cause the renal outer medullary potassium channels to excrete more potassium.[16] What is clear is that hypokalemia and hypomagnesemia often coexist as a result of drugs (diuretic administration) or disease states (diarrhea). When concomitant hypokalemia and hypomagnesemia occur, the magnesium deficiency should be corrected first, otherwise full repletion of the potassium deficit is difficult.

TREATMENT

Desired Outcomes

The goals of hypokalemia management are to prevent and/or treat serious life-threatening complications, normalize the serum potassium concentration, identify and correct the underlying cause of hypokalemia, and finally prevent overcorrection of the serum potassium concentration.

General Approach to Therapy

The general approach to therapy depends on the degree and rapidity with which hypokalemia developed and the presence of signs and symptoms. Serum potassium concentrations between 3.5 and 4 mEq/L (mmol/L) are a sign of early potassium depletion. No pharmacologic therapy is recommended; however, patients should be encouraged to increase their dietary intake of potassium-rich foods. When the serum potassium concentration is between 3 and 3.5 mEq/L (mmol/L), the patient's concomitant conditions and therapies will largely determine whether pharmacologic therapy should be initiated.

Most patients will not have signs or symptoms if serum potassium concentrations remain greater than 3 mEq/L (mmol/L). The presence of signs or symptoms with mild hypokalemia warrants the intiation of potassium supplementation. Oral potassium supplementation should be initiated in patients with underlying cardiac conditions that predispose them to cardiac arrhythmias. Patients with serum potassium concentrations less than 3 mEq/L (mmol/L) should always be treated to achieve values between 4 and 4.5 mEq/L (mmol/L). In asymptomatic patients, oral therapy is the preferred route of administration. Intravenous (IV) potassium may be necessary in symptomatic patients with severe depletion, or in patients who are intolerant to oral supplementation. In patients with concomitant moderate to severe hypomagnesemia, the magnesium deficit should be corrected before potassium supplementation is started.[2,9]

CLINICAL PRESENTATION Hypokalemia General

- The signs and symptoms of hypokalemia are usually nonspecific and highly variable between patients.

Symptoms

- Symptoms are dependent on the degree of hypokalemia and its rapidity of onset.
- Mild hypokalemia is often asymptomatic.
- Moderate hypokalemia is associated with cramping, weakness, malaise, and myalgias.

Signs

- Cardiovascular: In severe hypokalemia, electrocardiogram (ECG) changes often include ST-segment depression or flattening, T-wave inversion, and U-wave elevation. Clinical arrhythmias include heart block, atrial flutter, paroxysmal atrial tachycardia, ventricular fibrillation, and digitalis-induced arrhythmias.
- Musculoskeletal: Cramping and impaired muscle contraction.

Laboratory Tests

- Serum potassium concentration below 3.5 mEq/L (mmol/L) is diagnostic. Hypomagnesemia (serum magnesium concentration below 1.7 mg/dL [1.4 mEq/L; 0.70 mmol/L]) can also be present.

Nonpharmacologic Therapy

The best and most abundant sources of dietary potassium supplementation are fresh fruits and vegetables, fruit juices, and meats (**Table 51-2**). Increased dietary intake of foods with high potassium content, however, is not recommended long term because it can add unwanted calories to the patient's diet. Moreover, dietary potassium is almost entirely coupled with phosphate, rather than chloride, so it is not as effective in correcting potassium loss associated with hypochloremic conditions such as vomiting, nasogastric suctioning, and diuretic therapy. Salt substitutes that contain potassium chloride are another effective, inexpensive source of potassium and because they provide chloride as well they are frequently recommended.

TABLE 51-2 Foods that Are High in Potassium

High content (>250 mg)	Very high content (>500 mg)
Kidney beans, cooked	Potato, baked, flesh and skin
Lentils, cooked	Sweet potato, baked in skin
Soybeans, green, cooked	Juice, canned
Lima beans, cooked	Prunes
Soybeans, mature, cooked	Carrot
Pinto beans, cooked	Tomato
Lentils, cooked	Tomato paste
Halibut, cooked	Tomato puree
Rockfish, Pacific, cooked	Beet greens, cooked
Cod, Pacific, cooked	White beans, canned
Tuna, yellowfin, cooked	Plain yogurt, nonfat or low-fat
Rainbow trout, cooked	Clams, canned
Evaporated milk, nonfat	
Low-fat (1%) or reduced fat (2%) chocolate milk	
Skim milk (nonfat)	
Low-fat milk or buttermilk (1%)	
Orange juice, fresh	
Bananas	
Peaches, dried, uncooked	
Prunes, stewed	
Apricots, dried, uncooked	
Plantains, cooked	
Tomato sauce	
Pork loin, center rib, lean, roasted	
Spinach, cooked	

Pharmacologic Therapy

Formal guidelines for potassium supplementation were last published by the National Council on Potassium in Clinical Practice in 2000 (**Table 51-3**).[17] These guidelines provide a comprehensive framework for potassium administration as a prophylactic and therapeutic replacement for many patient populations. When deciding how to design the optimal regimen, one must consider: (a) the patient's normal, that is, baseline potassium concentration; (b) underlying medical conditions that can affect potassium balance; (c) concomitant medications that can affect potassium balance; (d) the patient's dietary salt intake; and (e) the patient's ability to comply with the therapeutic regimen.[17]

TABLE 51-3 General Consensus Guidelines for Potassium Replacement

Guideline	Comment

Guideline	Comment
Potassium replacement therapy should accompany dietary consumption of potassium-rich foods.	Potassium-rich foods often cannot completely replace potassium associated with chloride losses (vomiting, diuretics, or nasogastric suction) because it is almost entirely coupled to phosphate. Furthermore, increasing dietary intake of these foods can lead to unwanted weight gain.
Potassium replacement is recommended for sodium-sensitive and hypertensive patients.	A high-sodium diet often results in excessive urinary potassium excretion.
Potassium replacement is recommended in patients who are subject to vomiting, diarrhea, or diuretic/laxative abuse.	These conditions promote excessive renal and GI potassium loss.
Potassium supplementation is best administered orally in divided doses over several days to achieve full repletion.	
Laboratory measurement of serum potassium is convenient, but not always accurate.	Clinicians should be aware of the factors that result in transcellular potassium shifts. Monitoring 24-hour urinary potassium excretion can be necessary in high-risk patients.
Patient adherence to potassium replacement can be increased with compliance-enhancing regimens.	Microencapsulated products have no bitter smell or aftertaste and have much better GI tolerance. Regimens should be made as simple as possible to follow.
A potassium dosage of 20 mEq/day (mmol/day) is usually sufficient to prevent hypokalemia from occurring. Doses of 40-100 mEq (mmol) are usually sufficient to treat hypokalemia.	

A general rule for potassium replacement is that for every 1 mEq/L (mmol/L) decrease of serum potassium below 3.5 mEq/L (mmol/L), there is a corresponding total-body potassium deficit of 100 to 400 mEq (mmol). Because of the wide variance in projected deficits, each patient's therapy must be individualized and adjustments made on the basis of the patient's signs, symptoms, and frequent measurements of serum potassium. In the acute care setting, the administration of 10 mEq (mmol) of IV or oral potassium should increase the serum potassium concentration by 0.1 mEq/L (mmol/L). This approximation is used as a basis for dose calculations, with frequent measurements of serum potassium to avoid overestimation. In patients receiving chronic loop or thiazide diuretic therapy, 40 to 100 mEq (mmol) of oral potassium supplementation can correct mild to moderate potassium deficits. Doses up to 120 mEq (mmol) can be required in more severe deficiencies. When providing oral potassium supplementation, the total daily dose should be divided into three to four doses to minimize the development of GI side effects. Patients receiving diuretics can become chronically hypokalemic and can benefit from combination potassium-sparing diuretic therapy.

3 Whenever possible, potassium supplementation should be administered by mouth. Three salts are

available for oral potassium supplementation: chloride, phosphate, and bicarbonate. Potassium phosphate should be used when the patient is both hypokalemic and hypophosphatemic; potassium bicarbonate is most commonly used when potassium depletion occurs in the setting of metabolic acidosis. Potassium chloride, however, is the primary salt form used because it is the most effective treatment for the most common causes of potassium depletion (ie, diuretic and diarrhea-induced) as these conditions are associated with potassium and chloride losses.

Potassium chloride can be administered in either tablet or liquid formulations (**Table 51-4**). The liquid forms are generally less expensive; however, patient compliance can be low because of their strong, unpleasant taste. Liquid forms should be used when a rapid reponse to supplementation is desired. Two sustained-release solid dosage forms are currently available in the United States: a wax-matrix formulation, and a microencapsulated formulation. The microencapsulated tablet is generally preferred because it is associated with less GI irritation. IV potassium use should be limited to: (a) severe cases of hypokalemia (serum concentration less than 2.5 mEq/L [mmol/L]); (b) patients exhibiting signs and symptoms such as ECG changes or muscle spasms; or (c) patients unable to tolerate oral therapy. IV supplementation is more dangerous than oral therapy because it is more likely to result in hyperkalemia, phlebitis, and pain at the site of infusion.

TABLE 51-4 Differences Among Oral Potassium Supplements

Supplement	Comment
Controlled-release microencapsulated tablet	Disintegrates better in GI tract; fewer GI erosions as compared to wax-matrix tablets
Encapsulated controlled-release microencapsulated particles	Fewer erosions as compared to wax-matrix tablets
Potassium chloride elixir	Inexpensive, poor taste, poor compliance, immediate effect
Potassium chloride effervescent tablets for solution	More expensive than elixir, convenient
Wax-matrix extended-release tablets	Easier to swallow; more GI erosions as compared to other therapies

The vehicle in which IV potassium is administered is important. Whenever possible, potassium should be prepared in saline-containing solutions (eg, 0.9%-0.45% sodium chloride [NaCl]). Dextrose-containing solutions stimulate insulin secretion, which can cause intracellular shifting of potassium, worsening the patient's hypokalemia, and should be avoided whenever possible. Generally, 10 to 20 mEq (mmol) of potassium is diluted in 100 mL 0.9% NaCl for IV administration. These concentrations are safe when administered through a peripheral vein over an hour. When infusion rates exceed 10 mEq/h (mmol/h) ECG monitoring should be performed to detect cardiac changes. The serum potassium concentration should be evaluated following the infusion of each 30 to 40 mEq (mmol) to guide further potassium replacement administration. Multiple doses of potassium can be repeated as needed until the serum potassium concentration normalizes. To allow adequate time for the potassium to equilibrate between the intra- and extracellular spaces, one should wait at least 30 minutes from the end of each infusion and care should be taken to avoid sampling from the same line in which the potassium was infused, as this can result in a spuriously high potassium concentration.

In cases of severe potassium depletion, patients can require as much as 300 to 400 mEq/day (mmol/day). In this instance, it is common practice to dilute 40 to 60 mEq (mmol) in 1,000 mL 0.45% NaCl and infuse at a rate not exceeding 40 mEq/h (mmol/h). The total 24-hour dose should not exceed 400 mEq (mmol). This should be performed in an intensive care unit under continuous ECG monitoring. Because of the high potassium concentration, and the risk for burning pain and peripheral venous sclerosis, the infusion should be through a central venous catheter into a large vein (eg, superior vena cava) but care must be taken not to place the tip of the catheter into the right atrium.[18] Directly delivering high potassium concentrations into the heart can result in cardiac arrhythmias. Given the volume required to infuse this dose of potassium, this infusion strategy might be impractical in certain clinical situations (eg, patients requiring fluid restriction). A reasonable approach is to split the potassium dose between the oral and IV routes. For example, if a symptomatic patient requires 120 mEq (mmol) of potassium, the clinician can give 60 mEq (mmol) as the immediate-release potassium liquid, and the other 60 mEq (mmol) can be given through the IV route (20 mEq/100 mL/h [mmol/100 mL/h] in three doses). When giving large potassium doses, serum monitoring should be performed following the administration of half the dose to guide the need for additional potassium. This can also help avoid the development of hyperkalemia.

In the rare circumstances when cardiac arrest from hypokalemia is imminent, IV bolus dosing of potassium 10 mEq (mmol) over 5 minutes can be initiated and repeated once, if necessary.[18]

Alternative Therapies

Potassium-sparing diuretics are a viable alternative to chronic exogenous potassium supplementation, especially when patients are concomitantly receiving drugs that are known to deplete potassium (eg, diuretics). Spironolactone inhibits the effect of aldosterone in the renal distal convoluted tubule, thereby decreasing potassium elimination in the urine. Spironolactone is especially effective as a potassium-sparing agent in patients with primary or secondary hyperaldosteronism. Amiloride and triamterene are reasonable second-line agents that act by an aldosterone-independent but unknown mechanism.

Spironolactone is available as 25-, 50-, and 100-mg tablets. The usual starting dose is 25 to 50 mg daily, and can be titrated to a maximum dose of 400 mg/day. The potassium-retaining effects generally take 48 hours to be evident. Principle adverse effects include hyperkalemia, gynecomastia, breast tenderness, and impotence in men. Triamterene is available as 50- and 100-mg capsules. The usual starting dose is 50 mg twice daily, which can be titrated to 100 mg twice daily. Triamterene is also available as a combination product with hydrochlorothiazide (37.5/25 mg, 50/25 mg, or 75/50 mg) and is commonly used for the treatment of hypertension. Common side effects include hyperkalemia, sodium depletion, and metabolic acidosis. The usual starting dose of amiloride is 5 mg daily; however, 10 mg can be given in those with severe hypokalemia. This is also available as a combination product with hydrochlorothiazide 50 mg. The most common side effects are hyperkalemia and metabolic acidosis.

Concomitant use of potassium supplementation with potassium-sparing diuretics is generally not necessary and when used there is a significant risk of hyperkalemia, especially in patients with CKD or diabetes mellitus.

Evaluation of Therapeutic Outcomes

Serum potassium concentrations should be monitored regularly while the patient is receiving potassium supplementation. For ambulatory patients receiving prophylactic potassium supplementation during diuretic therapy, the serum potassium and magnesium concentrations, as well as renal function should be monitored every 1 to 2 months. In hospitalized patients receiving oral therapy for mild hypokalemia, the potassium concentration should be monitored every 2 to 3 days. If it does not increase by at least 1 mEq/L (mmol/L) within 96 hours, the clinician should suspect concomitant magnesium depletion. Patients receiving IV potassium supplementation require close ECG monitoring if the infusion rate is greater than 20 mEq/h (mmol/h): doses greater than this should be administered only in the presence of continuous ECG monitoring. Additionally, the patient should have potassium concentrations obtained halfway through, and 30 minutes following completion of the total potassium dose to guide further potassium administration. Finally, the patient should be assessed for adverse effects such as pain at the infusion site or phlebitis.

Clinical Bottom Line

Hypokalemia is a frequent medical condition caused by both biological processes as well as drug therapy. While mild hypokalemia is frequently asymptomatic, severe hypokalemia can cause fatal cardiac dysrhythmias, particularly in patients with underlying cardiac disease. Patients receiving drugs that cause potassium wasting (eg, thiazide or loop diuretics), should be closely followed for the development of hypokalemia and appropriate potassium supplementation should be started when necessary. Generally oral potassium is sufficient for the management of mild hypokalemia; IV potassium shoud be reserved for severe deficiency, and its use should be monitored closely.

HYPERKALEMIA

Hyperkalemia, defined as a serum potassium concentration greater than 5 mEq/L (mmol/L), can be further classified according to its severity: mild hyperkalemia (5.1-5.9 mEq/L [mmol/L]), moderate hyperkalemia (6-7 mEq/L [mmol/L]), and severe hyperkalemia (above 7 mEq/L [mmol/L]).[17]

EPIDEMIOLOGY

4 Hyperkalemia is much less common than hypokalemia. In fact, if all patients with AKI and CKD were excluded, the prevalence of hyperkalemia would be less than 1% in the rest of the population. The incidence of hyperkalemia in hospitalized patients is highly variable, and reports have ranged from 1% to 10%.[19] Most cases of hyperkalemia are the result of overcorrection of hypokalemia with IV potassium supplements. Severe hyperkalemia occurs more commonly in elderly patients with renal insufficiency who have been receiving chronic oral potassium supplementation.

Etiology and Pathophysiology

Hyperkalemia develops when potassium intake exceeds excretion (true hyperkalemia) (ie, elevated total-body stores), or when the transcellular distribution of potassium is disturbed (ie, normal

total-body stores). The four primary causes of hyperkalemia—(a) increased potassium intake, (b) decreased potassium excretion, (c) tubular unresponsiveness to aldosterone, and (d) redistribution of potassium into the extracellular space—are discussed further.

Hyperkalemia Associated with Increased Potassium Intake

Hyperkalemia in this setting is almost always associated with renal insufficiency. Patients with stage 4 or 5 CKD and dialysis patients who are noncompliant with dietary potassium restrictions often present with life-threatening hyperkalemia. Many of these patients do not realize that fresh fruits and vegetables contain large amounts of potassium. Anecdotally, in many dialysis centers the incidence of hyperkalemia peaks during the summer months, when fresh garden produce is available. Another common dietary source associated with the development of hyperkalemia is potassium chloride salt substitutes. Many dialysis patients are instructed to use salt substitutes to avoid excessive sodium intake in an attempt to control volume overload. These patients unwittingly become hyperkalemic because these products contain approximately 10 to 15 mEq (mmol) potassium per gram, or 200 mEq (mmol) per tablespoon. Finally, some over-the-counter herbal and alternative medicine products may contain significant amounts of potassium. It is thus essential for patients with CKD to receive education regarding dietary sources of potassium as well as information on the potassium content of herbal products when available.

Hyperkalemia Associated with Decreased Renal Potassium Excretion

Normally functioning kidneys excrete 90% of the daily potassium intake. Therefore, when the kidney is unable to excrete potassium appropriately, as in AKI and stage 4 to 5 CKD, potassium is retained and often results in hyperkalemia. Finally, because aldosterone is responsible for potassium excretion via the renal cortical collecting duct, medications and disesaes that inhibit this process contribute to hyperkalemia.[20]

Severe hyperkalemia is more common in AKI than in CKD because patients are often hypercatabolic and have underlying disorders, such as rhabdomyolysis or tumor lysis syndrome, which result in release of potassium from injured or lysed cells.[21] Severe hyperkalemia is rare in stable stage 1 to 4 CKD patients, perhaps because of enhanced GI and renal potassium excretion.[22] Data suggest that hyperkalemia directly stimulates renal potassium excretion through an effect that is independent of, and additive to, that of aldosterone.[22] Although the overall incidence of hyperkalemia is higher in patients with CKD when compared with patients without CKD, due to these adaptive mechanisms and patients' decreased susceptibility to cardiac effects of chronic hyperkalemia, they have a lower mortality rate than other patient populations.[23] Renal excretion of potassium is also inhibited by various endocrinologic disorders, including adrenal insufficiency, Addison disease, and selective hypoaldosteronism. All of these disorders involve a decreased production of aldosterone, which results in the retention of potassium.

Several drugs have profound effects on the kidney's ability to regulate potassium. Five drug classes in particular: angiotensin-converting enzyme inhibitors (ACEIs), angiotensin-II receptor blockers (ARBs), direct renin inhibitors, potassium-sparing diuretics, and prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs (NSAIDs). Although hyperkalemia is typically dose-dependent, the rates of

hyperkalemia have been reported to range from 2% to 10% in most clinical trials.[24,25,26] Other commonly used drugs that can cause hyperkalemia are digoxin, cyclosporine, tacrolimus, trimethoprim–sulfamethoxazole, heparin, and pentamidine.

Tubular Unresponsiveness to Aldosterone

Sickle cell anemia, systemic lupus erythematosus, and amyloidosis, can produce a defect in renal tubular potassium secretion, possibly as the result of an alteration in the aldosterone-binding site.

Redistribution of Potassium into the Extracellular Space

The efflux of potassium from within the cell into the extracellular space, which is associated with no change in total-body potassium stores, is often observed in the presence of metabolic acidosis, diabetes mellitus, CKD, or lactic acidosis. β-Blockers can also result in a transcellular potassium shift.

The serum potassium concentration can also be falsely elevated in some conditions and not reflect the actual in vivo potassium concentration, that is, pseudohyperkalemia. Pseudohyperkalemia occurs most commonly in the setting of extravascular hemolysis of red blood cells. When a blood specimen is not processed promptly and cellular destruction occurs, intracellular potassium is released into the serum. It can also occur in conditions of thrombocytosis or leukocytosis. If severe hyperkalemia is found in a patient who is asymptomatic with an otherwise normal laboratory report, the hyperkalemia is most likely pseudohyperkalemia, and a repeat blood sample should be collected. Truly elevated potassium concentrations are normally associated with other laboratory abnormalities, such as low carbon dioxide (acidosis) or elevated blood urea nitrogen and creatinine concentrations (indicating renal insufficiency).

CLINICAL PRESENTATION Hyperkalemia General

- Related to the effects of excessive potassium on neuromuscular, cardiac, and smooth muscle cell function.

Symptoms

- Frequently asymptomatic.
- The patient might complain of heart palpitations or skipped heartbeats.

Signs

- ECG changes (**Fig. 51-1**)

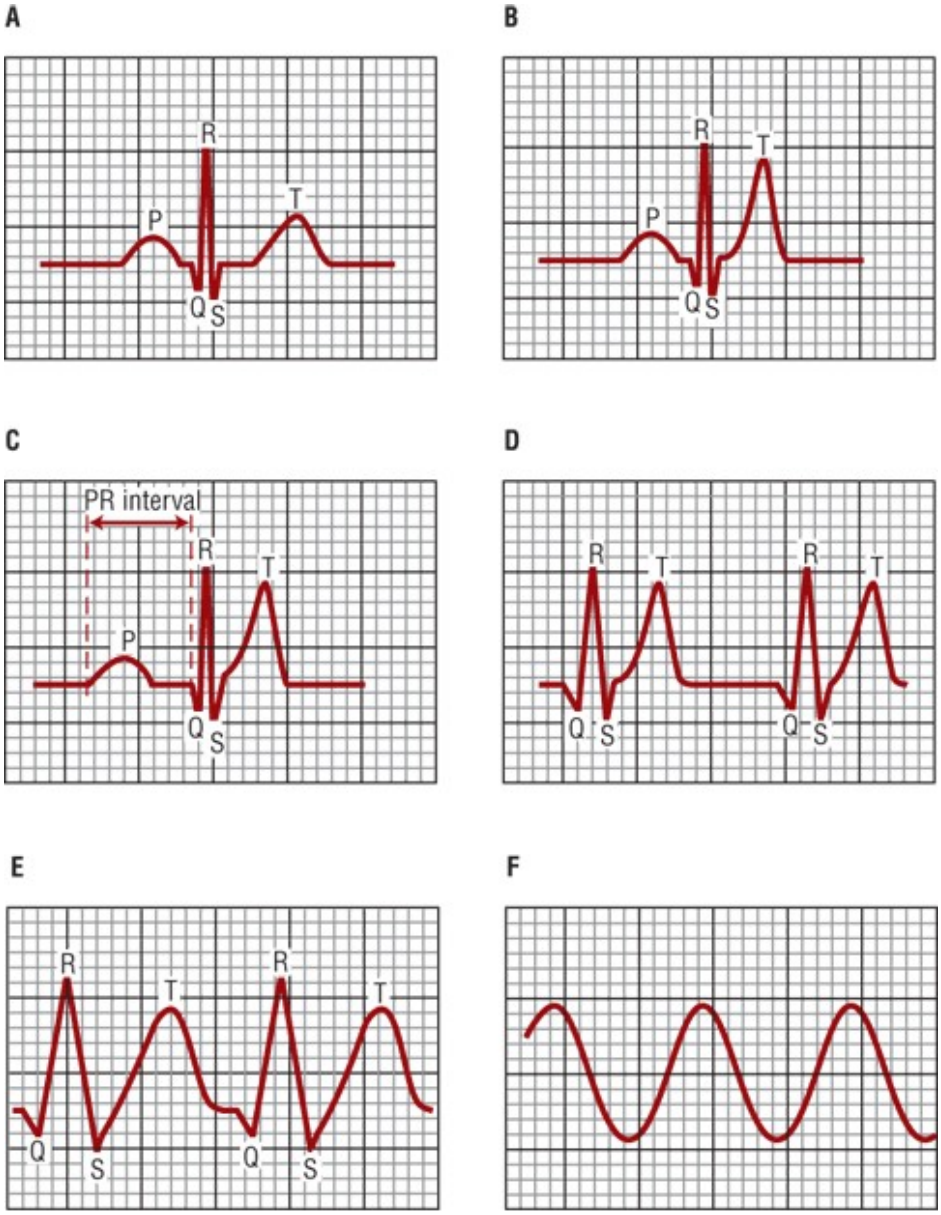
Laboratory Tests

- Serum potassium concentration above 5.0 mEq/L (mmol/L) is diagnostic.

FIGURE 51-1

The earliest electrocardiographic manifestation of hyperkalemia is an increase in the rate of ventricular repolarization, which results in a peaking of the T wave at serum potassium concentrations of ~5.5 to 6

mEq/L (mmol/L) (*B*), relative to the normal ECG presentation (*A*). Further increases in the serum potassium concentration above 6 mEq/L (mmol/L) result in conduction delays through the His-Purkinje system, the atrial myocardium, and the ventricular myocardium. The ECG manifestations of these conduction delays and the sequence in which they occur are a widening of the PR interval (*C*), delay through the His-Purkinje system, a loss of the P wave (*D*), delay through the atrial myocardium, a widening of the QRS complex (*E*), and delay through the ventricular myocardium. Finally, there is a merging of the QRS complex with the T wave (*F*), which results in a sine-wave appearance.



TREATMENT

Desired Outcomes

The goals of therapy for the treatment of hyperkalemia are to antagonize adverse cardiac effects,

reverse signs and symptoms that are present, and return the serum and total-body stores of potassium to normal. The optimal treatment approach is dependent on the severity of hyperkalemia, the rapidity of its development, and the patient's clinical condition. Although ECG changes are directly proportional to the plasma potassium concentration and its rate of increase, they may not be present in all patients. In contrast, ventricular fibrillation may be the first cardiac manifestation of hyperkalemia in some patients.[27] Asymptomatic patients with mild hyperkalemia usually require no specific therapy other than dietary education to control intake, and monitoring of serum potassium daily if an inpatient or weekly if an outpatient to assure resolution.

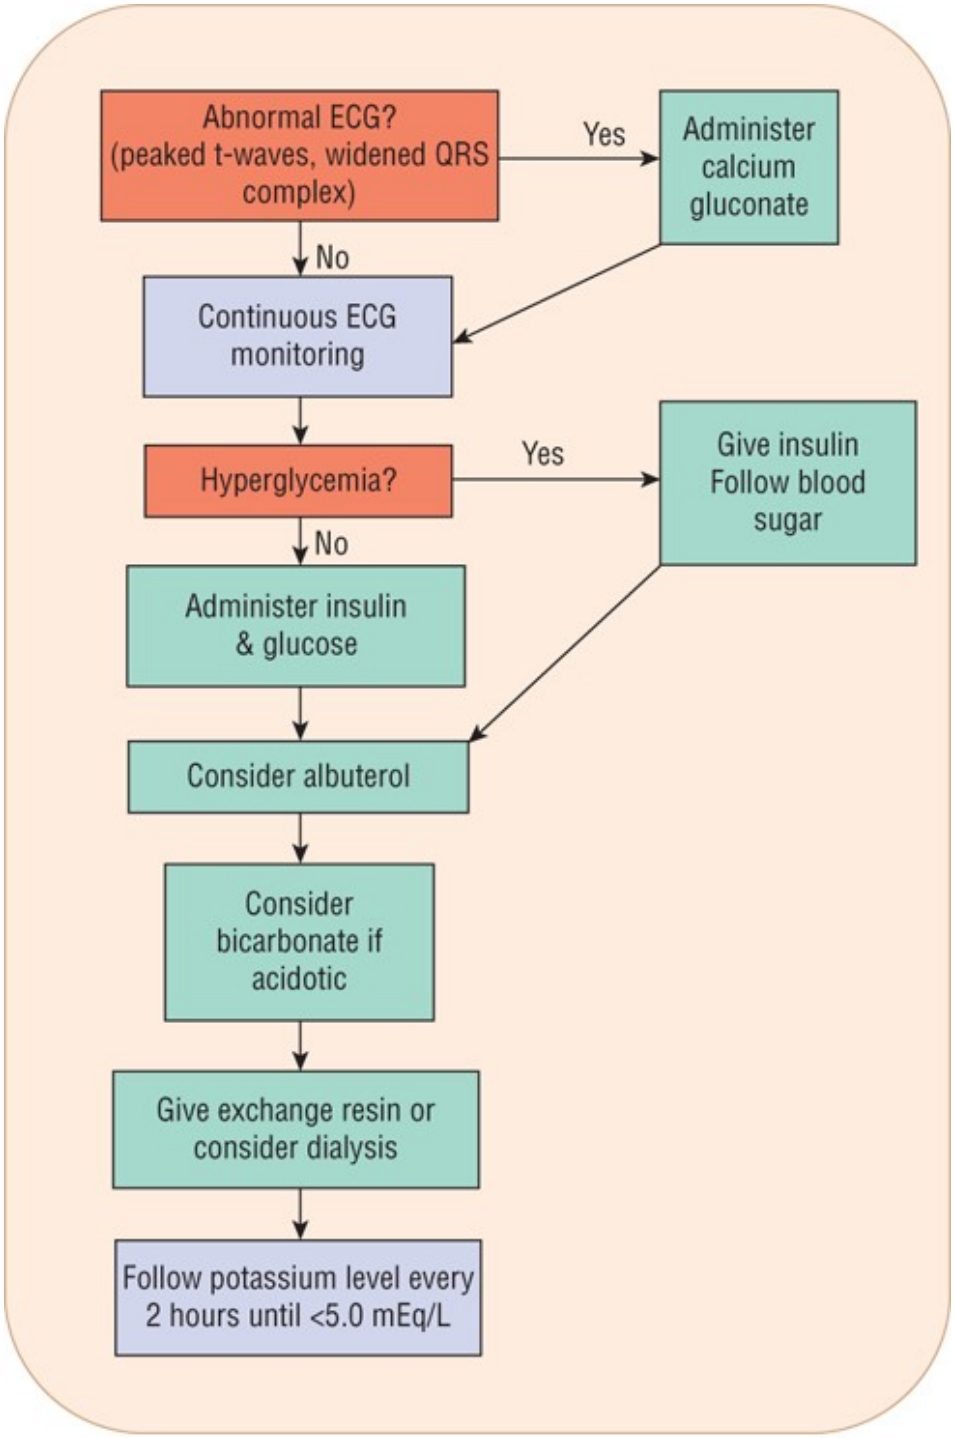
Severe hyperkalemia (above 7 mEq/L [mmol/L]) or moderate hyperkalemia (6-6.9 mEq/L [mmol/L]), when associated with clinical symptoms or ECG changes, requires immediate treatment. Initial treatment should be focused on antagonism of the cardiac membrane actions of hyperkalemia (eg, administration of calcium). Secondarily, one should attempt to decrease extracellular potassium concentration by promoting its intracellular movement (eg, with insulin, β_2-receptor agonists, or sodium bicarbonate) or enhance its removal from the body by hemodialysis: the oral administration of cation-exchange resins, and/or the use of loop diuretics may aslo be considered in some patients. In any case, the underlying cause of hyperkalemia should be identified and reversed, and exogenous potassium must be withheld.

General Approach to Treatment

A treatment approach for patients with hyperkalemia is outlined in **Fig. 51-2**. In patients who have acute ECG changes, IV calcium should be administered to prevent or treat any cardiac manifestations of hyperkalemia. At the same time, the serum potassium concentration should be rapidly decreased to below 5 mEq/L (mmol/L) within minutes by administering drugs that cause an intracellular shift of potassium, followed by the initation of those that increase the elimination of potassium from the body.[27] If the patient is asymptomatic, rapid correction may not be necessary and will likely depend on the clinical context associated with the rise in serum potassium concentration. If one anticipates the need to reduce total-body potassium stores, an ion exchange resin (eg, sodium polystyrene sulfonate [SPS]) that results in removal of potassium from the body over several hours to days may be initiated shortly after the emergent care has been instituted. Recently, two cation exchange agents with a similar effect have emerged. Patiromer (Veltassa™) is a potassium binder approved for the treatment of hyperkalemia and sodium zirconium cyclosilicate (ZS-9) is pending approval for a similar indication.

FIGURE 51-2

Treatment approach for hyperkalemia. (Serum potassium of 5.0 mEq/L is equivalent to 5.0 mmol/L.)



Nonpharmacologic Therapy

A recent study suggested that hemodialysis patients who ingested foods supplemented with glycyrrhetinic acid, the active ingredient in licorice, were better able to maintain plasma potassium concentrations within the normal range compared with hemodialysis patients given placebo.[28,29] Glycyrrhetinic acid inhibits the enzyme 11β-hydroxy-steroid dehydrogenase II, thereby increasing cortisol availability in the colon. The net result is enhanced potassium elimination in the feces. Other

nonpharmacologic therapies, specifically available for dialysis-dependent patients are the tailoring of their intermittent dialysis or hemofiltration therapy to include a low potassium dialysate to enhance the removal of potassium (see Chapter 45).

Pharmacologic Therapy

There are several drug therapy options to lower the serum potassium concentration. The optimal regimen for a given patient is dependent on the rapidity and degree of lowering that is necessary. **Table 51-5** provides an overview of the available therapies and their respective onset and duration of action.

TABLE 51-5 Therapeutic Alternatives for the Management of Hyperkalemia

Medication	Dose	Route of Administration	Onset/Duration of Action	Acuity	Mechanism of Action	Expected Result
Calcium	1 g	IV over 5-10 minutes	1-2 min/10-30 min	Acute	Raises cardiac threshold potential	Reverses electrocardiographic effects
Furosemide	20-40 mg	IV	5-15 min/4-6 h	Acute	Inhibits renal Na^+ reabsorption	Increased urinary K^+ loss
Regular insulin	5-10 units	IV or SC	30 min/2-6 h	Acute	Stimulates intracellular K^+ uptake	Intracellular K^+ redistribution
Dextrose 10%	1,000 mL (100 g)	IV over 1-2 hours	30 min/2-6 h	Acute	Stimulates insulin release	Intracellular K^+ redistribution
Dextrose 50%	50 mL (25 g)	IV over 5 minutes	30 min/2-6 h	Acute	Stimulates insulin release	Intracellular K^+ redistribution
Sodium bicarbonate	50-100 mEq (50-100 mmol)	IV over 2-5 minutes	30 min/2-6 h	Acute	Raises serum pH	Intracellular K^+ redistribution
Albuterol	10-20 mg	Nebulized over 10 minutes	30 min/1-2 h	Acute	Stimulates intracellular K^+ uptake	Intracellular K^+ redistribution
Hemodialysis	4 hours	N/A	Immediate/variable	Acute	Removal from serum	Increased K^+ elimination
Sodium polystyrene sulfonate	15-60 g	Oral or rectal	1 h/variable	Nonacute	Resin exchanges Na^+ for K^+	Increased K^+ elimination

Medication	Dose	Route of Administration	Onset/Duration of Action	Acuity	Mechanism of Action	Expected Result
Patiromer	8.4-25.2 g	Oral	Hours/variable	Nonacute	Resin exchanges Ca^{++} for K^{+}	Increased K^{+} elimination

While specific treatment recommendations vary, it is generally accepted that asymptomatic patients with potassium concentrations below 6 mEq/L (mmol/L) can be treated conservatively. In patients with normal renal function, or those with stage 3 or 4 CKD, this typically involves the administration of furosemide to promote urinary potassium excretion. When given IV at a dosage of 40 to 80 mg, urine flow usually increases within minutes and persists for approximately 4 to 6 hours. Oral furosemide can also be used, keeping in mind the IV:PO dose ratio (1:2) and delayed onset of action compared to IV. Close monitoring of the patient's volume status and other electrolyte concentrations is required while the patient is receiving furosemide. Of note, the effectiveness of diuretics in treating hyperkalemia has not been studied in a randomized, controlled fashion.

SPS (Kayexalate®) is a cation-exchange resin that can be administered orally or rectally by enema. SPS is available in powder form or prepackaged as a 33% sorbitol suspension. The oral route is more effective than the enema and is better tolerated by patients. As the resin passes through the intestines, each gram of SPS exchanges 1 mEq (mmol) of sodium for 1 mEq (mmol) of potassium, which is in a relatively higher concentration in the large intestine. The onset of action of SPS is within 1 hour, and it can be repeated every 4 hours as needed. The sorbitol component of the suspension promotes the excretion of the cationically modified potassium exchange resin by inducing diarrhea. The usual oral SPS dose is 15 to 60 g in the 33% sorbitol suspension.

There have been several reports of colonic necrosis with the use of SPS.[30,31] In 2009, the U.S. Food and Drug Administration (FDA) mandated a boxed warning for SPS due to reports of colonic necrosis and other serious GI toxicities.[32] The GI toxicities were believed to be associated with the 70% sorbitol; however, there are also reports of GI toxicity when the 33% sorbitol solution was administered. A common finding in these reports was that toxicity occurred most commonly in patients who had recently undergone GI surgery or had a current or history of bowel dysfunction. This FDA warning was updated in 2011. A recent commentary provided some needed perspective on the role of SPS in treating hyperkalemia.[33] While the authors echoed the FDA warning, they found little risk to using the SPS 33% sorbitol suspension or SPS powder mixed in water for oral administration. These authors recommended that the retention enema route of administration be abandoned given the risk of side effects and the fact that the enema route appears to be less effective compared with oral administration. Additionally, SPS use is contraindicated in patients with bowel dysfunction.

Clinical Controversy…

In 2015, the FDA issued a safety communication requiring the drug manufacturer to conduct studies to investigate the potential of SPS to bind to other orally administered medications. This comes after *in vitro* binding studies of another potassium binding agent, patiromer, demonstrated that the drug bound about half of the oral medications tested, which could affect their absorption and efficacy. The FDA recommends prescribers and patients consider separating the dose of SPS from other oral

medications by 6 hours and that they monitor the patient's clinical response closely. Based on the manufacturer's studies, there may be mandated updates to the drug label to include information about these interactions.[34]

In symptomatic patients, or in those with severe hyperkalemia, emergency care is indicated. Initial therapy in this setting is the administration of IV calcium chloride or gluconate 1 g to protect the heart from life-threatening arrhythmias.[27] Calcium antagonizes the cardiac membrane effect of hyperkalemia by reducing the electrical threshold potential for cardiac myocytes and reverses ECG changes within minutes. IV calcium should not be given to patients receiving digoxin as it can lead to digoxin toxicity. Its duration of action is 30 to 60 minutes, and it can be repeated as needed based on ECG findings. IV calcium can be given as either the chloride or gluconate salt; each is available as a 10% solution by weight. Calcium chloride provides approximately three times more calcium than equal volumes of the gluconate salt; however, it can cause tissue necrosis if extravasation occurs. For this reason, calcium gluconate is more commonly administered, with the standard dose being 10-mL IV bolus over 5 to 10 minutes.

Rapid correction of hyperkalemia may necessitate the administration of drugs that result in an intracellular shift of potassium, such as insulin and dextrose, sodium bicarbonate, and a β_2-adrenergic receptor agonist (eg, albuterol). The treatment of choice depends on the underlying medical disorders accompanying hyperkalemia. For example, in patients with concomitant metabolic acidosis, a sodium bicarbonate bolus or infusion of 50 to 100 mEq (mmol) is the preferred therapy. Sodium bicarbonate helps correct the metabolic acidosis by raising the extracellular pH, in addition to causing a rapid intracellular potassium shift. It should be noted that sodium bicarbonate is much less effective when hyperkalemia is not related to metabolic acidosis.[1] Sodium bicarbonate is also less effective in patients with end-stage renal disease (ESRD), in whom a decrease in serum potassium may not be seen for as long as 4 hours. Sodium bicarbonate can also lead to sodium and volume overload in patients with stage 4 or 5 CKD. Administration of a rapid-acting (eg, Insulin lispro 10 units IV) or regular insulin (10 units IV) and dextrose (10% or 50%) is an effective method of reducing potassium. Insulin increases the activity of the Na^+-K^+-ATPase pump, thereby intracellularly shifting potassium. Glucose should be given with insulin unless the serum glucose is above 250 mg/dL (13.9 mmol/L) because hypoglycemia can develop as a result of the effects of the insulin therapy. An IV bolus of 10 units of regular insulin and 25 g of dextrose usually lowers the serum potassium concentration by 0.6 mEq/L (mmol/L) in dialysis-dependent patients.[32] β_2-adrenergic agonists have a dual mechanism for lowering serum potassium. First, they stimulate the Na^+-K^+-ATPase pump to promote intracellular potassium uptake. Second, they stimulate pancreatic β-receptors to increase insulin secretion. Albuterol can be administered via IV (0.5 mg given over 15 minutes) or via nebulizer (10-20 mg nebulized over 10 minutes).

However, it should be noted that injectable albuterol is not available in the United States. In ESRD patients, decreases in plasma potassium concentration of 0.6 mEq/L (mmol/L) and 1 mEq/L (mmol/L) can be anticipated after inhalation of 10 and 20 mg of albuterol, respectively. Of note, the doses of inhaled albuterol used for hyperkalemia are at least four times higher than those typically used for bronchospasm. There are important limitations with albuterol therapy, most notably variable bioavailability via the inhaled route (leading to potential over- or underdosing and unpredictability of response) and second, cardiac side effects such as tachycardia, which are undesirable in patients who already have an abnormal ECG. Furthermore, as many as 40% of patients may be resistant to the

hypokalemic effects of albuterol and patients already receiving a nonselective β_2-receptor antagonist may not respond. Therefore, albuterol should not be used alone for the urgent treatment of hyperkalemia in CKD patients.[27]

A Cochrane Review evaluated the emergency treatment of hyperkalemia.[35] Many of the reviewed studies were small, and not all intervention groups had sufficient data for meta-analysis to be performed. Most of the data were from nonrandomized, noncontrolled observational studies and case reports. However, given these limitations, inhaled and nebulized β-agonists, and IV insulin and glucose were all deemed effective. The combination of nebulized β-agonists with IV insulin and glucose appeared to be more effective than either agent alone. The meta-analysis results were equivocal for IV bicarbonate, and notably, SPS was not effective by 4 hours. Given the limitations of this Cochrane Review, clinicians should exercise caution when extrapolating these findings to clinical practice. Nonetheless, the Cochrane database review corroborates the approach detailed in Fig. 51-2.

Frequently, management of hyperkalemia will be based on the clinician's personal judgment or institutional protocols. A recent prospective chart review examined how hyperkalemia was treated in an academic teaching hospital.[36] Overall, 95% of the patients received SPS, 21% received insulin, 21% received IV calcium, and less than 10% of patients received bicarbonate, albuterol, or hemodialysis. Combination therapy was given to 21% of patients, with SPS and insulin being the most common.

In nonhospitalized patients who have experienced chronic increases in serum potassium concentration, long-term management of hyperkalemia is focused on dietary restriction of potassium-rich foods and supplements, reducing and avoiding medications that impair renal potassium excretion, and using diuretics or other medications to counteract the effects of medications that increase serum potassium concentrations. Medications used for chronic conditions that are known to cause hyperkalemia include NSAIDs, ACEIs, ARBs, direct renin inhibitors, and aldosterone antagonists. These typically result in asymptomatic hyperkalemia without the need for emergent therapies. To prevent hyperkalemia, clinicians may attempt to lower the dose or switch to another medication without hyperkalemia as a side effect (eg, calcium channel blocker). However, medications that inhibit the renin–angiotensin–aldosterone system (RAAS) have significant beneficial effects on morbidity and mortality in patients with chronic diseases such as diabetes mellitus, congestive heart failure, and CKD. Therefore reducing or avoiding the use of these medications to prevent hyperkalemia is not often appropriate. The use of a combination of ACEI and ARB is generally avoided due to the increased risk of hyperkalemia.[37] Aldosterone antagonists have a different mechanism of action and their use in combination with an ACEI or ARB is considered acceptable. A recent study found that the extent of hyperkalemia was greater with a combination ACEI and aldosterone antagonist than a combination ACEI and ARB in patients with diabetic nephropathy, suggesting an extrarenal mechanism of this adverse effect in aldosterone antagonists.[38]

Using existing polymeric exchange resins (eg, SPS) in outpatient settings is not ideal given the risk of adverse effects and unknown efficacy.[31] Recently, two new cation exchange agents have emerged as potential therapies for acute and short-term treatment of outpatients with mild hyperkalemia. Veltassa™ (patiromer) is a nonabsorbable polymer that exhanges calcium for potassium in the intestine to increase fecal elimination of potassium. Two major studies examined its efficacy in lowering serum potassium concentrations. A phase 3 clinical trial consisting of a 4-week initial treatment phase and an

8-week randomized, placebo-controlled withdrawal phase assessed the response in adults with stage 3 or 4 CKD on stable doses of RAAS inhibitors.[39] A majority of patients in the initial phase achieved normokalemia. During the withdrawal phase, patiromer continued to decrease serum potassium concentrations (estimated mean reduction of 0.72 mEq/L (mmol/L)) whereas placebo had no effect on serum potassium concentration. In a phase 2 dose-finding study that included a similar patient population, normokalemia was maintained with patiromer in 77% to 95% of patients, depending on the degree of hyperkalemia at baseline.[40] Patiromer comes as 8.4, 16.8, and 25.2 g packets for oral suspension. The package insert cautions that it should not be used to treat life-threatening hyperkalemia due to its delayed onset of action.[41] Additionally, patiromer has been shown in *in vitro* studies to bind to many oral medications, which could lead to decreased absorption of other mediations and loss of efficacy. Therefore, it is recommended to administer other oral medications at least 6 hours before or after patiromer.[41] If this is not possible, alternative regimens should be considered.

Sodium zirconium cyclosilicate (ZS-9) is a nonabsorable inorganic compound that selectively enhances potassium excretion by the intestinal route. Two phase 3, randomized, placebo-controlled trials have assessed the efficacy of ZS-9 in lowering serum potassium concentrations in adult outpatients with asymptomatic mild to moderate hyperkalemia. Both trials found that ZS-9 significantly decreased serum potassium concentrations 48 hours after administration compared to placebo, with an average decrease of approximately 1 mEq/L (mmol/L) for the 10 g dose.[42,43] A majority of the patients maintained normokalemia during maintenances phases of 15 and 28 days, despite a high incidence of patients with CKD, congestive heart failure, diabetes mellitus, and use of RAAS inhibitors. The most common adverse effect in the ZS-9 group was edema, likely from the exchange of sodium for potassium.

Clinical Controversy…

For both ZS-9 and patiromer, efficacy in producing normokalemia in the short-term has been shown in outpatients on RAAS inhibitors who have asymptomatic mild to moderate hyperkalemia. It remains to be seen whether the effects are sustainable in the long-term or whether either agent can be used in the acute treatment of hospitalized patients. These agents should presently not be used in acute treatment of hyperkalemia, but may be appropriate for outpatient treatment in combination with nonpharmacological strategies.

Evaluation of Therapeutic Outcomes

The frequency and rigor with which one evaluates patients to ascertain if they have achieved the desired therapeutic outcomes depends on the severity and acuity of hyperkalemia. For example, cautious waiting is more common for those with mild or moderate asymptomatic hyperkalemia compared to those with acute symptomatic, severe hyperkalemia. Many drugs such as ACEIs, ARBs, direct renin inhibitors, and spironolactone result in asymptomatic hyperkalemia and changes in dosage or to a different agent may be all that is warranted. In patients with normal renal function, once these drugs are initiated and the dose titrated, clinicians should check the potassium concentration at least monthly. For those patients with renal dysfunction, monitoring should be biweekly until the dose is stabilized.

In patients who have acute symptomatic hyperkalemia (eg, ECG changes), frequent potassium concentration and ECG monitoring is warranted. The patient should receive continuous ECG telemetry monitoring until the serum potassium concentration decreases below 5 mEq/L (mmol/L), and the ECG abnormalities resolve. Similarly, while the patient is receiving emergent therapy, serial serum potassium concentrations should be obtained hourly until the potassium concentration decreases below 5 mEq/L (mmol/L). For patients who receive insulin and dextrose therapy for hyperkalemia, blood glucose monitoring should be performed hourly or more frequently if patients demonstrate signs and symptoms of hypoglycemia. For patients who receive large doses of sodium bicarbonate therapy for hyperkalemia, an arterial blood gas or serum chemistry profile should be obtained to assess their acid–base status. Furthermore, the patient should be evaluated for signs of fluid overload secondary to the high sodium load. Patients receiving albuterol therapy should be questioned regularly regarding the development of palpitations and tachycardia. The patient's medication records should be reviewed to assure the patient is not receiving drug therapy that increases the serum potassium concentration. Furthermore, the patient should be questioned regarding the occurrence of diarrheal stool output.

Clinical Bottom Line

Hyperkalemia commonly occurs in patients with reduced kidney function or other metabolic disturbances. It can rapidly evolve into a medical emergency; therefore, prompt identification and appropriate pharmacotherapy is needed. In patients with mild hyperkalemia, potassium binding resins or loop diuretics may be useful, and should be used as first-line therapy. In severe hyperkalemia with ECG changes, IV calcium should be given to protect against cardiac dysrhythmias. Additionally rapid-acting therapies such as IV insulin and β_2-adrenergic agonists are indicated to move potassium intracellularly.

DISORDERS OF MAGNESIUM HOMEOSTASIS

Magnesium plays a central role in cellular function and is an important cofactor in more than 300 biochemical reactions in the body, especially those systems that are dependent on adenosine triphosphate. Mitochondrial function, protein synthesis, cell membrane function, parathyroid hormone secretion, and glucose metabolism are just a few important functions affected by magnesium.[44] It is the fourth most abundant extracellular cation and the second most abundant intracellular cation, after potassium. Disorders of magnesium homeostasis are commonly encountered in clinical situations and most frequently are manifested as alterations in cardiovascular and neuromuscular function. Life-threatening conditions such as paralysis and cardiac arrhythmias can occur, making the proper recognition and treatment of these problems of paramount importance. Altered magnesium balance also plays a key role in chronic disease states such as diabetes mellitus, CKD, osteoporosis, development of kidney stones, as well as heart and vascular disease.[45]

Magnesium is principally distributed in bone (67%) and muscle (20%). Because of its predominantly intracellular distribution, measurement of magnesium in the extracellular compartment may not accurately reflect the total-body magnesium content. The majority of magnesium in the extracellular fluid is in the ionized form as only 30% is bound to serum proteins. The normal range for serum magnesium is 1.4 to 1.8 mEq/L (1.7-2.3 mg/dL or 0.70-0.95 mmol/L).

The recommended daily dietary magnesium intake for adults is approximately 420 mg/day and 320 mg/day for men and women, respectively. The maintenance of magnesium homeostasis depends on the balance between intake and output. Ingested magnesium (30%-40%) is absorbed in the small bowel. The absorption of magnesium decreases as the dietary intake increases. Reductions in absorption have also been noted in the elderly and those with CKD. A small amount is present in intestinal secretions and reabsorbed in the sigmoid colon. The kidneys play a major role in maintaining magnesium balance. Approximately 95% of the filtered magnesium is reabsorbed, thus in most patients less than 5% is excreted in the urine.[38] Renal magnesium handling is unique in that approximately 20% of the filtered magnesium is reabsorbed in the proximal tubule; the majority (up to 70%) of reabsorption occurs in the thick ascending limb of the loop of Henle. This explains why loop diuretics often cause profound urinary magnesium wasting. The remaining 10% is reabsorbed in the distal convoluted tubule.[46] Unlike most other important electrolytes, there is no hormonal regulation of the distribution of magnesium between bone and circulating or intracellular magnesium pools. Because of this, both hypomagnesemia and hypermagnesemia commonly occur.

CLINICAL PRESENTATION Hypomagnesemia General

- The dominant organ systems affected by hypomagnesemia are the neuromuscular and cardiovascular systems.

Symptoms

- Neuromuscular symptoms such as tetany, twitching, and generalized convulsions are common.
- Cardiac symptoms include heart palpitations.

Signs

- Neuromuscular: Presence of Chvostek sign, Trousseau sign, tremor, and tetany.
- Cardiovascular: Cardiac arrhythmias (ventricular fibrillation, torsade de pointes, or digoxin-induced arrhythmias), sudden cardiac death, and hypertension can be present. ECG abnormalities include widened QRS complex and peaked T waves with mild hypomagnesemia; and prolonged PR interval, progressive widening of QRS complex, and flattened T waves with moderate to severe hypomagnesemia.

Laboratory Tests

- Serum magnesium concentration less than 1.4 mEq/L (1.7 mg/dL [0.70 mmol/L]). Serum potassium and calcium concentrations can also be low.

HYPOMAGNESEMIA

Epidemiology

Hypomagnesemia is a common problem in both ambulatory and hospitalized patients. Although the exact prevalence is difficult to estimate, it has been reported that up to 65% of intensive care unit

patients are magnesium-deficient. Although serum magnesium concentrations are not a reliable index of total-body magnesium content, they remain the primary diagnostic tool to evaluate body stores.

Hypomagnesemia is associated with an increase in mortality in critically ill patients. There are limited data regarding the incidence and associated risks of hypomagnesemia in hospitalized general medicine patients, even though they are at an increased risk of hypomagensemia given the presence of comorbidities such as congestive heart failure, CKD, and diabetes mellitus. A recent study reported a 20% incidence of hypomagensemia in hospitalized general medicine patients, which was associated with increased mortality compared to normomagnesemic patients (17.2% vs 7.2%, respectively).[47]

Etiology and Pathophysiology

5 Hypomagnesemia is usually associated with disorders of the intestinal tract or kidney.[48] Drugs or conditions that interfere with intestinal absorption or increase renal excretion of magnesium can result in hypomagnesemia (**Table 51-6**). Decreased intestinal absorption as a result of small bowel disease is the most common cause of hypomagnesemia worldwide. These disorders include regional enteritis, radiation enteritis, ulcerative colitis, acute and chronic diarrhea, pancreatic insufficiency and other malabsorptive syndromes, small-bowel bypass surgery, and chronic laxative abuse. Proton pump inhibitors, especially when used chronically, can cause hypomagnesemia through impaired intestinal absorption. Hypomagnesemia is commonly associated with alcoholism, where the etiology is multifactorial, including reduced intake, pancreatic insufficiency, chronic vomiting and diarrhea, and urinary magnesium wasting.

TABLE 51-6 Causes of Hypomagnesemia

GI
Reduced intake
Protein-calorie malnutrition
Prolonged parenteral fluid administration without magnesium
Alcoholism
Reduced absorption
Primary hypomagnesemia
Malabsorption syndromes (eg, tropical sprue, celiac disease, radiation enteritis, or intestinal lymphectasia)
Short-bowel syndrome (eg, small-bowel resection or ileal bypass)
Pancreatic insufficiency
Proton pump inhibitors (long-term use)
Increased loss

Excessive vomiting

Prolonged nasogastric suction

Excessive laxative use

Intestinal and biliary fistulas

Prolonged diarrhea (ulcerative colitis, Crohn disease, or cancer of the colon)

Renal

Primary tubular disorders

Primary renal magnesium wasting

Bartter syndrome

Renal tubular acidosis

Diuretic phase of acute tubular necrosis

Postobstructive diuresis

Postrenal transplant diuresis

Glomerulonephritis

Pyelonephritis

Drug-induced renal losses

Aminoglycosides

Amphotericin B

Cyclosporine

Tacrolimus

Diuretics

Digitalis

Cisplatin

Pentamidine

Foscarnet

Hormone-induced renal losses

Primary hyperparathyroidism

Hyperthyroidism

Aldosteronism

"Hungry bone syndrome" after parathyroidectomy

Internal redistribution

Diabetic ketoacidosis

Glucose, amino acid, or insulin administration

Massive blood transfusion (citrate)

Pancreatitis with lipedema (magnesium soap)

Other

Excessive sweating and lactation

Hypercalcemia and hypercalciuria

Phosphate depletion

Chronic alcoholism

Extracellular fluid volume expansion

Primary renal magnesium wasting can be caused by a defect in renal tubular magnesium reabsorption, or inhibition of sodium reabsorption in those segments in which magnesium transport follows passively. The former condition is associated with hypercalciuria, nephrolithiasis, and progressive renal disease, while the latter is associated with Gitelman and Bartter syndromes.[48] Much more common than these is renal magnesium wasting secondary to thiazide and loop diuretics. Other commonly used drugs that can cause renal magnesium wasting include aminoglycosides, amphotericin B, cyclosporine, digoxin, tacrolimus, cisplatin, pentamidine, and foscarnet.[49]

TREATMENT

Desired Outcomes

The treatment goals in the management of hypomagnesemia are (a) resolution of the signs and symptoms, (b) restoration of normal magnesium concentrations, (c) correction of concomitant electrolyte abnormalities, and (d) identification and correction of the underlying cause of magnesium depletion.

General Approach to Treatment

Nearly all of the data regarding magnesium replacement therapy have been derived from relatively old

data in acutely ill, hospitalized patients. Magnesium supplementation can be given by the oral, intramuscular (IM), or IV route. The severity of the magnesium depletion and the presence of severe signs and symptoms should dictate the route of administration. Because IM administration is painful, it should be reserved for those patients with severe hypomagnesemia and limited venous access. IV bolus administration is associated with flushing, sweating, and a sensation of warmth; thus bolus administration should be avoided if possible. Additionally, because calcium forms a complex with the sulfate moiety, which is then excreted, large amounts of IV magnesium sulfate should be administered with caution to hypocalcemic patients, as it can further exacerbate calcium deficiency.[45] There have been no clinical trials assessing the optimal regimen for magnesium replacement; however, it is widely accepted that 8 to 12 g of magnesium sulfate be administered, in divided doses, in the first 24 hours followed by 4 to 6 g/day for 3 to 5 days to adequately replete body stores in those with severe hypomagnesemia.[50] Even if severe magnesium depletion is present, approximately 50% of the administered dose is excreted in the urine. Consequently, magnesium replacement should be performed over 3 to 5 days, and continued supplementation should be provided for patients unable to eat. **Table 51-7** lists the commonly used magnesium oral supplements and their respective elemental magnesium content.

TABLE 51-7 Common Magnesium Products and Their Elemental Magnesium Content

Product	Elemental Magnesium Content
Magnesium oxide	242 mg in a 400-mg tablet
Magnesium hydroxide	167 mg in a 400-mg tablet or 5-mL oral suspension
Magnesium chloride	64 mg in each 535-mg tablet
Magnesium citrate	48 mg in each 5 mL of the oral solution
Magnesium gluconate	27 mg in a 500-mg tablet
Magnesium lactate	84 mg in an 84 mg-tablet

Nonpharmacologic Therapy

There are currently no nonpharmacologic options for the management of hypomagnesaemia.

Pharmacologic Therapy

It is currently controversial whether all asymptomatic patients require magnesium supplementation when serum magnesium concentration falls below the normal range. In particular, it has been suggested that for patients with type 2 diabetes mellitus, hypomagnesemia contributes to diabetic complications by affecting glucose transport and insulin secretion and utilization. Indeed, it has been shown that oral magnesium supplementation in type 2 diabetic patients with hypomagnesemia improves insulin sensitivity and metabolic control.[51] Others suggest that hypomagnesemia is more likely a consequence of diabetes mellitus. Possible mechanisms of hypomagensemia in these patients include reduced GI absorption, enhanced renal excretion secondary to an increased filtered magnesium load and tubular flow, and reduced tubular reabsorption. Metabolic abnormalities such as hypokalemia, hypophosphatemia, and metabolic acidosis may also contribute to its development.[52] While it seems reasonable to provide a supplement for diabetic patients with low serum magnesium concentrations,

clinical trials have yet to prove that supplementation leads to improved clinical outcomes.

Should treatment be warranted, those patients with serum magnesium concentrations greater than 1 mEq/L (1.2 mg/dL [0.5 mmol/L]) can be treated with oral supplements. Oral supplementation is preferred because magnesium uptake is a slow process that may require prolonged administration. Several magnesium products are available, including magnesium-containing antacids or laxatives, comprising a variety of magnesium salts in tablet or capsule formulations. Many of the oral products contain very little magnesium, which necessitates three or four doses per day. As expected, diarrhea is the most common dose-limiting side effect of oral therapy, which can greatly reduce patient compliance. Therefore, sustained-release magnesium products are preferred as they not only improve patient compliance, but also reduce the occurrence of GI side effects.

In cases of severe magnesium depletion (serum concentrations less than 1 mEq/L [less than 1.2 mg/dL; less than 0.5 mmol/L]), or if signs and symptoms are present regardless of the serum concentration, IV magnesium should be administered. A dose of 4 to 6 g in 50 to 100 mL (maximum concentration 1 g/10 mL) should be administered in divided doses over 12 to 24 hours and repeated as necessary in order to maintain magnesium concentrations above 1 mEq/L (1.2 mg/dL [0.5 mmol/L]). Doses of 2 to 4 g in 50 mL infused over 1 hour are frequently used clinically; however, these result in transient benefit because of the extensive renal excretion, and usually have to be repeated daily over 3 to 5 days for adequeate repletion. Therapy should be continued until the signs and symptoms have completely resolved. In patients with renal insufficiency, some have reduced the does by 25% to 50%.

Clinical Controversy…

Hypomagnesemia in patients with type 2 diabetes may be associated with impaired insulin and glucose utilization. Other data suggest that hypomagnesemia is a consequence of diabetes itself. Supplementation in hypomagnesemic diabetes patients increases insulin sensitivity and metabolic control, but its effect on clinical outcomes has yet to be elucidated.

Evaluation of Therapeutic Outcomes

In patients with acute, asymptomatic mild to moderate hypomagnesemia, serum magnesium concentrations should be obtained at least daily during their hospitalization. Patients receiving oral magnesium therapy should be questioned regarding GI tolerance and the occurrence of diarrhea. Patients being treated for symptomatic severe hypomagnesemia should have their serum magnesium concentration monitored hourly until the serum concentration reaches 1.5 mEq/L (1.8 mg/dL [0.75 mmol/L]) and the symptoms resolve. At that point, the serum magnesium concentration can be monitored every 6 to 12 hours for the next 24 hours while receiving magnesium supplementation. Once the magnesium concentration is stable in the normal range, a concentration can be obtained daily. It should be reiterated that it typically takes 3 to 5 days to fully replete total-body magnesium stores. Patients receiving oral magnesium-containing antacids or supplements should be asked regularly about the occurrence of diarrhea.

Clinical Bottom Line

Hypomagnesemia is generally associated with kidney or GI tract disorders. In cases of mild, chronic

magnesium loss, oral magnesium preparations can be used; however, the dose-limiting side effect is diarrhea. For more severe cases of hypomagnesemia, IV magnesium sulfate can be safely administered. Repeated doses may be needed as IV magnesium is rapidly eliminated in urine. In such cases, close monitoring of serum magnesium concentrations is needed.

HYPERMAGNESEMIA

Epidemiology

6 Hypermagnesemia (serum magnesium greater than 2 mEq/L [greater than 2.4 mg/dL; greater than 1 mmol/L]) is a rare occurrence that is generally seen in patients with stage 4 or 5 CKD when magnesium intake exceeds the excretory capacity of the kidneys. Elderly patients are prone to hypermagnesemia because of their reduced glomerular filtration rate (GFR) and because of their tendency to consume magnesium-containing antacids and vitamins.

Etiology and Pathophysiology

Because magnesium excretion decreases as GFR declines, serum magnesium concentrations tend to increase in patients with moderate to severe CKD. Indeed, magnesium concentrations steadily increase as the GFR decreases below 30 mL/min/1.73 m^2. As long as the patient maintains a normal diet, the serum magnesium concentration typically stabilizes at approximately 2.5 mEq/L (3 mg/dL [1.25 mmol/L]). If patients with stage 4 or 5 CKD are taking concomitant magnesium-containing antacids, the serum concentration can approach 6 mEq/L (7.3 mg/dL [3 mmol/L]), a value associated with signs and symptoms of toxicity. Critically ill patients with multiorgan system failure receiving enteral or parenteral nutrition are also prone to develop hypermagnesemia. Finally, the parenteral treatment of eclampsia with magnesium sulfate can lead to hypermagnesemia. **Table 51-8** lists other causes of hypermagnesemia.

TABLE 51-8 Causes of Hypermagnesemia

Decreased renal excretion
Acute renal failure
CKD with exogenous intake
Excessive intake
Treatment of toxemia of pregnancy
Ureteral irrigants (hemiacidrin)
Cathartics
Other
Lithium therapy
Hypothyroidism

Milk-alkali syndrome

Addison disease

Viral hepatitis

Acute diabetic ketoacidosis

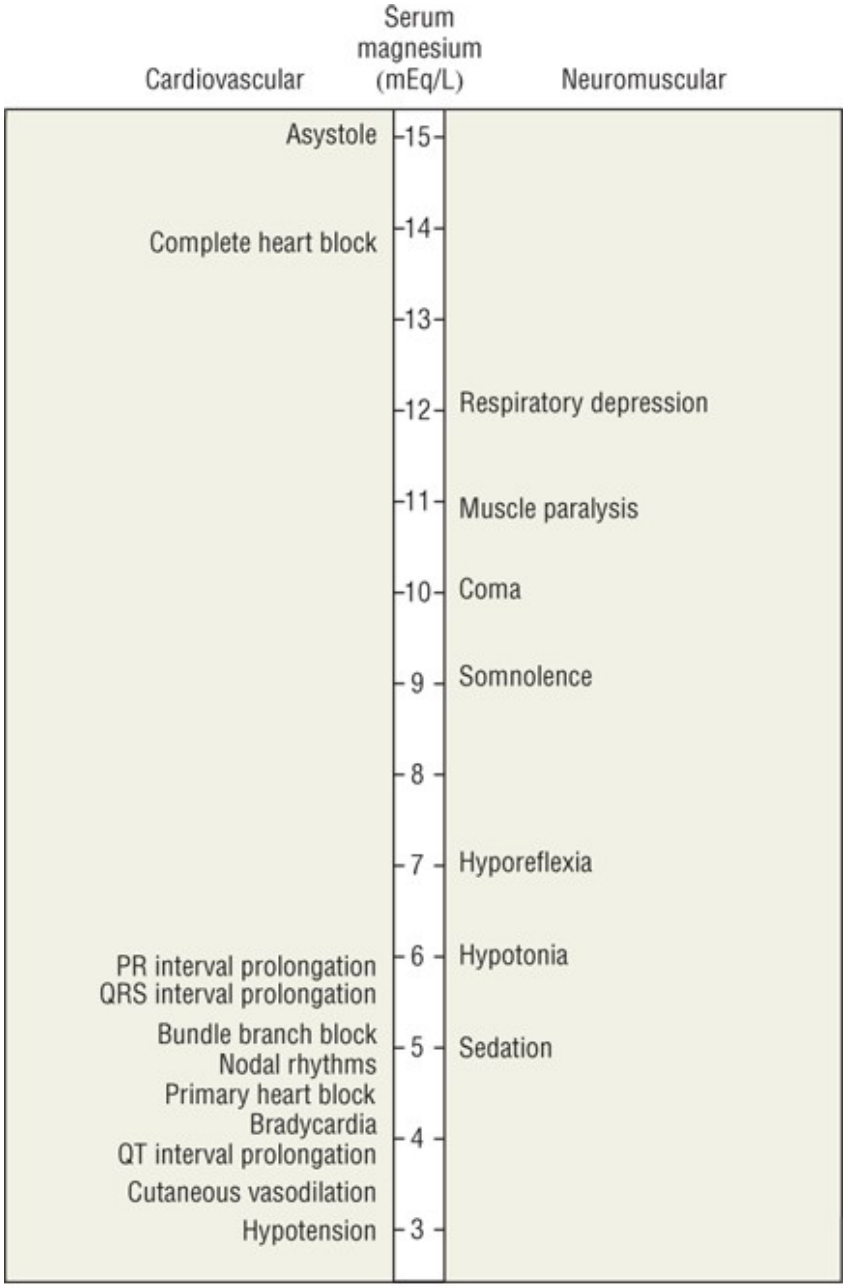
CKD, chronic kidney disease.

Clinical Presentation

7 The signs and symptoms of hypermagnesemia reflect magnesium's action on the neuromuscular and cardiovascular systems.[50,53] The main symptoms include lethargy, confusion, dysrhythmias, and muscle weakness. Symptoms are rare when the serum concentration is below 4 mEq/L (4.9 mg/dL [2 mmol/L]) (**Fig. 51-3**).

FIGURE 51-3

Clinical findings associated with hypermagnesemia. (Serum magnesium levels in mmol/L can be determined by multiplying the serum magnesium value expressed in mEq/L by 0.5.)



TREATMENT

Desired Outcome

The goals of therapy are to (a) reverse the neuromuscular and cardiovascular manifestations of hypermagnesemia, (b) decrease the magnesium concentration toward normal values, and (c) identify and treat the underlying cause of hypermagnesemia.

Nonpharmacologic Therapy

There are currently no nonpharmacologic options for the management of hypermagnesemia.

Pharmacologic Therapy

There are three primary means of treating hypermagnesemia: (a) reduce magnesium intake, (b) enhance elimination of magnesium, and (c) antagonize the physiologic effects of magnesium. The optimal treatment regimen for the management of hypermagnesemia depends on the severity of the patient's signs and symptoms and the degree of serum concentration elevation. IV elemental calcium doses of 100 to 200 mg directly antagonize the neuromuscular and cardiovascular effects of hypermagnesemia. Oral calcium is not effective because of its relatively poor bioavailability and slow onset of action. The clinical effect of calcium is immediate, but the effect is transient; hence, repeated IV doses of 100 to 200 mg of elemental calcium (eg, 2 g of calcium gluconate) might need to be administered hourly until the signs or symptoms abate and the magnesium concentration is normalized. Supportive care with cardiac pacing, vasopressors, and mechanical ventilation can be necessary in life-threatening situations. In patients with normal renal function, or those with stage 1, 2, or 3 CKD, forced diuresis with 0.45% NaCl and loop diuretics can promote magnesium elimination. An initial IV bolus of furosemide 40 mg or a similar equivalent can be used. Subsequent dosing can be determined based on the patient's clinical response. Patients with CKD can require long-term loop diuretic therapy to maintain adequate fluid and electrolyte balance. In dialysis patients, their hemodialysis prescription should be changed to employ magnesium-free dialysate.

Evaluation of Therapeutic Outcomes

Patients who are receiving IV calcium salts for the treatment of severe, symptomatic hypermagnesemia should have their serum magnesium concentration evaluated hourly until symptoms abate and the magnesium concentration decreases below 4 mg/dL (3.3 mEq/L [1.64 mmol/L]). Furthermore, the patient should be continuously monitored to detect ECG changes. In CKD patients who can produce urine, forced diuresis with saline and furosemide should reduce the serum magnesium concentration within 6 to 12 hours. Close monitoring of the urine output and physical examination for signs of volume overload are important. Emergency hemodialysis will usually correct the hypermagnesemia within 4 hours and is a reasonable option for those who are currently receiving hemodialysis. To prevent further episodes of hypermagnesemia, the patient should receive dietary education regarding foods and beverages that contain large quantities of magnesium (**Table 51-9**).

TABLE 51-9 Magnesium Content of Selected Foods

Food	Elemental Magnesium Content per Serving (mg)
Halibut, cooked, 3 oz (85g)	90
Almonds, dry roasted, 1 oz (28g)	80
Spinach, boiled, one-half cup (~125mL)	78
Cashews, dry roasted, 1 oz (28g)	74
Peanuts, oil roasted, one-fourth cup (~60 mL)	63
Shredded wheat cereal, two large biscuits	61
Soymilk, plain or vanilla, 1 cup (~250mL)	61
Black beans, cooked, one-half cup (~125mL)	60

Food	Elemental Magnesium Content per Serving (mg)
Edamame, shelled, cooked, one-half cup (~125mL)	50
Peanuts, dry roasted, 1 oz (28g)	50
Peanut butter, smooth, 2 tablespoons (~30 mL)	49
Bread, whole wheat, 2 slices	46
Avocado, cubed, 1 cup (~250mL)	44
Potato, baked with skin, 3.5 oz (~100g)	43
Yogurt, plain, low fat, 8 oz (~225g)	42
Rice, brown, cooked, one-half cup (~125 mL)	42
Breakfast cereals, fortified with 10% of the daily value for magnesium	40
Instant oatmeal, 1 cup (~250 mL)	36
Kidney beans, canned, one-half cup (~125 mL)	35
Banana, 1 medium	32

Clinical Bottom Line

Hypermagnesemia is generally associated with advanced CKD. Severe cases of hypermagnesemia can result in neurologic symptoms or cardiac dysrhythmias. Should these symptoms occur, IV calcium can counteract these effects. Forced diuresis with saline and loop diuretics is useful in lowering magnesium in patients with mild to moderate renal dysfunction; hemodialysis should be reserved for ESRD patients.

PERSONALIZED PHARMACOTHERAPY

As discussed throughout the chapter, there are numerous patient considerations that must be taken into account when designing appropriate pharmacotherapy for potassium and magnesium disorders. At this time, there are no genetic, genomic, or pharmacokinetic factors that are used to personalize pharmacotherapy for the treatment of these electrolyte disorders.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACEI	angiotensin-converting enzyme inhibitor
AKI	acute kidney injury
ARB	angiotensin-II receptor blocker
CKD	chronic kidney disease
ECG	electrocardiogram
ESRD	end-stage renal disease
FDA	Food and Drug Administration

GFR	glomerular filtration rate
GI	gastrointestinal
IM	intramuscular
IV	intravenous
NSAID	nonsteroidal anti-inflammatory drug
RAAS	renin–angiotensin–aldosterone system
SPS	sodium polystyrene sulfonate

Chapter 52: Acid–Base Disorders

John W. Devlin; Gary R. Matzke

INTRODUCTION

KEY CONCEPTS

- 1 The kidney plays a central role in the regulation of acid–base homeostasis through the excretion or reabsorption of filtered bicarbonate (HCO_3^-), the excretion of metabolic fixed acids, and the generation of new HCO_3^-.
- 2 Arterial blood gases (ABGs), along with serum electrolytes, physical findings, medical and medication history, and the clinical condition of the patient, are the primary tools to determine the cause of an acid–base disorder and to design and monitor a course of therapy.
- 3 Each acid-base disturbance has a compensatory response that attempts to correct the HCO_3^--to-$PaCO_2$ ratio toward normal and mitigate the change in pH. The respiratory compensatory response to metabolic disturbances is initiated rapidly whereas the metabolic compensatory response to respiratory disturbances occurs more slowly.
- 4 Metabolic acidosis and metabolic alkalosis are generated by a primary change in the serum bicarbonate concentration. In metabolic acidosis, bicarbonate is lost or a nonvolatile acid is gained, whereas metabolic alkalosis is characterized by a gain in bicarbonate or a loss of nonvolatile acid.
- 5 Renal tubular acidosis (RTA) refers to a group of disorders characterized by impaired tubular renal acid handling despite normal or near-normal glomerular filtration rates. These patients often present with hyperchloremic metabolic acidosis.
- 6 Although respiratory compensation for a primary metabolic acidosis begins rapidly (within 15-30 minutes) it does not reach a steady state for 12 to 24 hours after the onset of metabolic acidosis.
- 7 Primary therapy of most acid–base disorders must include treatment or removal of the underlying cause, not just correction of the pH and electrolyte disturbances.

- 8 Potassium supplementation is always necessary for patients with chronic metabolic acidosis, as the bicarbonaturia resulting from alkali therapy increases renal potassium wasting.
- 9 Effective treatment of the underlying cause of some organic acidoses (eg, ketoacidosis) can result in bicarbonate regeneration within hours thus mitigating the need for alkali therapy.
- 10 Loss of gastric acid from vomiting or nasogastric suctioning may lead to hypochloremia and hyperbicarbonatemia and may often lead to a metabolic alkalosis.
- 11 Aggressive diuretic therapy can produce a metabolic alkalosis, and the accompanying hypokalemia can be serious.
- 12 A patient's response to volume replacement can be predicted by the urine chloride concentration and permits the differential diagnosis of metabolic alkalosis.
- 13 Management of these disorders usually consists of treatment of the underlying cause of mineralocorticoid excess. In patients in whom the mineralocorticoid excess cannot be corrected, chronic pharmacologic therapy can be required.
- 14 In most cases of acute metabolic acidosis, such as following cardiopulmonary arrest, sodium bicarbonate therapy is not indicated and can be detrimental. Blood gas analysis should guide therapy.

Acid–base disorders are common and often serious disturbances that can result in significant morbidity and mortality. This chapter reviews the mechanisms responsible for the maintenance of acid–base balance and the laboratory analyses that aid clinicians in their assessment of acid–base disorders. The pathophysiology of the four primary acid–base disturbances is presented, evidence-based therapeutic options are reviewed, and management guidelines to optimize the outcome of patients with one of these disorders are presented. Given that medications are a frequent cause of acid–base abnormalities and that acid–base abnormalities are often preventable, clinicians must anticipate drug-related problems to avoid or minimize the clinical consequences of acid–base disorders, and when necessary, design appropriate treatment regimens.

ACID–BASE CHEMISTRY

An acid (in this equation, hydrochloric acid) is a substance that can *donate* protons (hydrogen ion [H^+]):

(Acid) HCl → H^+ + Chloride ion (Cl)

A base (in this equation, ammonia [NH_3]) is a substance that can *accept* protons (hydrogen ion [H^+]):

Ammonia (NH_3) + H^+ → NH^+_4 (base)

The acid–base pairs commonly encountered in clinical practice are listed in **Table 52-1**.

TABLE 52-1 Acid–Base Pairs

Carbonic acid/bicarbonate	H_2CO_3/HCO_3^-
Monobasic/dibasic phosphate	H_2PO_4/HPO_4^-
Ammonium/ammonia	NH_4^+/NH_3
Lactic acid/lactate	$H_6C_3O_2/H_5C_3O_2^-$

The acidity of body fluids is quantified in terms of the hydrogen ion concentration. By convention, the degree of acidity is expressed as pH, or the negative logarithm (base 10) of the hydrogen ion concentration. Thus, hydrogen ion concentration and pH are inversely related. Normally, the pH of blood is maintained at 7.40 ($[H^+]$ of 4×10^{-8} M) with a range of 7.35 to 7.45. A pH of less than 6.7 ($[H^+]$ of 2×10^{-7} M), representing a fivefold increase in hydrogen ion concentration, or greater than 7.7 ($[H^+]$ of 2×10^{-8} M), representing a 50% decrease in hydrogen ion concentration, is considered incompatible with life.

The hydrogen ion concentration in blood may not be indicative of that in other body compartments. For example, the pH within cells, within the cerebrospinal fluid, or on the surface of bone can all be altered without causing an alteration in blood pH.[1] Recognizing this caveat, the acid–base status of the body is usually analyzed based on measurement of blood pH. Alterations in blood pH serve as the basis for the diagnosis of acid–base disorders.

Because the dissociation of acid–base pairs is an equilibrium reaction, the relationship between hydrogen ion concentration or pH and the relative concentrations of the acid and base can be described mathematically in terms of the dissociation constant for the acid–base buffer pair. When expressed as a logarithmic relationship, where pK is the negative logarithm of the dissociation constant K, this is known as the Henderson–Hasselbalch equation:

$$pH = pK + \log([base]/[acid])$$

BUFFERS

The ability of a weak acid and its corresponding anion (base) to resist change in the pH of a solution with the addition of a strong acid or base is referred to as *buffering*. An acid–base pair is most efficient in functioning as a buffer at a pH close to its pK. The principal extracellular buffer is the carbonic acid/bicarbonate (H_2CO_3/HCO_3^-) system. Other physiologic buffers include plasma proteins, hemoglobin, and phosphates. Because the isohydric principle requires that all buffer systems remain in chemical equilibrium, the complex buffering of biologic fluids can be analyzed based on a single buffer pair.

The carbonic acid/bicarbonate buffer system plays a unique role in acid–base homeostasis. In addition to being the most abundant extracellular buffer, the components of this buffer pair exist under dynamic regulation by the body. In the presence of carbonic anhydrase, carbonic acid,

[H_2CO_3], is in equilibrium with carbon dioxide (CO_2) gas. Changes in ventilation that alter the partial pressure of CO_2 (PCO_2) in the blood regulate the carbonic acid level in the blood. The bicarbonate concentration is independently regulated by the kidney. Because the p*K* for the carbonic acid/bicarbonate system is 6.1, the relationship between pH, carbonic acid, and bicarbonate concentrations can be described by the Henderson–Hasselbalch equation. The concentration of carbonic acid is directly proportional to the amount of CO_2 dissolved in blood, which is equal to the product of PCO_2 and its solubility in physiologic fluids ($PCO_2 \times 0.03$ for PCO_2 expressed in mm Hg or $PCO_2 \times 0.226$ for PCO_2 expressed in kPa). This term can, therefore, be substituted into the equation below in place of [H_2CO_3].

$$pH = 6.1 + ([HCO_3^-]/[H_2CO_3])$$

$$pH = 6.1 + \log([HCO_3^-]/[PCO_2 \times 0.03]) \text{ for } PCO_2 \text{ in mm Hg}$$

or

$$pH = 6.1 + \log([HCO_3^-]/[PCO_2 \times 0.226]) \text{ for } PCO_2 \text{ in kPa}$$

Thus, hydrogen ion concentration and pH are determined not by the absolute amounts of bicarbonate and PCO_2 present but by their ratio.[1] Under normal physiologic conditions, the kidneys maintain the serum bicarbonate at approximately 24 mEq/L (mmol/L), whereas the lungs maintain the PCO_2 at approximately 40 mm Hg (5.3 kPa). The normal physiologic pH is thus 7.4:

$$pH = 6.1 + \log[24/(0.03 \times 40)] \text{ (or } pH = 6.1 + \log[24/(0.226 \times 5.3)])$$

$$pH = 6.1 + 1.3 = 7.4$$

If, in response to an acid load, the serum bicarbonate concentration were to decrease to 12 mEq/L (mmol/L), the predicted pH would be:

$$[HCO_3^-] = 12 \text{ mEq/L (mmol/L)}$$

$$PCO_2 = 40 \text{ mm Hg (5.3 kPa)}$$

$$pH = 6.1 + \log [12/0.03 \times 40] \text{ or}$$

$$pH = 6.1 + \log [12/(0.226 \times 5.3)]$$

$$pH = 6.1 + 1.0 = 7.1$$

However, the normal respiratory response to an acid load is hyperventilation. As a result, if the PCO_2 decreased to approximately 26 mm Hg (3.5 kPa), the change in pH would be less:

$$[HCO_3^-] = 12 \text{ mEq/L (mmol/L)}$$

$$PCO_2 = 26 \text{ mm Hg (3.5 kPa)}$$

$$pH = 6.1 + \log[12/0.03 \times 26]$$

$$(\text{or } pH = 6.1 + \log[12/(0.226 \times 3.5)])$$

$$pH = 6.1 + 1.19 = 7.29$$

Thus, the physiologic regulation of both P_{CO_2} and $[HCO_3^-]$ permits the carbonic acid/bicarbonate system to provide more effective buffering of the extracellular fluids (ECFs) than could be achieved on the basis of chemical buffering alone.

REGULATION OF ACID–BASE HOMEOSTASIS

Cellular metabolism results in the production of large quantities of hydrogen that need to be excreted to maintain acid–base balance. In addition, small amounts of acid and alkali are also presented to the body through the diet. The bulk of acid production is in the form of CO_2, with the average adult producing approximately 15,000 mmol of CO_2 each day from the catabolism of carbohydrate, protein, and fat.[2] When respiratory function is normal, the amount of CO_2 produced metabolically is equal to the amount lost by respiration, and the blood CO_2 concentration remains constant.

Digestion of dietary substances and tissue metabolism also result in the production of nonvolatile acids. These acids are derived primarily from the sulfur-containing amino acids cysteine and methionine, as well as from ingested sulfur. In addition, phosphates are generated from the metabolism of proteins and phospholipids. Neutral substances such as glucose can also be incompletely metabolized to intermediates, such as lactic and pyruvic acid, and fatty acids can be incompletely metabolized to acetoacetic acid and β-hydroxybutyric acid. These dietary and metabolic fixed acids are excreted primarily by the kidney to maintain acid–base homeostasis. On average, daily fixed acid excretion is approximately 0.8 mEq/kg per day (mmol/kg per day).[3]

Three processes, each of which varies in its onset, collectively maintain acid–base balance: extracellular buffering, ventilatory regulation of carbon dioxide elimination, and renal regulation of hydrogen ion and bicarbonate excretion. Extracellular buffering occurs rapidly and is the body's first defense against a sudden increase in hydrogen ion concentration. Hyperventilation then results in a decrease in P_{CO_2}, returning blood pH toward normal. Finally, over a period of day(s), the kidney will excrete the excess hydrogen ion and acid–base balance will return to normal.

Extracellular Buffering

The body's buffering system can be divided into three components: bicarbonate/carbonic acid, proteins, and phosphates. The bicarbonate buffer is the most important of the body's buffers, because: (a) there is more bicarbonate present in the ECF than any other buffer component; (b) the supply of CO_2 is unlimited; and (c) the acidity of ECF can be regulated by controlling either the bicarbonate concentration or the P_{CO_2}.

Carbonic acid represents the respiratory component of the buffer pair because its blood concentration is directly proportional to the P_{CO_2}, which is determined by ventilation. Bicarbonate represents the metabolic component because the kidney may alter its concentration by reabsorption, generating new bicarbonate, or altering elimination.[1] The bicarbonate buffer system easily adapts to changes in acid–base status by alterations in ventilatory elimination of acid (P_{CO_2}) and/or renal

elimination of base (HCO_3^-).

The phosphate buffer system consists of serum inorganic phosphate (3.5-5 mg/dL [1.13-1.62 mmol/L]), intracellular organic phosphate, and calcium phosphate in bone. Extracellular phosphate is present only in low concentrations, so its usefulness as a buffer is limited; however, as an intracellular buffer, phosphate is more useful. Calcium phosphate in bone is relatively inaccessible as a buffer, but prolonged metabolic acidosis will result in the release of phosphate from bone.

Intracellular and extracellular proteins also act as buffering systems. The charged side chains of amino acids provide the buffering action. Because the concentration of protein is much greater intracellularly than extracellularly, protein is much more important as an intracellular buffer.

Respiratory Regulation

The second process involved in maintenance of acid–base homeostasis is ventilatory regulation of CO_2 elimination. Both the rate and depth of ventilation can be varied to allow for excretion of CO_2 generated by diet and tissue metabolism. Medullary chemoreceptors in the brainstem sense changes in P_{CO_2} and pH and modulate the control of breathing. Increasing minute ventilation (the total amount of air exhaled over a 1-minute period), by increasing respiratory rate and/or tidal volume (the amount of air exhaled in one breath), will increase CO_2 excretion and decrease the blood P_{CO_2}. Conversely, decreasing minute ventilation decreases CO_2 excretion and increases blood P_{CO_2}. This system rapidly adjusts within minutes to changes in acid–base balance.[1]

Renal Regulation

1 Bicarbonate is freely filtered at the glomerulus because it is a small ion. The bicarbonate load delivered to the nephron is approximately 4,500 mEq/day (mmol/day). To maintain acid–base balance, this entire filtered bicarbonate load must be reabsorbed. Bicarbonate reabsorption occurs primarily in the proximal tubule (**Fig. 52-1**). In the tubular lumen, filtered bicarbonate combines with hydrogen ion, secreted by the apical sodium ion (Na^+)–H^+-exchanger, to form carbonic acid. The carbonic acid is rapidly broken down to CO_2 and water by carbonic anhydrase, an enzyme located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates to form hydrogen ions that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

FIGURE 52-1

Proximal tubular bicarbonate reabsorption. In the tubular lumen, filtered bicarbonate (HCO_3^-) combines with hydrogen ion (H^+) secreted by an apical sodium ion (Na^+)–H^+ exchanger to form carbonic acid (H_2CO_3). The carbonic acid is rapidly broken down to carbon dioxide (CO_2) and water by carbonic anhydrase located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular

carbonic anhydrase. The carbonic acid dissociates the former hydrogen ion that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

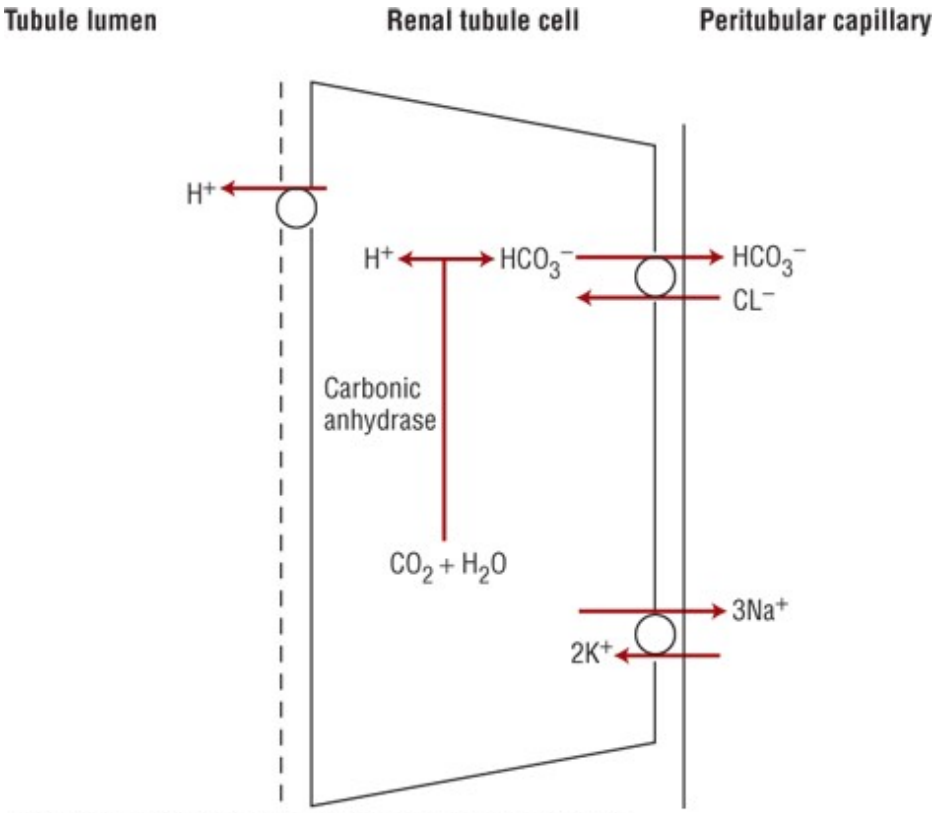
Excretion of metabolic fixed acids and generation of new HCO_3^- is achieved in nearly equal parts by renal ammoniagenesis and distal tubular hydrogen ion secretion. Ammoniagenesis plays a critical role in acid–base homeostasis, with ammonium (NH_4^+) excretion comprising approximately 50% of renal net acid excretion. Ammonium is generated from the deamination of glutamine in the proximal tubule. For each ammonium ion excreted in the urine, one bicarbonate ion is regenerated and returned to the circulation.[3]

Distal tubular hydrogen ion secretion accounts for the remaining 50% of net acid excretion (**Fig. 52-2**). In the distal tubular cell, CO_2 combines with water in the presence of intracellular carbonic anhydrase to form carbonic acid, which dissociates to H^+ and HCO_3^-. The H^+ is actively transported into the tubular lumen by a H^+–adenosine triphosphatase (ATPase). The bicarbonate exits the cell across the basolateral membrane and enters the circulation.[1]

FIGURE 52-2

Collecting duct acid excretion. Hydrogen ion (H^+) and bicarbonate (HCO_3^-) are generated intracellularly from carbon dioxide (CO_2) and water, in the presence of intracellular carbonic

anhydrase. The hydrogen ion is actively secreted into the tubular lumen by H^+–ATPase located in the apical (luminal) membrane. Bicarbonate exits the cell across the basolateral membrane and enters the peritubular capillary. (Cl^-, chloride ion; Na^+, sodium ion.)



ACID–BASE DISTURBANCES

2 Alterations in blood pH are designated by the suffix "-emia"; *acidemia* is an arterial blood pH less than 7.35 and *alkalemia* is an arterial blood pH more than 7.45. The pathophysiologic processes that result in alterations in blood pH are designated by the suffix "-osis." These disturbances are classified as either metabolic or respiratory in origin. In metabolic acid–base disorders, the primary disturbance is in the plasma bicarbonate concentration. Metabolic acidosis is characterized by a decrease in the plasma bicarbonate concentration whereas in metabolic alkalosis the plasma bicarbonate concentration is increased. Respiratory acid–base disorders are caused by alterations in alveolar ventilation that produce corresponding changes in the partial pressure of carbon dioxide from arterial blood ($PaCO_2$). In respiratory acidosis, the $PaCO_2$ is elevated; in respiratory alkalosis, it is decreased. 3 Each disturbance has a compensatory (secondary) response that attempts to correct the HCO_3^--to-$PaCO_2$ ratio toward normal and mitigate the change in pH (**Table 52-2**). Although the time course of the respiratory compensatory response to metabolic disturbances is rapid, the metabolic compensation for respiratory disturbances is slow. As a result, respiratory disturbances are characterized as acute (minutes to hours in duration), indicating that there has not been sufficient time for metabolic compensation, or chronic (days), indicating that sufficient time for metabolic

compensation has elapsed.

TABLE 52-2 Interpretation of Simple Acid–Base Disorders

Acid–Base Disorder	pH	Primary Disturbances	Compensation
Acidosis			
Respiratory	Decrease	Increase $PaCO_2$	Increase HCO_3^-
Metabolic	Decrease	Decrease HCO_3^-	Decrease $PaCO_2$
Alkalosis			
Respiratory	Increase	Decrease $PaCO_2$	Decrease HCO_3^-
Metabolic	Increase	Increase HCO_3^-	Increase $PaCO_2$

HCO_3^-, bicarbonate; $PaCO_2$, partial pressure of carbon dioxide from arterial blood.

CLINICAL ASSESSMENT OFACID–BASE STATUS

4 A blood gas is measured to determine not only a patient's acid–base status but also their oxygenation. Under normal circumstances, the pH difference between arterial and mixed venous blood is not clinically significant. However, the oxygenation difference between arterial and mixed venous blood is always substantial. Arterial samples are designated with the letter "a" (eg, partial pressure of oxygen from arterial blood [PaO_2] and $PaCO_2$), whereas mixed venous samples are labeled with the letter "v" or not labeled (eg, partial pressure of oxygen from venous blood [PvO_2] and partial pressure of carbon dioxide from venous blood [$PvCO_2$]). The normal values for arterial and venous blood gases are shown in **Table 52-3**. Arterial blood reflects how well the blood is being oxygenated by the lungs (an accurate measurement of PaO_2), whereas venous blood reflects how much oxygen tissues are using. Arterial blood rather than venous blood should be used whenever possible because venous blood obtained from an extremity can provide misleading information. If metabolism in the extremity is altered by hypoperfusion, exercise, infection, or some other cause, the difference in the amount of dissolved oxygen between arterial and venous blood can be dramatic. The venous pH and PCO_2 during cardiopulmonary resuscitation might be significantly lower and higher, respectively, than the arterial pH and arterial PCO_2. This indicates a severe tissue acidosis from CO_2 accumulation caused by hypoperfusion.

TABLE 52-3 Normal Blood Gas Values

	Arterial Blood	Mixed Venous Blood
pH	7.40 (7.35-7.45)	7.38 (7.33-7.43)
PO_2	80-100 mm Hg (10.6-13.3 kPa)	35-40 mm Hg (4.7-5.3 kPa)
SaO_2	95% (0.95)	70-75% (0.70-0.75)
PCO_2	35-45 mm Hg (4.7-6.0 kPa)	45-51 mm Hg (6.0-6.8 kPa)
HCO_3^-	22-26 mEq/L (mmol/L)	24-28 mEq/L (mmol/L)

HCO_3^-, bicarbonate; PCO_2, partial pressure of carbon dioxide; PO_2, partial pressure of oxygen; SaO_2, saturation of arterial oxygen.

Analysis of Arterial Blood Gas Data

ABGs provide an assessment of the patient's acid–base status.[2, 3] Low pH values (less than 7.35) indicate an acidemia, whereas high pH values (more than 7.45) indicate an alkalemia (**Fig. 52-3**). In a metabolic acidosis, the pH is decreased in association with a decreased serum bicarbonate concentration and a compensatory decrease in $PaCO_2$. In a respiratory acidosis while the pH is decreased, the $PaCO_2$ is elevated. The serum bicarbonate concentration is variable, depending on whether it is an acute disturbance (minimal increase in serum bicarbonate) or a chronic respiratory acidosis (substantial increase in serum bicarbonate). In a metabolic alkalosis, the pH is elevated in association with an increased bicarbonate concentration and a compensatory increase in $PaCO_2$. In a respiratory alkalosis, while the pH is also elevated, the $PaCO_2$ is decreased. As with respiratory acidosis, the metabolic compensation is variable: a minimal decrease in serum bicarbonate is often noted in acute respiratory alkalosis while a larger decrease in $[HCO_3^-]$ is common with chronic respiratory alkalosis. Although each measurement has a normal range (see Table 52-3), it is often easiest to consider the midpoint of each range as the normal value. This would correlate to a pH of 7.4, $PaCO_2$ of 40 mm Hg (5.3 kPa), and HCO_3^- of 24 mEq/L (mmol/L). Steps in acid–base interpretation are described in **Table 52-4**.

FIGURE 52-3

Analysis of arterial blood gases. (HCO_3^-, bicarbonate; PCO_2, partial pressure of carbon dioxide.)

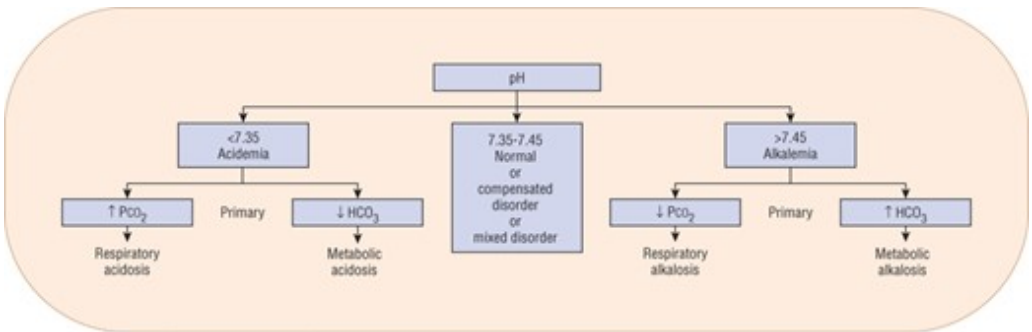


TABLE 52-4 Steps in Acid–Base Diagnosis

1. Obtain ABGs and electrolytes simultaneously
2. Compare $[HCO_3^-]$ on ABG and electrolytes to verify accuracy
3. Calculate SAG
4. Is acidemia (pH <7.35) or alkalemia (pH >7.45) present?

5. Is the primary abnormality respiratory (alteration in $PaCO_2$) or metabolic (alteration in HCO_3)?

6. Estimate compensatory response (Table 52-7)

7. Compare change in $[Cl^-]$ with change in $[Na^+]$

$[Cl^-]$, chloride ion; $[HCO_3^-]$, bicarbonate; $[Na^+]$, sodium ion; $PaCO_2$, partial pressure of carbon dioxide from arterial blood; SAG, serum anion gap.

When ABGs differ significantly from those expected on the basis of the patient's clinical condition and previous laboratory determinations, additional venous blood samples should be drawn to assess plasma electrolyte concentrations. The bicarbonate calculated from the patient's $PaCO_2$ and pH of the blood gas should be compared with the measured total CO_2 content (the amount of CO_2 gas extractable from plasma, consisting of HCO_3^-, H_2CO_3, and PCO_2). Ordinarily, the blood gas bicarbonate value is approximately 1 to 2 mEq/L (mmol/L) less than total CO_2 content.[3] If these values do not correspond, the results should be interpreted with caution because the difference can reflect an error in the blood collection or storage of the sample, or in the calibration of the blood gas analyzer.

METABOLIC ACID–BASE DISORDERS

Metabolic Acidosis

Metabolic acidosis is characterized by a decrease in pH as the result of a primary decrease in serum bicarbonate concentration.

Pathophysiology

Metabolic acidosis can result from the buffering (consumption of HCO_3^-) of an exogenous acid, an organic acid accumulating because of a metabolic disturbance (eg, lactic acid or ketoacids), or the progressive accumulation of endogenous acids secondary to impaired kidney function (eg, phosphates and sulfates).[4,5] The serum HCO_3^- can also be decreased as the result of a loss of bicarbonate-rich body fluids (eg, diarrhea, biliary drainage, or pancreatic fistula) or occur secondary to the rapid administration of non-alkali–containing IV fluids (dilutional acidosis).[4]

The serum anion gap (SAG), as defined below, can be used to infer whether an organic or mineral acidosis is present.

$$SAG = [Na^+] - [Cl^-] - [HCO_3^-]$$

To maintain electroneutrality, the total concentration of cations in the serum must equal the total concentration of anions.

$[Na^+] + [UCs] = ([Cl^-] + [HCO_3^-]) + [UAs]$

The cation concentration is equal to the sodium concentration plus that of "unmeasured" cations (UCs), predominantly magnesium, calcium, and potassium. The anion concentration is equal to the concentrations of chloride, bicarbonate, and "unmeasured" anions (UAs), including proteins, sulfates, phosphates, and organic anions. Therefore, as the result of the combination of the two equations above, the SAG can be expressed as:

$SAG = [UAs] - [UCs]$

The normal SAG is approximately 9 mEq/L (mmol/L), with a range of 3 to 11 mEq/L (mmol/L). This value is lower than the value of 12 mEq/L (mmol/L) cited in the literature in the past because of changes in the instrumentation for measurement of serum electrolytes.[3] Increases in the anion gap (AG) to values in excess of 17 to 20 mEq/L (mmol/L) are indicative of the accumulation of unmeasured anions in ECF.5

These unmeasured anions are generated as the result of the consumption of HCO_3^- by endogenous organic acids such as lactic acid, acetoacetic acid, or β-hydroxybutyric acid or from the ingestion of toxins such as methanol or ethylene glycol. The degree of elevation in the SAG is dependent on the clearance of the anion, as well as the multiple factors that influence HCO_3^- concentrations. Thus, the SAG is a relative rather than an absolute indication of the cause of metabolic acidosis. The SAG can also be elevated in the metabolic acidosis because of kidney disease, as the result of the accumulation of various organic anions, phosphates, and sulfates.

In hyperchloremic metabolic acidosis, bicarbonate losses from the ECF are replaced by chloride, and the SAG remains normal. This decrease in bicarbonate may be due to gastrointestinal (GI) tract losses, dilution of bicarbonate in the ECF as the result of the addition of sodium chloride solutions or chloride-containing acids. Common causes of metabolic acidosis with an increased or a normal SAG are listed in **Table 52-5**.

TABLE 52-5 Common Causes of Metabolic Acidosis

Increased Serum Anion Gap	Normal Serum Anion Gap/Hyperchloremic States
Lactic acidosis	**GI bicarbonate loss**
Lactic acidosis (see Table 52-6)	Diarrhea
	External pancreatic or small bowel drainage (fistula)
Renal failure (acute or chronic)	Ureterosigmoidostomy, ileostomy
Methanol ingestion	**Drugs**
Ethylene glycol ingestion	Cholestyramine (bile acid diarrhea)
Salicylate overdose	Magnesium sulfate (diarrhea)

Increased Serum Anion Gap	Normal Serum Anion Gap/Hyperchloremic States
	Calcium chloride (acidifying agent)
	RTA
	Hypokalemia
	Proximal renal tubular acidosis (type II)
	Distal renal tubular acidosis (type I)
	Carbonic anhydrase inhibitors (eg, acetazolamide)
	Drug-induced hypokalemia
	Amphotericin B
	Furosemide
	Ifosfamide
	Lithium
	Hyperkalemia
Starvation	Generalized distal nephron dysfunction (type IV)
	Mineralocorticoid deficiency or resistance
	Tubulointerstitial disease
	Drug-induced hyperkalemia
	Potassium-sparing diuretics (amiloride, spironolactone, triamterene)
	Trimethoprim
	Pentamidine
	Heparin
	ACE inhibitors and receptor blockers
	NSAIDs
	Cyclosporin A
	Other

Increased Serum Anion Gap	Normal Serum Anion Gap/Hyperchloremic States
	Acid ingestion (ammonium chloride, hydrochloric acid, hyperalimentation)
	Expansion acidosis (rapid saline administration)

ACE, angiotensin converting enzyme; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs; RTA, renal tubular acidosis.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis can result from increased GI bicarbonate loss, renal bicarbonate wasting, impaired renal acid excretion, or exogenous acid gain.[4] GI disorders such as diarrhea, biliary, or pancreatic drainage through either a surgical drain or fistula can result in the loss of large volumes of bicarbonate-containing fluids. Severe diarrhea, the most common cause of hyperchloremic metabolic acidosis, can lead to a daily loss of 5 to 10 L of fluid containing 100 to 140 mEq/L (mmol/L) of sodium, 20 to 40 mEq/L (mmol/L) of potassium, 80 to 100 mEq/L (mmol/L) of chloride, and 30 to 50 mEq/L (mmol/L) of bicarbonate.[4] Patients who have undergone ureteral diversion into the sigmoid colon or isolated ileal loop can also develop a hyperchloremic metabolic acidosis. This is the result of a net loss of bicarbonate, given that chloride is reabsorbed and bicarbonate is secreted by GI epithelial cells in the presence of the urine that is retained in the colon or bowel loop.

Hyperchloremic metabolic acidosis caused by renal bicarbonate wasting is the defining disturbance in proximal renal tubular acidosis (RTA) and is a complication of therapy with carbonic anhydrase inhibitors, particularly when they are administered for more than 24 to 48 hours.[4, 6] During the treatment of diabetic ketoacidosis, renal loss of β-hydroxybutyrate and acetoacetate, which would otherwise be metabolized to yield bicarbonate, can contribute to the development of hyperchloremic metabolic acidosis.[7,8] Impaired renal acid excretion that occurs as a result of distal tubular dysfunction in patients with distal RTAs can also occur in patients with moderate to severe kidney disease from other causes. The metabolic acidosis observed in patients with kidney disease is initially hyperchloremic but can progress to an anion-gap acidosis as kidney disease progresses and sulfates, phosphates, and other anions accumulate.[4] Hyperchloremic metabolic acidosis can also result from the exogenous administration of acid (hydrochloric acid, ammonium chloride) or the unbuffered administration of acid salts from the amino acids in total parenteral nutrition fluids.[9]

Renal Tubular Acidosis

5 Renal tubular disorders can involve the proximal tubule, with a resultant failure to reabsorb filtered bicarbonate, or affect acid excretion in the distal tubule. The distal RTAs are the most common, and are all characterized by impaired net acid excretion. The distal RTAs are subdivided into those that are associated with hypokalemia (type I) and those associated with hyperkalemia (type IV). Type II represents proximal RTA (see further). Type III is extremely rare and will not be discussed.

Patients with classic distal (type I) RTA have impaired hydrogen ion secretion and are unable to excrete the daily acid load necessary to maintain acid–base balance.[4,5] These patients are unable to maximally acidify their urine (ie, attain urine pH less than 5.5), even in the face of an acid challenge. Type I RTA may be the result of a primary tubular defect or develop secondary to a wide variety of disorders including hypercalcemia, multiple myeloma, systemic lupus erythematosus, Sjögren syndrome, sickle-cell disease, and kidney transplant rejection, or following the administration of amphotericin B, ifosfamide or lithium.[10,11] The primary form of this disorder usually occurs in children and can result in severe acidosis, slowed growth, nephrocalcinosis, and kidney stones.[7,9] In adults, clinical complications include osteomalacia, nephrocalcinosis, and recurrent kidney stones. The hypokalemia associated with classic distal (type I) RTA results from secondary hypoaldosteronism associated with volume depletion. The renal potassium wasting decreases considerably if bicarbonate therapy is administered.

The hyperkalemic distal (type IV) RTAs are a heterogeneous group of disorders characterized by hypoaldosteronism or generalized distal tubule defects. The most common form of type IV RTA is hyporeninemic hypoaldosteronism. This syndrome is most commonly associated with diabetic nephropathy, but can also be seen in a variety of other disorders, including chronic interstitial nephritis, sickle-cell disease, human immunodeficiency virus (HIV) nephropathy, and obstructive uropathy. The clinical presentation of this syndrome is often exacerbated by drugs that can interfere with the renin–angiotensin–aldosterone axis, such as β-adrenergic blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and nonsteroidal anti-inflammatory drugs (NSAIDs). Heparin can induce the syndrome by inhibiting adrenal aldosterone biosynthesis. Patients with this form of RTA are able to maximally acidify their urine (urine pH less than 5.5).[10] The primary defect in acid excretion is impaired ammoniagenesis caused by decreased kidney function. Hyperaldosteronism predisposes to the development of hyperkalemia, which results in further impairment of ammoniagenesis. Treatment to control the hyperkalemia is usually sufficient to reverse the metabolic acidosis, and mineralocorticoid replacement is frequently unnecessary.

Hyperkalemic distal (type IV) RTA resulting from generalized distal tubule defects is less common than hyporeninemic hypoaldosteronism but is more common than classic distal (type I) RTA. Patients with this defect have impaired tubular potassium secretion in addition to impaired urinary acidification (urine pH more than 5.5, despite acidemia or acid loading). Urinary obstruction is the most frequent cause of this disorder, which can also be associated with sickle-cell nephropathy, systemic lupus erythematosus, HIV nephropathy, analgesic abuse nephropathy, amyloidosis, kidney transplant rejection, and chronic cyclosporine nephrotoxicity.

Proximal (type II) RTA is characterized by defects in proximal tubular reabsorption of bicarbonate. Normally, more than 85% of filtered bicarbonate is reabsorbed in the proximal tubule. Defects in proximal tubular bicarbonate reabsorption result in increased delivery of bicarbonate to the distal nephron, which has a limited capacity for bicarbonate reabsorption. As a result, at a normal serum bicarbonate concentration, the filtered bicarbonate load is incompletely reabsorbed, and is lost in the urine. As the serum bicarbonate concentration decreases, the filtered load of bicarbonate is proportionately decreased. A new equilibrium is established in which the kidney is able to reabsorb the filtered bicarbonate load, albeit at a reduced serum bicarbonate concentration. Thus, patients

with proximal RTA present with a chronic, nonprogressive hyperchloremic metabolic acidosis. These patients are able to acidify their urine in response to an acid load, but develop bicarbonaturia at a reduced serum bicarbonate concentration following bicarbonate loading. The impaired bicarbonate reabsorption results in salt wasting and secondary hyperaldosteronism. Hypokalemia, which can be severe, usually develops as a result of the hyperaldosteronism and bicarbonaturia.[4,11] Unlike patients with classic distal (type I) RTA, the hyperkalemia if present in proximal RTA is exacerbated by alkali replacement. Proximal RTA can develop as an isolated defect, or it can be associated with generalized proximal tubular dysfunction (Fanconi syndrome), with impaired proximal tubular glucose, phosphate, and amino acid reabsorption. Proximal RTA usually presents as an acquired disorder, secondary to a variety of diseases (amyloidosis, multiple myeloma, or nephrotic syndrome) or exposure to toxins (lead, cadmium, mercury, or outdated tetracyclines). Pharmacologic therapy with carbonic anhydrase inhibitors produces an iatrogenic form of proximal RTA.

Elevated Anion Gap Metabolic Acidosis

Metabolic acidosis with an increased SAG commonly results from increased endogenous organic acid production.[12] In lactic acidosis, lactic acid accumulates as a by-product of anaerobic metabolism.[13] Accumulation of the ketoacids β-hydroxybutyric acid and acetoacetic acid defines the ketoacidosis of uncontrolled diabetes mellitus, alcohol intoxication, and starvation (**Table 52-5**).[8] In advanced kidney disease, accumulation of phosphate, sulfate, and organic anions is responsible for the increased SAG, which is usually less than 24 mEq/L (mmol/L).[2] The severe metabolic acidosis seen in myoglobinuric acute kidney injury caused by rhabdomyolysis may be caused by the metabolism of large amounts of sulfur-containing amino acids released from myoglobin.

The presence of mild elevations in the SAG cannot be automatically attributed to the presence of a high SAG metabolic acidosis. Elevations in the SAG are commonly seen in hospitalized patients, especially those who are critically ill.[14] A variety of factors can contribute to this nonspecific elevation in the SAG, including the presence of alkalemia, which increases the anionic charge of albumin and other plasma proteins. The usefulness of the SAG as a marker of acid–base status is dependent on proper interpretation of a patient's clinical status.[5,11] Despite these limitations, when the SAG exceeds 20 to 25 mEq/L (mmol/L) a significant organic acidosis is likely to be present.[12,13,14]

High anion gap metabolic acidosis can develop in many clinical settings, including uncontrolled diabetes mellitus (see Chapter 74), alcohol intoxication (see Chapters 37 and 66), and starvation (see Chapter 64).[8,10,15] Toxic ingestions of methanol and ethylene glycol are also associated with high anion gap metabolic acidosis and can be differentiated from other causes of SAG because of the presence of an elevated osmolar gap.[15] The mechanisms responsible for the development of acidosis in these settings are diverse.[14]

Lactic Acidosis

Lactic acidosis is one of the most common causes of high SAG metabolic acidosis and can impact approximately 1% of hospitalized patients. Lactic acid is the end product of anaerobic metabolism of

glucose (glycolysis).[13] In normal individuals, lactic acid derived from pyruvate enters the circulation in small amounts and is promptly removed by the liver. In the liver, and to a lesser extent in the kidney, lactic acid is reoxidized to pyruvic acid, which is then metabolized to CO_2 and H_2O. The normal plasma lactate concentration in healthy subjects is approximately 1 mEq/L (mmol/L).[1,2,13] The diagnosis of lactic acidosis should be considered in all patients with metabolic acidosis associated with an increased SAG. Lactic acidosis is considered to be present when lactate concentrations exceed 4 to 5 mEq/L (mmol/L) in an acidemic patient.

Classically, lactic acidosis has been differentiated into disorders associated with tissue hypoxia (type A lactic acidosis) and disorders associated with deranged oxidative metabolism (type B lactic acidosis), although the distinction between them is blurred (**Table 52-6**).[13] The etiologies of lactic acidosis can also be categorized on the basis of changes in lactate production and/or utilization.[7,12] Metabolic disturbances can result in increased tissue pyruvate production or impaired utilization, with proportional increases in lactate concentrations. Increased lactate production is more commonly associated with alterations in tissue redox state, resulting in preferential conversion of pyruvate to lactate. During anaerobic metabolism, reduced nicotinamide adenine dinucleotide accumulates, driving the conversion of pyruvate to lactate and increasing the lactate-to-pyruvate ratio. States of enhanced metabolic activity (eg, grand mal seizures, strenuous exercise, or hyperthermia), decreased tissue oxygen delivery (eg, severe anemia, hypoxia, circulatory shock, or carbon monoxide poisoning), or impaired oxygen utilization (eg, cyanide toxicity) all are associated with lactic acidosis. Impaired hepatic clearance of lactate, as seen in hypoperfusion states, liver failure, and alcohol intoxication, can also result in lactic acidosis.

TABLE 52-6 Causes of Lactic Acidosis

Primary decrease in tissue oxygenation
Shock
Severe anemia
Congestive heart failure
Asphyxia
Carbon monoxide poisoning
Deranged oxidative metabolism
Medications
Catecholamines
Linezolid
Metformin
Nalidixic acid

NRTIs (abacavir, lamivudine, tenofovir)

Overdose (iron, isoniazid, salicylates, theophylline)

Propofol infusion syndrome

Propylene glycol toxicity (IV lorazepam, IV pentobarbital)

Sodium nitroprusside (secondary to cyanide toxicity)

Streptozocin

Diabetes mellitus

Malignancy

Seizures

Methanol, ethanol, or ethylene glycol

Disorders associated with inborn errors of metabolism

Cardiovascular and septic shock, with resultant tissue hypoperfusion, are the most common causes of lactic acidosis.[13] Poor tissue perfusion and hypoxia influence enzymatic pyruvate and lactate metabolism to stimulate anaerobic glycolysis and to decrease lactate utilization. This leads to hyperlactatemia and lactic acidosis. The mortality rate of this type of lactic acidosis can be as high as 80% and correlates with the degree of hyperlactatemia.

Lactic acidosis associated with liver disease, toxins, and congenital enzyme deficiency can be caused by deranged oxidative metabolism or impaired lactate clearance.[2,3,4,13,15] The exact role of diabetes mellitus in the induction of lactic acidosis is not clear.[7,8] It may involve a decrease in pyruvate dehydrogenase activity, the enzyme responsible for pyruvate metabolism. Lactic acidosis in neoplastic disease is uncommon and reported mostly in patients with myeloproliferative disorders. Leukocytes and neoplastic cells in general have high rates of glycolysis. In the case of a large tumor or tightly packed bone marrow, oxygenation can be decreased, favoring the accumulation of lactate. Lactic acidosis has been reported in patients with massive liver tumors, and it has been postulated that the liver uptake of lactate is decreased in these patients. Lactic acidosis associated with seizures is usually transient and occurs because of excessive muscle activity.[13]

A number of medications can cause lactic acidosis.[9,10,13,16,17,18,19,20,21,22,23] Two of the most common medications associated with the development of lactic acidosis are nucleoside-analog reverse transcriptase inhibitors (NRTIs) (3.9 cases per 1,000 person-years) and metformin (0.03 cases per 1,000 person-years).[16,17] The proposed mechanism of NRTI-induced lactic acidosis is the inhibition of the enzyme DNA polymerase gamma that is responsible for mitochondrial DNA synthesis.[16] Disruption of this enzyme can inhibit the transport of lactate into the mitochondria, leading to an accumulation in the cytoplasm. Stavudine is the NRTI most frequently associated with

lactic acidosis; however, the combination of stavudine and didanosine confers the highest risk. Lactic acidosis has been rarely reported with tenofovir, lamiduvine and abacavir.

The primary suspected mechanism for metformin-induced lactic acidosis is inhibition of liver gluconeogenesis as the result of its inhibitory effects on pyruvate carboxylase, which is necessary for the conversion of pyruvate to glucose.[7,17,18] Other possible pathways for metformin-associated lactic acidosis include a decrease in both hepatic intracellular pH and cardiac output, an increase in lactate production in the gut, and increased renal loss of bicarbonate.[7,17,18] Risk factors for metformin-induced lactic acidosis include impaired kidney function, liver disease, dehydration, advanced age, alcohol consumption, and supratherapeutic dosing. Metformin should be discontinued during periods of tissue hypoxia (eg, myocardial infarction, sepsis), for 3 days after contrast media has been administered or 2 days before general anesthesia administration. In the latter two cases, metformin should only be reinstituted when the patient's kidney function is stable.

Linezolid inpairs mitcochondrial function and has been rarely reported to cause lactic acidosis, usually after prolonged (more than or equal to 4 weeks) therapy.[19] The weight loss combination medication phentermine-topiramate (Qysmia®) has been reported to cause lactic acidosis.[20]

Propylene glycol is commonly used as a solubilizing agent in IV drug preparations (eg, lorazepam, pentobarbital) and is predominantly metabolized to lactic acid via the hepatic enzyme alcohol dehydrogenase.[21,22] The administration of large doses of propylene glycol, particularly to patients with impaired kidney or liver function, can lead to a lactic acidosis with an osmolar gap. Thus, serial measurement of the osmolar gap can be used to detect propylene glycol accumulation.[21, 22]

Reports of the association between propofol and lactic acidosis were initially described in children.[23] This association is now recognized in adults and has come to be known as the propofol-related infusion syndrome. In addition to lactic acidosis, cardiac failure, rhabdomyolysis, and acute kidney injury have been observed primarily because of uncoupling of oxidative phosphorylation and impaired oxidation of free fatty acids. This syndrome is most frequently seen in patients receiving propofol at high doses (more than 5 mg/kg/h) for more than 2 days.

Clinical Presentation

Chronic metabolic acidosis is usually not associated with severe acidemia and is relatively asymptomatic. The major manifestations are bone demineralization with the development of rickets in children and osteomalacia and osteopenia in adults.[4,24] In infants and children, chronic metabolic acidosis is associated with growth failure and short stature and can be associated with nonspecific symptoms including anorexia, nausea, weight loss, and muscle weakness.

Severe metabolic acidosis is usually associated with acute processes. The manifestations of severe acidemia (pH less than 7.20) involve the cardiovascular, respiratory, and central nervous system (CNS). Hyperventilation is often the first sign of metabolic acidosis. At a pH of 7.2, pulmonary ventilation increases approximately fourfold, and an eightfold increase has been noted at a pH of 7.[3,25] Respiratory compensation can occur as Kussmaul respirations— the deep, rapid respirations

seen commonly in patients with diabetic ketoacidosis. In extremely severe acidosis (pH less than 6.8), CNS function is disrupted to such a degree that the respiratory center is depressed.

CNS depression correlates more closely with spinal fluid pH than with blood pH. For this reason, neurologic symptoms tend to occur more frequently and to a greater degree in patients with respiratory acidosis because the CO_2 accumulated in the respiratory form readily crosses the blood–brain barrier to cause acidosis in the CNS.[4] Because of the slow penetration of administered bicarbonate into the CNS, the CNS pH fails to normalize as rapidly as blood pH. Therefore patients continue to hyperventilate because of sustained CNS acidity, and severe respiratory alkalosis can occur. Sustained lowering of the $PaCO_2$ within 12 to 36 hours is to be anticipated during the correction of any metabolic acidosis.[4]

Systemic acidosis can cause peripheral arteriolar dilatation, characterized by flushing, a rapid heart rate, and wide pulse pressure. Initially, cardiac output can be increased, but as acidosis becomes more severe, myocardial contractility becomes impaired, and cardiac output decreases. The effects of vagal stimulation are also enhanced at pH levels lower than 7.1, probably as a consequence of inhibition of acetylcholinesterase. This increases the danger of vagally mediated bradycardia and heart block during acidosis.

GI symptoms of metabolic acidosis include loss of appetite, nausea, and vomiting. Severe acidosis (pH less than 7.1) interferes with carbohydrate metabolism and insulin utilization, and results in hyperglycemia. Metabolic acidosis alters potassium homeostasis and contributes to the development of hyperkalemia. The magnitude of the effect on serum potassium depends on the type of acidosis: Acidosis caused by mineral acids (eg, hydrochloric acid) is associated with a greater change in potassium levels than acidosis caused by organic acids (eg, lactic acidosis), in which the increase in potassium attributable to the acidosis per se is minimal.

Compensation

6 The patient's primary means to compensate for metabolic acidosis is to increase carbon dioxide excretion by increasing the respiratory rate. This results in a decrease in $PaCO_2$. This ventilatory compensation results from stimulation of the respiratory center by changes in cerebral bicarbonate concentration and pH.[1,25] For every 1-mEq/L (mmol/L) decrease in bicarbonate concentration below the average of 24, the $PaCO_2$ decreases by approximately 1 to 1.5 mm Hg (0.13-0.20 kPa) from the normal value of 40 (5.3 kPa) (**Table 52-7**).

TABLE 52-7 Guidelines for Initial Interpretation of Acid–Base Disorders

Acidosis	
Metabolic	$PaCO_2$ (in mm Hg) should decrease by 1.3 times the fall in plasma [HCO_3^-] (in mEq/L or mmol/L)
Acute respiratory	The plasma [HCO_3^-] should increase by 0.1 times the increase in $PaCO_2$ ± 3 (in mm Hg)

Chronic respiratory	The plasma [HCO_3^-] should increase by 0.35 times the increase in $PaCO_2$ ± 4 (in mm Hg)
Alkalosis	
Metabolic	$PaCO_2$ (in mm Hg) should increase by 0.4-0.6 times the rise in plasma [HCO_3^-] (in mEq/L or mmol/L)
Acute respiratory	The plasma [HCO_3^-] should decrease by 0.2 times the decrease in $PaCO_2$ (in mm Hg), but usually not to < 18 mEq/L (mmol/L)
Chronic respiratory	The plasma [HCO_3^-] should fall by 0.35 times the decrease in $PaCO_2$ (in mm Hg), but usually not to < 14 mEq/L (mmol/L)

HCO_3^-, bicarbonate; $PaCO_2$, partial pressure of carbon dioxide from arterial blood.

The anticipated $PaCO_2$ associated with a given bicarbonate concentration for patients with uncomplicated metabolic acidosis can be calculated as:[25]

$$PaCO_2 = (1.5 \times [HCO_3^-] + 8) \pm 2 \text{ for } PaCO_2 \text{ in mm Hg}$$

$$(PaCO_2 = (0.2 \times [HCO_3^-] + 1.1) \pm 0.3 \text{ for } PaCO_2 \text{ in kPa})$$

For example, 95% of patients with a plasma bicarbonate of 16 mEq/L (mmol/L) should have an arterial PCO_2 of 30 to 34 mm Hg (4.0-4.5 kPa). An observed arterial PCO_2 within this range is consistent with physiologic respiratory compensation for a metabolic acidosis and suggests that there is no respiratory disturbance. In contrast, if the PCO_2 is less than 30 mm Hg (4.0 kPa), a superimposed respiratory alkalosis can be present, whereas if the PCO_2 is greater than 34 mm Hg (4.5 kPa), a superimposed respiratory acidosis is likely present.

CLINICAL PRESENTATION Metabolic Acidosis General

- The patient usually is relatively asymptomatic if the acidosis is acute and mild. In those with severe acidemia (pH less than 7.15-7.20), the cardiovascular, respiratory, and CNS systems can be affected.

Symptoms

- The patient may complain of loss of appetite, nausea, and vomiting.

Signs

- Cardiac: Flushing, a rapid heart rate, wide pulse pressure, and an increase in cardiac output can be seen initially. This can be followed by a reduction in cardiac output, blood pressure, and liver and kidney blood flow.
- Cerebral: Obtundation or coma.
- Metabolic: Insulin resistance; increased protein degradation; increased metabolic demands.

- GI: Nausea, vomiting, loss of appetite.
- Respiratory: Dyspnea, hyperventilation with deep, rapid respirations is seen in those with severe acidosis.
- Chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteopenia in adults.

Laboratory Tests

- Serum CO_2 is low. Hyperglycemia and hyperkalemia are common. Patients with a pH of less than 7.2 are deemed to have a severe acidosis.

TREATMENT

7 Asymptomatic patients with mild to moderate degrees of acidemia (plasma bicarbonate of 12-20 mEq/L [mmol/L]; pH 7.2-7.4) do not require emergent therapy. They can usually be managed with gradual correction of the acidemia, over a period of days to weeks, using oral sodium bicarbonate or other alkali preparations (**Table 52-8**). In all forms of chronic metabolic acidosis, primary therapy should be directed at treating the underlying disease state. GI pathology should be treated to reduce ongoing bicarbonate losses, and factors that exacerbate RTA should be treated. If acidemia persists, alkali therapy should be instituted with the goal of normalization of blood pH. The loading dose (LD) of alkali to initially correct the acidemia can be calculated as follows:

$$\text{LD (mEq or mmol/L)} = (V_D\ HCO_3^- \times \text{body weight [BW]}) \times (\text{desired } [HCO_3^-] - \text{current } [HCO_3^-])$$

where V_D is the volume of distribution of bicarbonate.[4]

TABLE 52-8 Therapeutic Alternatives for Oral Alkali Replacement

Generic Name	Trade Name(s)	Milliequivalents of Alkali	Dosage Form(s)	Comment
Shohl's solution (sodium citrate/citric acid)	Bicitra (Willen)	1 mEq Na/mL; equivalent to 1 mEq bicarbonate	Solution (500 mg Na citrate, 334 mg citric acid/5 mL)	Citrate preparations increase absorption of aluminum
Sodium bicarbonate	Various (eg, Sodamint)	3.9 mEq bicarbonate/tablet (325 mg)	325 mg tablet	Bicarbonate preparations can cause bloating because of CO_2 production
		7.8 mEq bicarbonate/tablet (650 mg)	650 mg tablet	

Generic Name	Trade Name(s)	Milliequivalents of Alkali	Dosage Form(s)	Comment
	Baking soda (various)	60 mEq bicarbonate/tsp (5 g/tsp)	Powder	
Potassium citrate	Urocit-K (Mission)	5 mEq citrate/tablet	5 mEq tablet	See above
Potassium bicarbonate/potassium citrate	K-Lyte (Bristol)	25 mEq bicarbonate/tablet	25 mEq tablet (effervescent)	
	K-Lyte DS (Bristol)	50 mEq bicarbonate/tablet (double strength)	50 mEq tablet (effervescent)	See above
Potassium citrate/citric acid	Polycitra-K (Willen)	2 mEq K/mL; equivalent to 2 mEq bicarbonate	Solution (1,100 mg K citrate, 334 mg citric acid/5 mL)	See above
		30 mEq bicarbonate/unit dose packet	Crystals for reconstitution (3,300 mg K citrate, 1,002 mg citric acid/unit dose packet)	
Sodium citrate/potassium citrate/citric acid	Polycitra (Willen) Polycitra-LC (Willen)	1 mEq K, 1 mEq Na/mL; equivalent to 2 mEq bicarbonate	Syrup (Polycitra) solution (Polycitra-LC) (Both contain 550 mg K citrate, 500 mg Na citrate, 334 mg citric acid/5 mL)	See above

For a 60-kg patient with a serum bicarbonate of 15 mEq/L (mmol/L), the LD is calculated thus:

$$\begin{aligned}\text{LD (mEq)} &= (0.5\ \text{L/kg} \times 60\ \text{kg}) \times (24\ \text{mEq/L} - 15\ \text{mEq/L}) \\ &= 30\ \text{L} \times 9\ \text{mEq/L} \\ &= 270\ \text{mEq/L (mmol/L)}\end{aligned}$$

The calculated LD of alkali should be administered over several days to avoid volume overload from the accompanying sodium load. For this scenario, a regimen of 60 to 70 mEq (mmol) three times a day for 3 to 5 days should result in an increase in HCO_3^- levels toward normal. In addition to the calculated LD, supplemental alkali must also be provided to replace ongoing losses, which can be approximated to be 2 mEq/kg (mmol/kg) per day or 40 mEq (mmol) three times a day. In patients with associated volume depletion, bicarbonate replacement can be provided simultaneous with volume resuscitation by substituting bicarbonate for chloride in IV crystalloid solutions.

In patients with chronic metabolic acidosis because of GI bicarbonate losses, maintenance therapy

should provide sufficient alkali to replace ongoing bicarbonate losses. The magnitude of this replacement is variable and can be substantial (more than 10 mEq/kg [mmol/kg] per day). In addition, associated losses of other electrolytes, such as potassium and magnesium, may need to be replaced (see Chapter 51).

Proximal (type II) RTA is a bicarbonate-wasting disorder that requires the administration of large maintenance doses of alkali (10-15 mEq/kg [mmol/kg] per day). As alkali replacement raises the serum bicarbonate concentration toward normal, the proximal tubule's capacity to reabsorb bicarbonate is overwhelmed, and renal bicarbonate wasting increases. In children, aggressive therapy of proximal RTA is necessary to avoid growth retardation and osteopenia. Because this is generally a mild, nonprogressive acidosis in adults, the benefit of alkali therapy is frequently outweighed by the risks of increased potassium wasting. In patients with classic distal (type I) RTA, maintenance therapy usually requires only enough alkali to buffer the amount of acid generated from dietary intake and metabolism. This usually approximates 1 to 3 mEq/kg per day (mmol/kg per day).

8 After initial potassium deficits are replaced, ongoing potassium supplementation may not be required, as renal potassium losses decrease following initiation of appropriate alkali therapy. The use of potassium alkali salts can, however, be desirable in patients with associated nephrolithiasis, because sodium salts can increase urinary calcium excretion.

The metabolic acidosis associated with hyperkalemic distal (type IV) RTA with hyporeninemic-hypoaldosteronemia that is often seen in patients with diabetes mellitus can be corrected by the treatment of hyperkalemia alone (see Chapter 51). The use of supplemental alkali (1-2 mEq/kg [mmol/kg] per day) to increase sodium intake and stimulate distal tubular potassium secretion can be beneficial. A minority of patients require the administration of pharmacologic amounts of fludrocortisone.[4] Type IV RTA resulting from a generalized distal tubular disorder often responds to low doses of alkali (1.5-2.0 mEq/kg [mmol/kg] per day).[4,11] Corrections of the acidosis along with modest dietary potassium restriction (to 1 mEq/kg [mmol/kg] per day) will often result in the maintenance of serum potassium concentrations of 5 mEq/L (mmol/L) or less.

Acute Severe Metabolic Acidosis

9 The management of life-threatening acute metabolic acidosis (plasma bicarbonate of 8 mEq/L [mmol/L] and pH less than 7.20) is dependent on the underlying cause and the patient's cardiovascular status. In some cases, patients will require emergent hemodialysis therapy (see Chapter 45). Patients with hyperchloremic acidosis (eg, diarrhea-induced) are unable to regenerate bicarbonate, and the generation of new bicarbonate by the kidneys can require several days before one can observe a meaningful change in their status.[4] Thus IV alkali therapy is often required for these patients.

Although conventional wisdom recommends the use of alkali replacement in patients with severe acidemia because of the deleterious effects of acidemia on circulatory function,[2,4,7,8] studies have not demonstrated that its administration improves patient outcomes.[26,27] Alkali therapies may either improve or worsen clinically relevant endpoints such as $[H^+]$, $Paco_2$, lactate concentrations, and

cardiac output. The specific patient populations most likely to benefit or be harmed from alkalinizing therapy are presented in **Table 52-9**.

TABLE 52-9 Patient Populations Likely to Benefit or Suffer from Alkalinizing Therapy

Patients with Potential for Benefit	Patients with Potential for Harm
Distal (type 1) renal tubular acidosis	Hypernatremia
Severe hypochloremic metabolic acidosis secondary to diarrhea or surgical diversion	Hypervolemia
	Acute renal failure
	Congestive heart failure
Specific poisonings and intoxications (eg, salicylate overdose with metabolic acidosis)	Pulmonary disease resulting in decreased ventilation
	Acute lung injury where lung-protective ventilation strategy is used
	Diabetic ketoacidosis

There are several therapeutic alternatives available for the acute correction of severe metabolic acidosis. Sodium acetate, sodium citrate, and sodium lactate are unreliable sources of alkali because their alkalinizing effect is dependent on their oxidative conversion to bicarbonate by the liver. This process is often impaired in critically ill patients, especially those with hepatic disease or circulatory failure. Although sodium bicarbonate is the most widely used IV alkalotic agent,[4] several studies suggest that it is frequently ineffective and can actually be deleterious, especially in patients with lactic acidosis.[27,28] Among the two remaining alternatives, (Dichloroacetate [DCA]) is investigational and not available in most clinical settings. Tromethamine, or THAM, is a carbon dioxide—consuming, commercially available solution that buffers respiratory as well as metabolic acids.

Clinical Controversy…

The role of alkali therapy in patients with severe lactic acidosis is controversial. Treatment should be directed at the underlying causes as serial bicarbonate administration is often not effective and in some settings can be deleterious.

Sodium Bicarbonate

While sodium bicarbonate administration provides fluid and electrolyte replacement and increases arterial pH, neither animal nor clinical studies demonstrate an improvement in cardiac function, organ perfusion, or intracellular pH.[8,26,27,28,29,30] In addition, sodium bicarbonate administration can actually have paradoxical adverse effects on intracellular pH. When bicarbonate is given by IV infusion, the carbon dioxide generated diffuses more readily than bicarbonate across cell membranes and into cerebrospinal fluid. Therefore, the intracellular pH can actually be decreased by administration of bicarbonate.[4,28,31,32]

Excessive sodium bicarbonate administration can result in (a) a shift of the oxyhemoglobin saturation

curve to the left, thereby impairing oxygen release from hemoglobin to tissues; (b) sodium and water overload, with subsequent pulmonary congestion and hypernatremia; (c) paradoxical tissue acidosis as a result of the production of CO_2 that freely diffuses into myocardial and cerebral cells[32]; and (d) decreased ionized calcium with a resultant decrease in myocardial contractility. If there is an endogenous source of bicarbonate, such as can occur in the case of ketoacidosis or lactic acidosis, a bicarbonate "overshoot" can develop because the ketoacids (acetoacetic acid and β-hydroxybutyric acid) or lactic acid are converted in the liver to bicarbonate once the underlying cause of acidosis is corrected.[7,8,13] Alkalosis can also result if too much sodium bicarbonate is administered too quickly.

If IV sodium bicarbonate is used, one must be mindful that the goals are to increase, not normalize, pH (to approximately 7.20) and plasma bicarbonate (to 8-10 mEq/L [mmol/L]). There is no calculative method that will assure attainment of these goals with a given dose of sodium bicarbonate because of the multiplicity of competing processes that can affect acid–base status (eg, vomiting, potential increases in endogenous acid production, and kidney disease) and the marked variability in the volume of distribution of bicarbonate (50% of body weight in patients with mild acidosis to approximately 100% in those with severe acidosis).[4,30,31] The dose of sodium bicarbonate may be calculated using a distribution volume of 50% of body weight for all patients to avoid overtreatment.[31] The total dose calculated as described previously in the RTA section should be administered as an infusion over one-half to several hours. Follow-up monitoring of ABGs, beginning no sooner than 30 minutes after the end of the infusion, should be used to guide further therapeutic decisions.

Clinical Controversy…

Although it has been recommended that sodium bicarbonate be administered to raise the arterial pH to approximately 7.20, in an effort to prevent complications such as ventricular tachyarrhythmia, there are no controlled clinical trials demonstrating that sodium bicarbonate administration is significantly better than general supportive care in reducing morbidity and mortality in these patients.[5, 8, 27, 28]

Bicarbonate therapy is generally not necessary for patients with cardiac arrest, even if the initial arrest was unmonitored. The American Heart Association's Advanced Cardiac Life Support (ACLS) provider manual states that sodium bicarbonate is not useful or effective during resuscitation in hypoxic patients with lactic acidosis.[30] Additionally, sodium bicarbonate is considered to be not useful or effective in those who are undergoing prolonged resuscitation with effective ventilation.[4,29] Furthermore, if sodium bicarbonate is used, it should be used only after defibrillation, cardiac compression, support of ventilation including intubation, and drug therapies such as epinephrine and antiarrhythmic agents have been employed.[30] The initial dose of sodium bicarbonate in this situation is (1 mEq/kg [mmol/kg]) administered by rapid, direct IV injection.[30] Subsequent doses of sodium bicarbonate should be based on measurements of arterial blood pH and $Paco_2$ given the propensity for it to cause alkalemia.[28,29]

Tromethamine

THAM, available as a 0.3 N solution, is a highly alkaline, sodium-free organic amine that acts as a proton acceptor to prevent or correct acidosis.[4,33] THAM combines with hydrogen ions from carbonic acid to form bicarbonate and a cationic buffer. THAM also acts as an osmotic diuretic to increase urine flow, urine pH, and the excretion of fixed acids, CO_2, and electrolytes. At pH 7.4, 30% of THAM is not ionized and therefore can penetrate into cells and neutralize acidic anions of the intracellular fluid. Intracellular pH increases have been noted within 1 hour after the infusion of THAM. There is, however, no clinical or physiologic evidence that this action is beneficial, or that THAM is more efficacious than sodium bicarbonate.[31,33]

When THAM is used, it must be administered slowly, with careful monitoring to avoid alkalosis. The usual empiric dosage range for THAM is 1 to 5 mmol/kg administered IV over 1 hour, but doses up to 1.25 mmol/kg can be given over 5 to 15 minutes in acute situations. The dose of THAM can be individualized using the following equation[31]:

Dose of THAM (in mL) = 1.1 × BW (in kg) × base deficit

where base deficit = normal [HCO_3^-] – current [HCO_3^-].

The need for additional THAM is determined by serial measurements of the serum bicarbonate concentration and calculation of the base deficit. Large doses can cause respiratory depression as a result of an increase in blood pH and a decrease in $PaCO_2$ concentration.[31] THAM solution is highly alkaline and can cause severe inflammation, vascular spasm, or tissue damage (necrosis, sloughing, pain, chemical phlebitis, or thrombosis) if infiltration occurs. Hyperkalemia, hypoglycemia, hypocalcemia, and impaired coagulation have also been reported.[31] This agent should only be used with extreme caution in patients with severe liver or kidney failure.

Dichloroacetate

DCA, another investigational agent, facilitates aerobic lactate metabolism by stimulating the activity of lactate dehydrogenase, thus reversing hyperlactatemia and elevating blood pH.[34,35,36,37] DCA, when compared to conventional management in controlled studies, however, has not been shown to improve hemodynamic parameters or clinical outcomes.[34,35,36,37] DCA can cause mild drowsiness and peripheral neuropathy that can be ameliorated or prevented with thiamine supplementation.[31] The future role of DCA in the management of metabolic acidosis, particularly lactic acidosis, remains to be clarified.[13]

Metabolic Alkalosis

Pathophysiology

Metabolic alkalosis is a simple acid–base disorder that presents as alkalemia (increased arterial pH) with an increase in plasma bicarbonate.[1,2] It is an extremely common entity in hospitalized patients with acid–base disturbances. Under normal circumstances, the kidney is readily able to excrete an alkali load. Thus evaluation of patients with metabolic alkalosis must consider two separate issues: (a)

the initial process that generates the metabolic alkalosis; and (b) alterations in kidney function that maintain the alkalemic state.[38,39]

10 The generation of metabolic alkalosis can also result from excessive losses of hydrogen ions from the kidneys or stomach or from a gain secondary to the ingestion or administration of bicarbonate-rich fluids. Gastric juice, rich in chloride and hydrogen ions, is secreted at a rate of less than 50 mL/h in the basal state, but can increase up to fivefold with stimulation.[3] In the gastric parietal cells, the hydrogen ion and bicarbonate are generated from CO_2 and water.[3,39] The hydrogen ion is secreted into gastric fluid, and the bicarbonate is retained in the ECF. Normally, an amount of bicarbonate equal to the bicarbonate generated in the stomach is eliminated in the alkaline pancreatic and small-bowel secretions, maintaining hydrogen ion balance. With vomiting and nasogastric suctioning, the hydrogen ion is lost externally and metabolic alkalosis results. Diarrhea, as seen with secretory villous adenomas and other secretory diarrheas, often results in excessive GI losses of chloride-rich, bicarbonate-poor fluid, and thus leads to the generation of metabolic alkalosis.

11 Diuretic agents acting on the thick ascending limb of the loop of Henle (eg, furosemide, bumetanide, and torsemide) and distal convoluted tubule (eg, thiazides) have most commonly been associated with the generation of metabolic alkalosis.[3,40] These agents promote the excretion of sodium and potassium almost exclusively in association with chloride, without a proportionate increase in bicarbonate excretion. Collecting duct hydrogen ion secretion is stimulated directly by the increased luminal flow rate and sodium delivery, and indirectly by intravascular volume contraction, which results in secondary hyperaldosteronism. Renal ammoniagenesis can also be stimulated by concomitant hypokalemia, further augmenting net acid excretion.

Increased renal acid excretion can also be the result of excess mineralocorticoid activity. Elevated mineralocorticoid levels directly stimulate collecting duct hydrogen ion secretion and indirectly increase ammoniagenesis by causing hypokalemia.[1,3,38,41] Increased mineralocorticoid activity can result from Cushing syndrome, primary hyperaldosteronism, or hyperaldosteronism secondary to increased renin activity (eg, malignant hypertension). In Bartter and Gitelman syndromes, defects in sodium transport in the loop of Henle (Bartter) or distal convoluted tubule (Gitelman) lead to hypokalemia, secondary hyperaldosteronism, and metabolic alkalosis.[41] In Liddle syndrome, enhanced sodium reabsorption by the cortical collecting duct epithelial sodium channel results in a syndrome of pseudohyperaldosteronism.[38,39] Administration of high doses of penicillins (eg, ticarcillin) can produce metabolic alkalosis because they act as nonreabsorbable anions.[10] High concentrations of poorly reabsorbable anions in the distal renal tubule increase luminal flow rate and luminal electronegativity, which enhances the secretion of potassium and hydrogen ions and results in hypokalemia and metabolic alkalosis.

Metabolic alkalosis can also be generated by the gain of exogenous alkali. This can be seen as a result of bicarbonate administration or from the infusion of organic anions that are metabolized to bicarbonate, such as acetate, lactate, and citrate. The milk-alkali syndrome was historically a common cause of metabolic alkalosis in patients with peptic ulcer disease secondary to the ingestion of large

quantities of milk products and antacids. With the advent of alternative therapies for dyspeptic syndromes that are far more effective than milk, this syndrome is now rarely seen.

Metabolic alkalosis is predominantly maintained because of an abnormality in kidney function. Normally, the kidneys are capable of excreting all of the excess bicarbonate presented to them, even during periods of increased bicarbonate loads.[2] As the serum bicarbonate concentration increases, the filtered bicarbonate load exceeds the maximal rate for bicarbonate reabsorption, and the excess bicarbonate is excreted in the urine. Under normal circumstances, the excess bicarbonate is rapidly excreted, and metabolic alkalosis does not occur or is corrected in a matter of hours.[38]

12 Bicarbonate excretion becomes impaired via several mechanisms, which collectively contribute to the maintenance phase of metabolic alkalosis.[38] In general, these mechanisms can be divided into volume-mediated processes (sodium chloride-responsive) and volume-independent processes (sodium chloride-resistant) that are predominantly associated with excess mineralocorticoid activity and hypokalemia (**Table 52-10**).[1,3] Intravascular volume depletion perpetuates metabolic alkalosis a number of different ways. A decrease in the glomerular filtration rate reduces the filtered load of bicarbonate at any given serum concentration, thereby decreasing the kidney's ability to excrete a bicarbonate load. Although this can play a role in patients with chronic kidney disease, it is also an important factor in patients in whom intravascular volume contraction accompanies metabolic alkalosis. Decreased effective arterial blood volume also enhances proximal and distal tubular sodium reabsorption. Sodium reabsorption must be coupled with reabsorption of an anion, such as chloride or bicarbonate, or exchange with a cation, such as potassium or hydrogen, to maintain charge neutrality. In the proximal tubule, increased sodium reabsorption stimulates bicarbonate reabsorption. In the distal nephron, enhanced sodium reabsorption, particularly in the setting of hypokalemia, stimulates hydrogen ion secretion.

TABLE 52-10 Causes of Metabolic Alkalosis Differentiated on the Basis of Their Responsiveness to Sodium Chloride

Sodium chloride-responsive (urinary chloride concentration <10 mEq/L [mmol/L])
GI disorders
Vomiting
Gastric drainage
Villous adenoma of the colon
Chloride diarrhea
Diuretic therapy
Correction of chronic hypercapnia
Cystic fibrosis

Excessive bicarbonate therapy of an organic acidosis

Mild/moderate potassium deficiency

Sodium chloride-resistant (urinary chloride concentration >20 mEq/L [mmol/L])

Excess mineralocorticoid activity

Hyperaldosteronism

Cushing syndrome

Bartter syndrome

Gitelman syndrome

Excessive black licorice intake

Profound potassium depletion

Magnesium deficiency

Liddle syndrome

Estrogen therapy

Unclassified

Alkali administration

Milk-alkali syndrome

Massive blood or plasma protein fraction transfusion

Nonparathyroid hypercalcemia

Carbohydrate refeeding after starvation

Large doses of penicillin

Mineralocorticoid excess also plays a significant role in the maintenance of metabolic alkalosis. In patients with volume-responsive metabolic alkalosis, intravascular volume depletion stimulates aldosterone secretion. As discussed earlier, excess mineralocorticoid activity can also underlie the generation of metabolic alkalosis. In either situation, the increased mineralocorticoid effect stimulates collecting duct hydrogen ion secretion. Metabolic alkalosis can also be maintained by persistent hypokalemia, enhancing proximal tubular bicarbonate reabsorption, stimulating ammoniagenesis, and increasing distal tubular hydrogen ion secretion.[38]

Clinical Presentation

There are no unique signs or symptoms associated with mild-to- moderate metabolic alkalosis, but patients may complain of symptoms related to the underlying cause of the disorder (eg, muscle weakness with hypokalemia or postural dizziness with volume depletion).[38,39] They may have a history of vomiting, gastric drainage, or diuretic use, all of which contribute to the development of metabolic alkalosis. Severe alkalemia (blood pH more than 7.60) has been associated with cardiac arrhythmias, particularly in patients with heart disease, hyperventilation, and hypoxemia.[38] Neuromuscular irritability can be present, with signs of tetany or hyperactive reflexes, possibly caused by the decreased ionized calcium concentration that occurs secondary to the increase in pH. This decrease in ionized calcium may be caused by a conformational change in the albumin molecules to which the calcium is bound, resulting in increased binding, or by decreased competition from hydrogen ions for binding sites on the albumin molecule. Mental confusion, muscle cramping, and paresthesia can also occur. Lastly, patients will be more difficult to liberate from mechanical ventilation.

Compensation

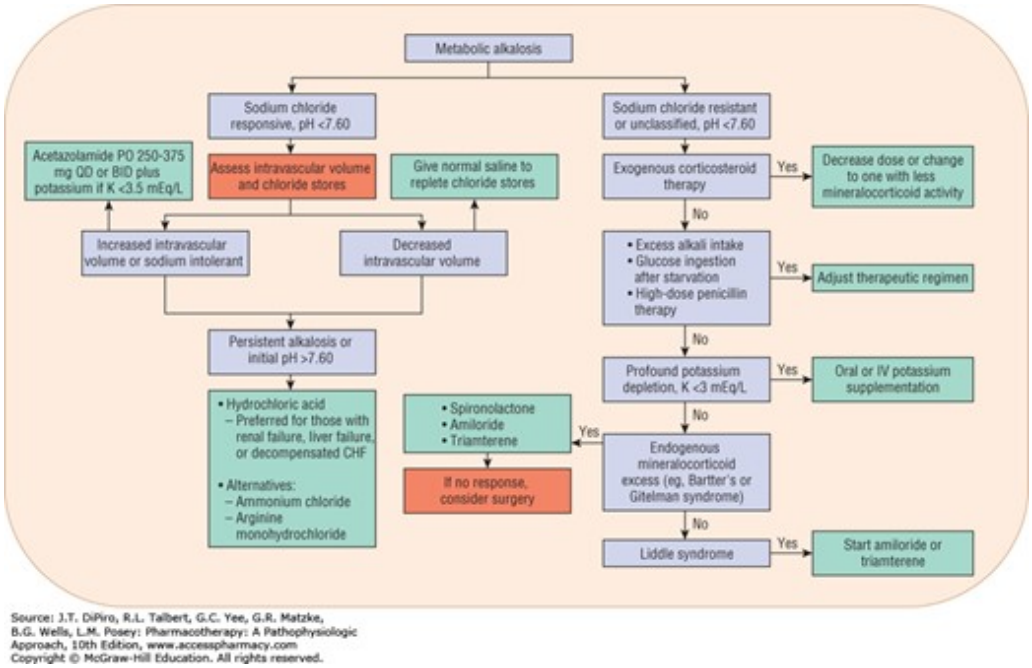
The respiratory response to metabolic alkalosis is hypoventilation, which results in an increased $PaCO_2$. Respiratory compensation is initiated within hours when the central and peripheral chemoreceptors sense an increase in pH. The $PaCO_2$ increases 6 to 7 mm Hg (0.8-0.9 kPa) for each 10 mEq/L (mmol/L) increase in bicarbonate, up to a $PaCO_2$ of approximately 50 to 60 mm Hg (6.7-8.0 kPa) (see Table 52-7) before hypoxia sensors react to prevent further hypoventilation.[1,25] If the $PaCO_2$ is normal or less than normal, one should consider the presence of a superimposed respiratory alkalosis, which can be secondary to fever, gram-negative sepsis, or pain.

TREATMENT

Because the body tolerates alkalemia far less well than acidemia, treatment of metabolic alkalosis is nearly always required and should be aimed at correcting the factor(s) responsible for the maintenance of the alkalosis.[38] For example, vomiting should be treated with antiemetics, gastric losses of hydrogen ions during nasogastric suction can be modulated by giving histamine blockers such as ranitidine or proton pump inhibitors such as omeprazole, and reducing or discontinuing diuretic therapy.[38,42] Metabolic alkalosis will persist until the renal mechanism responsible for maintaining the disorder is corrected, despite the fact that the original cause of the elevated plasma bicarbonate may have resolved. For example, hypovolemia should be treated with sodium chloride to allow excretion of bicarbonate by the kidney. However, patients with severely compromised cardiovascular function may not be able to tolerate this therapeutic approach. In situations such as this and/or the presence of life-threatening alkalosis, some have advocated reduction in pH by control of ventilation.[38] Although controlled hypoventilation, sometimes using inspired CO_2 with supplemental oxygen to prevent hypoxia can be lifesaving,[2] this approach is not universally accepted.[38] Therapy for metabolic alkalosis can be conceptualized on the basis of the sodium chloride responsiveness of the disorders as shown in **Fig. 52-4**.

FIGURE 52-4

Treatment algorithm for patients with primary metabolic alkalosis. (BID, twice daily; CHF, chronic heart failure; K, potassium [serum potassium in mEq/L is numerically equivalent to mmol/L]; PO, orally; QD, every day.)



Sodium Chloride-Responsive Metabolic Alkalosis

Sodium chloride-responsive disorders usually result from volume depletion and chloride loss, which can accompany severe vomiting, prolonged nasogastric suction, and diuretic therapy. Initially, therapy is directed at expanding intravascular volume and replenishing chloride stores. Sodium and potassium chloride-containing solutions should be administered to patients who can tolerate the volume load.[2,38] Patients with metabolic alkalosis who are volume overloaded or intolerant to volume administration because of congestive heart failure can benefit from the carbonic anhydrase inhibitor acetazolamide. This agent inhibits the action of carbonic anhydrase, thereby inhibiting renal bicarbonate reabsorption. Unfortunately, it also increases the renal losses of potassium and phosphate. Administration of acetazolamide (250-375 mg once or twice daily) can promote a sufficient bicarbonate diuresis and return the pH toward normal.[43] However, because the clinical effectiveness of the drug declines as the HCO_3^- concentration decreases, only rarely will this approach fully correct the alkalosis.[38]

Acidifying agents including hydrochloric acid, ammonium chloride, and arginine monohydrochloride can be used to treat severe (pH more than 7.6) symptomatic metabolic alkalosis.[44,45] In general, this management is reserved for patients who are unresponsive to conventional fluid and electrolyte management or who are unable to tolerate the requisite volume load because of decompensated congestive heart failure or advanced kidney disease.[44] Alternatively, hemodialysis using a low-bicarbonate dialysate can be used for the rapid correction of metabolic alkalosis.

Hydrochloric Acid

Hydrochloric acid is usually infused IV via a large central vein as a 0.1 to 0.25 N HCl solution in either 5% dextrose or normal saline, although sterile water has also been used. Extemporaneously prepared solutions can be made by adding 100 to 250 mEq (mmol) of HCl through a 0.22-mm filter into a glass container of saline or dextrose. Hydrochloric acid can also be added to parenteral nutrient solutions and administered via a central line without serious degradation of proteins.[31] The rate of infusion should be 100 to 125 mL/h (10-25 mEq/h [mmol/h]), with frequent monitoring of ABGs. To prevent overcorrection, the infusion should be stopped when the arterial pH decreases to 7.50.[38]

The dose of hydrochloric acid can be based on an estimate of the total body chloride deficit:[31]

Dose HCl (in mEq or mmol) = [0.2 L/kg × BW (in kg)] × [103 – observed serum chloride]

where the estimated chloride space is 0.2 times the body weight, and the average serum chloride is 103 mEq/L (mmol/L). Alternatively, the dose can be calculated based on the estimated base deficit:[31]

Dose HCl (in mEq or mmol) = [0.5 L/kg × BW (in kg)] × (desired $[HCO_3^-]$ – observed $[HCO_3^-]$)

Clinical Controversy…

At present, there are no comparative data that address the relative accuracy of these two formulas for determining the dose of hydrochloric acid.

The dose of hydrochloric acid is usually infused IV over 12 to 24 hours.[31] A severe transient respiratory acidosis can occur if the hydrochloric acid is infused too quickly because of a slower reduction of the elevated bicarbonate concentration in the cerebrospinal fluid than in the ECF. Improvement is usually seen within 24 hours of initiating therapy. ABGs and serum electrolytes should be drawn every 4 to 8 hours to evaluate and adjust therapy.

Ammonium Chloride

Ammonium chloride has a limited role in the treatment of metabolic alkalosis. The liver converts ammonium chloride (NH_4Cl) to urea and free hydrochloric acid[31]:

$$2NH_4Cl + 2HCO_3^- \rightarrow CO(NH_2)_2 + CO_2 + 3H_2O + 2Cl^-$$

The dose of ammonium chloride can be calculated on the basis of the chloride deficit using the same method as for HCl and assuming that 20 g ammonium chloride will provide 374 mEq (mmol) of H^+. However, only one half of the calculated dose of ammonium chloride should be administered so as to avoid ammonia toxicity. Ammonium chloride is available as a 26.75% solution containing 100 mEq (mmol) of H^+ in 20 mL, which should be further diluted prior to administration. A dilute solution can be prepared by adding 20 mL of ammonium chloride to 500 mL of normal saline and infusing the solution at a rate of no more than 1 mEq/min (mmol/min). Improvement in metabolic status is usually seen within 24 hours. CNS toxicity, marked by confusion, irritability, seizures, and coma, has been associated with more rapid rates of administration. Ammonium chloride must be administered cautiously to patients with impaired kidney or hepatic function. In patients with impaired hepatic

function, decreased conversion of ammonia to urea can result in increased ammonia levels and worsened encephalopathy. In patients with kidney disease, the increased urea synthesis can exacerbate uremic symptoms.[31,38]

Arginine Monohydrochloride

Arginine monohydrochloride at a dose of 10 g/h given IV has been used to treat metabolic alkalosis, although it was never FDA-approved for this purpose.[31] Like ammonium chloride, arginine must undergo metabolism by the liver to produce hydrogen ions, with a conversion of 100 g to 475 mEq (mmol) of H^+. Unlike ammonium chloride, arginine combines with ammonia in the body to synthesize urea; thus it can be used in patients with relative hepatic insufficiency. Patients with kidney disease should not receive arginine monohydrochloride because it can significantly elevate blood urea nitrogen and is associated with severe hyperkalemia.[31,38] The increase in potassium is caused by arginine-induced shifts of potassium from the intracellular to the extracellular space. One recent study of critically ill children with metabolic alkalosis resistant to standard treatment practices found that acetazolamide was more efficacious in resolving the alkalosis than arginine.[45]

Sodium Chloride-Resistant Metabolic Alkalosis

13 Management of these disorders usually consists of treatment of the underlying cause of the mineralocorticoid excess. For patients taking a corticosteroid, a dosage reduction or a switch to a corticosteroid with less mineralocorticoid activity (eg, methylprednisolone) should be considered. Patients with an endogenous source of excess mineralocorticoid activity can require surgery or the administration of spironolactone, amiloride, or triamterene.[2,14,38]

Spironolactone is a competitive antagonist of the mineralocorticoid receptor. Amiloride and triamterene are potassium-sparing diuretics that inhibit the epithelial sodium channel in the distal convoluted tubule and collecting duct. All three agents inhibit aldosterone-stimulated sodium reabsorption in the collecting duct. In addition, spironolactone directly inhibits aldosterone stimulation of the hydrogen ion secretory pump. Thus, most patients with mineralocorticoid excess, including Bartter and Gitelman syndromes, respond to therapy with these agents.[38,41] Liddle syndrome, which is a form of pseudohypoaldosteronism caused by overactivity of the epithelial sodium channel, is not responsive to spironolactone but can be treated with either amiloride or triamterene. Although experience is limited, some patients with Bartter and Gitelman syndromes may respond to NSAIDs or ACE inhibitors.[46,47] Finally, aggressive potassium repletion can correct the alkalosis in those who have not responded to the approaches outlined above (see Chapter 51).

RESPIRATORY ACID–BASE DISORDERS

As with the metabolic acid–base disturbances, there are two cardinal respiratory acid–base disturbances: respiratory acidosis and respiratory alkalosis. These disorders are generated by a primary alteration in CO_2 excretion, which changes the concentration of CO_2, and therefore the

carbonic acid concentration in body fluids.[1,48] A primary reduction in $PaCO_2$ causes an increase in pH (respiratory alkalosis), and a primary increase in $PaCO_2$ causes a decrease in pH (respiratory acidosis). Unlike the metabolic disturbances, for which respiratory compensation is rapid, metabolic compensation for the respiratory disturbances is slow. Hence, these disturbances can be further divided into acute disorders, with a duration of minutes to hours, and where metabolic compensation has yet to occur, and chronic disorders that have been present long enough for metabolic compensation to be complete.

Respiratory Alkalosis

Respiratory alkalosis is characterized by a primary decrease in $PaCO_2$ that leads to an elevation in pH. The $PaCO_2$ decreases when the excretion of CO_2 by the lungs exceeds the metabolic production of CO_2. It is the most frequently encountered acid–base disorder, occurring physiologically in normal pregnancy and in persons living at high altitudes.[1] Respiratory alkalosis also occurs frequently among hospitalized patients (**Table 52-11**).

TABLE 52-11 Causes of Respiratory Alkalosis

Central stimulation of respiration
Anxiety
Pain

Severe anemia

Peripheral stimulation of respiration

Pulmonary emboli

Asthma

$PaCO_2$, partial pressure of carbon dioxide from arterial blood.

Pathophysiology

A decrease in $PaCO_2$ occurs when ventilatory excretion exceeds metabolic production. Because endogenous production of CO_2 is relatively constant, negative CO_2 balance is primarily caused by an increase in ventilatory excretion of CO_2 (hyperventilation). The metabolic production of CO_2, however, can be increased during periods of stress or with excess carbohydrate administration (eg, parenteral nutrition). Hyperventilation can develop from an increase in neurochemical stimulation via either central or peripheral mechanisms, or be the result of voluntary or mechanical (iatrogenic) hyperventilation.

A decrease in $PaCO_2$ can occur in patients with cardiogenic, hypovolemic, or septic shock because oxygen delivery to the carotid and aortic chemoreceptors is reduced. This relative deficit in PaO_2 stimulates an increase in ventilation. The hyperventilation in sepsis is also mediated via a central mechanism. Hyperventilation-induced respiratory alkalosis with an elevation in cardiac index and hypotension without peripheral vasoconstriction can therefore be an early sign of sepsis.

Clinical Presentation

Although most patients are asymptomatic, respiratory alkalosis can cause adverse neuromuscular, cardiovascular, and GI effects.[2,3,48] During periods of decreased $PaCO_2$, there is a decrease in cerebral blood flow, which can be responsible for symptoms of light-headedness, confusion, decreased intellectual functioning, syncope, and seizures. Nausea and vomiting can occur, probably as a result of cerebral hypoxia. In severe respiratory alkalosis, cardiac arrhythmias can occur because of sensitization of the myocardium to the arrhythmogenic effects of circulating catecholamines.[2,29] Acute respiratory alkalosis has no effect on blood pressure or cardiac output in awake individuals. Anesthetized patients, however, can experience a decrease in both cardiac output and blood pressure, possibly owing to the lack of a tachycardic response.[29]

The concentration of serum electrolytes can also be altered secondary to the development of respiratory alkalosis. The serum chloride concentration is usually slightly increased, and serum potassium concentration can be slightly decreased. Clinically significant hypokalemia can be a consequence of extreme respiratory alkalosis, although the effect is usually very small or negligible.[2,29] Serum phosphorus concentration can decrease by as much as 1.5 to 2.0 mg/dL (0.48-0.65 mmol/L) because of the shift of inorganic phosphate into cells. Reductions in the blood

ionized calcium concentration can be partially responsible for symptoms such as muscle cramps and tetany. Approximately 50% of calcium is bound to albumin, and an increase in pH results in an increase in binding.[29]

Compensation

The initial response of the body to acute respiratory alkalosis is chemical buffering: hydrogen ions are released from the body's buffers—intracellular proteins, phosphates, and hemoglobin—and titrate down the serum bicarbonate concentration. This process occurs within minutes. Acutely, the bicarbonate concentration can be decreased by a maximum of 3 mEq/L (mmol/L) for each 10-mm Hg (1.3 kPa) decrease in $PaCO_2$ (see Table 52-7).[24] When only physicochemical buffering has occurred, the disturbance is referred to as acute respiratory alkalosis.

Metabolic compensation occurs when respiratory alkalosis persists for more than 6 to 12 hours. In response to the alkalemia, proximal tubular bicarbonate reabsorption is inhibited, and the serum bicarbonate concentration decreases. Renal compensation is usually complete within 1 to 2 days. The renal bicarbonaturia, as well as decreased NH_4^+ and titratable acid excretion, are direct effects of the reduced $PaCO_2$ and pH on renal reabsorption of chloride and bicarbonate.[2,29] The acuity of the respiratory alkalosis can be assessed on the basis of the degree of renal compensation (see Table 52-7). In fully compensated respiratory alkalosis, the bicarbonate concentration decreases by 4 mEq/L (mmol/L) below 24 for each 10-mm Hg (1.3 kPa) drop in $PaCO_2$. For example, a sustained decrease in $PaCO_2$ of 20 mm Hg (2.7 kPa) will lower serum bicarbonate from 24 to 16 mEq/L (mmol/L) with a resultant pH of 7.46. Bicarbonate concentrations differing from those anticipated using the preceding guidelines suggest a mixed acid–base disorder.

TREATMENT

Because most patients with respiratory alkalosis, especially chronic cases, have few or no symptoms and pH alterations are usually mild (pH not exceeding 7.50), treatment is often not required.[29,50] The first consideration in the treatment of acute respiratory alkalosis with pH more than 7.50 is the identification and correction of the underlying cause. Relief of pain, correction of hypovolemia with IV fluids, treatment of fever or infection, treatment of salicylate overdose, and other direct measures can prove effective. A rebreathing device, such as a paper bag, can be useful in controlling hyperventilation in patients with the anxiety/hyperventilation syndrome.[57] Oxygen therapy should be initiated in patients with severe hypoxemia. Patients with life-threatening alkalosis (pH more than 7.60), particularly if it is a mixed respiratory and metabolic condition, tend to have complications, such as arrhythmias or seizures, which can require mechanical ventilation with sedation and/or paralysis to control hyperventilation.

Respiratory alkalosis in patients receiving mechanical ventilation is usually iatrogenic. It can often be corrected by decreasing either the set respiratory rate or tidal volume, although other measures can also be employed. The use of a capnograph and spirometer in the breathing circuit enables a more precise adjustment of the ventilator settings. Another method of treating respiratory alkalosis is to increase the amount of dead space in the ventilator circuit by placing a known length of tubing

between the artificial airway and the “T” piece of the ventilator. This results in “rebreathing” of expired gas, and therefore an increase in the inspired carbon dioxide concentration, which should increase the carbon dioxide tension of the patient, correcting the respiratory alkalosis. In patients breathing more rapidly than the ventilator settings, sedation with or without paralysis can be employed.

CLINICAL PRESENTATION Respiratory Alkalosis General

- The patient is usually asymptomatic if the condition is chronic and mild.

Symptoms

- The patient may complain of light-headedness, confusion, muscle cramps and tetany, and decreased intellectual functioning.
- Nausea and vomiting can occur, probably as a result of cerebral hypoxia.

Signs

- In severe respiratory alkalosis pH more than 7.60
    - Syncope and seizures
    - Cardiac arrhythmias
    - Hyperventilation

Laboratory Tests

- Serum chloride concentration is usually slightly increased. Serum ionized calcium, potassium, and phosphorus concentration can be decreased.

Respiratory Acidosis

Pathophysiology

Respiratory acidosis occurs when the lungs fail to excrete CO_2 resulting in a lower pH. This can be the result of conditions that centrally inhibit the respiratory center, diseases that interfere with pulmonary perfusion or neuromuscular function, and intrinsic airway or parenchymal pulmonary disease (**Table 52-12**). Acute respiratory acidosis with hypoxemia, hypercarbia, and acidosis is life-threatening. Those disorders that produce an increase in $PaCO_2$ and hypoxemia to a degree compatible with life (eg, chronic obstructive pulmonary disease), with or without oxygen therapy, can result in chronic respiratory acidosis (**Table 52-13**). These patients can function normally without noticeable neurologic defects with $PaCO_2$ concentrations in the range of 90 to 100 mm Hg (12-13.3 kPa) (normal, 40 mm Hg [5.3 kPa]), provided that adequate oxygenation is maintained.[48]

Clinical Presentation

Respiratory acidosis can produce neurologic symptoms, including altered mental status, abnormal behavior, seizures, stupor, and coma. Hypercapnia can mimic stroke or CNS tumors by producing headache, papilledema, focal paresis, and abnormal reflexes. These CNS symptoms are attributable to the vasodilator effects of CO_2 in the brain that result in an increase in cerebral blood flow.[2] The CNS response to hypercapnia is extremely variable between patients and is most influenced by the acuity of presentation. Given that chronic hypercapnia blunts the usual respiratory stimulus of an elevated $PaCO_2$, hypoxemia rather than hypercapnia provides the primary ventilatory stimulus in patients with severe chronic respiratory acidosis.[48]

The degree to which cardiac contractility and heart rate are altered depends on the severity of the acidosis and the rapidity with which it develops. Modest acute hypercapnia ($PaCO_2$ of 50-55 mm Hg [6.7-7.3 kPa]) stimulates a stress-like response, with elevated catecholamines and corticosteroid

hormone levels, and can result in increased cardiac output and pulmonary artery pressure.[29] As the severity increases, cardiac output declines and vascular resistance decreases leading to refractory hypotension in some patients.[2]

In respiratory acidosis, the serum potassium concentration increases modestly secondary to cellular shifts. The increases are less than those seen with inorganic metabolic acidosis and are difficult to predict for individual patients.

Compensation

The body responds to acute respiratory acidosis with chemical buffering. The increase in $PaCO_2$ results in increased carbonic acid levels. The carbonic acid dissociates, releasing hydrogen ions, which are buffered by nonbicarbonate buffers (ie, proteins, phosphate, and hemoglobin) and bicarbonate. Thus, on the basis of physicochemical factors, increases in $PaCO_2$ raise the serum bicarbonate concentration. In general, in acute respiratory acidosis, the bicarbonate concentration increases by 1 mEq/L (mmol/L) above 24 for each 10 mm Hg (1.3 kPa) increase in $PaCO_2$ above 40 (5.3 kPa) (see Table 52-7).

CLINICAL PRESENTATION Respiratory Acidosis General

- The patient is usually symptomatic.

Symptoms

- The patient may complain of confusion or difficulty thinking and headache.

Signs

- In severe respiratory acidosis.
- Cardiac: Increased cardiac output if moderate that decreases if severe. Refractory hypotension can be present in some patients.
- CNS: Abnormal behavior, seizures, stupor, and coma. Papilledema, focal paresis, and abnormal reflexes can also be present.

Laboratory Tests

- Serum potassium concentration can be modestly increased. Hypercapnia can be moderate ($PaCO_2$ of 50-55 mm Hg [6.7-7.3 kPa]) to severe ($PaCO_2$ of more than 80 mm Hg [more than 10.6 kPa]). Hypoxia (PaO_2 is less than 70 mm Hg [less than 9.3 kPa]) is often present.

Metabolic compensation occurs when respiratory acidosis is prolonged beyond 12 to 24 hours. In response to hypercapnia and acidemia, proximal tubular bicarbonate reabsorption, ammoniagenesis, and distal tubular hydrogen secretion are enhanced, resulting in an increase in the serum bicarbonate concentration that raises the pH toward normal. Renal compensation for chronic hypercapnia generally results in the plasma bicarbonate concentration increasing by 4 mEq/L (mmol/L) above 24

for each 10 mm Hg (1.3 kPa) increase in $PaCO_2$ above 40 (5.3 kPa) (see Table 52-7). The new steady state in acid–base values is generally achieved within 5 days of the onset of hypercapnia in dogs; the time interval necessary for compensation in humans has not been established.

TREATMENT

The treatment of respiratory acidosis is dependent on the chronicity of the patient's condition. Respiratory decompensation in patients with chronic elevations in $PaCO_2$ is frequently seen in those with acute infections and those recently started on narcotic analgesics or oxygen therapy.[29] Aggressive treatment of these conditions can offer considerable benefit and should be initiated. Furthermore, tranquilizers and sedatives should be avoided and supplemental oxygen, if used, should be minimized.

Acute Respiratory Acidosis

14 When carbon dioxide excretion is severely impaired ($PaCO_2$ more than 80 mm Hg [more than 10.6 kPa]) and/or life-threatening, hypoxia is present (PaO_2 less than 40 mm Hg [less than 5.3 kPa]); the immediate therapeutic goal is to provide adequate oxygenation. Under these circumstances, hypoxia, not acidemia, is the principal threat to life. A patent airway needs to be established, which can necessitate intubation. Excessive secretions must be cleared from the airway and oxygen administered to restore adequate oxygenation. Mechanical ventilation is usually required.

The underlying cause of the acidosis should be treated aggressively (ie, bronchodilators for treatment of severe bronchospasm; narcotic or benzodiazepine antagonists to reverse the deleterious effects of these agents on the respiratory center). Bicarbonate administration is rarely necessary in the treatment of respiratory acidosis. Furthermore, rapid correction of acidosis with bicarbonate can eliminate the patient's respiratory drive or precipitate metabolic alkalosis. Cautious use of alkali (bicarbonate or THAM) can restore the responsiveness of bronchial muscles to β-adrenergic agonists and thus can be beneficial for those patients with severe bronchospasm.[29] ABGs should be monitored closely to ensure that the respiratory acidosis is resolving without creating a metabolic alkalosis as the result of compensatory elevation in HCO_3^- and decrease in $PaCO_2$. ABGs should be obtained every 2 to 4 hours during the acute phase and less frequently (every 12-24 hours) as the acidosis improves.

Acute Respiratory Acidosis in a Compensated Chronic Respiratory Acidotic Patient

Patients with a history of chronic respiratory acidosis (ie, those with chronic obstructive pulmonary disease) can experience an acute worsening of their respiratory acidosis. This can result in severe life-threatening hypoxemia. As with acute respiratory acidosis, the goals of therapy are maintenance of a patent airway and adequate oxygenation. Individuals with chronic respiratory acidosis are routinely able to tolerate a low PaO_2 and an elevated $PaCO_2$ because of compensation (increased number of red blood cells, hemoglobin content, and 2,3-diphosphoglycerate). The drive to breathe in these patients is dependent on hypoxemia rather than hypercarbia. Administration of oxygen to a patient with chronic respiratory acidosis can eliminate this drive to breathe and result in the

syndrome of carbon dioxide narcosis. In this case, if the Pa_{O_2} is 50 mm Hg (6.7 kPa), no oxygen treatment is necessary. If the Pa_{O_2} is less than 50 mm Hg (less than 6.7 kPa), oxygen therapy should be initiated carefully using a controlled flow of oxygen.[2]

ABGs should be checked periodically to ensure adequate oxygenation. If the Pa_{CO_2} increases during oxygen therapy, it can be a sign of impending carbon dioxide narcosis and oxygen therapy may need to be discontinued. The underlying cause of the acute exacerbation should be aggressively managed. Pulmonary infections should be treated with the appropriate antibiotics and bronchodilators administered as necessary. Excess secretions should be cleared from the airway to allow proper gas exchange. This can involve increasing oral fluid intake to decrease the viscosity of secretions, deep breathing, and postural drainage, suction, or bronchoscopy.

MIXED ACID–BASE DISORDERS

Diagnosis

The diagnosis of a mixed disorder depends on an understanding of the appropriate quantitative response of the compensatory mechanisms for each of the simple acid–base disturbances.[2,3,25] To diagnose mixed disorders, one must know how each of the four simple disorders alters pH, Pa_{CO_2}, and (HCO_3^-) (see Table 52-7). If a given set of blood gases does not decrease within the range of expected responses for a simple acid–base disturbance, a mixed disorder should be suspected. In addition to laboratory information, a thorough history and physical examination of the patient will often lead to the diagnosis, even before the laboratory data are available. Examples of common mixed disturbances follow.

Mixed Respiratory Acidosis and Metabolic Acidosis

A mixed respiratory and metabolic acidosis disturbance is characterized by a failure of compensation. The respiratory disorder prevents the compensatory decrease in Pa_{CO_2} expected in the defense against metabolic acidosis. The metabolic disorder prevents the buffering and renal mechanisms from raising the bicarbonate concentration as expected in the defense against respiratory acidosis. In the absence of these compensatory mechanisms, the pH decreases markedly.

Mixed respiratory and metabolic acidosis may develop in patients with cardiorespiratory arrest, in those with chronic lung disease who are in shock, and in metabolic acidosis patients who develop respiratory failure. When treating this mixed disorder, clinicians need to respond to both the respiratory and metabolic acidosis. Improved oxygen delivery must be initiated to improve hypercarbia and hypoxia. Mechanical ventilation may be needed to reduce Pa_{CO_2}. During the initial stage of therapy, appropriate amounts of alkali should be given to reverse the metabolic acidosis (see "Treatment," "Metabolic Acidosis" above).

Mixed Respiratory Alkalosis and Metabolic Alkalosis

The combination of respiratory and metabolic alkalosis is the most common mixed acid–base disorder. This mixed disorder occurs frequently in critically ill surgical patients with respiratory alkalosis caused by mechanical ventilation, hypoxia, sepsis, hypotension, neurologic damage, pain, or drugs, and with metabolic alkalosis caused by vomiting or nasogastric suctioning and massive blood transfusions. It can also occur in patients with hepatic cirrhosis who hyperventilate, receive diuretics, or vomit, as well as in patients with chronic respiratory acidosis and an elevated plasma bicarbonate concentration who are placed on mechanical ventilation and undergo a rapid decrease in Pa_{CO_2}.

The renal excretion of bicarbonate that usually occurs as compensation for the respiratory alkalosis is prevented by the complicating metabolic alkalosis. Likewise, the retention of Pa_{CO_2} expected to compensate for metabolic alkalosis is prevented by the primary respiratory alkalosis. The failure of compensation that occurs with mixed respiratory and metabolic alkalosis can result in a severe alkalemia.

Administration of sodium chloride and potassium chloride solutions will help correct the metabolic component of a mixed respiratory and metabolic alkalosis, and adjustment of the ventilator and/or treatment of an underlying process that is causing hyperventilation can correct or ameliorate the respiratory component of this mixed disorder.

Mixed Metabolic Acidosis and Respiratory Alkalosis

This mixed disorder is often seen in patients with advanced liver disease, salicylate intoxication, and pulmonary-renal syndromes. The respiratory alkalosis will decrease the Pa_{CO_2} beyond the appropriate range for the respiratory compensation usually seen with metabolic acidosis. The plasma bicarbonate concentration also decreases below the level expected in compensation for a simple respiratory alkalosis. In a sense, the defense of pH for either disorder alone is enhanced; thus the pH can be normal or close to normal, with a low Pa_{CO_2} and a low (HCO_3^-). Treatment of this disorder should be directed at the underlying cause. Because of the enhanced compensation, the pH is usually closer to normal than in either of the two simple disorders.

Mixed Metabolic Alkalosis and Respiratory Acidosis

This mixed disorder often occurs in patients with chronic obstructive pulmonary disease and chronic respiratory acidosis who are treated with salt restriction, diuretics, and possibly glucocorticoids. When diuretics are initiated, the plasma bicarbonate may increase because of increased renal bicarbonate generation and reabsorption, providing mechanisms for both generating and maintaining metabolic alkalosis. The elevated pH diminishes respiratory drive and may therefore worsen the respiratory acidosis.

Although the pH may not deviate significantly from normal, treatment may need to be initiated to maintain Pa_{O_2} and Pa_{CO_2} at acceptable levels. Because it is often difficult to correctly identify this mixed disorder, it is helpful to observe the patient's response to discontinuation of diuretics and administration of sodium and potassium chloride.[2,25] The Pa_{CO_2} will normalize if the patient has a simple metabolic alkalosis, but it will be minimally affected in the setting of a mixed disorder.

Treatment should be aimed at decreasing the plasma bicarbonate with sodium and potassium chloride therapy, thereby allowing the renal excretion of retained bicarbonate from the diuretic-induced metabolic alkalosis. This therapy should be used cautiously to avoid exacerbating any underlying congestive heart failure.

CLINICAL BOTTOM LINE

Acid–base disorders are a common and widespread problem, and clinicians can play a key role in identifying, preventing, and properly treating them. Acid–base disorders do not occur only in the intensive care unit setting. Patients in ambulatory and extended care settings have many chronic conditions and drug therapies that commonly affect acid–base balance. Thus clinicians in all practice settings should strive to identify patients at high risk for developing drug-related problems that affect acid–base balance and to undertake appropriate prevention and treatment measures to improve the quality of life of their patients.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

BW	body weight
DCA	dichloroacetate
ECF	extracellular fluid
H^+	hydrogen ion
HCO_3^-	bicarbonate
H_2CO_3	carbonic acid
HIV	human immunodeficiency virus
NH_4^+	ammonium
$PaCO_2$	partial pressure of carbon dioxide from arterial blood
PaO_2	partial pressure of oxygen from arterial blood
pH	the negative logarithm (base 10) of the hydrogen ion concentration
pK	the negative logarithm of the dissociation constant
$PvCO_2$	partial pressure of carbon dioxide from venous blood
PvO_2	partial pressure of oxygen from venous blood
RTA	renal tubular acidosis
SAG	serum anion gap
THAM	tromethamine (Tris[hydroxymethyl]-aminomethane)
UCs	unmeasured cations
UAs	unmeasured anions

Chapter e53: Evaluation of Neurologic Illness

FIGURE e53-1

Melody Ryan; Stephen J. Ryan; Susan C. Fagan

INTRODUCTION

KEY CONCEPTS

- 1 Accurate diagnosis of neurological disorders leads to effective pharmacotherapy.
- 2 The clinical neurologic history and examination are the cornerstones of neurologic diagnosis and management.
- 3 The neurologic history and examination are directed at localization of the disease process so that evaluation and management may be planned appropriately.
- 4 Appropriate history taking and examination techniques are useful for monitoring and evaluating the pharmacotherapeutic plan.
- 5 After forming the differential diagnosis, appropriate testing helps pinpoint the correct diagnosis.

1 Accurate diagnosis of neurological disorders leads to effective pharmacotherapy. This diagnosis is built upon history, a detailed neurological examination, and appropriate testing. To contribute most effectively to the care of patients with neurologic illness, one must understand the tools used in the diagnosis and management of these patients. In addition, clinicians must be able to gather their own data through history taking and a targeted neurologic examination to ensure optimal pharmacotherapy in neurologic patients. 2 Despite technologic advances that have led to the development of sensitive diagnostic tests in neuroscience, the clinical neurologic history and examination are still the cornerstones of neurologic diagnosis and management.[1]

SIGNS AND SYMPTOMS OF NEUROLOGIC DISORDERS

As in all of medicine, obtaining an accurate and complete history is of utmost importance in the evaluation of neurologic diseases. In many instances, the diagnosis can be made on the basis of the history, and the neurologic examination can be tailored to optimally evaluate the patient and confirm the diagnosis.[1] Open-ended questions allow the patient to provide the salient history without leading the patient toward preconceived diagnoses. Obtaining an accurate history may be difficult because a number of neurologic diseases may affect patients' communication and memory. Details obtained from the family or other observers support and further expand the data obtained from the patient during history taking; additionally family history can be helpful in diagnosis.[1] Through the patient's history, one can determine the main symptoms, location, onset (acute, subacute, or chronic), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses or risk factors for neurologic disease.[2] The history should also identify factors that might precipitate or ameliorate the symptoms.[2] Each complaint of the patient should be thoroughly investigated while taking the history. See **Table e53-1** for questions to assist the clinician in obtaining the neurologic history.

TABLE e53-1 Questions to Ask Regarding Neurologic Symptoms

For each symptom:

- How would you describe the sensation (quality, severity)?
- Where is the symptom?
- When did it begin?
- Did it start suddenly or slowly?
- Has it stayed the same/improved/worsened?
- Does anything make the symptom occur?
- Does anything improve/worsen the symptom?

Data from reference 2.

As part of the history, special attention should be given to the medication history. It is important to determine current medications, doses, dosing schedule (times, relationship to other medications, and relationship to meals), duration, and adherence. Additionally, adverse effects should be recorded in detail. Past and recently discontinued medications as well as any medications used previously, including reasons for discontinuation, to treat the main complaints may also be important. Clinicians should also consider if the patient's symptoms may be drug-induced.

Additional history is necessary for pediatric patients. History may be obtained from the patients, guardians, or caretakers rather than the child in most cases.[3] The child should be allowed to provide

as much history as he/she is developmentally able to do so. Because of the differing developmental stages of children, the amount of information the child is able to provide will vary with age. Family history is particularly important because some pediatric illnesses have an inherited genetic cause.[3] History of the pregnancy, including maternal illnesses, medication or toxin exposures, and complications, should be noted.[3] Details of labor and delivery including duration, method of delivery, and complications may also be important.[3] Developmental history requires comparison of the child's developmental stage to standard age-related developmental milestones.[3]

THE NEUROLOGIC EXAMINATION

A general physical examination is important because it can reveal evidence of systemic disease that may secondarily affect the nervous system.[2] The neurologic examination is one component of a complete general physical examination. 3 A detailed neurologic examination is an extremely important tool for localizing a lesion within the nervous system.

The neurologic examination consists of seven main components: higher cortical function (mental status), cranial nerves, motor function, reflexes, cerebellar function, sensory function, and gait.[2] **Table e53-2** describes the common approaches to assessing each of the seven domains and includes examples of the diseases in which abnormal findings are common. Readers are encouraged to consult other references to better understand the intricacies of the neurologic examination.[4,5]

TABLE e53-2 Neurologic Complaints and Corresponding Examination

Domain	Common Complaints	Example Tests Performed	Example Diseases with Abnormal Findings
Mental status	Confusion, forgetfulness, disorientation, speech difficulties, calculation difficulties, lack of facial recognition	While obtaining the history: general mental and emotional status, speech, memory, alertness, abstract reasoning, ability to follow commands (motor integration), ability to communicate	Dementias, stroke, metabolic encephalopathies
Cranial nerves	Blurred vision, ptosis, diplopia, anosmia, dysgeusia, dysarthria, dysphagia, facial asymmetry, tinnitus	Visual acuity, visual fields, eye movements, jaw strength, corneal reflex, facial symmetry, auditory acuity, gag reflex, shoulder and neck strength	Myasthenia gravis, stroke, ALS, Bell palsy
Motor function	Weakness, muscle cramps, muscle twitches, dropping items, muscle wasting, shaking	Motor strength with and without resistance, seen on examination: tremors, atrophy, fasciculations, hypertonia, hypotonia	Stroke, myasthenia gravis, Parkinson disease, ALS, essential tremor
Reflexes		Deep tendon reflexes, plantar response, superficial cutaneous reflexes (eg, abdominal)	Stroke, spinal cord lesions, peripheral neuropathy, ALS,

Domain	Common Complaints	Example Tests Performed	Example Diseases with Abnormal Findings
			multiple sclerosis
Sensation	Tingling, numbness, burning, throbbing	Asymmetry or decreased sensation to pinprick, vibration, temperature, position	Stroke, peripheral neuropathy, spinal cord lesions
Cerebellar function	Unsteady gait, incoordination, tremor, speech abnormalities	Nystagmus check, saccades, coordination (rapid alternating movements, finger-to-nose test, heel–to-shin test, finger tapping)	Stroke, posterior fossa tumors, alcoholic cerebellar degeneration
Gait	Unsteadiness, falls, tripping, freezing, slow gait, poor balance	Walking (tandem, on heels, on toes), standing (Romberg test—closing eyes tests proprioception)	Stroke, Parkinson disease, spinal cord lesions, multiple sclerosis

ALS, amyotrophic lateral sclerosis.

Data from reference 2.

The neurologic examination of pediatric patients should be adapted to their age and developmental stage. Some adaptations of the standard examination techniques may include observing walking and playing for cerebellar and motor function or observing facial expressions, withdrawal, and avoidance responses to tickling, touching, and finger or toe pinching to assess sensory function.[6] In addition to the standard domains of the neurologic examination, an assessment of the weight, height, and head circumference of the patient should be included. These measurements should be evaluated with reference to age- and gender-adjusted charts to identify any abnormalities.[7] In infants, the fontanels should be assessed for size and whether they are open or closed.[6] Specific child neurology texts may be consulted for more detailed examination techniques for children.[3,8] The clinician must synthesize the results of the history and physical examination to arrive at an anatomic localization of the lesion and create a differential diagnosis. The history and examination are essential to the clinician in order to provide a pharmacotherapeutic plan for an individual patient. 4 Additionally, appropriate history taking and examination techniques are useful for monitoring and evaluating the pharmacotherapeutic plan. For example, learning motor examination techniques can assist with evaluating the usefulness of Parkinson disease therapy. 5 After forming the differential diagnosis, appropriate testing helps pinpoint the correct diagnosis.

LABORATORY EVIDENCE FOR NEUROLOGIC DISORDERS AND ITS INTERPRETATION

Laboratory testing should be guided by the specific localization for each patient; examples may include treponemal testing for neurosyphilis, creatine kinase for myopathy, or vitamin B_{12} for peripheral neuropathy. One of the most neurologic-specific laboratory tests is examination of the

cerebrospinal fluid (CSF). Lumbar puncture (LP) is used to obtain CSF for further evaluation. It is used most often as an evaluation for markers of central nervous system (CNS) infections, such as meningitis and encephalitis, but it is also useful in diagnosing subarachnoid hemorrhage or multiple sclerosis.[2] A long needle is inserted between the vertebrae of the lumbar spine and CSF is drained through the needle into collection vials (**Fig. e53-1**).[9] Opening pressure, cell count and differential, glucose concentration, total protein concentration, Gram stain, and culture and sensitivity are measured routinely; normal CSF laboratory values are given in **Table e53-3**.[9,10] A space-occupying lesion in the brain with mass effect is a relative contraindication to LP because herniation of the brainstem could result.[9,10] Before performing an LP, the patient should be checked for papilledema, which may indicate increased intracranial pressure. Additionally, coagulopathies are a relative contraindication because of the difficulty of compressing the site of the LP.[9]

TABLE e53-3 Commonly Obtained Cerebrospinal Fluid Measurements

Laboratory Value	Normal Value	Common Abnormalities	Abnormalities May Suggest
Color	Clear	Xanthochromia	Subarachnoid hemorrhage
		Turbidity	Meningitis, encephalitis
Opening pressure (cm H_20)	Less than 20 (2.0 kPa) (adults) Less than 28 (2.7 kPa) (children)	Increased pressure	Hydrocephalus, cerebral edema
Protein (g/L)	0.15-0.50	Increased protein	Trauma, infection, cerebral hemorrhage, subarachnoid hemorrhage, tumor
Glucose (mg/dL) (mmol/L)	30-60 1.7-3.3	Decreased glucose	Bacterial meningitis
White blood cells (cells/mm^3 or $\times 10^6$/L)	Less than or equal to 5	Greater than 5	Meningitis, encephalitis
Red blood cells (cells/mm^3 or $\times 10^6$/L)	0	Greater than 0	Subarachnoid hemorrhage, cerebral hemorrhage, traumatic lumbar puncture
Bacteria	0	Positive	Meningitis, encephalitis

Data from references 9 and 10.

PROCEDURES USED IN THE DIAGNOSIS AND ASSESSMENT OF NEUROLOGIC DISORDERS

In addition to the history, neurologic examination, and laboratory examinations, certain imaging techniques and procedures may be essential in the diagnosis of neurologic disorders. Electroencephalography (EEG) records the electrical activity of the brain through electrodes placed on the scalp. The record is interpreted by observing the basic rhythms and waveforms, the symmetry of the recording, and abnormal electrical discharges.[9] It also may be used to assess the response to photic stimulation or hyperventilation. It is used primarily in the diagnosis of seizures and may be helpful in the evaluation of patients with altered mental status. In some cases, long duration (more than 24 hours) EEGs are obtained, but most are approximately 30 minutes in length.[9]

Evoked potentials (EP) can be used to measure the responses to electrical signals sent along various sensory pathways (visual, auditory, and somatosensory).[9] EP testing examines conduction along those pathways and may be helpful for localizing a lesion within them. EP may be useful in evaluating conditions such as spinal cord lesions, hearing problems, and multiple sclerosis.

Electromyography (EMG) and nerve conduction velocities (NCVs) are used to assess the function of the peripheral nerves, neuromuscular junction, and muscles.[9] NCVs are measured by stimulating the nerve and recording the speed and amplitude of conduction of the impulse. NCV can be used to detect the presence of localized peripheral nerve injuries (eg, carpal tunnel syndrome) or diffuse neuropathies.[9] It may also be used to look for neuromuscular junction disorders such as myasthenia gravis. EMG assesses muscle dysfunction as a result of primary muscle disease or secondary to nerve injury.[9] A needle is placed in the muscle to measure the resting and contractual electrical activity of the muscles. EMG is used to diagnose peripheral neuropathies, amyotrophic lateral sclerosis, radiculopathies, and muscle diseases.[9]

PROCEDURES USED IN THE DIAGNOSIS OF NEUROLOGIC ANATOMIC ABNORMALITIES

Modern radiological imaging provides the clinician with several modalities to examine anatomical lesions of the nervous system itself and its vasculature. Computed tomography (CT) uses X-rays to produce images of thin "slices" of the brain.[9] It is currently available in most communities and is used to evaluate patients with intracranial disease. Because CT scans can be done relatively rapidly, they are used to evaluate patients in urgent circumstances such as acute strokes. CT scans are used to identify tumors, hemorrhages, infarctions, hydrocephalus, and atrophy, as well as other intracranial pathologies.[9] Intravenous contrast agents can provide imaging of vessel structure; they may also be used to identify areas of breakdown of the blood–brain barrier as the result of abscesses, other inflammatory conditions, tumors, or stroke.[9]

Magnetic resonance imaging (MRI) uses the magnetic properties of the hydrogen atom to produce computer-processed scans that provide improved anatomic detail compared with CT scans.[9] MRI offers the advantages of better differentiating between white and gray matter and delineating lesions close to bone (brainstem and cerebellum) and has no radiation risk; however, it is not as readily available as CT, takes longer to perform, and is more expensive.[9] Patients who have metal implants or who have claustrophobia may be unable to undergo MRI. MRI has a proven advantage over CT in evaluating lesions in the posterior fossa and in detecting lesions in the white matter, such as plaques in multiple sclerosis.[9] MRI is also useful in the diagnosis of tumors and very early ischemic stroke (diffusion-weighted imaging [DWI]).

The cerebral circulatory system can be imaged or evaluated in a number of ways, depending on the type and location of the abnormality suspected. Imaging techniques can be used to identify local arterial stenosis, aneurysms, and vascular malformations.[9] Atherosclerosis of the extracranial arteries, a frequent cause of stroke, can be evaluated using ultrasonography (referred to as duplex sonography, carotid Doppler, or color-flow Doppler), magnetic resonance angiography (MRA), or computed tomographic angiography (CTA).[9] The intracranial arterial circulation can be evaluated using transcranial Doppler, MRA, CTA, or conventional dye angiography.[9] Each technique has its own advantages and disadvantages. Conventional dye angiography provides the best imaging of the smaller arteries of the cerebral circulation but is more invasive than the other measures.[9]

Imaging of the spinal canal and its contents can be accomplished by conventional dye myelography, CT myelography, CT, or MRI. Myelography refers to injecting a contrast agent via LP into the CSF which is then imaged by X-ray (conventional dye myelography) or CT scan.[9] Myelography outlines the spinal cord and provides indirect information about the spinal cord, nerve roots, and surrounding structures. CT or MRI provides direct imaging of the soft tissue of the spinal cord. MRI provides higher quality images for structures around bones than CT because the bony structures cause the X-ray beams to scatter and produce artifacts on the images.[9] Compressive lesions and fractures can be identified by any of these methods; soft tissue lesions such as tumors, radiculopathies, and vascular malformations are better seen by MRI.[9]

SPECIAL PROCEDURES USED IN THE DIAGNOSIS OF NEUROLOGIC DISORDERS

Other imaging techniques, such as positron emission tomography (PET), single-photon emission computed tomography (SPECT), and functional MRI (fMRI), are considered tests of brain function. These tests are being studied extensively in epilepsy as well as in cerebrovascular disorders, cerebral tumors, movement disorders, and dementia.[9] PET scans use a positron-emitting isotope to image regional metabolic changes in the brain.[9] SPECT scans measure radiotracer uptake by tissues to assess cerebral blood flow. Although the resolution of SPECT is not as good as PET, it has use in localizing epileptic foci.[9] Functional MRI visualizes blood flow to focal areas of the brain by measurement differences in oxygenated blood concentrations to determine areas of greater activity.[9] Unlike PET scans, injection of radioactive isotopes is not necessary. It is used for epilepsy and cognitive research.

CONCLUSION

Through collation and interpretation of the patient's history, the neurologic examination, and other diagnostic tests, the clinician can fully understand the patient's diagnosis and assessment. This comprehension allows the clinician to devise and monitor a pharmacotherapeutic plan that will be of most benefit to the patient with neurological disorders.

Chapter 54: Alzheimer Disease

FIGURE 54-1

Emily P. Peron; Patricia W. Slattum; Kacie E. Powers; Sarah E. Hobgood

INTRODUCTION

KEY CONCEPTS

- 1 Alzheimer disease (AD) is the most common form of dementing illness, and the prevalence of AD increases with each decade of life.
- 2 The etiology of AD is unknown, and current pharmacotherapy neither cures nor arrests the pathophysiology.
- 3 Neuritic plaques and neurofibrillary tangles (NFTs) are the pathologic hallmarks of AD; however, the definitive cause of this disease is yet to be determined.
- 4 Alzheimer disease affects multiple areas of cognition and is characterized by a gradual onset with a slow, progressive decline.
- 5 A thorough physical examination (including neurologic examination), as well as laboratory and imaging studies, is required to rule out other disorders and diagnose AD before considering drug therapy.
- 6 Pharmacotherapy for AD focuses on impacting three domains: cognition, behavioral and psychiatric symptoms, and functional ability.
- 7 Nondrug therapy and social support for the patient and family are the primary treatment interventions for AD.
- 8 Cholinesterase inhibitors and memantine are used to treat cognitive symptoms of AD; other medications have been suggested to be beneficial because of their potential preventive or

cognitive effects.

- 9 Appropriate management of vascular disease risk factors may reduce the risk for developing AD and may prevent the worsening of dementia in patients with AD.

- 10 A thorough behavioral assessment and plan with careful examination of environmental factors should be conducted before initiating drug therapy for behavioral symptoms.

"I now begin the journey that will lead me into the sunset of my life."

Ronald Reagan

Alzheimer disease (AD), first characterized by Alois Alzheimer in 1907, is a gradually progressive dementia affecting cognition, behavior, and functional status. The exact pathophysiologic mechanisms underlying AD are not entirely known, and no cure exists.[1] Although drugs may reduce AD symptoms for a time, the disease is eventually fatal.

Alzheimer disease profoundly affects the family as well as the patient. The need for supervision and assistance increases until the late stages of the disease, when AD patients become totally dependent on a caregiver for all of their basic needs. These are the all-too-common experiences of the millions of people in the United States who care for someone with AD. To address the growing AD crisis facing the United States, the first national strategic plan, the National Alzheimer's Plan, was released in 2012 with the goals of coordinating efforts across the federal government to prevent and treat AD, increase public awareness, and improve the quality of care and support for patients and their caregivers.[2] The U.S. Department of Health and Human Services released an update to this strategic plan in 2015 that includes a timeline for achieving its goal of preventing and effectively treating AD by 2025.[2]

EPIDEMIOLOGY

1 Alzheimer disease is the most common cause of dementia, accounting for approximately 60% of cases in persons over age 65 years.[3] Its prevalence among dementia patients increases to 80% if AD lesions in conjunction with other pathologic brain lesions are considered.[3,4,5] **Table 54-1** lists the most common types of dementia. Dementia can result from multiple etiologies. This chapter focuses exclusively on dementia of the Alzheimer type; however, the reader is encouraged to use the nonpharmacologic approaches and management of behavioral problems outlined in this chapter as a general treatment approach for other types of dementia that may share similar features with AD.

TABLE 54-1 Common Types of Dementia in Late Life

Alzheimer disease
Vascular dementia
Dementia with Lewy bodies

Mixed dementia

Other (eg, Parkinson disease dementia, Frontotemporal dementia, Huntington disease, Creutzfeldt–Jakob disease)

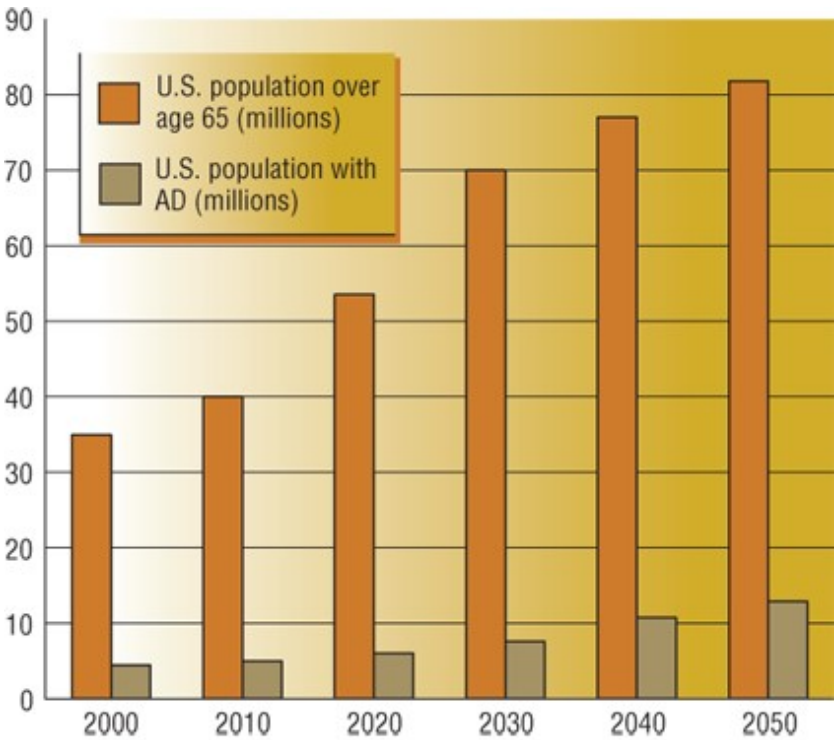
Potentially reversible causes of cognitive dysfunction (eg, normal pressure hydrocephalus, thyroid dysfunction, vitamin B_{12} deficiency, delirium, depression, Wernicke–Korsakoff syndrome)

Data from References 2 and 123.

Approximately 5.3 million Americans have AD.[3,6] By the year 2050, one in five people will be older than age 65 years, and the number of AD patients is projected to be 13.8 million (**Fig. 54-1**).[6] Most cases present in persons older than age 65 years, but approximately 4% of cases occur in persons younger than age 65 years. Onset can be as early as age 30 years, resulting in the arbitrary age classifications of early-onset (age less than 65 years) and late-onset (age 65 years and older).[5]

FIGURE 54-1

Our aging population. The percentage of the U.S. population older than age 65 years and the percentage with AD projected from years 2000 to 2050.[1,6] (*Estimates based on data from references 1 and 6.*)



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Increasing age is the greatest risk factor for AD, but AD is not a normal part of aging. The prevalence of AD increases exponentially with age, affecting approximately 11% of people age 65 years and

older and 32% of people age 85 years and older.[3] Factors determining age of onset and rate of progression remain largely undefined.

Survival following AD diagnosis is typically 4 to 8 years but may be as long as 20 years. It is the fifth leading cause of death for those age 65 years and older in the United States. AD may not cause death directly. The most common cause of death in patients with AD is pneumonia, possibly resulting from swallowing difficulties and immobility in the terminal stage of the disease.[3] Those diagnosed with AD spend, on average, more years in the most severe stage of the disease than any other stage, and much of this time is spent in a nursing home.[3]

ETIOLOGY

Etiology and Genetics

2 The exact etiology of AD is unknown; however, several genetic and environmental factors have been explored as potential causes. Genetic factors have been linked to both early- and late-onset AD.

Dominantly inherited forms of AD account for less than 1% of cases.[7,8] More than half of early-onset, dominantly inherited cases of AD can be attributed to alterations on chromosomes 1, 14, or 21. The majority and most aggressive early-onset cases are attributed to mutations of a gene located on chromosome 14, which produces a protein called presenilin 1.[9] A structurally similar protein, presenilin 2, is produced by a gene on chromosome 1. Both presenilin 1 and presenilin 2 encode for membrane proteins that may be involved in amyloid precursor protein (APP) processing. Scientists have identified more than 160 mutations in presenilin genes, and these mutations appear to result in reduced activity of γ-secretase, an enzyme important in β-amyloid peptide (Aβ) formation.[9] APP is encoded on chromosome 21. Only a small number of early-onset familial AD cases have been associated with mutations in the APP gene, resulting in overproduction of Aβ or an increase in the proportion of Aβ ending at residue 42.[9]

Genetic susceptibility to late-onset AD is primarily linked to the apolipoprotein E (*APOE*) genotype. There are three major subtypes or alleles of *APOE* (eg, **2*, **3*, and **4*). Inheritance of the *APOE*4* allele is believed to account for much of the genetic risk in late-onset AD. The mechanism through which *APOE*4* confers an increased risk is unknown, although *APOE*4* is associated with factors that may contribute to AD pathology, such as abnormalities in mitochondria, cytoskeletal dysfunction, and low glucose usage.[5] The risk for AD is twofold to threefold higher in individuals with one *APOE*4* allele and 12-fold higher in individuals with two *APOE*4* alleles compared to those with no *APOE*4* alleles.[10] Moreover, onset of symptoms occurs at a relatively younger age as compared with patients having zero or only one copy of *APOE*4* in their genotype[10] Of note, the *APOE*4* allele is not diagnostic of AD or even essential for disease presence. Moreover, as of 2015, more than 25 different genetic loci have been discovered that are known to be associated with late-onset AD.[11,12] Genetic explanatory factors continue to be investigated.[12]

Environmental and Other Factors

A number of environmental factors are associated with an increased risk of AD, including age, decreased reserve capacity of the brain (reduced brain size, low educational level, and reduced mental and physical activity in late life), head injury, Down syndrome, depression, mild cognitive impairment (MCI), and risk factors for vascular disease (hypercholesterolemia, hypertension, atherosclerosis, coronary heart disease, smoking, elevated homocysteine, obesity, metabolic syndrome, and diabetes).[3,5] Whether these vascular risk factors are true causal risk factors for AD contributing to AD pathology, or whether they result in cerebrovascular pathology that, in turn, contributes to the symptoms of AD, remains to be established.

The incidence of AD rises with increasing age, and AD may develop in individuals over the course of decades,[3] suggesting that AD is a disease most people are in the process of developing throughout adulthood. The debate about whether dementia is a distinct disease or part of aging remains unresolved. An in-depth discussion of the aging—AD controversy is not possible in this chapter; it is reviewed elsewhere.[13,14]

PATHOPHYSIOLOGY

3 The signature lesions in AD are amyloid plaques and neurofibrillary tangles (NFTs) located in the cortical areas and medial temporal lobe structures of the brain.[4] Along with these lesions, degeneration of neurons and synapses, as well as cortical atrophy occurs. Plaques and NFTs may also be present in other diseases, even in normal aging, but at least in younger demographics there tends to be a higher burden of plaques and NFTs in AD-affected subjects than there is in age-matched controls. Several mechanisms have been proposed to explain changes in the brain that result in symptoms of AD, including misfolding of proteins (Aβ aggregation and deposition leading to the formation of plaques and hyperphosphorylation of tau protein leading to NFT development); synaptic failure and depletion of neurotrophin and neurotransmitters; and mitochondrial dysfunction (oxidative stress, impaired insulin signaling in the brain, vascular injury, inflammatory processes, loss of calcium regulation, and defects in cholesterol metabolism).[4]

Amyloid Cascade Hypothesis

Amyloid plaques are extracellular lesions found in the brain and cerebral vasculature. Plaques largely consist of Aβ. Aβ peptides consisting of 36 to 43 amino acids are produced via processing of a larger protein, APP. Aβ_{42} is less common than other Aβ peptides, but is prone to aggregation and plaque formation.[4] The amyloid cascade hypothesis states that there is an imbalance between the production and clearance of Aβ peptides resulting in aggregation that causes accumulation of Aβ ultimately leading to AD.[4] Studies on early-onset AD and patients with Down syndrome led to the formulation of the amyloid cascade hypothesis. Recent versions of the amyloid cascade hypothesis assume Aβ that is not sequestered in plaques actually drives the disease.[4] Even so, the amyloid cascade hypothesis seems most applicable in cases of early-onset, autosomal dominant AD. It is not clear whether it is reasonable to etiologically extrapolate to the late-onset form (which afflicts the vast majority of those affected). Whether individuals with late-onset AD also carry genetic variations that promote a primary Aβ amyloidosis remains to be shown. If this turns out not to be the case, the

possibility that amyloidosis in late-onset AD is secondary to a more upstream event will require consideration. Before this conceptual conundrum is laid to rest, however, the amyloid cascade hypothesis will likely undergo a therapy-based practical test. If treatments that efficiently reduce Aβ production or remove brain Aβ fail to arrest disease progression, it would argue amyloidosis is not the primary pathology in most of those with AD.

Neurofibrillary Tangles

At the same time as Aβ was being identified in plaques, other researchers showed that NFTs are commonly found in the cells of the hippocampus and cerebral cortex in persons with AD and are composed of abnormally hyperphosphorylated tau protein. Tau protein provides structural support to microtubules, the cell's transportation and skeletal support system.[4] When tau filaments undergo abnormal phosphorylation at a specific site, they cannot bind effectively to microtubules, and the microtubules collapse. Without an intact system of microtubules, the cell cannot function properly and eventually dies. The density of the NFTs correlates with the severity of the dementia.[4] NFTs are found in other dementing illnesses besides AD, and may represent a common method by which various inciting factors culminate in cell death.[4]

Inflammatory Mediators

Inflammatory or immunologic paradigms are often viewed as a corollary of the amyloid cascade hypothesis. Certainly, brain amyloid deposition associates with local inflammatory and immunologic alterations. This led some to propose that inflammation is relevant to AD neurodegeneration.[4] Inflammatory/immunologic hypotheses argue that although Aβ may have direct neurotoxicity, at least some of its toxicity might actually be an indirect consequence of an Aβ protofibril-induced microglia activation and astrocyte recruitment. This inflammatory response may represent an attempt to clear amyloid deposition; however, it is also associated with release of cytokines, nitric oxide, and other radical species, and complement factors that can both injure neurons and promote ongoing inflammation.[4] Indeed, levels of multiple cytokines and chemokines are elevated in AD brains, and certain proinflammatory gene polymorphisms are reported to be associated with AD.[4]

Consistent with these molecular observations are epidemiologic data suggesting that exposure to nonsteroidal antiinflammatory drugs (NSAIDs) may reduce AD risk.[15] However, multiple prospective short duration trials of NSAIDs in AD prevention and of NSAIDs as AD treatment have been disappointing.[4,16]

The Cholinergic Hypothesis

Multiple neuronal pathways are destroyed in AD. Neuronal damage can be seen in conjunction with plaque structures.[4] Widespread cell dysfunction or degeneration results in a variety of neurotransmitter deficits, with cholinergic abnormalities being the most prominent.[4] Loss of cholinergic activity correlates with AD severity. In the late stage of AD, the number of cholinergic neurons is reduced, and there is loss of nicotinic receptors in the hippocampus and cortex.

Presynaptic nicotinic receptors control the release of acetylcholine, as well as other neurotransmitters important for memory and mood, including glutamate, serotonin, and norepinephrine.[4]

The discovery of vast cholinergic cell loss led to the development of a cholinergic hypothesis of the pathophysiology of AD. The cholinergic hypothesis targeted cholinergic cell loss as the source of memory and cognitive impairment in AD. Consequently, it was presumed that increasing cholinergic function would improve symptoms of memory loss. This approach is flawed because cholinergic cell loss appears to be a secondary consequence of AD pathology, not the disease-producing event, and cholinergic neurons are only one of many neuronal pathways destroyed in AD. Simple addition of acetylcholine cannot compensate for the loss of neurons, receptors, and other neurotransmitters lost during the course of the illness. Thus the goal is to minimize or improve symptoms through augmentation of neurotransmission at remaining synapses.

Other Neurotransmitter Abnormalities

Although the cholinergic system has received particular attention in AD pharmaceutical research, deficits also exist in other neuronal pathways. For example, serotonergic neurons of the raphe nuclei and noradrenergic cells of the locus ceruleus are lost, while monoamine oxidase type B activity is increased. Monoamine oxidase type B is found predominantly in the brain and in platelets, and is responsible for metabolizing dopamine. In addition, abnormalities appear in glutamate pathways of the cortex and limbic structures, where a loss of neurons leads to a focus on excitotoxicity models as possible contributing factors to AD pathology.

Glutamate is the major excitatory neurotransmitter in the cortex and hippocampus. Many neuronal pathways essential to learning and memory use glutamate as a neurotransmitter, including the pyramidal neurons (a layer of neurons with long axons carrying information out of the cortex), hippocampus, and entorhinal cortex. Glutamate and other excitatory amino acid neurotransmitters have been implicated as potential neurotoxins in AD.[17] Dysregulated glutamate activity is thought to be one of the primary mediators of neuronal injury after stroke or acute brain injury. Although intimately involved in cell injury, the role of excitatory amino acids in AD is as yet unclear; however, blockade of *N*-methyl-D-aspartate (NMDA) receptors decreases activity of glutamate in the synapse and may hypothetically lessen the degree of cellular injury in AD.

Brain Vascular Disease and High Cholesterol

There is growing evidence of a causal association between cardiovascular disease and its risk factors and the incidence of AD. Cardiovascular risk factors that are also risk factors for dementia include hypertension, hypercholesterolemia, and diabetes.[18] Brain vascular disease may augment the cognitive impairment observed for a given amount of AD pathology in the brain. Dysfunctional blood vessels may impair nutrient delivery to neurons and reduce clearance of Aβ from the brain.[4] Vascular disease may accelerate amyloid deposition and increase amyloid toxicity to neurons.[4] Midlife hypertension is adversely associated with AD, while late-life hypertension may show an inverse association with AD.[19] Mechanistically, the increased risk of AD seen among patients with prediabetes and diabetes may be a result of microvascular damage or direct neurotoxicity related to

increased glucose and insulin levels.[19] Disturbances in insulin-signaling pathways, both in the periphery and the brain, have been linked to AD. Insulin may also regulate the metabolism of Aβ and tau protein.[20]

Research has found multiple links between cholesterol and AD. *APOE* is synthesized in the liver, central nervous system, and cerebrospinal fluid (CSF) and is responsible for transporting cholesterol in the blood through the brain. It is carried by low-density lipoprotein into neurons and binds to NFTs. *APOE*4* is associated with increasing deposition of Aβ and is thought to act as an accelerating modulator in vascular dementia. Elevated cholesterol levels in brain neurons may alter membrane functioning and result in the cascade leading to plaque formation and AD.

Other Mechanisms

Other hypotheses proposed to explain AD pathogenesis include oxidative stress, mitochondrial dysfunction, and loss of estrogen. Each of these mechanisms may contribute to AD pathogenesis, but the extent of the contribution is uncertain. There is a growing body of evidence of a role for oxidative stress and the accumulation of free radicals in the brain of AD patients.[4] Some epidemiologic studies suggest vitamin E, and possibly the combination of vitamin E and vitamin C, may reduce AD risk while others do not.[4] Mitochondrial dysfunction may result in disruption of energy metabolism in the neuron.[4,21,22,23] The role of estrogen in cognitive aging and dementia continues to be an active area of investigation. Despite convincing evidence that estrogens affect the brain in ways that would be expected to improve cognitive aging and reduce the risk of AD, the results of clinical studies have been largely disappointing.[21] A single common mechanism for producing AD does not exist. Regardless of the source, however, the features remain the same: degeneration of neurons in higher brain areas; accumulation of NFTs and amyloid plaques; profound destruction of cholinergic pathways; and an insidious dementia, slowly progressive until death.

CLINICAL PRESENTATION AND DIAGNOSIS

4 The onset of AD is almost imperceptible, without abrupt changes in cognition or function. Deficits occur progressively over time, affecting multiple areas of cognition.[3,23] For treatment and assessment purposes, it is helpful to divide AD symptoms into two basic categories: cognitive symptoms and noncognitive (behavioral) symptoms. Cognitive symptoms are present throughout the illness, whereas behavioral symptoms are less predictable. **Table 54-2** summarizes the stages of AD.

TABLE 54-2 Stages of Alzheimer Disease

Mild (MMSE score 26–21)	Patient has difficulty remembering recent events. Ability to manage finances, prepare food, and carry out other household activities declines. May get lost while driving. Begins to withdraw from difficult tasks and to give up hobbies. May deny memory problems
Moderate (MMSE score 20–10)	Patient requires assistance with activities of daily living. Frequently disoriented with regard to time (date, year, and season). Recall for recent events is severely impaired. May forget some details of past life and names of family and friends. Functioning may

	fluctuate from day to day. Patient generally denies problems. May become suspicious or tearful. Loses ability to drive safely. Agitation, paranoia, and delusions are common
Severe (MMSE score 9–0)	Patient loses ability to speak, walk, and feed self. Incontinent of urine and feces. Requires care 24 hours a day, 7 days a week

MMSE, Mini-Mental State Examination.

Data from References 38 *and* 124.

Diagnosis

A family member often first brings memory complaints to the attention of a primary care clinician. Up to 75% of patients who meet criteria for dementia are not given a diagnosis in the primary care setting, leading some to believe that an appropriate screening tool may be helpful in aiding diagnosis and leading to earlier treatment.[24] Despite the phenomenon of underdiagnosis, the U.S. Preventative Services Task Force concluded that there are insufficient data to recommend for or against cognitive screening for AD because it could not be determined if the benefits outweigh the risks.[24] Screening is being promoted as part of the Medicare Annual Wellness Visit by the Alzheimer's Association (AA).[25] The Mini-Mental State Examination (MMSE) is a widely used 30-point assessment tool for AD; because of its copyrighted status, however, the MMSE must either be administered from memory or paid for by the user. Alternatives to the MMSE include the Mini-Cog, the St. Louis University Mental Status Exam (SLUMS), and the Montreal Cognitive Assessment (MoCA).[26]

Until recently the only way to confirm a clinical diagnosis of AD was through direct examination of brain tissue at autopsy or biopsy. Several criteria have been used in clinical practice and research for the detection and diagnosis of dementia, including the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) criteria,[27] the Agency for Healthcare Research and Quality (AHRQ) Guidelines,[28] the American Academy of Neurology Guidelines,[29] the National Institute of Neurological Disorders and Stroke (NINDS) criteria,[30] and the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Disorders Association (ADRDA) Criteria.[31] In 2011, revisions to the NINCDS-ADRDA Criteria for the clinical diagnosis of AD were recommended by the National Institute on Aging (NIA) and the AA.[32] DSM-5 provides criteria for diagnosis of minor and major neurocognitive disorders, with specific criteria for neurocognitive disorders due to AD.[27] The new NIA-AA criteria view AD as a spectrum beginning with a preclinical phase progressing to increasingly severe clinical stages of AD. Three workgroups formulated diagnostic criteria for the dementia phase,[33] the symptomatic, predementia phase (MCI),[34] and the asymptomatic, preclinical phase of AD.[35] The preclinical phase has been further broken down into three stages—Stage 1 (asymptomatic cerebral amyloidosis), Stage 2 (asymptomatic amyloidosis plus neurodegeration), and Stage 3 (amyloidosis plus neurodegeneration plus subtle cognitive/behavioral decline).[35] As U.S. guidelines are being updated, groups from Europe and the U.K. have published guidance documents in the meantime.[36,37]

CLINICAL PRESENTATION Alzheimer Disease General

- The patient may have vague memory complaints initially, or the patient's significant other may report that the patient is "forgetful." Cognitive decline is gradual over the course of illness. Behavioral disturbances may be present in moderate stages. Loss of daily function is common in advanced stages.

Symptoms

Cognitive

- Memory loss (poor recall and losing items)
- Aphasia (circumlocution and anomia)
- Apraxia
- Agnosia
- Disorientation (impaired perception of time and unable to recognize familiar people)
- Impaired executive function

Noncognitive

- Depression, psychotic symptoms (hallucinations and delusions)
- Behavioral disturbances (physical and verbal aggression, motor hyperactivity, uncooperativeness, wandering, repetitive mannerisms and activities, and combativeness)

Functional

- Inability to care for self (dressing, bathing, toileting, and eating)

Laboratory Tests

- Rule out vitamin B_{12} and folate deficiency
- Rule out hypothyroidism with thyroid function tests
- Blood cell counts, serum electrolytes, liver function tests

Other Diagnostic Tests

- Computed tomography (CT) or magnetic resonance imaging (MRI) scans may aid diagnosis

Clinical Controversy…

Publication of the DSM-5 has changed the diagnostic criteria for AD, including the elimination of MCI and amendments to other terminology. Patients diagnosed and educated using the NIA-AA

dementia staging recommendations may require assimilation to the new DSM-5 approach, which describes a spectrum of minor to major neurocognitive disorder rather than a diagnosis of dementia of the Alzheimer type. Controversy surrounds the potential implications for patients to process their diagnosis and its implications and the added burden placed on healthcare professionals to interpret the new criteria themselves. Despite the DSM update, many clinicians continue to educate patients and their loved ones using previous diagnostic criteria to enhance understanding. Clearly, translation of the new criteria and its terminology into widely used medical jargon will require time, money, and a commitment on the part of healthcare professionals and health systems.

At this time, AD is primarily a clinical diagnosis, but this will likely change in coming years as brain imaging, CSF, and other AD biomarkers become increasingly available for routine clinical use. The patient's examination should suggest that cognitive decline from a previously higher baseline has occurred. The history should corroborate this, and further indicate that cognitive decline has reached the point where changes in social or occupational functioning are present. It is possible to administer a sophisticated exam that defines cognitive domain strengths and weaknesses and enables a neuroanatomic localization of the observed deficits. When approached in this way, the exam can indicate a pattern of cognitive decline that is consistent with AD, and assist with rendering a diagnosis that is as much a diagnosis of inclusion as it is of exclusion.

Discussing the diagnosis of dementia is potentially distressing for patients and their loved ones, especially at first. Most people, however, prefer to be told about a dementia diagnosis, as it allows them to appropriately plan for the future and access necessary support and treatment services in the meantime.[38]

Objectively defining social or occupational dysfunction can prove tricky in the older patient who may be retired, and who may also lead a socially restricted lifestyle for reasons of frailty. For such patients, the minimal requirement is to establish a change in activities of daily living. Early on, this usually involves a change in instrumental activities of daily living (handling finances and organizing medications) rather than basic activities of daily living (hygiene and dressing). Some AD subspecialists use a detailed, standardized, semistructured interview of a nonpatient informant as the most critical piece of the diagnostic evaluation.[39]

5 For patients who meet criteria for dementia (whether the underlying cause is ultimately felt to be AD or not), current recommendations from the American Academy of Neurology include a neuroimaging study (CT or MRI), as well as a serologic evaluation that includes blood cell counts, serum electrolytes, liver function tests, a test of thyroid function, and a vitamin B_{12} level.[29] When circumstances suggest AD is not the leading entity on the differential diagnosis, other neurologic tests such as CSF analysis or electroencephalogram can occasionally be justified. Neuropsychological testing is also optional, but can prove quite useful for the diagnosis of AD by helping to establish a neuroanatomical localization for the patient's cognitive deficits.

Almost any medication can contribute to cognitive impairment in vulnerable individuals, but certain classes of medication are more commonly implicated. Benzodiazepines and other sedative hypnotics, anticholinergics, opioid analgesics, antipsychotics, and anticonvulsants have been associated with

cognitive impairment.[40,41] NSAIDs, histamine H_2-receptor antagonists, digoxin, amiodarone, antihypertensives, and corticosteroids have been implicated in cases of delirium.[32] Because medications are a reversible cause of cognitive symptoms, medication review and management are essential.

Guidelines from the U.S., U.K., and Europe currently recommend that structural imaging (noncontrast enhanced CT or, ideally, MRI) be performed in the evaluation of patients with suspected dementia.[42] Efforts to define the role of other AD diagnostic tests are ongoing. Positron emission tomography scanning may reveal a pattern of hypometabolism typical of AD, but by itself the diagnostic accuracy of positron emission tomography scanning still lags behind that of the clinical examination and history.[35] *APOE* genotyping by itself is also insufficient to make or break a diagnosis of AD, but demonstrating an *APOE*4* allele in a suspected patient increases the specificity of the diagnosis and can help predict which patients with MCI are most likely to progress to a diagnosis of AD over the next several years.[43] Unless the patient developed dementia prior to age 60 years and also had a parent that developed AD before age 60 years, presenilin 1, presenilin 2, or APP genotyping is usually not indicated.

Mild Cognitive Impairment

It has long been recognized that aging individuals experience changes in cognitive function. MCI constitutes a syndromic designation that categorizes patients with cognitive complaints insufficient to warrant a diagnosis of dementia. The NIA-AA diagnostic criteria specifically address the diagnosis of MCI.[34] Persons diagnosed with MCI carry a 10% to 15% chance per year of progressing to an AD diagnosis.[44] What clinicians are likely seeing in most people with MCI is the initial manifestation of a progressive degenerative dementia that will eventually meet AD diagnostic criteria.[34,44] However, it is important to note that not everyone meeting MCI criteria will develop AD; the rate of progression of MCI to dementia remains uncertain.[45] As the MCI designation is increasingly applied, MCI criteria continue to evolve.[34,44]

TREATMENT

Desired Outcomes

6 The primary goal of treatment in AD is to symptomatically treat cognitive difficulties and preserve patient function as long as possible. Secondary goals include managing psychiatric and behavioral sequelae. Current AD treatments have not been shown to prolong life, cure AD, or halt or reverse the pathophysiologic processes of the disorder.[39]

General Treatment Approach

Clinical trials have consistently demonstrated modest benefits of early and continuous treatment with cholinesterase inhibitors.[46] Memantine added in moderate to severe disease may also provide

benefit. Following this approach allows for maximal maintenance of cognition and activities of daily living. A symptomatic approach is used to treat behavioral symptoms as they arise.

Provision of education to the patient and family at the time of diagnosis, including discussion of the course of illness, realistic expectations of treatment, and the importance of legal and financial planning, are essential to appropriate treatment.

Nonpharmacologic Therapy

7 Alzheimer disease has a profound effect on both the patient and family, so appropriate treatment is needed. Nonpharmacologic interventions are the current primary interventions for management of AD, and medications should be used in the context of multimodal interventions. Behavioral and psychiatric symptoms are among the most challenging and distressing symptoms of the disease and may be the determining factor in a family's decision to seek institutional care. Symptoms, such as sleep disturbances, wandering, urinary incontinence, agitation, and aggression in patients with dementia are best managed using behavioral interventions rather than medications whenever possible.[46,47]

Upon initial diagnosis, the patient and caregiver should be educated on the course of illness, prognosis, available treatments, legal decisions, and quality-of-life issues. Caregiving strategies, including stress-management techniques and support group options, should also be discussed. Caregiver education and support programs have been shown to improve caregiver skill, knowledge, confidence, and quality-of-life, and even delay time to nursing home placement for their loved one.[48] **Table 54-3** lists basic principles of care for the AD patient. The general approach to nonpharmacologic strategies for behavioral symptoms is to identify the symptom, identify causative factors, and adapt the caregiving environment to remedy the situation.[3] Environmental triggers may include noise, glare, and too much background distraction, including television. Personal discomfort may also trigger behaviors, so it is important to monitor for pain, hunger, thirst, constipation, full bladder, fatigue, infections, skin irritation, comfortable temperature, fears, and frustrations.[49] Medical comorbidity is a major source of functional and cognitive impairment in patients with AD, so general health maintenance is warranted.[3] Interventions should redirect the patient's attention rather than be confrontational and should specifically address known triggers. Creating a calm environment and removing stressors and triggers is key. Other nonpharmacologic approaches include exercise, light therapy, music therapy, reminiscence therapy, aroma therapy, relaxation techniques, validation therapy, massage and touch therapy, and multisensory stimulation.[50] Caregivers should be referred to support services, such as the AA, for assistance in developing nonpharmacologic strategies for managing difficult behaviors.

TABLE 54-3 Basic Principles of Care for the Patient with Alzheimer Disease

- Consider vision, hearing, or other sensory impairments
- Find optimal level of autonomy and adjust expectations for patient performance over time

- Avoid confrontation. Remain calm, firm, and supportive if the patient becomes upset
- Maintain a consistent, structured environment with stimulation level appropriate to the individual patient
- Provide frequent reminders, explanations, and orientation cues. Employ guiding, demonstration, and reinforcement
- Reduce choices, keep requests and demands of the patient simple, and avoid complex tasks that lead to frustration
- Bring sudden declines in function and the emergence of new symptoms to professional attention

Data from References 2 and 77.

The caregiver must be prepared to face the changes in life that will occur, and acceptance rarely comes easily. Denial on the part of the patient and rationalization on the part of the family are common. The clinician should encourage the family to address legal and financial matters and designate a durable power of attorney for execution of financial and medical decisions once the patient is incompetent. The caregiver will need to address issues such as respite services to provide time for rest, relaxation, and conduct of personal business. Eventually, the caregiver will need to face critical and difficult questions with respect to institutionalization. Local resources, such as the AA, can provide detailed information regarding support services. **Table 54-4** lists this and other referral sources for caregivers.

TABLE 54-4 Resources for Caregivers of Persons with Alzheimer Disease

The following organizations provide educational literature and information on diagnosis, treatment, social support, and ongoing research in Alzheimer disease:

U.S. Administration on Aging, National Family Caregiver Support Program *http://www.aoa.gov*

National Institute on Aging Alzheimer's Disease Education & Referral Center (ADEAR) *http://www.nia.nih.gov/alzheimers*

The Alzheimer's Association *http://www.alz.org*

The Alzheimer's Research Forum *http://www.alzforum.org*

AARP *http://www.aarp.org*

National Family Caregivers Association *http://www.thefamilycaregiver.org*

Family Caregiver Alliance *http://www.caregiver.org*

ElderCare Online *http://www.ec-online.net*

Education, communication, and planning are key nonpharmacologic components of caring for a patient with AD. Preparation in the early stages of illness may lessen some of the caregiver stress as the illness progresses.

Pharmacologic Therapy

Pharmacotherapy for Cognitive Symptoms

Table 54-5 presents pharmacologic treatment recommendations for managing cognitive symptoms in AD. Cholinesterase inhibitors and NMDA-receptor antagonists are indicated for treatment of AD. Current guidelines recommend initiation of cholinesterase inhibitors for AD with no preference for a specific agent.[46] Donepezil, rivastigmine, and galantamine are indicated in mild to moderate AD; donepezil is also indicated in severe disease. Despite inconclusive evidence for early intervention, cholinesterase inhibitors are commonly prescribed off-label prior to formal diagnosis of AD.[51] Memantine is indicated for moderate to severe AD; current evidence does not support its use in earlier stages of the disease.[52] Additional benefit may be achieved when memantine is added to cholinesterase inhibitor therapy in moderate to severe AD.[52] There is no evidence supporting combination therapy of more than one cholinesterase inhibitor. No head-to-head trials comparing memantine monotherapy to cholinesterase inhibitor therapy have been conducted to date.

TABLE 54-5 Pharmacologic Treatment Options for Cognitive Symptoms in Alzheimer Disease

- In mild to moderate disease, consider therapy with a cholinesterase inhibitor:
  - Donepezil or
  - Rivastigmine or
  - Galantamine
- Titrate to recommended maintenance dose as tolerated
- In moderate to severe disease, consider adding antiglutamatergic therapy:
  - Memantine
- Titrate to recommended maintenance dose as tolerated
- Alternatively, consider memantine or cholinesterase inhibitor therapy alone
- Behavioral symptoms may require additional pharmacologic approaches

Data from References 1 and 52.

Disagreement exists about how best to determine effectiveness of treatments for AD. Selection of qualitative versus quantitative assessment may bias a clinician's impression of response. Subtle

changes are often detected only by psychometric testing. Because no standard has been suggested to define the effectiveness of medications for AD, great variation exists between clinicians, and the duration of treatment ranges from months to years. Realistic expectations for treatment success may include slowed decline in behavioral, functional, and cognitive abilities and delayed long-term care placement.[53] An initial dramatic improvement in symptoms is unlikely but may be reported by a minority of patients or their caregivers.[54]

Unfortunately, clinical trials have failed to provide answers to key questions in treating AD patients. Information from clinical trials is insufficient to know if a cholinesterase inhibitor dose–response relationship exists, or if additional cognitive improvement may be gained by increasing to the maximum tolerated dose, rather than continuing with the usual recommended daily dosage. Guidance in extrapolating data related to changes in cognition is needed, so that a reasonable duration of clinical treatment with cholinesterase inhibitors and NMDA-antagonists can be determined. One concern is that those who respond to treatment may lose the benefits of that treatment once the medication is stopped.[55] Gaps in treatment have been linked with worse cognitive outcomes in clinical trial extension studies;[56] in a more recent observational study there was no increased risk of institutionalization or death associated with gaps in cholinesterase inhibitor therapy.[57] Regardless, dosing regimens should be simplified and patient/caregiver preferences considered in an effort to improve adherence and persistence.

In natural disease progression studies, scores on the Alzheimer's Disease Assessment Scale—Cognition (ADAS-cog) have been shown to worsen (increase) by an average of less than or equal to five points over 1 year in mild dementia and 7 to 11 points annually in moderate dementia. Based on these findings, the general consensus is that a four-point change in the ADAS-cog represents a clinically significant change.[46] Therefore, if a pharmacotherapeutic agent decreases the ADAS-cog score by four points, one could think of this as having delayed progression of disease symptoms by 6 months. The usefulness of the ADAS-cog in clinical practice is limited because of the time required for administration; it is much more practical to assess changes in disease severity using the MMSE. An untreated patient has an average decline of two to four points in MMSE score per year. Successful treatment would reflect a decline of less than two points a year. It is reasonable to change to a different cholinesterase inhibitor if the decline in MMSE score is greater than two to four points after 1 year with the initial agent.[58]

8 **Cholinesterase Inhibitors** In the early 1980s, researchers began to examine means to enhance cholinergic activity in patients with AD by inhibiting the hydrolysis of acetylcholine through reversible inhibition of cholinesterase. Tacrine was the first such drug to be examined in a systematic fashion. However, tacrine was fraught with significant side effects, including hepatotoxicity, which severely limited its usefulness. Tacrine is no longer available in the United States market, having been replaced by safer, more tolerable cholinesterase inhibitors. The newer cholinesterase inhibitors donepezil, rivastigmine, and galantamine show similar modest symptomatic improvements in cognitive, global, and functional outcomes in patients with mild to moderate AD, and duration of benefit varies from 3 to 24 months.[59,60] One open-label extension study of galantamine showed benefit beyond the 24-month mark.[61]

The mechanism of action differs slightly between drugs in this class.[58] Donepezil specifically and reversibly inhibits acetylcholinesterase. Rivastigmine inhibits both butyrylcholinesterase and acetylcholinesterase. Galantamine is a selective, competitive, reversible acetylcholinesterase inhibitor and also enhances the action of acetylcholine on nicotinic receptors. The clinical relevance of these differences is unknown.

Choice of cholinesterase inhibitor therapy for an individual patient is based primarily on ease of use, patient preference, cost, and safety issues, such as potential for drug interactions. Pharmacokinetic properties should also be considered, as rivastigmine and galantamine have short half-lives (1.5 and 7 hours, respectively) compared to donepezil (70 hours). As such, if rivastigmine or galantamine treatment is interrupted for several days or longer, the patient should be restarted at the lowest dose and titrated to the current dose. This is true for all formulations of these drugs, including the rivastigmine transdermal patch.[62,63,64] Dosing strategies for cholinesterase inhibitors and memantine are summarized in **Table 54-6**.

TABLE 54-6 Dosing of Drugs Used for Cognitive Symptoms

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Cholinesterase Inhibitors					
Donepezil	Aricept, Aricept ODT	5 mg daily in the evening	5-10 mg daily in mild to moderate AD 10-23 mg daily in moderate to severe AD	No dosage adjustments recommended	Available as: tablet, ODT Can be taken with or without food Weight loss associated with 23 mg daily dose
Rivastigmine	Exelon, Exelon Patch	1.5 mg twice daily (capsule, oral solution) 4.6 mg/day (transdermal patch)	3-6 mg twice a day (capsule, oral solution) 9.5-13.3 mg/day (transdermal patch)	Capsule/oral solution: Renal impairment, hepatic impairment, or low body weight (≤50 kg [<110 lb]): Patients may be able to only tolerate lower doses Transdermal patch: Mild to moderate hepatic impairment or low body weight: consider maximum daily dose of 4.6 mg every 24 hours	Available as: capsule, oral solution, transdermal patch Take with meals Also indicated for Parkinson disease dementia Application of multiple transdermal patches at same time associated with hospitalization

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
					and death
Galantamine	Razadyne, Razdyne ER	4 mg twice daily (tablet, oral solution) 8 mg daily in the morning (extended-release capsule)	8-12 mg twice a day (tablet, oral solution) 16-24 mg (extended-release capsule)	Moderate renal or hepatic impairment: maximum daily dose of 16 mg Severe renal or hepatic impairment: not recommended	Available as: tablet, oral solution, extended-release capsule Take with meals
***N*-methyl-D-aspartate (NMDA) Receptor Antagonist**					
Memantine	Namenda, Namenda XR	5 mg daily 7 mg daily (extended-release capsule)	10 mg twice daily 28 mg daily (extended-release capsule)	Severe renal impairment: recommended maintenance dose of 5 mg twice daily (tablet, oral solution) or 14 mg daily (extended-release capsule) Severe hepatic impairment: administer with caution	Available as: tablet, oral solution, extended-release capsule Can be taken with or without food Can open extended-release capsule and sprinkle contents on applesauce for ease of administration
Cholinesterase Inhibitor + NMDA Receptor Antagonist					
Memantine + Donepezil	Namzaric	28 mg/10 mg	14-28 mg/10 mg daily	Severe renal impairment: 14 mg/10 mg daily	Available as: memantine extended-release and donepezil capsule Can be taken with or without food Can open capsule and sprinkle contents on applesauce for ease of administration

ODT, orally disintegrating tablet.

Data from References 62,63,64, 69, 70, 125, and 126.

Adverse drug reactions and corresponding monitoring parameters are described in **Table 54-7**. Cholinesterase inhibitors have similar adverse event profiles, and this class of drugs is generally well-tolerated. The most frequent adverse events associated with these agents are mild to moderate GI symptoms (eg, nausea, vomiting, and diarrhea).[45] Gradual dose titration over several months can improve tolerability.[26] Alternatives to the immediate-release tablet/capsule dosage form are available for patients who have complex dosing regimens, tolerability issues, or difficulty swallowing, though cost may be prohibitive until they are generically available. Patients and caregivers should be cautioned against abrupt discontinuation of cholinesterase inhibitor therapy, as this can lead to worsening cognition and behavior in some patients.[65] Concurrent use of anticholinergic medications with cholinesterase inhibitors should be avoided and nonpharmacologic interventions employed to manage urinary incontinence, if possible.[66]

TABLE 54-7 Monitoring Drug Therapy for Cognitive Symptoms

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Galantamine	Serious skin reactions (Stevens-Johnson syndrome and acute generalized exanthematous pustulosis)	Appearance of skin rash	Discontinue galantamine at first sign of skin rash, unless clearly not drug-related If signs/symptoms are suggestive of a serious reaction, consider alternative treatment and do not rechallenge
Rivastigmine	Allergic dermatitis	Application site reaction spread beyond patch size, evidence of a more intense local reaction (increasing erythema, edema, papules, vesicles), and if symptoms do not improve within 48 hours of patch removal	Discontinue rivastigmine if evidence of disseminated allergic dermatitis appears Patients sensitized by exposure to the transdermal patch may not be able to take rivastigmine by mouth either; allergy testing and close medical supervision recommended
Cholinesterase inhibitors	Dizziness, syncope, bradycardia, atrial arrhythmias, myocardial infarction, angina, seizures,	Report of dizziness or falls, pulse, blood pressure, and postural blood pressure change	Dizziness is usually mild, transient, and not related to cardiovascular problems Routine pulse checks at

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
	sinoatrial and atrioventricular block		baseline, monthly during titration, and every 6 months thereafter
			Take with food to decrease GI upset
			Usually transient, dose-related GI adverse effects seen with drug initiation, dosage titration, or drug switch
Cholinesterase inhibitors	Nausea, vomiting, diarrhea, anorexia, and weight loss	Weight and GI complaints	Debilitated patients or those weighing <55 kg (<121 lb) may be more likely to experience GI adverse effects and significant weight loss, particularly when rivastigmine is prescribed or when titrating to donepezil 23 mg
			GI adverse effects less prominent with transdermal versus oral rivastigmine
Cholinesterase inhibitors	Peptic ulcer disease, GI bleeding	Signs or symptoms of active or occult GI bleeding	Of particular concern for patients at increased risk of developing ulcers, such as those with a history of ulcer disease or concurrently taking NSAIDs
Cholinesterase inhibitors	Insomnia, vivid/abnormal dreams, nightmares	Complaints of sleep disturbances, daytime drowsiness	Donepezil can be taken in the morning to decrease risk of sleep disturbances
Memantine	Headache, confusion, dizziness, hallucinations	Report of dizziness or falls, hallucinations	Confusion may be observed during dose titration and is usually transient
			Memantine may mitigate GI adverse effects associated with cholinesterase inhibitor therapy
Memantine	Constipation	GI complaints	

NSAIDs, nonsteroidal antiinflammatory drugs.

Data from References 3, 46, 62,63,64, 69, 70, 125, and 126.

Depending on individual patient response, tolerability, and preference, switching to an alternate dosage form of cholinesterase inhibitor agent may be necessary during the course of AD treatment. Manufacturer recommendations for switching between dosage forms of the same drug are specified in the prescribing information, but the optimal procedure for switching between agents remains uncertain. When switching from one cholinesterase inhibitor to another due to side effect intolerance, a washout period is recommended.[54] Length of the washout period may vary based on drug pharmacokinetics and time to side effect resolution.[54,58] Some patients who fail to respond to donepezil, rivastigmine, or galantamine, may respond when switched to a different drug; in the case of lack of initial benefit, an overnight switch is preferred to minimize potential for clinical deterioration.[54,58] To clarify, loss of benefit over time may not be an appropriate reason to switch cholinesterase inhibitors, as the progressive nature of AD is likely to become more noticeable over time.[58] Indeed, initiation of memantine may be a more appropriate next step as patients progress in their disease course.[58]

8 **Antiglutamatergic Therapy** Memantine is the only NMDA-antagonist currently available. At concentrations achieved at least under in vitro conditions, memantine blocks glutamatergic neurotransmission by antagonizing NMDA receptors. Glutamate is an excitatory neurotransmitter in the brain implicated in long-term potentiation, a neuronal mechanism important for learning and memory.[67] Blocking NMDA receptors can mitigate excitotoxic neurotoxicity and potentially provide neuroprotection (as has been suggested in animal models); however, there is currently no clinical evidence to indicate memantine confers neuroprotection in AD.[68]

Memantine is currently indicated for use in moderate to severe AD. Its use has been studied in patients with moderate and severe AD as monotherapy and in combination with donepezil with favorable results on cognition and function.[52] Studies of memantine alone and in combination with cholinesterase inhibitors in mild AD performed to date have provided insufficient evidence to support an indication for mild AD.[52]

In its tablet or oral solution form, memantine should be initiated at 5 mg once a day and titrated weekly in 5 mg intervals to the target maintenance dose of 10 mg twice daily. The extended-release capsule form of memantine is to be initiated at 7 mg daily and titrated up to a maximum of 28 mg daily. Dose titration is achieved in 7 mg intervals with at least 1 week between dose adjustments. Dosing of 5 mg twice daily (tablet and oral solution) or 14 mg daily (extended-release capsule) is recommended in patients with severe renal impairment (creatinine clearance of 5-29 mL/min [0.08-0.49 mL/s]).

Overall, memantine has been well-tolerated in clinical trials. The most common adverse events include headache, constipation, confusion, and dizziness. Memantine has 100% bioavailability regardless of administration with or without food. Protein binding is relatively low (45%). Memantine is not metabolized by the liver and does not inhibit cytochrome P450 activity. It is primarily excreted

unchanged in the urine, and the half-life of memantine ranges from 60 to 80 hours.[69,70]

Role of Combination Therapy Combination therapy with memantine added to cholinesterase inhibitor therapy is generally prescribed for patients with moderate to severe AD. The rationale for this add-on therapy is that the drug classes have different mechanisms of action.

Combination therapy has been supported in several randomized controlled trials (RCTs) and reviews.[71] Combination therapy has been shown to slow cognitive and functional decline to a statistically significant degree compared to cholinesterase inhibitor monotherapy or no treatment.[71] One trial randomized patients with moderate to severe AD already receiving stable donepezil treatment to either memantine or placebo. At the end of this 6-month trial, patients randomized to receive memantine (combination therapy) had significantly better outcomes in measures of cognition, function, behavior, and global status than those continued on donepezil monotherapy. The group randomized to receive memantine also had a lower rate of discontinuation due to adverse events versus placebo.[72] Based on data from this study and others, memantine may have a role in mitigating GI adverse events associated with cholinesterase inhibitors.[46]

In 2014, a combination product containing memantine extended-release and donepezil was approved by the U.S. Food and Drug Administration (FDA) for moderate to severe dementia in patients already stabilized on memantine and donepezil. As drug effectiveness was based on bioequivalence with the two active ingredients, the package insert separately lists the most common side effects of memantine extended-release (headache, diarrhea, and dizziness) and donepezil (diarrhea, anorexia, vomiting, nausea, and ecchymosis). The fixed-dose combination product comes in two strengths, and dosage reduction is recommended in the case of severe renal impairment. No dosage adjustments are needed in patients with mild or moderate renal or hepatic impairment. The drug has not been studied in patients with severe hepatic impairment.

Clinical Controversy…

In light of the irreversible nature of AD and prolonged benefits seen with long-term use of cholinesterase inhibitors alone and in combination with memantine,[71] the question of when, if ever, to stop drug therapy for AD remains controversial. In the case of AD, treatment benefits are not always evident, and the combined perception of slowed progression and fear of deterioration can lead patients to be prescribed drug therapy from diagnosis to death. One could choose to withdraw medications until the time of nursing home placement; then, however, it is possible that drug therapy could help manage behavioral disturbances of AD. Some clinicians will recommend withdrawing AD drug therapy if the patient significantly deteriorates in cognition or function, while others wait until the patient has lost all cognitive and functional abilities. As such, side effects, cost, and family request factor heavily into drug therapy discontinuation decisions. If cholinesterase inhibitors are discontinued and cognition worsens or behavioral issues emerge, the drugs can be restarted.

Effect of Current Treatments on Neurodegenerative Processes AD is a progressive disorder. Affected individuals typically experience some degree of cognitive decline and histologic change years (if not decades) before a diagnosis is made. Therefore, the ideal treatment will be one that not only reverses symptoms by enhancing cognitive function (a symptomatic treatment), but also arrests

the neurodegeneration-relevant molecular processes that underlie cognitive decline (a disease-modifying treatment).

Clinical trials for AD prompt consideration of whether positive outcomes suggest either a symptomatic or disease-modifying effect. Any rapid performance improvement in cognitive ability, activities of daily living, or behavioral end points is indicative of a symptomatic effect. All cholinesterase inhibitor agents and memantine demonstrate this pattern. On the other hand, arrest of decline or a sustained reduction in the slope of decline would argue the presence of a disease-modifying effect. It has not been possible to unequivocally demonstrate this in trials of the currently approved treatments. Long-duration, double-blind, placebo-controlled trials to evaluate whether cholinesterase inhibitors, with or without memantine, have disease-modifying effects are difficult to perform, because doing so would require continuing a placebo arm over an extended period, well beyond demonstration of symptomatic benefit. Also, subject attrition over an extended study would complicate both intent-to-treat and observed case analyses.

With the currently approved AD drug treatments, pivotal placebo-controlled trials were followed by open-label extension studies. Published studies have lasted as long as 5 years, and as part of these studies, decline in the treatment group was compared with “projected” placebo groups based on the placebo groups followed during the 6-month randomized phase of the efficacy study, as well as natural history cohorts from the precholinesterase inhibitor therapy era. Although analyses of this sort conclude that, for up to at least 5 years, persons receiving treatment exceed their projected nontreatment cognitive performance, no convincing evidence of a disease-modifying effect emerges.[61,73,74,75,76]

Management of Brain Vascular Health

9 Guidelines for the care of patients with AD support the management of vascular brain disease and its associated risk factors as part of the treatment of AD.[77] There is a growing body of evidence that brain vascular disease plays a role in the progression of dementia. For a given level of AD pathology, vascular disease in the brain may add to the degree of cognitive impairment.[78] Management of brain vascular disease includes monitoring blood pressure, glucose, cholesterol, and homocysteine and initiation of appropriate interventions.[78] Elevated homocysteine levels are associated with vascular disease. Some studies also suggest an association with brain atrophy, NFTs, and AD, but there remains insufficient evidence of a benefit of B vitamin supplementation on cognitive function in patients with AD at this time.[1,19,79]

The World Health Organization and Alzheimer’s Disease International encourage primary prevention through public health campaigns targeting smoking, underactivity, midlife obesity, midlife hypertension, and diabetes.[80] Adherence to the Mediterranean Diet (MeDi) or Dietary Approaches to Stop Hypertension (DASH) diet may reduce the risk of cognitive impairment or decline.[19,79] Physical activity is an important component of vascular brain health and has been shown in some short-term studies to be associated with a reduced risk of cognitive impairment as well.[19] Of note though is that most positive trial findings have been from cognitively healthy older adults.[19,79]

While appropriate management of vascular disease risk factors may reduce the risk for developing AD,[81] insufficient evidence exists to draw definitive conclusions on the association between risk factor modification and risk of AD.[19,78]

Other Potential Treatment Approaches

Estrogen replacement has been studied extensively for the treatment and prevention for AD. Most, but not all, retrospective epidemiologic studies show a lower incidence of AD in women who took estrogen replacement therapy postmenopausally. Prospective clinical trials have not supported the use of estrogen as a treatment for cognitive decline, and longer trials tend to suggest harm. Overall, the evidence does not support the use of estrogen to treat or prevent dementia.[82] Although phytoestrogens, found in soy-containing foods and soy-derived dietary supplements, have been suggested for the treatment or prevention of dementia, there are no clinical trials supporting the use of these treatments for dementia.[82]

Antiinflammatory Agents Retrospective epidemiologic studies suggest a protective effect against AD in patients who have taken NSAIDs. The benefits of antiinflammatory agents have been less compelling in prospective clinical studies. NSAIDs have had no cognitive benefit in AD patients or else benefits so minimal the risk of harm exceeds the potential benefit.[83] Because there is a lack of compelling data and also a significant incidence of adverse effects, particularly gastritis and the possibility of GI bleeds, NSAIDs and prednisone are not recommended for general use in the treatment or prevention of AD.[83]

Lipid-Lowering Agents An AD protective effect has been postulated for lipid-lowering agents, particularly the 3-hydroxy-3-methylglutaryl-coenzyme A-reductase inhibitors. Longitudinal epidemiologic studies suggest an association between elevated midlife total cholesterol levels and AD.[18] Increased risk of dementia does not appear to be associated with hypercholesterolemia in late life however.[18] Other studies note that the incidence of AD is lower in patients who have taken either a statin or another lipid-lowering agent, but not in patients who were taking other cardiovascular medications.[18] It is important to note that not all epidemiologic studies suggest an association between cholesterol and AD.[18]

Randomized controlled trials of statin therapy given in late life to patients at risk for vascular disease indicate that statins do not prevent AD.[84] Four randomized placebo-controlled trials of statin therapy indicated no significant benefit of statin therapy in patients with probable or possible AD.[84] Interestingly, cognitive impairment has been recognized as a rare adverse event associated with statin therapy. More research is needed to understand the complex relationship between cholesterol, statin therapy, and cognitive functioning. For now these agents should be reserved for patients who have other indications for their use.

Dietary Supplements

Dietary supplements are widely used for the prevention and treatment of AD, and available evidence

has been reviewed.[85,86,87,88] A detailed discussion of the many nutraceuticals, herbal products, and medical foods that have been promoted for the prevention and treatment of AD is beyond the scope of this chapter. The more commonly used dietary supplements are described here.

Vitamin E Based on pathophysiologic theories involving oxidative stress and the accumulation of free radicals in AD, significant interest has evolved regarding the use of antioxidants in the treatment of AD. Two RCTs have evaluated the effects of vitamin E supplementation (1,000 IU twice daily) in patients with AD.[89] The first studied patients with moderate AD for 2 years and demonstrated a significant delay in the time to institutionalization in the treatment group compared to placebo. The second trial studied the efficacy of α-tocopherol, memantine or their combination in delaying clinical progression of AD in patients taking an acetylcholinesterase inhibitor with mild to moderate AD (mean follow-up time of 2.3 years) and showed a reduced annual rate of decline in ADLs in those treated with vitamin E but no cognitive benefits. No significant side effects were reported between treatment groups in either study; however, a meta-analysis found that high-dose vitamin E increases mortality in supplemented subjects.[90] In addition, vitamin E had no benefit in patients with MCI in the progression to AD.[91] In light of these findings, there is insufficient evidence to recommend vitamin E supplementation for the treatment of AD. Vitamin E remains under investigation for the prevention of AD.

Ginkgo biloba *Ginkgo biloba* for the prevention and treatment of AD has been extensively studied. Proposed mechanisms for Ginkgo's use in AD include its potential to increase blood flow, decrease blood viscosity, antagonize platelet-activating factor receptors, increase anoxia tolerance, inhibit monoamine oxidase, and serve as an antioxidant. Active ingredients in *Ginkgo biloba* include flavonoids, the Ginkgo flavone glycosides, and bioflavonoids. Most studies reporting benefit in patients with cognitive impairment or dementia have studied a standardized extract, EGb 761, in doses of 240 mg/day for 22 to 26 weeks.[92] The clinical significance of the modest benefits detected is unclear, and direct comparisons to cholinesterase inhibitors or memantine are lacking. A large trial of *Ginkgo biloba* in which the 120 mg twice a day dose was studied did not reduce either the overall incidence rate of dementia or AD incidence in elderly individuals with normal cognition or MCI.[93] Another large trial found that the long-term use of *Ginkgo biloba* extract did not reduce the risk of progression to AD among older adults suffering from memory complaints compared with placebo.[94] Side effects reported from EGb 761 studies were typically mild, including nausea, vomiting, diarrhea, headaches, dizziness, palpitations, restlessness, and weakness. Because EGb also has a potent antiplatelet effect, it should be avoided by individuals taking anticoagulant or antiplatelet therapies, and should be used cautiously in patients taking NSAIDs.[94,95]

Huperzine A It is an alkaloid isolated from the Chinese club moss, *Huperzia serrata*. It reversibly inhibits acetylcholinesterase and is administered orally in doses of 50 to 200 mcg two to four times daily. Short-term clinical studies suggest huperzine A shows efficacy in the symptomatic treatment of AD compared to placebo, but more studies are needed to determine its place in therapy. The current consensus is that huperzine A has not been adequately studied for use in AD, its consistent potency and purity in commercially available products remains a concern, and potential side effects could be significant, especially in those taking cholinesterase inhibitors.[96]

Polyphenols Several epidemiological studies have demonstrated that moderate ingestion of wine, but not distilled spirits, is associated with a lower incidence of AD.[86] One of the components of red wine, resveratrol, has been the focus of research related to dementia. Resveratrol, a phenolic compound with antioxidant properties, is found commonly in foods such as grapes, peanuts, chocolate, blueberries, and red wine. Resveratrol's proposed benefits in AD are to prevent reactive oxygen species-induced Aβ production and apoptosis-mediated neurodegeneration.[86] A Phase II randomized, double-blind, placebo-controlled study of resveratrol 500 mg daily for 13 weeks followed by 1,000 mg daily for 39 weeks in patients with mild to moderate AD found alterations in plasma and CSF biomarkers, but further studies are needed to establish the clinical significance of these changes.[97]

The polyphenol curcumin (turmeric) is a spice used in Indian curry that has antioxidant and antiinflammatory properties and has been proposed as one explanation for the lower incidence of AD in India compared to the United States.[98] Curcumin may prevent or treat AD by decreasing amyloid plaque formation, clearing existing plaques, and chelating metal ions.[98] Early studies with curcumin in AD did not provide evidence supporting its benefit in AD, but this may have been due to the poor oral availability of curcumin, insufficient dosing, and short duration of the trials. Synthetic formulations of curcumin as well as pharmaceutical modifications of the naturally occurring curcumin are being developed to improve the bioavailability of curcumin.[98] Studies are ongoing to evaluate the efficacy, safety, and dosing of curcumin for the treatment of AD.

Medical Foods Several medical foods have been studied for the treatment of MCI or AD. Medical foods constitute a unique category that consists of ingestible entities specifically intended for the treatment of diseases that have "specific nutritional requirements" and in which the medical food may manipulate disease-relevant pathophysiology. Although medical foods regulatory approval standards are not as rigorous as those required for approvals of new medications, medical foods are obtained only by prescription. The only medical food studied in mild to moderate AD is AC1202 (Axona), a mixture of medium-chain fatty acids, consisting primarily of the C8 fatty acid caprylic acid.[99] AC1202 is converted by the liver to a ketone body, β-hydroxybutyrate, which is released into the blood stream. β-hydroxybutyrate crosses the blood–brain barrier and can be used as an oxidative phosphorylation substrate by neuronal mitochondria. Support for AC1202 efficacy in the treatment of AD comes mostly from a phase IIb trial in which subjects randomized to 40 mg/day of AC1202 for 45 days performed relatively better on the ADAS-cog than did subjects randomized to a placebo.[100] A subanalysis of these data revealed that this benefit was entirely driven by subjects who did not have an *APOE*4* allele. For *APOE*4* carriers, ADAS-cog performance between subjects receiving AC1202 and placebo were comparable at all time points studied. GI-related side effects were common, but in general side effects were felt to be mild. Coconut oil is a source of caprylic acid, but does not contain sufficient quantities to meet the needs of a person with AD.[85] Coconut oil continues to be used by some patients as a less expensive alternative to AC1202 however.

Tramiprosate Tramiprosate (homotaurine), or Alzhemed, showed promise as a treatment for AD in early development. In animal studies, homotaurine demonstrated the ability to interfere with amyloid plaque formation and subsequent degeneration of neuronal cells. Phase III trials were disappointing, and the FDA declined to approve marketing of homotaurine as a prescription drug. Homotaurine is

naturally occurring in seaweed, and is now available as the dietary supplement Vivimind for age-associated memory impairment.[67]

Omega-3 Fatty Acids Arguments that omega-3 fatty acids found in fish oil, such as docosahexaenoic acid and eicosapentaenoic acid, could benefit AD subjects have existed for some years. A large prospective, placebo-controlled trial of docosahexaenoic acid in AD subjects was recently reported. For the most part, results were disappointing, and although it could not be ruled out that population subsets did benefit, the primary study end points were negative.[101] There is insufficient evidence at this time to recommend docosahexaenoic acid for the treatment of AD.

Drugs and Treatment Strategies in Development

New drug development is focused on disease-modifying and prevention strategies and falls broadly into several categories: treatments designed to reduce levels of brain Aβ or manipulate its configuration, treatments targeting tau protein, antiinflammatory approaches, and therapies to address insulin resistance in the brain. Although many potential new drugs have advanced to early clinical studies, there have been no new agents entering the market since 2004. Progress has been made in developing novel biomarkers and improving clinical trial designs, but results of clinical trials remain disappointing.[102]

Reducing Aβ Formation To reduce brain amyloid levels, approaches to both reducing Aβ production and enhancing its removal have been and still are undergoing evaluation. Aβ is produced through enzymatic processing of APP by two enzyme complexes, the β- and γ-secretases. β-Secretase inhibitors have entered phase II and III human trials and promising agents remain in the pipeline.[103] Agents that specifically inhibit γ-secretase have proved to be problematic both from a side-effect perspective, as γ-secretase is also critical for processing Notch3, a protein of developmental importance and perhaps brain maintenance, and also from an efficacy perspective. Stimulation of α-secretase blocks the formation of Aβ and generates neuroprotective peptide that is another strategy to reduce Aβ. Therapies aimed at activating α-secretase are currently under investigation.[104]

Increasing Aβ Clearance Immunotherapy approaches have been studied as a way to enhance Aβ removal. Active and passive immunization have been most widely studied immunotherapy approaches for AD over the past decade. Active immunization involves administering a vaccine containing antigens designed to cause antibody generation in the patient. In passive immunization, exogenous antibodies are administered. In both cases the goal is for the antibodies to clear amyloid plaques from the brain of patients with AD. An advantage of active immunization is that a small number of vaccine administrations results in a long-term antibody response. Research on active immunization strategies has been hampered by variability in response among patients, serious and persistent adverse events, and potentially reduced immune response by a senescent immune system; however, this remains an active area of research.[105] Passive immunization approaches with polyclonal and monoclonal antibodies allow for reproducible administration and rapid clearance of the antibodies, but have the disadvantage of requiring repeated administration. Although some agents for passive immunization have failed in Phase III clinical trials (bapineuzumab and solanezumab) due to lack of efficacy, others remain under active investigation.[105]

Preventing Aβ Aggregation Proponents of the amyloid cascade hypothesis claim the species of Aβ that is most likely to prove relevant to AD neurodegeneration are Aβ oligomers formed through limited aggregation of Aβ monomers. Tramiprosate was designed to prevent Aβ oligomer formation and tested clinically in a large phase III trial. No evidence of efficacy was seen.[106] Other agents targeted at this mechanism, including inositol, remain under clinical investigation. Metals such as zinc, copper, and iron play a role in Aβ aggregation. Metal chelators are also being developed for potential treatment of AD.[106]

Targeting Tau Targeting tau has been challenging, and thus far there are few therapeutic options in clinical trials. One approach is to administer small molecular weight compounds such as the dye methylene blue that inhibit formation of tau oligomers and fibrils and thus prevent tau aggregation.[103] Another approach is inhibition of kinase-mediated phosphorylation since tau hyperphosphorylation leads to tau dysfunction and aggregation. Agents studied included lithium and valproate, but trials results were disappointing.[103] Immunotherapy is also under investigation, with the first clinical investigation of vaccines targeting misfolded, truncated tau underway.[103]

Reducing Oxidative Stress and Inflammation in the Brain Inflammation, oxidative stress, and mitochondrial dysfunction in chronic neurodegenerative disorders contribute to the neuronal dysfunction and loss that occurs in these conditions. Production of Aβ and hyperphosphorylated tau may simply be downstream cell responses to the cycle of inflammation and oxidative stress that eventually overwhelms the neuron's ability to compensate. Targeting the upstream oxidative stress and inflammation is an active area of investigation. Nutriceuticals and vitamins, as well as antiinflammatory medications (etanercept, prednisone, ibuprofen, indomethacin, naproxen, celecoxib, rofecoxib, atorvastatin, simvastatin, rosuvastatin, pravastatin, rosiglitazone, and the mitochondrial stabilizer latrepirdine) have shown promising results in preclinical studies and early clinical investigations, but subsequent clinical trials have often been conflicting or negative.[107] One possible explanation is that the benefit from these agents may be in primary prevention before damage is severe enough that symptoms of cognitive decline are evident.[107]

Targeting Insulin Resistance in the Brain Low levels of insulin and insulin resistance in the brain are associated with cognitive impairment and AD. Individuals with type 2 diabetes have a twofold higher risk of developing AD.[108] One of the actions of insulin in the brain is to modulate the levels of Aβ, leading researchers to explore this area for potential treatment opportunities. One promising approach is a new class of diabetes medications, glucagon-like peptide-1 receptor agonists. Liraglutide has been shown to reduce amyloid production and protect neurons from resulting damage in animal models, and early clinical trials are ongoing.[106] Early clinical studies with intranasal insulin showed improvement in memory and daily functioning in patients with MCI and mild or moderate AD.[109] A large multicenter trial of this treatment strategy is underway.[108]

Suggestions of efficacy in phase II trials in no way ensure efficacy will be seen in phase III trials. This caveat seems especially pertinent in AD drug development, as phase II trials of flurbiprofen, tramiprosate, rosiglitazone, latrepirdine, bapineuzumab, and solanezumab all reported some evidence of efficacy that did not bear out in phase III studies. Obviously, successful development of new AD treatments depends on elucidating AD's true underlying pathophysiology. One reason for

the failure of so many AD therapies may be that current strategies do not target the pathways that ultimately result in AD. Another reason may be that medications are being initiated when the disease has already progressed too far to be reversed.[103] New approaches include studying amyloid-blocking agents in patients with genetic predisposition to early-onset AD before symptoms are present and studying patients with biomarkers of disease risk or presymptomatic signs of disease to determine the potential value of new treatments. Prevention trials are currently underway in both genetically determined AD and sporadic AD.[103]

Pharmacotherapy of Noncognitive Symptoms

Most patients with AD manifest noncognitive symptoms at some point in the illness.[110] These symptoms can be roughly divided into three categories: (1) psychotic symptoms, (2) inappropriate or disruptive behavior, and (3) depression. Effective management of these problems is important because behavioral symptoms are distressing to both the patient and the caregiver, necessitate increased caregiver supervision and patience, and are a leading reason for nursing home placement.

10 Strategies for treatment of psychotic or behavioral symptoms should include nonpharmacologic interventions first, then pharmacologic interventions only when necessary. Behaviors, such as agitation, aggression, delusions, hallucinations, repetitive vocalizations, and wandering, may be caused by medications, medical illness (eg, pain, constipation, dehydration, and infection), environmental precipitants, poor caregiving, physical/verbal abuse, and unmet physical or psychological needs. These possible underlying causes should be explored and corrected when possible before initiating drug therapies.[110] The need for medications may exist when neuropsychiatric symptoms are of sufficient severity to cause significant distress to the patient or caregiver, interfere with function or cause disability, impede delivery of necessary care, or pose a danger to self or others and have not responded to nonpharmacologic interventions.[46,110,111] The balance between risks of the medication and expected benefits must be acceptable to the patient or surrogate decision maker. Medications should be used cautiously, with adequate monitoring for efficacy and adverse events.

Despite the high prevalence of noncognitive symptoms in AD, relatively little research has been conducted in these patients. To date, no drug has been approved by the FDA for the treatment of behavioral disturbances in patients with dementia. Because of limited clinical data, treatment is primarily empiric, with side-effect profiles used as a guide in selecting the appropriate treatment. Psychotropic medications with anticholinergic effects should be avoided because they may actually worsen cognition and interfere with cholinesterase inhibitor therapy.

General guidelines governing pharmacologic therapy can be summarized as follows: reserve for situations where nonpharmacologic therapies have failed, use reduced doses, monitor closely, titrate dosage slowly, minimize the duration of therapy, and document carefully. Treatment should be considered as temporary.[110,111] Caregivers may have unrealistic expectations regarding the effects of psychotropic medications, and the anticipated benefits and risks of therapy should be clearly explained. Disruptive behaviors and delusions wax and wane with disease progression, and some behaviors (eg, wandering, hoarding, screaming, and repetitive behaviors) lack evidence of response

to medication.[112] Attempts to slowly taper and discontinue medication should be undertaken regularly in minimally symptomatic patients, as behaviors often fluctuate, changing in character and intensity over time, and the medication may no longer be providing a benefit.[110]

Cholinesterase Inhibitors and Memantine

Clinical trials with cholinesterase inhibitors have reported modest benefit in managing neuropsychiatric symptoms, although these are generally not the primary outcomes studied in the trials, and the clinical significance is controversial.[110] Cholinesterase inhibitors may not significantly reduce agitation when administered to patients experiencing acute agitation.[113] Memantine shows modest behavioral benefits as well in trials of patients with moderate to severe dementia, either alone or in combination with cholinesterase inhibitors;[110] however, a recent trial of memantine specifically evaluating the effect of memantine to treat agitation in patients with AD found no difference compared to placebo.[114] These benefits should be considered along with cognitive benefits in treatment decisions and weighed against the side effects associated with these medications. Long-term effects on behavior have not been demonstrated to date, and further research is needed.

Antipsychotics

Antipsychotics are often used in the management of neuropsychiatric symptoms in AD despite efforts by CMS and other groups to reduce their use in nursing homes.[115] There is modestly convincing evidence that most of the atypical antipsychotics provide some benefit for particular neuropsychiatric symptoms, but these data have been insufficient to gain FDA approval as an indication for the management of behavioral symptoms in AD. More than 15 RCTs have evaluated atypical antipsychotics for behavioral symptoms of dementia, with more than 5,000 patients participating and treatment durations of 8 to 12 weeks for most trials. Based on one systematic review and meta-analysis, aripiprazole (three trials), risperidone (five trials) but not olanzapine (five trials) showed benefit for managing behavioral symptoms of dementia. Studies of quetiapine (three trials) could not be statistically combined due to methodological differences in inclusion criteria and outcomes assessed, so the evidence for quetiapine was insufficient for evaluation. The analysis showed that lower efficacy was associated with having less severe cognitive impairment and having psychosis.[110] Similar results were noted in a second meta-analysis, except that olanzapine showed efficacy for treating the symptoms of aggression and agitation, but not psychosis.[110] In a double-blind, placebo-controlled trial of 421 outpatients with AD and psychosis, aggression, or agitation randomized to receive olanzapine, quetiapine, risperidone, or placebo for up to 36 weeks, there were no significant differences among the treatments in time to discontinuation of treatment or improvement based on the Clinical Global Impression–Change (CGI-C) response. The investigators concluded that adverse effects offset advantages in the efficacy of atypical antipsychotic drugs for treatment of psychosis, aggression, or agitation in patients with AD.[116] Adverse events are common with atypical and typical antipsychotics in patients with AD. Adverse events associated with atypical antipsychotics include somnolence, extrapyramidal symptoms, abnormal gait, worsening cognition, cerebrovascular events, and increased risk of death.[110] In 2005, the FDA mandated the addition of a

"black box warning" to all atypical antipsychotics due to increased risk of mortality in older adults with dementia-related psychosis. Compared to atypical agents, typical antipsychotics are more commonly associated with more severe extrapyramidal effects and hypotension. In 2008, the FDA "black box warning" for increased mortality in older adults treated for dementia-related psychosis was expanded to include typical antipsychotics.[117] Chapter 67 includes a more detailed discussion of antipsychotic adverse events. Overall, there is a modest expectation of treatment benefit and potential for significant harm associated with antipsychotic use in patients with AD. Individual risk and benefit must be considered when initiating therapy. Prescribing of antipsychotics in AD should be restricted to patients with severe symptoms that have not responded to other measures, and treatment should be tapered as early as possible.[111] Diligent monitoring during treatment is essential, as is frequent reassessment of continued need. A meta-analysis of RCTs of antipsychotic discontinuation showed no significant difference in change in severity of behavioral and psychological symptoms of dementia upon discontinuation compared to the continuation group.[118]

Antidepressants

Depressive symptoms are common in patients with AD. Apathy is seen in 48% to 92% of individuals with dementia, and clinically significant depression occurs in approximately 32% with mild dementia, 23% with moderate disease, and 18% in the severe stage of the dementia.[119] Some trials have studied the efficacy of antidepressants in treating depression in patients with AD, but the results are conflicting.[110] Small sample size, short duration of treatment, and differing measures of therapy outcomes limit comparison across studies and may account in part for conflicting study results.[119] Improvement in patients receiving placebo is also common. In practice, treatment with selective serotonin reuptake inhibitors (SSRIs) is initiated most commonly in patients with AD, based on side-effect profile and evidence of efficacy;[110] however, a study comparing sertraline, mirtazapine, and placebo found no benefit for these agents in treating depression in patients with dementia.[120] Among the SSRIs, the best evidence exists for sertraline and citalopram.[110] Serotonergic function may also play a role in some of the other behavioral symptoms of AD, such as agitation, and some studies support the use of SSRIs in the management of these behaviors, even in the absence of depression.[110] Clinical trials are needed to compare the efficacy of SSRIs to atypical antipsychotics. Tricyclic antidepressants have efficacy similar to the SSRIs but should generally be avoided because of their anticholinergic activity.[110] Chapter 68 has a more complete discussion of treatment of depression.

Clinical Controversy…

The appropriate use of medications—and antipsychotics in particular—for the management of behavioral disturbances in patients with dementia continues to be controversial. Nonpharmacologic approaches are considered first-line therapy, but evidence for individual nonpharmacologic strategies is often lacking. Additionally, commonly cited institutional barriers to implementing nonpharmacologic approaches include education and training, staffing resources and time, and availability of necessary supplies or equipment. Overcoming these barriers may be challenging and costly initially, but doing so is an important first step in minimizing reliance on and potentially

inappropriate use of medications for behavioral disturbances in AD.

Miscellaneous Therapies

Because antipsychotic and antidepressant therapy have shown only modest efficacy and pose the potential for undesirable side effects, medications traditionally used to treat disruptive behaviors and aggression in other psychiatric and neurologic disorders have been suggested as potential alternatives. These alternatives include benzodiazepines and anticonvulsants.[110]

Benzodiazepines have been used to treat anxiety, agitation, and aggression, but the benefit is unclear. There are no RCTs that have investigated the use of benzodiazepines for the management of behavioral disturbances in AD.[110]

Because benzodiazepine use is associated with impaired cognition, respiratory depression, oversedation, and increased risk of falls in patients with AD, their routine use is not advised, except on an "as needed basis" for infrequent acute episodes of agitation.[110] "Mood stabilizer" anticonvulsants, such as carbamazepine, valproic acid, and gabapentin, may be appropriate alternatives, but evidence is conflicting.[110] More rigorous placebo-controlled studies are needed to determine the relative efficacy and place in therapy for these medication alternatives.

Noncognitive symptoms are often the most difficult aspect of AD for the caregiver. When nonpharmacologic approaches fail, selected antipsychotics and antidepressants have been useful for effective management of behavioral, psychotic, and depressive symptoms, thereby easing caregiver burden and allowing the patient to spend additional time at home. All too often, however, nonpharmacologic measures are not implemented appropriately and medication overuse is an ongoing problem. Adverse events remain an important concern in this population as well.

PERSONALIZED THERAPY

At this time there are no specific recommendations regarding the choice of agent or dosing regimen for current cognitive enhancing therapies based on genotype or other biomarkers. There is a great deal of attention among AD researchers to identify biomarkers for AD, and recommendations are likely to evolve over time as we better understand the underlying pathophysiology of AD and the predictors of patient response.

Given the exponentially increasing number of individuals and families facing the diagnosis of AD, the National Institutes of Health, FDA, pharmaceutical companies, and nonprofit organizations have joined together in an "Accelerating Medicines Partnership." Contributing almost 130 million dollars over the next 5 years, these groups will combine forces to create networks, share data, and manage clinical trials (http://www.nih.gov/science/amp/alzheimers.htm).

Recommendations for patients with renal or hepatic dysfunction or low body weight are detailed in Table 54-6. It is important to consider that most patients with AD are older adults and therefore may be taking multiple medications for other acute and chronic health conditions. The potential for adverse events due to drug interactions increases as the number of medications increases.

EVALUATION OF THERAPEUTIC OUTCOMES

An evaluation of therapeutic outcomes in the patient with AD begins with a thorough assessment at baseline and a clear definition of therapeutic goals. Cognitive status, physical status, functional performance, mood, and behavior all need to be evaluated before initiation of drug therapy. The clinician should interview both the patient and the caregiver to assess response to drug therapy. In evaluating response to cognitive agents, the clinician should ask questions about the patient's ability to perform daily functional tasks and about mood and behavior, as well as questions about memory and orientation. Objective assessments (eg, MMSE for cognition, Bristol Activities of Daily Living Scale for function, Neuropsychiatric Inventory for behavioral disturbances) can be used to quantify changes in symptoms and function.[121]

Because target symptoms of psychiatric disorders may respond differently in dementia patients, a detailed list of symptoms to be treated should be documented in the pharmacotherapy plan to aid in monitoring. These could include, for example, "striking at spouse because patient believes spouse is an impostor," "verbal threats and refusal to allow clothes to be changed," and so on, as opposed to documenting vague symptoms such as "aggression" or "delusions." To make an accurate assessment of depression, multiple symptoms (eg, sleep, appetite, and activity and interest levels) need to be assessed in addition to the patient's stated mood.

The patient should be observed carefully for potential side effects of drug therapy. The specific side effects to be monitored and the method and frequency of monitoring should be documented. Patients should be monitored for therapeutic effect 8 weeks after initiation of therapy and at least every 6 months thereafter.[122] However, patients must be treated for an adequate duration to see a therapeutic effect from a given intervention. The effects of cognition-enhancing medications will not necessarily be obvious, and a treatment period of several months to a year may be necessary before it can be determined whether therapy is beneficial. Cognitive effects of the drug are often noticed only as a plateauing during treatment or as deterioration following drug discontinuation. In general, cognitive agents should be continued if the patient is demonstrating no change in clinical status. However, if there is doubt, the medication can be slowly tapered and discontinued, and the patient monitored off the drug for 4 to 6 weeks to determine the need for continued therapy.

Chapter 55: Multiple Sclerosis

Jacquelyn L. Bainbridge; Augusto Miravalle; Pei Shieen Wong

INTRODUCTION

KEY CONCEPTS

- 1 The etiology of multiple sclerosis (MS) is unknown, but it appears to be autoimmune in nature. Currently there is no cure.
- 2 Multiple sclerosis is characterized by central nervous system (CNS) demyelination and axonal damage.
- 3 Multiple sclerosis is classified by the nature of progression over time into several categories, which have different clinical presentations and responses to therapy.
- 4 Although studies do not support the general use of any of the FDA-approved disease-modifying therapies (DMTs), except mitoxantrone, in patients with progressive forms of the illness, information derived from multiple studies suggests younger patients with progressive illness and those with either superimposed acute relapses or enhancing lesions on magnetic resonance imaging (MRI) scans may benefit from some of the presently used DMTs.
- 5 Diagnosis of MS requires evidence of dissemination of lesions over time and in multiple parts of the CNS and/or optic nerve, and is made primarily on the basis of clinical symptoms and examination. Diagnostic criteria also allow for the use of MRI, spinal fluid evaluation, optical coherence tomography, and evoked potentials to aid in the diagnosis.
- 6 Exacerbations or relapses of MS can be disabling. When this is the case, exacerbations and relapses are treated with high-dose glucocorticoids, such as methylprednisolone intravenous (IV), with onset of clinical response typically within 3 to 5 days.
- 7 Treatment of relapsing-remitting multiple sclerosis (RRMS) with the DMTs interferon-β (IFN-β) (Avonex, Betaseron, Rebif, Extavia), glatiramer acetate (Copaxone), natalizumab (Tysabri), mitoxantrone (Novantrone), fingolimod (Gilenya), teriflunomide (Aubagio), dimethyl fumarate (Tecfidera), and alemtuzumab (Lemtrada) can reduce annual relapse rate, lessen severity of

relapses, slow progression of changes on MRI scans, slow progression of disability, and slow cognitive decline. In addition, they have been shown to reduce the likelihood of developing a second attack after a first clinically isolated syndrome (CIS) consistent with MS.

- 8 In most cases, treatment with DMTs should begin promptly after the diagnosis of RRMS, or after a CIS if the brain MRI is suggestive of high risk of further attacks. Natalizumab and other choices that have been associated with problematic adverse events should be reserved for those patients who have failed one or more standard therapies and those with poor prognostic signs.

- 9 The definition of treatment inadequacy for RRMS remains unclear, and therapy changes after "treatment failure" should be individualized.

- 10 Patients suffering with MS frequently have symptoms such as spasticity, bladder dysfunction, fatigue, neuropathic pain, cognitive dysfunction, and depression that can require treatment. Patients must be counseled that DMTs will not relieve these symptoms. Depression is common in MS and can pose the risk of suicide.

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS) that affects approximately 1 in 200 women and fewer men in the United States.[1] The term "multiple sclerosis" refers to two characteristics of the disease: numerous affected areas of the brain and spinal cord producing multiple neurologic symptoms that accrue over time, and the characteristic plaques or sclerosed areas that are the hallmark of the disease.

1 Although MS was first described almost 140 years ago, the cause remains a mystery, and a cure is still unavailable. Nevertheless, many advances have been made in treating and managing the disease complications and improving the quality-of-life of affected individuals.

EPIDEMIOLOGY

Epidemiologic aspects of MS have been reviewed in many publications.[1,2,3,4,5] MS affects approximately 2.3 million people worldwide.[6] MS is usually diagnosed between the ages of 15 and 45 years; peak incidence occurs in the fourth decade. Women are afflicted more than men by a ratio of 2:1. Men usually develop the first signs of MS at a later age than women, and are more likely to develop a progressive form of the disease. The most important factors in determination of risk for developing the disease are geography, age, environmental influences, and genetics. In general, disease prevalence is higher the greater the distance from the equator; within the United States the prevalence of MS is higher in states above the 37th parallel. Recent studies, however, suggest a waning latitude gradient as demonstrated by a substantial increase in MS incidence in Mediterranean regions. Rising incidence of MS in females appears to be associated with urbanization.[7]

Multiple sclerosis occurs more frequently in whites of Scandinavian ancestry than in other ethnic groups. In addition, an inverse relationship between MS risk and 25-hydroxyvitamin D levels has been proposed.[1,8]

ETIOLOGY

The exact cause of MS is still unknown, but the disease is thought to develop in genetically susceptible individuals, that are exposed to random events and environmental factors that could trigger immune mediated CNS damage. Genetic variation accounts for approximately 30% of the overall disease risk, and with the advent of genome-wide association studies (GWASs), more than 100 distinct genetic regions have been identified as being associated with MS, collectively explaining approximately one-third of the genetic component of the condition. However, nongenetic factors have a proportionately larger contribution than genetic factors to immunological heterogeneity. Environmental determinants of risk in MS are still under investigation, but there are interesting advances in our understanding of the epidemiology of MS. To date, the reported environmental factors implicated in MS variably, but not exclusively, include vitamin D deficiency, human cytomegalovirus infection, Epstein–Barr virus (EBV), Human Herpesvirus (HHV)-6, smoking, high levels of dietary sodium, and circadian disruption.

It is thought that genetically susceptible individuals below 15 years of age who have lived in a high-risk area for at least 2 years and were exposed to a crucial environmental agent are at risk for developing MS. Interestingly, an individual who migrates from a low- to high-risk area prior to the age of 15 years acquires the same chance of developing MS as those who live in a high-risk area all their lives.[2] If the move is made from a high- to a low-risk area, the individual retains the high risk if the move is made after the age of 15 years, but acquires the lower risk if the move is made prior to this age.[2] Smoking cigarettes has been associated with both an increased risk of developing MS and with more severe progression of disability.[5,9]

Although no clear association has been identified, certain viral or bacterial infections might participate in the pathogenesis of MS by initiating or activating autoreactive immune cells in genetically susceptible individuals, leading to subsequent demyelination. Evidence to support a viral etiology includes increased immunoglobulin G (IgG) synthesis in the CNS, increased antibody titers to certain viruses, and epidemiologic studies that indicate a childhood exposure factor, suggesting that "viral" infections may precipitate exacerbations. In addition, viruses have been shown to cause diseases with prolonged incubation periods, myelin destruction, and a relapsing-remitting course in both humans and experimental animal models.[1,10]

Although numerous viruses have a hypothetical proposed association with MS, the greatest evidence supports EBV. Autoreactive T-cells could be activated by EBV through molecular mimicry, whereby sequence similarities between EBV and self-peptides are sufficient to result in the cross-activation of autoreactive T- or B-cells. Other potential mechanisms of demyelination include enhanced breakdown and presentation of self-antigens, expression of viral superantigens, or bystander activation.[11] Antibody titers to Epstein–Barr nuclear antigen (EBNA) complex are higher in MS patients versus controls, especially if blood is collected 5 years or more before onset. These titers increase over time in MS patients (controls are unchanged), and a fourfold increase in EBNA titers over time results in a threefold increased risk of developing MS (almost an 18-fold increase in those with first samples before age 20).[12] Interestingly, one paper notes individuals positive for human leukocyte antigen (*HLA) DRB1*1501* have a 24-fold increased risk of developing MS when they also

have antibodies to certain epitopes within EBNA-1 compared with others.[13] This is consistent with a genetic-environmental interaction. In addition, anti-EBNA titers have been associated with RRMS, conversion of CIS to clinically definite multiple sclerosis (CDMS, confirmed diagnosis of MS), and with magnetic resonance imaging (MRI) measures such as gadolinium-enhancing lesions, change in T2 lesion volume (r = 0.27; P = 0.044), and Expanded Disability Status Scale (EDSS) score (r = 0.3; P = 0.035). Zivadinov et al. also found anti-EBNA and anti-vascular cell adhesion (VCA) titers associated with gray matter atrophy in MS.[14] While Serafini et al. have claimed to identify evidence of abortive infection in a significant number of MS patients,[15] others have not been able to replicate these findings.[16] The majority of data would lead to a conclusion that exposure to EBV is somehow associated with developing MS, but does not support the concept of an active or aborting EBV infection directly causing MS.

The familial recurrence rate of MS is approximately 5%, with siblings being the most commonly reported relationship,[4] and a concordance rate among monozygotic twins of approximately 25%. This is consistent with the idea that an environmental agent is important in the etiology of MS, but also suggests a role for one or more genes. Genes that lie within the major histocompatibility complex (MHC), which is located on the sixth chromosome in humans, have been linked to MS.[1,4] Recent data show a significant association of risk with mutations in the interleukin-2α (IL-2α) and interleukin-7α (IL-7α) receptor genes.[17,18,19] African Americans are significantly less likely to be diagnosed with MS compared with whites, although there is emerging evidence that they are more likely to have a severe disease course[20] and respond less to interferon (IFN) therapy.[21] A locus on chromosome 1 may be associated with increased susceptibility in African Americans.[22]

PATHOPHYSIOLOGY

An important feature to consider when understanding pathophysiology of MS and its potential clinical applications is the concept that immune cell infiltration from the periphery is a prominent feature of early-stage MS. Peripheral immune cells can enter the CNS parenchyma by direct crossing of the blood–brain barrier, the subarachnoid space, or from the choroid plexus across the blood-cerebrospinal fluid (CSF) barrier.

Once in the CNS, immune cells promote neurodegeneration by stripping of the myelin sheath surrounding CNS axons. This activity is associated with an inflammatory, perivenular infiltrate consisting of T and B lymphocytes, macrophages, antibodies, and complement.[10] Demyelination renders axons susceptible to damage, which becomes irreversible when they are severed. Irreversible axonal damage correlates with disability and can be visualized as hypointense lesions, or "black holes," on T1-weighted MRI.[23,24]

Peripheral immune cells, along with activated CNS-resident microglia and astrocytes, promote demyelination as well as oligodendrocyte and neuroaxonal injury. This is mediated through direct cell contact-dependent mechanisms and the action of soluble inflammatory and neurotoxic mediators. The exact trigger for activation of T-cells in the periphery remains unclear, but the T-cells in MS patients recognize myelin basic protein (MBP), proteolipid protein, myelin oligodendrocyte

glycoprotein, and myelin-associated glycoprotein. T-helper subtypes can be either pathogenic or protective in MS. Furthermore, theory holds that certain T-cell subsets are not terminally differentiated, but instead engender a level of plasticity that allows for their conversion from pathogenic to protective and vice versa under certain conditions (**Fig. 55-1**).[25]

FIGURE 55-1

Upon interaction with an antigen-laden APC and specific cytokines, the innate T-cells undergo differentiation into a few lineages (subtypes). Four subtypes significant for MS pathophysiology are illustrated here (Th1, Th2, Th17, and Treg). Th1 and Th17 are proinflammatory, Th2 is antiinflammatory, and Treg is regulatory. Th1 and Th2 are mutually suppressive and are relatively stable differentiated subtypes. In contrast, Th17 and Treg subtypes are recently found to exhibit "plasticity." In other words, they can undergo phenotypic conversion to another T-cell subtype (Th1 or Th2) in the presence of specific cytokine conditions. This plasticity of Th17 and Treg is the immunologic basis for development of therapeutic agents to favor the production of suitable Th subtypes for combating microbial invasion and also concurrently achieving neurocellular recovery after an infection.[25] (APC, antigen presenting cell.)

A new concept of T-cell entry into the CNS suggests that the initial lymphocyte invasion in MS may proceed through the ventricles, toward the choroid plexus along a CCL 20 gradient that attracts activated Th17 (T-helper) cells.[26] The actual mediator of myelin and axonal destruction has not been established, but may reflect a combination of macrophages, antibodies, destructive cytokines, and reactive oxygen intermediates. In patients with stable or mild disease, increased numbers of cells are found that express messenger RNA (mRNA) for transforming growth factor-β (TGF-β) and interleukin-10 (IL-10) compared with patients with severe disease. Conversely, a reduction in the number of T-regulatory (Treg) cells, which exhibit suppressor activity, is associated with active MS and can be found in patients with progressive disease. It should be noted, however, that Treg ratios do not always correlate with disease activity. Of note, experimental evidence associates high 25-hydroxyvitamin D levels with improved Treg function, favoring the Th2 phenotype in the Th1/Th2 balance.[27] Finally, the significance of one of the immunological hallmarks of MS, the intrathecal synthesis of multiple clones of immunoglobulins, remains unclear. The antigen(s) against which these immunoglobulins are directed remain unknown, but do not appear to include common CNS myelin

antigens.[28] The complex interplay of a variety of cells, antibodies, and cytokines remains to be elucidated.

It is well accepted that MS lesions are heterogeneous, which may be due in part to differences in the stage of evolution of the lesions over time, differences in underlying immunopathogenesis, or a combination. Acute lesions show demyelination and axonal destruction with lymphocytic activity consistent with an inflammatory state. In contrast chronic lesions display less inflammatory lymphocytes with active remyelination.[10] As the disease progresses, immune cell infiltration wanes, perhaps due to adaptive immune cell exhaustion from chronic antigen exposure. Chronic CNS-intrinsic inflammation and neurodegeneration continues independent of peripheral immune activation. As a consequence, meningeal tertiary lymphoid-like structures, which have specifically been documented in secondary progressive disease, may contribute to late-stage inflammation in patients with this form of MS.

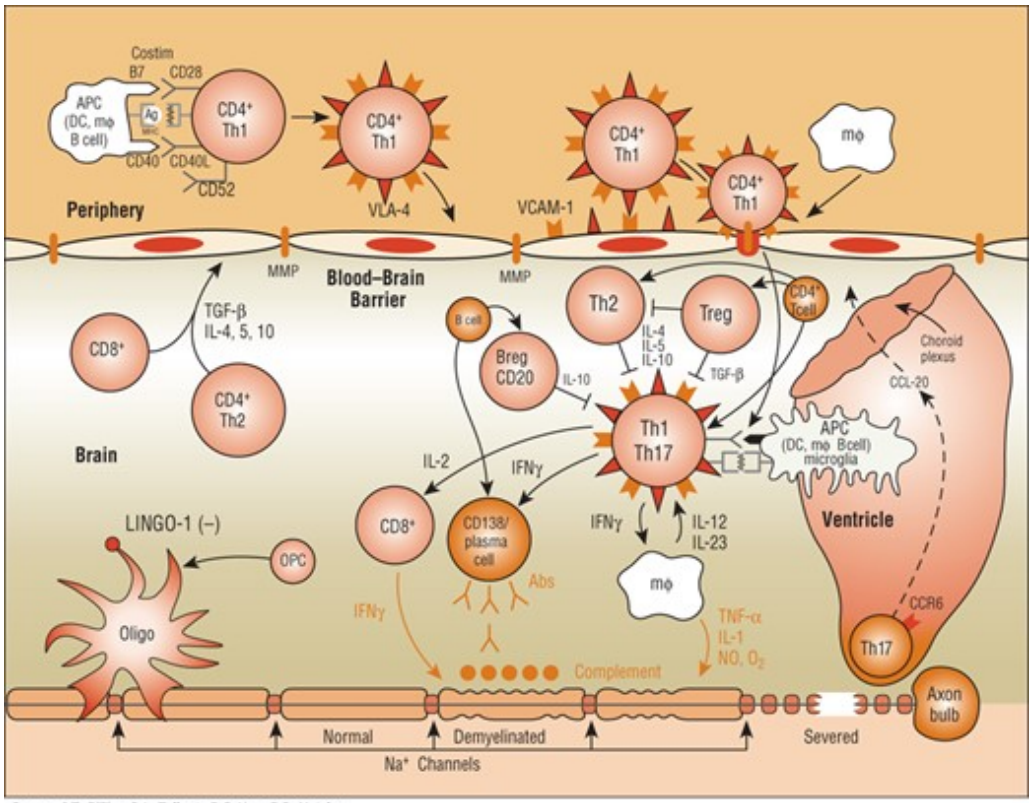
Although traditional descriptions have focused on white matter as the sole location of MS lesions, more recent studies have clearly identified cortical and subcortical gray matter lesions both pathologically[29] and radiographically.[30] In addition, a subset of patients with progressive MS are noted to have abnormalities consistent with B-cell follicles in the meninges.[31]

Just as the full dimensions of the neuropathology are uncertain, so is the pathogenesis of the MS lesion. Substantial evidence suggests it is an autoimmune process directed against myelin and oligodendrocytes, the cells that make myelin[10] (**Fig. 55-2**).

FIGURE 55-2

Autoimmune theory of the pathogenesis of multiple sclerosis (MS). In MS, the immunogenic cells tend to be more myelin-reactive, and these T-cells produce cytokines mimicking a Th1-mediated proinflammatory reaction. T-helper cells ($CD4^+$) appear to be key initiators of myelin destruction in MS. These autoreactive $CD4^+$ cells, especially of the T-helper cell type 1 (Th1) subtype, are activated in the periphery, perhaps following a viral infection. The activation of T- and B-cells requires two signals. The first signal is the interaction between MHC and APC (macrophage, dendritic cell, and B-cell). The second signal consists of the binding between B7 on the APC and CD28 on the T-cell for T-cell activation. Similarly, CD40 expressed on APCs and CD40L expressed on T-cells interact to signal the proliferation of B-cells within the blood–brain barrier following the entry to T-cells. The T-cells in the periphery express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood–brain barrier. The activated T-cells also produce MMP that help to create openings in the blood–brain barrier, allowing entry of the activated T-cells past the blood–brain barrier and into the CNS. Once inside the CNS, the T-cells produce proinflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor-α (TNF-α), and interferon-γ (INF-γ), which further create openings in the blood–brain barrier, allowing entry of B-cells, complement, macrophages, and antibodies. The T-cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and

transforming growth factor-β (TGF-β) also has been described. These cytokines are the products of $CD4^+$, $CD8^+$, and Th1-cells.[10] New pathogenic mechanisms involve, but are not limited to, receptor-ligand mediated T-cell entry via choroid plexus (CCR6-CCL20 axis),[26] coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75 or TROY complex, Jagged-Notch signaling). (Ag, antigens; APC, antigen presenting cell; DC, dendrite cell; IgG, immunoglobulin G; MΦ, macrophage; Na^+, sodium ion; MMP, matrix metalloproteinases; MHC, major histocompatibility complex; OPC, oligodendrocyte precursor cell; VLA, very late antigen; VCAM, vascular cell adhesion molecule.)



Clinical Presentation Multiple Sclerosis General

- Most patients with MS present with nonspecific complaints. Many have problems with their vision or paresthesias

Primary Symptoms/Signs

- Visual complaints/optic neuritis
- Gait problems and falls
- Paresthesias
- Pain
- Spasticity

- Weakness
- Ataxia
- Speech difficulty
- Psychological changes
- Cognitive changes
- Fatigue
- Bowel/bladder dysfunction
- Sexual dysfunction
- Tremor

Laboratory Tests

- MS is a diagnosis of exclusion
- MRI
- CSF studies
- Evoked potentials

Secondary Symptoms

- Recurrent UTIs
- Urinary calculi
- Decubiti and osteomyelitis
- Osteoporosis
- Respiratory infections
- Poor nutrition
- Depression

Tertiary Symptoms

- Financial problems
- Personal/social problems
- Vocational problems

- Emotional problems

CLINICAL PRESENTATION AND COURSE OF ILLNESS

3 The clinical presentation of MS is extremely variable among patients and typically varies over time in a given patient. The signs and symptoms of MS can be divided into three categories. Primary symptoms are a direct consequence of conduction disturbances produced by demyelination and axonal damage, and reflect the area of the CNS that is damaged. Secondary symptoms are complications resulting from primary symptoms. For example, urinary retention, a primary symptom, can lead to frequent urinary tract infections (UTIs), a secondary symptom. Tertiary symptoms relate to the effect of the disease on the patient's everyday life.[32]

The clinical course of CDMS is classified into four categories.[33] At the onset of symptoms, about 85% of patients have exacerbations—new symptoms lasting at least 24 hours and separated from other new symptoms by at least 30 days—followed by remissions (complete or incomplete). Exacerbations are frequently referred to as relapses or attacks. This course is called RRMS; the first clinical presentation is typically CIS. During the RRMS phase, there is a correlation between new brain MRI lesions and clinical attacks, but typically there are many more new MRI lesions than new clinical symptoms. In RRMS patients, attack frequency tends to decrease over time and becomes independent of the development of progressive disabilities.[34] Neurologic recovery following an exacerbation is often quite good early in the disease course, but following repeated relapses, recovery tends to be less complete. In addition, there is a new concept of a radiologically isolated syndrome (RIS), referring to individuals who have clinical scenarios not typical of MS, yet obtain MRI scans for other reasons (eg, headache) and have radiological signs suggestive of MS. Some percentage of these patients convert to RRMS over time,[35] although when to start DMT remains unclear and varies by practice.

Approximately 10% to 20% of RRMS patients have a benign course, characterized by few relapses, often sensory, with minimal disability accruing over time. Most RRMS patients eventually enter a progressive phase in which attacks and remissions are difficult to identify. This is referred to as secondary-progressive multiple sclerosis (SPMS). Disability tends to accumulate more significantly during this phase of the illness. New brain MRI lesions, especially those seen only after the injection of contrast media, are less common, and brain atrophy and T1 holes increase.[36]

4 Approximately 15% of patients never have discrete phases of attacks and remissions but have progressive disease from the outset, known as primary-progressive multiple sclerosis (PPMS). These patients will have symptoms, especially spastic paraparesis that may worsen rapidly or relatively slowly over time, and accrue progressively more disability. Patients with PPMS are diagnosed at a later age, with the number of males roughly equal to that of females. In general, PPMS patients tend to have a worse prognosis than those who present initially with RRMS, although data suggest progression is variable.[37] Many clinical trials have suggested that a significant portion of patients with PPMS do not receive benefit from studied therapies. However, a study using rituximab suggests a subgroup of PPMS patients who are less than 51 years of age and have at least one gadolinium-

enhancing lesion may benefit from this therapy.[38] Finally, a small percentage of patients may have a mixture of both progression and relapses, referred to as progressive-relapsing multiple sclerosis (PRMS). These patients are generally treated as relapsing patients.

Progression of the illness throughout the lifetime can be measured in many ways. The most widely used clinical rating scale is the EDSS, which uses a numerical value ranging from 0 (no disability) to 10 (death) to evaluate neurologic functions.[39] The limitations of this scale are the relative insensitivity to clinical changes not involving impairment of ambulation, such as changes in cognition, fatigue, and affect. Other tools, such as the multiple sclerosis functional composite (MSFC), are being evaluated for increased sensitivity and utility in describing changes in MS-related disability over time.[40] Increasingly, MRI is being used as an index of both disease activity and progression.[10] Specifically, the appearance of new lesions or changes in lesion number, size, and volume are being used as outcome measures in research studies. Optical coherence tomography measures the retinal neural fiber layer thickness, and may also be a measurable sign of pathological progression over time.[41]

The unpredictable nature of MS makes it impossible to anticipate when an exacerbation will occur. However, certain factors, including infections, heat (including fever), sleep deprivation, stress, malnutrition, anemia, concurrent organ dysfunction, exertion, and childbirth, may aggravate symptoms or lead to an attack. Interestingly, many patients experience a significant reduction in relapses during the third trimester of pregnancy, followed by a relative increase postpartum.[42]

Between 60% and 80% of individuals diagnosed with the MS have been reported to be sensitive to environmental heat. Clinically, increased body temperature might result in worsening of previous neurological deficits, including fatigue and decreased muscular endurance. Blurred vision, known as Uthoff's phenomenon, is caused by increased body temperature due to physical exercise or physical restraint. Body temperature influences nerve impulses, which are blocked or slowed down in a damaged nerve. After normalization of the temperature, signs and symptoms improve or disappear.

Multiple sclerosis usually does not directly diminish life expectancy, although the development of secondary complications such as pneumonia or septicemia (secondary to aspiration in those with swallowing difficulties, decubitus ulcers, or UTIs) or rapid progression of primary lesions affecting respiratory function can lead to a shorter than expected life span. Most of the decrease in life span is seen in patients with rapidly progressive disease. Suicide rates as high as seven times that seen in the general population have been reported.[43] Clinical and demographic factors used to predict prognosis of MS are listed in **Table 55-1**.[5,44] Several MRI features also have been shown to correlate with progression of disease (see below).[45,46,47]

TABLE 55-1 Prognostic Indicators in Multiple Sclerosis

Indicator	Favorable Prognosis	Unfavorable Prognosis
Age at onset	<40 years	>40 years
Gender	Female	Male
Initial symptoms	Optic neuritis or sensory symptoms	Motor or cerebellar symptoms; polysymptomatic

Indicator	Favorable Prognosis	Unfavorable Prognosis
Disability	Late	Early
Attack frequency in early disease	Low	High
Course of disease	Relapsing/remitting	Progressive
Recovery after first event	Good	Poor
T2 lesions	Low load	High load
T1 black hole lesions	Low rate	High rate
Growth of lesions	Slow	Rapid
Locations of lesions	Single	Multiple

Data from references 48 and 49.

DIAGNOSIS

5 Multiple sclerosis is a diagnosis of exclusion; symptoms frequently can be attributed to other neurologic diseases, just as many syndromes can mimic MS. The diagnosis remains primarily a clinical one that requires demonstration of "lesions separated in space and time," referring to the occurrence of at least two episodes of neurologic disturbance reflecting distinct sites of CNS damage that cannot be explained by another mechanism.[50] An international panel of MS experts established the McDonald criteria,[50] which allows brain MRI lesions, CSF abnormalities, and visual-evoked potential (VEP) studies to substitute for clinical lesions in defining "separated in space and time" A reevaluation of the McDonald criteria has simplified the use of these laboratory studies.[45] In the new scheme, diagnostic categories are MS, possible MS (for those individuals at high risk of developing MS), and not MS; these new criteria allow for earlier diagnosis.[45] Newer, simpler MRI criteria defining dissemination in space and time may be somewhat more sensitive and equally specific.[51,52,53] A consensus panel of the American Association of Neurology endorses the utility of MRI for diagnostic purpose,[47] and the US FDA has approved several of the immunotherapies to be used after a single attack (CIS) of demyelination in the context of an appropriately abnormal brain MRI. A proposed set of criteria now being considered will allow for earlier diagnosis in patients with CIS to establish "dissemination in space and time" with a single MRI. Therefore, patients will need to have lesions in different areas of their CNS with at least one enhancing lesion that correlates with clinical symptomatology. By fulfilling these criteria, a patient can be diagnosed with CDMS.

Laboratory Studies

To date, there are no tests specific for MS. Evidence provided by MRI of the brain and spine,[46,47] CSF evaluation (presence of increased oligoclonal bands and increased IgG), evoked potentials,[45,50] and optic coherence tomography,[54] used in conjunction with the physical examination and history, aids in establishing the diagnosis of MS. MRI, the most valuable diagnostic tool, produces images of the brain and spine that reflect damage that is characteristic of MS plaques in multiple areas of the CNS.

MRI is the preferred technique for establishing a diagnosis, prognosis, and for following disease progression. Optic neuritis, a lesion or lesions on the optic nerve, is a common first symptom of MS. A greater number of T2-weighted lesions (called *T2 burden of disease*) on MRI following optic neuritis or CIS appears to correlate with the development of disability and progression to CDMS.[46] Lesions that enhance after injection of the contrast media gadolinium indicate new lesions and disruption of the blood–brain barrier and are associated with early conversion to CDMS in CIS patients.[46,55] However, they do not correlate well over time with progression of disability. Brain atrophy, even early in the course of the illness, probably correlates better with progression of disability.[47]

Differential Diagnosis

Because a number of disorders can mimic MS, most patients are screened with blood tests for rheumatologic, collagen-vascular, infectious, and sometimes inherited metabolic diseases. Electromyography may help in diagnosing amyotrophic lateral sclerosis and neuropathies.

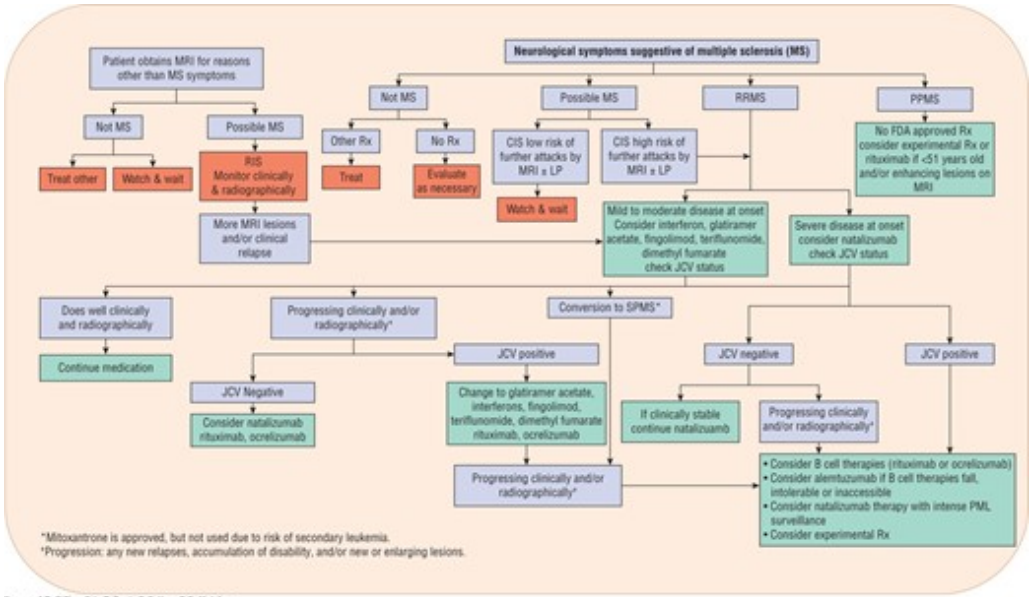
Magnetic resonance imaging, used to rule out tumors and cervical spondylosis, may also lead to evaluations for MS in many patients with little or no clinical history of MS. While some of these patients may have MRI scans suggestive of MS (so-called RIS), most have nonspecific MRI scans with identifiable causes for their scan abnormalities, including age greater than 50 years, hypertension, and migraine.[56] The use of established criteria for distinguishing MS lesions from other etiologies enhances diagnostic accuracy.

TREATMENT

Treatment of MS falls into three broad categories: (1) treatment of exacerbations, (2) DMTs, and (3) symptomatic therapies. Treatment of exacerbations will shorten the duration and possibly decrease the severity of the attack. DMTs alter the course of the illness, and diminish progressive disability over time. Symptomatic management of the disease is of utmost importance to maintain the patient's quality-of-life. Although different treatment modalities have been studied in the last 30 years, many older trials had flawed designs. As there are no universally accepted treatment algorithms, treatments vary among clinicians and centers. Perhaps more importantly, treatment decisions are frequently based on the wishes and goals of individual patients rather than evidence-based algorithms. One potential algorithm for the immunotherapy of CDMS is shown in **Fig. 55-3**.

FIGURE 55-3

Algorithm for management of clinically definite multiple sclerosis.



Desired Outcomes

The main goals of treatment are to improve patients overall quality-of-life and minimize long-term disability. Treatment goals are attained by altering MS exacerbations or relapses, decreasing the number of white matter lesions and black holes on MRI, averting brain atrophy, and ultimately halting disease progression. This can be achieved by early recognition of the disease and immediate utilization of FDA-approved DMTs.

General Approach to Treatment

The severity of symptoms at initial presentation will determine whether an induction or escalation algorithm will be assigned to an individual patient. When FDA-approved drugs do not alter the naturally progressive disease, investigational agents or non–FDA-approved medications, such as rituximab, may be used. As a general rule, MS affects patients in their most productive years of life. Practitioners must work with their patients to set realistic expectations over their lifetime and develop a long-term treatment and management plan. With disease progression, patients are likely to acquire secondary and tertiary symptoms of MS. In clinical trials, high nonadherence rates are reported as an important issue for potential treatment failure. Potential reasons identified for nonadherence are lack of perceived benefit, cost, adverse effects, depression, and undesirable routes of administration (eg, subcutaneous, intramuscular injection, intravenous [IV]). With the advance of FDA-approved medications to treat MS, patients are experiencing fewer relapses, slower disease progression, and improved quality-of-life.

Treatment of Exacerbations

Exacerbations are the hallmark of early RRMS. Although recovery after relapses is in general complete, over time a substantial accumulation of disability occurs. Controversy exists about the relationship between relapses and subsequent accumulation of disability. Frequent relapses (more

than three relapses per year in the first 2 years after diagnosis) have shown consistent positive correlation with later development of neurological disability. Generally, mild exacerbations that do not produce functional decline may not require treatment. Decisions to treat relapses are usually substantiated by patient expectations, prior experience with corticosteroids, and predicted course of recovery. Generally accepted indications are based on mono- or polysymptomatic presentations; relapses that localize to the optic nerve, spinal cord, or brainstem; functional limitations that affect activities of daily living; and symptoms that continue to worsen over a period of 2 weeks. When functional ability is affected, the standard intervention is IV injection of high-dose corticosteroids. The American Academy of Neurology (AAN) recommends that if treatment with steroids is warranted, it is best to use IV methylprednisolone.[57] The mechanism of action for corticosteroids in MS is unknown, but it is speculated that steroids improve recovery by decreasing edema in the area of demyelination. IV methylprednisolone has been shown to shorten the duration of exacerbations; it may also delay repeat attacks for up to 2 years after optic neuritis,[57] although it has not been shown to definitively affect disease progression.[58] In some circumstances, equipotent doses of oral prednisone can be substituted for IV methylprednisolone. Interestingly, adrenocorticotropic hormone (ACTH) is the only agent that is FDA approved for treatment of MS exacerbation treatment, although it is rarely used due to cost and availability.

Methylprednisolone doses range from 500 to 1,000 mg/day, given IV. Duration of therapy is variable and can range from 3 to (rarely) 10 days, depending on clinical response. Functional recovery after an exacerbation is more rapid if corticosteroids are initiated within 2 weeks of symptom onset. If improvement occurs, it usually begins after 3 to 5 days. Short-term use is often accompanied by sleep disturbance, a metallic taste in the mouth, and rarely, gastrointestinal (GI) upset. Patients with diabetes mellitus or a predilection to diabetes mellitus may have significant elevations of blood sugar, requiring the use of insulin. Longer durations of IV methylprednisolone therapy are associated with acne and fungal infections, mood alteration, and, rarely, GI hemorrhage (especially in hospitalized patients or in those taking aspirin). If methylprednisolone is not available, equipotent doses of dexamethasone have been used as a substitute, although this is not well supported in the literature.

A small number of patients have more severe attacks, manifested by hemiplegia, paraplegia, or quadriplegia. If these patients fail to improve with aggressive steroid therapy, plasma exchange (PLEX) every other day for seven treatments can be beneficial for approximately 40% of patients, or intravenous immunoglobulin (IVIG) can be given.

A “pseudoexacerbation” is an episode with symptoms consistent with an exacerbation, but precipitated by something other than the natural course of the disease. A pseudoexacerbation can be precipitated by heat, infections (eg, UTIs), or stress (emotional or physical); these must be ruled out before exacerbation treatment is initiated or DMTs are altered.

Disease-Modifying Therapy

7 Indications and dosing of DMTs are shown in **Table 55-2**. MS is a complex, heterogeneous disease with clear variability in pathogenesis between patients and within patients over time. As a

result, treatment decisions are usually based on clinical predictors of disease severity, our incomplete understanding of the mechanism of action of currently available therapies, and the safety and tolerability profile of the medications. There is some degree of agreement that use of escalation approaches early in the course of the disease, with safer yet partially effective medications, is useful. Currently, FDA-approved first-generation therapies (self-injected medications that decrease annualized relapse rate by about 30% and decrease the formation of new white matter lesion) include four IFN formulations (five brand names), and glatiramer acetate (a non-IFN). The first-generation DMTs are not immediately efficacious for patient symptoms. However, their efficacy is noted approximately 1 to 2 years after starting therapy. In addition to first-generation DMTs, the FDA has approved natalizumab, mitoxantrone, fingolimod, teriflunomide, dimethyl fumarate, and alemtuzumab for the treatment of relapsing forms of MS. Mitoxantrone also has an FDA indication for progressive or worsening MS.

TABLE 55-2 Disease Modifying Therapy

Drug	Brand Name	Indication	Initial Dose	Usual Dose	Comment
First generation agents					
Self-injectables					
Interferon-β_{1a}	Avonex	Relapsing forms of MS	30 mcg (6 million international units) IM once weekly	30 mcg IM once weekly	Avonex is considered as a low potency interferon Cost per year[a]: $78,530
Interferon-β_{1a}	Rebif	Relapsing forms of MS	22 mcg SQ three times a week	22 or 44 mcg SQ three times a week	Rebif is considered as a high potency interferon Cost per year[a]: $84,766
Interferon-β_{1b}	Betaseron, Extavia	Relapsing forms of MS	250 mcg (8 million international units) SQ every other day	250 mcg SQ every other day	Betaseron/Extavia is considered as a high potency interferon Pregnancy category C Cost per year[a]: $83,276/$73,504 (Betaseron/Extavia)
Pegylated Interferon-β_{1a}	Plegridy	RRMS	6.3 mcg SQ day 1, then 94 mcg SQ on day 15, then 125 mcg SQ on day 29, then 125 mcg SQ every 14 days	125 mg SQ every 14 days	Pregnancy category C Can premedicate or concurrently use an antipyretic/analgesic for flu-like symptoms Cost per year[a]: 157,040

Drug	Brand Name	Indication	Initial Dose	Usual Dose	Comment
Glatiramer acetate	Copaxone Glatopa	CIS, RRMS	20 mg SQ once daily or 40 mg SQ three times a week	20 mg SQ once daily or 40 mg SQ three times a week	Pregnancy category B Cost per year[a]: $89,213 (Copaxone 20 mg/day), $78,125 (Copaxone 40 mg three times a week), $78,991 (Glatopa 20 mg/day)
IV infusion					
Mitoxantrone	Novantrone	SPMS, PRMS, and worsening RRMS	12 mg/m^2 IV every 3 months	12 mg/m^2 IV every 3 months	Lifetime dose should not exceed 140 mg/m^2 Pregnancy category D
Second generation agents					
Oral agents					
Fingolimod	Gilenya	Relapsing forms of MS	0.5 mg orally once daily	0.5 mg orally once daily	REMS Pregnancy category C Cost per year[a]: $85,136
Teriflunomide	Aubagio	Relapsing forms of MS	7 mg orally once daily	7 or 14 mg orally once daily	Pregnancy category X Cost per year[a]: $79,438 Cholestyramine and charcoal accelerate teriflunomide elimination
Dimethyl fumarate	Tecfidera	Relapsing forms of MS	120 mg delayed release twice daily for 7 days	240 mg delayed release twice daily	Pregnancy category C Cost per year: $79,716
IV infusion					
Natalizumab	Tysabri	Relapsing forms of MS	300 mg IV every 4 weeks	300 mg IV every 4 weeks	REMS Pregnancy category C Cost per year[a]: $5,468
Alemtuzumab	Lemtrada	RRMS	1st treatment course: 12 mg/day IV for 5 consecutive days		May premedicate with high dose corticosteroid (1,000 mg methylprednisolone or equivalent) immediately prior

Drug	Brand Name	Indication	Initial Dose	Usual Dose	Comment
					to infusion for first 3 days Also administer herpes viral prophylaxis starting on first day of treatment and continued for at least 2 months after completion of treatment or until $CD4^+$ count is at least 200 cells/μL (0.2×10^9/L), whichever occurs last Pregnancy category C REMS Total treatment cost[a]: $158,000
			(60 mg total dose) 2nd treatment course: 12 mg/day IV for 3 consecutive days (36 mg total dose) administered 12 months after 1st treatment course		
Self-injectable					
Daclizumab	Zinbryta	Relapsing forms of MS	150 mg SQ once monthly	150 mg SQ once monthly	REMS Cost per year: $98,400

CIS, clinically isolated syndrome; IM, intramuscular; PRMS, primary relapsing multiple sclerosis; REMS, Risk Evaluation and Mitigation Strategy; RRMS, relapsing remitting multiple sclerosis; SPMS, secondary progressive multiple sclerosis; SQ, subcutaneous.

[a]Cost: Cost as reported in Red Book, Not all drug companies publish average wholesale price (AWP), and those are calculated in accordance with Truven Health Analytics AWP Policy. Does not include nursing, pharmacy, and technical fees.

8 In some patients with poor prognostic factors and poor clinical presentation, natalizumab, fingolimod, teriflunomide, and dimethyl fumarate may be prescribed as initial therapy, as opposed to starting first generation DMTs that are associated with less serious side-effect risk. This type of algorithm would be considered an induction therapy, where you concentrate all therapeutic efforts in the early phases of disease. Drugs used to treat MS can be considered either immunomodulatory (able to alter the immune signals without cytotoxic effect or bone marrow suppression) or immunosuppressive (able to alter the immune system through a direct cytotoxic activity or bone marrow suppression). However, these agents have a higher risk-to-benefit ratio based on their safety profile.[59] Adverse drug reactions and monitoring parameters of DMTs are shown in **Table 55-3**.

TABLE 55-3 Adverse Drug Reactions and Monitoring Parameters

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Interferon-β_{1a}	Depression, flu-like symptoms, leukopenia, injection site reactions	Electrolytes, CBC, LFTs, thyroid function, LVEF, depression LFTs at baseline, 1 month, and every 3 months for a year, and every 6 months thereafter	Avoid use in untreated severe depression
Interferon-β_{1b}	Depression, injection site reactions, leukopenia, flu-like symptoms	Electrolytes, CBC, LFTs, thyroid function, depression	Avoid use in untreated severe depression More frequent injection site reactions reported
Glatiramer acetate	Injection site reactions, infection, hypersensitivity, chest tightness, urticaria	MRI, tissue necrosis, postinjection reaction	Chest tightness, urticaria can occur at any dose
Mitoxantrone	Bone marrow suppression, neutropenia, cardiotoxicity, AML, nausea, vomiting, diarrhea, alopecia	CBC, ECG, LVEF, LFTs	Secondary leukemia Lifetime maximum dose due to cardiac toxicity
Natalizumab	PML, depression, fatigue, respiratory infection, arthralgia, hepatotoxicity	JCV antibody, infection, MRI, LFTs	Risk of PML Risk of IRIS when discontinued due to PML Requires first dose observation
Fingolimod	Lymphocytopenia, macular retinal edema, AV block, infection, headache	CBC, ECG, varicella zoster antibody, blood pressure, ophthalmic examination, LFTs	Contraindicated in patients receiving Class I and III antiarrhythmic drugs and those with recent cardiac disease,[a] second and third degree AV block Ketoconazole increases fingolimod serum concentration (3A4 inhibition) Vaccine efficacy may be decreased
Teriflunomide	Steven–Johnson syndrome, liver failure, neutropenia, respiratory infection, activation of TB, alopecia, neuropathy	CBC, LFTs, blood pressure, pregnancy, TB test	Contraindicated in severe hepatic impairment Possibility of TB reactivation

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
			Active metabolite of leflunomide
Dimethyl fumarate	Flushing, rash, pruritus, GI discomfort, lymphocytopenia, increased LFTs, albuminuria	CBC, LFTs	Taking with food decreases incidence of flushing
Alemtuzumab	Infusion reactions, infections (nasophyaryngitis, UTI, URI, herpes viral infections), autoimmune disorders, thyroid disorders, immune-mediated thrombocytopenic purpura, Goodpasture syndrome	CBC, thyroid function, antibodies to varicella zoster virus, HPV screening, serum creatinine, TB prior to treatment, infusion reactions, skin exams, urinalysis	May premedicate with high dose corticosteroid (1,000 mg methylprednisolone or equivalent) immediately prior to infusion for first 3 days. Also administer herpes viral prophylaxis starting on first day of treatment and continued for at least 2 months after completion of treatment or until $CD4^+$ count is at least 200 cells/μL (0.2×10^9/L), whichever occurs last Contraindicated with HIV infection Birth control should be used during treatment and for 4 months after each treatment course Breastfeeding not recommended during treatment and for 4 months following each treatment course
Daclizumab	Upper respiratory tract infection, depression, rash, pharyngitis, increased ALT	LFTs & bilirubin (prior to treatment then monthly during treatment & for 6 months after the last dose) Contraindicated in hepatic disease or hepatic impairment	Live vaccines are not recommended during treatment and up to 4 months after discontinuation Evaluate for tuberculosis prior to treatment

AML, acute myeloid leukemia; CBC, complete blood count; ECG, electrocardiogram; LVEF, left ventricular ejection fraction; IRIS, immune reconstitution inflammatory syndrome; PML, progressive multifocal leukoencephalopathy; LFT, liver function test.

[a]Cardiac disease including myocardial infarction, unstable angina, stroke, transient ischemic attack, and heart failure NYHA Class III/IV.

It is important to note that the efficacy of the DMTs may vary considerably between individual patients and for any given patient at different points in time. Moreover, patients with MS may have different tolerance for side effects and risks, as well as preference for different routes of administration. Therefore, access to the full range of options is critical in order for patients with MS and their clinicians to make optimal treatment decisions.

Clinical Controversy…

Current MS therapies target inflammatory activity, defined by clinical relapses and MRI lesions, as a way to impact disability development. So, the absence of clinical and MRI activity are accepted paradigms of disease-free status in treated patients. The development of highly effective therapies is allowing neurologists to consider their use early on the course of the disease in order to prevent permanent disability. However, certain therapies (natalizumab, fingolimod, dimethyl fumarate) have an inherent increased risk of serious complications (eg, PML). For that reason, it is imperative to consider risk benefit assessments regularly in the care of MS patients. The rationale behind escalating therapy is that treatment starts with safer drugs and moves on to more effective therapies if the ongoing treatment fails. In the escalating approach, glatiramer acetate and interferon betas are regarded as first-line drugs, whereas immunosuppressants (natalizumab, fingolimod, dimethyl fumarate, alemtuzumab) are considered second-line drugs. The concept of induction treatment with highly effective therapies early on in the course of the disease followed by long-term maintenance treatment has attracted considerable attention. Given that all the immunosuppressants that are currently available present potentially serious side effects, the induction strategy has generally been reserved for patients with very active and aggressive disease from onset. In general, there is acceptance on defining treatment success, and that is by the absence of any clinical evidence of progression (eg, relapses, progression of disability, and new MRI findings). However, controversy arises because there is a lack of biomarkers to reveal the extent of tissue damage in MS. In the coming years, new MRI techniques should help us to identify those RRMS patients, especially individuals without any real disability, who are most at risk of developing destructive CNS lesions with or without first-line therapy and who are therefore more eligible for an early and more aggressive treatment strategy.

Interferon-β_{1b} and Interferon-β_{1a}

IFN-β_{1b} (Betaseron, Extavia) was the first agent proven to favorably alter the natural course of the illness (**Table 55-4**).[60] Although the exact mechanism of action is unknown, effect of IFN-β_{1b} in MS may be caused by its immunomodulating properties, including the ability to augment suppressor cell function and reduce IFN-γ secretion by activated lymphocytes, its macrophage-activating effect, and its ability to downregulate the expression of IFN-γ–induced class II MHC gene products on antigen-presenting glial cells. IFN suppresses T-cell proliferation and may decrease blood–brain barrier permeability by decreasing matrix metalloproteinases.[60] IFN-β also increases the production of regulatory CD56 (bright) natural killer cells and Treg cells.[61] In general, all IFNs exert these actions in

the periphery and at the blood–brain barrier level.

TABLE 55-4 Evidenced-Based Recommendations for Disease Modifying Treatment of Multiple Sclerosis

Recommendations	Recommendation Grades[a]
Interferon-β	
• Interferon-β has been shown to reduce attack rates in patients with MS or those with CIS who are at high risk of developing MS	A-I
• It is appropriate to consider IFN-β for any patient with clinically definite MS or who already has RRMS or SPMS and is still experiencing relapses	A-I
• The effectiveness of IFN-β in patients with SPMS but without relapses is uncertain	U-I
• Route of administration of IFN-β products is probably not clinically important with regards to efficacy; however, the side-effect profile does differ	B-II B-I
• Rate of production of neutralizing antibodies is probably less with IFN-β_{1a} than with IFN- β_{1b}	C-I
• Presence of neutralizing antibodies may be associated with a reduction in the clinical effectiveness of IFN-β treatment	
Glatiramer acetate	
• Glatiramer acetate has been shown to reduce the attack rate in patients with RRMS	A-I
• Treatment with glatiramer acetate may slow sustained disability progression in RRMS	C-I
Mitoxantrone	
• Mitoxantrone probably reduces the attack rate in patients with relapsing forms of MS	B-II, III
• Mitoxantrone may have a beneficial effect on disease progression in MS	C-II, III
Natalizumab	
• Natalizumab decreases clinical relapse rate, Gd-enhancing lesions, and new T2 lesions	A-I A-I

Recommendations	Recommendation Grades[a]
• Natalizumab in RRMS positively changes measures of disease severity such as EDSS progression rate and changes lesions on MRI in RRMS	

CIS, Clinically isolated syndrome; RCT, randomized controlled trial; RRMS, relapsing-remitting multiple sclerosis; SPMS, secondary-progressive multiple sclerosis.

[a]Strength of recommendations: A: established. B: probable. C: possible. U: inadequate data to support recommendation.

Quality of evidence: Class I, evidence from one or more prospective, randomized, controlled clinical trial; Class II, evidence from cohort or RCT not meeting criteria for class I; Class III, evidence from other controlled trials; Class IV, evidence from uncontrolled studies, case reports, case series, or expert opinion.

Data from references 60 and 124.

IFN-β_{1b} is a nonglycosylated synthetic analog of recombinant IFN-β that is produced in *Escherichia coli*. IFN-β_{1b} is administered subcutaneously every other day at a dose of 250 mcg (8 million international units). Clinical trials have demonstrated that at these doses, IFN-β_{1b} significantly reduces annual relapse rate and MRI burden of disease compared with placebo. No significant differences were noted between the IFN and placebo-treated groups with respect to clinical disability.[60] Betaseron is packaged in partially premixed syringes with a new formulation that does not require refrigeration and can be used with an autoinjector. In 2009, an additional IFN product was introduced with the trade name Extavia; Extavia is the same medicinal product as Betaseron.

IFN-β_{1a} (Avonex, Rebif) is a natural-sequence glycosylated IFN produced in Chinese hamster ovary cells. Avonex is administered as a 30-mcg dose (6 million international units) intramuscularly once weekly. Rebif is made in a very similar fashion to Avonex but given as either 22 or 44 mcg subcutaneously three times weekly. Both are supplied in a 0.5-mL prefilled syringe and should be refrigerated, but remain stable at room temperature for 30 days. Rebif may have lower immunogenicity and a slightly better side-effect profile.[62]

When given 30 mcg intramuscularly once weekly for 2 years, patients receiving IFN-β_{1a} (Avonex) demonstrated, compared with placebo, statistically significant reductions (approximately one-third) in annual relapse rate as well as disease progression, defined as a confirmed decrease of one point on the EDSS.[63] When disease progression was assessed by MRI studies, patients receiving active drug had significantly fewer new enhancing lesions compared with placebo-treated patients. Similar results were seen with higher dose (44 mcg), more frequent administration (three times weekly), and subcutaneous injection of IFN-β_{1a} (Rebif).[60] Other studies reveal significant effects on slowing brain atrophy[64] and the progression of cognitive decline[63] in patients treated with Avonex. These observations show that IFN-β possesses significant disease-modifying activity.

Pegylated IFN-β_{1a} (Plegridy) was approved by FDA for treatment of relapsing forms of MS in August 2014. The attachment of polyethylene glycol (PEG) polymer chains to the interferon molecules results in a longer half-life and allows for less frequent dosing. Peg-IFN-β_{1a} is given by subcutaneous injections once every 2 weeks. Results from the pivotal study ADVANCE demonstrated significant reduction in annualized relapse rates (35.6%), reduction of new lesions on MRI scans and reduction of risk of disability progression (as measured by EDSS scale) when compared to placebo.[65]

Side effects are similar with all the IFNs. Baseline CBCs, platelet determinations, and LFTs should be documented before starting therapy, at 1 month, every 3 months for 1 year, and every 6 months thereafter. Small percentages of patients develop depressed cell counts and liver enzyme elevations that are usually transient and respond to discontinuation of therapy. Rarely patients have developed true liver failure requiring liver transplant, and package inserts for IFN-β products have been altered to reflect this risk. The most common adverse effects include injection-site redness and swelling, menstrual irregularities, flu-like symptoms (eg, fever, chills, and myalgias), and rarely injection-site necrosis. The flu-like side effects are seen in most patients and typically occur for up to 24 hours after injection and typically abate within 1 to 3 months after starting the injections, but can persist in some patients. Injection-site reactions are probably worse with IFN-β_{1b}, can occur at any time, and can be lessened by using appropriate injection technique, including site rotation, topical lidocaine, application of ice before and after the injection, or use of an autoinjector. Injecting the medications at body temperature (place under armpits to warm) will decrease injection-site pain. By taking the injection at night prior to bed time the patient may sleep through most of the flu-like symptoms; nonsteroidal antiinflammatory agents or acetaminophen taken before and at regular intervals for 24 hours after administration can alleviate the flu-like symptoms. Initiation of one-quarter or one-half the standard dose, with increase to full dosage over 1 to 2 months, is also beneficial in reducing flu-like side effects.[66] Some authors suggest that because of the transient immune activation that can occur following the introduction of IFN-β, a short burst of oral prednisone can alleviate some adverse effects.[66]

Less commonly reported side effects include transient shortness of breath or tachycardia, thyroid dysfunction, and neutralizing antibodies. Although depression is a common finding in MS patients, all the IFNs, especially IFN-β_{1b}, can produce depressive symptoms. Clinicians must monitor patients carefully for signs of depression. Patients who develop depression should be monitored closely for suicide risk. Most patients will not feel better or have improvement in MS symptoms when taking IFNs, and many will experience side effects; thus, adherence can become a major issue. Finally, safety data on IFN-β in pregnancy and lactation are lacking. Abortifacient activity in primates has been noted, and until adequate safety data are available, women should be counseled as to appropriate contraception while using these products.

Glatiramer Acetate (Copaxone)

Glatiramer acetate (formerly known as copolymer-1) is a synthetic polypeptide consisting of L-alanine, L-glutamic acid, L-lysine, and L-tyrosine. Although the precise mechanism of action of this compound is unknown, glatiramer acetate appears to mimic the antigenic properties of MBP.[67] This agent also may act by directly binding to MHC class II receptors and inhibiting binding of MBP peptides to T-cell

receptor complexes.[67] Glatiramer acetate has demonstrated that it induces Th2 (antiinflammatory) lymphocytes in experimental allergic encephalomyelitis.[67] This is thought to contribute to "bystander" suppression at the site of the MS lesion and thereby reduction of inflammation, demyelination, and axonal damage.[60] Glatiramer acetate may also suppress T-cell activation; recent studies suggest that it may be associated with a neuroprotective effect by inducing brain-derived neurotrophic factor.[68]

Given as a daily 20 mg or three times weekly 40-mg subcutaneous dose, glatiramer acetate appears to have a relatively mild adverse effect profile. Mild pain and pruritus at the injection site are the most frequent patient complaints. Approximately 10% of patients experience a one-time transient reaction consisting of chest tightness, flushing, and dyspnea beginning several minutes after injection and lasting usually no longer than 20 minutes. The postinjection reaction can occur with any dose, and is not limited to the first injection. If patients have no history or evidence of coronary artery disease, they may be assured these reactions are almost always self-limited and benign. Multicenter trials with glatiramer acetate have demonstrated significant reductions in mean annual relapse rate (approximately 29%), comparable with the IFNs.[60] An extension trial, completed after the original, pivotal 2-year study, suggests that glatiramer acetate may slow the progression of disability in patients with RRMS.[60] Glatiramer acetate also delays development of T1 holes on brain MRIs;[69] long-term uncontrolled data show that it remains safe and effective for individuals who continue to take it over 10 years.[70] Glatiramer acetate needs to be stored in the refrigerator but can be kept at room temperature for up to 1 week.

On Jan 28, 2014, the FDA approved glatiramer acetate (Copaxone) 40 mg/mL administered three times weekly by subcutaneous injection for the treatment of RRMS based largely on the results of the Glatiramer Acetate Low-frequency Admnistration (GALA) study.[71] This placebo-controlled trial in treatment-naïve patients demonstrated significant reduction in mean annual relapse rate (approximately 34%), reduction of new T2 lesions as well as T1 lesions, and comparable safety profile. Another open-label study Glatiramer Acetate low frequency safety and patient experience (GLACIER), further demonstrated comparable efficacy with favorable injection-related adverse events and convenience profile when patients were switched from glatiramer acetate 20 mg daily to 40 mg three times weekly.[72]

Clinical Controversy…

The US Food and Drug Administration approved a generic equivalent of daily glatiramer acetate 20 mg in April 2015. It has been launched in the United States as a disease-modifying therapy for people with relapsing forms of MS and CIS.

The mechanism of action of glatiramer acetate is unique. It does not appear to depend on general or selective immunosuppression in any form, but rather mediates its effects in MS through immunoregulatory pathways. It acts as an antigen, yet the precise mechanism of action remains to be fully elucidated, and no validated pharmacokinetic or pharmacodynamic biomarkers exist. In order to better characterize glatiramer acetate's biological impact, genome-wide expression studies were conducted with a human monocyte (THP-1) cell line. Consistent with previous literature, branded

glatiramer acetate upregulated antiinflammatory markers (eg, IL10), and modulated multiple immune-related pathways. Despite some similarities, significant differences were observed between expression profiles induced by branded glatiramer acetate and a differently manufactured glatiramoid purported to be a generic. These observations suggest differential biological impact by the two glatiramoids and warrant further investigation.

Natalizumab (Tysabri)

Natalizumab is a partially humanized monoclonal antibody directed at the cell surface adhesion molecule $\alpha_4\beta$-integrin (also known as very-late antigen 1, VLA-1). Natalizumab works by attaching to VLA-1 and blocking its interaction with its ligand on CNS endothelium vascular cell adhesion molecule 1 (VCAM-1). Thus, activated lymphocytes are denied entry past the blood–brain barrier. In a phase II study, compared with placebo, natalizumab significantly reduced the number of new gadolinium-enhancing lesions by more than 90%, and diminished relapses.[73] In a 2-year phase III trial (A Randomized, Placebo-Controlled Trial of Natalizumab for Relapsing Multiple Sclerosis [AFFIRM]), compared with placebo, annual relapse rate was reduced by more than 60%, gadolinium-enhancing lesions were lessened by more than 90%, and progression of disability was significantly delayed.[74] In a separate 2-year, phase III trial (The Safety and Efficacy of Natalizumab in Combination with Interferon Beta-1a in Patients with Relapsing Remitting Multiple Sclerosis [SENTINEL]) in patients already taking IFN-β_{1a} (Avonex), those who had natalizumab added had a relapse rate reduction of more than 50% and gadolinium-enhancing lesion reduction of 84% compared with patients who continued with IFN-β_{1a} alone.[75] In these trials, natalizumab was infused IV every 4 weeks and was relatively well tolerated, although approximately 1% of patients developed infusion reactions, and 6% developed neutralizing antibodies that diminished the efficacy of the drug.

On November 23, 2004, the FDA approved natalizumab for use in relapsing MS in patients with inadequate response or intolerance to other MS therapies with the stipulation that the studies would continue. In February 2005, Biogen and Elan voluntarily removed natalizumab from the market after receiving reports of two patients (one patient from the SENTINEL trial, and one patient in a Crohn's disease study), who died after developing progressive multifocal leukoencephalopathy (PML), a rare brain infection most commonly seen in patients with human immunodeficiency virus.[76,77,78] One other patient who developed PML in the SENTINEL trial survived.[76,77,78] Further safety analysis did not identify other cases, so on March 9, 2006, an FDA advisory panel reviewing the data suggested reapproval of natalizumab for use in relapsing patients with a mandatory Risk Evaluation and Mitigation Strategy (REMS) program called TOUCH. On June 5, 2006, the FDA reapproved use of natalizumab in the United States with a black-box warning about PML. The estimated risk for developing PML is low. Three factors appear to impact the overall risk of developing PML while receiving natalizumab therapy: duration of treatment (24 months or longer), history of John Cunningham virus (JCV) infection, and prior use of immunosuppressive therapies (mycophenolate mofetil, alemtuzumab, efalizumab, and rituximab).[79,80] A two-step enzyme-linked immunosorbent assay (ELISA, STRATIFY TEST) is available for qualitative detection of serum antibodies to the JCV, offering a false-negative rate of 2.5%.[79,80]

Plasma exchange has been utilized to help clear the drug more rapidly from the blood of patients who develop PML.[81] An acute syndrome, referred to as immune reconstitution inflammatory syndrome (IRIS), has been associated with acute neurological deterioration after PLEX, requiring the use of steroids.[82]

Natalizumab is indicated for relapsing forms of MS to delay the accumulation of physical disability and decrease the number of relapses in patients who have a documented inadequate response or intolerance to traditional MS therapies. Patients receiving natalizumab must be enrolled in the TOUCH program. The overall predicted seroconversion rate for JCV is 2% to 3% per year. For that reason, the current recommendation is to screen patients at baseline and every 6 months with a JCV test while receiving natalizumab therapy.[83]

Fingolimod (Gilenya)

Approved September 21, 2010, fingolimod is the first oral DMT for MS. It has a unique mechanism of action as a sphingosine 1-phosphate receptor agonist. Fingolimod exhibits its immunosuppressant properties by sequestering circulating lymphocytes into secondary lymphoid organs and reduces the infiltration of T lymphocytes and macrophages into the CNS. It may have neuroprotective effects. In clinical trials it decreased annualized relapse rates by approximately 52% compared to IFN-β_{1a}. After 7 years of continuous fingolimod therapy, approximately 92% of patients were free of gadolinium-enhancing lesions, although this data used the 1.25 mg dose and the recommended dose approved by the FDA is 0.5 mg once daily.

Major side effects include pronounced first dose bradycardia and, rarely, bradyarrhythmia or atrioventricular block, infections, macular edema, a decrease in forced expiratory volume over 1 second in patients with previously compromised lung function, elevation of liver enzymes, and a sustained increase of approximately 1 to 2 mm Hg in systolic and diastolic blood pressure. Rare cases of lymphoma have also been identified. The reversal of lymphopenia can take 2 to 4 weeks after discontinuation of the drug. It is recommended that all patients starting fingolimod treatment be monitored for signs of bradycardia for at least 6 hours after the first dose. The FDA also recommends hourly pulse and blood pressure monitoring for all patients starting treatment, with electrocardiogram monitoring prior to dosing and at the end of the observation period or continued until all symptoms resolve. The period should extend past 6 hours in patients at higher risk, in some cases overnight. Additionally, the package insert requires a new 6-hour observation period in patients who have discontinued and wish to restart therapy. The recommendation varies depending on the time of discontinuation and days of therapy missed. To reduce risks related to bradycardia or atrioventricular block, extended monitoring is now recommended in patients with certain preexisting conditions such as QT prolongation. This is also a concern in patients receiving concomitant drugs that slow the heart rate or atrioventricular conduction, drugs that cause QT interval prolongation, and those who have a known risk for torsades. The following class Ia and class III antiarrhythmic agents are contraindicated with concurrent use of fingolimod: quinidine, procainamide, disopyramide, amiodarone, bretylium, sotalol, ibutilide, azimilide, dofetilide, and dronedarone.[84] PML has been reported with fingolimod use in three patients after 3 years of exposure as of September 2015.

Additional monitoring recommendations include baseline CBCs, LFTs, ophthalmologic examinations, and ECG in patients with known heart problems. To date, one important drug interaction has been reported with concomitant use of ketoconazole and fingolimod. Ketoconazole has been shown to increase the area under the curve by 70%. If a live vaccine is to be administered to a patient (Zostavax, Flumist, YF-VAX, etc.), consider doing so prior to starting fingolimod or wait until 2 months after discontinuation.

Teriflunomide (Aubagio)

Teriflunomide is an oral immunomodulatory agent, which was FDA approved on September 12, 2012 for the treatment of relapsing forms of MS. The medication works by inhibiting dihydroorotate dehydrogenase to prevent the proliferation of peripheral lymphocytes (T and B cells). The reduction of activated lymphocytes in the CNS reduces the inflammation and demyelination, which occurs in patients with MS. Teriflunomide is the active metabolite of leflunomide, an agent approved for the treatment of rheumatoid arthritis; however, teriflunomide is dosed as 7 or 14 mg orally once daily.

O'Connor et al. studied 1,088 patients with CDMS. Patients receiving 7 or 14 mg daily of teriflunomide had a statistically significant reduction in annualized relapse rate compared with placebo (relative risk reductions: 31.2% and 31.5%; $P = 0.0002$ and 0.0005, respectively). The risk of disability progression was statistically significantly reduced for those receiving 14 mg of teriflunomide daily (hazard ratio reduction: 29.8%; $P = 0.0279$).[85]

In a 36-week randomized, double-blinded, placebo-controlled study in 179 MS subjects with relapse, the primary outcome was the average number of unique active lesions per MRI scan during treatment. A statistically significant reduction in the primary endpoint was reported for both 7 and 14 mg of teriflunomide compared with placebo (0.98 and 1.06; $P = 0.0052$ and 0.0234, respectively).[86]

Although teriflunomide is not metabolized by CYP 450 enzymes, it inhibits CYP2C8 and induces CYP1A2. This medication is also a substrate for the breast cancer resistant protein (BCRP). Thus, inhibitors of BCRP (cyclosporine) may increase serum concentrations of teriflunomide. Additionally, teriflunomide inhibits OATP1B1 and OAT3, however, the significance of these drug interactions is unknown at this time. Studies found that concomitant use of warfarin and teriflunomide resulted in a 25% decrease in international normalized ratio (INR), rendering the need for close monitoring. When teriflunomide is coadministered with estradiol and levonorgestrel, the mean maximum serum concentration and area under the curve are increased.

The most common adverse effects seen with teriflunomide are increases in LFTs, alopecia, nausea, diarrhea, influenza, headache, and paresthesias.

Teriflunomide carries a black-box warning because of the risk of hepatotoxicity and teratogenicity (based on animal data). Monitoring for teriflunomide includes LFTs, within 6 months prior to initiating teriflunomide and monthly for the first 6 months. Animal studies have found that oral teriflunomide resulted in fetal malformations and embryolethality in female rats as well as reduced sperm count in male rats. Therefore, teriflunomide is contraindicated in pregnancy and in women of childbearing potential not using reliable contraception. Patients who become pregnant during therapy or within 2

years after discontinuation of therapy should enroll in the Aubagio Pregnancy Registry and consider a cholestyramine washout. Additionally, men taking this medication with partners who wish to become pregnant may consider a cholestyramine washout to reduce serum drug levels, as this drug may remain in the blood for up to 2 years after discontinuation. Teriflunomide may activate tuberculosis so a negative skin test or treatment of the disease must be documented prior to starting therapy.

Dimethyl Fumarate (Tecfidera)

Dimethyl fumarate has an unknown mechanism of action; however, it is an in vitro nicotinic acid receptor agonist and an in vivo activator of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) pathway that is involved in cellular response to oxidative stress. It is approved by the FDA for relapsing forms of MS. Dimethyl fumarate is metabolized by esterases in the GI tract, blood, and tissues. There are no known drug interactions. It is classified as pregnancy category C. Dimethyl fumarate is dosed initially at 120 mg (delayed release) orally twice daily. After 7 days, the dose should be increased to 240 mg (delayed release) orally twice daily. Laboratory monitoring includes a CBC prior to starting therapy and within 6 months of initiating treatment and annually. Side effects include lymphocytopenia (2%-6%), increased LFTs, and flushing (40%), which should improve over 1 month and is decreased by taking it with food. Two cases of PML have been reported in patients treated with dimethyl fumarate as of September 2015. Rash, abdominal pain, diarrhea, nausea, and vomiting have also been reported. GI side effects decrease over 1 month and respond to symptomatic treatment. It is unclear if slowing the dose escalation may decrease the risk of GI side effects.

In the "Efficacy and Safety Study of Oral Dimethyl Fumarate (BG-12) with Active Reference in Relapsing Remitting Multiple Sclerosis (CONFIRM)" dimethyl fumarate decreased the annualized relapse rate by 44% and 51% with twice daily or three times daily dosing, respectively.[87] In "The Determination of the Efficacy and Safety of Oral BG-12 in Relapsing-Remitting MS" the annualized relapse rate decreased by 47% and 52% with 240 mg twice daily or three times daily dosing, respectively.[88]

Clinical Controversy…

Progressive multifocal leukoencephalopathy is caused by the reactivation of the JCV, a common virus to which many people have been exposed. PML has emerged in MS patients as a consequence of certain treatments including natalizumab, fingolimod, and dimethyl fumarate. At this time, there have been two cases of PML in MS patients receiving dimethyl fumarate and three cases in patients receiving fingolimod.

Even though it is premature to determine the exact risk stratification of PML with new oral agents, it is very likely that the presence of positive JCV serology, duration of therapy, and prolonged lymphopenia are factors to consider in making therapeutic decisions.

Alemtuzumab (Lemtrada)

Alemtuzumab is a humanized monoclonal antibody against CD52 approved for the therapy of RRMS. Alemtuzumab has proven high efficacy in clinical phase II and III trials, where INF-β_{1a} was used as

active comparator. CD52 is a glycosylphosphatidylinositol (GPI)-anchored protein consisting of 12 amino acids expressed at high levels on T and B lymphocytes, and to a lesser extent on monocytes, macrophages, and eosinophil granulocytes. Within a few minutes after infusion alemtuzumab leads to depletion of CD52 positive cells through antibody-dependent cell-mediated cytolysis (ADCC) and complement-dependent cytolysis (CDC).

The two Phase III trials, CARE-MS I[89] and II,[90] were randomized, rater-blinded studies with subcutaneous IFN-β_{1a} as active comparator designed to test clinical application of alemtuzumab. CARE-MS I included 581 treatment-naïve RRMS patients, whereas CARE-MS II enrolled 637 RRMS patients with breakthrough disease under previous DMTs. Alemtuzumab demonstrated a significant reduction in relapses compared to IFN-β_{1a} therapy (0.18 vs 0.39 = 54.9% ARR reduction in CARE-MS I; 0.26 vs 0.52 = 49.4% ARR reduction in CARE-MS II; each with $p < 0.0001$). However, a significant reduction in 6-month accumulation of disability was observed in CARE-MS II (42% reduction; 21% with IFN-β_{1a} vs 13% with alemtuzumab; $p < 0.01$), but not in CARE-MS I (11% with IFN-β_{1a} vs 8% with alemtuzumab; $p = 0.22$). The latter might be attributed to the unexpectedly low rate of disability progression in the IFN-β_{1a} group, indicating a relatively underpowered trial. MRI measures also proved superiority of alemtuzumab with significantly less gadolinium-enhancing lesions, new or enlarging T2 lesions and brain atrophy. Significantly more alemtuzumab than IFN-β_{1a} treated patients were free of any clinical disease (CARE-MS I: 74% vs 56%, $p < 0.0001$; CARE-MS II: 60% vs 41%; $p < 0.0001$) and free of any clinical and MRI disease activity (CARE-MS I: 39% vs 27%, $p < 0.01$; CARE-MS II: 32% vs 14%; $p < 0.0001$).

The high efficacy of alemtuzumab contrasts with its considerable high risks. Infusion Associated Reactions (IARs) affect over 90% of patients. Most are mild to moderate and consisted of headache, rash, pyrexia, and nausea. Respiratory tract and urinary tract infections are common. The accumulation of herpes infections during the CARE-MS studies led to the implementation of prophylactic acyclovir treatment (0-4 weeks after alemtuzumab infusion) significantly reducing infection rates. Moreover, there are single case reports of spirochetal gingivitis, pyogenic granuloma, esophageal candidiasis, tuberculosis, and listeria meningitis; the latter leading to dietary advice to avoid, for example, unpasteurized cheese.[91] No cases of PML have been reported to date.

Secondary autoimmune disease affects approximately 30% to 40% of patients, predominantly impairing thyroid function. Thyroid autoimmune disease mainly comprised hyperthyroidism, hypothyroidism, goiter, and thyroiditis. There is also a small but serious risk of immune thrombocytopenia (ITP). This complication can occur at any time ranging from 1 to 34 months post-alemtuzumab administration. Additionally, glomerulonephritis and single cases of autoimmune neutropenia, hemolytic anemia, and type 1 diabetes have been reported.[91] Extensive monitoring and early intervention allow for an appropriate risk management.

According to the labeling information, 12 mg of alemtuzumab are infused for five consecutive days in the first course and for 3 days in the second course 1 year later. Currently, alemtuzumab therapy is approved for the initial two courses. Concomitant corticosteroids, antihistamine, and antipyretic drugs are utilized with the infusion in order to avoid IARs.

Mitoxantrone (Novantrone)

Mitoxantrone, a member of the anthracenedione family, is approved by the FDA for reducing neurologic disability and the frequency of clinical relapses in patients with SPMS (chronic), PRMS, or worsening RRMS.[92] The MRI outcomes, however, were not as robust as those typically seen in the trials of relapsing patients alone.[93] Mitoxantrone is administered as a brief (5- to 15-minute) IV infusion dosed at 12 mg/m^2 every 3 months. An evaluation of left ventricular ejection fraction and ECG are required prior to administration of each dose, and if signs or symptoms of congestive heart failure develop. The maximum allowable lifetime cumulative dose of mitoxantrone is 140 mg/m^2. Other potential side effects noted are nausea, alopecia, menstrual disorder, amenorrhea, upper respiratory tract infection, UTIs, and leukemia. The role that mitoxantrone will ultimately play in the treatment of MS remains unclear, because potential cardiac toxicity limits its long-term use. More recent estimates also suggest the risk of leukemia may be as high as 1 in 145 patients, which has significantly decreased interest in its use for MS patients.[94] In addition, although patients with SPMS were included in the mitoxantrone in multiple sclerosis (MIMS—effect of mitoxantrone on MRI in progressive MS) trial, resulting in FDA approval for use in SPMS, there was no substudy documenting slowing of progression specifically in this subgroup of patients.[92,93] Thus, support for use of mitoxantrone in this context is lacking.[94]

Remaining Questions for Disease-Modifying Therapy

9 Despite encouraging results from well-conducted clinical trials, several relevant issues remain. Important questions in the use of the DMTs include when to begin therapy, which agent to initiate, and when to switch and stop therapies. The MS Coalition has developed an evidence-based paper, which is endorsed by the Americas Committee for Treatment and Research in Multiple Sclerosis (ACTRIMS), to provide guidance on the use of DMT in MS. Key recommendations regarding treatment and access considerations are summarized in **Table 55-5**.[95]

TABLE 55-5 Key Recommendations on Treatment and Access Considerations

- Initiation of therapy with an FDA-approved disease-modifying treatment is recommended as soon as possible following a definite diagnosis of relapsing MS, and can also be considered for selected patients with a first clinical attack consistent with MS where other potential causes have been excluded as well as patients with progressive MS with clinical relapses and/or inflammatory activity
- Choice of initial or alternative disease modifying therapy is complex and should be collaboratively done by the treating clinician and the patient
- Therapy is to be continued indefinitely, unless there is clear lack of benefit, intolerable side effects, inadequate patient compliance, new data that reveal other reasons for cessation, or better therapy becomes available
- Absence of relapses while on treatment should not justify discontinuation of treatment

- When switching disease modifying therapy due to suboptimal response, an agent with an alternative mechanism of action should be chosen
- Patient and clinician access to all available therapies is necessary due to significant variability in the MS population such as response to therapies, contraindications, risk tolerance, and compliance that may be influenced by route of administration and/or side effects
- Patient access to medication should not be limited by the frequency of relapses, age or other personal characteristics, or level of disability and should not be withheld to allow for determination of coverage by payers, as this puts the patient at increased risk for recurrent disease activity

Data from reference 95.

Decisions about the use of any medication rest on determination of the severity of the illness, the efficacy of the medication, side effects, and costs related to the therapy. Clearly, these drugs slow the course of the illness but do not suppress it completely, and in some individuals, there is no apparent benefit. There is now, however, overwhelming evidence that the vast majority of untreated patients will have progressive disease over time. Pathologic data clearly show that even in acute lesions there is significant axonal damage that is essentially irreversible. MRI data show that 80% to 90% of all new enhancing lesions are asymptomatic, suggesting that a "quiet" clinical course does not necessarily mean there is not ongoing disease activity that ultimately will lead to cognitive deficits and progressive spastic paraparesis.

It is clear that very early therapy is effective. In patients with CIS and two or more T2 lesions on brain MRI (ie, at high risk for developing CDMS), placebo-controlled studies with all three of the IFN agents and glatiramer acetate have shown significant delay in a second attack and positive outcomes on a variety of MRI measures (BENEFIT, Betaseron in Newly Emerging Multiple Sclerosis for Initial Treatment; CHAMPS, Controlled High Risk Subjects Avonex Multiple Sclerosis Prevention Study; and ETOMS, Early Treatment of Multiple Sclerosis).[60,96] Thus, very early therapy is potentially warranted, and IFN-β_{1b}, IFN-β_{1a} (Avonex), and glatiramer acetate are approved by the FDA for use after CIS in those patients with abnormal MRIs consistent with demyelination. The MS Coalition recommends that patients with relapsing disease should be initiated on an FDA-approved DMT as soon as possible following diagnosis.[95]

A second major issue is which drug to use in which patient. There has not been a single, randomized study comparing DMTs with one another in a similar patient population at the same time.[97] In the case of the first generation self-injectables, the pivotal, placebo-controlled trials produced results that were more similar than different when comparing across trials, including a nearly identical one-third reduction in relapse rate for all four drugs over 2 years. A small number of studies suggested higher dose, more frequent administration of IFN may be more efficacious than lower dose, less frequent administration.[98,99] Other studies argue against this,[100,101] and recent studies note no significant difference in outcomes between standard and double dose IFN-β_{1b} and glatiramer acetate,[102] and no difference between IFN-β_{1a} (Rebif) and glatiramer acetate.[103]

A concern with all three IFN products that further muddies our understanding of the clinical differences between IFN products is the development of neutralizing antibodies. In clinical trials, 30% to 40% of patients receiving IFN-β_{1b} developed antibodies directed against the drug.[104] In these patients, the exacerbation rate was similar to that in placebo-treated patients. In patients on IFN-β_{1b}, neutralizing antibodies can occur as early as 3 to 6 months and as late as 18 months. This product tends to be the most antigenic.[105] With IFN-β_{1a}, neutralizing antibodies were found in 22% of early trials of Avonex, but later studies reported that only 2% to 5% of treated patients developed antibodies; this decrease was caused by a formulation change of the drug making it the least antigenic.[101,105] Percentages of antibody formation for Rebif (approximately 12%) are intermediate, therefore moderately antigenic occuring in the first 9 to 15 months of treatment similar to Avonex.[60,104,105] Neutralizing antibodies are seen in approximately 6% of patients treated with natalizumab, and the antibodies seem to diminish efficacy.[75] The long-term clinical significance of these findings is still not completely clear, although three recent studies have further confirmed the effect of neutralizing antibodies on relapses, MRI lesions, and progression of disability.[105,106,107,108] Whether these antibodies are truly cross-reactive between products is unknown, as is the duration during which antibodies can be detected. There are no general consensus guidelines regarding when to test for neutralizing antibodies, which assay to use, or what titer cutoff to apply to patients in clinical settings.[109] An important question is whether production of antibodies might be diminished with treatments such as corticosteroids.

8 We now have experience for more than two decades with MS patients taking DMTs, yet they continue to have more relapses, more lesions on MRI, more disability, and ongoing slippage into SPMS.[110] There is no accepted definition of treatment inadequacy, although the Canadian Multiple Sclerosis Research Council has suggested a relatively simple approach that incorporates the elements of relapse rate, new MRI lesions, and change on the EDSS.[111] If a patient develops significant and persistent IFN antibodies, movement to a non-IFN (glatiramer acetate, natalizumab, fingolimod, teriflunomide, dimethyl fumarate, mitoxantrone, or possibly rituximab[112]) is reasonable. A second option is addition of an immunosuppressant agent, such as monthly methylprednisolone,[113] azathioprine, methotrexate, or mycophenolate. As noted above, the addition of natalizumab to IFN-β_{1a} was effective, but produced rare cases of PML, and thus, this combination should not be used. The addition of a statin agent may worsen MS[114] although these results are not definitive.

Symptomatic Management

10 Many of the symptoms of MS do not require pharmacologic management or do not respond to it. This section addresses the primary symptoms in which pharmacologic management may be of benefit (**Table 55-6**).[32,111,115,116,118,121] See the preceding section on the treatment of exacerbations for a discussion of optic neuritis.

TABLE 55-6 Treatment of Selected Primary MS Symptoms

Spasticity	Bladder Symptoms	Sensory Symptoms	Fatigue
Baclofen	Propantheline	Carbamazepine	Amantadine

Spasticity	Bladder Symptoms	Sensory Symptoms	Fatigue
	Oxybutynin		
	Dicyclomine		
Dantrolene			
	DDAVP		
Diazepam		Phenytoin	
	Self-catheterization		Antidepressants
Tizanidine		Amitriptyline or other TCAs	
	Imipramine or amitriptyline		Modafinil
Tiagabine		Gabapentin	
	Prazosin		Methylphenidate
Gabapentin		Lamotrigine	
	Botulinum toxin type A		Dextroamphetamine
Pregabalin		Pregabalin	
	Solifenacin		Armodafinil
Botulinum toxin type A		Duloxetine	
	Darifenacin		
Dalfampridine			
	Trospium		
	Hyoscyamine		

DDAVP, desmopressin acetate; TCA, tricyclic antidepressant.

Gait Difficulties and Spasticity

Problems with gait can be caused by spasticity, weakness, ataxia, defective proprioception, or a combination of these factors. Spasticity often presents late in disease and is amenable to pharmacologic intervention, whereas physical therapy may be required in treating gait disturbances caused by other factors. Spasticity is encountered commonly and tends to affect the legs more markedly than the arms. Spasticity can result in falls; however, in the later stages of the disease, the increased muscle tone of a spastic limb often lends pseudo strength to patients with underlying weakness. Therefore, when using muscle relaxants, one must be careful not to decrease the tone to an extent that ambulation is actually hindered.[32,115] Baclofen (Lioresal), a short acting γ-aminobutyric acid (GABA) analog, is the preferred agent and usually is started in dosages of 10 mg three times daily and titrated upward to achieve the desired response. Most patients achieve a satisfactory response with dosages between 40 and 80 mg/day; however, dosages higher than the recommended daily maximum of 80 mg are required by some patients.[32,115] A wearing-off is common, due to the relatively short duration of action. Continuous intrathecal administration of baclofen (Gablofen) may be an option for patients unable to tolerate or unresponsive to oral therapy. Baclofen should not be discontinued abruptly to avoid the possibility of seizures.[115]

Another effective agent with a different mechanism of action is tizanidine (Zanaflex). This short-acting, α-adrenergic agonist acts in the CNS to reduce spasticity by increasing presynaptic inhibition

of motor neurons. It appears to have efficacy comparable with that of baclofen.[115] Dosage must be titrated slowly over 2 to 4 weeks, starting with 4 mg at bedtime, with adjustments based on clinical response. Effective tolerated dosages have ranged from 2 to 36 mg/day. Sedation, dizziness, and dry mouth are the most commonly reported adverse effects, but hypotension also can occur, as well as a rare but severe hepatotoxicity. Tizanidine can be added in small dosages to baclofen, sometimes creating better results and making possible smaller doses of each drug.

In patients who are unable to tolerate baclofen or tizanidine, diazepam (Valium; 2-10 mg/day), clonazepam (Klonopin; 1-3 mg/day), or dantrolene sodium (Dantrium; 100-400 mg/day) may be considered as alternatives, but they generally are less effective than either baclofen or tizanidine. Mild spasticity also may respond to moderately high doses of gabapentin (Neurontin; 1,800-3,600 mg/day). Tiagabine (Gabitril 8-56 mg/day) may be useful in some patients with spasticity, but side effects can prohibit its use. Pregabalin (Lyrica; 75-300 mg/day) has similar features and mechanism of actions as gabapentin, although pregabalin is approximately three times more potent and does not saturate the L-transporter system in the GI tract, so it may prove useful in the treatment of spasticity in MS patients.

Botulinum toxin type A (Botox; dose depending on the muscles injected) has been shown to be effective in alleviating spasticity.[32] The amount of toxin required to exert an effect on spasticity is often too excessive to use safely in the larger muscles; therefore, its use is best limited to smaller areas of focal muscle spasm.

An alternative approach to gait disruption employs K^+ channel blockers such as 4-aminopyridine (4-AP), which can potentiate synaptic transmission and increase muscle twitch tension. In 2010, the FDA approved the use of a long-acting proprietary version of 4-AP, dalfampridine (Ampyra; 20 mg/day) to improve walking speed in patients with MS. Studies have shown that dalfampridine may improve walking speed by approximately 25% in responders.[116,117] In other countries, dalfampridine is referred to as fampridine.[117] A REMS program is in place to manage risks associated with dalfampridine use.

Safety concerns with the use of dalfampridine include the risk of seizures, particularly when patients exceed the maximum dose of 10 mg twice daily, and is contraindicated in patients with a history of seizures. It is important to educate patients on not taking compounded 4-AP with dalfampridine, which is the comparable extended release product. Additionally, the drug should not be chewed, crushed, or cut. If the patient misses a dose, they should take it immediately upon recognition and never double up on the dose, due to the risk of seizures. Commonly reported side effects of dalfampridine include UTIs, insomnia, dizziness, headaches, and balance disorders.

Tremor

Cerebellar symptoms such as tremor can be troubling and difficult to control. Medications that can be helpful include propranolol, primidone, and isoniazid.

Bowel and Bladder Symptoms

Patients commonly complain of incontinence, urgency, frequency, and nocturia, which are indications of a hyperreflexic bladder (ie, inability to store urine). A number of anticholinergic agents are used to treat this problem if symptoms are mild. In addition, tricyclic antidepressants have been used for their anticholinergic properties to treat this condition. With all anticholinergic agents, great care must be used to avoid falls, decreased cognition, and constipation, which is worsened by the patient's natural instinct to limit fluid intake. Antimuscarinic agents are also used to treat incontinence. Patients with significant sphincter detrusor dyssynergia may benefit from the oral use of α-adrenergic blockers or intramuscular use of botulinum toxin type A (Botox; dose depends on the muscles injected) to relax the internal sphincter (see Chapter e86).

Intermittent self-catheterization and the crede maneuver with or without a concomitant anticholinergic agent are recommended in patients with large postvoid residual volumes (more than 100 mL) or when the urinary problem is hyporeflexic in nature (failure to empty). Cholinergic agents (bethanechol) may be useful in patients with a hyporeflexive bladder. Patients with large post-void residual volumes are at risk for developing UTIs and often are prescribed urinary acidifiers such as vitamin C or antiseptics such as methenamine mandelate to prevent infections. Antibiotics used for UTI prophylaxis include sulfamethoxazole/trimethoprim, cephalexin, cinoxacin, and nitrofurantoin.

Constipation is the most common bowel complaint. Many medications (eg, narcotics, anticholinergics) in common use may worsen this problem, as may voluntary water restriction in those patients with urinary urgency and incontinence. Increases in dietary fiber and hydration may alleviate this problem, but in some instances laxatives or enemas may be necessary (see Chapter 36).

Major Depression

Major depression is common in patients with MS, and the risk of suicide may be increased markedly compared with healthy subjects.[118] Patients should be monitored closely for the development of major depressive symptomatology and treated accordingly (see Chapter 68). IFN products and natalizumab should be used cautiously in patients with significant depression.

Sensory Symptoms

Numbness and paresthesia are frequent sensory complaints but usually do not require treatment. Some MS patients may develop acute or chronic pain syndromes[115] such as trigeminal neuralgia and painful dysesthesias, for which treatment is necessary (see Chapter 60).

Sexual Dysfunction

Sexual dysfunction in both men and women are common in MS, and counseling should be offered to both partners. Phosphodiesterase inhibitors or Alprostadil, a prostaglandin E1, can be very effective in men with MS who have erectile dysfunction (see Chapter 84). Viagra is currently being studied in females with MS and sexual dysfunction. In patients needing antidepressant therapy for whom sexual dysfunction is a concern, bupropion is preferable to selective serotonin reuptake inhibitors as it has a much lower incidence of sexual side effects.

Fatigue

Fatigue, one of the most common complaints in MS patients, can be severely disabling, but treatment is often overlooked. Typically present in the mid to late afternoon, it can increase with heat exposure, exertion, intercurrent infection, spasticity, weakness, and depression. Amantadine hydrochloride (100 mg twice daily) is used often and may offer significant relief.[32,111] Methylphenidate (Ritalin) and related products, and dextroamphetamine (Dexedrine) are used commonly for fatigue in MS. Modafinil (Provigil), 200 mg daily, up to 400 mg daily may be helpful for MS-related fatigue. The *R*-enantiomer of modafinil is armodafinil (Nuvigil) dosed at 150 or 250 mg daily, which reaches peak concentrations more quickly with potentially fewer side effects than modafinil. In patients suffering from both depression and fatigue, a more activating antidepressant such as fluoxetine may be employed.

Cognition

Cognitive dysfunction is common in MS, affecting up to 50% or more of patients. It generally manifests itself as word-finding difficulties and problems with concentration and short-term memory. Cognitive dysfunction can be treated with stimulants or cholinesterase inhibitors.

Pseudobulbar Palsy

Pseudobulbar palsy is a condition caused by progressive degeneration of the corticobulbar tract in patients with MS. Symptoms include dysarthria, dysphonia, dysphagia, and sudden, inappropriate, uncontrollable, emotional outbursts such as crying or laughing. Dextromethorphan/quinidine 20 mg/10 mg is used for the treatment of this pseudobulbar affect. The recommended dosing for this combination medication is one capsule daily for 1 week, followed by one capsule twice daily. The mechanism of action is unknown. The rationale for utilization of this combination is that dextromethorphan is rapidly metabolized by CYP2D6, and quinidine inhibits the CYP2D6 enzyme to increase the serum concentration of dextromethorphan.

Complementary and Alternative Therapies for MS

Approximately 33% to 80% of patients with MS use complementary and alternative medicine (CAM) instead of, or in addition to, disease-modifying and symptomatic therapies.[119] Common CAM therapies include diet and dietary supplements such as vitamins, minerals, and herbs. Antioxidant supplements vitamin A, C, E, α-lipoic acid, coenzyme Q10, grape seed, pine bark extracts, mangosteen, and acai have suggestive evidence of benefiting MS patients. However, for patients with MS, there is a theoretical risk associated with taking antioxidant supplements owing to their ability to stimulate the immune system (T-cells and macrophages). Stimulating the immune system in patients with MS could be counterproductive, possibly worsening or exacerbating their disease, and may counteract the effects of immunomodulators. Other immune-stimulating supplements that should be used with caution are garlic, ginseng (Asian and Siberian), Echinacea, cat's claw, astragalus, alfalfa, and stinging nettle.[120]

The American Academy of Neurology recently updated evidence-based recommendations for the use of CAM in MS[119] (**Table 55-7**). Oral cannabis extract is established as effective treatment for spasticity and pain (Level A). Tetrahydrocannabinol (THC) and Sativex oromucosal spray may also reduce symptoms of spasticity and pain. (Level B). Of note, the safety and interactions with concurrent MS disease-modifying therapies (DMTs) has not been studied. There are limited data to support the effectiveness and safety of most of the CAM therapies for MS. However, for patients with MS who are willing to try new approaches with limited evidence, CAM may be a consideration in some cases. Healthcare providers can be a source of objective information regarding the use of CAM for MS and can assist their patients in making the best decision.[120]

TABLE 55-7 AAN Evidence-based Recommendations on CAM Therapies in MS

CAM Therapy	Type of MS	Symptoms and Reported Use	Effective	Ineffective	Recommendation Level
Oral cannabis extract	RRMS, SPMS, PPMS, MSU	Symptoms of spasticity and pain			A
	RRMS,SPMS, PPMS	Signs of Spasticity (short-term), tremor (short-term)	x		B
	MSU	Signs and symptoms of spasticity (long-term)	x	x	C
	RRMS, SPMS, PPMS, MSU	Bladder symptoms, urge incontinence			U
Synthetic THC	RRMS, SPMS, PPMS	Symptoms of spasticity, pain			B
	RRMS, SPMS, PPMS	Signs of spasticity (short-term), tremor (short-term)	x		B
	MSU	Signs and symptoms of spasticity (long-term)	x	x	C
	RRMS, SPMS, PPMS, MSU	Bladder symptoms, urge incontinence, central neuropathic pain			U
Sativex oromucosal spray	MSU	Symptoms of spasticity, pain, urinary frequency	x	x	B
				x	B

CAM Therapy	Type of MS	Symptoms and Reported Use	Effective	Ineffective	Recommendation Level
		Signs of spasticity, incontinence episodes			
		Tremor			C
		Anxiety/sleep, cognition, QOL, fatigue			U
Smoked cannabis	RRMS, SPMS, MSU	Spasticity, pain, balance and posture, cognition			U
Ginkgo biloba	RRMS, SPMS, PPMS	Fatigue	x	x	C
		Cognitive function			A
Lofepramine plus phenylalanine with B_{12} (Cari Loder regimen)	RRMS, SPMS, PPMS	Disability, symptoms, depression, fatigue		x	C
		Paresthesia			
Reflexology	MSU	Pain, HRGOL, disability, spasticity, fatigue, cognition, bowel/bladder function, depression, anxiety, insomnia	x		C U
Bee venom	RRMS, SPMS	MRI lesion number and volume, relapses, disability, fatigue, HRQOL		x	C
Magnetic therapy	RRMS, SPMS, PPMS	Fatigue	x	x	B
		Depression			B
Low-fat diet with omega-3 supplementation	RRMS	Relapses, disability, MRI lesions, fatigue, QOL		x	B

CAM, complementary and alternative medicine; HRQOL, health-related QOL; MS, multiple sclerosis; MSU, MS type unspecified; PCE, oral cannabis extract; PPMS, primary progressive MS; QOL, quality-of-life; RRMS, relapsing remitting MS; SPMS, secondary progressive MS; THC, tetrahydrocannabinol. A, established as effective or ineffective; B, probably effective or ineffective; C, possibly effective or ineffective; U, insufficient evidence to determine effectiveness or ineffectiveness.

Data from reference 119.

Vaccine Recommendations

A yearly flu shot is recommended for all patients with MS, including patients on any of the DMTs. The intranasal influenza vaccine, FluMist, which is a live, attenuated vaccine, is not recommended for patients with MS, however. As DMTs suppress the immune system, a patient taking one of these medications is at increased risk for developing an infection of the strain of virus given in the vaccine. Live virus vaccines are also more likely to cause an increase in MS disease activity than inactivated virus vaccines. Finally, it is unknown whether there are any direct interactions between DMTs and the intranasal influenza vaccine.[121] This information can likely be extrapolated to other vaccines, so if a patient is in need of a vaccination of any kind, "killed" virus vaccines are recommended.

Patients opting to take fingolimod who are varicella zoster virus antibody negative should receive the varicella zoster virus immunization (even though it is a live attenuated vaccine) at least 2 months prior to beginning fingolimod. This should allow time to mount an antibody response prior to immunosuppression with fingolimod.

Personalized Pharmacotherapy

The initial presentation of MS differs between individuals. When a patient is newly diagnosed modifiable risk factors may be considered prior to selecting therapy. Some of these modifiable risk factors include vitamin D deficiency, excess body weight, and smoking. Vitamin D deficiency has been associated with the risk of developing MS, and higher vitamin D levels may reduce MRI brain activity and thus reduce relapse rates.[8] Excess body weight is also associated with a higher risk of developing MS.[122] Smoking is associated with the development of MS, disability, MRI abnormalities, and conversion to CDMS (51%-75% in 3 years).[9,123]

Treatments available for MS need to be individualized based on the initial symptomatology, MRI presentation, and the risk associated with the chosen therapy. Essentially when patients present, they can be given a modestly effective therapy with a low side-effect profile (eg, IFNs and glatiramer acetate) or a more aggressive therapy with a higher risk profile (natalizumab, fingolimod, or dimethyl fumarate). The weighing of the risks and benefits is ultimately dependent on a patient's presentation or progression of disease, along with comorbid conditions such as depression.

The importance of adherence cannot be underestimated in patients taking DMTs. Nonadherence has been reported anywhere between 17% and 50%. The reason many patients stop taking their DMTs is multifactorial, and includes perceived lack of efficacy, side effects, undesirable route of administration, and depression. Patients who remain adherent to their DMTs generally remain employed full-time compared with those who are nonadherent. It is crucial that we establish realistic expectations for our patients on DMTs. Overall, untreated MS patients generally relapse about every 6 months, whereas treated patients relapse about every 2 to 5 years. Adherence is the key to successful treatment of MS.

EVALUATION OF THERAPEUTIC OUTCOMES

Response to treatment of acute exacerbations of MS is commonly seen within days. With respect to DMTs, it is important for the clinician to recognize that over the short term (days to weeks), little or no apparent benefit may be noted by either patient or clinician. Evaluation of therapeutic outcomes, such as decreased MS exacerbations and hospitalizations or perhaps slowed disease progression and disability (as measured using scales such as EDSS), must be conducted over a period of months to years. Patients should be provided with realistic goals and expectations of these treatment options and encouraged to participate in the evaluation of therapeutic response. Initially, it may be important to reevaluate patients at relatively short time intervals to monitor for adverse effects.

Safety monitoring of patients on IFN includes regular laboratory monitoring, patient observation, and questioning for adverse effects or changing disability, and regular neurologic examinations. Laboratory monitoring for individuals on IFN therapy should include a CBC, platelet count, and LFTs. These should be completed at baseline, every 3 months for 1 year, and every 6 months thereafter. Glatiramer acetate requires no laboratory monitoring. Teriflunomide requires a transaminase, bilirubin, CBC, tuberculin skin test, and blood pressure prior to initiating therapy and alanine aminotransferase monthly for 6 months after starting. Teriflunomide is associated with renal failure and increased serum potassium; therefore, patients should be monitored as needed. Dimethyl fumarate requires a CBC prior to starting therapy and within 6 months of treatment initiation and annually and LFTs. Natalizumab, fingolimod, and alemtuzumab have REMS programs to monitor safety.

In addition to counseling patients regarding the adverse effects associated with these drugs, clinicians should actively encourage patients to adhere with their prescribed regimens.

ACKNOWLEDGMENT

The authors acknowledge Felecia Hart, PharmD, Rebecca Barnhart, PharmD, and Joan Kaufman, illustrator, for their contributions to this chapter.

Chapter 56: Epilepsy

Viet-Huong V. Nguyen; Christine B. Baca; Jack J. Chen; Susan J. Rogers

INTRODUCTION

KEY CONCEPTS

- 1 Accurate classification and diagnosis of seizure type/epilepsy syndrome, including mode of seizure onset, is critical to selection of appropriate pharmacotherapy.
- 2 The goal of pharmacotherapy is seizure freedom with minimal side effects, and two-thirds to 80% percent of patients can achieve this.
- 3 Patients who do not respond to drug therapy should be referred to a comprehensive epilepsy center to determine if nonpharmacologic treatments such as surgery are potential options.
- 4 Patient specific treatment goals should be identified as early as possible, and patient characteristics such as age, comorbid conditions, ability to adhere with the prescribed regimen, presence or absence of insurance coverage, gender, child-bearing ability, and ethnicity should be considered.
- 5 If the therapeutic goal is not achieved with monotherapy, a second antiseizure drug (ASD), preferably with a different mechanism of action, can be added, or a switch to an alternative single ASD can be made.
- 6 Pharmacotherapy of epilepsy is highly individualized and requires titration of the dose to optimize ASD therapy (maximal seizure control with minimal or no side effects).
- 7 Newer ASDs appear to have comparable efficacy to older ASDs and are perhaps better tolerated.
- 8 Despite numerous drug trials, 20% to 35% of patients will have unsatisfactory control with ASDs.

Epilepsy is a common neurologic condition in which a person is prone to recurrent epileptic seizures.

There are many types of epilepsies characterized by different seizure types, ranging in severity and etiologies. While the specific pathophysiologic mechanisms behind different epilepsies are complex, the underlying general pathophysiologic process at the heart of all epilepsies is disturbed regulation of electrical activity in the brain resulting in synchronized and excessive neuronal discharge.

Beyond seizures, people with epilepsy face many challenges. It is important to recognize the coexisting health conditions and psychosocial effects of epilepsy. Patients with epilepsy may display neurodevelopmental delay, cognitive impairment, and often suffer from comorbid depression and anxiety.[1] Furthermore, patients with epilepsy may face educational and vocational challenges, have difficulties with independent living, and be victims of stigma and common public misunderstanding.[2] Such comorbid and psychosocial issues must be taken into account when treating and caring for patients with epilepsy. Indeed, the International League Against Epilepsy (ILAE) defines epilepsy not only as "a chronic condition of the brain characterized by an enduring propensity to generate epileptic seizures" but also by "the neurobiological, cognitive, psychological, and social consequences of this condition."[3] Clinicians treating epilepsy must try to address these common issues and comorbidities. Drug therapy should be selected to not only reduce the frequency of seizures as much as possible, but also with the goal of minimizing side effects, addressing coexisting health and social conditions, and enhancing quality of life (QOL).

EPIDEMIOLOGY

Epilepsy is the fourth most common neurologic disorder globally and in the United States following stroke, migraine, and Alzheimer's disease.[4] According to the World Health Organization (WHO), more than 65 million people worldwide suffer from epilepsy with 2.4 million people being diagnosed with epilepsy each year.[2] In the United States, approximately 2.2 million people suffer from epilepsy with 150,000 new cases being diagnosed each year.[4] Worldwide, the prevalence of epilepsy is believed to range from 1% to 3% and in the United States the prevalence is estimated at 1%.[4]

Epilepsy is a chronic disease and can present at all ages. One in 26 people in the United States will be diagnosed with epilepsy at some point in their lives across the age spectrum.[5] However, the highest number of new cases (incidence) will occur in childhood and in the geriatric population. The number of cases in childhood has been reported to be as high as 82.8 per 100,000 children compared to 40 to 70 cases per 100,000 in the general population.[6,7] Among children, epilepsy is most highly prevalent in children under 5 years of age with the highest number of new cases occurring under 2 years of age.[7] The high frequency of epilepsy in the elderly is now also being recognized with 1.5% of people older than 65 being affected by epilepsy in the United States.[2]

The majority of patients with epilepsy have a good prognosis and will be able to attain seizure freedom and enjoy normal life expectancy.[2] However overall, the mortality rate of patients with epilepsy is 2 to 3 times that of the general population and life expectancy in some of these patients is reduced.[2] This increase in mortality has been attributed to a wide variety of reasons including sudden unexplained death in epilepsy (SUDEP).[2]

Although all individuals with epilepsy experience seizures, not all individuals who experience seizures will be diagnosed with epilepsy. Some seizures are provoked and occur as a result of systemic, toxic, or metabolic insults such as drug overdose; alcohol, barbiturate or benzodiazepine withdrawal; or acute neurologic (eg, brain hemorrhage) or systemic illnesses (eg, hypocalcemia, hypoglycemia, uremia, and eclampsia). Some patients will have seizures only associated with fever (eg, febrile seizures). These seizures do not constitute epilepsy, as they are a symptom of the provoking insult and do not constitute "an enduring predisposition to generate epileptic seizures," once the provoking insult is removed or treated. For example, seizures provoked by transient high-temperature fevers will not recur when the patient is afebrile. Therefore, it is possible to have a seizure and to not have epilepsy.

Each year, 120 per 100,000 people in the United States will be evaluated for a newly recognized seizure whether it be provoked or unprovoked, but only 40 to 70 cases per 100,000 will be diagnosed with epilepsy. At least 10% of the general population will have at least one seizure from *any* cause in their lifetime. Furthermore, 8% of the general population will have at least one unprovoked seizure.[2]

Clinical Controversy…

SUDEP is the sudden, unexpected death of someone with epilepsy, who was otherwise healthy. Each year, more than 1 out of 1,000 people with epilepsy die from SUDEP. If seizures are uncontrolled, the risk of SUDEP increases to more than 1 out of 150. Seizure severity appears to be the strongest risk factor for SUDEP. Other potential risk factors include gender, seizure etiology, and younger age at onset. Sudden deaths are rare in children, but are the leading cause of death in young adults with uncontrolled seizures. The exact mechanisms underlying SUDEP are unclear, but recent research suggests there may be a cardiac mechanism involved.[2]

ETIOLOGY

Thousands of medical conditions can cause epilepsy, from genetic mutations to acquired injury (eg, stroke or traumatic brain injury). The most common causes vary depending on population. For instance, childhood-onset epilepsy is predominantly caused by genetic issues, while epilepsy with onset in older age is most often caused by acquired structural injury (eg, stroke or traumatic brain injury). In 2014, the ILAE issued a new report on etiologically based diagnoses. In this report they identified epilepsy etiologies that could be generally classified into six categories reviewed here: (1) genetic; (2) structural; (3) infectious; (4) metabolic; (5) immune; and (6) unknown.[8] These categories are not mutually exclusive as many epilepsies having etiologies that can belong to two or more categories.

Epilepsies with genetic etiology usually present in infancy or childhood. Examples of genetic epilepsies are Juvenile Myoclonic Epilepsy (JME) associated with many different mutations including mutations in EF-hand containing protein-1 (EFHC1), Dravet Syndrome associated with mutations in sodium channel, voltage gated, type I alpha subunit (SCN1A), and Childhood Absence Epilepsy (CAE) associated with many different mutations in T-type Ca^{2+} channels and GABA receptor subunits.[9,10,11,12] Prior to 2010, genetic epilepsies have historically been labeled primary generalized

epilepsy or idiopathic generalized epilepsy (IGE), as there were no clear structural brain abnormalities that could be found to be responsible for the epilepsy.[13,14] However, it is now recognized that most of these disorders have abnormalities at the molecular level and are genetic in origin and have thus been reclassified as genetic epilepsies.[14,15] Genetic etiologies cannot be acquired.

Structural etiologies can be of acquired or genetic origin and refer to abnormalities visible on structural neuroimaging.[8,15] Common epilepsies caused by structural abnormalities include mesial temporal lobe epilepsy and post-traumatic epilepsy. Mesial temporal lobe epilepsy is a common type of adult-onset epilepsy and is responsible for many of the drug resistant epilepsies seen in tertiary care epilepsy clinics. In mesial temporal lobe epilepsy, sclerosis occurs in the hippocampus, the main structure of the mesial temporal lobe and is characterized by glial scarring, reduced hippocampal volume seen on magnetic resonance imaging (MRI), and decreased cellular density seen on biopsy.[16] Traumatic brain injury from blunt force injury or stroke may cause structural lesions in the brain that may also cause epilepsy.[17] Prior to 2010, epilepsies with structural etiologies were referred to as symptomatic epilepsies.[14]

The most common epilepsy etiology worldwide is infectious and is generally acquired.[17] An infectious etiology refers to a patient who develops epilepsy as the sequelae of an infection, and not to a patient who is experiencing seizures in the setting of acute infection such as meningitis or encephalitis. In developing countries, the most common epilepsy is acquired from neurocysticercosis, a tapeworm in pork that infects the brain when ingested, causing subsequent structural injury that promotes the development of epilepsy.[17]

Metabolic and immune etiologies are less common, although they are increasingly being recognized and understood. Metabolic etiologies refer to a range of metabolic disorders that are associated with epilepsy such as Lafora disease, which is associated with abnormal glycogen metabolism and subsequent development of insoluble glycogen inclusion bodies resulting in epilepsy.[18] A range of immune epilepsies are also being recognized, such as anti-*N*-methyl-D-aspartate (anti-NMDA) receptor encephalitis which causes autoimmune-mediated central nervous system (CNS) inflammation and resulting epilepsy.[19] Both etiologies carry specific treatment implications that are currently evolving.

Lastly, patients can also present with unprovoked seizures that do not have an identifiable cause, and thus by definition have epilepsy of unknown cause.[8] Prior to 2010, these epilepsies were known as cryptogenic epilepsies.[14] These epilepsies may be due to an as yet unidentified gene or may be the consequence of an as yet unrecognized structural or metabolic disorder.

Risk Factors and Seizure Triggers

Separate from etiology are epilepsy risk factors and seizure triggers. While certain risk factors may suggest a predisposition to epilepsy, they are not necessarily the causative agent. Epilepsy risk factors include premature birth with small gestational weight, perinatal injury (eg, anoxia), history of alcohol withdrawal seizures, history of febrile seizures, and family history of seizures.[20] The presence of such

risk factors aid in establishing the diagnosis of epilepsy and may help in identifying the underlying epilepsy etiology.

Many factors have been shown to trigger seizures in susceptible individuals. Two of the best known seizure triggers are hyperventilation and photostimulation (eg, flashing lights or rapidly changing or alternating images) in certain genetic epilepsies including JME and CAE.[21] Physical and emotional stress, sleep deprivation, sensory stimuli, and hormonal changes occurring around the time of menses, puberty, or pregnancy have been associated with the onset of or an increased frequency of seizures.[21] Drugs including theophylline, alcohol, high-dose phenothiazines, antidepressants (especially bupropion), and street drug use have been associated with lowering seizure threshold and provoking seizures.[21]

PATHOPHYSIOLOGY

The underlying general pathophysiologic process at the heart of all epilepsies is neuronal hyperexcitability and hypersynchronization. Initially during a seizure, a small number of hyperexcitable neurons fire abnormally in synchrony. Normal membrane conductances and inhibitory synaptic currents break down, and excess excitability spreads, either locally to produce a localized focal seizure or more widely to produce a generalized seizure. This onset is propagated by physiologic pathways and networks to involve adjacent or remote areas. The clinical manifestations depend on the site of the focus, the degree of irritability of the surrounding area of the brain, and the intensity of the impulse.[22]

Hyperexcitability occurs because there is an enhanced predisposition of a neuron to depolarize and discharge when stimulated. Hyperexcitability may result from a number of mechanisms. Among these mechanisms, alterations in the number, type, and biophysical properties of voltage- or ligand-gated K^+, Na^+, Ca^{2+}, and Cl^- ion channels in neuronal membranes may play a significant role.[23] While mutations in these ion channels have been found to be associated with multiple different epilepsies, the exact nature of these alterations likely differ between epilepsies and are not fully elucidated. A large number of antiseizure drugs (ASDs) have mechanisms of actions that act on these specific ion channels, highlighting the importance of these channels in promoting hyperexcitability. For instance, carbamazepine and phenytoin reduce excitability by slowing Na^+ channel recovery from inactivation, thereby preventing hyperexcitable neurons from rapidly and repetitively firing and blocking firing in a use-dependent fashion.[24] Ezogabine acts on K^+ channels and enhances transmembrane potassium currents, thereby stabilizing the resting membrane potential and reducing excitability.[25] Benzodiazepines bind to the gamma subunit of the $GABA_A$ receptor leading to an increase in chloride ion conductance and inhibition of action potentials.[24]

Other mechanisms of epileptogenesis, which may play roles in hyperexcitability, are related to alterations in vesicle trafficking and neurotransmitter release. For instance, synaptic vesicle protein 2-A, a protein responsible for fusion of vesicles to the membrane, has been found to be upregulated in certain models of epilepsy, and is the target of the ASD levetiracetam.[25] Alterations in neurotransmitter uptake and metabolism may also play a role. Vigabatrin, an irreversible inhibitor of

γ-aminobutyric acid transaminase (GABA-T), the enzyme responsible for the metabolism of the inhibitory neurotransmitter GABA, works on this possible mechanism, increasing GABA and promoting inhibition.[24]

There are many other possible mechanisms which promote hyperexcitability including: (a) biochemical modifications of receptors; (b) modulation of second messaging systems and gene expression; and (c) changes in extracellular ion concentrations.[23,26] However, hyperexcitability that results simply in increased firing of random individual neurons by itself does not result in epileptic seizures. Epileptic seizures result only when there is also synchronization of excessive neuronal firing.[27] The intrinsic organization of local circuits of certain cerebral structures including the hippocampus, the neocortex and the thalamus contribute to synchronization and promote generation of epileptiform activity.[27,28] Modifications in the ratio and function of inhibitory circuits in these structures play an important role in promoting epileptogenesis, as a large number of these neurons are interconnected and can become simultaneously inhibited, and then synchronously excited. Although under normal circumstances, these neurons are asynchronous, it is believed that under abnormal circumstances, they become synchronous and act as pacemakers promoting epileptiform activity. Furthermore, sprouting and reorganization of neuronal projections in abnormal tissue may also lead to a chronic susceptibility to seizures.[27] Therefore, both excitation and inhibitory connections lie at the heart of the pathophysiologic mechanisms behind epileptogenicity.

CLASSIFICATION OF SEIZURES, EPILEPSIES, AND EPILEPSY SYNDROMES

An epileptic seizure is defined as a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.[3] Because a seizure is a symptom that occurs within the disease or the syndrome, it is important to understand that the classification of seizures is separate from the classification of epilepsies and epilepsy syndromes. In some cases the classification of seizures will be very similar to the epilepsy classification. In other cases there will be many seizure types occurring within an epilepsy syndrome. 1 Regardless, these classifications are important to distinguish because medication choices, treatment strategies (eg, epilepsy surgery) and prognosis may differ depending on these classifications. Classification strategies and seizure/epilepsy terminology has changed over the years.[13,14,15] Revised terminology as well as older terminology for classification of seizures and epilepsy will be reviewed in these sections. It is still important to be familiar with older terminology, as many practitioners continue to use this terminology and because much of the prior literature in epilepsy references this terminology. Throughout this chapter, we will try to use revised terminology where appropriate and refer to older terminology only when the referenced literature requires we do so.

Classification of Seizures—Mode of Onset

Epileptic seizures can manifest physically in a variety of ways and can range from intense involuntary repetitive muscular contractions (eg, convulsions) to subtle alterations in sensation or consciousness.

Due to the wide range of seizure types that may present it is often difficult to describe and classify seizures. However, in general, most seizures can be classified by their mode of onset and can be divided broadly into two categories: (1) generalized and (2) focal.[15] In the broadest terms, generalized *onset* seizures begin in *both* hemispheres of the brain, while focal *onset* seizures begin in only *one* hemisphere of the brain. Understanding seizure onset is important, as it is the fundamental characteristic by which to classify seizures. Recognizing mode of seizure onset has significant treatment and prognostic implications. For instance, patients with generalized onset seizures may have seizure exacerbation when treated with certain ASDs (eg, treating a patient who has CAE with carbamazepine).[29] Likewise, patients with focal onset seizures who are drug resistant may be good candidates for surgical resection, while patients with generalized onset seizures are not.

Focal Onset Seizures

Focal seizures may be further characterized by whether impairment or alteration of consciousness occurs. Impairment of consciousness is usually defined by loss of awareness of external stimuli or by the inability to respond to external stimuli in a purposeful and appropriate manner. When consciousness is not impaired and when awareness and responsiveness are retained, such seizures are termed focal seizures without dyscognitive features under the newest classification system released by the ILAE in 2010.[15] These seizures correspond to what has historically been termed simple partial seizures, as by definition consciousness is not impaired.[13] When impairment of consciousness occurs during a focal onset seizure, such seizures are termed focal seizures *with* dyscognitive features.[15] These seizures correspond to what have historically been termed *complex partial seizures* (CPS).[13] Focal dyscognitive seizures may have similar clinical signs and symptoms as those described for focal nondyscognitive seizures (see Clinical Presentation section), but the essential feature that distinguishes them is the presence of impaired consciousness.

Focal seizures may spread beyond the one hemisphere of the brain to the contralateral hemisphere to involve both hemispheres. When both hemispheres of the brain become involved, the seizure is said to have generalized. During generalization, the person usually becomes unconscious and may display bilateral convulsive features such as tonic-clonic motor features (see Clinical Presentation section for further details). Under the 2010 ILAE classification system, focal seizures that generalize into GTC seizures are now referred to as focal seizures evolving to a bilateral convulsive seizure which is considered to be a more precise and descriptive term. Such seizures have historically been referred to as CPS with *secondary* generalization.[15,30]

Generalized Onset Seizures

Generalized *onset* seizures begin in *both* hemispheres of the brain and have previously been referred to as primary generalized seizures. The ILAE now recognizes six types of generalized onset seizures including (1) absence seizures, (2) myoclonic seizures, (3) tonic-clonic seizures, (4) clonic seizures, (5) tonic seizures, and (6) atonic seizures.[15,31] Like secondarily generalized seizures, generalized onset seizures typically have clinical manifestations that indicate involvement of both hemispheres (eg, motor manifestations are bilateral and symmetric). Recognizing the difference between generalized

onset seizures and secondarily generalized seizures may be difficult, but certain distinguishing features such as presence of aura and characteristic findings on electroencephalogram (EEG) aid in distinguishing between the two (see Clinical Presentation section for more details).

Classification of Epilepsies and Epileptic Syndromes

In 1989, the ILAE defined an epileptic syndrome as an epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together.[14] These include such characteristics as type of seizure, etiology, anatomy, precipitating factors, age of onset, severity, chronicity, diurnal and circadian cycling, and sometimes prognosis. These syndromes have historically been classified along two main axes with the first axis separating epilepsies with generalized seizures from epilepsies with partial or focal seizures. Partial or focal seizures were then further subcategorized based on etiology. Many practitioners continue to categorize epilepsies along these axes. This distinction is important, as many practitioners also base initial ASD selection according to these axes. ASDs that can be used in both axes are often considered broad-spectrum ASDs. Narrow spectrum ASDs can only be used in one axis or in particular seizure types or epilepsy syndromes.

In 2010, the ILAE defined four categories by which to organize the epilepsies and epilepsy syndromes according to specificity of the diagnosis.[15] These categories are: (1) the electroclinical syndromes which have the most specific diagnoses and are distinct clinical entities that are reliably identified by a cluster of characteristics such as symptoms, signs, age of onset, EEG characteristics, and seizure types; (2) epilepsies with distinctive constellations/surgical syndromes which do not meet the criteria of an electroclinical syndrome yet can and should be recognized based on clinical features; (3) epilepsies attributed to and organized by structural-metabolic causes which are nonsyndromic epilepsies that do not fit into a specific electroclinical syndrome and which would have previously been termed “symptomatic focal epilepsies”; and (4) epilepsies of unknown cause which would have previously been termed “cryptogenic” epilepsies. Epilepsy classification and seizure classification are still evolving. This classification schema for seizures and epilepsy syndromes and epilepsies is depicted in **Fig. 56-1** and **Table 56-1**. It is important to be familiar with older as well as revised terminology for classification of epilepsies and epilepsy syndromes.

TABLE 56-1 2010 ILAE Electroclinical Syndromes and Other Epilepsies

I. **Electroclinical Syndromes** (and common examples arrange by age at onset)

Infancy:

- West Syndrome
- Dravet Syndrome

Childhood:

- Febrile Seizure Plus (FS+)
- Lennox-Gastaut Syndrome

- Childhood Absence Epilepsy

Adolescent-Adult:

- Juvenile Myoclonic Epilepsy (JME)
- Progressive Myoclonic Epilepsy (PME—including Lafora)
- Epilepsy with Generalized Tonic-Clonic Seizures Alone

II. **Distinctive Constellations** (and common examples):

Mesial Temporal Lobe Epilepsy with Hippocampal Sclerosis

III. **Epilepsies Attributed to and Organized by Structural-Metabolic Causes** (and common examples):

Malformations of Cortical Development

Tuberous Sclerosis

Tumor

Trauma

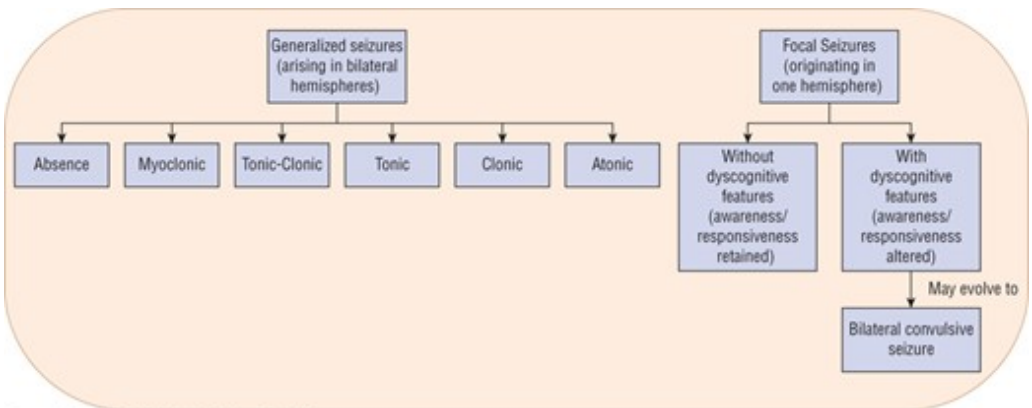
Strokes

IV. **Epilepsies of Unknown Cause**

Data from reference 15.

FIGURE 56-1

2010 ILAE Revised Terminology for Classification of Seizures.



CLINICAL PRESENTATION

Characteristics of Focal Seizures

Focal seizures without dyscognitive features may manifest clinically in a variety of ways and may be further characterized by one or more features including motor or autonomic symptoms.[15] Such symptoms will vary depending on where the abnormal firing occurs. For example, seizures may manifest as alterations in motor functions such as clonic movements (eg, twitching or jerking) of the arm, shoulder, face, or leg indicating seizure activity in motor pathways. Sensory or somatosensory symptoms may also occur, such as feelings of numbness or tingling or a feeling of déjà vu, indicating parietal or temporal lobe seizure activity. Visual disturbances or hallucinations may also indicate seizure activity involving the occipital lobe, while ringing or buzzing sounds in the ears may indicate seizure activity in auditory areas of the brain. Autonomic symptoms such as sweating, salivation, or pallor may also occur, indicating seizure activity in autonomic areas of the brain. In all the above examples of focal nondyscognitive seizures, only a portion of the brain is affected during the seizure, and the person retains consciousness, awareness, and responsiveness.[15,31]

The hallmark of focal dyscognitive seizures is amnesia to the event. Depending on the area of the brain involved, focal dyscognitive seizures may have similar clinical signs and symptoms as that described except with impairment of consciousness. The patient may still be able to perform routine tasks such as walking, although such movements are not purposeful or planned and after the event is over the patient may not recall their actions. The patient may also be able to respond to questions during the seizure, although they may not respond appropriately. The degree of alteration in awareness and responsiveness may be so subtle that witnesses may sometimes not be able to recognize that anything is overtly wrong. For example, during these seizures the patient may simply display behavioral arrest and stare off into space for a minute. They may also display subtle automatisms such as lip smacking, chewing, or picking at their clothing unpurposefully. On the other hand, some patients may display extreme aberrations of behavior, and some are even mistakenly diagnosed as having psychotic episodes. After the seizure (postictal period), the patient may display altered consciousness, drowsiness, confusion, or even paranoia for a variable period of time and frequently go into a deep sleep.[15,30]

Focal seizures are sometimes followed by convulsive seizures. During convulsive or generalized tonic-clonic (GTC) seizures, the patient experiences loss of consciousness, followed by a sudden sharp tonic contraction of muscles with a subsequent period of rigidity and clonic movements oftentimes described as jerking of the arms and legs. During the seizure, the patient may cry or moan, due to muscles in the larynx being activated. The patient may also lose sphincter control with bladder and/or bowel incontinence or bite the tongue. Postictally, after the patient regains consciousness, the patient may experience confusion, drowsiness, lack of coordination, soreness throughout the body, and amnesia for the event.

Focal seizures evolving to a bilateral convulsive seizure have clinical features that differentiate it from generalized onset convulsive seizures (eg, seizures with onset in bilateral brain hemispheres). For instance, in some cases of secondarily generalized seizures, patients will describe somatosensory

symptoms as a “warning” prior to the convulsive seizure. These warnings are frequently termed auras, which are by definition restricted focal epileptic discharges. Auras are subjective and may be sensory or experiential. Sensory auras may include feelings of tingling, numbness, flashing lights, odors, tastes, and epigastric distress. Experiential auras include feelings of fear, depression, joy, anger, or memory phenomena such as feelings of familiarity (déjà vu) or unfamiliarity (jamais vu). Auras are focal nondyscognitive seizures which may progress to focal dyscognitive seizures and then to seizures with bilateral convulsions.[15,31] Other features that aid in distinguishing generalized-onset seizures from secondarily generalized seizures are age of onset, family history of seizures, the presence of genetic mutations, and findings on EEG, computed tomography (CT), and MRI that are beyond the scope of this chapter.

Characteristics of Generalized Seizures

Clinical descriptions of the six types of generalized onset seizures recognized by the ILAE including (1) absence seizures, (2) myoclonic seizures, (3) clonic seizures, (4) tonic seizures, (5) tonic-clonic seizures, and (6) atonic seizures are described hereunder:

1. Generalized absence seizures are manifested by a sudden onset interruption of ongoing activities, a blank stare, and possibly a brief upward rotation of the eyes indicating the abrupt onset and offset of impaired consciousness. The staring and behavioral arrest lasts 2 to 30 seconds during which time the patient is unaware of the environment and unresponsive. The patient has neither a warning that the seizure is going to occur, nor does the patient have postictal confusion or lethargy after the seizures. After cessation of the seizure, the patient will often return to the previous activity as if nothing had happened. These absence seizures generally occur in young children through adolescence. It is important to differentiate these seizures from focal dyscognitive seizures. In general, absence type seizures are much more brief then the staring spells associated with focal dyscognitive seizures and have minimal post-ictal manifestations.[15,31]

2. Myoclonic seizures are characterized by brief, shock-like muscle contractions commonly referred to as jerks. These jerks can occur as a single jerk or as a series of jerks with each jerk typically lasting only milliseconds. These jerks are synchronous and display bilateral features usually involving the whole body simultaneously, although they can be asymmetric and confined to body parts. They are not associated with an alteration in consciousness and are typically worse in the late evening or early morning either prior to going to sleep or soon after awakening.[15,31]

3. Generalized clonic seizures are seizures involving bilaterally rhythmic jerking that are more sustained and rhythmic than that seen in a myoclonic seizure.[15,31]

4. Generalized tonic seizures involve bilaterally increased tone or “stiffening” of the limbs typically lasting seconds to a minute.[15,31]

5. Generalized onset tonic-clonic seizure is a seizure consisting of an initial tonic phase followed by a clonic phase. It is important to remember that GTC seizures can also be secondarily

generalized and that these seizures must be differentiated from generalized onset tonic-clonic seizures.[15,31]

6. In contrast to tonic seizures in which there is a sudden onset of increased tone, a sudden loss of muscle tone occurs in *atonic seizures*. Atonic seizures are not preceded by myoclonic or tonic features and can be very brief. They often occur in patients with intellectual impairment. They may present as a head drop, the dropping of a limb, or a slumping to the ground (due to loss of postural tone). These patients often wear protective headware to prevent trauma. Atonic seizures are the hallmark of Lennox-Gastaut Syndrome.[15,10,31]

Diagnosis

Epilepsy is a clinical diagnosis, meaning that it is a diagnosis made on the basis of medical signs and patient-reported symptoms, rather than any one diagnostic test. As previously noted, the ILAE has defined epilepsy as a "disease characterized by an enduring predisposition to generate epileptic seizures and by the neurobiological, cognitive, psychological, and social consequences of this condition."[3] However, this definition is theoretical and not sufficiently detailed for the purposes of diagnoses. Therefore, in 2014 the ILAE developed a practical (operational) definition of epilepsy, designed for use by doctors and patients.[32] According to the ILAE, a person is considered to have epilepsy if they meet any of the following conditions: (1) at least two unprovoked (or reflex) seizures occurring greater than 24 hours apart; (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (3) diagnosis of an epilepsy syndrome.[32]

When a person presents with possible epilepsy, the most important initial step in clinical evaluation is to get a detailed description of the event. In most cases, the healthcare provider will not be in a position to witness a seizure. Many patients (particularly those with focal dyscognitive seizures or focal seizures evolving to bilateral convulsions) are amnestic to the actual seizure event, and obtaining an adequate description from a witness is critically important. Firstly, the presence of an aura should be determined. If the presence of an aura can be confirmed, it becomes very likely that the seizure is focal. The presence of ictal motor, sensory, or autonomic features should all be noted. The degree of mental status impairment during the event should be determined. Tongue biting, cheek biting, and bladder or bowel incontinence during the seizures should be asked about and the seizure time course noted. Finally, postictal phenomena (eg, fatigue, headaches, confusion, and psychosis) should be assessed.

CLINICAL PRESENTATION Epilepsy Recall That:

- Focal (eg, partial) seizures may present with just motor symptoms (twitching or shaking, usually one-sided) or just sensory symptoms (numbness, tingling, usually one-sided)
- Focal dyscognitive (eg, complex partial) seizures are associated with altered consciousness or impairment in awareness
- Absence seizures can be almost nondetectable with only very brief (seconds) periods of altered

consciousness

- Convulsive (eg, GTC) seizures are major convulsive episodes and are always associated with a loss of consciousness

Some Pertinent Questions to Ask

- Was there any warning that something was going to happen? What were the warning signs?
- Were there any abnormal movements or shaking?
- Was there loss of bowel or bladder function?
- Did you bite your tongue?
- Was there any post-event confusion?
- How much of the event do you remember?
- How long did the event last?
- How often do you have these events?

Signs

- Interictally (between seizure episodes), there are typically no objective or pathognomonic signs

Laboratory Tests

- There are currently no diagnostic laboratory tests for epilepsy
- In some cases, particularly following generalized convulsive seizures, serum prolactin levels obtained within 10 to 20 minutes can be transiently elevated[33]
- Laboratory tests can be done to rule out treatable causes of seizures (eg, hypoglycemia, altered electrolyte concentrations, infections, etc.) that do not represent epilepsy

Other Diagnostic Tests

- An abnormal epileptiform EEG is found in only approximately 50% of the patients who have epilepsy. Sometimes several EEGs must be obtained before convincing epileptiform activity is detected. Video EEG is the gold standard for diagnosing epilepsy and involves admission to the hospital and recording video and EEG until the patient has a typical event. However, this is not the standard for most patients and is generally reserved for cases unresponsive to medication or difficult to characterize.[34,35]
- Brain MRI is indicated in patients with epilepsy. MRI is the preferred imaging technique to identify structural abnormalities (eg, sclerosis in the mesial temporal lobes and traumatic brain injury).[35]

- A computed tomography (CT) scan typically is not helpful except in the initial evaluation for a brain tumor, cerebral bleeding, or gross anatomical injury.[35]

Epilepsy-Related Health Screening

- Screening for comorbid medical, psychiatric, and neurodevelopmental conditions commonly coexisting with epilepsy is useful.[35]
- Common conditions that are typically screened for in patients with epilepsy include depression (and suicidal ideation), learning and development in children, and bone health.[35]

Beyond the actual ictal event, age of onset of seizures, frequency of, and evolution of the seizures over time must be assessed. Although seizures tend to be stereotyped within an individual, the clinical presentation of the seizure may change over time or with treatment. Furthermore, triggers should be identified because avoiding them may have a significant impact on seizure control. Seizures that result in injuries should also be noted and mental health problems should be identified.

Accurate diagnosis also depends on the neurologic examination and diagnostic techniques such as electroencephalography (EEG) and brain imaging. The EEG can identify abnormal brain wave patterns that are associated with certain seizure types and epilepsy syndromes and is one of the most important diagnostic tests that can be performed for patient with epilepsy. Brain imaging with either CT or MRI can detect structural lesions that can aid in the diagnosis of seizures and epilepsy types. Though CT is commonly initially performed in a patient who presents with a first seizure, an MRI is preferred for validation of an epilepsy diagnosis.

TREATMENT

Desired Outcomes

Antiseizure drug therapy is the mainstay of epilepsy treatment. However, ASDs are symptomatic treatment only. None have been proven to have any disease modifying properties, and no ASDs are curative. Surgery is the only possibly curative therapy, and only a select number of patients qualify for surgery. Therefore, the majority of patients will be on life-long ASD therapy. 2 The goal of ASD therapy is to eliminate symptoms (eg, seizures) with minimal side effects. In most patients the goal is complete seizure freedom. However, in 20% to 35% of patients this may not be possible, and seizure control must be balanced with QOL goals.

Treatment goals can change over time.[36] For those who cannot obtain seizure freedom despite these therapies, more obtainable goals should be established (eg, decrease in the number of seizures and minimized drug adverse effects).

Clinical Controversy…

Currently available drugs used in the treatment of epilepsy are commonly called antiepileptic drugs (AEDs). However, all currently available drugs act to prevent seizures only. None of the currently available AEDs have been proven to have any disease modifying or antiepileptogenic properties.

Therefore, there is controversy as to whether such drugs should be labeled AEDs or antiseizure drugs (ASDs). In this chapter, we refer to drugs used in epilepsy treatments as ASDs. However, it is important to recognize that AED is a commonly used term that is often used interchangeably with ASD.

General Approach to Treatment

The general approach to treatment involves assessment of seizure type and frequency, identification of treatment goals, development of a care plan, and a plan for follow-up evaluation. During the assessment phase, it is critical to establish an accurate diagnosis of the seizure type and epilepsy classification. Once the assessment is complete and the most accurate epilepsy diagnosis is made for patients with new onset seizures, the choice is whether to use drug therapy and, if so, which one.

Once the decision to initiate therapy has been determined, patient-specific treatment goals must be identified. The drug treatments of first choice depend on the type of epilepsy as well as patient characteristics such as age, gender, comorbid medical conditions, susceptibility to adverse effects, ability to comply with a prescribed regimen, and insurance coverage.

When starting ASD therapy, monotherapy is preferred.[37] Polytherapy should be considered for those patients who cannot achieve seizure freedom on ASD monotherapy. Those who have unsatisfactory control despite multiple drug treatment may be candidates for vagal nerve stimulators, surgery, or ketogenic diet.

Once the care plan is established and an ASD is selected, patient education and assurance of patient understanding of the plan is essential. Detailed directions regarding titration, what to do in the event of a treatment-emergent side effect, and what to do if a seizure occurs must be provided to patients. Providing the patient with a seizure and side-effect diary will assist in the follow-up and evaluation phase.

At the follow-up stage of treatment (which can be done in the hospital, clinic, pharmacy, or by phone), the treatment goals must be reviewed. If the goal has been achieved, new goals should be identified. For example, if convulsive seizures are now controlled, the goal may be to control focal seizures. If a patient fails to respond to the first ASD, trials with other ASDs should be attempted as appropriate. Patient adherence, drug efficacy, and safety of treatment should be taken into account. For a patient with long-standing epilepsy, adequacy of the current medication regimen should be routinely evaluated.

When seizures are not controlled, medication nonadherence must always be considered as it is the single most common reason for treatment failure. It is estimated that up to 60% of patients with epilepsy are nonadherent.[38] The rate of nonadherence is increased by the complexity of the drug regimen and by doses taken three and four times a day.[38] Frequent uncontrolled seizures can also predispose a patient to nonadherence secondary to confusion over whether the drug was taken. Nonadherence is not influenced by age, sex, psychomotor development, or seizure type.[12]

When to Start Antiseizure Drugs

If a patient presents after a single isolated seizure, one of three treatment decisions can be made: (1) treat, (2) possibly treat, or (3) do not treat. These decisions are based on the probability of the patient having a second seizure. For patients with no risk factors, normal MRI, and normal EEG, the probability of a second seizure is less than 10% in the first year and approximately 21% by the end of 2 years. If risk factors are present, the probability of seizure recurrence is 26% in the first year and 41% by the end of the second year.[39]

Some clinicians start ASD treatment after the first seizure, whereas others start ASD treatment after one unprovoked seizure with a definite abnormal epileptiform EEG. Others do not initiate treatment until a second, unprovoked seizure has occurred. The decision on whether to start ASD therapy depends on the provider and on patient-specific factors such as patient's lifestyle and preferences. However, patients who have had two or more unprovoked seizures should be started on ASDs.[32]

When to Stop Antiseizure Drugs

The ASDs used to control seizures may not need to be given for a lifetime. Polypharmacy can be reduced, and some patients can discontinue ASDs altogether. The drug considered least effective or the agent deemed most responsible for adverse effects should be discontinued first. In some cases, decreasing the number of ASDs can decrease side effects and increase cognitive abilities.[40] This improvement in cognition may be small, especially if the patient is on a drug that primarily affects psychomotor speed with less effect on higher-order cognitive functioning.

Factors favoring successful withdrawal of ASDs include a seizure-free period of 2 to 4 years, complete seizure control within 1 year of onset, an onset of seizures after age 2 but before age 35, and a normal neurologic examination and EEG.[41,42] Factors associated with a poor prognosis in discontinuing ASDs, despite a seizure-free interval, include a history of a high frequency of seizures, repeated episodes of status epilepticus (SE), a combination of seizure types, and development of abnormal mental functioning.[41,42] The American Academy of Neurology (AAN) has issued guidelines for discontinuing ASDs in seizure-free patients.[43] After assessing the risks and benefits to both the patient and society, ASD withdrawal can be considered in a patient meeting the following profile: seizure free for 2 to 5 years, a history of a single type of focal seizure or primary generalized seizures, a normal neurologic exam and normal IQ, and an EEG that has normalized with treatment. When these factors are present, the relapse rate at 1 year is expected to be 35% and 29% at 2 years.[44] ASDs can be restarted in patients who relapse after ASD withdrawal. Seizure freedom can be regained for most patients who restart ASDs although not for all.[42]

Antiseizure drug withdrawal should be done gradually. Some patients will have a recurrence of seizures as the ASDs are withdrawn. Sudden withdrawal can be associated with the precipitation of SE. Withdrawal seizures are of particular concern for agents such as benzodiazepines and barbiturates, and these ASDs should be withdrawn more slowly over a period of many months.

Nonpharmacologic Therapy

Nonpharmacologic therapy for epilepsy includes diet, surgery, and vagus nerve stimulation (VNS)

among other modalities. A vagal nerve stimulator is an implanted medical device that is Food and Drug Administration (FDA) approved for use as adjunctive therapy in reducing the frequency of seizures in adults and adolescents older than 12 years of age with partial-onset seizures that are refractory to ASDs. It is also used off-label in the treatment of refractory primary generalized epilepsy. The mechanisms of antiseizure actions of VNS are unknown. Human clinical studies have shown that VNS changes the cerebrospinal fluid (CSF) concentration of inhibitory and stimulatory neurotransmitters and activates specific areas of the brain that generate or regulate cortical seizure activity through increased blood flow. There is experimental evidence to suggest that the anticonvulsant effect of VNS is mediated by the locus coeruleus.[45]

The VNS device is relatively safe. It may also have a positive effect on mood and behavior, often independent of seizure reduction.[46] The most common side effect associated with stimulation is hoarseness, voice alteration, increased cough, pharyngitis, dyspnea, dyspepsia, and nausea. Serious adverse effects reported include infection, nerve paralysis, hypoesthesia, facial paresis, left vocal cord paralysis, left facial paralysis, left recurrent laryngeal nerve injury, urinary retention, and low-grade fever. In the VNS studies, the percentage of patients who achieved a 50% or greater reduction in their seizure frequency (responders) ranged from 23% to 50% at 3 months.[47,48] VNS effects are not noted immediately and are more long term. VNS is also unlikely to lead to seizure freedom but may allow for reduced seizure frequency and reduced medication burden.[49]

3 Surgery is the treatment of choice in selected patients with refractory focal epilepsy, especially those patients with seizures originating from the temporal lobe. A 2001 randomized controlled trial focusing on temporal lobe epilepsy, found that 58% of patients who underwent surgery were seizure free at 1 year compared to 8% of patients who did not undergo surgery.[50] A second randomized controlled study, initiated to evaluate the efficacy of early surgery versus continued medical management in patients who had failed two ASD trials, showed that 11 of 15 patients who had undergone surgery were seizure free at 2 year follow-up, compared to none in the medical therapy group.[51] Certain factors have been found to predict good outcomes in surgical patients including presence of a focal brain lesion on MRI, presence of unilateral mesial temporal sclerosis, presence of a localized temporal lobe positron emission tomography (PET) abnormality (even if brain MRI is normal), concordant EEG data showing location of ictal onset and shorter preoperative seizure duration.[52,53,54] The last finding is important to emphasize, as it is imperative to identify possibly drug-resistant patients with epilepsy quickly and to refer them to an epilepsy center as soon as possible. Epilepsy surgery is not without risk. Learning and memory can be impaired postoperatively, and general intellectual abilities are also affected in a small number of patients.[54] Patients may need to continue ASD therapy for a period of time following successful epilepsy surgery, but dosage reduction may be achievable.[55]

The ketogenic diet, devised in the 1920s, is high in fat and low in carbohydrates and protein, and it leads to acidosis and ketosis. Protein and calorie intake are set at levels that will meet requirements for growth. Most of the calories are provided in the form of heavy cream and butter. No sugar is allowed. Vitamins and minerals are supplemented. Medium-chain triglycerides can be substituted for the dietary fats. Fluids are also controlled. It requires strict control and parent compliance. Although

some centers find the diet useful for medically refractory epilepsy patients, particularly those with certain etiologies such as GLUT1 deficiency, others have found that it is poorly tolerated by patients. Long-term effects include kidney stones, increased bone fractures, and adverse effects on growth.[56] An international consensus statement has been published, which offers recommendations employing various forms of the ketogenic diet which may be more tolerable, including the use of the modified Atkins diet and the Low Glycemic Index Treatment.[57] Subsequent data support the use of these variations in the ketogenic diet, as well as the medium chain triglyceride ketogenic diet in select patients.[58]

Pharmacologic Therapy

4 Selection and optimization of ASD therapy first requires consideration of the seizure type, epilepsy classification, and epilepsy etiology, as an ASD must be effective for the specific seizure type and epilepsy or epilepsy syndrome being treated. Patient characteristics such as age, gender, medical conditions must also be considered, as different patient groups may be better suited to receive one ASD over another, not only because of seizure type but also because of susceptibility or relative risk for certain adverse effects (eg, children may be more susceptible to neuropsychiatric adverse effects, women of child-bearing potential should not be on teratogenic drugs, and the elderly may be more susceptible to adverse effects on cognition). Furthermore, patients with comorbid conditions, such as migraine headache, tremor, or neuropathy, may benefit from the use of particular ASDs that can also treat that condition. Also of extreme importance to consider is a patient's ability to adhere to a prescribed regimen and insurance coverage, as these factors can influence nonadherence to the regimen or cause financial hardship if the medicine is expensive and not covered. Ultimately, ASD effectiveness is the result of the interaction of each of these factors.

ASD Selection

When selecting an ASD, the following should be considered:

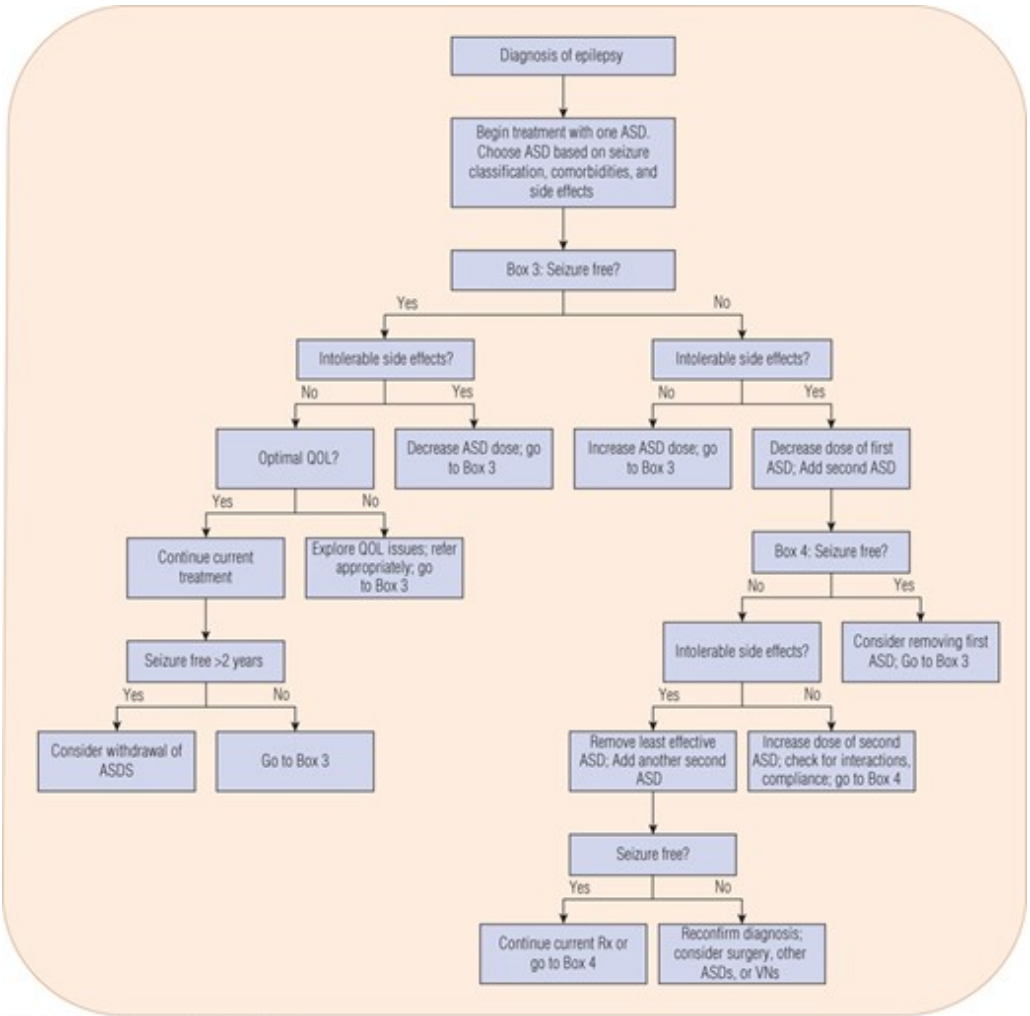
1. ASD effectiveness for the specific seizure type, epilepsy, or epilepsy syndrome
2. Selection of an ASD with the most tolerable adverse effect profile, considering patient specific factors including age and gender
3. Selection of an ASD that can also treat the patient's other comorbid conditions
4. Ability to comply with a regimen (eg, three or four times daily dosing) and insurance coverage, as this can affect ASD adherence and effectiveness
5. Interactions with other medications
6. Need for therapeutic levels to be reached quickly (eg, avoid ASDs which require slow titration such as lamotrigine or topiramate)

5 Once an ASD has been selected, start with a low dose, and gradually titrate to a moderate dose

goal, taking into account the patient's response to treatment. If the patient is seizure free with no adverse effects at a moderate therapeutic dose, then no further increase in dose is necessary. If the patient continues to have seizures at this moderate dose, titrating the patient to a maximum dose is recommend. If the first ASD monotherapy is ineffective, or if the patient experiences intolerable adverse effects, adding a second AED and then tapering and discontinuing the ineffective or intolerable first ASD is appropriate. Selecting an ASD with a different mechanism of action than the first intolerable or ineffective ASD may increase the likelihood of success.[59] If the second ASD is ineffective, polytherapy may be indicated, and an adjunctive ASD should be gradually titrated on. Selection of an adjunctive ASD with a different or complementary mechanism of action is the basis behind rational polytherapy and is recommended, although there is no clear evidence in humans to support this. A suggested algorithm for a general approach to the treatment of epilepsy is shown in **Fig. 56-2**.

FIGURE 56-2

Algorithm for the treatment of epilepsy (ASD, antiseizure drug; QOL, quality of life).



6 Some patients, such as elderly patients who are sensitive to falls, sedation, and other

neurocognitive side effects, need to have ASDs titrated much more slowly and start at much lower initial doses. In such cases, a slow titration can last over many weeks or months and may have a lower goal dose. In other patients, such as patients with multiple recent seizures, a therapeutic dose needs to be reached much more quickly, and a more rapid titration over days instead of weeks is appropriate. For such patients, loading doses, either administered orally or intravenously, may be indicated. When loading, it is important to select ASDs that can be administered safely as loading doses (eg, lamotrigine requires titration and should not be used in patients who require loading to reach therapeutic levels quickly).

Efficacy and Effectiveness

7 There are more than 20 ASDs available in the United States and worldwide for the treatment of epilepsy. Efficacy of ASDs as monotherapy or as add-on treatment in epilepsy is generally established through clinical trials. However, monotherapy efficacy has not been studied for all agents. Although many newer ASDs have been tested only as add-on treatment, many providers will use most ASDs off-label as monotherapy in clinical practice.

Due to the paucity of well-designed, properly conducted, randomized, controlled trials for comparing ASDs, there is a lack of quality evidence to describe comparative efficacy and effectiveness of ASDs. Evidence for comparable effectiveness is primarily available for older agents and some newer agents.[29] Generally speaking, however, the newer ASDs appear to have comparable efficacy to the older agents and are perhaps better tolerated, but we do not have quality evidence to decisively conclude that. What has become obvious is that individuals respond differently to each AED, and that an understanding of each of these agents is needed to optimize therapy for individual patients.

The evidence we do have for long-term effectiveness was summarized in 2013 by the ILAE who reviewed evidence for initial ASD monotherapy in six age-related seizure types and two epilepsy syndromes. Some ASDs including carbamazepine, ethosuximide, gabapentin, levetiracetam, oxcarbazepine, phenytoin, valproic acid, and zonisamide, have strong enough evidence to be labeled as efficacious or effective, or as probably efficacious or effective as initial monotherapy in certain seizure types, while others have weaker evidence and can only be labeled as possibly or potentially efficacious or effective.[59] Furthermore, there is limited evidence that some ASDs may possibly or potentially precipitate or aggravate certain seizure types, and therefore it is suggested that they should be used with caution in those patients (eg, carbamazepine and phenytoin in generalized onset tonic-clonic seizure types or carbamazepine, gabapentin, oxcarbazepine, phenytoin, tiagabine, and vigabatrin among others in children with absence or in JME).[29] The ILAE findings are summarized in **Table 56-2**. Also included in Table 56-2 are evidenced-based treatment recommendations from the American Academy of Neurology (AAN)-American Epilepsy Society (AES) and recommendations from a US panel of experts, which included more recent drug treatment data compared to the AAN-AES recommendations.[29,60,61,62].

Drug Resistance

8 Approximately 65% of patients can be expected to be maintained on one ASD and be considered well controlled, although not necessarily seizure free.[36] The percentage of patients who are seizure free on one drug varies by seizure type. After 12 months of treatment, the percentage who are

seizure free is highest for those who have only GTC seizures (48%-55%), lowest for those who have only focal seizures (23%-26%), and intermediate for those with mixed seizure types (25%-32%).[63] Polytherapy with two or more ASDs is appropriate for those patients who cannot achieve seizure freedom on ASD monotherapy. Of the 35% of patients with unsatisfactory control on monotherapy, 10% will be well controlled with a two-drug treatment. Of the remaining 25%, 20% will continue to have unsatisfactory control despite greater than two drug treatment and are deemed to be drug resistant.[36] In 2009, the ILAE issued a consensus definition for drug resistant epilepsy which defined drug resistance as "failure of adequate trials of two tolerated and appropriately chosen and used AED schedules (whether as monotherapies or in combination) to achieve sustained seizure freedom."[64]

Pharmacokinetic and Drug-Drug Interactions

An appreciation of pharmacokinetic variability (**Table 56-3**) is necessary when selecting drug treatment. Knowledge of ASD metabolic pathways as well as inducer or inhibitory effects on liver enzymes (**Table 56-4**) can aid in the optimization of ASD therapy. Pharmacokinetic interactions are a common complicating factor in ASD selection. Interactions can occur in any of the pharmacokinetic processes: absorption, distribution, metabolism, or elimination. Caution should be used when ASDs are added to or withdrawn from a drug regimen.

TABLE 56-3 Antiseizure Drug Pharmacokinetic Data

ASD	$t_{1/2}$ (Hours)	Time to Steady State (Days)	Unchanged (%)	V_D (L/kg)	Clinically Important Metabolite	Protein Binding (%)
Carbamazepine	12 M; 5-14 Co	21-28 for completion of autoinduction	<1	1-2	10,11-epoxide	40-90
Clobazam	36-42	7-14	3	1.4	*N*-desmethylclobazam	80-90
Eslicarbazepine	13-20	4-5	67%	0.87	oxcarbazepine	<40

Adverse Effects

Individual ASDs have their own unique adverse effect profile. However, there are some common adverse effects shared by ASDs as a class. Since all ASDs act on the CNS to exert their antiseizure effects, CNS side effects are among the most common adverse effects of ASDs and include sedation, dizziness, blurred or double vision, difficulty with concentration, and ataxia. ASD effects on cognition

are of particular concern. Barbiturates in particular appear to cause more cognitive impairment than other commonly used ASDs (although in children it paradoxically causes hyperactivity).[65] In general, newer agents have less effects on cognition, although topiramate is known to cause substantial cognitive impairment.[66] In many cases, these effects can be avoided by titrating the dose upward very slowly or can be alleviated by decreasing the dose. Patients changed from polytherapy to monotherapy may also demonstrate improvement in cognition.

Concentration-dependent effects are common and troublesome but not usually life-threatening. It is important to note that patients dosed and maintained within "therapeutic ranges" are also capable of experiencing toxicities to ASDs.[67] More uncommon are idiosyncratic side effects which are generally not concentration-dependent. Most idiosyncratic reactions are mild, but they can be serious and even life threatening if the hypersensitivity involves one or more organ systems. Perhaps the most widely recognized idiosyncratic reactions are ASD-induced drug rashes. As discussed earlier, some rashes can progress to Steven Johnsons Syndrome (SJS)/Toxic Epidermal Necrolysis (TEN). Other serious but rare idiosyncratic side effects include hepatitis or blood dyscrasias. Acute organ failure due to an idiosyncratic reaction, when it occurs, generally occurs within the first 6 months of ASD therapy.[68] In any patient, laboratory assessment, including white blood cell (WBC) counts and liver function tests, may be reasonable if the patient reports an unexplained illness (eg, lethargy, vomiting, fever, or rash). ASD treatment itself may sometimes worsen seizures and can represent a paradoxical toxic effect of the drug.[65]

Antiseizure drugs are often used life-long and as such, adverse effects associated with long-term use have been recognized. One such adverse effect of chronic ASD treatment is osteomalacia and osteoporosis.[69,70] The effects on bone can range from asymptomatic high-turnover disease with findings of normal bone mineral density, to markedly decreased bone mineral density sufficient to warrant the diagnosis of osteoporosis. It has been hypothesized that certain drugs, including phenytoin, phenobarbital, carbamazepine, oxcarbazepine, felbamate, and valproic acid, may interfere with vitamin D metabolism.[71] It is currently unknown whether other ASDs also cause these effects. Patients receiving these drugs should receive supplemental vitamin D and calcium, as well as bone mineral density testing if other risk factors for osteoporosis are present.

Role of Serum Concentration Monitoring

Serum concentrations of the older ASDs should be viewed as a tool with which to optimize therapy for an individual patient, not as a therapeutic end point in itself. The serum concentration is a target that should be correlated with clinical response. The desired outcome is the cessation of seizures without side effects. Seizure control can occur before the "minimum" of the published therapeutic range is achieved, and side effects can appear before the "maximum" of the range is achieved. Some patients may need and tolerate concentrations beyond the maximum. The therapeutic range for ASDs can be different for different seizure types. Serum concentrations may need to be higher to control focal dyscognitive seizures than to control tonic–clonic seizures. Clinicians should define a therapeutic range for an individual patient above which there are side effects and below which the patient experiences seizures. Then serum levels can be useful to document lack of efficacy, loss of efficacy, noncompliance, and to determine how much room there is to increase a dose based on

expected toxicity. Depending on the ASD, serum levels can also be useful in patients with significant renal and/or hepatic disease, patients taking multiple drugs, and women who are pregnant or taking OCs. Therapeutic concentration ranges have not been clearly defined for some of the second-generation ASDs.[67]

PERSONALIZED PHARMACOTHERAPY

The most important aspect of ASD therapy is tailoring the choice of drug to the individual patient. Besides seizure type(s) and concomitant medical problems (including hepatic function, renal function, and concurrent medications), patient specific characteristics that must be considered include age, gender, child-bearing ability, and ethnicity. Therapeutic considerations in these groups are discussed hereunder.

Therapeutic Considerations in the Elderly and Young

Use of ASDs in the elderly and young can pose special challenges. The elderly are often on many different medications which may contribute to increased sensitivity to neurocognitive effects as well as increased possibility of drug-drug interactions with ASDs that affect the cytochrome P450 (CYP450) system (eg, carbamazepine, phenytoin, and valproic acid). Hypoalbuminemia is also common in the elderly, and highly albumin-bound ASDs (eg phenytoin and valproic acid) can be problematic.[67] The elderly also experience body mass changes, such as an increase in fat to lean body mass or decrease in body water, which can affect the drug volume of distribution and elimination half-life.[67] In addition, the elderly may have compromised renal or hepatic function that require ASD dosage adjustment.[67] Lamotrigine is often considered the medication of choice in elderly patients with focal-onset seizures, as results from a VA cooperative trial found that it had equal efficacy to carbamazepine and gabapentin and was better tolerated than carbamazepine.[73]

For neonates and infants, an increase in the total body water to fat ratio and a decrease in serum albumin and α-acid glycoprotein can result in volume of distribution changes that affect ASD elimination half-life. Additionally, infants up to the age of 3 years have decreased renal elimination of ASDs, with neonates being the most affected. Hepatic activity is also reduced in neonates and infants, but by age 2 to 3 years, hepatic activity then becomes more robust than that seen in adults. Therefore, whereas neonates and infants require lower doses of ASDs, children require higher doses than that seen in adults. Therapeutic drug monitoring becomes especially important in the young, even though the definitions of therapeutic blood levels are less certain in these patients than in adults.[67]

Therapeutic Considerations in Women (and Men)

Estrogen and progesterone are among the many hormones that can influence brain electrical excitability. Estrogen has a slight proconvulsant effect, whereas progesterone exerts a mild anticonvulsant effect.[21] In some women, vulnerability to seizures is highest just before and during the menstrual flow (catamenial seizures) and at the time of ovulation, and is believed to be due to a

slight increase of estrogen relative to progesterone, or due to progesterone withdrawal and changes in the estrogen-to-progesterone ratio.[21] The risk of catamenial seizures is estimated be anywhere from 10% to 70% in women with epilepsy.[21] In such women, conventional ASDs should be used as primary agents, but intermittent supplementation with higher dose of ASD or benzodiazepines should be considered. Acetazolamide has also been used during catamenial periods, but with variable and limited success. Hormonal therapy with progestational agents, particularly cyclic natural progesterone therapy, may be effective in certain subsets of patients.[72]

At menopause, seizures often improve in frequency, particularly in women with a catamenial seizure pattern. However, for those women who need hormone replacement therapy, it has been reported that conjugated equine estrogens plus 2.5 mg of medroxyprogesterone acetate may increase the frequency of epileptic seizures. Therefore a hormone replacement therapy that consists of just a single estrogenic compound, such as 17-β-estradiol, along with a natural progesterone, may be recommended for women with disruptive menopausal symptoms.[74]

Antiseizure drugs may also have an effect on endogenous and exogenous hormones. Enzyme-inducing ASDs increase the metabolism of estrogen, progesterone, and testosterone and increase production of sex hormone-binding globulin, leading to decreases in the free fraction of these hormones endogenously. These alterations lead to disturbances in the regulation of the hypothalamic–pituitary–adrenal axis and contribute to reproductive endocrine disorders including menstrual irregularity, infertility, sexual dysfunction, and in some patients polycystic ovary syndrome (PCOS).[75] Valproic acid, in particular, may affect sex hormone concentrations causing hyperandrogenism and polycystic changes, especially in women who have gained weight or those who start valproic acid at age less than 20 years.[75]

Exogenously, enzyme-inducing ASDs (eg, carbamazepine and topiramate and oxcarbazepine at higher doses, and possibly clobazam, felbamate, lamotrigine, and rufinamide) can cause treatment failures in women taking oral contraceptives (OCs) due to increased metabolism of ethinyl estradiol and progestin. Medroxyprogesterone depot injections and hormone-releasing intrauterine systems on the other hand, are not similarly affected by ASDs, and it is unclear if there is an effect of ASDs on the transdermal contraceptive patch or the emergency contraceptive pill. A supplemental or alternative form of birth control (eg, IUD) is advised if breakthrough bleeding occurs in woman taking certain types of ASDs (eg, enzyme-inducing ASDs) and OCs, and it has been suggested that women use twice the normal dose of emergency contraception.[76]

Antiseizure drugs may also have reproductive endocrine effects in men. Data suggests that men with epilepsy have reduced fertility, and that carbamazepine, oxcarbazepine, and valproic acid are associated with sperm abnormalities in these men. In addition, valproic acid seems to cause testicular atrophy resulting in reduced testosterone volume. Levetiracetam on the other hand, appears to slightly increase serum testosterone. Various ASDs have also been anecdotally reported to affect libido and sexual function in both men and women.[76]

Therapeutic Considerations for Pregnancy and Breastfeeding

Pregnancy and epilepsy is a particularly complex topic. The goal of treatment in pregnant women with epilepsy is to achieve the best possible control of seizure with the minimal adverse effects for both the mother and the child. Epilepsy-related complications during pregnancy include possible changes in seizure frequency, fluctuating ASD plasma levels, and possible teratogenic effects of ASDs.[77,78,79]

Despite multiple reports of both increased and decreased seizure frequency during pregnancy, a recent practice parameter update issued by the AAN found that there was inconclusive evidence to conclude that changes in seizure frequency occurred during pregnancy.[77] What was concluded however, was that women with epilepsy who were seizure free for at least 9 months to 1 year prior to pregnancy, had a very high probability (84%-92%) of remaining seizure free during pregnancy.[77] It should be noted, however, that if seizures are increasing during pregnancy, a commonly over-looked reason for this increase is nonadherence in a normally adherent patient, due to concerns about the potential adverse drug effects on the developing fetus.[80]

Fluctuations in ASD concentration may be caused by physiologic changes that occur during pregnancy including reduced gastric motility, nausea and vomiting, increased drug distribution, increased renal elimination, altered hepatic enzyme activity as well as changes in protein binding during pregnancy.[76] Physiologic changes, such as changes in protein binding, can begin as early as the first 10 weeks of pregnancy, and may require up to 4 weeks postpartum to normalize (eg, protein binding in carbamazepine, phenobarbital, and phenytoin). Fluctuations in ASD plasma concentrations due to increased ASD clearance has been found to be true for lamotrigine, carbamazepine, phenytoin, oxcarbazepine, levetiracetam.[78] Clinical consequences of ASD fluctuations are variable and some women will not experience increased seizure frequency despite fluctuating levels. Women on lamotrigine however have been found to undergo a 40% decrease in the ratio of plasma lamotrigine concentration to dose, resulting in deterioration of seizure control in approximately 75% of pregnant patients.[76] It is therefore recommended that ASD levels, particularly lamotrigine levels, be monitored closely during pregnancy, and to increase doses if needed over the course of the pregnancy with rapid decrease in the postpartum period. Of note, fluctuations have also been reported for phenobarbital, valproic acid, primidone, and ethosuximide, although strong evidence for this is lacking.[78]

Adverse pregnancy outcomes associated with ASD use include an increased risk of major congenital malformations (MCMs) compared to nonepileptic women.[79] This risk is believed to be due to ASD exposure and not maternal seizures, as infants born to women with epilepsy who do not take ASDs have the same risk of birth defects as infants born to seizure-free women (2%-3%).[80] The most concerning effects are found with the use of valproic acid which is associated with a risk of MCMs that is 3.5 to 4 times that of offspring from nonepileptic women, especially if taken during the first trimester of pregnancy.[79] Furthermore there is an increased risk of neurodevelopmental deficits, including effects on cognition in children exposed to valproic acid *in utero*.[79] These effects are dose-dependent, and the risk of major congenital malformation significantly increases at 600 mg/day, with the greatest risk observed at doses that exceed 1,000 mg/day.[66] However, individual susceptibility is genetically determined, and teratogenicity can occur at much lower doses in some

persons. Due to these findings, it is recommended that valproate should preferably not be used in epilepsy and that withdrawal of valproate or switch to an alternative treatment should be considered in these patients. When valproate is used, doses should not exceed 500 to 600 mg/day.[66]

Data on teratogenic risk with the newer agents are limited, although topiramate was recently reclassified from pregnancy category C to D due to an increased association with cleft palate (it may also have a negative effect on birth weight and cause increases in hypospadias).[66,81] In general, higher ASD doses, higher ASD serum concentrations, polytherapy (especially polytherapy with valproate), and a family history of birth defects appear to increase the teratogenic risk of ASDs.[79] As such, the risk of birth defects is believed to have gone down with decreasing doses and decreasing use of polytherapy. Deciding on the most effective single-drug treatment prior to conception is vitally important. Teratogenic effects of ASD must always be considered when choosing ASDs for women of reproductive age, even when they do not plan on becoming pregnant, as many unplanned pregnancies occur and MCMs generally occur early in pregnancy before women know that they are pregnant. With proper counseling and management, more than 90% of these pregnancies will still have satisfactory outcomes. Updated practice parameters are available to aid in the counseling and management of pregnant women with epilepsy.[77,78,79,81]

Teratogenic effects may possibly be prevented by adequate folate intake, although strong data are lacking.[81] However, as the risk of MCM is possibly decreased by folic acid supplementation, prenatal vitamins with folic acid (0.4-5 mg/day) are recommended for women of child-bearing potential who are taking ASDs.[81] Higher folate doses should be used in women with a history of a previous pregnancy with a neural tube defect or taking valproic acid. Additionally, some ASDs may possibly cause neonatal hemorrhagic disorder. There is a lack of strong evidence to determine if prenatal vitamin K supplementation can reduce this complication. However, vitamin K 10 mg/day is often administered orally to the mother during the last month of pregnancy and/or administered parenterally to the newborn at delivery.[81]

Some ASDs pass into the breast milk. ASDs with less protein binding will accumulate more in breast milk. Treatment with ASDs is not necessarily a reason to discourage breastfeeding, although ASD concentrations are measureable in breastfeeding infants. In fact, an argument could be made that since ASDs should rarely be discontinued abruptly, breastfeeding allows for a downward titration of a medication that the baby was exposed to for the past 9 months. Infants born to women taking any ASD (particularly barbiturates or benzodiazepines) should be closely observed for signs of excess sedation, irritability, or poor feeding.[81,82]

Therapeutic Considerations in Asians and South Asians

A common idiosyncratic side effect of ASDs is rash. However, in some cases, the rash can quickly progress to SJS, TEN, or Drug Reactions with Eosinophilia and Systemic Symptoms (DRESS) which are severe and life threatening conditions. Studies have found that there is a strong association between the presence of an inherited variant of the *HLA-B* gene, *HLA-B*1502*, in these populations, and the risk of developing SJS/TEN with carbamazepine (and possibly phenytoin, lamotrigine, and oxcarbazepine as well).[83,84] This *HLA-B* variant is found in up to 15% of individuals from many Asian,

Southeast Asian and South Asian populations including Hong Kong, Thailand, Malaysia, Philippines, Taiwan, North China, India, and to a much lesser extent Japan and Korea. The variant is largely absent in individuals not of Asian origin. Testing for *HLA-B*1502* may be recommended for patients in these populations who may need to be initiated on carbamazepine, phenytoin, lamotrigine, or oxcarbazepine therapy. If positive, these ASDs should generally be avoided in these patients. In addition, the *HLA* genotype *HLA-A*3101* has also been found to be associated with multiple carbamazepine-induced cutaneous reactions in Chinese, Japanese, and European populations.[83] It should be noted that many *HLA-B*1502*-positive and *HLA-A*3101*-positive patients treated with ASDs will not develop SJS/TEN or other hypersensitivity reactions, and these reactions can still occur infrequently in *HLA-B*1502*-negative and *HLA-A*3101*-negative patients of any ethnicity. Of those who do experience SJS/TEN with carbamazepine, 90% will have this reaction within the first few months of treatment.[83]

Clinical Considerations with Specific Drugs

Tables 56-5 and **56-6** list specific data (including adverse effects and dosing) for each of the commonly used ASDs. Here we summarize the pharmacology, advantages and disadvantages, and perspectives on the place in therapy of some specific ASD.

TABLE 56-5 Antiseizure Drug Side Effects and Monitoring

	Adverse Drug Reaction Acute Side Effects		
Drug	**Concentration Dependent**	**Idiosyncratic**	**Chronic Side Effects**
Carbamazepine	Diplopia Dizziness Drowsiness Nausea Unsteadiness	Blood dyscrasias Rash (HLA antigen testing may be relevant to avoid Stevens-Johnson or toxic epidermal necrolysis)	Hyponatremia Metabolic bone disease (monitor Vit D and serum calcium)
Clobazam	Lethargy Somnolence Sedation Pyrexia Ataxia	Drooling Aggression Irritability Constipation	
Eslicarbazepine	Dizziness Ataxia Somnolence/fatigue Cognitive changes Visual changes	Rash	Hyponatremia

Adverse Drug Reaction Acute Side Effects			
Drug	**Concentration Dependent**	**Idiosyncratic**	**Chronic Side Effects**
Ethosuximide	Ataxia	Blood dyscrasias	Behavior changes
	Drowsiness	Rash	Headache
	GI distress (avoid by multiple daily dosing)		
	Unsteadiness		
	Hiccoughs		
Ezogabine	Dizziness	Urinary retention	Blue gray skin discoloration
	Somnolence	QT prolongation (get baseline ECG and during treatment)	Retinal abnormalities
	Fatigue	Euphoria	
	Confusion		
	Vertigo		
	Tremors		
	Blurred vision		
Felbamate	Anorexia	Aplastic anemia (follow CBC)	Not established
	Nausea	Acute hepatic failure (follow liver enzymes)	
	Vomiting		
	Insomnia		
	Headache		
Gabapentin	Dizziness	Pedal edema	Weight gain
	Fatigue		
	Somnolence		
	Ataxia		
Lacosamide	Dizziness	Liver enzyme elevation	Not established
	Vertigo		
	Headache		
	Nausea		
	Vomiting		
	PR interval increase (get baseline ECG and during treatment)		

Adverse Drug Reaction Acute Side Effects			
Drug	**Concentration Dependent**	**Idiosyncratic**	**Chronic Side Effects**
Lamotrigine	Diplopia Dizziness Unsteadiness Headache	Rash (slower titration of dose may decrease chance of occurrence)	Not established
Levetiracetam	Sedation Behavioral disturbance	Psychosis (rare but more common in elderly or persons with mental illness)	Not established
Oxcarbazepine	Sedation Dizziness Ataxia Nausea	Rash	Hyponatremia
Perampanel	Severe behavior changes Dizziness Ataxia/falls Somnolence/fatigues	Rash	Weight gain
Phenobarbital	Ataxia Hyperactivity Headache Unsteadiness Sedation Nausea	Blood dyscrasias Rash	Behavior changes Connective tissue disorders Intellectual blunting Metabolic bone disease Mood change Sedation
Phenytoin	Ataxia Nystagmus Behavior changes Dizziness Headache Incoordination Sedation Lethargy	Blood dyscrasias Rash (HLA antigen testing may be relevant to avoid Stevens-Johnson or toxic epidermal necrolysis) Immunologic reaction	Behavior changes Cerebellar syndrome (occurs high serum levels) Connective tissue changes Skin thickening Folate deficiency Gingival hyperplasia Hirsutism Coarsening of facial features

Drug	Adverse Drug Reaction Acute Side Effects		Chronic Side Effects
	Concentration Dependent	Idiosyncratic	
			Acne
	Cognitive impairment		Cognitive impairment
	Fatigue		Metabolic bone disease (monitor Vit D and serum calcium)
	Visual blurring		
			Sedation
	Dizziness		
	Somnolence	Pedal edema	
Pregabalin	Incoordination	Creatine kinase elevation	Weight gain
	Dry mouth	Decrease platelets	
	Blurred vision		
Primidone	Behavior changes	Blood dyscrasias	Behavior change
	Headache	Rash	Connective tissue disorders
	Nausea		Cognitive impairment
	Sedation		Sedation
	Unsteadiness		
Rufinamide	Dizziness	Multiorgan hypersensitivity	Not established
	Nausea	Status epilepticus	
	Vomiting	Leukopenia	
	Somnolence	QT shortening	
Tiagabine	Dizziness	Spike-wave stupor	Not established
	Fatigue		
	Difficulties concentrating		
	Nervousness		
	Tremor		
	Blurred vision		
	Depression		
	Weakness		
Topiramate	Difficulties concentrating	Metabolic acidosis	Kidney stones
	Psychomotor slowing	Acute angle glaucoma	Weight loss

Drug	Adverse Drug Reaction Acute Side Effects		Chronic Side Effects
	Concentration Dependent	**Idiosyncratic**	
	Speech or language problems	Oligohydrosis	
	Somnolence, fatigue		
	Dizziness		
	Headache		
Valproic acid	GI upset	Acute hepatic failure	Polycystic ovary-like syndrome (increase incidence in females <20 years or overweight)
	Sedation	Acute pancreatitis	
	Unsteadiness	Alopecia	Weight gain
	Tremor		Hyperammonemia
	Thrombocytopenia		Menstrual cycle irregularities
	Permanent vision loss		
Vigabatrin	Fatigue	Abnormal MRI brain signal changes (infants with infantile spasms)	Permanent vision loss (greater frequency, adults vs. children vs. infants)
	Somnolence		
	Weight gain	Peripheral neuropathy	
	Tremor	Anemia	
	Blurred vision		
Zonisamide	Sedation	Rash (is a sulfa drug)	Kidney stones
	Dizziness	Metabolic acidosis	Weight loss
	Cognitive impairment	Oligohydrosis	
	Nausea

TABLE 56-6 Antiseizure Drug Dosing and Target Serum Concentration Ranges

Drug	Brand Name	Initial or Starting Dose	Usual Range or Maximum Dose	Comments Target Serum Concentration Range
Barbiturates				
Phenobarbital	Various	1-3 mg/kg/day (10-20 mg/kg LD)	180-300 mg	10-40 mcg/mL[a] (43-172 µmol/L)
Primidone	Mysoline	100-125 mg/day	750-2,000 mg	5-10 mcg/mL (23-46 µmol/L)

Drug	Brand Name	Initial or Starting Dose	Usual Range or Maximum Dose	Comments Target Serum Concentration Range
Benzodiazepines				
Clobazam	Onfi	≤30 kg 5 mg/day; >30 kg 10 mg/day	≤30 kg up to 20 mg; >30 kg up to 40 mg	0.03-0.3 ng/mL (0.1-1.0 nmol/L)
Clonazepam	Klonopin	1.5 mg/day	20 mg	20-70 ng/mL (67-233 pmol/L)
Diazepam	Valium	PO: 4-40 mg IV: 5-10 mg	PO: 4-40 mg IV: 5-30 mg	100-1,000 ng/mL (0.4-3.5 µmol/L)
Lorazepam	Ativan	PO: 2-6 mg IV: 0.05 mg/kg IM: 0.05 mg/kg	PO: 10 mg IV: 0.05 mg/kg	10-30 ng/mL (31-93 nmol/L)
Hydantoin				
Phenytoin	Dilantin	PO: 3-5 mg/kg (200-400 mg) (15-20 mg/kg LD)	PO: 300-600 mg	Total: 10-20 mcg/mL (40-79 µmol/L) Unbound: 0.5-3 mcg/mL (2-12 µmol/L)
Succinimide				
Ethosuximide	Zarontin	500 mg/day	500-2,000 mg	40-100 mcg/mL (282-708 µmol/L)
Other				
Carbamazepine	Tegretol Tegretol XR	400 mg/day	400-2,400 mg	4-12 mcg/mL (17-51 µmol/L)
Eslicarbazepine	Aptiom	400 mg/day	800-1,600 mg	Not defined
Ezogabine	Potiga	300 mg/day	1,200 mg	Not defined
Felbamate	Felbatol	1,200 mg/day	3,600 mg	30-60 mcg/mL (126-252 µmol/L)
Gabapentin	Neurontin	300-900 mg/day	4,800 mg	2-20 mcg/mL (12-117 µmol/L)
Lacosamide	Vimpat	100 mg/day	400 mg	Not defined
Lamotrigine	Lamictal Lamictal XR	25 mg every other day if on VPA; 25-50 mg/day if not on VPA	100-150 mg if on VPA; 300-500 mg if not on VPA	4-20 mcg/dL (16-78 µmol/L)
Levetiracetam	Keppra Keppra XR	500-1,000 mg/day	3,000-4,000 mg	12-46 mcg/mL (70-270 µmol/L)

Drug	Brand Name	Initial or Starting Dose	Usual Range or Maximum Dose	Comments Target Serum Concentration Range
Oxcarbazepine	Trileptal Oxtellar XR	300-600 mg/day	1,200-2,400 mg	3-35 mcg/mL (MHD) (12-139 µmol/L)
Perampanel	Fycompa	2 mg/day	8-12 mg	Not defined
Pregabalin	Lyrica	150 mg/day	600 mg	Not defined
Rufinamide	Banzel	400-800 mg/day	3,200 mg	Not defined
Tiagabine	Gabitril	4-8 mg/day	80 mg	0.02-0.2 mcg/mL (0.05-0.5 µmol/L)
Topiramate	Topamax Trokendi XR	25-50 mg/day	200-1,000 mg	5-20 mcg/mL (15-59 µmol/L)
Valproic acid	Depakene Depakote DR/ER Depacon	15 mg/kg (500-1,000 mg)	60 mg/kg (3,000-5,000 mg)	50-100 mcg/mL (347-693 µmol/L)
Vigabatrin	Sabril	1,000 mg/day	3,000 mg	0.8-36 mcg/mL (6-279 µmol/L)
Zonisamide	Zonegran	100-200 mg/day	600 mg	10-40 mcg/mL (47-188 µmol/L)

IM, intramuscular; LD, loading does; MHD, 10-monohydroxy-derivative; PO, orally; VPA, valproic acid.

[a]Units mcg/mL and mg/L are numerically equivalent, and units of ng/mL and mcg/L are numerically equivalent.

Clinical Controversy…

A warning on suicidal behavior and ideation accompanies all ASDs. This is based on pooled analyses of almost 200 placebo-controlled trials of 11 different ASDs showing that patients randomized to an ASD had approximately twice the risk of suicidal thinking or behavior compared to patients randomized to placebo. The estimated incidence of suicidal ideation was low, less than 0.5% of patients on ASDs compared to 0.24% of patients on placebo. While some believed that this risk is nonsignificant, responsible providers must carefully assess this risk when evaluating their patients for ASD therapy, especially as depression and anxiety are common comorbid conditions in epilepsy. Patients and caregivers should be informed that ASDs increase the risk of suicidal thoughts and should be advised to be on the alert for any unusual changes in mood or behavior.

Carbamazepine

Mechanism of Action

Carbamazepine acts primarily by enhancing fast inactivation of voltage-gated Na^+ channels. Interaction with voltage-gated Ca^{2+} and K^+ channels may also contribute.[85]

Pharmacokinetics

Absorption of carbamazepine immediate-release (IR) tablets is slow and erratic with large variability in the peak-to-trough concentrations of up to 40% due to its low water solubility. Suspension is absorbed faster than the tablets.[86] There is no first-pass metabolism. Food, especially fat, may enhance the bioavailability of carbamazepine. Controlled-release (Tegretol-XR) and sustained-release (Carbatrol) preparations are also available, and if dosed every 12 hours, they are bioequivalent to the immediate-release tablets dosed every 6 hours. Compared with carbamazepine IR tablets, both these formulations have lower peaks and higher troughs, which may decrease side effects and improve QOL and seizure control. Patients should be told to take Tegretol-XR with food and that the casing will be excreted in the feces. It cannot be broken or crushed. Tegretol-XR and Carbatrol appear to be bioequivalent; however, there is less variability in the absorption of Carbatrol.[87]

Carbamazepine is a neutral and highly lipophilic drug that is highly protein bound to α_1-acid glycoprotein and albumin. The major metabolite of carbamazepine is carbamazepine-10,11-epoxide, which has anticonvulsant activity, and is affected by concurrent use of other enzyme-inducing or enzyme-inhibiting drugs (eg, valproate and felbamate).

Carbamazepine induces its own metabolism (autoinduction). Its half-life starts decreasing 3 to 5 days after initiation of therapy, and induction is complete within 21 to 28 days (although reversal of autoinduction is rapid upon discontinuation). Therefore, initial therapeutic concentrations may fall out of range despite good adherence. Carbamazepine also displays diurnal variation in its serum level with evening levels lower than morning levels. Carbamazepine is cleared significantly faster in females than males and in Caucasians compared to African Americans, and therefore variable dosing may be needed.[86]

Adverse Effects

Neurosensory side effects are the most common (35%-50% of patients) especially during initiation of therapy and can dissipate with continued treatment, dose adjustment or use of the controlled-release or sustained-release formulation. Food may help with nausea caused by a local effect of the drug on the gastrointestinal (GI) tract, but discontinuation may be required if nausea comes from any brainstem effect. Importantly, carbamazepine can cause hyponatremia (although less so than with oxcarbazepine), especially in the elderly, and monitoring of serum sodium is recommended.[85]

The incidence of leukopenia can be as high as 10% but is usually transient, even when the drug is continued, and can be caused by a redistribution of WBCs rather than a decrease in their

production.[85] In about 2% of patients, leukopenia is persistent, but therapy is generally continued unless the WBC count drops to less than 2,500/mm^3 (2.5 × 10^9/L) and the absolute neutrophil count drops to less than 1,000/mm^3 (1 × 10^9/L).

Drug Interactions

Carbamazepine has significant drug interactions and can induce the metabolism of other drugs. Additionally, CYP3A4 inhibitors may potentially increase carbamazepine serum concentrations.

Dosing and Administration

During initiation, it must be remembered that carbamazepine clearance increases with time. The initial adult dose is 400 mg/day and may be increased by 200 mg at weekly intervals. For those patients who need to reach therapeutic levels more quickly, the dose may be increased by 200 mg every few days. However, faster titrations may increase the risk for rash, and this should be monitored. Extended-release preparations can be dosed twice a day while immediate-release preparations require doses to be given four times a day.

Advantages

Carbamazepine has been well studied and is also available in liquid dosage forms and extended release and controlled release preparations. Compared with other first-generation ASDs, carbamazepine causes minimal cognitive impairment.

Disadvantages

It induces its own metabolism, which complicates dosage titration. It also has many drug interactions including interactions which may increase its active metabolite causing toxicity. Carbamazepine also has known teratogenicity and chronic use has been associated with decreases in bone mineral density and 25-hydroxy (OH) vitamin D.

Place in Therapy

Carbamazepine is a commonly used ASD and is considered first-line in many seizure types as it is well studied. It is FDA approved for use in patients with focal onset seizures, GTC seizures, and mixed seizure types. It may worsen absence seizures and possibly precipitate or aggravate tonic-clonic seizures in patients with other generalized seizure types.

Clobazam

Mechanism of Action

Clobazam is a 1, 5-chlorinated benzodiazepine derivative that potentiates GABA's effect at the subunit of the $GABA_A$ receptor, increasing the chloride current by increasing chloride channel

opening.[24]

Pharmacokinetics

The drug is metabolized in the liver to the primary active metabolite *N*-desmethylclobazam which achieves plasma concentrations three to five times higher than clobazam with 1/5 the activity and elimination half-lives of 36 to 42 hours and 71 to 82 hours, respectively.[24]

Adverse Effects

CNS effects are the most common side effects. Abrupt discontinuation may cause a withdrawal syndrome which consists of convulsions, psychosis, hallucinations, behavioral disorder, tremor, and anxiety; milder symptoms can present as dysphoria, anxiety, and insomnia.[24]

Drug Interactions

Clobazam inhibits CYP2D6 and may affect metabolism of other drugs in this pathway. It is also a weak inducer of CYP3A4 and may lower the serum levels of some OCs.[24]

Dosing and Administration

Patients weighing less than or equal to 30 kg are started at 5 mg/day and increased slowly to 20 mg/day, while those weighing more than 30 kg are started at 10 mg/day and increased slowly to 40 mg/day; doses greater than 5 mg should be given in two divided doses. Dosing in geriatric patients is initiated as in patients weighing less than or equal to 30 kg, but increased up to 40 mg depending on the weight of the patient. Poor metabolizers of CYP2C19 are dosed like geriatric patients.[24]

Advantages

Clobazam is more efficacious than clonazepam in the treatment of LGS. Though tolerance can develop to benzodiazepines, 30% of patients do not develop tolerance to clobazam, so the drug can often be used for years.

Disadvantages

It is a class IV controlled substance. Patients must be carefully weaned off the drug to avoid significant withdrawal symptoms. The drug is much less effective than clonazepam in treatment of myoclonic jerks and absence seizures.

Place in Therapy

It is FDA approved for adjunctive treatment of seizures associated with LGS. However, it may also have a role in focal onset epilepsies and other generalized onset epilepsies after failure of other

agents.

Eslicarbazepine

Mechanism of Action

Eslicarbazepine prolongs the inactivation phase of voltage-gated Na^+ channels. It is structurally similar to carbamazepine and oxcarbazepine but is different at the 10, 11 position and does not form the carbamazepine-10, 11-epoxide.[24,89]

Pharmacokinetics

Eslicarbazepine is a prodrug that undergoes hydrolysis to S-licarbazepine and is subsequently glucuronidated and renally excreted. Unlike oxcarbazepine, which is metabolized to both S- and R-licarbazepine, eslicarbazepine is extensively converted to S-licarbazepine (eslicarbazepine). The half-life is about 24 hours. Eslicarbazepine is highly bioavailable, and food has no effect. It is not highly protein bound and is extensively metabolized by hydrolytic first pass metabolism with no clinically relevant effects on most CYP enzymes and only a moderately inhibitory effect on CYP2C19. It moderately induces UGT1A1 mediated glucuronidation. Dosage adjustment is needed in patients with creatinine clearance of less than 50 mL/min (0.83 mL/s).[89]

Adverse Effects

The most common adverse effects include dizziness and somnolence. Nausea, headache, diplopia, vomiting, fatigue, vertigo, ataxia, blurred vision, and tremor were also commonly reported. Like carbamazepine or oxcarbazepine, hyponatremia can occur but is less common. Eslicarbazepine may increase the PR interval on the ECG.[89]

Drug Interactions

Carbamazepine, phenobarbital, phenytoin, and primidone can induce enzymes that metabolize eslicarbazepine. Eslicarbazepine can inhibit CYP2C19 and affect plasma concentration of drugs metabolized by this isoenzyme.[89]

Dosing and Administration

Eslicarbazepine is initiated with a starting dose of 400 mg as a single daily dose. It may be increased by 400 mg/day on a weekly basis to a maximum dose of 1,200 mg/day.[89]

Advantages

Eslicarbazepine has once daily dosing and may cause less hyponatremia than oxcarbazepine. Eslicarbazepine has potentially less CNS adverse effects than oxcarbazepine.

Disadvantages

It is a new drug, and further data on its effectiveness is needed.

Place in Therapy

Eslicarbazepine is FDA approved as monotherapy or adjunctive treatment for focal onset seizures. It is the newest ASD and should be reserved for failure of other ASD agents.

Ethosuximide

Mechanism of Action

Inhibition of T-type Ca^{2+} channels[24,90]

Pharmacokinetics

Absorption is unaffected by food, and metabolism occurs in the liver by hydroxylation to inactive metabolites with some evidence of nonlinear pharmacokinetics at higher concentrations.[24,90]

Adverse Effects

Nausea and vomiting are reported in up to 40% of patients, which may be minimized by administration of smaller and more frequent doses.[24]

Drug Interactions

Valproic acid may inhibit ethosuximide's metabolism, but only if the metabolism of ethosuximide is near saturation.[24]

Dosing and Administration

Titration over 1 to 2 weeks to maintenance doses of 20 mg/kg/day usually results in therapeutic concentrations. Once-a-day therapy is efficacious; however, GI distress appears to be dose related, and the total daily dose is usually divided into two equal doses.[24]

Advantages

This drug is very effective in the treatment of CAE and is well tolerated.

Disadvantages

Ethosuximide has a very narrow spectrum of activity.

Place in Therapy

Ethosuximide is a first-line treatment for absence seizures.

Ezogabine

Mechanism of Action

The primary mechanism of action of ezogabine is as a selective positive allosteric opener of KCNQ2-5 channels, which stabilizes the resting membrane potential and reduces brain excitability.[24,91]

Pharmacokinetics

Ezogabine's oral bioavailability is 60%; high fat food increases its maximal blood drug concentration (C_{max}) 38%. Ezogabine has a 30% lower trough serum level in the evening than in the morning. The drug undergoes glucuronidation and acetylation with the major metabolite, *n*-acetyl metabolite (NAMR) being less active than the parent compound in animal models. Elderly subjects show a 40% to 50% higher area under the drug concentration time curve (AUC) and a 30% higher half-life compared to younger subjects, and therefore dosage reduction is recommended.[92]

Adverse Effects

Ezogabine can cause abnormalities of the retina usually after long term use (eg, 4 years) with features similar to those seen in retinal pigment dystrophies known to cause vision loss. Because of this potential vision loss, ezogabine is recommended only after several alternatives have been tried. Urinary retention can also occur, usually within the first 6 months, and caution is advised in persons with benign prostatic hypertrophy, those on anticholinergics, or those persons unable to communicate clinical symptoms. Ezogabine can also cause QT prolongation, usually within 3 hours of administration, and caution is advised when using with other QT prolonging drugs and in persons with congestive heart failure, ventricular hypertrophy, hypokalemia, or hypomagnesemia. Lastly, ezogabine can cause blue or gray-blue skin discoloration predominantly around the lips or in the nailbeds of fingers and toes and sometimes also face, legs, palate, sclera, and conjunctiva usually occurring 2 or more years after treatment at doses of 900 mg or greater. Consequences and reversibility of this adverse effect are unknown, but discontinuation should be considered if this occurs. Otherwise, CNS effects are the most common side effects.[92]

Drug Interactions

Ezogabine can increase lamotrigine clearance by 22% and decrease AUC by 18% while NAMR may inhibit renal clearance of digoxin. Ezogabine serum levels may be reduced 35% by phenytoin and 31% by carbamazepine. Lastly, alcohol may increase systemic exposure, C_{max} and AUC, of ezogabine, resulting in an increase in adverse drug effects.[92]

Dosing and Administration

Ezogabine is initiated at 300 mg/day dosed three times a day, with dosage increases of 150 mg every week until a goal dose of 600 to 1,200 mg/day is reached.[92]

Advantages

Ezogabine works by an entirely different mechanism than other ASDs and therefore may be valuable when added to another ASD as adjunctive therapy.

Disadvantages

Ezogabine is a class V controlled substance. The drug may interfere with both urine and serum bilirubin clinical lab assays causing falsely elevated readings. It is dosed three times per day. Most importantly, it's potential for vision loss, and other unique adverse effects including urinary retention, skin discoloration, and QT prolongation are disadvantages for use.

Place in Therapy

Ezogabine is approved as adjunctive treatment for focal onset seizures. Due to the potential for vision loss, ezogabine is recommended only after several alternatives have been tried.

Felbamate

Mechanism of Action

Felbamate inhibits *N*-methyl-D-aspartate (NMDA) glutamate receptors and modulates $GABA_A$ receptors. At higher doses it may modulate voltage-gated Na^+ channels and inhibit high-voltage gated Ca^{2+} channels.[93,94]

Pharmacokinetics

Felbamate is unaffected by food or antacids. Approximately 40% to 50% of a felbamate dose is metabolized by hydroxylation and conjugation pathways in the liver, and the remainder is excreted unchanged in the urine. It displays linear pharmacokinetics.[93,94]

Adverse Effects

Felbamate is associated with potentially fatal idiosyncratic reactions including aplastic anemia (1 in 3,000 patients) and acute liver failure (1 in 10,000 patients) with reported onset between 68 and 354 days of therapy. The risk for aplastic anemia may be increased in women, those with a history of cytopenia, ASD allergy or significant toxicity, viral infection, and/or immunologic problems.[93] Use of felbamate now requires signed written consent. Otherwise, the most common side effects are insomnia, nausea, and headache (sometimes severe). Anorexia and weight loss are also common and may be especially problematic in children and in patients with diminished caloric intake.[93,94]

Drug Interactions

Felbamate can induce or inhibit the metabolism of the older AEDs. Interactions between warfarin and felbamate have also been reported.[93,94]

Dosing and Administration

Felbamate is initiated at doses of 1,200 mg/day in 3 to 4 divided doses and can be increased at 1- to 2-week intervals to 2,400 mg/day and then to 3,600 mg/day.[93]

Advantages

Felbamate has a unique mechanism of action and a broad spectrum of activity (eg, useful in atonic seizures of LGS and focal seizures).

Disadvantages

Use is limited by the risk of possibly fatal aplastic anemia and hepatotoxicity.

Place in Therapy

Felbamate is approved as either monotherapy or adjunctive therapy in patients with focal onset seizures with or without generalization, and for the treatment of seizures associated with LGS in children. Its use is reserved for patients not responding to other ASDs.

Gabapentin

Mechanism of Action

Gabapentin elevates human brain GABA levels, possibly via alterations in GABA synthesis or reversal of the neuronal GABA transporter, resulting in nonvesicular release of GABA. Gabapentin appears to bind to an amino acid carrier protein and to act at a unique receptor. It binds to the α2δ subunit of Ca^{2+} channels which is believed to underlie its antinociceptive effects.[24]

Pharmacokinetics

Gabapentin is a substrate of the L-amino acid carrier protein in the gut and in the CNS which actively transports the drug across membranes.[95] Binding is saturable causing dose-dependent bioavailability that varies considerably between patients.[96] Food does not affect absorption.[97] Concentrations in human CSF are 5% to 35% of plasma levels, and tissue concentrations are approximately 80% of plasma levels. Gabapentin is renally eliminated, and dosage adjustments may be necessary in patients with significantly impaired renal function.[24]

Adverse Effects

CNS effects, as well as weight gain, are the most common side effects seen with gabapentin. Aggressive behavior has been reported in children.[98] A withdrawal reaction characterized by anxiety, insomnia, nausea, sweating, and increased pain has also been reported with abrupt discontinuation in patients taking it for pain.

Drug Interactions

There is a 10% reduction in the clearance of gabapentin in patients taking cimetidine and a 20% reduction in the bioavailability if aluminum antacids are taken simultaneously with gabapentin, although this may not be clinically significant.[24]

Dosing and Administration

Typical starting doses of gabapentin are 300 mg at bedtime on the first day, increasing to 900 mg/day over 3 days. Faster titration rates (eg, starting at 300-900 mg three times daily) have been well tolerated.[99] Data suggest gabapentin should be given at least four times a day when the total daily dose is 3,600 mg or greater.[100] It does not appear to be absorbed rectally. Patients on hemodialysis should receive an initial 300- to 400-mg dose with 200 to 300 mg given after every 4 hours of hemodialysis.

Advantages

It has a broad therapeutic index with minimal CNS adverse effects and few drug interactions. Doses can be escalated rapidly. It is available in a liquid dosage form.

Disadvantages

It is oftentimes considered a poorly efficacious ASD. However, it is well tolerated, and studies in elderly patients suggest it may be as efficacious as lamotrigine in this population.

Place in Therapy

Gabapentin is FDA approved for patients with focal onset seizures with or without secondary generalization in patients 3 years and older. It is usually considered a second-line agent for patients with focal seizures who have failed initial treatment, although it may have a role in new-onset focal epilepsy in the elderly. It may be most useful in treating epilepsies with comorbid conditions such as neuropathic pain.

Lacosamide

Mechanism of Action

Lacosamide is a functionalized amino acid that enhances slow inactivation of voltage-gated Na^+ channels, stabilizing hyperexcitable neuronal membranes and inhibiting repetitive neuronal firing. It

may also bind to collapsin response mediator protein (CRMP-2 involved in neuronal differentiation and axonal outgrowth), although the clinical significance of this is unclear.[24,101]

Pharmacokinetics

Lacosamide is almost completely absorbed after oral administration, and bioavailability is not affected by food. There is a linear relationship between daily doses and serum concentrations up to 800 mg/day. Moderate hepatic and renal impairment have both been shown to increase systemic drug exposure up to approximately 40%.[24,101]

Adverse Effects

CNS and GI effects, such as dizziness, nausea, diplopia, and ataxia, are the most common side effects seen with lacosamide. These effects are dose related and may occur more commonly in patients receiving concomitant treatment with other Na^+ channel inhibitors. The drug can also cause a small increase in median PR interval on the electrocardiogram (ECG).[24,101]

Drug Interactions

Lacosamide blood levels are decreased by approximately 15% to 20% by enzyme-inducing ASDs.[33] It is a substrate of CYP2C19; however, there are no known drug interactions between lacosamide and drugs metabolized by CYP2C19 including OCs.[24,101]

Dosing and Administration

The starting dose is 100 mg/day given in two divided doses. The dose is increased by 100 mg/day every week until a daily dose of 200 to 400 mg has been reached. Studies have shown that a dose of 600 mg daily may be efficacious for some patients, but at the expense of more CNS side effects.[24,101]

Advantages

An IV form of lacosamide is available for short-term replacement that appears to be safe, well tolerated, and easy to administer as well as a liquid dosage form. It also has a novel mechanism of action.[24,101]

Disadvantages

Lacosamide is a class V controlled substance.[101]

Place in Therapy

Lacosamide is approved as monotherapy or adjunctive treatment for focal onset seizures. Due to ease of use, including availability of intravenous loading and lack of drug interactions, it has become

a first-line agent among many providers, although there is no strong evidence to support this. Although many providers use it first-line, it is only available as brand and due to cost should be reserved as second-line or third-line therapy after failure of other equally efficacious, less expensive ASDs.[24,101]

Lamotrigine

Mechanism of Action

Lamotrigine inhibits voltage-gated Na^+ channels; it also modulates high voltage-gated Ca^{2+} channels, modulates hyperpolarization-activated cation (HCN) channels, and attenuates release of glutamate and to a lesser extent, GABA and dopamine.[24,102]

Pharmacokinetics

Lamotrigine is completely and rapidly absorbed, and absorption is unaffected by food. Rectal bioavailability is approximately 50% of that of the oral dosage forms. Lamotrigine clearance is higher in children and lower in the elderly compared with young adults. Severe hepatic disease can influence lamotrigine pharmacokinetics. Its half-life is also prolonged in renal failure. If a patient is on hemodialysis, approximately 17% of the dose can be removed by hemodialysis, with the half-life being reduced to approximately 13 hours.[24,102]

Adverse Effects

Lamotrigine can cause rash, which usually appears in the first 3 to 4 weeks of therapy and is more likely to occur if the patient has had a prior rash to another ASD.[103] The rash typically is generalized, erythematous, and morbilliform, although SJS can occur. Some rashes can necessitate the withdrawal of lamotrigine. Risk factors for the emergence of more serious rashes appear to be concomitant use of valproic acid and situations where high initial doses or rapid dosage escalation is used. When dosed appropriately, the incidence of rash is similar to that of carbamazepine and phenytoin. The incidence is higher in children than in adults.[104] Otherwise, the most common side effects are CNS related.

Drug Interactions

Valproic acid substantially inhibits the metabolism of lamotrigine, with maximal inhibition occurring at valproic acid doses and serum concentrations of 500 mg/day and 40 to 50 mcg/mL (mg/L; 277-347 µmol/L) respectively.[105] A pharmacodynamic interaction can occur with concurrent carbamazepine therapy, causing an increase in CNS side effects.[105] Lamotrigine does not inhibit liver enzymes and has a low potential for pharmacokinetic interactions with other drugs although such interactions are still possible. It has been found to decrease the bioavailability of the progesterone component (levonorgestrel) of a combination OC by 19%, although the clinical relevance of this interaction is unclear.[106] Concomitant treatment with OCs can lead to a reduction in the serum concentrations of

lamotrigine because of an induction of lamotrigine glucuronidation by ethinyl estradiol.[107] In addition, lamotrigine serum levels can significantly increase during the week off OC treatment in some patients.[107]

Dosing and Administration

In patients who are taking enzyme-inducing drugs, lamotrigine can be started more rapidly than in patients receiving valproic acid. The maintenance doses are also different. For patients on monotherapy, lamotrigine should be started at 25 mg daily for 2 weeks, increased to 25 mg twice daily for 2 weeks, and then increased by 50 mg/day every 2 weeks until the goal dose of 200 to 400 mg/day is reached. For patients on concomitant valproic acid, lamotrigine should be started at doses of 25 mg every other day for 2 weeks, then 25 mg daily for 2 weeks, and then increased by 25 mg/day every 2 weeks until goal doses of 100 and 200 mg/day are reached. For patients on concomitant enzyme inducing ASDs such as carbamazepine or phenytoin, lamotrigine should be started at 50 mg daily for 2 weeks, then increased to 50 mg twice daily for 2 weeks, then increased by 100 mg/day every 2 weeks until goal doses of 300 to 500 mg/day are reached. Removal of inducers from a lamotrigine regimen may necessitate decreases in lamotrigine dose, whereas removal of valproic acid can necessitate an increase in the lamotrigine dose.[105]

Advantages

Lamotrigine is potentially a broad-spectrum ASD, having efficacy in focal onset seizures and several types of generalized seizures. Pediatric dosage forms are available as a chewable dispersible tablet and an oral disintegrating tablet, and it is also available as an extended release product for once daily dosing. Besides rash, it is generally well tolerated in children, adults, and elderly patients.

Disadvantages

Lamotrigine is associated with rash, and the initial doses must be low (especially if the patient is on valproic acid) and escalated slowly to maximize safety. Because of the need for slow titration, it is not a good agent for patients who need to reach therapeutic ASD levels quickly.

Place in Therapy

Lamotrigine is broad spectrum and is approved as both monotherapy and adjunctive treatment in patients with focal onset seizures and can be considered first- or second-line therapy. It is also approved for primary GTC seizures and for primary generalized seizures of LGS.[105] The elderly may experience less cognitive effects than with other ASDs.[66] Its use is mainly limited by its slow titration and risk of rash.

Levetiracetam

Mechanism of Action

Levetiracetam binds to synaptic vesicle protein SV2A, in presynaptic terminals and prevents neurotransmitter release.[108]

Pharmacokinetics

Absorption of levetiracetam is rapid and complete and not significantly affected by food.[109] Renal elimination of unchanged parent drug accounts for the majority of clearance (66%), with the remainder being metabolized via nonhepatic enzymatic hydrolysis to inactive metabolites. Levetiracetam clearance appears to be approximately 40% higher in children than in adults. Patients with severe liver cirrhosis should initially receive one-half the recommended starting dose because of a 57% decrease in clearance. Levetiracetam is excreted into breast milk in potentially clinically important amounts.[24,104]

Adverse Effects

Levetiracetam is extremely well tolerated. CNS effects are the most common side effects seen with levetiracetam, and they are usually mild. In children and young adults, agitation, irritability, or somnolence/lethargy are the most frequently reported CNS side effects.[24,110]

Drug Interactions

It does not significantly interact with other AEDs, warfarin, digoxin, or OCs.[24,110]

Dosing and Administration

Typically the initial dose is 500 mg given twice daily. The dose may be increased by 500 to 1,000 mg every 1 to 2 weeks. Doses above the maximum FDA approved 3,000 mg/day are often used. To minimize CNS side effects, dosing may be initiated at 250 mg twice daily, especially in the elderly. Levetiracetam can be loaded orally or intravenously. Doses can be converted on a 1:1 basis.[24,110]

Advantages

Levetiracetam has a novel mechanism of action, is well tolerated, has no significant drug interactions and can be loaded when therapeutic levels need to be reached quickly.

Disadvantages

Behavioral problems can limit therapy in some patients.

Place in Therapy

Levetiracetam is FDA approved as adjunctive therapy in the treatment of focal onset seizures in patients 12 years of age or older although it is routinely used as first-line monotherapy. It is also

approved for adjunctive treatment of myoclonic seizures in patients with JME and as adjunctive treatment of primarily generalized seizures in patients with IGE (eg, genetic generalized epilepsies).[24,110]

Oxcarbazepine

Mechanism of Action

Oxcarbazepine is structurally related to carbamazepine and is a prodrug that is rapidly converted to the active 10-monohydroxy derivative (MHD). Like carbamazepine, oxcarbazepine and MHD block voltage-gated Na^+ channels, and also modulate Ca^{2+} and K^+ currents, although it displays differing affinities for these ion channels compared to carbamazepine. Whereas carbamazepine may modulate L-type Ca^{2+} channels, oxcarbazepine appears to modulate N- and P-type Ca^{2+} channels,[103] although the clinical significance of these difference is unclear.[111,112]

Pharmacokinetics

Oxcarbazepine is completely absorbed, and MHD is inactivated by glucuronide conjugation and eliminated by the kidneys. Oxcarbazepine and MHD do not undergo autoinduction, and the relationship between dose and serum concentration is linear. Children 2 to 6 years of age need larger doses to achieve the same serum concentration, suggesting a more rapid clearance, whereas elderly patients may have decreased renal elimination. Patients with significant renal impairment may require a dosage reduction.[13,24]

Adverse Effects

CNS effects are the most frequent side effects seen with oxcarbazepine especially at doses greater than 1,200 mg/day and in the elderly, although in comparative trials oxcarbazepine generally caused fewer side effects than phenytoin, valproic acid, or carbamazepine. Hyponatremia has been reported in up to 25% of patients and occurs more often in elderly patients and in patients receiving concomitant sodium-depleting drugs such as diuretics. Hyponatremia occurs less frequently in children. Monitoring serum Na^+ levels and for symptoms of hyponatremia are recommended. Approximately 25% to 30% of patients who develop a rash with carbamazepine will experience a similar reaction with oxcarbazepine.[24,113]

Drug Interactions

Oxcarbazepine decreases the bioavailability of ethinyl estradiol and levonorgestrel and may cause contraceptive failure. Unlike carbamazepine, there are no interactions between cimetidine, erythromycin, or warfarin, and oxcarbazepine. Oxcarbazepine dosed greater than 1,200 mg can cause a 40% increase in the concentration of phenytoin, consistent with inhibition of CYP 2C19. Oxcarbazepine treatment may also modestly reduce lamotrigine serum concentrations, suggesting induction of UGT isozymes. The replacement of carbamazepine with oxcarbazepine may result in a

drug interaction because an enzyme-inducing drug is being removed.[24,113,114]

Dosing and Administration

Dosing in adults can be initiated at 300 to 600 mg/day in two divided doses and increased by 300 mg/day every 3 days or weekly to a recommended dose of 1,200 mg/day (although doses of up to 2,400 mg/day are recommended in conversion to monotherapy). In children 4 years of age and older, the dose can be initiated at 8 to 10 mg/kg/day and increased by 5 mg/kg every 3 days up to 60 mg/kg/day. Doses up to 60 mg/kg/day have also been used in infants and children younger than 4 years of age.[106] In patients being converted from carbamazepine, the typical maintenance dose of oxcarbazepine is 1.5 times the carbamazepine dose (or less if the carbamazepine is dosed high due to autoinduction).[24,113,115]

Advantages

There is strong evidence for its effectiveness in seizure disorders. It is also effective in patients not demonstrating a response to carbamazepine, and its efficacy is comparable with that of carbamazepine, phenytoin, and valproic acid. It may also be better tolerated than phenytoin as monotherapy.[116]

Disadvantages

There are more reports of hyponatremia with oxcarbazepine. About 30% of patients who had carbamazepine-induced rash will also have rash with oxcarbazepine. Enzyme-inducing drugs can increase the clearance of MHD.

Place in Therapy

Oxcarbazepine is FDA approved for use as monotherapy or adjunctive therapy in the treatment of focal seizures in adults and children as young as 4 years of age and can be considered first-line.

Perampanel

Mechanism of Action

Perampanel is a highly selective noncompetitive AMPA-type glutamate receptor antagonist.[117]

Pharmacokinetics

Perampanel is rapidly and almost completely absorbed. It is highly protein bound (95%) and eliminated primarily via CYP3A4 metabolism to an inactive metabolite with an elimination half-life of about 100 hours. Its clearance is increased twofold to threefold when given with enzyme-inducing ASDs.[117]

Adverse Effects

The most common adverse effects include dizziness, somnolence, headache, and ataxia. Perampanel has an FDA boxed warning pertaining to monitoring of psychiatric, behavioral, mood, or personality changes which may be life-threatening.[117]

Drug Interactions

Serum levels of perampanel are decreased by enzyme inducing ASDs. It displays modest enzyme inducing properties of its own at the high end of its dose range (12 mg/day).[117]

Dosing and Administration

Perampanel is initiated with starting doses of 2 mg/day and titrated by 2 mg/day on a weekly basis to a maximum dose of 12 mg/day. If the patient is taking enzyme inducing ASDs, the dose should be initiated at 4 mg/day. In hepatic failure, the dose should be increased every 2 weeks, and the target dose is decreased to 4 to 6 mg/day.[117]

Advantages

Perampanel has a novel mechanism of action and can be dosed once per day.

Disadvantages

There is limited experience with perampanel.

Place in Therapy

Perampanel is approved for focal onset seizure with or without secondary generalization in patients with epilepsy 12 years of age or older. It is also approved for primary GTC seizures in patients 12 years of age or older.[117] It is a new drug and should be reserved for use after failure of other ASDs.

Phenobarbital

Mechanism of Action

Phenobarbital potentiates the action of GABA on $GABA_A$ receptors by prolonging the opening of the GABA receptor-chloride ionophore complex. It also depresses normal excitatory synaptic transmission by inhibiting glutamate release through an effect on P/Q type high-voltage activated Ca^{2+} channels and blocking AMPA/Kainate receptors.[24,118]

Pharmacokinetics

Phenobarbital is hepatically metabolized by CYP2C9 (major), CYP2C19, and CYP2E1 to two inactive

metabolites although approximately 25% is renally cleared with a half-life of 70 to 130 hours. It is an inducer of many CYP proteins, including CYP1A2, CYP2B6, CYP2A6, CYP2C8, CYP2C9, and CYP3A4 and induces metabolism. It also induces lamotrigine metabolism by inducing UGT1A4 enzyme. Usual adult therapeutic levels are between 10 and 40 mcg/mL (mg/L; 43-172 µmol/L). Side effects including sedation occur commonly at higher dosage levels.[24,118]

Adverse Effects

The most common side effects are somnolence, dizziness, decreased coordination, impaired cognition, mental confusion, depressed affect, and behavior problems seen in children. Long-term use is associated osteomalacia, megaloblastic anemia, and folate deficiency. Serious side effects include hepatotoxicity, and serious dermatologic effects such as SJS and TEN.[24,118]

Drug Interactions

Phenobarbital increases the metabolism of clobazam, midazolam, and lamotrigine and decreases their serum levels but may increase *or* decrease phenytoin serum levels. Felbamate, oxcarbazepine, phenytoin, and valproate may inhibit the metabolism of phenobarbital, thereby increasing phenobarbital serum levels. Common drugs that interact with phenobarbital include amitriptyline, citalopram, cyclosporine, haloperidol, felodipine, nifedipine, propranolol, verapamil, and warfarin.[24,118]

Dosing and Administration

The initial starting dose of phenobarbital in adults is 60 mg/day and can be titrated up to a target dose of 100 to 300 mg/day over several weeks.[24,118]

Advantages

Phenobarbital is an effective ASD and has been in use for the longest period of time and is readily available worldwide.

Disadvantages

Phenobarbital causes much sedation.

Place in Therapy

Due to the availability of better tolerated ASDs with fewer drug interactions, phenobarbital should be reserved for second line use in focal onset and generalized seizures.

Phenytoin

Mechanism of Action

Phenytoin inhibits voltage-gated Na^+ channels.[24]

Pharmacokinetics

The pharmacokinetics of phenytoin are complex, and the reader is referred to a more extensive review for a more in-depth understanding.[119] The oral absorption of phenytoin may be saturable at higher doses above 400 mg. Absorption following IM administration is erratic and delayed, and IM injections are painful; however, IM fosphenytoin absorption is rapid and well tolerated. Phenytoin is highly protein bound, and it is essential to know the patient's serum albumin level when interpreting serum phenytoin concentrations.[120] Significant renal dysfunction will also alter phenytoin protein binding, whereas obesity increases the volume of distribution. Phenytoin is metabolized in the liver by parahydroxylation mainly by CYP2C9 and CYP2C19.[24] Phenytoin displays Michaelis–Menten pharmacokinetics, and the metabolism of phenytoin saturates at doses used clinically, so that a small change in dose can result in a disproportionally large increase in serum concentrations, potentially leading to toxicity.[119] This can also occur at low serum concentrations in some patients. Phenytoin metabolism may also decrease in the elderly although this been challenged.[121]

Adverse Effects

CNS effects are the most frequent side effects seen with phenytoin. Most of these effects usually are transient and can be minimized by slow dosage titration. At very high concentrations of greater than 50 mcg/mL (mg/L; 200 µmol/L), phenytoin can exacerbate seizures. Phenytoin has multiple side effects associated with chronic use including gingival hyperplasia (minimized by good oral hygiene), vitamin D deficiency, osteomalacia, carbohydrate intolerance, immunologic disturbances, hypothyroidism, and peripheral neuropathy. Phenytoin is associated with rare hypersensitivity and idiosyncratic reactions resulting in rashes, SJS, pseudolymphoma, bone marrow suppression, lupus-like reactions, and hepatitis.[24,122]

Drug Interactions

Phenytoin has numerous drug interactions. It is an inducer of both CYP450 and UGT isozymes. The absorption of phenytoin can be increased or decreased with the administration of food depending on the composition of the meal. The bioavailability of phenytoin suspension can be decreased in patients receiving continuous enteral nutrient tube feedings.[24] Phenytoin decreases folic acid absorption. Replacement of folic acid can reduce phenytoin concentration and result in loss of efficacy.[24]

Dosing and Administration

Immediate-release capsules and liquid dosage forms are available, although the extended-release capsule is most often used. Only the extended-release capsules should be dosed once daily. An oral loading dose (eg, 20 mg/kg), should be divided into 3 to 4 doses and given at 4 to 6-hour intervals to therapeutic levels of between 10 and 20 mcg/mL (mg/L; 40-79 µmol/L).[124] When adjusting dosages

based on levels one can increase the daily dose by 100 mg if the serum levels are less than 7 mcg/mL (mg/L; 28 μmol/L), by 50 mg if the serum levels are between 7 and 12 mcg/mL (mg/L; 28-48 μmol/L), and by 30 mg if serum levels are greater than 12 mcg/mL (mg/L; 48 μmol/L).[123] A common maintenance dose is 300 mg/day. One should also remember that 100 mg of phenytoin acid is equal to 92 mg of phenytoin sodium. Intravenous and IM administration of phenytoin is available although IM is not recommended. Fosphenytoin is a prodrug for phenytoin, has less side effects, and is available intravenously (see chapter on status epilepticus for more information on phenytoin and fosphenytoin IV).

Advantages

After more than 66 years, phenytoin's risk-to-benefit ratio is well established. It is available intravenously for emergent situations.

Disadvantages

Phenytoin has numerous side effects associated with chronic use. It has a relatively narrow therapeutic window, and dose titration is complicated by Michaelis–Menten kinetics. There are also many drug interactions associated with its metabolism and protein binding. It can also be present in breast milk and it crosses the placenta.

Place in Therapy

Phenytoin is FDA approved for focal onset seizures and GTC seizures. It may exacerbate seizures in generalized epilepsies and should be avoided in those epilepsies. It has known efficacy and has long been used as a first line ASD for many seizure types. However, known side effects with chronic use may limit its use, and its place in therapy is being reevaluated as newer ASDs with fewer side effects become more common.

Pregabalin

Mechanism of Action

Pregabalin is structurally related to gabapentin and binds to the $\alpha^2\delta$ subunit of voltage-gated Ca^{2+} channels which possibly results in decreased release of the excitatory neurotransmitters glutamate, noradrenaline, substance P, and calcitonin gene-related peptide.[24]

Pharmacokinetics

Pregabalin is a substrate of the L-amino acid carrier protein in the CNS. It does not display dose-dependent bioavailability, and bioavailability is unaffected by food.[125] Pregabalin is eliminated renally as unchanged drug, and dosage adjustment is required in patients with significantly impaired renal function. In anuric patients, 50% of the dose is removed by 4 hours of hemodialysis.

Adverse Effects

CNS effects, as well as weight gain, are the most frequently reported side effects seen with pregabalin. It is unknown if pregabalin causes aggressive behavior in children. A withdrawal reaction characterized by anxiety, nervousness, and irritability has been noted in patients being treated for generalized anxiety upon abrupt discontinuation of the drug.[125]

Drug Interactions

Drug interactions are unlikely.

Dosing and Administration

Pregabalin is started at doses of 150 mg/day divided into twice or thrice daily intervals. Doses can be increased by 50 to 100 mg/day every 1 to 2 weeks. Doses greater than 600 mg/day are uncommon. The manufacturer recommends that patients with end-stage renal disease maintained on hemodialysis receive a 25 to 75 mg daily dose with 25 to 75 mg given after every 4 hours of hemodialysis.[24]

Advantages

Pregabalin is somewhat more potent than gabapentin without the dose-limiting GI absorption properties. It has minimal CNS side effects and no drug interactions.

Disadvantages

Pregabalin is a class V controlled substance. Like gabapentin it can cause weight gain and peripheral edema, especially as the dose is increased.

Place in Therapy

Pregabalin is FDA approved for focal onset seizures in adults. It has been used as monotherapy, although generally it is reserved for patients who have failed initial treatment with other ASDs or for patients who also have chronic neuropathic pain or generalized anxiety disorder.[24]

Rufinamide

Mechanism of Action

Rufinamide is a triazole derivative that suppresses neuronal hyperexcitability through prolongation of the inactivation phase of voltage-gated Na^+ channels.[126]

Pharmacokinetics

Rufinamide is slowly absorbed (T_{max} of 4-6 hours) with decreasing absorption at higher doses (85% at 600 mg). Absorption is improved when taken with food. It is extensively metabolized by primary biotransformation via carboxylesterases with no active metabolites. The drug may have a higher clearance in children.[126]

Adverse Effects

CNS effects are the most common side effects and are dose-dependent. Rufinamide may increase the incidence of convulsions in some patients, and may precipitate SE. Multiorgan hypersensitivity has occurred within 4 weeks of starting treatment in patients younger than 12 years of age.

Drug Interactions

Rufinamide is a weak inhibitor of CYP2E1 and a weak inducer of CYP3A4. It is responsible for a modest increase in the clearance of carbamazepine, lamotrigine, phenobarbital, and phenytoin. This effect may be greater in children than adults. Similarly, carbamazepine, phenytoin, primidone, and phenobarbital significantly increase the clearance of rufinamide. Valproic acid significantly decreases the clearance of rufinamide and elevates serum levels by 70%.[24]

Dosing and Administration

The initial dose of rufinamide is 400 to 800 mg/day given in divided doses with an increase in dose every other day until a maximum dose of 45 mg/kg/day or 3,200 mg/day (whichever is less) is obtained.

Advantages

The drug is effective for seizures associated with LGS without causing cognitive and psychiatric adverse effects. The dose can be rapidly escalated.

Disadvantages

Drug interactions are common with rufinamide, and patients with LGS are usually on multiple medications. The drug has caused convulsions and SE in some patients.

Place in Therapy

Rufinamide is FDA approved as an adjunctive agent for seizures in LGS and is efficacious in the treatment of tonic-atonic seizures. It should be reserved for use after patients have failed other ASDs.

Tiagabine

Mechanism of Action

Tiagabine is a potent specific inhibitor of GABA transporter type 1 (GAT1), and enhances GABA by decreasing its removal from the synaptic space and prolonging inhibitory postsynaptic potentials.[127]

Pharmacokinetics

Tiagabine is well absorbed, and there is a linear relationship between dose and serum concentrations. Children eliminate tiagabine slightly faster than adults. Hepatic impairment causes higher and more prolonged plasma concentrations of the drug, although renal dysfunction does not change its pharmacokinetics.[127] Tiagabine evening levels are lower than morning levels.

Adverse Effects

Tiagabine has increased the incidence of nonconvulsive SE in patients with chronic refractory partial epilepsy, and there are reports of SE or new-onset seizures occurring in patients without a history of epilepsy.[128,129] Otherwise, mild and transient CNS and GI effects are the most frequent side effects, mostly occurring during dose titration and can be alleviated with food which slows absorption.[128]

Drug Interactions

Tiagabine is displaced from protein by naproxen, salicylates, and valproate but does not itself displace phenytoin, valproic acid, amitriptyline, tolbutamide, or warfarin.[127]

Dosing and Administration

The initial dose of 7.5 to 15 mg/day is given in divided doses and is increased by 5 to 10 mg/day weekly to a minimum effective dose of 30 mg/day, although individuals on enzyme-inducing drugs may require doses up to 50 to 60 mg/day.

Advantages

It has a unique mechanism of action with few drug interactions.

Disadvantages

Tiagabine has been associated with an increase in seizure frequency and SE.

Place in Therapy

Tiagabine is FDA approved as adjunct therapy for patient with focal seizures with or without generalization. It should be reserved for those who have failed other therapies due to the potential to cause seizures and SE in some patients.

Topiramate

Mechanism of Action

Topiramate has multiple modes of action involving voltage-dependent Na^+ channels, $GABA_A$-receptor subunits, high-voltage Ca^{2+} channels, and kainate/α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) subunits. It also inhibits carbonic anhydrase, which may have some antiseizure effects but is likely not a major mechanism of action.[130]

Pharmacokinetics

Although generally considered to have linear absorption and elimination pharmacokinetics, there is saturable binding to erythrocytes that may affect C_{max} and AUC.[131] Approximately 50% of the dose is excreted renally unchanged and should be dose adjusted in renally impaired patients. Renal tubular reabsorption may affect elimination. Metabolism is increased 50% when given with enzyme-inducing ASDs.

Adverse Effects

CNS effects are frequently reported including word-finding difficulties and problems with cognition, occurring more often during rapid titration and at higher doses.[132,133] Kidney stones occur in 1.5% of patients (2-4 times that of the general population), and patients should be encouraged to maintain adequate fluid intake. Topiramate can also cause metabolic acidosis at doses as low as 50 mg/day, especially in patients with renal disease, severe respiratory disorders, diarrhea, surgery, and in patients on the ketogenic diet.[132]

Drug Interactions

Topiramate can increase phenytoin serum concentrations in some patients due to decreasing CYP2C19 metabolism, although the extent of its effect depends on whether the patient is a "poor metabolizer" phenotype. Topiramate can modestly increase the clearance of valproic acid and increase formation of toxic metabolites. It also increases the clearance of ethinyl estradiol in a dose-dependent manner, although doses of less than 200 mg/day are unlikely to alter OC pharmacokinetics. Topiramate also slightly increases the clearance of digoxin.[134]

Dosing and Administration

Topiramate should be titrated slowly to avoid adverse events. Doses can be initiated at 25 mg/day and increased by 25 to 50 mg/day every 1 to 2 weeks. For patients on other ASDs, doses greater than 400 mg/day do not appear to lead to improved efficacy and can cause increased adverse effects.[24,135]

Advantages

Topiramate has multiple mechanisms of action and is a broad-spectrum ASD. Elimination is primarily

renal, although hepatic metabolism occurs at higher doses.

Disadvantages

With rapid dosage escalation, topiramate can compromise cognitive functioning, including impaired word finding and impaired short-term memory. Therefore, initial doses should be low, and titration must be slow. Renal stones and weight loss have been associated with topiramate use.

Place in Therapy

Topiramate is FDA approved as monotherapy or adjunctive therapy for focal onset seizures is patients 2 years or older. It is also approved for the treatment of tonic–clonic seizures in primary generalized epilepsy and generalized seizures in patients with LGS. It can be considered first- or second-line therapy but use is limited by CNS effects and slow titration. It has benefit in patients with comorbid migraines or obesity.

Valproic Acid/Divalproex Sodium

Mechanism of Action

Valproic acid may potentiate postsynaptic GABA responses, may have a direct membrane-stabilizing effect, and may affect Na^+ and K^+ channels.[136]

Pharmacokinetics

Valproic acid is completely absorbed orally,[136] although the rate of absorption differs among preparations. Peak concentrations occur in 0.5 to 1 hour with the syrup, 1 to 3 hours with the capsule, and 2 to 6 hours with the enteric-coated tablet.[136] Divalproex is composed of sodium valproate and valproic acid in a 1:1 molar relationship and dissociates to the valproate ion in the GI tract.

Valproic acid is extensively bound to albumin, and the valproic acid free fraction will increase as the total serum concentration increases. Because binding is saturable, monitoring of free fractions, although uncommon, may be better than total concentrations, especially at higher concentrations or in patients with hypoalbuminemia.

The primary pathway of valproic acid metabolism is β-oxidation, although up to 40% of a dose may be excreted as the glucuronide. At least 10 metabolites of valproic acid have been identified, some with weak anticonvulsant activity, and at least one metabolite (4-ene-VPA), which may be increased with concomitant enzyme-inducing drugs, may be responsible for the reported hepatotoxicity.[136] Valproic acid has lower evening serum levels than morning levels. It crosses into the placenta and concentrations may be up to five times higher in cord serum blood than in the mother due to higher binding in the fetal compartment.[137]

Adverse Effects

GI side effects including nausea, vomiting, anorexia, as well as weight gain are most commonly reported (20%). Pancreatitis is rare. GI complaints may be minimized by food or by giving the enteric-coated or ER formulation. Alopecia and hair changes are temporary, and hair growth returns even with continued dosing. Weight gain can be significant for many patients and is associated with an increase in fasting insulin and leptin serum levels,[138] possibly due to the inhibition of insulin metabolism by the liver[139] and leading to the development of insulin resistance in obese patients.[136]

Serious hepatotoxicity has occurred with most deaths in patients younger than 2 years of age, occurring early in the course of therapy, in children with mental retardation and receiving multiple ASDs (as ASDs can alter valproic acid metabolism and lead to development of possible toxic metabolites). Hyperammonemia is common (50%) but does not necessarily imply liver damage. Valproic acid has also been shown to alter carnitine metabolism, and it is possible that carnitine deficiency may cause both liver toxicity and hyperammonemia[140] but routine carnitine supplementation is not generally supported.[141] Thrombocytopenia is also common especially at concentrations greater than 100 mcg/mL (mg/L; 693 µmol/L) and may occur more frequently in children than adults.[142]

Drug Interactions

Highly protein-bound drugs (eg, free fatty acids and aspirin) can displace valproic acid. Valproic acid can inhibit specific CYP450 isozymes, epoxide hydrolase, and UGT isozymes. Valproic acid decreases clearance of phenobarbital and lamotrigine by 30% to 50% and can lead to phenobarbital and lamotrigine toxicity. OCs may also increase the clearance of valproic acid and lower serum levels by 20%.[65] In addition, carbapenems, especially meropenem, can lower valproic acid levels.[143]

Dosing and Administration

Once-daily dosing is possible with extended-release divalproex, but more frequent dosing is the norm due to reports of breakthrough seizures on once daily dosing. The concentration-dose ratio decreases with increasing dose probably because of increasing free concentrations and a resulting increase in clearance. Valproic acid is available as a soft gelatin capsule, an enteric-coated tablet, a syrup, a "sprinkle capsule," an extended-release formulation designed for once-daily dosing, and an IV formulation.[136] This parenteral formulation must not be given IM because it can cause tissue necrosis. The sprinkle capsule, designed to be opened and mixed with food, has a slower rate of absorption, which results in fewer fluctuations in the peak-to-trough ratio. The syrup is absorbed more rapidly than any solid dosage form. The enteric-coated divalproex tablet is not sustained-release but reduces GI distress and delays absorption. Dosing may be initiated at 10 to 15 mg/kg/day and increased by 5 to 10 mg/kg weekly. Valproate may be intravenously loaded at a dose of 15 to 20 mg/kg. Depakote-ER is approximately 15% less bioavailable than the enteric-coated divalproex sodium delayed-release.

Advantages

Valproic acid is available in multiple dosage formulations, has a wide therapeutic index, and is considered a broad-spectrum ASD. It is also used in other neurologic or psychiatric disorders (eg, migraine headache and bipolar disorder).

Disadvantages

Valproic acid causes significant weight gain and has other side effects, such as alopecia, tremor, pancreatitis, PCOS, and thrombocytopenia, and it is teratogenic. It also has multiple drug–drug interactions as an enzyme inhibitor.

Place in Therapy

Valproic acid is first-line therapy for generalized seizures, including myoclonic, atonic, and absence seizures. It can be used as both monotherapy and adjunctive therapy for focal-onset seizures, and it is very useful in patients with mixed seizure disorders. Its use is limited by potential long-term side effects such as weight gain and teratogenicity.

Vigabatrin

Mechanism of Action

Vigabatrin is an amino acid that is a structural analog of GABA and is a selective, irreversible inhibitor of GABA-transaminase, the enzyme that degrades GABA, thereby increasing GABA levels in the CNS.[144]

Pharmacokinetics

Vigabatrin undergoes virtually no metabolism and is excreted unchanged in the urine dosage. No dose adjustment is required for renally impaired patients. Food has no effect on its absorption. Duration of effect is not related to serum levels and is directly related to regeneration of the GABA-transaminase enzyme. Children have a higher vigabatrin clearance than adults and require higher mg/kg doses.[65]

Adverse Effects

Vigabatrin may aggravate seizures, particularly absence and myoclonic seizures in patients with generalized epilepsies. Patients with history of depression, psychosis, or behavioral disturbances may be at greater risk to develop psychiatric effects.[144] Vigabatrin causes progressive, irreversible, bilateral concentric visual field constriction in a high percentage of patients. It may also reduce visual acuity in a dose-related and life exposure-related manner. Vigabatrin is associated with weight gain and edema, peripheral neuropathy, somnolence, and fatigue. In up to 11% of patients (up to age 3 years) treated with high doses of the drug for infantile spasms, MRI findings have been strongly suggestive of intramyelinic edema in select brain areas. These findings appear to be reversible, and their significance is unclear.[145]

Drug Interactions

Vigabatrin induces CYP2C9 and therefore decreases phenytoin plasma levels by approximately 20% and possibly increases serum carbamazepine by 10%.

Dosing and Administration

The initial dose is 1,000 mg/day given in two divided doses. Doses are increased by 500 mg/day weekly until 3,000 mg/day is reached. The dose in infants and children for infantile spasms is 50 mg/kg/day given in two divided doses with an increase by 25 to 50 mg/kg/day every 3 days to a maximum dose of 150 mg/kg/day.

Advantages

Vigabatrin is first-line for infantile spasm and has been widely studied.

Disadvantages

Adverse effects are significant, and it is available only through a restricted distribution program (SHARE program), which requires providers and patients to register. Vision should be checked at baseline and every 3 months for up to 6 months after drug discontinuation.

Place in Therapy

It is a first-line agent for infantile spasms, particularly those with tuberous sclerosis as the etiology. It is a third-line adjunctive agent for refractory focal onset epilepsy.

Zonisamide

Mechanism of Action

Zonisamide, a sulfonamide, exerts its antiepileptic effect by inhibition of slow Na^+ channels and T-type Ca^{2+} channels, and possibly by inhibition of glutamate release. Like topiramate, it also has a weak carbonic anhydrase inhibitory effect.[146]

Pharmacokinetics

Zonisamide is well absorbed and reaches a maximum concentration in 2 to 5 hours. It is metabolized by CYP450 system, although it has minimal drug interactions, and 30% is excreted unchanged in the urine. It crosses the placenta, and the concentration in breast milk is similar to that in the plasma.[146]

Adverse Effects

Common CNS effects include sedation and effects on cognition especially with rapid dose escalation.

Paresthesias, modest weight loss, oligohidrosis with effects on body temperature control are also reported. Hypersensitivity reactions can occur (0.02% of patients), and it should be used with caution (if at all) in patients with sulfonamide allergies. A 2.6% incidence of symptomatic kidney stones has been reported.[147]

Drug Interactions

Zonisamide does not inhibit or induce the CYP450 system.

Dosing and Administration

Zonisamide is given once or twice daily. Once-daily dosing of zonisamide causes greater fluctuations in serum concentrations and perhaps more side effects, and therefore it should be dosed twice daily at doses of greater than 400 mg/day. It can be initiated at 100 mg once daily and the dose should be increased by 100 mg/day every 1 to 2 weeks to response. Doses greater than the FDA approved maximum of 600 mg/day are uncommon.

Advantages

Zonisamide has multiple mechanisms of action and may be a broad-spectrum ASD with minimal drug interactions and can be dosed once daily. There is broad international experience with this drug especially in Asian populations, and patients may experience modest weight loss.

Disadvantages

Cognitive impairment can limit its use, especially with rapid dose escalation. It should be avoided in patients allergic to "sulfa drugs." Renal stones may limit its use.

Place in Therapy

Zonisamide is approved for the adjunctive treatment of focal onset seizures and may be considered first-line. However, it may be potentially effective in a variety of focal onset and generalized onset seizure types.

EVALUATION OF THERAPEUTIC OUTCOMES

Clinical response is more important than the serum drug concentrations and involves identifying the number and type of seizures and adverse effects. Patients should record the severity and the frequency of seizures in a seizure diary, and there should be a decrease with treatment. Patients and family should be questioned regularly to determine whether patients are truly seizure free. Patients should also be monitored long term for comorbid conditions, social adjustment (including QOL assessments), drug interactions, and adherence. Periodic screening for comorbid neuropsychiatric disorders, such as depression and anxiety, is also important.

Outcomes are focusing increasingly more on optimal QOL. The AAN has developed quality performance measures for the clinician that define a high quality of care of these patients. Among those performance measures, it is important to remember to counsel patients about ASD side effects, initiate discussion about depression, and assess their knowledge about referral of the intractable epilepsy patient for surgery. Besides seizure control and ASD side effects, factors that can impact QOL in epilepsy patients and which should be addressed include issues about driving, economic security, forming relationships, epilepsy safety such as precautions when swimming, social isolation, and social stigma.

Chapter 57: Status Epilepticus

FIGURE 57-1

Stephanie J. Phelps; James W. Wheless

INTRODUCTION

KEY CONCEPTS

- 1 Status epilepticus (SE) is a neurologic emergency that may be associated with significant morbidity and mortality.
- 2 Generalized convulsive status epilepticus (GCSE) is defined as any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. Any seizure that does not stop within 5 minutes should be aggressively treated as impending SE.
- 3 There are two types of SE, GCSE and nonconvulsive status epilepticus (NCSE). GCSE is the most common type and can be divided into four stages: (1) impending, (2) established, (3) refractory, and (4) super-refractory.
- 4 Although the pathophysiology of GCSE is unknown, experimental models have shown that there is a dramatic decrease in *γ*-aminobutyric acid–mediated inhibitory synaptic transmission and that glutamatergic excitatory synaptic transmission sustains the seizures.
- 5 During prolonged GCSE, $GABA_A$ receptors move from the synaptic membrane into the cytoplasm where they become functionally inactive. A loss of these receptors on the synaptic surface may result in time-dependent pharmacoresistance to benzodiazepines.
- 6 The main purpose of treatment is to prevent or decrease morbidity and mortality of prolonged seizures. Pharmacologic treatment needs to be rapid and aimed at terminating both electrical and clinical seizures. The probability of poorer outcomes increases with increased length of electrographic seizure activity.

- 7 Lorazepam is the preferred benzodiazepine in treatment of GCSE because of its efficacy and long duration of action in the central nervous system (CNS). Midazolam is the preferred benzodiazepine for intramuscular (IM) and intranasal (IN) administration.
- 8 Although practice is slowly moving to other anticonvulsants, the hydantoins (phenytoin and fosphenytoin) continue to be the long-acting anticonvulsants used most frequently. Either phenytoin or fosphenytoin should be given concurrently with benzodiazepines.
- 9 If GCSE is not controlled by two anticonvulsants, the GCSE is considered to be refractory. In these cases, anesthetic doses of midazolam, pentobarbital, ketamine, or propofol may be used.

1 Status epilepticus (SE) is a common neurologic emergency that is associated with brain damage and death. The Commission on Classification and Terminology and the Commission on Epidemiology of the International League Against Epilepsy (ILAE) have recently proposed a new definition: Conceptually, SE results from the failure of the mechanisms responsible for seizure termination or from the initiation of mechanisms, which lead to abnormally, prolonged seizures. There are two operational dimensions to this new definition. First, the length of the seizure and the time point (5 minutes) beyond which the seizure should be regarded as "continuous seizure activity." Second, is the time of ongoing seizure activity after which there is a risk of long-term consequences (30 minutes). Both time points are based on animal experiments and clinical research; hence, these time points should be considered the best estimates currently available.[1] 2 The traditional definition defines SE as (a) any seizure lasting longer than 30 minutes whether or not consciousness is impaired or (b) recurrent seizures without an intervening period of consciousness between seizures.[2] Clinically, this definition has limited use, as the average seizure is less than 2 minutes; and only 40% of seizures lasting 10 to 29 minutes cease without treatment.[3] Pharmacoresistance and mortality significantly increase with prolonged seizure duration.[2] 2 Therefore, aggressive treatment of seizures lasting 5 minutes or more is strongly recommended. 3 SE can present in several forms (**Table 57-1**), including generalized convulsive status epilepticus (GCSE) and nonconvulsive status epilepticus (NCSE).

TABLE 57-1 International Classification of Status Epilepticus

Convulsive		Nonconvulsive	
International	**Traditional Terminology**	**International**	**Traditional Terminology**
Generalized SE			
• Tonic–Clonic[a,b] • Tonic[c] • Clonic[c] • Myoclonic[b]	Grand mal, epilepticus convulsivus	Absence[c]	Petit mal, spike-and-wave stupor, spike and-slow-wave or 3/s spike-and-wave, epileptic fugue, epilepsia minora continua, epileptic twilight, minor SE

Convulsive		Nonconvulsive	
International	**Traditional Terminology**	**International**	**Traditional Terminology**
• *Erratic*[d]			
		Partial SE[a,b]	
Secondary generalized SE[a,b]		Simple partial	Focal motor, focal sensory, epilepsia partialis continua, adversive SE
• Tonic		Somatomotor	Elementary
• Partial seizures with secondary generalization		Dysphasic	Temporal lobe, psychomotor, epileptic fugue state, prolonged epileptic stupor, prolonged epileptic confusional state, continuous epileptic twilight state
		Other types	
		Complex partial	

SE, status epilepticus.

[a]Most common in older children.

[b]Most common in adolescents and adults.

[c]Most common in infants and young children.

[d]Most common in neonates.

Nonconvulsive status epilepticus occurs in 25% of those with SE and is characterized by a fluctuating or continuous “epileptic twilight” state that produces altered consciousness and/or behavior (eg, lethargy and decreased mental function).[4] An electroencephalogram (EEG) is the most important diagnostic and management tool.[4] In most instances, a benzodiazepine and/or valproate remain drugs of choice.[4] Although intravenous (IV) hydantoin, levetiracetam, or phenobarbital can be tried in nonresponders, general anesthesia is usually not appropriate.[4]

3 This chapter will focus on GCSE, which is the most common and severe form of SE. GCSE can be divided into four stages: (1) impending, (2) established, (3) refractory, and (4) super-refractory (**Table 57-2**).[5] It is characterized by repeated primary or secondary generalized seizures that involve both hemispheres of the brain, results in a loss of consciousness, and are associated with a persistent postictal state.

TABLE 57-2 Stages of Generalized Convulsive Status Epilepticus

Stage		Definition
Stage 1 (0-30 minutes)	Impending GCSE	an acute condition characterized by continuous seizures for at least 5 minutes, or by two seizures without full recovery of consciousness

Stage		Definition
		between them
Stage 2 (30-60 minutes)	Established GCSE	an acute condition characterized by continuous seizures for at least 30 minutes, or by 30 minutes of intermittent seizures without full recovery of consciousness between events
Stage 3 (>120 minutes)	Refractory GCSE	an acute condition characterized by continuous seizures despite initial treatment with 2-3 AEDs
Stage 4 (>24 hours)	Super-refractory GCSE	an acute condition characterized by seizures that continue 24 hours or longer after the administration of anesthesia, including cases in which SE recurs on reduction or withdrawal of anesthesia

AED, antiepileptic drug; GCSE, generalized convulsive status epilepticus; SE, status epilepticus.

EPIDEMIOLOGY

The worldwide and United States incidence ranges between 1.2 to 5 million and 100,000 to 152,000 cases each year, respectively.[2] GCSE has no predilection for gender or socioeconomic status but does occur more frequently in nonwhites across all ages.[6] Most GCSE occurs in individuals with no history of epilepsy; however, approximately 5% of adults and 10% to 25% of children with epilepsy will develop GCSE.[7] The incidence is highest in those younger than 1 year of age and in those older than 60 years of age.

ETIOLOGY

Precipitating events for GCSE vary and generally reflect different populations and referral patterns. Most episodes in individuals with epilepsy occur because of acute anticonvulsant withdrawal, a metabolic disorder or concurrent illness, or progression of a preexisting neurologic disease. Common etiologies and mortality rates are shown in **Table 57-3**.[6,8] Precipitating events are divided into those with or without neurologic structural lesions or those with a precipitating injury or insult. Cases with structural lesions or those with a specific neurologic insult are associated with a poor prognosis.

TABLE 57-3 Etiology and Mortality for Pediatric and Adult Cases of Status Epilepticus

Etiology	Mortality Number of Cases (%) *n* = 200 Cases of Pediatric SE	Mortality Number of Cases (%) *n* = 512 Cases of Adult SE
Type I (no Structural Lesion)		
Infection	55 (5)	6 (35)
CNS infection	11 (0)	2 (20)
Metabolic	20 (5)	12 (36)
Low AED levels	16 (0)	24 (7)
Alcohol	0 (0)	13 (8)

Etiology	Mortality Number of Cases (%) *n* = 200 Cases of Pediatric SE	Mortality Number of Cases (%) *n* = 512 Cases of Adult SE
Idiopathic	6 (0)	13 (18)
Type II (Structural Lesion)		
Anoxia/hypoxia	27 (13)	14 (65)
CNS tumor	3 (50)	5 (22)
CVA	5 (0)	26 (27)
Drug overdose	5 (0)	3 (23)
Hemorrhage	5 (11)	4 (35)
Trauma	13 (0)	3 (23)
Remote causes[a]	33 (5)	7 (13)

AED, antiepileptic drug; CVA, cerebrovascular accident; SE, status epilepticus. Percentages do not add up to 100% because some patients had multiple etiologies.

[a]More than half of remote causes were congenital malformations and CVA in pediatric and adult patients, respectively.

Data from references 6 and 8.

There are major differences in etiologies for pediatric and adult patients (see Table 57-3). During their first few weeks of life, infants who are born to addicted mothers can develop drug withdrawal seizures. Other neonates can develop GCSE because of pyridoxine deficiency, which should resolve within hours following IV pyridoxine (100 mg). Acute encephalopathy and metabolic disorders are the major causes of GCSE in those younger than 1 year of age. In young children, the cause is often a nonspecific illness such as fever and/or a viral illness. The most frequent precipitating events in adults are cerebrovascular disease, rapid anticonvulsant withdrawal, and low anticonvulsant serum concentrations. Cerebrovascular disease is the leading cause in those who have their first seizures after age 60. Prescription, over-the-counter, herbal, and recreational drugs should be considered in anyone with new-onset GCSE.

MORBIDITY AND MORTALITY

Generalized convulsive status epilepticus is harmful to the brain. While most contend that the GCSE is responsible for the damage, it is unknown if the morbidity results from the underlying etiology or the GCSE. Regardless of the inducing stimulus, neuronal damage in animal models is evident following 30 to 60 minutes of GCSE, and most progress to develop epilepsy following a prolonged seizure. Interestingly, inhibiting the seizure-induced neuronal damage does not prevent the development of epilepsy, suggesting that the seizures themselves may be harmful. It is hard to establish a relationship between GCSE and long-term outcomes because it is difficult to weigh the effects of seizure type, etiology, duration, concurrent physiologic events, and therapy or lack thereof. It has been shown that

patients with a history of prolonged febrile seizures who later developed epilepsy share similar histopathologic changes (ie, hippocampal sclerosis) to those found in animal models of GCSE.[9,10] In these cases, the period between the initial GCSE and the first epileptic seizure may be months to decades, suggesting a possible link between GCSE and the development of epilepsy. Importantly, studies of GCSE show that the currently available anticonvulsants do not reproducibly prevent the development of epilepsy following prolonged seizures.[9,11]

Patients who develop epilepsy following prolonged GCSE are less likely to experience remission of their seizures and may have decreased cognitive and memory function, mental retardation, or neurologic deficits when compared to those who develop epilepsy and subsequently have GCSE.[2] Most studies have found that younger children, the elderly, and those with preexisting epilepsy have a higher propensity for sequelae. Unless accompanied by an underlying neurologic abnormality, febrile SE is less likely to be associated with sequelae.

Estimated mortality in the United States following GCSE ranges between 22,000 and 42,000 individuals per year,[8] with rates up to 16% in children,[12] 20% in adults,[2] and 38% in the elderly.[6] When compared with other populations, neonates have a higher mortality and more neurologic sequelae.

Table 57-3 summarizes the etiology and corresponding mortality rates for GCSE.[6,8] Interestingly, the mortality associated with many etiologies is significantly greater in adults than in children. Unresponsive patients may die from GCSE, but more frequently they die from the acute illness that precipitated the GCSE. For example, patients with serious central nervous system (CNS) structural changes (eg, hemorrhage and stroke) have a poor prognosis, compared to those with no structural lesion.

Outcome is affected by the time between onset of GCSE and the initiation of treatment and the duration of the seizure. Mortality significantly increases with increased seizure duration (eg, 2.6% for seizures 10-29 minutes, 19% for seizures lasting greater than 30 minutes, and 32% for seizures lasting greater than 60 minutes).[3,8] Mortality has decreased over the past decade and probably reflects a recognition of the need to initiate sequenced therapy using large doses as soon as possible.

PATHOGENESIS

Seizures occur when the excitatory neurotransmission overcomes inhibitory impulses in one or more brain regions. After a single, brief, generalized tonic–clonic seizure (less than 5 minutes), the seizure threshold is significantly elevated. The brain's inhibitory mechanisms restore the balance of normal neurotransmission and prevent runaway excitation. Although it is unknown why the mechanisms that control normal brain homeostasis fail, when seizures occur in close succession or the magnitude of the proconvulsant stimulus is severe, compensatory mechanisms can be overwhelmed, and seizures become self-sustaining.

4 While the exact cellular mechanisms are unknown, it appears that seizure initiation is caused by an imbalance between excitatory (eg, glutamate, calcium, sodium, substance P, and neurokinin B) and

inhibitory neurotransmission (eg, γ-aminobutyric acid [GABA], adenosine, potassium, neuropeptide Y, opioid peptides, and galanin).[13] $GABA_A$-mediated inhibition becomes less effective while glutamate excitatory actions are enhanced. These alterations have implications to understanding how GCSE progresses to refractory disease and impacts decisions related to sequencing antiepileptic medications.

Most of what is known has focused on gated ion channels. GCSE is largely caused by glutamate acting on postsynaptic *N*-methyl-d-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate (AMPA)/kainate receptors.[13] During GCSE, NMDA subunits are recruited to the synaptic membrane where they form additional receptors that are proconvulsant. Glutamate activation of the NMDA and AMPA receptors causes opening of the gated calcium and sodium channels, which lead to neuronal depolarization.[13] Sustained depolarization may maintain GCSE and eventually cause neuronal death through calcium-, free radical-, and kinase-mediated events.[14] Although drugs acting as NMDA and AMPA receptor antagonists seem attractive, it is likely that glutamate is not the sole mechanism for sustaining GCSE and that other mechanisms become increasingly important as the duration of seizures increases.

Within minutes of repetitive seizures receptor trafficking (eg, metabotropic GABA and glutamate receptors) occurs. $GABA_A$ postsynaptic receptors control chloride channels to produce hyperpolarization (inhibition) of the postsynaptic cell membrane.[14] These receptors have binding sites for GABA and select anticonvulsants (eg, phenobarbital and benzodiazepines) and enhance $GABA_A$-mediated chloride inhibitory currents. It was previously thought that a decrease in presynaptic GABA led to prolonged seizures; however, it is currently held that GABA concentrations increase during the early phases of GCSE and continue to be elevated during late GCSE. During prolonged seizures postsynaptic $GABA_A$ receptors experience endocytosis. This results in a decrease in the number of γ_2 and $\beta_{2\text{-}3}$ subunits as the receptors move from the synaptic membrane into the cytoplasm where they are functional inactive. These modifications of $GABA_A$ receptors may decrease response to both endogenous GABA and GABA agonists.[13] The γ_2 subunit is associated with benzodiazepine effectiveness; hence, a loss of these on the synaptic surface would result in time-dependent pharmacoresistance to benzodiazepine. Clinically, the relative potencies of benzodiazepines can be reduced up to 20-fold if seizures persist for more than 30 minutes.[14] For this reason, a benzodiazepine should always be combined with another drug that acts at a different site. A similar phenomenon occurs with sodium channel antagonists (phenytoin); however, the magnitude of resistance is less.

PATHOPHYSIOLOGY

As GCSE persists, complex pathophysiologic and biochemical changes lead to systemic alterations, progression of motor phenomena, and development of specific EEG findings.[15] Two distinct and predictable phases have been identified. Phase I occurs during the first 30 minutes of seizure activity, and phase II immediately follows.[15] Although these systemic complications affect the prognosis of GCSE, a prolonged seizure can destroy neurons independent of these events.[14] In fact, the systemic

effects of induced seizures in animals can be blocked, but the damage to the neocortex, cerebellum, and hippocampus persists.

During phase I, each seizure markedly increases plasma epinephrine, norepinephrine, and steroid concentrations, which can cause hypertension, tachycardia, and cardiac arrhythmias Within minutes, arterial systolic pressures can rise to above 200 mm Hg, and heart rate can increase by 83 beats per minute.[15] Mean arterial pressure does not fall below 60 mm Hg (8.0 kPa); hence, cerebral perfusion pressure is not compromised. In animals, cerebral blood flow is also increased, thereby protecting neurons from hypoxic injury.

In the presence of a hypoxic myocardium, seizure-induced increases in sympathetic and parasympathetic stimulation of the heart can result in ventricular arrhythmias.[15] Autonomic neuron stimulation can cause a release of insulin and glucagon. Concurrently, circulating catecholamines cause an elevation of hepatic cyclic adenosine monophosphate, producing glycogenolysis. Although the patient can be hyperglycemic initially, serum glucose begins to fall.[15]

Seizure-induced muscular contractions and hypoxia cause lactic acid release, which can produce severe acidosis that may be accompanied by hypotension and shock. Muscle contractions can be so severe that rhabdomyolysis with secondary hyperkalemia and acute tubular necrosis can occur. The airway can be obstructed, causing the patient to become cyanotic or hypoxic. Additionally, an increase in salivation and tracheal and pulmonary secretions can cause aspiration pneumonia. Although transient pleocytosis can develop, it should not be attributed to SE until infectious causes have been eliminated. Between seizures, the EEG slows, and blood pressure normalizes. Although metabolic demands are increased, the brain is able to adequately compensate.

When seizures exceed 30 minutes (phase II), the EEG ictal discharge and clonic motor activity become continuous, and the patient begins to decompensate.[15] Despite elevated levels of catecholamines, the patient can become hypotensive. During this time, autoregulation of cerebral blood flow becomes dependent on mean arterial pressure and begins to fail. There continues to be an excessive consumption of oxygen and glucose; however, compensatory mechanisms are no longer able to meet demands.

During Phase II, the serum glucose concentration may be normal or decreased. Profound hypoglycemia, secondary to hyperinsulinemia, can occur in those with hepatic dysfunction or reduced glycogen stores.[15] Hyperthermia and respiratory deterioration with hypoxia and ventilatory failure can develop. Metabolic and biochemical complications, including respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and azotemia, may develop. There is increased sweating and salivation.

CLINICAL PRESENTATION AND DIAGNOSIS

Accurate diagnosis requires observation, physical examination, laboratory assessment, EEG, and neurologic imaging. The nature and duration of the seizure should be obtained, but a diagnosis of GCSE should not be made until a clinician has observed a seizure. Most patients have an altered

consciousness that ranges from obtunded to marked lethargy and somnolence with pronounced eyes-open unresponsiveness and waxy rigidity. Motor features can include muscle contractions, extensor or flexor posturing, and spasms. Over time, the clinical manifestations become less apparent. This has important ramifications, in that seizures appear to have terminated without treatment or when an ineffective therapy is given.

In addition to an assessment of language and cognitive abilities, the physical and neurological examinations should assess motor, sensory, and reflex abnormalities, pupillary response, asymmetry, and posturing. The patient should also be examined for secondary injuries (eg, tongue lacerations, shoulder dislocations, and head and facial trauma).

Laboratory tests are essential to the diagnosis of various etiologies. Hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, and renal failure all can cause seizures. A urine drug screen can help eliminate illicit drug use or drug overdose. Serum drug concentration(s) should be obtained in those on chronic anticonvulsants, as low concentrations can reflect partial adherence or rapid drug withdrawal. A baseline serum concentration is necessary to determine whether a loading dose of a specific anticonvulsant is required. Assessment of other laboratory parameters (eg, hematology and chemistries to include albumin, renal function, and hepatic function) that affect anticonvulsant dosing also can be useful. An EEG is a valuable diagnostic tool, particularly in those with prolonged GCSE in whom clinically apparent seizures are not always evident, but therapy should not be delayed while awaiting testing or results.

CLINICAL PRESENTATION GCSE Symptoms

- Impaired consciousness (eg, lethargy to coma)
- Disorientation once GCSE is controlled
- Pain associated with injuries (eg, tongue lacerations, shoulder dislocations, back pain, myalgias, headache, and head trauma)

Early Signs

- Generalized convulsions
- Acute injuries or CNS insults that cause extensor or flexor posturing
- Hypothermia or fever suggestive of intercurrent illnesses (eg, sepsis or meningitis)
- Incontinence
- Normal blood pressure or hypotension and respiratory compromise

Late Signs

- Clinical seizures may or may not be apparent
- Pulmonary edema with respiratory failure

- Cardiac failure (dysrhythmias, arrest, and cardiogenic shock)
- Hypotension or hypertension
- Disseminated intravascular coagulation, multisystem organ failure
- Rhabdomyolysis
- Hyperpyrexia

Initial Laboratory Tests

- Complete blood count (CBC) with differential
- Serum chemistry profile (eg, electrolytes, calcium, magnesium, glucose, serum creatinine, alanine aminotransferase [ALT], and aspartate aminotransferase [AST])
- Urine drug/alcohol screen
- Blood cultures
- Arterial blood gas to assess for metabolic and respiratory acidosis, oxygenation
- Serum drug concentration if previous anticonvulsant suspected or known

Other Diagnostic Tests

- Spinal tap if CNS infection suspected
- EEG should be obtained on presentation and once clinical seizures are controlled
- CT with and without contrast
- MRI
- Radiograph if indicated to diagnose fractures

Clinical Presentation GCSE

Once seizures have stopped, it is important to determine if the patient is febrile or has a systemic or CNS infection. Many physiologic consequences of GCSE (eg, leukocytosis, pleocytosis, and hyperthermia) produce symptoms that can be confused with other conditions. If a CNS infection is suspected, a spinal tap should be performed, and empiric antibiotics should be started. If vascular, neoplastic, or infectious etiologies are suspected, computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained once the seizures are controlled.

TREATMENT

Various treatments are available for the management of GCSE. These range from abortion of

impending SE with rescue medications to the use of pharmacologic and nonpharmacologic therapies for GCSE and refractory/resistant SE.

Desired Outcomes

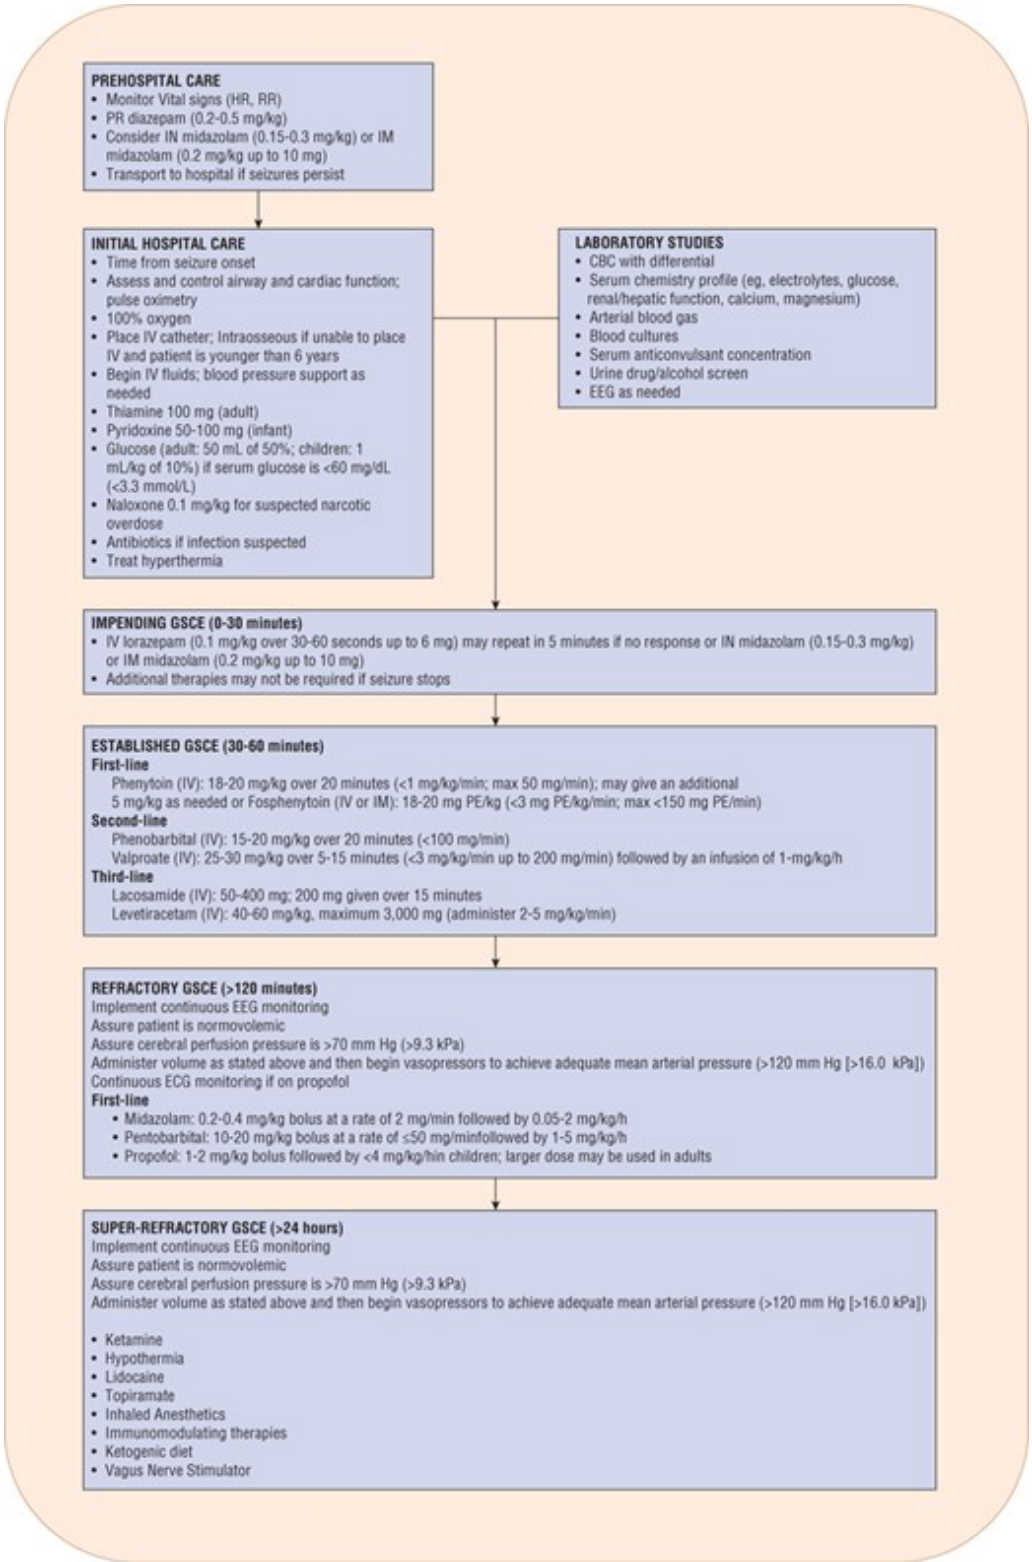
6 Short-term desired outcomes include (a) immediate termination of all clinical and electrical seizure activity, (b) no clinically significant adverse effects, and (c) lack of recurrent seizure activity. The long-term outcomes involve minimizing or avoiding pharmacoresistant epilepsy and/or the development of neurologic sequelae that significantly impact quality of life.

Nonpharmacologic Therapy

The time of seizure onset should be noted. Vital signs should be assessed, an adequate and protected airway should be established, ventilation should be maintained, and oxygen should be administered (**Fig. 57-1**).

FIGURE 57-1

Algorithm for the treatment of GCSE. BP, blood pressure; CBC, complete blood count; EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; HR, heart rate; PR, per rectum; RR, respiratory rate. [a]Because variability exists in dosing, monitor serum concentration. [b]If seizure is controlled, begin maintenance doses and optimize using serum concentration monitoring.



Hyperthermia, if present, should be aggressively treated (eg, rectal acetaminophen and cooling blanket). Febrile GCSE is common in the pediatric patient, and normalization of body temperature helps minimize neurologic morbidity.

Intravenous access should be established. Laboratory studies including serum glucose and electrolyte levels (including calcium and magnesium), complete blood count, and renal and hepatic function

tests should be performed. Anticonvulsant serum concentration should be obtained as needed, and a urine drug screen should be performed if there is suspicion of ingestion.

Although hypoglycemia rarely causes GCSE, adults and children with a blood glucose less than 60 mg/dL (3.3 mmol/L) should receive 50 mL of a 50% dextrose solution, and 1 mL/kg of a 25% dextrose solution, respectively.[2,6] Because Wernicke's encephalopathy can develop in alcoholics, adults should receive IV thiamine (100 mg) prior to glucose.[2] Serum glucose concentration should be determined to assess the need for further supplementation. For children younger than 12 to 18 months of age, a trial of pyridoxine (Vitamin B6) should be initiated until metabolic causes have been ruled out.

If infection is suspected, blood cultures, lumbar puncture, and urinalysis may be needed. Antibiotic administration does not need to wait until after the lumbar puncture if the patient is medically unstable. Patients with persistent GCSE should also have frequent arterial blood gas determinations to assess for metabolic acidosis, which should be treated with sodium bicarbonate if the pH is less than 7.2. Assisted ventilation should be used to correct respiratory acidosis.

Because electrical seizures may persist in the absence of overt clinical motor manifestations, an EEG should be performed in patients who continue to have altered consciousness after clinical control of their seizures. Patients with persistent GCSE should also have continuous EEG monitoring.

Pharmacologic Therapy: Impending and Established GCSE

When a seizure does not stop within 5 minutes, or when doubt exists regarding the diagnosis, patients should be treated as if they have GCSE (see Fig. 57-1). There are four immediate goals: (a) patient stabilization, including adequate oxygenation, preservation of cardiorespiratory function, and management of systemic complications; (b) accurate diagnosis of the subtype of GCSE and identification of precipitating factors; (c) termination of clinical and electrical seizures as early as possible; and (d) prevention of seizure recurrence. The benzodiazepines, hydantoins, and barbiturates are the most commonly used classes of anticonvulsants for the initial treatment of GCSE; however, there are no class I data to support recommendations for most anticonvulsants in established, refractory, and super-refractory GCSE.[16]

Benzodiazepines

The benzodiazepines are effective initial therapy in most patients and should be administered as soon as possible. Generally, one or two IV doses will terminate seizures within 2 to 3 minutes.[2,5] All benzodiazepines are effective; therefore, preference is determined by differences in pharmacokinetics, route of administration, pharmacoeconomics, adverse-effect profile, and current availability.

Diazepam is extremely lipophilic with a large volume of distribution (1-2 L/kg). Although it initially distributes into the brain within seconds, it rapidly redistributes into fat, causing its CNS half-life to be less than 1 hour and its duration of effect to be less than 30 minutes. The rapid decrease in brain concentration and pharmacoresistance can cause seizure recurrence; hence, a longer-acting anticonvulsant (eg, phenytoin or phenobarbital) should also be given immediately after diazepam.

Dosing can be found in **Table 57-4.**

TABLE 57-4 Dosing of Medications Used in the Initial Treatment of GCSE

Drug (Route)	Brand name	Initial Dose (Maximum Dose)	Maintenance Dose	Comments
Diazepam (IV)	Valium plus generic			
Adult		0.25 mg/kg[a,b,c] (20 mg)	Not used	Given IV at a rate not to exceed 5 mg/min
Pediatric		0.25-0.5 mg/kg[a,c] (20 mg)	Not used	
Fosphenytoin (IV)	Cerebyx plus generic			
Adult		20-25 mg PE/kg	4-5 mg PE/kg/day	Given IV at a rate not to exceed 150 mg PE/min in adults and 3 mg PE/kg/min in pediatric patients
Pediatric		20-25 mg PE/kg	5-10 mg PE/kg/day	
Lorazepam (IV)	Ativan plus generic			
Adult		4 mg[b,c] (6 mg)	Not used	Given IV at a rate not to exceed 2 mg/min in adult and pediatric patients
Pediatric		0.1 mg/kg[a,c] (6 mg)	Not used	
Midazolam (IV, IM)	Versed plus generic			
Adult		200 mcg/kg[a,d] (10mg)	50-500 mcg/kg/h[e]	Given IV at a rate 0.5-1 mg/min in adults and over 2-3 minutes in pediatric patients
Pediatric		150 mcg/kg[a,d] (10 mg)	60-120 mcg/kg/h[e]	
Phenobarbital (IV)	Generic			
Adult		10-20 mg/kg[e]	1-4 mg/kg/day[e]	Given IV at a rate not to exceed 100 mg/min in adults and 30 mg/min in pediatric patients
Pediatric		15-20 mg/kg[e]	3-5 mg/kg/day[e]	

Drug (Route)	Brand name	Initial Dose (Maximum Dose)	Maintenance Dose	Comments
Phenytoin (IV)	Dilantin plus generic			
Adult		20-25 mg/kg[f]	4-5 mg/kg/day[e]	Given IV at a rate not to exceed 50 mg/min[g] in adults and 3 mg/kg/min (max 50 mg/min) in pediatric patients
Pediatric		20-25 mg/kg[f]	5-10 mg/kg/day[e]	

GCSE, generalized convulsive status epilepticus; PE, phenytoin equivalents.

[a]Doses can be repeated every 10 to 15 minutes until the maximum dosage is given.

[b]Initial doses in the elderly are 2 to 5 mg.

[c]Larger doses can be required if patients chronically on a benzodiazepine (eg, clonazepam).

[d]Can be given by the intramuscular, rectal, or buccal routes.

[e]Titrate dose as needed.

[f]Administer additional loading dose based on serum concentration.

[g]The rate should not exceed 25 mg/min in elderly patients and those with known atherosclerotic cardiovascular disease.

7 Most practitioners consider IV-administered lorazepam the benzodiazepine of choice for impending or established GCSE (see Table 57-4).[2,5] A Cochrane Database Review concluded that lorazepam is as effective, but safer than diazepam in children.[17] Another Cochrane Database Review that included pediatric and adults data noted no difference in death, requirements for ventilator support, or adverse effects between the two agents; however, when compared to diazepam, there was a significantly lower risk of persistent seizures with lorazepam.[18]

Lorazepam is less lipid soluble than diazepam and takes longer to achieve peak concentrations in the brain; however, its minimal redistribution into fat results in a longer duration of action in the CNS, which can provide seizure protection for up to 24 hours.[1,5] It also has a higher-affinity binding to the benzodiazepine receptor than diazepam.

Patients chronically on a benzodiazepine (eg, clobazam and clonazepam) might have developed tolerance and could require large doses. Diazepam and lorazepam contain propylene glycol, which can cause dysrhythmia and hypotension if administered too rapidly (**Table 57-5**). They also cause vein irritation; therefore, the parenteral product should be diluted with an equal volume of

compatible diluent before administration. Because of slow and erratic absorption, standard parenteral formulations should not be given IM.

TABLE 57-5 Adverse Drug Reactions and Monitoring of Patients Receiving Drugs for GCSE

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Diazepam	Hypotension and cardiac arrhythmias	Vital signs and ECG during administration	Propylene glycol causes hypotension and cardiac arrhythmias when administered too rapidly; hypotension may occur with large doses
Fosphenytoin	Hypotension and cardiac arrhythmias; paresthesia, pruritus	Vital signs and ECG during administration	Hypotension is less than that noted with phenytoin, as this product does not contain propylene glycol; pruritus generally involves the face and groin areas, is dose and rate related, and subsides 5-10 minutes after infusion
Lidocaine	Fasciculations, visual disturbances, tinnitus, seizures		Occur at serum concentrations between 6 and 8 mg/L (25.6-34.1 µmol/L); seizures >8 mg/L (>34.1 µmol/L)
Lorazepam	Apnea, hypotension, bradycardia, cardiac arrest, respiratory depression, metabolic acidosis, and renal toxicity	Vital signs and ECG during administration; HCO_3 and serum creatinine; cumulative dose of propylene glycol	Accumulation of propylene glycol during prolong continuous infusions may cause acidosis
Pentobarbital	Hypotension	Vital signs and ECG during administration	Rate of infusion should be slower or dopamine should be added if hypotension occurs
Phenytoin	Hypotension and cardiac arrhythmia; nystagmus	Vital signs and ECG during administration	Propylene glycol causes hypotension and cardiac arrhythmias when administered too rapidly. Large loading doses are generally not given to elderly individuals with preexisting cardiac disease or in critically ill patients with marginal blood pressure. The infusion rate should be slowed if the QT interval widens or if hypotension or arrhythmias develop; horizontal nystagmus suggests serum concentration above the reference range and toxicity; if a serum phenytoin concentration validates this, the dose should be decreased

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Phenobarbital	Hypotension, respiratory, and CNS depression	Vital signs and mental status; EEG if used in anesthesia doses	Contains propylene glycol; if hypotension occurs, slow the rate of administration or begin dopamine; apnea and hypopnea can be more profound in patients treated initially with benzodiazepines
Propofol	Progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias	Vital signs, ECG, osmolar gap; EEG if used in anesthesia doses	Referred to as propofol-related infusion syndrome, which can be fatal
Topiramate	Metabolic acidosis	Acid base status (serum bicarbonate)	Extremely rare

CNS, central nervous system; ECG, electrocardiogram; EEG, electroencephalogram.

Unfortunately, there are insufficient data comparing IV lorazepam to IV midazolam in GCSE. Midazolam has an extremely short half-life, and maintenance doses must be given by continuous infusion (see Table 57-4). Because of its increased solubility, midazolam has a more reliable IM absorption than either diazepam or lorazepam. A recent study showed that when emergency personnel give IM midazolam as first-line treatment in the prehospital setting, it was superior to IV lorazepam for cessation of seizures, requirement for intensive care unit (ICU) admission, and subsequent hospitalization.[19] There was not a difference in recurrent seizures or adverse effects.

Recent studies have focused on aborting impending SE via transmucosally delivered benzodiazepine when IV and/or IM administration may be difficult or impossible (eg, home setting, extended care, and paramedic).[5,20] Benzodiazepines have been given via the rectal, intranasal, and buccal routes. Rectal absorption of diazepam is rapid but varies significantly (50%-100%) due to first-pass metabolism and is difficult to administer in the home environment. Buccal and sublingual routes also bypass gastric and hepatic first pass metabolism, but bioavailability can be incomplete as the drug is often swallowed. Buccal administration is easily accomplished, and the volume of fluid is small enough (eg, 2-5 mL) that aspiration is unlikely. While successful administration is unlikely due to muscular contractions of the jaw and clenching of teeth, a Cochrane Database Review concluded that buccal midazolam is more effective than rectal diazepam in children.[17]

Intranasally administrated benzodiazepines readily cross the nasal mucosa and the blood-brain barrier to produce a rapid rise in both serum and cerebrospinal fluid concentrations.[5,20] In fact, serum concentrations are comparable to those noted following IV injection. When compared to rectally administered diazepam, all studies have concluded that intranasal midazolam results in higher serum concentrations, faster onset of action, more effective seizure control and fewer adverse effects.[5]

Although most reports have used a variety of delivery systems (eg, drops, sprays, and atomization

devices), the lack of standardization in delivery and availability of a commercial kit has not impacted efficacy. Because the dose must be administered in a 100 to 200 µL spray or solution, this route can only be used for products that are highly concentrated and have good aqueous solubility. It is imperative to account for medication that will remain in the dead space within the syringe and atomizer tip by overfilling the syringe with 0.1 mL of medication.

Medication should be drawn up at the time it is needed and not stored in a plastic syringe, as this may negatively impact efficacy as medication leaches into the plastic.

Effective delivery is best achieved by briskly compressing the syringe plunger to distribute the drug as a mist rather than as larger droplets that may aggregate and run out of the nose or down the back of the throat, rendering it ineffective.[20] By delivering *half* of the dose into each nostril the surface area available for absorption is doubled. Upper airway infections, the extent of nasal mucosa irritation, and differences in the amount of spray that is swallowed may all impact absorption. However, the variability in the amount absorbed after nasal administration should be comparable to that after oral administration.

Clinical Controversy…

The positioning of midazolam among the medications used to treat GCSE is changing. It is now recommended that midazolam be a first-line anticonvulsant for intramuscular (IM) or intranasal (IN) administration for out-of-hospital treatment, when IV access cannot be established. Its intranasal use in the hospital setting for the management of acute seizures is also increasing, and it may eventually replace IV administration in the emergency department.

Although rare, brief cardiorespiratory depression can necessitate assisted ventilation or require intubation (see Table 57-5). This is especially true if a benzodiazepine is used concomitantly with a barbiturate; however, cardiorespiratory depression is more likely due to ongoing seizures than benzodiazepines. Hypotension secondary to a reduction in vasomotor tone can occur following large doses.[5]

Clinical Controversy…

The choice of which long-acting anticonvulsant to give following the initial benzodiazepine is controversial. For decades phenytoin has been used to prevent and treat seizures that recur after treatment with a benzodiazepine; however, no studies have documented the superiority of a hydantoin over other anticonvulsants. One meta-analysis concluded that evidence does not support the use of phenytoin as a first-line agent. Thus, it is questionable if a hydantoin should be administered alone, in larger doses, or at all when seizures recur following benzodiazepine administration.

Phenytoin

8 A hydantoin is the second-line agent in GCSE that is unresponsive to the benzodiazepines or in seizures that recur after successful treatment with a benzodiazepine.[2,21] It is effective in terminating

seizures when first-line agents fail and continue to be recommended for this purpose in recent guidelines[21]; however, it has been noted to be inferior to lorazepam, phenobarbital, or diazepam plus phenytoin at stopping GCSE within 20 minutes of infusion.[22,23] Despite a meta-analysis that concluded evidence does not support the use of phenytoin as a first or second-line agent,[24] it continues to be used.

Phenytoin has a long half-life (20-36 hours) and causes less respiratory depression and sedation than the benzodiazepines or phenobarbital; however, it cannot be delivered rapidly enough to be considered a first-line single agent.[2,5] Injectable phenytoin should be diluted to less than or equal to 5 mg/mL in normal saline. Microcrystals will precipitate if it is mixed in a glucose-containing solution. The vehicle (40% propylene glycol) can cause administration-related hypotension and cardiac arrhythmias (see Table 57-5). For this reason, the maximum rate of infusion is limited (see Table 57-4).

Suggested IV loading doses are provided in Table 57-4. A reduction in the loading dose is recommended for elderly patients, and a larger loading dose is required in obese individuals.[25] If the patient has been on phenytoin prior to admission and the serum concentration is known, this should be considered in determining a loading dose. Although some advocate the administration of an additional 5 mg/kg dose in those with unresponsive GCSE, there is no evidence that this will be beneficial. This practice can cause concentrations to exceed the reference range and produce toxicity. Because phenytoin has poor lipid solubility and enters the brain slowly, it can take up to 60 minutes before the pharmacodynamic effect is apparent. This delay is important when considering administration of a second loading dose. Therapeutic serum concentrations, 10 to 20 mg/L (40-79 µmol/L), generally do not persist more than 24 hours; hence, maintenance doses (see Table 57-4) should be started within 12 to 24 hours of the loading dose.

Phenytoin has an alkaline pH, which may cause pain and burning during infusion; phlebitis can occur with chronic infusion, and tissue necrosis is likely on infiltration. IM administration is not recommended because absorption is delayed and erratic, and phenytoin can crystallize in tissue. Although oral loading doses have been used in patients not actively seizing, it may take 4 to 12 hours before adequate serum concentrations are obtained; thus, this practice is not recommended.

Fosphenytoin

Fosphenytoin, a water-soluble phosphate ester, has no known pharmacologic activity. It is converted rapidly (7-15 minutes) and completely (100%) to phenytoin by blood and tissue phosphatases after IV and IM dosing.[26] The conversion delay was a concern initially; however, this time is offset by high protein binding, saturable binding at high concentrations, and the rapid rate of infusion.[26] It does not contain propylene glycol and is compatible with most common IV fluids.

Fosphenytoin should be dosed using phenytoin equivalents (PE), thereby obviating the need for interconversion between phenytoin and fosphenytoin. The loading dose and rates of administration of fosphenytoin can be found in Table 57-4. Because of delays in achieving adequate phenytoin serum concentrations, a loading dose should not be given IM unless IV access is impossible.

Fosphenytoin serum concentrations have no value. Serum phenytoin concentrations should be used for therapeutic drug monitoring, and the desired serum concentration range is the same as that for phenytoin. Fosphenytoin cross reacts with some phenytoin immunoassays causing an overestimation of phenytoin concentration; hence, blood should not be obtained for at least 2 hours after IV and 4 hours after IM administration.[26]

Phenobarbital

Phenobarbital has biphasic distribution into body organs. During phase I, the drug distributes into highly vascular organs, but does not distribute into the brain. With the exception of fat, phenobarbital distributes throughout the body during phase II; hence, lean body mass should be used in calculating doses in obese patients.[27] Although the highest brain concentrations occur 12 to 60 minutes after an IV dose,[27] seizures are controlled within minutes of the loading dose.[23] Despite two studies that found phenobarbital to be as effective as phenytoin, lorazepam, or diazepam plus phenytoin in patients with GCSE,[22,23] and a meta-analysis noting that no evidence to support the use of phenytoin as a first-line agent[24] phenobarbital continues to be given after a benzodiazepine plus phenytoin has failed.

The loading and maintenance dose are given in Table 57-4. When necessary, larger loading doses (30 mg/kg) have been used in neonates without adverse effects. If the initial loading dose does not stop the seizures within 20 to 30 minutes, an additional 10 to 20 mg/kg can be given. If seizures continue, a third 10 mg/kg load can be given.[28] Phenobarbital exhibits first-order linear pharmacokinetics, and there is no maximum dose beyond which further doses are likely to be ineffective. Once GCSE is controlled, the maintenance dose should be started within 12 to 24 hours. Although injectable phenobarbital contains propylene glycol, it can be given more rapidly than phenytoin (see Table 57-4). While it can be given IM, its rate of absorption is too slow to be effective. Adverse drug reactions and monitoring can be found in Table 57-5.[2,5]

Pharmacologic Therapy: Refractory GCSE

9 When adequate doses of a benzodiazepine, hydantoin, or barbiturate have failed, the condition is termed *refractory*.[5] Approximately 10% to 15% of patients will develop refractory GCSE, and approximately 30% whose seizures are "clinically" controlled will have persistent electrical manifestations after administration of these anticonvulsants. When a patient develops refractory GCSE, an intense search should be performed for an acute or progressive cause.

While the goal is to stop electrical epileptiform activity, there is no consensus regarding the anticonvulsant of choice, sequencing of therapy, or treatment of refractory GCSE. Most recommend the administration of anesthetic doses of midazolam, pentobarbital, or propofol, while other approaches include the use of valproate, levetiracetam, lacosamide, or topiramate. Doses for these agents can be found in **Table 57-6.**

TABLE 57-6 Dosing of Medications Used to Treat Refractory or Supr-Refractory GCSE

Drug (Brand Name)	Initial Dose (Maximum Dose)	Maintenance Dose	Comments
Ketamine (generics)			
Adult	1-4 mg	1-5 mg/kg/h	
Pediatric	0.5-2 mg/kg	1-10 mg/kg/h	
Lacosamide (Vimpat)			
Adult	200-400 mg	200 mg bid	Administer IV over 15 minutes, monitor serum concentrations
Pediatric	4-6 mg/kg	6-8 mg/kg/day, given twice a day	
Levetiracetam (Keppra plus generics)			
Adult	2,000-3,000 mg	1,000 mg thrice a day	Administer IV over 5-15 minutes
Pediatric	40-60 mg/kg	40-60 mg/kg/day, given twice or thrice a day	
Lidocaine (generics)			
Adult	50-100 mg	1.5-3.5 mg/kg/h	Administer IV in ≤2 minutes
Pediatric	1 mg/kg (maximum 3-5 mg/kg in the first hour)	1.2-3 mg/kg/h	
Midazolam (Versed plus generic)			
Adult	200 mcg/kg[a]	50-500 mcg/kg/h[b]	Initial dose may be given IM; administer IV over 0.5-1 mg/min; continuous-infusion rate should be increased every 15 minutes in those who do not respond and should be guided by EEG response; development of tachyphylaxis can require frequent increases in dose; decrease dose by 1 mcg/kg/min every 2 hours once GCSE is controlled
pediatric	150 mcg/kg[a]	60-120 mcg/kg/h[b]	
Pentobarbital (generics)			
Adult	10-20 mg/kg	1-5 mg/kg/h[b]	Over 1-2 hours, rate of infusion should be slowed or dopamine should be added if hypotension occurs; gradually titrate dose upward until there is evidence of burst suppression on EEG (ie, isoelectric EEG) or prohibitive adverse effects occur. Twelve hours after a burst suppression is obtained, the rate should be titrated downward every 2-4 hours
Pediatric	15-20 mg/kg	1-5 mg/kg/h[b]	

Drug (Brand Name)	Initial Dose (Maximum Dose)	Maintenance Dose	Comments
Propofol (Diprivan plus generic)			
Adult	2 mg/kg	5-10 mg/kg/h[b]	Over 10 seconds in adults and 20-30 seconds in pediatric patients
Pediatric	3 mg/kg	2-4 mg/kg/h[c]	
Topiramate (Topamax plus generic)			
Adult	300-500 mg	400-1,600 mg/day	Given orally in divided dose every 12 hours. Doses as large as 25 mg/kg/day for 2-5 days have been used in children. Monitor serum bicarbonate levels and serum concentrations
Pediatric	5-10 mg/kg	5-10 mg/kg/day, given thrice a day	
Valproate (Depacon plus generic)			
Adult	15-30 mg/kg	1-4 mg/kg/h[b]	Administer at 3 mg/kg/min; and follow by a continuous or intermittent infusion; larger doses may be required in those on hepatic enzyme inducers, monitor serum concentrations
Pediatric	20-25 mg/kg	1-4 mg/kg/h[b], or give every 4-6 hour	

EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; IM, intramuscular; IV, intravenous.

[a]Doses can be repeated twice at 10 to 15 minute intervals until the maximum dosage is given.

[b]Titrate dose as needed.

[c]Generally recommended not to exceed a dose of 4 mg/kg/h and a duration of 48 hours.

Benzodiazepines

Although time-dependent pharmacoresistance to benzodiazepines may occur in refractory GCSE, some advocate that anesthetic doses of midazolam should be the first-line agent in refractory GCSE. Table 57-6 shows the loading and maintenance doses of midazolam.[29] Most patients respond to these doses within an hour. Most studies used termination of seizures on EEG as the endpoint for success; however, EEG burst suppression is rarely achieved with the recommended doses of midazolam. Tachyphylaxis rapidly develops within 24 to 48 hours; hence, the dose is often increased to prevent seizure relapse.[5]

Clinical Controversy…

During prolonged seizures the number of γ_2 and $\beta_{2\text{-}3}$ subunits on the $GABA_A$ receptors decrease as the receptors move from the synaptic membrane into the cytoplasm where they are functionally

inactive. These modifications may decrease effectiveness of both endogenous GABA and GABA agonists and result in time-dependent pharmacoresistance to benzodiazepines. Following SE that persist more than 30 minutes, the relative potencies of benzodiazepines can be reduced up to 20-fold. For this reason, some believe that that anesthetic doses of midazolam should be the first-line agent in refractory GCSE. If a benzodiazepine is used, it should always be combined with another drug that acts at a different site.

After initial control, seizures have been observed to recur in 6% to 19% of patients. There is no specific protocol for tapering of midazolam, but some suggest a seizure-free period of 24 to 48 hours followed by decreasing by 1 to 2 mcg/kg/min every 15 minutes.[5] Maintaining the patient's phenytoin and phenobarbital serum concentration(s) above 20 mg/L (79 µmol/L) and 40 mg/L (172 µmol/L), respectively enhances successful discontinuation.

Because of midazolam's short half-life, patients can return to consciousness more rapidly than those receiving larger doses of more sedating anticonvulsants (eg, phenytoin and phenobarbital). Generally, continuous-infusion midazolam has been well tolerated, with few cases of hypotension and respiratory depression. Hypotension and poikilothermia can occur and can require supportive therapies. When adverse effects do occur, patients recover quickly. The availability of a pharmacological antidote for benzodiazepines, flumazenil, lends to the safe use of midazolam.

Valproate

The IV dosage form approved by the FDA is not labeled for GCSE. IV valproate and continuous infusion diazepam are comparable in GCSE.[29,30] One meta-analysis noted that valproate controlled refractory SE sooner than diazepam; however, there was no difference within 30 minutes of administration.[31] There was also no difference in control of GCSE between valproate and phenytoin.[32] A second meta-analysis noted that there is sufficient evidence to use valproate as first-line therapy in those with SE refractory to benzodiazepines.

A number of loading and continuous-infusion doses (see Table 57-5) have been used in both adult and pediatric patients. Although the manufacturer originally recommended IV valproate be given no faster than 20 mg/min, much faster rates have been studied (40 mg/min; 2-10 mg/kg/min) and are used for administration of the loading dose. One study suggested the need to consider the effects of enzyme-inducing anticonvulsants when dosing and recommended that the continuous-infusion rate be determined by the presence of concurrent anticonvulsants (no inducers present, 1 mg/kg/h; one or more inducers [eg, phenytoin and phenobarbital], 2 mg/kg/h; and inducers and pentobarbital coma, 4 mg/kg/h).[33] In general, IV valproate has been well tolerated, with no cases of respiratory depression. Hemodynamic instability is extremely rare, but patients' vital signs should be monitored closely during the loading dose for hypotension.

Clinical Controversy…

The role and position of the newer anticonvulsants as first-line agents in SE remains controversial. At this time, evidence supports the use of valproate and levetiracetam in refractory SE. Insufficient evidence exists to support using lacosamide and topiramate. That said, selection of an agent is

complicated by the shortages in the availability of some first-line medications. There is a clear consensus that if the traditional antiepileptic drug does not work, an anesthetic agent may be indicated.

Levetiracetam and Lacosamide

Historically, levetiracetam was used in cases of super-refractory SE, but it is being used earlier due to medication shortages that have made traditional drugs unavailable. IV levetiracetam has been used for GCSE and has been noted to be as effective as IV lorazepam in aborting seizures and preventing recurrence.[34,35,36] When compared to phenytoin, levetiracetam was equally effective at terminating seizures and preventing recurrence at 24 hours.[36] One meta-analysis noted that sufficient evidence exist to support the use of levetiracetam as first-line therapy in those refractory to benzodiazepines.[24] Levetiracetam is not hepatically metabolized and is minimally protein bound, which makes drug–drug interactions unlikely. Doses for IV levetiracetam are noted in Table 57-5. Doses larger than 3,000 mg/day do not increase efficacy.

Although effective in refractory GCSE, literature supporting the use of lacosamide comes from case reports or case series. Two meta-analyses noted there is insufficient evidence to support the routine use of lacosamide in benzodiazepine-resistant GCSE.[24,37,38]

Pentobarbital

If the patient has refractory disease, anesthetizing the patient to suppress the cerebral ictal discharge is recommended.[5,21] Although it is likely that the patient is already being mechanically ventilated, intubation and respiratory support are mandatory during barbiturate coma, along with continuous EEG monitoring (see Table 57-5). A short-acting barbiturate (ie, pentobarbital or thiopental) is preferred because it allows a more rapid reversal of coma.

Although barbiturates are frequently used, there are no controlled trials to support this practice. A meta-analysis comparing studies involving midazolam, propofol, and pentobarbital in refractory GCSE found overall response rates were significantly greater in those treated with pentobarbital compared to midazolam or propofol.[39] The recurrence of seizures was also less frequent with pentobarbital and propofol. Mortality rates were similar for the three drugs, but significant hypotension was more common with pentobarbital.

Several sources note that the initial loading dose of pentobarbital is 5 mg/kg; however, this dose is inadequate to achieve the serum concentrations (40 mg/L; 172 µmoL/L) necessary to induce an isoelectric EEG (see Table 57-6).[37] Although the duration of barbiturate coma in most studies has been 2 to 3 days, it has been used safely for 53 days in an 18-year-old patient.[40] To avoid complications (eg, pneumonia and pulmonary edema), pentobarbital should be discontinued as soon as possible. The risk of seizure recurrence is minimized if other anticonvulsants are at therapeutic concentrations before pentobarbital is withdrawn. Because pentobarbital is a potent hepatic enzyme inducer, doses of most concurrent anticonvulsants will need to be larger than usual maintenance doses, and the patient will need to be monitored for side effects as deinduction occurs and

anticonvulsant concentrations increase. This can take up to 1 month after pentobarbital's discontinuation.

Propofol

Propofol is extremely lipid soluble, has a large volume of distribution, and has a very rapid onset of action. Its extremely short half-life promotes easy titration and rapid awakening on drug discontinuation. Although several studies have compared propofol and barbiturates, most studies were underpowered. Its efficacy appears to be comparable to midazolam for refractory GCSE.[39,41] Propofol is given as a loading dose that is followed by a continuous infusion. The loading dose can be repeated every 3 to 5 minutes until the desired clinical response is obtained. Once EEG burst suppression is achieved, the dose should be reduced.

Adverse drug reactions can be found in Table 57-6. Prolonged infusions greater than 4 mg/kg/h have been associated with propofol-related infusion syndrome (PRIS).[42,43] Signs and symptoms of PRIS include progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias that are refractory to aggressive pharmacological treatments. It may occur with or without the presence of hepatomegaly, rhabdomyolysis, or lipemia. A retrospective case series of 41 patients with refractory GCSE noted that 10% had sudden unexplained cardiorespiratory arrests, and 35% had non-life-threatening features of PRIS.[43] Propofol may be proconvulsant in some patients and involuntary myoclonic movements have been reported.

Vital signs, should be carefully monitored, and continuous electrocardiogram (ECG) should assess for dysrhythmias. While no guidelines have been proposed for laboratory monitoring, it would seem advisable to assess serum lactic acid, serum triglycerides, serum creatinine, creatine kinase, and hepatic enzymes in patients receiving doses larger than 4 mg/kg/h and/or those receiving therapy for more than 48 hours.

Pharmacologic Therapy: Super-Refractory GCSE

Ketamine

Because medications targeting GABA may be less effective in prolonged GCSE, NMDA-targeted agents such as ketamine have been investigated. Ketamine may increase the number of NMDA receptor to increase glutamate's effect and may also possesses an antagonistic effect on NMDA receptors. A summary of the findings appears in recently published review papers.[5,44] Ketamine appears to be a reasonable agent to consider in refractory GCSE that has failed general anesthesia, especially in those with cardiac instability. Doses can be found in Table 57-6. An advantage of ketamine is its ability to maintain arterial blood pressure, pulse rate, and cardiac output. It may cause hallucinations upon awakening, increased salivation, and increased intraocular and intracranial pressures.

Topiramate

Topiramate has been given orally in adults and in children with GCSE and should be implemented at full therapeutic doses and divided three times a day (see Table 57-6).[5,45] To administer nasogastrically, the tablets should be crushed, mixed with water, and administered via syringe into the nasogastric tube. Response tends to be delayed hours to days. Once seizures are controlled, the dose should be tapered to a normal age/weight-appropriate maintenance dosage.

Aggressive implementation of large doses may cause hyperchloremic, non-anion gap, metabolic acidosis due to inhibition of type II and IV carbonic anhydrase enzymes. Dose does not appear to be the sole determinate, as it has been noted following small doses and after overdoses. If metabolic acidosis occurs, it can be treated with citrates, with a goal of maintaining a serum bicarbonate of at least 20 mEq/L (mmol//L).[5]

Lidocaine

Currently, weak evidence supports the use of lidocaine in refractory or supra-refractory SE. Lidocaine has been used in refractory GCSE, but is not recommended unless other agents have failed.[46] It is administered IV (see Table 57-5) and has a rapid onset of action. Although the reference serum concentration range for the antiarrhythmic effects of lidocaine is 2 to 6 mg/L (8.5-25.6 µmol/L), the reference range for GCSE has not been established. Serum lidocaine concentrations should be monitored to avoid drug accumulation and toxicity (see Table 57-6).

Inhaled Anesthetics

Today inhaled anesthetics are not used until other approaches fail, and only a few studies have used inhaled anesthetics (particularly isoflurane) for the treatment of refractory SE.[47,48] Halothane, isoflurane, and other inhaled anesthetics can produce EEG suppression; however, these gases are difficult to deliver outside the operating room and require an anesthesiologist. No proven advantages have been shown over traditional anticonvulsants (eg, barbiturate coma or continuous-infusion benzodiazepine), and these gases can increase intracranial pressure. If used, dosing is titrated to obtain EEG burst suppression.

Although concentrations required to maintain burst suppression are variable, isoflurane generally stops seizure at concentrations of 0.5% to 3%, which are not ordinarily associated with hemodynamic effects. Isoflurane can induce hypotension, so close hemodynamic monitoring is necessary, with administration of isotonic fluids and vasopressors as needed.

Immunomodulating therapies

The use of corticosteroids and IV immune globulin is based upon animal data that suggest the development of super-refractory GCSE may be due to antibodies directed against the voltage-gated potassium channels and the NMDA receptor.[48] There is also mounting evidence that inflammation plays a role in epileptogenesis, specifically the activation of select inflammatory signaling pathways (eg, interleukin-1 receptor/toll-like receptor [IL-1R/TLR]). Steroids may also decrease blood-brain barrier opening and reverse GABAergic inhibition.

Little evidence supports the use of steroids; however, in the absence of contraindications, a trial of large doses of steroids (eg, 1 g/day of IV prednisolone for 3 days followed by 1 mg/kg/day in four divided doses) should be used in patients with an unidentified etiology for the super-refractory GCSE. Patients who respond should continue long-term steroids, IV immunoglobulins, and other immunomodulatory agents such as cyclophosphamide or rituximab.

Hypothermia

Controlled hypothermia reduces excitatory transmission and epileptic discharges and reduces brain edema, cerebral metabolic rate, oxygen utilization, and ATP consumption. Few studies have assessed the efficacy or safety of hypothermia in refractory GCSE.[47,49,50,51] Despite a resurgence in use, a recent meta-analysis suggested that only level D evidence supports the use of hypothermia in refractory SE.[52]

When used, a core body temperature of about 32°C to 35°C is targeted for at least 24 to 48 hours. It may or may not be given in combination with barbiturate anesthetics.[47] Cardiovascular and coagulation parameters, biochemistry and acid-base balance, and serum lactate should be monitored. Hypothermia may significantly reduce the clearance of several drugs, including anesthetics and antiepileptics, resulting in a need for monitoring of serum concentrations.[5]

Ketogenic Diet

A small number of reports have shown that an orally or intravenously administered ketogenic diet in a 4:1 ratio of fat to combined protein and carbohydrate should be tried in severe cases of super-refractory SE.[47,52] Before initiating the diet, metabolic disorders as a possible etiology should be eliminated. Close monitoring of total daily fluid, ketosis, and potential complications is essential. If a metabolic acidosis develops, treatment is suggested to maintain serum bicarbonate levels greater than 18 to 20 mEq/L (mmol/L).[47]

Vagus Nerve Stimulator

Acute placement of a vagus nerve stimulator has been used in both pediatric and adult patients with refractory SE.[48] Currently its use for refractory SE is not recommended, as only grade D evidence suggest improvement in generalized refractory SE.[53]

PERSONALIZED PHARMACOTHERAPY

If the patient has been on phenytoin, phenobarbital, valproate, or levetiracetam prior to admission, a stat serum concentration should be obtained and the results considered in determining a loading dose or redosing. A serum concentration should be obtained in any patient who is unresponsive to therapy or who exhibits concentration-associated adverse drug reactions. Pharmacogenetics produces differences in metabolic pathways and rate of drug metabolism, which can influence efficacy or toxicity. Obviously, a patient who is a poor metabolizer would theoretically have changes

in drug metabolism based on expression of specific isoenzymes. For example, many Asians have decreased CYP2C19 activity; therefore, they may respond to lower doses of diazepam. If one were concerned about benzodiazepine-associated adverse effects in this population, lorazepam would be preferred.

Although a patient may have an alteration in gene expression that could be important in development of refractory SE or in response to various anticonvulsants, there are no data to support that this is important in GCSE and no evidence to support a change in treatment protocol based on underlying genetics.

While HLA-B*1502 has been associated with severe skin reactions in patients receiving phenytoin, this is applicable to chronic and not acute, single dose therapy. Recently, CYP2C variants that included CYP2C9*3, which is known to reduce drug clearance, were identified as important genetic factors associated with phenytoin-related severe cutaneous adverse reactions.

Drug resistance factors have also been identified in human epileptogenic tissue that has been removed surgically. Multidrug resistance proteins (P-glycoprotein) are localized to endothelial cells in brain capillaries and associated astroglia. Since multidrug resistance factors are localized to abnormal tissues, they appear to have little or no effect on systemic pharmacokinetic parameters of a drug, but may affect the local distribution of the drug within the target epileptogenic areas. If a role in refractory human epilepsy is confirmed, drugs that inhibit P-glycoprotein (eg, verapamil) may prove useful. That said, no reports have suggested that such an association exists.

EVALUATION OF THERAPEUTIC OUTCOMES

Initial success is defined as termination of all clinical and electrical seizure activity, but ultimate success is measured by the patient's subsequent quality of life. The morbidity and mortality associated with GCSE are affected by the underlying etiology; however, morbidity and mortality can be minimized by the rapid implementation of a rational therapeutic plan. An EEG is an extremely important tool that not only allows practitioners to determine when abnormal electrical activity has been aborted, but also can assist in determining which anticonvulsant was effective. Because many of the anticonvulsants affect the cardiorespiratory system, it is imperative that vital signs (eg, heart rate, respiratory rate, and blood pressure) be monitored during drug loading and infusion. Finally, it is imperative that the infusion site be assessed for any evidence of infiltration before and during administration of phenytoin. Information regarding the patient's past medical and drug history and imaging studies (eg, MRI) also can help to determine if there is a defined etiology for the original episode of GCSE. This information then can be used to guide future medication therapy, as well as help in determining if the patient is at risk for a poor outcome.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

AMPA	α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate
CNS	central nervous system

CT	computed tomography
ECG	electrocardiogram
EEG	electroencephalogram, electroencephalography
GABA	γ-aminobutyric acid
GCSE	generalized convulsive status epilepticus
ICU	intensive care unit
IL-1R/TLR	interleukin-1 receptor/toll-like receptor
ILAE	International League Against Epilepsy
IM	intramuscular
IN	intranasal
IV	intravenous
MRI	magnetic resonance imaging
NCSE	nonconvulsive status epilepticus
NMDA	*N*-methyl-d-aspartate
PE	phenytoin equivalents
PRIS	propofol-related infusion syndrome
SE	status epilepticus

Chapter 58: Acute Management of the Brain Injury Patient

Bradley A. Boucher; G. Christopher Wood

INTRODUCTION

KEY CONCEPTS

- 1 Cerebral ischemia is the key pathophysiologic event triggering secondary neuronal injury following severe traumatic brain injury (TBI). Intracellular accumulation of calcium is postulated to be a central pathophysiologic process in amplifying and perpetuating secondary neuronal injury via inhibition of cellular respiration and enzyme activation.
- 2 *Guidelines for the Management of Severe Brain Injury*, published by the Brain Trauma Foundation (BTF)/American Association of Neurological Surgeons (AANS), serve as the foundation on which clinical decisions in managing adult neurotrauma patients are based; comparable guidelines for infants, children, and adolescents have also been published.
- 3 Correcting and preventing early hypotension (systolic blood pressure [SBP] less than 90 mm Hg) and hypoxemia (PaO_2 less than 60 mm Hg [8.0 kPa]) are primary goals during the initial resuscitative and intensive care of severe TBI patients.
- 4 Nonpharmacologic treatment in the management of intracranial hypertension includes raising the head of the bed 30°, short-term mild hyperventilation ($PaCO_2$ 30-35 mm Hg [4.0-4.7 kPa]), ventricular drainage if a ventriculostomy is present, and decompressive surgery.
- 5 The principal monitoring parameter for severe TBI patients within the intensive care environment is intracranial pressure (ICP). Cerebral perfusion pressure (CPP) is also a critical monitoring parameter and should be maintained between 50 and 70 mm Hg (6.7 and 9.3 kPa) (greater than 40 mm Hg [5.3 kPa] in pediatric patients) through the use of fluids, vasopressors, and/or ICP normalization therapy.
- 6 Nonspecific pharmacologic treatment in the management of intracranial hypertension should include analgesics, sedatives, antipyretics, and paralytics under selected circumstances.

- 7 Specific pharmacologic treatment in the management of intracranial hypertension includes mannitol, hypertonic saline, furosemide, and high-dose pentobarbital. Neither routine use of corticosteroids nor aggressive hyperventilation (ie, $PaCO_2$ less than 25 mm Hg [3.3 kPa]) should be used in the management of intracranial hypertension.

- 8 Use of phenytoin for the prophylaxis of posttraumatic seizures usually should be discontinued after 7 days if no seizures are observed.

- 9 Numerous investigational strategies targeted at limiting injury and/or stimulating axonal repair following severe TBI have been employed, but no proven therapeutic benefits have been identified.

Traumatic brain injury (TBI) is currently the leading cause of death and disability among children and young adults in the industrialized world.[1] A focus on TBI prevention, improved acute care, and rehabilitation must remain national priorities. This chapter summarizes TBI epidemiology and pathophysiology, and highlights the major guidelines and systematic reviews of the literature pertaining to the management of severe TBI patients.

EPIDEMIOLOGY

It is estimated that approximately 1.7 million persons sustain a TBI each year in the United States equating to a TBI every 15 seconds.[1] Among these individuals, 275,000 require hospital admission, and 53,000 die annually.[1] Importantly, an estimated 5.3 million Americans currently live with disabilities as a result of their TBI, highlighting the enormous physical and emotional toll of this health care problem.[2] The economic effects of acute neurotrauma are also enormous, with estimates of direct and indirect spending on TBI patients requiring hospitalization of $76.5 billion in the United States in 2010.[2] Economic costs to society from lost productivity are also massive, especially considering the young age of many TBI patients.[2] Falls are the leading cause of TBI (35.2%), while firearm-related and motor vehicle accidents result in the greatest number of TBI-related hospitalizations and deaths overall.[1,2] Death rates from TBI are highest in patients aged 75 years or older.[1]

PRIMARY AND SECONDARY BRAIN INJURY PATHOPHYSIOLOGY

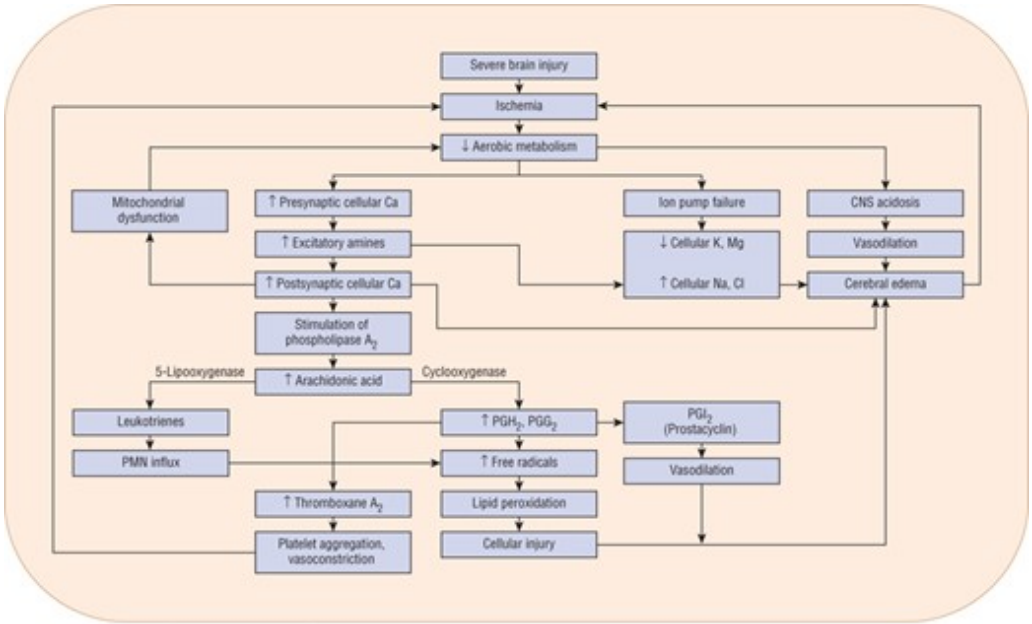
The neurologic sequelae of brain trauma can occur instantaneously as a consequence of the primary injury or can result from secondary injuries that follow within minutes, hours, or days.[3] Primary injury involves the external transfer of kinetic energy to various structural components of the brain (eg, neurons, nerve synapses, glial cells, axons, and cerebral blood vessels). The biomechanical forces responsible for primary brain injury can be classified broadly as contact (eg, blunt-object blow, penetrating-missile injuries) and acceleration/deceleration (eg, instantaneous brain movements following motor vehicle accidents).[4] Contact forces commonly result in skull fractures, brain

contusions, and/or hemorrhages. Primary injuries are categorized further as focal (eg, contusions, hematomas) or diffuse.[4] The latter usually are associated with shearing or stretch forces, which primarily affect axons within the brain (ie, diffuse axonal injury).[4] The type of primary injury (ie, focal vs diffuse) is a major factor as to which of the secondary injury mechanisms discussed below will predominate following a TBI; however, many patients, especially those involved in high-speed accidents, sustain both types of injury.[4]

1 A complex sequence of pathophysiologic events precipitated by primary brain injury may seriously disrupt the normal central nervous system (CNS) balance between oxygen supply and demand resulting in a metabolic crisis.[5,6] Hypotension in particular during the early posttraumatic period is a major contributor to this imbalance and a primary determinant of outcome. The end result of this imbalance may be cerebral ischemia, the key pathophysiologic event triggering secondary injury.[5] **Figure 58-1** is a simplified schematic of the processes that constitute secondary brain injury and their various interrelationships. The brain is particularly susceptible to ischemia because of its normally high resting energy requirement and its limited capacity to store oxygen, glucose, and adenosine triphosphate (ATP).[3] These phenomena can result in imbalances in cerebral oxygen delivery (CDO_2) and consumption ($CMRO_2$), processes that are closely autoregulated under normal circumstances.[5] Factors that can diminish cerebral oxygen supply following brain injury include cerebral edema, expanding mass lesions (eg, epidural, subdural, and intracerebral hematomas), cerebral vasospasm, and loss of vasoregulatory control. Vasogenic cerebral edema can develop as a consequence of cerebral capillary endothelial damage and disruption of the blood–brain barrier.[6] Cytotoxic cerebral edema is a consequence of loss of cell wall integrity that accompanies ischemia or hypoxia with accumulation of lactic acid secondary to anaerobic metabolism.[6] With cytotoxic and vasogenic edema comes expansion of the intracellular and extracellular fluid spaces, respectively. Elevated intracranial pressure (ICP) is the most detrimental consequence of cerebral edema formation and occurs as the brain tissue volume increases within the nondistensible skull. A significant increase in ICP may further compromise cerebral blood flow (CBF) and extend cytotoxic edema. Hence an increase in ICP can be self-perpetuating unless this cycle is reversed. Hypoxemia can further exacerbate local decreases in cerebral oxygen supply following acute respiratory failure and systemic hypotension. Metabolic demand also can increase following neurotrauma secondary to seizures, agitation, and temperature elevation.[7,8]

FIGURE 58-1

Schematic illustration of the cascade of biochemical events proposed to occur following severe neurotrauma (secondary brain injury). (Ca, calcium; Cl, chloride; CNS, central nervous system; K, potassium; Mg, magnesium; Na, sodium; PMN, polymorphonucleocyte; PGH_2, prostaglandin H_2; PGG_2, prostaglandin PGG_2; PGI_2, prostaglandin PGI_2).



The two distinctive end points along the spectrum of secondary neuronal injury are: (a) energy-independent cellular necrosis characterized by membrane cell lysis, edema, and inflammation, and (b) energy-independent apoptosis that leads to cell shrinkage and cell membrane dissolution.[4] Apoptosis, which is also known as programmed cell death, requires a cascade of intracellular events for completion of cell death.[4] The loss of ionic homeostasis is postulated to be a key event in fostering secondary brain injury following cerebral ischemia. Cellular influx of sodium, chloride, magnesium, and water with a corresponding efflux of potassium secondary to cytotoxic edema and Na^+-K^+-ATPase pump dysfunction.[3] An influx of calcium into the presynaptic terminal ends of damaged neurons is mediated by N-type voltage-sensitive calcium channels. This influx is postulated to stimulate excessive release of the excitatory amines glutamate and aspartate from the affected neurons. These amines then accumulate in the neuronal synaptic cleft in the presence of cellular energy failure.[3] The result is ongoing stimulation of postsynaptic cells, which can result in an extension of neurotoxicity and cell death. Influx of calcium and additional sodium is stimulated by activation of ionophore receptors including the *N*-methyl-d-aspartate (NMDA) receptor.[4] Calcium influx and its intracellular accumulation initiate a number of events that amplify and perpetuate secondary neuronal injury. High intracellular concentrations of calcium result in mitochondrial dysfunction, which further inhibits cellular respiration, a process already affected by ischemic and/or hypoxic insults.[3,4,5]

A second major deleterious effect of calcium is to stimulate activation of autodestructive enzymes, including phospholipases, endonucleases, and proteases, such as the caspase family of enzymes.[4] The effect of phospholipase A_2 stimulation includes formation of several arachidonic acid metabolites derived from membrane lipids: thromboxane A_2, prostaglandins, and leukotrienes. The subsequent effects of these metabolites are lipid peroxidation and the formation of reactive oxygen species.[3,4,5] Data suggest that this event occurs very early after injury (eg, before hospitalization), which may limit the effectiveness of exogenously administered antioxidants.

Cell-mediated injury involving inflammatory mediators (eg, proinflammatory cytokines) and nitric oxide activation is yet another possible mechanism involved in secondary neuronal injury.[5,6] Among the cell lines implicated are polymorphonuclear neutrophils, platelets, endothelial cells, and macrophages. Noteworthy is that limited data suggest that activation of some inflammatory mediators may actually be beneficial such that the relative balance of the mediators rather than absolute concentrations may be the most significant pathophysiologic factor following TBI. Stimulation of platelet aggregation, vasodilation, and vasoconstriction also may occur.[5]

CLINICAL PRESENTATION Acute Brain Injury General

- Level of consciousness on admission ranges from awake and alert to completely unresponsive (ie, Glasgow Coma Scale [GCS] 15-3, respectively).

Symptoms

- Posttraumatic amnesia (eg, greater than 1 hour), increasing dizziness, a moderate-to-severe headache, nausea/vomiting, limb weakness, or paresthesia may indicate more severe injury.

Signs

- Cerebrospinal fluid (CSF) otorrhea or rhinorrhea, seizures, or unequal or unreactive pupils may indicate more severe injury.
- A rapid deterioration in mental status strongly suggests the presence of an expanding lesion within the skull.
- Severe TBI may be accompanied by significant alterations or instability in vital signs, including abnormal breathing patterns (eg, apnea, Cheyne–Stokes respiration, tachypnea), hypertension, or bradycardia.

Laboratory Tests

- Arterial blood gases (ABGs) indicating hypoxia (ie, decreased PaO_2) or hypercapnia (ie, increased $PaCO_2$) may indicate compromised ventilation.
- A positive blood ethanol concentration and/or positive urine drug screen indicates that drug intoxication may be affecting the patient's mental status in addition to the TBI.
- Electrolyte disturbances can cause alterations in mental status, and their effects may interfere with assessment of neurological status relative to brain lesion.

Other Diagnostic Tests

- Computed tomography (CT) of the head is an important diagnostic tool for detecting the presence of mass lesions and structural signs of edema (eg, midline shift, compressed ventricles).

CLINICAL PRESENTATION

The GCS was designed over 40 years ago and is still the most widely used system to grade the arousal and functional capacity of the cerebral cortex.[7] The GCS defines the level of consciousness according to eye opening, motor, and verbal response (**Table 58-1**). A GCS score of 15 corresponds to a normal neurologic examination based on eye, motor, and verbal responses. A GCS score of 3 to 8, 9 to 12, and 13 to 15 is consistent with severe, moderate, and mild or minor brain injury, respectively.[7] The possibility of ethanol or drug intoxication, hypotension, hypoxia, postictal state, hypoglycemia, electrolyte imbalances, or hypothermia altering the neurologic examination always should be considered. Because opiates, sedatives, and neuromuscular blockers affect the neurologic examination, they should not be administered until the initial examination is complete if at all possible. Simple, rapidly attainable clinical variables that are predictive of poor outcomes include patient age, presence of hypotension, increased ICP, decreased GCS score (especially the motor score), pupillary reactivity, and findings on a CT scan of the head that include the presence and size of a hematoma, subarachnoid hemorrhage, midline shift, and compression of the ventricular cisterns.[9]

TABLE 58-1 Glasgow Coma Scale

Response	Score
Eyes	
Open spontaneously	4
To verbal command	3
To pain	2
No response	1
Best motor response	
To verbal command	
Obeys	6
To painful stimulus (pressure to nailbeds)	5
Localizes pain	4
Flexion, withdrawal	3
Flexion, abnormal (decorticate rigidity)	2
Extension (decerebrate rigidity)	1
No response	

Response	Score
Best verbal response	
(Arouse patient with painful stimulus if necessary)	5
Oriented and converses	4
Disoriented and converses	3
Inappropriate words	2
Incomprehensible sounds	1
No response	3-15
Total	

GENERAL TRAUMATIC BRAIN INJURY TREATMENT PRINCIPLES

In July 1995, the Brain Trauma Foundation (BTF) published an extensive document entitled *Guidelines for the Management of Severe Brain Injury* as a joint initiative with the Guidelines Committee of the American Association of Neurological Surgeons (AANS) and the Joint Section on Neurotrauma and Critical Care of the AANS and the Congress of Neurological Surgeons, with subsequent revision in 2000. A third revision was released in 2007.[10] This landmark publication constitutes the most widely accepted series of evidence-based standards, guidelines, and options for the care of severe TBI patients in the United States.[11] Recommendations are reported as Level I (standards), Level II (guidelines), or Level III (options) based on the corresponding classes of evidence. As important are the data documenting that compliance with the BTF/AANS guidelines can result in improved outcomes relative to mortality rate, functional outcome scores, length of hospitalization, and cost. Since then, guidelines addressing prehospital TBI management[12] and surgical management[13] have been published. Furthermore, TBI management guidelines for infants, children, and adolescents were developed in 2003 with a second edition published in 2012.[14] The recommendations emanating from these published guidelines on TBI management and various published systematic reviews will be highlighted throughout the remaining portion of this chapter. Until further clinical studies become available, recommendations from the published guidelines should serve as the foundation on which all clinical decisions in managing severe TBI are based. Nonetheless, it should be noted that the majority of the guidelines are based on Class II evidence (primarily prospective clinical trials) and Class III evidence (primarily retrospective clinical trials). Few Class I evidence studies (ie, prospective, randomized, controlled trials) are available for treatment of TBI. The pharmacologic management of TBI is summarized in **Table 58-2**. Recommendations provided in this chapter pertain to adults and children unless specifically noted to the contrary.

TABLE 58-2 Pharmacologic Management of TBI

Hyperosmolar therapy

Mannitol is effective for control of raised ICP at doses of 0.25-1 g/kg body weight (Level II).

Hypertonic saline is effective in small studies, but no guideline recommendation is given in adults. In pediatric patients, hypertonic saline should be considered in severe TBI associated with intracranial hypertension (Level II).

Infection prophylaxis

Periprocedural antibiotics for intubation should be administered to reduce the incidence of pneumonia (based largely on a single study) (Level II).

Routine prophylactic antibiotic use for ventricular catheter placement is not recommended to reduce infection (Level III).

Deep venous thrombosis prophylaxis

LMWH or low-dose unfractionated heparin should be used in combination with mechanical prophylaxis. However, there is an increased risk of expansion of intracranial hemorrhage (Level III).

Anesthetics, analgesics, and sedatives

Prophylactic administration of barbiturates to reduce burst suppression ECG is not recommended (Level II).

High-dose barbiturate administration is recommended to control elevated ICP refractory to maximum standard medical and surgical treatment in adults. Hemodynamic stability is essential before and after barbiturate therapy (Level II). In pediatric patients, high-dose barbiturate therapy can be used to treat refractory intracranial hypertension in hemodynamically stable patients (Level III).

Propofol is recommended for the control of ICP, but not for improvement in mortality or 6-month outcomes. High-dose propofol can produce significant morbidity (Level II).

Antiseizure prophylaxis

Prophylactic use of phenytoin or valproate is not recommended for preventing late PTS (>7 days) (Level II).

Anticonvulsants are indicated to decrease the incidence of early PTS (within 7 days of injury) (Level II).

Corticosteroids

The use of steroids is not recommended for improving outcome or reducing ICP in adults or pediatric TBI patients. In patients with moderate or severe TBI, high-dose methylprednisolone is associated with increased mortality and is contraindicated (Level II).

ECG, electrocardiogram; ICP, intracranial pressure; LMWH, low-molecular weight heparin; PTS,

posttraumatic seizures; TBI, traumatic brain injury.

Level I: Recommendation based on a high level of clinical certainty from Class I evidence (eg, good quality randomized controlled trial [RCT]).

Level II: Recommendation based on a moderate level of clinical certainty from Class II evidence (eg, moderate quality RCT; good quality cohort; good quality case–control).

Level III: Clinical certainty has not been established based on Class III evidence (eg, poor quality RCT; moderate or poor quality cohort; moderate or poor quality case–control; case series, databases, or registries).

Data from reference 10, 14.

Desired Outcomes

The overall goal in TBI management is not only reduction in morbidity and mortality, but also optimization of long-term functional outcome for these patients. This requires careful attention to the following short-term therapeutic goals: (a) establishment of an adequate airway and maintenance of ventilation and circulation during the initial period of resuscitation and evaluation, (b) maintenance of balance between CDO_2 and $CMRO_2$, (c) prevention or attenuation of secondary neuronal injury, and (d) prevention and/or treatment of associated medical complications.

Initial Resuscitation

The first priority in the unconscious patient is the establishment of an airway, which ensures adequate oxygenation and prevents aspiration.[7] Thereafter, restoration and maintenance of systolic blood pressure (SBP) between 120 and 140 mm Hg is desired since admission SBP outside this range is associated with increased mortality.[15] In particular, correcting and preventing early hypotension (SBP less than 90 mm Hg in adults) and hypoxia (PaO_2 less than 60 mm Hg [8.0 kPa]) are essential, because these two factors are among the most powerful predictors of outcome.[8,9,10] Isotonic saline (0.9% normal saline) and lactated Ringer's solution have been traditionally used as initial resuscitation fluids of choice in TBI patients. However, some clinicians believe that hypertonic saline (eg, 3% or 7.5% saline) is beneficial in the resuscitation of TBI patients. Clinical studies have yielded equivocal results relative to superiority over isotonic solutions.[8,16] Regardless, no clear consensus exists as to the optimal initial resuscitation fluid. While albumin therapy may be considered an alternative to crystalloid fluid resuscitation, a retrospective analysis of 460 TBI patients revealed an increase in mortality (33.2%) compared with those patients receiving 0.9% normal saline.[17] Vasopressors and inotropic agents may be needed to maintain an adequate mean arterial pressure (MAP) if hypotension persists after adequate restoration of intravascular volume. **Figure 58-2** is an algorithm summarizing treatment priorities in the initial management of acute TBI.

FIGURE 58-2

Algorithm for the acute management of the TBI patient. (ABG, arterial blood gas; BP, blood pressure; CBC, complete blood count; CPP, cerebral perfusion pressure; CT, computed tomography; EtOH Cp, ethanol plasma concentration; GCS, Glasgow coma scale; Hct, hematocrit; ICP, intracranial pressure; ICU, intensive care unit; NS, normal saline; OR, operating room; $PaCO_2$, partial pressure of arterial blood carbon dioxide; PRBC, packed red blood cells; SBP, systolic blood pressure.) *(Reprinted with permission from Wood CG, Boucher BA. Postresuscitative Care

Following successful resuscitation, priorities shift toward diagnostic evaluation of intracranial and extracranial injuries and emergent surgical intervention as needed. In many patients, evacuation of

intracranial hematomas (ie, epidural, subdural, and intracerebral hematomas) is essential to control ICP and improve outcome. Elevation of depressed skull fractures and debridement of penetrating wound tracts are other important emergent surgical procedures in TBI patients. 4 Decompressive craniectomies (ie, removal of variable amount of skull bone) with or without temporal or frontal lobectomy may be considered in patients with increases in ICP refractory to more conservative measures.[5] The beneficial effects of routine decompressive surgery in adult TBI patients to date are controversial.[18] However, a recent pivotal randomized trial, while demonstrating acute effectiveness in ICP control using decompressive craniectomy, also found worse long-term outcomes compared with controls. This latter study calls into question the routine use of decompressive craniectomy in patients with refractory ICP.[19] Continuous ICP monitoring (eg, intraventricular catheter, intraparenchymal fiberoptic catheter) is indicated in salvageable patients with a GCS score of 3 to 8 after resuscitation with an abnormal admission CT scan. In addition, continuous ICP monitoring is indicated in high-risk severe TBI patients with a normal CT scan and two of the following criteria: age older than 40 years, motor posturing, or SBP less than 90 mm Hg.[10] Intraventricular catheters have a therapeutic advantage over the alternatives but are associated with a higher complication rate and can be difficult to place in the setting of the swollen brain. Specifically, CSF can be drained using this device as a means to lower ICP. Continuous ICP monitoring is the only means to objectively evaluate the success of therapies used to decrease ICP.[7] Once the ICP exceeds 20 to 25 mm Hg (2.7-3.3 kPa), therapy should be initiated to decrease ICP below 20 mm Hg (2.7 kPa).[10,14,20,21] While used extensively in TBI patients and advocated within consensus guidelines, a randomized controlled trial did not demonstrate a superior outcome in patients with ICP managed with an intraparenchymal monitor compared with patients treatment based on imaging and clinical examination.[22]

Clinical Controversy...

Continuous ICP monitoring has been the mainstay of managing selected severe TBI patients for decades. This management practice is now being questioned based on data suggesting no improvement in outcome with ICP monitoring compared with treatment based on imaging and clinical examination.

Jugular venous oxygen saturation ($SjvO_2$) monitoring is advocated by some practitioners for detection of global cerebral hypoxia (ie, adequacy of CBF relative to $CMRO_2$), although it is technically difficult to achieve consistent results.[7] Hence its use remains confined predominantly to academic centers and for research purposes. The use of brain tissue oxygen monitoring is another alternative to $SjvO_2$ to measure oxygen diffusion in TBI patients.[7] Cerebral microdialysis is yet another technique that has been used successfully as a research tool to measure the cerebral extracellular chemistry of TBI patients.[7] Biochemical markers (eg, S-100 calcium-binding protein B, neuron-specific enolase, glial fibrillary acid protein, serum substance P[23]) have been suggested to have utility in diagnosing and monitoring TBI patients.[24,25] However, no clear role has yet to be defined for such markers with each having assorted limitations.[24,25]

5 Another important monitoring parameter for severe TBI patients within the intensive care environment is the CPP. The CPP is the difference between MAP and ICP (ie, CPP = MAP – ICP).

Maintenance of an acceptable CPP has been postulated to be critical in reducing cerebral ischemia and secondary injury. The BTF/AANS guidelines recommend maintaining a range of CPP between 50 and 70 mm Hg (6.7 and 9.3 kPa) and specifically indicate avoiding CPP values less than 50 mm Hg (6.7 kPa).[10] Current guidelines also recommend that aggressive attempts to maintain CPP greater than 70 mm Hg (9.3 kPa) in adults should be avoided because of the risk of the acute respiratory distress syndrome.[10] In children, the recommended CPP goal is greater than 40 mm Hg (5.3 kPa).[14] Despite being commonly used, the optimal approach to CPP management continues to be debated.

The goal CPP can be achieved by increasing MAP through the use of fluids and/or vasopressors or by lowering elevated ICP. The goal of volume expansion should be euvolemia as well as avoidance of a hypoosmolar state and negative fluid balance.[7,14] If the hemoglobin is below 7 g/dL (70 g/L; 4.34 mmol/L), transfusion of packed red blood cells (PRBCs) is indicated. Nevertheless, liberal transfusions should be avoided since using a hemoglobin target goal of 10 g/dL (100 g/L; 6.21 mmol/L) has been associated with higher incidence of thromboembolic events without an improvement in neurologic outcome based on a recent randomized trial.[26] However, more data are needed before these findings can be applied to all TBI patients.[8] Furthermore, use of erythropoietin was not associated with an improved neurologic outcome in the same trial.[26] Volume status should be targeted to a central venous pressure of 7 to 12 cm H_2O (0.7-1.2 kPa) if invasive monitoring is employed. After achievement of euvolemia, the patient's head should be elevated at 30 degrees to promote venous drainage and decrease ICP. If restoration of the intravascular volume is inadequate in elevating MAP to an acceptable level, hypertension should be induced using vasopressors (eg, norepinephrine, phenylephrine, dopamine).[7] Patients should be monitored for renal dysfunction, lactic acidosis, and signs of peripheral ischemia when vasopressors are used, especially in large doses.

TREATMENT OF INTRACRANIAL HYPERTENSION

Several general and specific pharmacologic and nonpharmacologic strategies are used in the treatment of intracranial hypertension.

General Pharmacologic Strategies

6 The use of analgesics and sedatives has an important primary role in the management of intracranial hypertension (**Fig. 58-3** and **Table 58-3**). This is related directly to the association of pain, agitation, excessive muscle movement, and resisting mechanical ventilation with transient increases in ICP. Paralytics are a secondary option in refractory patients.[27] Nonetheless, there is no strong evidence that one agent is superior to another relative to affecting outcome in patients with severe TBI based on a recent systematic review of randomized clinical trials.[28] Effects on ICP, CPP, and MAP are variable.[29] Morphine sulfate is the most commonly used analgesic and sedative in this setting.[10,28] Noteworthy is that bolus doses of opiates may increase ICP by increasing CBF.[28] However, while continuous infusions of fentanyl and sufentanil are gaining in popularity, their use also may be associated with mild elevations in ICP.[10,28] Propofol has become the sedative of choice in TBI patients among many clinicians because of its ease of titration, rapidly reversible effects on

discontinuation, and possible neuroprotective effects.[10] Although it is used for sedation in infants and children who are mechanically ventilated in the intensive care unit (ICU) setting, the Food and Drug Administration (FDA) requires that the manufacturer labeling contains specific information that propofol is not approved for sedation of pediatric patients admitted to an ICU. One of the biggest safety concerns with the use of propofol is the propofol infusion syndrome (PRIS) characterized by hyperkalemia, hepatomegaly, lipemia, metabolic acidosis, myocardial failure, rhabdomyolysis, renal failure, and death in some cases.[10] While initially reported in children, PRIS can also occur in adults. Doses greater than 5 mg/kg/hour and infusion exceeding 48 hours should be used with extreme caution.[10] Triglyceride concentrations also should be monitored in patients receiving prolonged propofol infusions and/or high dosages of propofol considering its lipid emulsion formulation and the potential for inducing hypertriglyceridemia under these conditions. Increased mortality with propofol in an animal TBI study has also raised concerns regarding use of this sedative in TBI patients.[30] Alternative sedatives include short-acting benzodiazepines (eg, midazolam), especially if there is a reasonable suspicion of alcohol withdrawal as the underlying etiology of the agitation,[31] intermittent low-dose pentobarbital, ketamine,[32] dexmedetomidine,[33] or etomidate (particularly useful in rapid-induction anesthesia). The potential for these agents to decrease MAP and CPP must be monitored closely. Additionally, the cumulative sedative effects of longer-acting drugs, especially benzodiazepines, must be taken into account. The use of any sedative agent also must be weighed against its potential to obscure the neurologic examination of the patient. Interference with the neurologic examination is also a problem with paralytic agents.

TABLE 58-3 Drug Dosing and Monitoring in TBI Patients

Drug	Adverse Drug Reactions	Monitoring Parameter	Dosing	Comments
				Caution in patients with renal dysfunction
Levetiracetam (Keppra)	CNS changes	Seizures, SCr	500 mg IV Q12 h (dose during first 14 days)	If used for active seizures: increase to 1,000 mg every 12 hours after 14 days, then to 1,500 mg every 12 hours after 28 days
Mannitol (Generic)	Hypotension, renal dysfunction, hyperosmolality	ICP, CPP, BP, serum osmolality, Na, UO, SCr	0.25 to 1 g/kg IV every 2-4 hours	Avoid in patients with renal failure or CHF
Pentobarbital (Nembutal)	Hypotension, GI hypomotility, induction of hepatic drug metabolism	ICP, CPP, BP, EEG, GI function	10 mg/kg IV over 30 minutes, then 5 mg/kg over 3 hours, then 1 mg/kg/h	Administer via central line. General dose range for infusion is 1-3 mg/kg/h

Drug	Adverse Drug Reactions	Monitoring Parameter	Dosing	Comments
				Administer <50 mg/min; use central line if available
Phenytoin (Dilantin)	Hypotension, dysrhythmias, nystagmus, ataxia, mental status changes, exfoliative dermatitis	Seizures, BP, ECG, phenytoin concentrations, skin	15-20 mg/kg IV over 60 minutes, then 5 mg/kg/day divided every 8 hours or every 12 hours	Round loading doses up to nearest 250 mg, round maintenance doses up to nearest 25 mg Trauma patients often require higher doses (ie, >6 mg/kg/day) to achieve therapeutic concentrations
Propofol (Diprivan)	Hypotension, hyperkalemia, metabolic, acidosis, rhabdomyolysis, renal failure, hepatomegaly, lipemia	ICP, CPP, BP, SCr, K, arterial pH, triglycerides, lactate	General range: 0.5-3 mg/kg/h titrated to desired effect	Avoid doses greater than 5 mg/kg/h or prolonged infusions; not approved for use in children

BP, blood pressure; CHF, congestive heart failure; CPP, cerebral perfusion pressure; ECG, electrocardiogram; EEG, electroencephalogram; GI, gastrointestinal; ICP, intracranial pressure; K, potassium; Na, sodium; SCr, serum creatinine; UO, urine output.

The reader is referred to other appropriate chapters regarding other drugs not listed in this table.

FIGURE 58-3

Algorithm for the management of increased ICP. [a]Treatment thresholds: ICP 20 to 29 mm Hg (2.7-3.9 kPa) for >15 minutes; ICP 30 to 39 mm Hg (4.0-5.2 kPa) for >2 minutes; ICP more than or equal to 40 mm Hg (≥5.3 kPa) for more than 1 minute. Note: Transient increases may occur following respiratory procedures (eg, suctioning, chest physiotherapy, bronchoscopy, and intubation). [b]Hold if serum osmolality is more than 320 mOsm/kg (320 mmol/kg). [c]Partial pentobarbital loading dose (mg) = (30 mg/L – measured Cp) (1 L/kg × wt[kg]) (pentobarbital concentration in µmol/L must first be divided by 4.439 to convert to mg/L). (Cp, plasma concentration; EEG, electroencephalogram; ICP, intracranial pressure; ICU, intensive care unit; OR, operating room; PaCO2, partial pressure of arterial blood carbon dioxide.) *(Reprinted with permission from Wood CG, Boucher BA. Hyperventilation

4 The practice of prolonged aggressive hyperventilation ($PaCO_2$ less than 25 mm Hg [3.3 kPa]) to decrease ICP is no longer recommended.[10] Hyperventilation acutely decreases systemic and cerebral $PaCO_2$. The resulting hypocapnia, in turn, induces cerebral vasoconstriction, thereby decreasing CBF and cerebral blood volume (CBV). For decades, it was a widely held belief that a reduction in CBV and any accompanying decrease in ICP were beneficial. Nonetheless, a comprehensive literature review concluded that there are no data demonstrating improved outcomes using this therapeutic intervention.[34] Hyperventilation should be avoided during the first 24 hours following acute TBI when CBF is often critically reduced according to the most current BTF/AANS guidelines.[10] 7 Hyperventilation for brief periods with a goal of 30 to 35 mm Hg (4.0-4.7 kPa) nonetheless may be considered a temporary maneuver in the setting of refractory intracranial hypertension or in the initial management of patients with signs of cerebral herniation.[10] If hyperventilation is performed, the use of $SjvO_2$ or cerebral tissue oxygen perfusion monitoring is recommended.[10]

Hypothermia

Therapeutic hypothermia has been an attractive strategy for attempting to minimize secondary brain injury after TBI for decades. The mechanism underlying a protective effect of hypothermia is likely multifactorial, although a reduction in $CMRO_2$ is offered most frequently as the basis of any therapeutic benefits. Early TBI studies suggested promise for therapeutic hypothermia. In addition, some other patient populations with brain ischemia (eg, cardiac arrest patients) have improved outcomes with hypothermia. Unfortunately, data from large clinical trials of prophylactic therapeutic hypothermia in TBI patients have not shown improved outcomes. The first of two large randomized clinical trials of therapeutic hypothermia in 392 patients with nonpenetrating TBI using a targeted temperature of 33°C (91°F) revealed no improvement in outcome compared with the normothermic group.[10] In addition, more hypotension was observed in the therapeutic hypothermia group. The second major multicenter study focused on early cooling (ie, ≤2.5 hours) to 35°C (95°F), then 48 hours at 33°C (91°F) followed by gradual rewarming.[35] The control group was treated under normothermic conditions. This study was discontinued after enrollment of 108 patients because of futility with poorer outcomes including death observed in the hypothermic group. Based on the clinical evidence to date, prophylactic therapeutic hypothermia is not recommended as a routine neuroprotective strategy in patients with TBI.[7] Nevertheless, a report emanating from five critical care societies would not recommend for or against therapeutic hypothermia (ie, "targeted temperature management") based on available data.[36] Furthermore, a recent systematic review of therapeutic hypothermia in TBI found some evidence supporting its use.[37] In pediatric patients, moderate hypothermia within 8 hours of TBI should be considered in patients with intracranial hypertension.[14] Noteworthy is that a large, multicenter study of hypothermia for ICP reduction in TBI patients (Eurotherm3235Trial) is currently underway that may provide additional insights on the use of this therapeutic intervention in adults.[38] Potential side effects of therapeutic hypothermia include coagulation disturbances, infectious complications, and cardiac arrhythmias. An increase in ICP also may occur secondary to hypothermia-associated shivering that can be prevented with neuromuscular blocking agents. Therapeutic hypothermia can have effects on the pharmacokinetics of drugs that should also be considered.[39] Specifically, cardiac output decreases by 7% for every 1°C (1.8°F) decrease in core body temperature.[40]

Osmotic Agents

7 Although a number of osmotic diuretics (eg, urea, glycerol) can be used to decrease ICP, mannitol is unquestionably the most widely employed.[10,41] Despite the common practice of administering mannitol to patients with suspected or actual increases in ICP following brain injury, no clinical trial comparing its effects against placebo has been performed.[29,42] The mechanisms responsible for mannitol's beneficial effects likely relate to (a) an immediate plasma-expanding effect that reduces blood viscosity and increases CBF and (b) establishment of an osmotic concentration gradient across an intact blood–brain barrier that decreases ICP as water diffuses from the brain into the intravascular compartment.[10] Recommended doses of mannitol typically range from 0.25 to 1 g/kg IV every 2 to 4 hours.[10, 41] Increased ICP is reduced within minutes following mannitol administration, and the duration of action ranges from 90 minutes to 6 hours depending on the dose and the clinical conditions that are present.[10] In order to maximize benefit and minimize adverse events, it has been

suggested that mannitol be administered as a bolus and not as a continuous infusion in this setting. However, more recent analyses conclude that there is no demonstrable benefit using one administration approach over the other.[10]

Several adverse effects are associated with mannitol.[41] In addition to hypotension resulting from its diuretic effect, a reversible acute renal dysfunction may occur in patients with previously normal renal function after long-term, large-dose administration, especially in patients with advanced age and preexisting renal dysfunction based on data in patients with intracranial hemorrhage.[43] As such, mannitol should be avoided in patients with acute kidney injury or chronic kidney diseases. Acute exacerbation of underlying congestive heart failure and pulmonary edema also may occur following rapid intravascular volume expansion. Furosemide is recommended as an alternative diuretic for lowering ICP in these latter patient groups.

While hypertonic saline solutions have been advocated by some as a resuscitative fluid following TBI as previously mentioned, solutions ranging from concentrations of 2% to 23.4% have also been used to acutely lower increased ICP.[44] Not only do hypertonic saline solutions create an osmotic gradient in favor of reducing cerebral edema, but evidence suggests that they may also have beneficial vasoregulatory, immunologic, and neurochemical effects as well.[44] Plasma expansion may also lead to an increase in CBF. It is noteworthy, however, that the 2007 BTF guidelines do not recommend hypertonic saline due to a lack of supporting evidence.[10] Nevertheless, two recent meta-analyses also suggested that hypertonic saline may be modestly more effective than mannitol.[44,45] In contrast, two clinical trials of equimolar doses of mannitol versus 7.45% and 15% hypertonic saline, respectively, revealed similar effects between the regimens in TBI patients.[46,47] In most studies, the goal of therapy was to treat an elevated ICP. However, in some studies the goal of therapy was to increase the serum sodium regardless of ICP. If used in this way, hypertonic saline should target serum sodium concentration less than 160 mEq/L (160 mmol/L) since additional benefit is unlikely at higher concentrations.[41]

Barbiturates

7 High-dose barbiturate therapy (ie, barbiturate coma) has been used for decades in the management of increased ICP despite a lack of evidence documenting beneficial effects on patient morbidity and mortality.[48] Nonetheless, based largely on beneficial outcomes observed in a randomized clinical trial published in 1988, BTF/AANS and pediatric guidelines recommend that high-dose barbiturate therapy be considered in hemodynamically stable severe TBI patients refractory to maximal medical ICP-lowering therapy and decompressive surgery.[10,14] A recent study indicated survival at a discharge of 40% (22 of 55) and good functional outcomes in 68% of survivors (13 of 19 evaluable patients) at 1 year in this TBI patient subset receiving high-dose barbiturate therapy.[49] Prophylactic use of barbiturates is not advocated in light of insufficient evidence supporting this practice and the potential for adverse events (eg, hypotension).[10,14,48] The mechanism responsible for the cerebral protective effects of barbiturates is generally attributed to suppression of cerebral metabolism thereby cerebral metabolic demands and CBV.[48] Prior to inducing a barbiturate coma, the severe TBI patient must be mechanically ventilated with continuous

monitoring of arterial blood pressure, electrocardiogram (ECG), and ICP. Pentobarbital is the most commonly used barbiturate for this indication, although thiopental also has been used. Pentobarbital should be administered as an IV loading infusion totaling 25 mg/kg (ie, 10 mg/kg over 30 minutes and then 5 mg/kg per hour for 3 hours), followed by a maintenance infusion of 1 to 2 mg/kg per hour.[10] If the SBP falls during the loading or maintenance infusions, the rate should be slowed temporarily and blood pressure support initiated. The goal of a barbiturate coma is to maintain ICP and CPP at the previously discussed target thresholds in addition to achieving a pentobarbital steady-state concentration of between 30 and 40 mg/L (133 and 178 mmol/L) (despite poor correlation between serum concentrations and outcome) and electroencephalography (EEG) burst suppression.[10] Initiation of barbiturate therapy withdrawal can occur when ICP has been controlled satisfactorily for 24 to 48 hours. Barbiturates should be tapered over 24 to 72 hours to prevent ICP spikes.

Side effects associated with high-dose barbiturate therapy involve primarily the cardiovascular system. Hypotension caused by peripheral vasodilation may occur, necessitating decreasing the barbiturate dose or the administration of fluids and vasopressors to maintain blood pressure. A systematic review of the literature suggested that one of every four patients receiving barbiturate therapy will develop hypotension.[48] Gastrointestinal (GI) effects of barbiturates include decreased GI muscular tone and decreased amplitude of contraction. On emergence from coma, there may be a period of GI hypermotility. Care should be taken to avoid extravasation of pentobarbital and thiopental solutions because severe tissue damage may occur. Barbiturates should be administered by continuous infusion through a central line dedicated for this purpose. The potential for barbiturates to induce the hepatic drug metabolism of concurrent medications should be also considered. Lastly, the potential for prolonged interference with the neurologic examination of TBI patients must be considered prior to the initiation of high-dose barbiturate therapy.

Corticosteroids

7 Although corticosteroids are effective in preventing or reducing cerebral edema in patients with nontraumatic conditions producing vasogenic edema, studies in TBI patients have not demonstrated the ability of corticosteroids to lower ICP or improve outcome.[10,14] Specifically, use of corticosteroids following TBI has been associated with increased mortality and complications, including GI bleeding, glucose intolerance, electrolyte abnormalities, and infection. The largest investigation to date was known as the corticosteroid randomization after significant head injury (CRASH) study.[50] In this study, 10,008 patients with a GCS score less than or equal to 14 were randomized to receive a 48-hour continuous infusion of methylprednisolone or placebo. Results of this study indicated a higher risk of death within 2 weeks of enrollment (relative risk 1.18) in those patients receiving corticosteroids compared with patients receiving placebo (*P* less than 0.001).[50] Based on this and several other major randomized trials, the BTF/AANS adult and pediatric guidelines recommend that high-dose corticosteroids not be used in patients with moderate to severe TBI.[10,14]

TREATMENT AND PROPHYLAXIS OF COMPLICATIONS

In addition to specific management of TBI problems such as intracranial hypertension, the potential for secondary complications must also considered in addition to rendering general supportive care. Development and implementation of clinical pathways for consistency of care, and clinical investigation of neuroprotective agents are important in advancing TBI treatment in the future.

Posttraumatic Seizures

It is generally agreed that adult patients who have experienced one or more seizures following a moderate-to-severe TBI should receive anticonvulsant therapy to avoid increases in $CMRO_2$ that occur with the onset of subsequent seizures and to prevent the development of (sometimes subclinical) status epilepticus with associated increase in mortality.[10] Initial therapy in these persons should consist of incremental IV doses of diazepam (5-40 mg adults, 0.1-0.5 mg/kg infants and children) or lorazepam (2-8 mg adults, 0.03-0.1 mg/kg infants and children) to terminate any active seizure activity, followed by IV phenytoin to prevent seizure recurrence. Phenytoin dosing regimens for adults and pediatric patients include an IV loading dose of 15 to 20 and 10 to 15 mg/kg, respectively, followed by a maintenance dose of 5 mg/kg per day. Alternatively, fosphenytoin, a water-soluble phosphate ester of phenytoin, can be administered IV or intramuscularly using the same doses, specified as phenytoin equivalents (PE). The merits of preventive anticonvulsant therapy in patients who have not had a seizure postinjury historically have been more controversial. Risk factors for early posttraumatic seizures (less than 7 days after injury) include a GCS score of less than 10, a cortical contusion, a depressed skull fracture, a subdural hematoma, an epidural hematoma, an intracerebral hematoma, a penetrating head wound, or a seizure within the first 24 hours of injury.[10] In a landmark randomized, placebo-controlled study, the incidence of early posttraumatic seizures in patients receiving placebo was 14.2% compared with 3.6% in patients receiving phenytoin (*P* less than 0.05) without a significant increase in drug-related side effects.[51] Thus, it is recommended that phenytoin (or alternatively carbamazepine) should be used to prevent seizures in TBI patients at high risk for the first 7 days after injury.[10,51] Recommendations in pediatric TBI patients state that phenytoin may be used in the first 7 days postinjury to prevent early seizures.[14] Interestingly, recent data suggest that phenytoin may not decrease early posttraumatic seizures and may diminish functional outcome after blunt TBI, challenging this longstanding practice.[52]

Clinical Controversy…

Prophylactic phenytoin therapy for TBI patients deemed at risk of posttraumatic seizures has been a traditional management strategy for decades. Recent data challenge this practice based on failure of phenytoin to decrease posttraumatic seizures and possibly diminish functional outcomes in TBI patients.

Valproate therapy is not recommended based on a trend for higher mortality in a study comparing valproate-treated patients with those receiving phenytoin short-term therapy.[51] Levetiracetam is a potentially attractive option;[53,54] however, the drug should be used cautiously because it is not approved as monotherapy for seizures, and effectiveness in patients with TBI has not been studied in a large randomized clinical trial. Furthermore, the cost-effectiveness of levetiracetam versus

phenytoin favors phenytoin.[55,56] A high-quality, randomized, clinical trial demonstrating superiority is needed before levetiracetam displaces phenytoin as the drug of choice following TBI. Nonetheless, if used in TBI patients, the potential for increased levetiracetam systemic clearance should be considered in dosing this agent.[57] The benefits of prophylactic anticonvulsants beyond 7 days have not been demonstrated, and thus their use for this indication is not recommended.[10,14] Unfortunately, despite reducing the incidence of early seizures following brain injury, no beneficial effects have been documented for anticonvulsants on patient mortality or long-term disability.[10,51] This is particularly disconcerting considering that the long-term risk of epilepsy after TBI has been documented up to 10 years or longer based on the results of a recent population-based cohort study.[58]

Supportive Care

While normalizing ICP and maintaining an adequate CPP are the highest priorities in preventing secondary injury following severe TBI, attention also must be given to preventing and/or treating systemic and extracranial complications.[10] One such complication is systemic hypertension. Antihypertensives that can be used include IV labetalol, nicardipine, and enaliprilat.[7] Fluid and electrolyte management is another important area of focus in the critically ill TBI patient. Common electrolyte disturbances in TBI patients that should be monitored and treated aggressively include hyponatremia, hypomagnesemia, hypokalemia, and hypophosphatemia. Aggressive nutritional support of the TBI patient is another important therapeutic consideration. Evidence suggests that early feeding of TBI patients (ie, by 7 days) may be associated with a trend toward better outcomes in terms of survival and disability.[7,10,59] Early enteral nutrition, in particular, within 48 hours is associated with better survival and better outcome at 1 month postinjury based on a recent retrospective study of severe TBI patients compared with matched controls who did not receive early enteral nutrition.[60] Hyperglycemia (glucose ≥160 mg/dL [8.9 mmol/L]) is also common in patients with TBI and is associated with worse outcomes.[61] Nevertheless, intensive insulin therapy versus conventional glucose control should not be used since it is associated with adverse effects on brain glucose metabolism[62] and poor outcomes.[63] Infectious complications commonly encountered in severe TBI patients include nosocomial pneumonia, sepsis, urinary tract infections, and meningitis. Treatment of these potentially devastating infections should be aggressive, with careful attention being paid to antibiotic blood–brain barrier penetration for intracranial infections. Hyperthermia also should be avoided in TBI patients because patients with elevated temperatures have poorer outcomes than normothermic patients.[64,65] Hence aggressive maintenance of a core temperature of less than 37.5°C (99.5°F) using acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and cooling blankets is indicated for patients following severe TBI. Other important therapeutic interventions include acute gastritis prophylaxis, and prevention of decubiti and contractures. Prevention of thromboembolic events is also extremely important supportive care in TBI patients since the incidence of a deep venous thrombosis is higher in TBI patients compared with patients without brain injury.[66] This can be accomplished with the use of intermittent pneumatic compression devices (preferred) or graduated compression stockings initially. Thereafter, the decision to start systemic therapy (eg, low-molecular weight heparin) depends on multiple factors. Generally, patients who had relatively

minor bleeding on the initial CT scan and good ICP control can have pharmacological prophylaxis started within 24 to 48 hours postinjury.[67,68] Data suggest that TBI patients with an intracranial hemorrhage can have systemic anticoagulation prophylaxis safely and effectively (ie, reduced deep venous thromboses) initiated 24 hours after a follow-up CT scan shows no worsening of bleeding in patients with an intracranial hemorrhage.[69] However, a recent evidence-based review recommends waiting 72 hours for patients at moderate to high-risk of intracranial hemorrhage postinjury.[67] Regardless of initiation time, prophylaxis is continued until they are ambulatory.[10,70,71] Nevertheless, systemic anticoagulation must be used with caution in patients with more severe intracerebral hemorrhage, or in patients who may need to undergo craniotomy early in their course. Monitoring for a coagulopathy is important in any severe TBI patient, since the incidence is high (greater than 30%), and coagulopathy is associated with a significantly longer ICU length of stay and an almost 10-fold increase in mortality based on data from a recent study.[72] Low platelet count was the strongest predictor of intracranial bleeding progression compared with other coagulation tests in isolated TBI patients based on a recent retrospective study.[73] Reversal of coagulopathy with recombinant factor VIIa in critically ill trauma patients with TBI is popular among some practitioners despite lacking an approved indication or large clinical trials demonstrating its safety and efficacy in TBI patients.[74,75,76] Tranexamic acid is a less expensive hemostatic alternative to recombinant factor VIIa. However, more data are needed to determine the role of this agent in isolated TBI patients before it is used routinely despite being generally advocated in bleeding trauma patients.[77,78,79] A study known as CRASH-3 is currently underway investigating the role of early administration tranexamic acid in TBI patients with intracranial bleeding.[80]

Clinical Controversy...

Tranexamic acid is an antifibrinolytic agent that has been demonstrated to improve mortality in bleeding trauma patients. It is unclear if tranexamic acid should be administered to TBI patients with isolated intracranial bleeding.

Clinical Pathways/Guideline Implementation

Use of clinical pathways and formal TBI management guidelines have been demonstrated to improve TBI patient outcomes and reduce institutional resource utilization.[81,82] A cost–benefit analysis revealed that adoption of the BTF guidelines resulted in an increase of more than 3,600 adult severe TBI patients surviving at least 1 day from the more than 23,000 patients with severe TBI admitted annually to U.S. hospitals. Furthermore, patients having a good outcome based on their Glasgow Outcome Scale (GOS) increased from 35% to 66% with an overall estimated annual cost savings exceeding $4 billion.[83] Few practitioners would dispute the overall importance of integrating current evidence-based management guidelines into clinical practice as a means to optimize care and improve the functional outcome of TBI patients.

Investigational Therapy

9 The steady decrease in morbidity and mortality following severe neurotrauma over the past 30

years can be attributed largely to expeditious and aggressive management of events resulting in secondary injury (ie, ischemia, hypoxia, increased ICP) using conventional treatment strategies. Numerous neuroprotective agents targeting specific pathophysiologic processes that are theorized to occur following severe TBI have been investigated over the past decade in an attempt to further enhance the prospects for a meaningful recovery. Prominent among these strategies have been attempts to modulate calcium influx through the administration of calcium antagonists[84] and glutamate antagonists including magnesium, and the use of antioxidants/free radical scavengers.[85] Inhibitors of inflammatory mediators also are under consideration as neuroprotective agents.[86] Unfortunately, none of these agents to date has demonstrated a significant reduction in morbidity or mortality following severe TBI in phase III clinical trials. More recently there was immense enthusiasm for progesterone as a neuroprotective agent based on two moderately sized clinical studies that demonstrated improved outcome following acute TBI.[87] However, results of two subsequent large prospective trials of progesterone in patients with acute TBI were halted early due to lack of improving functional outcomes dashing hopes for this promising therapy.[88,89] In contrast, interest continues to exist for erythropoietin-stimulating agents as neuroprotective agents.[85] One prospective clinical trial comparing the erythropoiesis-stimulating agent (ESA), darbepoetin alfa, in severe TBI patients also demonstrated significantly improved survival in those receiving the darbepoetin compared with matched patients not receiving an ESA.[90] Other agents that have may have beneficial effects in TBI based on limited clinical or epidemiologic data include 3-hydroxy-3-methylglutaryl (HMG) coenzyme A reductase inhibitors[91] and β-blockers.[92] However, confirmation of the benefits from either drug class will require additional prospective, randomized, clinical trials in TBI patients. Miscellaneous agents being considered as viable neuroprotective agents based on experimental TBI studies including calpain inhibitors, the immunosuppressant, cyclosporine,[85] as well as inhibitors of caspases (enzymes involved in apoptosis). Others have proposed that stimulation of axonal repair processes versus limiting injury may be the most fruitful neuroprotective pathway for future investigations.[85,93] Acknowledging the complexities surrounding acute TBI, a broad-based, multidisciplinary approach is undoubtedly needed before breakthrough therapies are identified for this multifaceted, catastrophic condition.[94,95] The BRAIN Initiative—Brain Research Through Advancing Neurotechnologies, a Presidential and National Institutes of Health focused program aimed at revolutionizing understanding of the human brain launched in 2014 exemplifies the commitment to this extremely important yet daunting task.[96]

Other Treatment Strategies

The concept of administering commercially available CNS-active agents for nonapproved indications in TBI patients should presently be considered investigative therapy. One example is the use of CNS stimulants in the management and rehabilitation of TBI patients. Data supporting this approach are equivocal.[85] Another example is the use of Parkinson disease medications (eg, amantadine, bromocriptine, carbidopa/levodopa) in severe TBI patients in an attempt to enhance dopamine release and inhibit reuptake within the injured region of the brain. The results of a multicenter, prospective, double-blind, randomized, placebo controlled trial of amantadine, which was conducted in nonpenetrating TBI patients, were recently published.[97] Patients were enrolled 4 to 16 weeks after

their TBI. The amantadine-treated patients had a significantly faster recovery and favorable rehabilitation outcomes compared with placebo. Unfortunately, the two groups became indistinguishable relative to neurologic improvement following taper of amantadine. Regardless, this agent holds excellent promise in TBI patients during the postinjury rehabilitation period. Cholinergic agents such as donepezil have also undergone limited investigation in TBI patients.[98] Antidepressants represent yet another class of agents that has been studied in TBI patients.[98] While intuitively appealing, use of psychostimulants to improve cognitive outcomes in TBI patients should be done cautiously with perhaps the lone exception of amantadine until large, well-controlled studies demonstrating beneficial effects are available. Additionally, the timing of administration of these drugs is controversial; the potential for cardiovascular side effects in the face of uncertain benefit would suggest that these drugs should be reserved for the postacute phase of treatment (ie, weeks to months postinjury).

PERSONALIZED PHARMACOTHERAPY

There are several opportunities for personalized pharmacotherapy in severe TBI patients. The most common general pharmacokinetic challenge is that TBI patients have a larger volume of distribution and more rapid hepatic clearance of drugs than most other patient populations. These pharmacokinetic changes often make the optimizing of phenytoin and, less commonly, pentobarbital concentrations very difficult. As such, recommendations for phenytoin and pentobarbital dosing are weight based, and in the case of phenytoin, usually higher than the 300 mg/day dose that is commonly seen in ambulatory patients. Pharmacodynamically, there can be wide interpatient variability in the efficacy of pharmacologic and nonpharmacologic interventions for ICP control. For some patients, there is a high degree of trial and error to find the best combination of interventions that are effective and not contraindicated by other factors. Lastly, the decision to start pharmacologic deep venous thrombosis prophylaxis may also be highly personalized depending on CT findings, neurologic progress, ICP control, and the possible need for surgery.

EVALUATION OF THERAPEUTIC OUTCOMES

The process for evaluation of therapeutic outcomes is summarized in **Table 58-4**. Patients with severe TBI require ICU monitoring initially with the goals of maintaining or reestablishing neurologic and systemic homeostasis as well as readily detecting any neurologic deterioration. This requires frequent evaluation of the patient's neurologic status (eg, GCS) and measurement of vital signs, urine output, and arterial oxygen saturation (as well as ICP in patients with an ICP monitor in place). Furthermore, careful attention must be paid to the potential for development of a variety of electrolyte, mineral, and acid–base disturbances; coagulopathies; and infections by obtaining various laboratory tests on a daily basis initially. The intensity of monitoring will be a function of the relative degree of neurologic and hemodynamic stability of the patient in the hours and days following the neurologic insult. Lastly, radiologic tests (eg, CT scans) are essential not only for the initial diagnostic evaluation of TBI patients but also as means to evaluate the etiology for any subsequent neurologic deterioration.

TABLE 58-4 Evaluation of Therapeutic Outcomes

General	GCS: Record hourly initially, decrease frequency as neurologic status stabilizes
	Vital signs (BP, HR, RR, temperature): Record hourly initially, decrease frequency as neurologic status stabilizes
	UO: Record hourly initially, decrease frequency as neurologic status stabilizes
Risk of increased ICP	Arterial oxygen saturation: Continuously while in ICU
	ICP: Record hourly, decrease frequency as ICP stabilizes <20 mm Hg (2.7 kPa) (usually not until 48-72 hours postinjury at a minimum)
	CPP: Record hourly, decrease frequency as CPP stabilizes in the desired range[a]
	Ethanol concentration and urine drug screen: On admission
	ABGs: Daily at a minimum while intubated, repeated as needed based on pulmonary instability requiring ventilator setting changes
Laboratory tests	CBC: Daily while in ICU
	Serum electrolytes (Na, K, Cl): Daily while in ICU. Serum sodium and osmolality may be monitored as frequently as every 6 hours if osmotherapy (mannitol, furosemide, hypertonic saline) is being used
	Minerals (Mg, Ca, P): Daily initially until concentrations stable
Radiologic procedures	CT scan: Postresuscitation initially with repeat scan(s) as needed based on degree of neurologic instability (eg, decrease in GCS) or initial CT appearance

ABG, arterial blood gas; BP, blood pressure; Ca, calcium; CBC, complete blood count; Cl, chloride; CPP, cerebral perfusion pressure; CT, computed tomography; GCS, Glasgow Coma Scale; HR, heart rate; ICP, intracranial pressure; K, potassium; Mg, magnesium; Na, sodium; P, phosphorus; RR, respiratory rate; UO, urine output.

[a]Continuous monitoring mandated initially if technologically feasible.

Chapter 59: Parkinson Disease

Jack J. Chen; Khashayar Dashtipour

INTRODUCTION

KEY CONCEPTS

- 1 Awareness and continuous surveillance of motor and nonmotor symptoms in combination with thoughtful consideration of initial and adjunctive therapies with adjustment of drug dosing throughout the course of idiopathic Parkinson disease (PD) is required to optimize long-term therapeutic outcomes, minimize adverse effects, and improve quality of life.
- 2 The optimal time to start drug therapy varies. In general, treatment should be initiated when the disease begins to interfere with activities of daily living, employment, or quality of life.
- 3 Surgery is reserved for patients who require additional symptomatic relief or control of motor complications despite receiving medically optimized therapy.
- 4 Anticholinergic medication can be useful for mild symptoms of PD but, due to anticholinergic side effects, should be used with caution in the elderly and in those with preexisting cognitive difficulties.
- 5 As monotherapy, amantadine and monoamine oxidase type B (MAO-B) inhibitors provide symptomatic benefit, but less than that of dopamine agonists or carbidopa/levodopa (l-dopa).
- 6 Carbidopa/l-dopa is the most effective medication for symptomatic treatment and eventually all patients with PD will require it.
- 7 Most carbidopa/l-dopa–treated patients will develop motor complications (eg, fluctuations and dyskinesias).
- 8 MAO-B inhibitors and catechol-*O*-methyl-transferase inhibitors are useful add-on therapies to attenuate motor fluctuations in carbidopa/l-dopa–treated patients.
- 9 Amantadine is a useful add-on agent to attenuate dyskinesias.

- Dopamine agonists are effective and, compared to l-dopa, associated with less risk of developing motor complications but more risk of causing psychiatric symptoms, such as hallucinations and impulse control disorders.

The presence of tremor at rest, rigidity, bradykinesia, and postural instability (instability of balance) are considered the hallmark motor features of idiopathic Parkinson disease (PD), a disorder of the extrapyramidal system. These clinical features of PD were adeptly described in 1817 by James Parkinson.[1]

EPIDEMIOLOGY

Up to 1 million individuals in the United States have PD. The approximate annual incidence of PD (ie, number of persons diagnosed with PD per year) is age-dependent and ranges from 10 per 100,000 persons in the sixth decade of life (ie, 50-59 years) to 120 per 100,000 persons in the ninth decade of life (ie, 80-89 years).[2] Likewise, the prevalence of PD also increases with age, affecting less than 0.5% of people in their 60s and 2.5% of those older than 80 years.[3] The usual age at time of diagnosis ranges between 55 and 65 years. Overall, a higher preponderance of PD is reported among males.[3]

ETIOLOGY

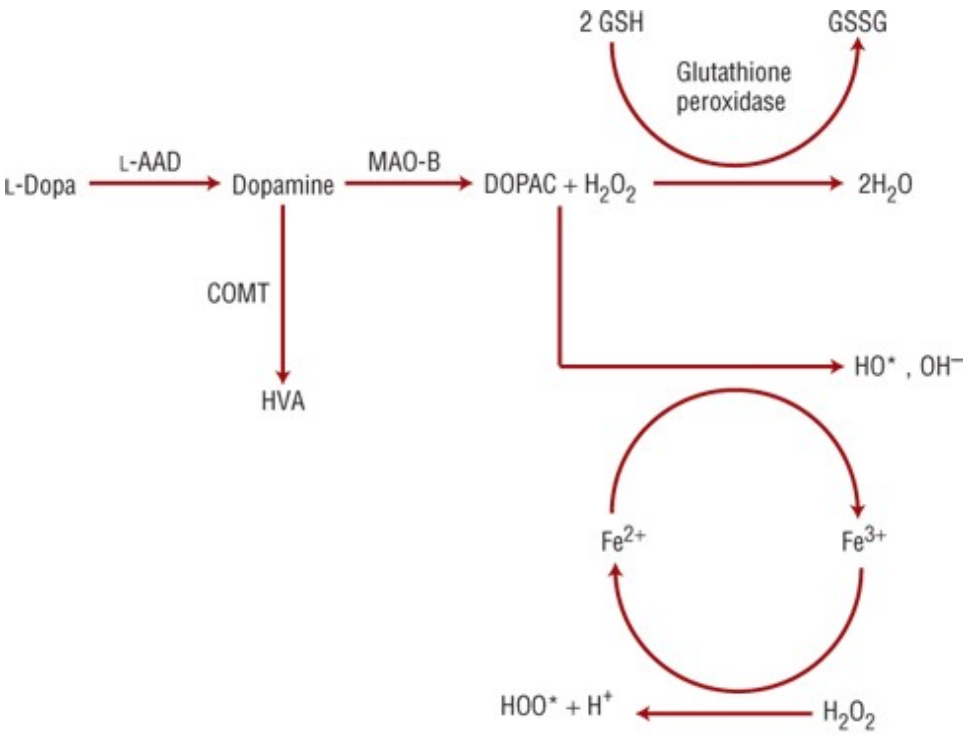
PD occurs sporadically and the true etiology is unknown. At the cellular level, degeneration of dopaminergic neurons (axons and soma) projecting from the substantia nigra pars compacta (SNc) to the striatum (caudate nucleus and putamen) are a hallmark of PD.[4] Additionally, neurons in autonomic ganglia, enteric nervous system, limbic system, olfactory bulb, spinal cord, and neocortex are affected. The underlying mechanisms are interconnected and multifaceted with involvement of toxic biochemical reactions (excitotoxicity, nitric oxide toxicity, oxidative stress), abnormal cellular and cell death signaling pathways (apoptosis, inflammation), dysfunctional organelles (lysosomes, mitochondria), and dysfunctional protein degradation systems (autophagy, ubiquitin proteasomal system) resulting in cytoplasmic protein (α-synuclein) accumulation.[5] Several of these mechanisms result in excessive production of free radicals which exert stress on cells by damaging membranes and organelles. The SNc and the striatum are regions characterized by high levels of oxidative stress due to dopamine degradation and the Fenton reaction (**Fig. 59-1**). Normally, intrinsic antioxidants (eg, glutathione) buffer against oxidant stress, but in PD, this buffer might be impaired or overwhelmed. Pathologic findings reveal a correlation between the extent of nigrostriatal dopamine loss and the severity of certain PD motor features (eg, bradykinesia). At the time of PD onset, the estimate losses of SNc neurons and striatal dopamine content are 30% and 50%, respectively.[6] The loss of striatal dopamine exceeds the loss of SNc cell bodies because cellular degeneration begins in the distal presynaptic axon terminals and proceeds over time toward the cell body/soma (ie, "dying back" axonopathy).[6]

Aging, genetic constitution, and environmental factors likely increase an individual's risk for PD.[7,8] Epidemiologic research links environmental factors (eg, chronic exposure to pesticides), with an

elevated risk. Interestingly, cigarette smoking and caffeine consumption are consistently associated with a lower risk.[9,10] Genetic polymorphisms and epigenetics also modify an individual's risk for PD. It is known that pesticide exposure and genetic forms of parkinsonism (eg, *leucine-rich repeat kinase 2 [LRRK2]*, *parkin*, *PTEN-induced putative kinase 1 [PINK1]*) are associated with mitochondrial dysfunction and oxidative stress.

FIGURE 59-1

Dopamine metabolism results in hydrogen peroxide (H_2O_2) formation. In the Fenton reaction, H_2O_2 accepts an electron from ferrous iron (Fe^{2+}) to produce ferric iron (Fe^{3+}) and the hydroxyl radical (HO^*). Fe^{3+} is reduced back to Fe^{2+} by another molecule of H_2O_2, forming a hydroperoxyl radical (HOO^*). The radicals damage cell membranes and organelles (eg, mitochondria) and also induce apoptotic signaling. (COMT, catechol-*O*-methyl transferase; DOPAC, 3,4-dihydroxyphenylacetic acid; GSH, glutathione; GSSG, glutathione disulfide; H^+, proton; H_2O, water; HVA, homovanillic acid; L-AAD, L-aromatic amino acid decarboxylase; OH^-, the hydroxide ion; MAO-B, monoamine oxidase B.)



PATHOPHYSIOLOGY

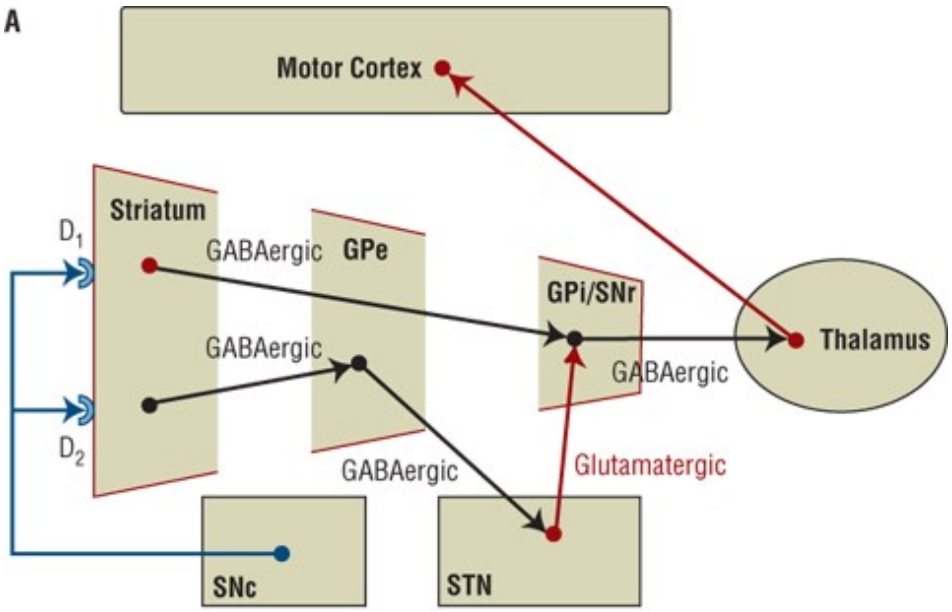
A function of the basal ganglia (composed of subcortical structures including the substantia nigra, striatum, globus pallidus, and subthalamic nucleus) is to regulate voluntary movement. These subcortical structures exist in duplicate, with one structure on each side of the midline. The substantia nigra consists of two parts: the SNc and pars reticulata (SNr). Neuronal projections from the SNc to

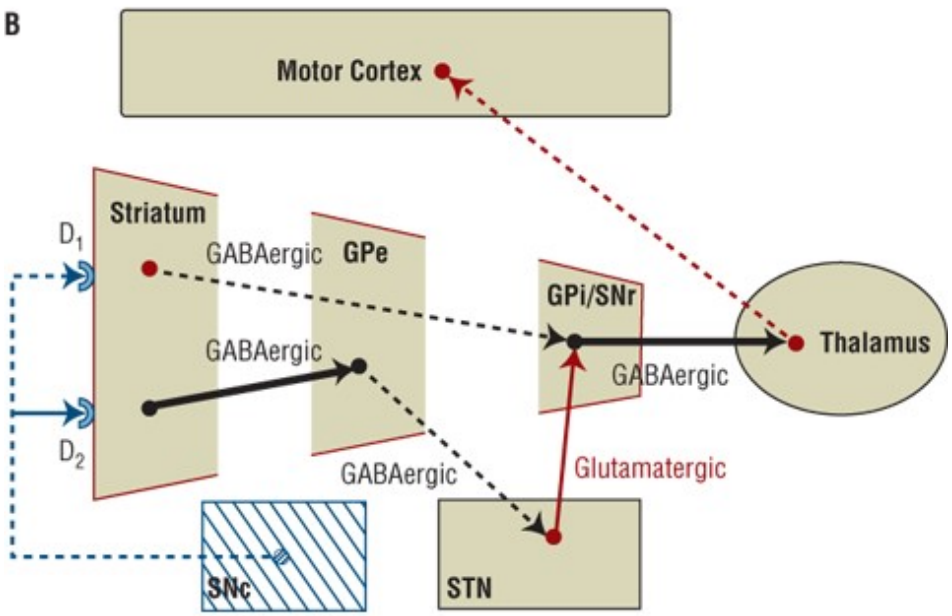
the striatum are referred to as the *nigrostriatal pathway*. The striatum conveys signals to the SNr, via the dopamine$_1$ (D_1) direct and the dopamine$_2$ (D_2) indirect pathways (**Fig. 59-2a**). The SNr (which is closely linked to the globus pallidus interna [GPi]) receives signals from the striatum and conveys final processed signals to the thalamus, which serves as the "gateway" to the motor cortex. When examining the basal ganglia circuitry, it is important to note that striatal D_1 receptors are coupled to adenylate cyclase and mediate postsynaptic depolarization, thus D_1 receptor activation results in stimulation of the striatal GABAergic neurons.[11] In contrast, striatal D_2 receptors are coupled to a guanosine triphosphate-binding protein and mediate postsynaptic hyperpolarization, thus D_2 receptor activation results in inhibition of striatal GABAergic neurons.[11] In PD, reduced dopaminergic activation of D_1 and D_2 receptors and the sequential downstream effect on signaling pathways results in a net inhibitory tone on the thalamus (**Fig. 59-2b**). Dopaminergic therapies help restore functional activity within the D_1 and D_2 pathways with the latter primarily responsible for mediating clinical improvements.

Within the SNc, histopathologic features of PD are (1) depigmentation of dopamine-producing neurons (ie, loss of SNc neurons) and (2) presence of Lewy bodies (cytoplasmic filamentous aggregates composed of the protein α-synuclein) in the remaining neurons.[4] Lewy bodies appear in association with adjacent gliosis (ie, a response of glial cells to injury) and the formation and spread of Lewy pathology is proposed to occur in stages. In the premotor stage of PD, Lewy bodies are found in the medulla oblongata, locus coeruleus, raphe nuclei, enteric nervous system, and olfactory bulb. This provides anatomic correlates to observations that mood (eg, anxiety, depression) and peripheral symptoms (eg, constipation, impaired olfaction) are present in premotor stages of PD. Evidence suggests that Lewy pathology develops peripherally in the enteric nervous system and olfactory system and may spread anterogradely or retrogradely to the brain.[12] With the development of Lewy pathology in the midbrain (particularly the SNc), motor features begin to emerge. In advanced stages, Lewy pathology spreads to the cortex, and this may correlate with cognitive and additional behavior changes. Lewy pathology has also been shown to spread into adjacent healthy neurons in a prion-like manner.

FIGURE 59-2

A. Dopaminergic pathways of the basal ganglia–thalamocortical circuit. Activation of D_1 and D_2 receptors results in depolarization and hyperpolarization, respectively, of postsynaptic neurons. (Red dots and lines represent excitatory input; black dots and lines represent inhibitory input) *B.* In Parkinson disease, degeneration of presynaptic nigrostriatal neurons results in inhibition of the thalamocortical circuit and reduced signaling to the motor cortex. (*Dashed lines* represent reduction of neurotransmitter activity; GPe, globus pallidus externa; GPi, globus pallidus interna; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus.)





Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

CLINICAL PRESENTATION Idiopathic Parkinson Disease General Features

- The patient exhibits bradykinesia and at least one of the following: resting tremor, rigidity, or postural instability. Asymmetry of motor features is supportive.

Motor Symptoms

- The patient experiences hypokinetic movements, decreased manual dexterity, difficulty arising from a seated position, diminished arm swing during ambulation, dysarthria (slurred speech), dysphagia (difficulty with swallowing), festinating gait (tendency to pass from a walking to a

running pace), flexed posture, “freezing” at initiation of movement, hypomimia (reduced facial animation), hypophonia (reduced voice volume), and micrographia (**Fig. 59-3**).

Autonomic and Sensory Symptoms

- The patient experiences bladder dysfunction, constipation, diaphoresis, fatigue, olfactory impairment, orthostatic intolerance, pain, paresthesia, paroxysmal vascular flushing, seborrhea, sexual dysfunction, and sialorrhea (drooling).

Mental Status Changes

- The patient experiences anxiety, apathy, bradyphrenia (slowness of thought processes), cognitive impairment, depression, and hallucinosis/psychosis (typically drug-induced).

Sleep Disturbances

- The patient experiences excessive daytime sleepiness, insomnia, obstructive sleep apnea, and rapid eye movement (REM) sleep behavior disorder.

Laboratory Tests

- No laboratory tests are available to diagnose PD.

Other Diagnostic Tests

- Genetic testing is not routinely helpful.
- Neuroimaging may be useful for excluding other diagnoses.
- Medication history should be obtained to rule out drug-induced parkinsonism.

The synaptic organization of the basal ganglia also involves a variety of other neurotransmitters and neuromodulators, including acetylcholine, adenosine, enkephalins, γ-aminobutyric acid (GABA), glutamate, serotonin, and substance P. The potential role for drug modulation of these other neurotransmitters and receptor types is an active area of research and novel drug discovery.[13]

Atypical parkinsonian disorders such as multiple system atrophy and progressive supranuclear palsy are characterized by damage to postsynaptic striatal neurons and dopamine receptors. Therefore, dopaminergic therapies are less efficacious in atypical parkinsonism.

CLINICAL PRESENTATION

The clinical diagnosis of PD is based on the presence of bradykinesia and at least one of three other features: muscular rigidity, resting tremor, and postural instability (**Table 59-1**).[14] Asymmetry of motor features is a supportive finding. It is important to note that tremor is not always present at the time of diagnosis, and postural instability typically occurs in later stages of PD. Overall, a diagnosis of PD can be made with a high level of confidence in a patient who has bradykinesia (along with rest

tremor and/or rigidity), prominent asymmetry, and a good response to dopaminergic therapy. For the diagnosis of PD, other conditions must be reasonably excluded (see Table 59-1). Medication-induced parkinsonism can mimic PD and is the second most common form of parkinsonism. It is important to assess for recent use of medications, especially drugs that block D_2 receptors, such as antipsychotics (eg, haloperidol), metoclopramide, or phenothiazine antiemetics (eg, prochlorperazine).[15] Neurologic conditions that can be mistaken for PD include atypical parkinsonisms and tremor disorders (eg, dystonic tremor, essential tremor). Because the management and prognosis of PD differs from these other conditions, obtaining an accurate diagnosis is important. When the diagnosis is in doubt, referral to a movement disorders specialist is recommended. Currently, efforts are underway to develop and validate diagnostic tools based on personalized clinical, laboratory, imaging, and genomics data.

TABLE 59-1 Diagnostic Criteria and Differential Diagnosis for Parkinson Disease

Parkinson Disease

Step 1: Presence of bradykinesia and at least one of the following: resting tremor, rigidity, or postural instability

Step 2: Exclude other types of parkinsonism or tremor disorders (see Differential Diagnosis)

Step 3: Presence of at least three supportive positive criteria:

- Asymmetry of motor signs/symptoms
- Unilateral onset
- Progressive disorder
- Resting tremor
- Excellent response to carbidopa/L-dopa
- L-dopa response for 5 years or longer
- Presence of L-dopa dyskinesias

Differential Diagnosis

Essential tremor

Pharmacotoxicity (drug-induced)

Antiemetics (eg, metoclopramide, prochlorperazine)

Antipsychotics (eg, chlorpromazine, fluphenazine, haloperidol, olanzapine, risperidone, thioridazine)

Other drugs (α-methyldopa, cinnarizine, flunarizine, tetrabenazine)

Environmental toxicity (eg, manganese, organophosphates)

Infections (eg, human immunodeficiency virus, subacute sclerosing panencephalitis)

Metabolic disorder (eg, hypothyroidism, parathyroid abnormalities)

Neoplasms, strokes, traumatic lesions involving the nigrostriatal pathways

Normal-pressure hydrocephalus

Parkinsonism with other neuronal system degenerations

  Corticobasal ganglionic degeneration

Dementia with Lewy bodies

Multiple-system atrophies

Progressive supranuclear palsy

Familial (hereditary) parkinsonism

  Autosomal dominant

    α-Synuclein gene mutation (*PARK1* and *PARK4*)

  L-responsive dystonia

  Leucine-rich repeat kinase 2 (LRRK2) mutation

  Rapid-onset dystonia parkinsonism (DYT12)

  Spinocerebellar ataxias (SCA2, SCA3)

Autosomal recessive

  Wilson disease

  Young-onset parkinsonism (DJ-1, parkin, PINK1)

X-linked recessive

  Fragile X tremor/ataxia syndrome (FXTAS)

  Lubag (DYT3 or Filipino dystonia parkinsonism)

PD develops insidiously and progressively worsens over many years. Tremor of an upper extremity occurring at rest (and occasionally an action or postural tremor) is often the sole presenting complaint; however, only two-thirds of patients with PD have tremor on diagnosis, and some never develop this sign. Tremor in PD is present most commonly in the hands, sometimes with a

characteristic pill-rolling motion. Less commonly, tremor may involve the jaw or legs. Like other motor features of PD, resting tremor often begins unilaterally and becomes bilateral with disease progression. Stressful or emotional (either negative or positive) situations often increase the tremor amplitude and severity. Usually, tremor is absent during sleep. Although resting tremor is visibly noticeable in PD and may cause social embarrassment for the patient, it often is the least physically disabling of the motor features.

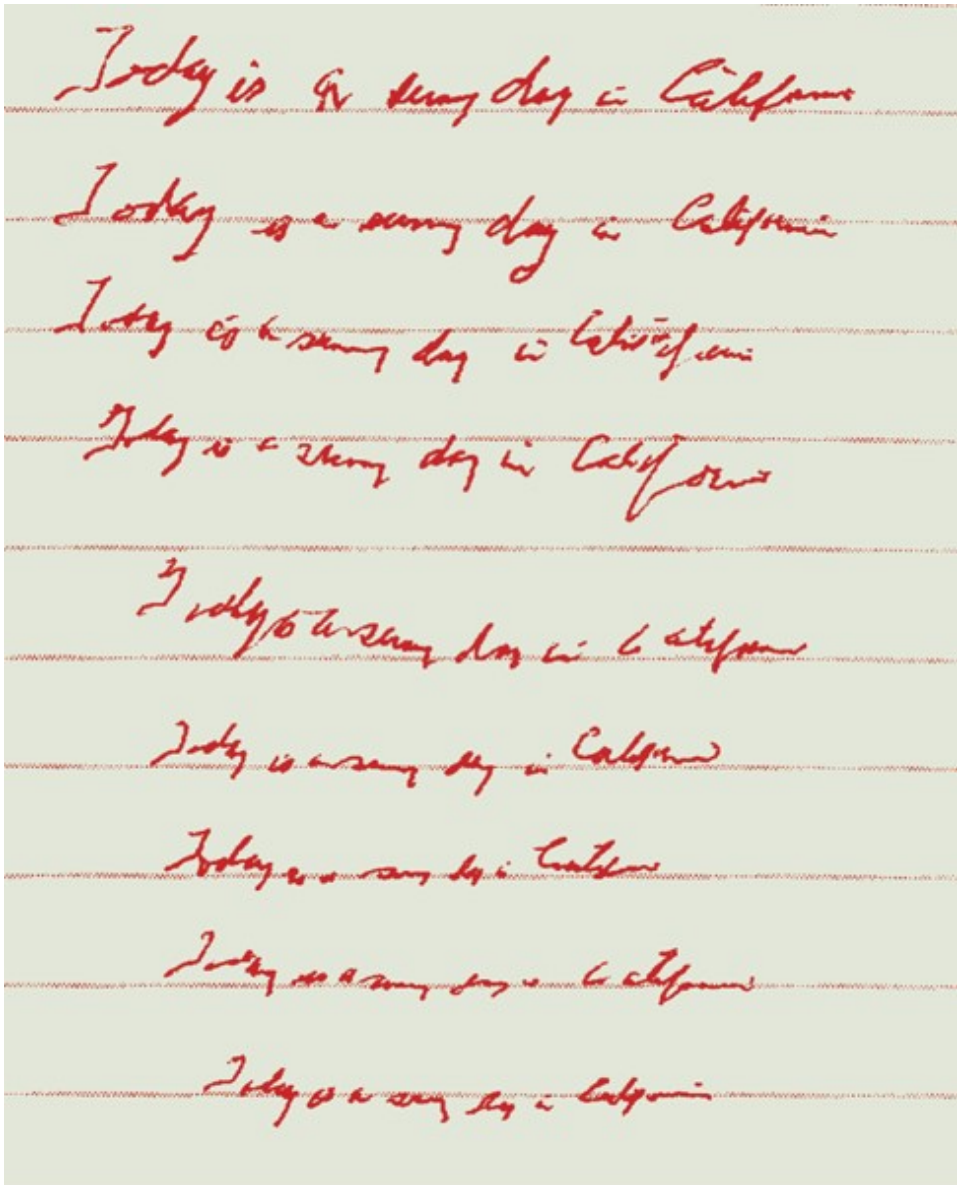
Rigidity is the increased muscular resistance to passive range of motion and most commonly affects the upper and lower extremities, and occasionally the neck. If tremor is present in the affected extremity, the rigidity is associated with a cogwheel or ratchet-like quality upon examination. Facial muscles also are affected, resulting in hypomimia that may be erroneously interpreted as apathy, depression, or unfriendliness.

Hypokinesia is decreased movement and often described as either bradykinesia (slowness of movement) or akinesia (absence of movement). Movement in PD is often slow throughout an intended action, and difficulty with the initiation of movement also occurs. A progressive slowing and decline in dexterity may impair tasks such as hand clapping, finger tapping, and handwriting (**Fig. 59-3**). Intermittent immobility or akinesia (freezing) is another common characteristic. Freezing is especially likely to occur in situations such as when walking through a narrow doorway or initiating a turn.

Currently, the clinical diagnosis of PD relies on motor findings; however, researchers have identified markers associated with the premotor stage of PD, such as REM sleep behavior disorder, and olfactory impairment.[16] Such markers may someday aid in very early detection of PD (before onset of motor impairment).

FIGURE 59-3

Example of micrographia in a patient with Parkinson disease. As the sentence, “Today is a sunny day in California” is repeatedly handwritten, progressive diminution of letter size occurs (micrographia). The height of each lined row is approximately 5/16 inches (8 mm). *(Used with permission from Jack J. Chen, PharmD.)*



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Postural instability, most common in advanced stages of PD, is one of the most disabling problems of PD because it increases the fall risk and is least amenable to pharmacotherapy. Testing for impaired postural responses by means of the pull test (in which a patient is unable to recover balance after sudden backward displacement at the shoulders) can help identify the risk for falling. Many patients with impaired postural responses also have tendencies for propulsive gait with difficulty halting their steps while in motion (festination) and freezing, which also increases the risk of falling.

Nonmotor symptoms are common in PD and must be identified, assessed, managed, and monitored (**Table 59-2**). These include anxiety, cognitive impairment, constipation, daytime sleepiness, depression, drooling, dysphagia, falling, fatigue, impulsivity, insomnia, orthostatic hypotension, overactive bladder, pain, hallucinations/psychosis, REM sleep behavior disorder, and restless legs syndrome.[17] As a component of managing these nonmotor symptoms, it is important to maintain continuous surveillance of prescription and nonprescription medications for potential side effects

that can exacerbate, mimic, or precipitate nonmotor symptoms. If feasible, any identified offending medication should be removed.

TABLE 59-2 Nonmotor Symptoms and Possible Treatments

Symptom	Possible Treatments
Anxiety	Cognitive behavioral therapy, selective serotonin reuptake inhibitors, venlafaxine, minimize "off" times.
Cognitive impairment	Eliminate anticholinergic agents. Add cholinesterase inhibitor.
Constipation	Fiber, hydration, exercise, laxatives, stool softeners.
Daytime sleepiness	Proper night time sleep hygiene, reduce dose of dopamine agonist, referral to sleep specialist to rule out apnea and sleep disorders.
Depression	Selective serotonin reuptake inhibitor, newer-generation serotonin norepinephrine reuptake inhibitor, cognitive behavioral therapy.
Drooling	Local injection of botulinum toxin, atropine sublingual drop, glycopyrrolate, ipratropium sublingual spray.
Dysphagia	Referral to speech therapist, dysphagia diet, avoid anticholinergic medications, manage dry mouth.
Fatigue	Caffeine, armodafinil, modafinil, proper night time sleep hygiene, referral to sleep specialist to rule out sleep disorder.
Falling	Referral to physical therapy; assistance with ambulation, minimize risk for bone fractures, treat osteoporosis.
Hallucinations/psychosis	Eliminate adjunctive medications, especially anticholinergic agents and dopamine agonists. Add clozapine, quetiapine, pimavanserin.
Impulse control disorder	Discontinue dopamine agonist or add clozapine, quetiapine, or naltrexone
Insomnia	Nonbenzodiazepine $GABA_A$ agonists, trazodone.
Orthostatic hypotension	Reduce dose of alpha-blockers, dopamine agonist, diuretics, vasodilators. Abdominal compression, add salt and water to diet, water boluses, fludrocortisone, midodrine, droxidopa, pyridostigmine.
Overactive bladder	Behavioral therapies (eg, bladder training, fluid management, pelvic floor muscle exercises), antimuscarinic agents, mirabegron, intradetrusor injections of botulinum toxin.
Pain	Treatment as per type of pain (eg, dystonic, musculoskeletal, neuropathic), minimize "off" times, appropriate referral to orthopedics, physical therapy, pain specialist, rheumatology.
REM sleep behavior disorder	Clonazepam, melatonin.
Restless legs syndrome	Dopamine agonist at bedtime; gabapentin.

GABA, γ-aminobutyric acid; REM, rapid eye movement.

TREATMENT

Desired Outcomes

The goal in the management of PD is to improve motor and nonmotor symptoms so that patients are able to maintain the best possible quality of life.[18] Specific objectives to consider when selecting an intervention include preservation of the ability to perform activities of daily living; employment; improvement of mobility; minimization of adverse effects and treatment complications, putative disease modification; and improvement of nonmotor features. To accomplish some of these objectives, consultation with a specialist is helpful (eg, movement disorders, pharmacotherapy, physical therapy, psychiatry, and sleep medicine).

General Approach to Treatment

1 2 Awareness and surveillance of motor and nonmotor symptoms in combination with thoughtful selection of initial and adjunctive therapies with adjustment of drug dosing throughout the course of PD is required to optimize long-term therapeutic outcomes, minimize adverse effects, and improve quality of life. The optimal time to start drug therapy in PD varies, but in general, treatment should be initiated when the disease begins to interfere with activities of daily living, employment, or quality of life. **Figure 59-4** illustrates a general treatment approach for early and advanced PD. **Table 59-3** summarizes antiparkinsonian medications and dosing, and **Table 59-4** summarizes monitoring parameters for potential adverse reactions. Treatment guidelines and monographs are updated frequently to keep up with new information and changes in treatment paradigms.[17,19,20,21] Additionally, general guidelines and recommendations for geriatric health maintenance and disease prevention (eg, bone health, routine vaccinations, vitamin and mineral supplementations) should also be observed.

FIGURE 59-4

General approach to the management of early to advanced Parkinson disease. *Age is not the sole determinant for drug choice. Other factors such as cognitive function and overall tolerability of drug (especially in the elderly) should be considered.

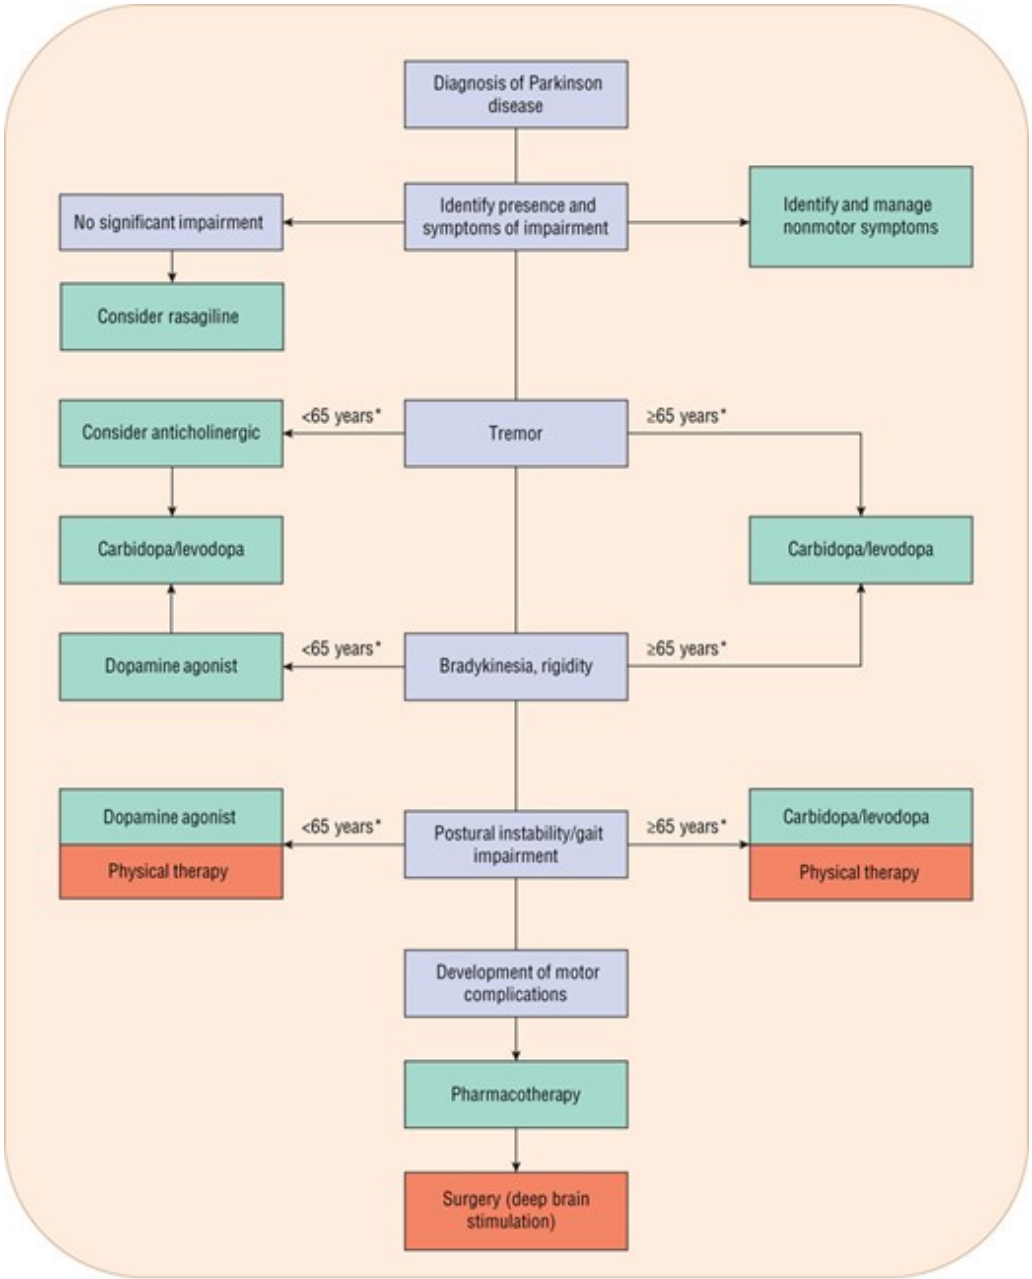


TABLE 59-3 Dosing of Drugs Used in Parkinson Disease[a]

Generic Name	Trade Name	Starting Dose[b] (mg/day)	Maintenance Dose[b] (mg/day)	Dosage Forms (mg)
Anticholinergic Drugs				
Benztropine	Cogentin	0.5-1	1-6	0.5, 1, 2
Trihexyphenidyl	Artane	1-2	6-15	2, 5, 2/5 mL
Carbidopa/Levodopa Products

COMT, catechol-*O*-methyltransferase; CR, controlled release; IR/ER, immediate-release/extended-release; MAO, monoamine oxidase; ODT, orally disintegrating tablet.

[a]Marketed in the United States for Parkinson disease.

[b]Dosages may vary.

[c]Dosages expressed as L-dopa component.

[d]Dosages of Rytary were developed to avoid confusion with other oral carbidopa/L-dopa products that contain L-dopa in multiples of 50 mg.

[e]Dosages expressed as entacapone component.

[f]Sterile solution of subcutaneous injection with supplied pen injector.

TABLE 59-4 Monitoring of Potential Adverse Reactions to Drug Therapy for Parkinson Disease

Generic Name	Adverse Drug Reaction	Monitoring Parameter	Comments
Amantadine	Confusion	Mental status; renal function	Reduce dosage; adjust dose for renal impairment
	Livedo reticularis	Lower extremity examination; ankle edema	Reversible upon drug discontinuation
Benztropine	Anticholinergic effects, confusion, drowsiness	Dry mouth, mental status, constipation, urinary retention, vision	Reduce dosage; avoid in elderly and in those with a history of constipation, memory impairment, urinary retention
Trihexyphenidyl	See benztropine	See benztropine	See benztropine
Carbidopa/L-dopa	Drowsiness	Mental status	Reduce dose
	Dyskinesias	Abnormal involuntary movements	Reduce dose; add amantadine
	Nausea	Nausea	Take with food
COMT Inhibitors			
Entacapone	Augmentation of L-dopa side effects; also diarrhea	See carbidopa/L-dopa; also bowel movements	Reduce dose of L-dopa; antidiarrheal agents
Tolcapone	See entacapone; also liver toxicity	See carbidopa/L-dopa; also ALT/AST	See carbidopa/L-dopa; also at start of therapy and for every dose increase, ALT and AST levels at baseline and every 2-4 weeks for the first 6 months of therapy; afterward monitor based on clinical judgment.
Dopamine Agonists			

Generic Name	Adverse Drug Reaction	Monitoring Parameter	Comments
Apomorphine	Drowsiness	Mental status	Reduce dose
	Nausea	Nausea	Premedicate with trimethobenzamide
	Orthostatic hypotension	Blood pressure, dizziness upon standing	Reduce dose
Bromocriptine	See pramipexole; also pulmonary fibrosis	Mental status; also chest radiograph	Reduce dose; chest radiograph at baseline and once yearly
Pramipexole	Confusion	Mental status	Reduce dose
	Drowsiness	Mental status	Reduce dose
	Edema	Lower extremity swelling	Reduce dose or discontinue medication
	Hallucinations/delusions	Behavior, mental status	Reduce dose or discontinue medication
	Impulsivity	Behavior	Discontinue medication
	Nausea	Nausea	Titrate dose upward slowly; take with food
	Orthostatic hypotension	Blood pressure, dizziness upon standing	Reduce dose
Ropinirole	See pramipexole	See pramipexole	See pramipexole
Rotigotine	See pramipexole; also skin irritation at site of patch application	See pramipexole; also skin examination	See pramipexole; rotate patch application site
MAO-B Inhibitors			
Rasagiline	Nausea	Nausea	Take with food
Selegiline	Agitation/confusion	Mental status Sleep	Reduce dose
	Insomnia	Behavior, mental status	Administer dose earlier in day
	Hallucinations		Reduce dose
	Orthostatic hypotension	Blood pressure, dizziness upon standing	Reduce dose

ALT, alanine aminotransferase; AST, aspartate aminotransferase; COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase.

Clinical Controversy…

For younger patients with mild PD, the question of when to initiate l-dopa therapy is a matter of debate. Proponents for the l-dopa sparing strategy cite evidence indicating that (1) this approach is associated with a reduced risk of developing motor complications, such as fluctuations and dyskinesias and (2) initial monotherapy with a dopamine agonist or MAO-B inhibitor provides benefits that are sufficient for symptomatic management of mild PD. Opponents of this strategy recommend that l-dopa should be the drug of choice for initial therapy in mild PD because (1) l-dopa is inexpensive, more effective, and potent; (2) dopamine agonists are associated with more side effects; and (3) once l-dopa is added, dopamine agonists no longer provide a preventive effect on development of motor complications. For older patients (ie, older than 65 years), most clinicians would agree that initial therapy should begin with l-dopa. Overall, clinical necessity and not age should be the major deciding factor for selection of initial drug therapy. Ultimately, the best approach for guiding therapeutic interventions is to take into consideration the patient's disability, comorbidities, and potential side effects and to align decisions with the patient's goals and expectations.

Nonpharmacologic Therapy

Surgical Therapy

3 Currently, surgery should be considered an adjunct to pharmacotherapy when patients are experiencing frequent motor fluctuations or disabling dyskinesia or tremor despite an optimized medical regimen. There are several patient-selection criteria for surgery, including a diagnosis of l-dopa–responsive PD and absence of cognitive impairment. Anatomic targets include the thalamus, GPi, and the subthalamic nucleus (STN). Bilateral, chronic, high-frequency electrical stimulation, also known as deep-brain stimulation (DBS), is the preferred surgical modality.[22]

In DBS surgery, a battery-powered neurostimulator is implanted subcutaneously below the clavicle and provides constant electrical stimulation, via electrode wires, to the targeted brain structure. Thalamic DBS is very effective for suppressing tremor (specifically arm tremor), but it does not significantly improve the other parkinsonian features (bradykinesia, rigidity, motor fluctuations, or dyskinesias). Both STN and GPi DBS are associated with improvements in tremor, rigidity, bradykinesia, motor fluctuations, dyskinesia, and activities of daily living, however, STN DBS allows for greater reduction in medications.[23]As with pharmacotherapy, DBS uncommonly improves gait or postural instability.

DBS procedures require routine adjustment of the electrical stimulation parameters (eg, voltage, frequency, and pulse width) to achieve optimal control while minimizing side effects. The electrical stimulation parameters (or "electrical dosage") are adjusted via a programmable handheld device to meet each patient's needs and are performed by physicians as well as other trained individuals, including nurse practitioners and clinical pharmacists.

Cell-based restorative procedures such as implantation of dopamine-producing cells (ie, human fetal mesencephalon tissue or retinal pigmented epithelial cells) into the striatum have yielded disappointing clinical results.[24] However, other biotherapies, such as stem cell and gene-based approaches, are currently under investigation and remain highly experimental. Of note, gene delivery of neurotrophic factor directly into the putamen and substantia nigra in patients with advanced PD has not demonstrated benefit.[25]

Pharmacologic Therapy

Anticholinergic Medications

4 Because dopamine provides negative feedback to acetylcholine neurons in the striatum, the degeneration of nigrostriatal dopamine neurons also results in a relative increase of striatal cholinergic interneuron activity. This increased cholinergic activity is believed to contribute to the tremor of PD. The anticholinergic drugs (eg, benztropine and trihexyphenidyl) are considered effective against tremor, but no more so than dopaminergic agents.[18] Sometimes dystonic symptoms associated with PD are also improved by anticholinergic agents. Use of anticholinergic agents is limited due to the development of intolerable side effects (eg, anticholinergic effects), necessitating drug discontinuation. Common adverse effects include blurred vision, confusion, constipation, dry mouth, memory difficulty, sleepiness, and urinary retention (see Table 59-4). Younger patients are better able to tolerate anticholinergic side effects, whereas, this drug class is avoided in patients with advanced age, preexisting cognitive deficits, and dysphagia.

Amantadine

5 Although amantadine can be used for managing tremor, rigidity, and bradykinesia, it is most often used for management of l-dopa–induced dyskinesia.[21] Amantadine is typically administered 300 mg/day in divided doses. An amantadine controlled-release formulation (ADS-5102) is in Phase III testing for treatment of l-dopa–induced dyskinesias. The precise mechanism of action of amantadine for management of PD is unknown, but enhancement of dopamine release from presynaptic terminals and inhibition of glutamatergic *N*-methyl-d-aspartate (NMDA) receptors are implicated. The antidyskinetic properties of amantadine are presumed to be mediated by antiglutamate properties which, in the setting of dyskinesias, appears to dominate over dopaminergic properties. Amantadine is eliminated renally, and a reduced dose should be administered when renal dysfunction is present (100 mg/day with creatinine clearances of 30-50 mL/min [0.50-0.84 mL/s], 100 mg every other day for creatinine clearances of 15-29 mL/min [0.25-0.49 mL/s], and 200 mg every 7 days for creatinine clearances of less than 15 mL/min [0.25 mL/s], and patients on hemodialysis).

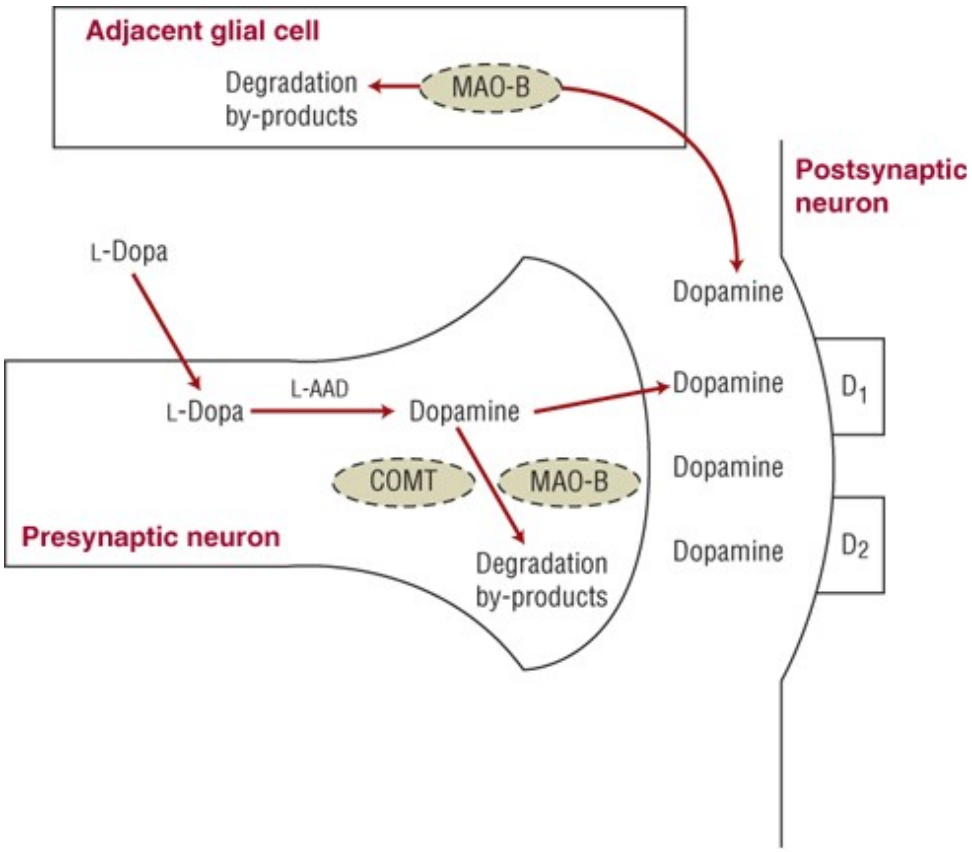
Side effects of amantadine include confusion, dizziness, dry mouth, and hallucinations. The elderly are particularly prone to develop confusion. Not uncommonly, amantadine may cause livedo reticularis, a reversible condition characterized by diffuse mottling of the skin affecting the upper or lower extremities and often accompanied by lower-extremity edema (see Table 59-4).

Carbidopa/l-Dopa

L-Dopa is the immediate precursor of dopamine and, in combination with a peripherally acting L-amino acid decarboxylase inhibitor (carbidopa or benserazide), remains the most effective drug for the symptomatic treatment of PD.[21] In the United States, L-Dopa is combined with carbidopa. L-Dopa crosses the blood–brain barrier, whereas carbidopa does not. Carbidopa reduces the unwanted peripheral conversion of L-dopa to dopamine. As a result, increased amounts of L-dopa are transported into the brain, and peripheral adverse effects of dopamine, such as nausea, are reduced. In the SNc, L-dopa is converted to dopamine by the enzyme L-amino acid decarboxylase and inactivated by the enzymes MAO and catechol-*O*-methyltransferase (COMT) (**Figs. 59-1** and **59-5**).

FIGURE 59-5

Dopamine synthesis and metabolism within the striatal neurons. See also Fig. 59-1 for additional details. (COMT, catechol-*O*-methyl transferase; D_1–D_2, dopamine receptors; L-AAD, L-aromatic amino acid decarboxylase; L-Dopa, levodopa; MAO-B, monoamine oxidase B.)



Regardless of what the initial therapeutic agent is, ultimately all patients with PD will require L-dopa. With regard to carbidopa, about 75 mg/day is required to sufficiently inhibit the peripheral activity of L-amino acid decarboxylase, but some patients require more. Therefore, the usual initial maintenance carbidopa/L-dopa regimen is 25/100 mg three times daily. As the motor features of PD become progressively more severe, use of higher dosages is required. There is no maximum

allowable total daily L-dopa dose; however, in patients with severe PD, the usual maximal dose tolerated is approximately 1,000 to 1,500 mg/day. Slow buildup of dose (eg, increments of 100 mg L-dopa per week) can help minimize treatment-emergent side effects, such as drowsiness and nausea (see Table 59-4).

For patients with difficulty swallowing intact tablets, an orally disintegrating tablet (ODT) preparation of carbidopa/L-dopa is available. Although the ODT formulation rapidly dissolves on contact with saliva, the carbidopa/L-dopa does not undergo transmucosal absorption and the dissolved drug in saliva must be swallowed for absorption in the proximal duodenum. Additionally, carbidopa/L-dopa is available in a capsule formulation containing immediate-release (IR) and extended-release (ER) beads (ie, Rytary) which can be sprinkled on food (eg, apple sauce).

Pharmacokinetics

There is marked intra- and intersubject variability in the time to peak plasma concentrations after oral carbidopa/L-dopa, and this may in part be attributed to differences in gastric emptying. L-Dopa is absorbed in the proximal duodenum by a saturable large neutral amino acid transport system. Competition for this transporter by dietary (or pharmaceutical) large neutral amino acids (eg, leucine, phenylalanine) may result in reduced L-dopa bioavailability. However, for patients with early PD, this interaction is generally not significant.

L-Dopa is not bound to plasma proteins. Active transport across the blood–brain barrier also occurs by the large neutral amino acid transporter system. In advanced PD, special diets involving protein restriction may improve L-dopa responsiveness and are sometimes implemented. A metabolite of L-dopa, 3-*O*-methyldopa, also competes for transport, but it is not clear how this affects L-dopa clinical response.

When peripheral decarboxylation of L-dopa is inhibited by carbidopa, 3-*O*-methylation (via COMT) becomes the predominant catabolic pathway. The elimination half-life of L-dopa is about 1 hour, and this is extended to about 1.5 hours with the addition of carbidopa. With the addition of a COMT inhibitor such as entacapone to carbidopa/L-dopa, the elimination half-life is extended to about 2 to 2.5 hours.

It is important to note that the controlled release (ie, Sinemet CR) and IR/ER carbidopa/L-dopa formulations (ie, Rytary) are 70% and 75% bioavailable, respectively, compared to standard IR carbidopa/L-dopa. Manufacturer-provided dosage conversion recommendations are available to guide dosing conversions between carbidopa/L-dopa formulations.

Motor Complications of L-Dopa

Long-term L-dopa therapy is associated with a variety of motor complications, of which end-of-dose "wearing off" (motor fluctuations) and L-dopa peak-dose dyskinesias are the two most commonly encountered.[26] These motor complications can become disabling and a challenge to manage. The approximate risk of developing either motor fluctuations or dyskinesia is 10% per year of L-dopa therapy.[27,28] However, motor complications can occur as early as 6 months after starting L-dopa

therapy, especially if excessive doses are used initially.[29] **Table 59-5** lists the common motor complications associated with long-term treatment with L-dopa and suggested initial management strategies. Initiating therapy with the CR form of carbidopa/L-dopa (ie, Sinemet CR) does not reduce the development of motor complications compared with IR carbidopa/L-dopa.[19]

TABLE 59-5 Common Motor Complications and Possible Initial Treatments

Effect	Possible Treatments
End-of-dose "wearing off" (motor fluctuation)	Increase frequency of carbidopa/L-dopa doses; add either COMT inhibitor or MAO-B inhibitor or dopamine agonist; add or switch to extended release carbidopa/L-dopa (ie, Rytary)
"Delayed on" or "no on" response	Give carbidopa/L-dopa on empty stomach; use carbidopa/L-dopa ODT; avoid carbidopa/L-dopa SR; use apomorphine subcutaneous
Start hesitation ("freezing")	Increase carbidopa/L-dopa dose; add a dopamine agonist or MAO-B inhibitor; utilize physical therapy along with assistive walking devices or sensory cues (eg, rhythmic commands, stepping over objects)
Peak-dose dyskinesia	Provide smaller doses of carbidopa/L-dopa; reduce dose of adjunctive dopamine agonist; add amantadine

COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase; ODT, orally disintegrating tablet; SR, sustained release.

End-of-Dose Wearing Off

The terms "off" and "on" refer to periods of poor movement (ie, return of tremor, rigidity, or slowness) and good movement, respectively. End-of-dose wearing off prior to a dose of medication is a common type of response fluctuation. This phenomenon is related to the increasing loss of neuronal storage capability for dopamine as well as the short half-life of L-dopa. Initially, exogenous L-dopa is taken up by the remaining SNc neurons, converted to dopamine, and stored in synaptic vesicles. With progressive loss of SNc neurons and storage capacity, patients become more dependent on exogenous carbidopa/L-dopa. Hence the peripheral pharmacokinetic properties of L-dopa increasingly become the determinant of central dopamine synthesis. With advancing PD, the duration of action of a single carbidopa/L-dopa dose progressively shortens, and in some cases may produce benefits for as little as 1 hour. As a result, carbidopa/L-dopa needs to be given more frequently. In addition to administering L-dopa doses more frequently, other options are available (see Table 59-5). In particular, the addition of the COMT inhibitor entacapone or the MAO-B inhibitor rasagiline extends the action of L-dopa, and either should be considered.[19] A dopamine agonist (eg, pramipexole, ropinirole, or rotigotine) also can be added to a carbidopa/L-dopa regimen for management of wearing off. The older CR L-dopa product (ie, Sinemet CR) has been investigated for management of motor fluctuations, but the evidence is not compelling.[19] A newer IR/ER carbidopa/L-dopa formulation (ie, Rytary) contains beads that dissolve at different rates. Following administration, therapeutic L-dopa levels are rapidly achieved and are maintained for 4 to 5 hours providing efficacy for management of motor fluctuations.[30] Also in development, is a novel controlled-release, biodegradable, gastroretentive dosage form consisting of a carbidopa/L-

dopa-polymer matrix strip folded like an accordion within a capsule. After administration, the "accordion" strip unfolds and is retained in the stomach due to its larger unfolded dimension which prevents passage through the pyloric sphincter.

Carbidopa/l-dopa enteral suspension is effective and safe for patients with advanced PD experiencing persistent, on/off fluctuations.[31] This carbidopa/l-dopa enteral suspension is contained within a medication cassette reservoir and infusion into the small intestine is achieved by a portable pump device. This treatment is semi-invasive as it requires placement, through the abdominal wall, of a percutaneous endoscopic gastrostomy tube along with a jejunal extension. The drug infusion typically runs for 16 continuous hours per day and is turned off at night.

For acute off episodes, a subcutaneously administered short-acting dopamine agonist, apomorphine, provides a rapid onset of effect (within 20 minutes), and it is administered as needed.[32] An investigational l-dopa inhaled powder formulation (CVT-301) is in clinical testing and administered "as needed" for acute off episodes. Although not commonly performed, sipping small amounts of carbidopa/l-dopa solution very frequently throughout the day is also a method for managing on/off fluctuations. A solution that is stable for 72 hours at room temperature can be prepared by adding 10 crushed tablets of carbidopa/l-dopa 10/100 (or 25/100) mg and 2 g crystalline ascorbic acid to 1 L of water.[33]

Often, off episodes occur during the night, and patients will awaken in an off state (as a consequence of an overnight decline of drug levels). Bedtime administration of a dopamine agonist or a drug formulation that provides sustained drug levels overnight (eg, carbidopa/l-dopa CR or IR/ER, ropinirole XL, pramipexole ER, rotigotine transdermal patch) can help reduce nocturnal off episodes and improve functioning upon awakening.

Nonadherence to medications also contributes to the frequency of off episodes. Therefore, engaging and supporting patients and caregivers in overcoming barriers to medication adherence is important.

"Delayed-On" and "No-On" Response

"Delayed-on" or "no-on" (a delayed or absent onset of drug effect, respectively) responses to individual doses of carbidopa/l-dopa can be a result of delayed gastric emptying or decreased absorption in the duodenum. Chewing a tablet or crushing it and then drinking a full glass of water or using the ODT formulation on an empty stomach can help mitigate effects of delayed gastric emptying. Additionally, subcutaneously administered apomorphine may be used as rescue therapy for delayed-on or no-on periods. A drug-free period ("drug holiday") may be initiated in an attempt to modify postsynaptic dopamine receptors and thus decrease unpredictable off states. Although not commonly performed because of discomfort (to the patient) and medical risks, when drug holidays are performed, it should be under close medical supervision.

Freezing

"Freezing," or a sudden, episodic akinesia of the lower extremities, may occur and will interfere with ambulation and increase the risk of falls. Patients may report that their "feet suddenly feel stuck to the floor" during ambulation or that they have difficulty initiating steps (start hesitation) or turns (turn

hesitation). Freezing often is exacerbated by anxiety or when perceived obstacles (eg, doorways, turnstiles) are encountered. Management consists of physical therapy along with use of assistive walking devices and sensory cues.

Dyskinesias

Another complication of l-dopa therapy is "on" period dyskinesias (involuntary choreiform movements involving usually the neck, trunk, and lower/upper extremities). Among all the antiparkinson medications, dyskinesias are specific to l-dopa therapy. If patients report "shakiness," it is important to clarify if they are referring to tremor or dyskinesias. Dyskinesias usually are associated with peak striatal dopamine levels (peak-dose dyskinesia) and, simplistically, can be thought of as too much movement secondary to extension of the l-dopa pharmacologic effect. Lowering the dose of carbidopa/l-dopa to counteract dyskinesias should be attempted. However, the use of a lower dose may result in suboptimal control of parkinsonian features, thus, necessitating addition of another antiparkinson agent (eg, dopamine agonist). Glutamate overactivity may also be involved, as suggested by the dyskinesia improvement observed with amantadine (NMDA receptor antagonist) and other antiglutamate ligands.[34] Less commonly, dyskinesias also can develop during the rise and fall of l-dopa effects (the dyskinesia–improvement–dyskinesia or diphasic pattern of response). For severe dyskinesias (despite pharmacologically optimized therapy), surgery should be considered.

"Off-Period" Dystonia

In PD, dystonias (sustained muscle contractions) can occur and more commonly affect a distal lower extremity (eg, clenching of toes or involuntary turning of a foot). Dystonias often occur in the early morning hours (as a result of waning drug levels) and improve with the first carbidopa/l-dopa dose of the day. Remedies for early morning dystonia include bedtime administration of a long-acting dopamine agonist, long-acting carbidopa/l-dopa, or baclofen. Additionally, focal injections of botulinum toxin type A or B are effective for persistent focal dystonias. Focal dystonias can also occur as l-dopa peak dose effect and management is similar to that of dyskinesias.

Monoamine Oxidase B Inhibitors

5 Two selective MAO-B inhibitors, rasagiline and selegiline, are available for management of PD. The selective inhibition of MAO-B in the brain interferes with the degradation of dopamine and results in prolonged dopaminergic activity. Both drugs contain a propargylamine moiety, which is essential for conferring irreversible ("suicide") inhibition of MAO-B. At therapeutic doses, these agents preferentially inhibit MAO-B over MAO-A.

A common concern with use of these agents is the potential for interactions with drugs that possess serotonergic activity. Concomitant use of MAO-B inhibitors with meperidine and other selected opioid analgesics is contraindicated because of a small risk of serotonin syndrome. However, concomitant use of serotonergic antidepressants is not contraindicated, and these drugs can be used concomitantly when clinically warranted.[35]

5 8 Selegiline, also known as l-deprenyl, is marketed for extending l-dopa effects and is typically

administered 5 mg twice daily. Selegiline is also available as an ODT formulation administered 1.25 to 2.5 mg once daily. A transdermal formulation of selegiline is also available but is not indicated for PD. As monotherapy in early PD, selegiline provides modest improvements in motor function.[2] In advanced PD, adjunctive use of selegiline can provide up to 1 hour of extra on time for patients with wearing off, although the data are inconsistent.[19] This inconsistent effect may be explained, in part, by poor and erratic bioavailability of selegiline.

As an amphetamine pharmacophore, selegiline undergoes first-pass hepatic metabolism (predominantly via cytochrome P450 [CYP450] 2B6 and 2C19) to end products of L-methamphetamine and L-amphetamine. Adverse effects of selegiline are minimal but can include agitation, insomnia (especially if administered at bedtime), hallucinations, and orthostatic hypotension (see Table 59-4). Selegiline also increases the peak effects of L-dopa and can worsen preexisting dyskinesias or psychiatric symptoms such as delusions. With the selegiline ODT formulation, first-pass hepatic metabolism is bypassed as a consequence of transmucosal absorption of the drug. Hence, bioavailability is improved and formation of amphetamine metabolites is reduced.

5 8 Rasagiline is a second-generation, irreversible, selective MAO-B inhibitor administered at 0.5 or 1 mg once daily.[36] Rasagiline is effective as monotherapy in early PD and also as add-on therapy for managing motor fluctuations in advanced PD. For the management of motor fluctuations, the efficacy of rasagiline appears similar to that of entacapone, offering approximately 1 hour of extra on time during the day. Consequently, when an adjunctive agent is required for managing motor fluctuations, rasagiline is considered a first-line agent (as is entacapone).[19] Rasagiline is well tolerated with minimal gastrointestinal (GI) or neuropsychiatric side effects. Rasagiline is metabolized by hepatic CYP1A2 to aminoindan, which is inactive and devoid of amphetamine-like properties.[36]

MAO-B inhibitors with a propargylamine molecular scaffolding have been investigated for neuroprotective properties (clinically referred to as *disease modification*). MAO-B inhibitors possess antiapoptotic properties, and MAO-B inhibition diverts dopamine degradation to an alternate route (ie, COMT) that does not generate free radicals (see Figs. 59-1 and 59-5). To date, clinical studies to demonstrate disease modification with MAO-B inhibitors have yielded inconclusive results.

Clinical Controversy…

The optimal timing to initiate drug therapy in patients newly diagnosed with PD is a subject of debate. The traditional approach is to initiate symptomatic therapy when there is evidence of functional impairment. However, others believe that early treatment with a dopaminergic agent, in the absence of functional impairment, acts to alleviate stress on intrinsic compensatory mechanisms, and greater long-term benefit is derived. Randomized controlled studies designed to specifically address this approach have not been conducted, and there is insufficient information on whether treatment in the absence of functional impairment has an acceptable risk-benefit profile or whether this is cost-effective.

Catechol-*O*-Methyltransferase Inhibitors

8 Two COMT inhibitors, entacapone and tolcapone, have been developed to extend the effects of l-dopa and are indicated for managing wearing off. Both reduce the peripheral conversion of l-dopa to dopamine, thus enhancing central l-dopa bioavailability. Consequently, in the absence of l-dopa, they have no effect on PD symptoms. COMT inhibitors increase l-dopa area under the curve by approximately 35% and, for patients with wearing off, can increase on time by about 1 to 2 hours.[19]

Tolcapone inhibits both peripheral and central COMT. Its use is limited by reports of fatal hepatotoxicity, such that strict monitoring of hepatic function, especially during the first 6 months of therapy, is required (see Table 59-4). Because of the hepatotoxicity risk, tolcapone is reserved for patients with fluctuations that are not responding to other therapies.

Entacapone has a shorter half-life than tolcapone, and 200 mg needs to be given with each dose of carbidopa/l-dopa up to a maximum of eight times per day. A triple-combination product of carbidopa/l-dopa/entacapone offers convenience for some patients (ie, fewer tablets to administer). Unlike tolcapone, entacapone is not associated with hepatotoxicity. Entacapone is considered one of the first-line choices for adjunctive therapy to manage motor fluctuations.[19]

With both agents, augmentation of dopaminergic adverse effects may occur and generally are manageable by reduction of the carbidopa/l-dopa dosage. Patients should be advised that other adverse effects include brownish-orange urinary discoloration and delayed onset of diarrhea (weeks to months later).

Dopamine Agonists

Dopamine agonists fall into two pharmacologic subtypes: ergot-derived agonists (bromocriptine) and the nonergot agonists (apomorphine, pramipexole, ropinirole, and rotigotine).[37] Nonergot dopamine agonists have a better safety profile and are more commonly used. Dopamine agonists stimulate dopamine receptors (eg, D_1, D_2, D_3) and are useful as monotherapy in mild-moderate PD, and also as adjuncts to carbidopa/l-dopa therapy to reduce off time in patients with motor fluctuations.[19]

10 Compared with long-term carbidopa/l-dopa therapy, dopamine agonist significantly reduce the risk of developing motor complications.[38,39] For younger patients, who are more likely to develop motor complications, dopamine agonists are preferred over carbidopa/l-dopa. For older patients, dopamine agonists should be used conservatively due to greater likelihood for development of intolerable side effects. For patients with cognitive problems or dementia, dopamine agonists should be avoided.

Common adverse effects of dopamine agonists include nausea, confusion, drowsiness, hallucinations, lower-extremity edema, and orthostatic hypotension (see Table 59-4). When initiating therapy, a slow dose titration is required to minimize development of adverse effects, particularly nausea. The addition of a dopamine agonist to carbidopa/l-dopa therapy also can induce dyskinesias, especially in patients with preexisting dyskinesias. Less common but serious adverse effects include impulsive and compulsive behaviors (eg, pathologic gambling or shopping; paraphilia), delusions/psychosis, and sleep attacks (sudden, unexpected episodes of sleep). Hallucinations and delusion should be

managed using a systematic approach that starts with dose reduction or discontinuation of the dopamine agonist, and if needed, addition of an atypical antipsychotic medication such as clozapine, pimavanserin, or quetiapine.[17,20] Involvement of caregivers in surveillance for potential adverse effects of dopamine agonists, particularly development of delusions, hallucinations, and impulsive behaviors, facilitates earlier detection and management.

Pramipexole is initiated at a dose of 0.125 mg three times a day and increased every 5 to 7 days, as tolerated, to a maximum of 1.5 mg three times a day. An extended-release pramipexole formulation is also available. Immediate-release ropinirole is initiated at 0.25 mg three times a day and increased by 0.25 mg three times a day on a weekly basis to a maximum of 24 mg/day. An extended-release ropinirole formulation also is available.

Pramipexole is renally excreted with an 8- to 12-hour half-life. The initial dosage must be adjusted in renal insufficiency (0.125 mg twice daily for creatinine clearances of 35-59 mL/min [0.58-0.99 mL/s], 0.125 mg once daily for creatinine clearances of 15-34 mL/min [0.25-0.57 mL/s]). Ropinirole has a 6-hour half-life and is metabolized by CYP1A2. Potent inhibitors (eg, fluoroquinolone antibiotics) and inducers (eg, cigarette smoking) of this enzyme likely will lead to alterations in ropinirole clearance. Rotigotine transdermal patch is initiated at 2 mg once daily and increased weekly by 2 mg increments to achieve desired therapeutic effect. The rotigotine transdermal patch provides continuous release of drug over a 24-hour period.[40] Patch application sites should be rotated to minimize skin irritation and rash. Rotigotine disposition is not affected by hepatic or renal impairment, and CYP-mediated drug interactions are not significant.

Apomorphine is an aporphine alkaloid originally derived from morphine, but lacks narcotic properties.[32] Because of poor oral bioavailability due to extensive hepatic first-pass metabolism, apomorphine is administered subcutaneously. Apomorphine is indicated for patients with advanced PD who are experiencing intermittent off episodes despite optimized therapy. Upon subcutaneous administration, apomorphine produces an “on” response within 20 minutes. The effective dose ranges from 2 to 6 mg per injection. Sites of injection (abdomen, upper arm, and upper thigh) should be rotated to avoid development of subcutaneous nodules. Apomorphine elimination half-life is approximately 40 minutes, and the duration of benefit can be up to 100 minutes. Nausea and vomiting are common side effects, and prior to the initiation of apomorphine, patients should be premedicated with the antiemetic trimethobenzamide.

PERSONALIZED PHARMACOTHERAPY

Currently, there are no pharmacogenomic parameters used to guide PD pharmacotherapy. Personalized therapy should take into account patient-specific factors including age; comorbidities; severity of functional impairment; nonmotor symptoms; patient preferences, therapeutic goals and outcomes; employment status; drug tolerability; presence of cognitive impairment or motor complications; need for skilled assistance; and health-related economics. The lowest dose of antiparkinson medication that provides satisfactory symptomatic results should be used, and for patients already on carbidopa/l-dopa, optimization of the regimen should be attempted before adding adjunctive agents. With the increasing motor disability, emergence of medication side effects,

and changes in severity of nonmotor symptoms, therapy adjustments (eg, dose reductions, medication addition or discontinuation) are expected, and desired therapeutic endpoints should be routinely reassessed.

For mild functional impairment, initial monotherapy may be initiated with an MAO-B inhibitor, such as rasagiline, with the addition of other therapeutic agents as PD motor symptoms progressively worsen. Dopamine agonist monotherapy provides greater symptomatic benefit for patients with mild to moderate impairment. However, dopamine agonists are less well tolerated, especially in older patients. For patients who are older, cognitively impaired, intolerant of dopamine agonists, or experiencing moderate or severe functional impairment, carbidopa/l-dopa is preferred. Ultimately, all patients will require the use of carbidopa/l-dopa (either as monotherapy or in combination with other agents). With the development of motor fluctuations, patients should administer carbiopa/l-dopa more frequently. Alternatively, addition of a COMT inhibitor, MAO-B inhibitor, or dopamine agonist to the carbidopa/l-dopa regimen should be considered. For management of carbodopa/l-dopa–induced peak-dose dyskinesias, a reduction in l-dopa dose and/or addition of amantadine should be considered. Surgery is considered only in patients who need more symptomatic control or who are experiencing severe motor complications despite pharmacologically optimized therapy.

The treatment plan evolves as the disease progresses and must include consideration of short-term symptomatic relief as well as long-term effects. Patient education should be communicated with realistic optimism. For example, it should be explained that although there is no cure for PD, modern medicine has many medications that can provide relief of symptoms. Nonpharmacologic interventions such as exercise should be encouraged, and problematic nonmotor features of PD should always be addressed.

EVALUATION OF THERAPEUTIC OUTCOMES

1 Comprehensive medication management with optimization of medications related to PD improves patient outcomes.[41] Routine evaluation and monitoring of motor and nonmotor symptoms should occur every 3 to 6 months for patients on a stable treatment regimen. With the changes in pharmacotherapy (eg, drug addition, discontinuation, dose change), follow-up monitoring for efficacy and side effects should occur within 1 or 2 weeks and may occur via telephone. **Table 59-6** lists the monitoring parameters for PD therapy. Patient and caregiver satisfaction is an important component of evaluating therapeutic outcomes. Toward this end, establishing appropriate treatment expectations is important. Patients and caregivers should be educated that symptoms of PD often progresses with time, and adjustments to the medication regimen will be required to manage motor and nonmotor features. Additionally, some symptoms do not respond to pharmacotherapy (eg, freezing, gait, and postural instability). Assessment of the patient's general level of functioning, including activities of daily living and mobility, is important to determine when medication adjustments or physical therapy interventions are needed. It is also important to be aware of and adhere to the general guidelines and recommendations for geriatric health maintenance and disease prevention (eg, bone health, routine vaccinations, and vitamin and mineral supplementations).

TABLE 59-6 Monitoring Parkinson Disease Therapy

1. Monitor medication administration times. Educate the patient that immediate-release carbidopa/l-dopa is absorbed best on an empty stomach but is commonly taken with food to minimize nausea. Avoid administration of conventional selegiline in the late afternoon or evening to minimize insomnia.

2. Monitor to ensure that the patient and/or caregivers understand the prescribed medication regimen. For example, they should understand that catechol-*O*-methyltransferase inhibitors work by enhancing the effect of l-dopa and that the patient should not discontinue medication without notifying the clinician.

3. Monitor and inquire specifically about dose-by-dose effects of medication, including response to doses of medication and the presence of dyskinesias, wearing-off effects, dizziness, nausea, orthostasis, or visual hallucinations. Offer suggestions to help alleviate these, or encourage the patient to discuss them with the clinician.

4. Monitor caregiver involvement and facilitation for early detection of abnormal behaviors, dyskinesias, falls, hallucinations, impulsivity, memory problems, mood changes, and sleep disorders.

5. Monitor for nonadherence and, if present, inquire for possible reasons (eg, dosing convenience, financial issues, and adverse effects) and offer suggestions.

6. Monitor for presence of drugs that can exacerbate idiopathic Parkinson disease motor features (eg, D_2 receptor blockers).

7. Monitor for presence of drugs that can exacerbate nonmotor symptoms. Evaluate whether the presence of an anticholinergic agent is causing confusion or cognitive impairment.

Patients and caregivers can participate in treatment by recording medication administration times as well as the duration of on and off times that can be reviewed at each visit. Periodic review of all prescription and nonprescription medications that the patient is taking should be performed to identify use of medications with side effects that can exacerbate PD motor and nonmotor features. For example, D_2 blockers (such as metoclopramide and typical antipsychotics) can worsen motor features and should be avoided. If the patient reports memory problems, medications with anticholinergic properties should be avoided.

Nonmotor symptoms must be identified, assessed, managed, and monitored. These include anxiety, cognitive impairment, constipation, daytime sleepiness, depression, drooling, dysphagia, fatigue, falls, hallucinations/psychosis, impulsivity, insomnia, orthostatic hypotension, overactive bladder, pain, REM sleep behavior disorder, and restless legs syndrome. Screening for anxiety or depressive disorders will help determine if antidepressant or antianxiety therapy is needed. If falling is a problem, it is important to investigate whether falls are secondary to insufficient motor control, orthostatic hypotension, or drug side effects, such as dizziness. The former may necessitate an increase in dose of antiparkinson agents, and the latter two conditions, a reduction in drug dosage. Physical therapy is also helpful for strengthening ambulation and balance skills to minimize falls. The

patient should be questioned about any difficulties with their antiparkinson medications, including presence of adverse effects. Recommendations always should be made in view of the patient's perception of the severity of symptoms and effect on quality of life.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

COMT	catechol-*O*-methyltransferase
CR	controlled release
CYP450	cytochrome P450
D_1	dopamine receptor subtype 1
D_2	dopamine receptor subtype 2
DBS	deep-brain stimulation
ER	extended release
GABA	γ-aminobutyric acid
GI	gastrointestinal
GPi	globus pallidus interna
IR	immediate release
l-dopa	levodopa
MAO	monoamine oxidase
NMDA	*N*-methyl-d-aspartate
ODT	orally disintegrating tablet
PD	Parkinson disease
REM	rapid eye movement
SNc	substantia nigra pars compacta
SNr	substantia nigra pars reticulate
STN	subthalamic nucleus

Chapter 60: Pain Management

Chris M. Herndon; Jennifer M. Strickland; James B. Ray

INTRODUCTION

KEY CONCEPTS

- 1 It is important, whenever possible, to ask patients if they have pain, to identify the source of pain, and to assess the characteristics of the pain.
- 2 Patients taking analgesics should be monitored for response and side effects, particularly respiratory depression, sedation and constipation associated with opioids.
- 3 Oral analgesics are preferred over other dosage forms whenever feasible, but it is important to adjust the route of administration to the needs of the patient.
- 4 Equianalgesic doses are useful as a guide when converting from one agent to another, but further dose titration usually is required to achieve treatment goals.
- 5 Doses must be individualized for each patient and administered for an adequate duration of time. Around-the-clock regimens should be considered for acute and chronic pain. As needed regimens should be used for breakthrough pain or when acute pain displays wide variability and/or has subsided greatly.
- 6 For chronic pain that has a maladaptive inflammatory and/or neuropathic component, anticonvulsants, topical analgesics, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and opioids should be considered based on evidence based recommendations when available.
- 7 Whenever possible, a multidisciplinary approach and nonpharmacologic strategies should be used.
- 8 Placebo therapy should not be used as an attempt to diagnose psychogenic pain.
- 9 Etiology of pain may not always be identifiable.

If we know that pain and suffering can be alleviated, and do nothing about it, then we ourselves, become the tormentors.

– Primo Levi[1]

Humans have always known and sought relief from pain.[2] Today, pain's impact on society still is great, and pain complaints remain a primary reason patients seek medical advice.[3]

Regrettably, many healthcare providers do not receive adequate training in the treatment of pain. Understanding the pathophysiology of pain and maintaining a thorough understanding of both pharmacologic and nonpharmacologic treatment modalities are important factors in addressing pain control.

DEFINITION

Pain is defined as: "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[4] Pain is subjective, however, and many clinicians define pain as "whatever the patient says it is."

EPIDEMIOLOGY

Data presented in the recently released Institute of Medicine report, "Relieving Pain in America" suggests that greater than 100 million persons in the United States live with chronic pain.[5] Given that greater than 50% of persons reporting low back pain in the previous 3 months also reported interference with basic and complex activities, it is not surprising that the estimated economic burden of chronic pain alone exceeds 500 billion dollars (US) annually.[5] In 1 year, an estimated 25 million Americans will experience acute pain due to injury or surgery, and one third will experience severe chronic pain at some point in their lives.[3] Unfortunately, despite much public attention, pain often remains inadequately or inappropriately treated.[6,7]

PHYSIOLOGY AND PATHOPHYSIOLOGY

The pathophysiology of pain involves complex interactions between neural and immune networks within the peripheral and central nervous system (CNS) in response to afferent sensory stimuli that produces the conscious experience we know as pain. It can be physiologic and protective (adaptive) or pathophysiologic and harmful (maladaptive).[8]

Adaptive Pain

The pain experienced from touching something too cold, hot, or sharp is called nociceptive pain, a primitive evolutionary mechanism to protect our body from actual or potential tissue damage from external noxious stimuli. Pain that occurs as a result of unavoidable tissue damage (trauma or surgery) creates sensitization at and adjacent to the site of tissue injury. This process also engages

the immune system, and is called inflammatory pain. Nociceptive and inflammatory pain are both adaptive and protective. The physiological processing of pain occurs within a neurotransmission circuit via a number of steps known as transduction, conduction, transmission, perception, and modulation.[8]

Transduction

The first step leading to the sensation of pain is stimulation of nerve fiber receptors known as *nociceptors*. These receptors are found in both somatic and visceral structures and help to discriminate between noxious and innocuous stimuli. Nociceptors are activated and subsequently sensitized by mechanical, thermal, and chemical stimuli.[8] The underlying mechanism of these noxious stimuli (which in and of themselves may sensitize/stimulate the receptor) may be the release/activation of numerous cytokines and chemokines that sensitize and/or activate the nociceptors[8,9] (**Fig. 60-1**).

FIGURE 60-1

Schematic representation of nociceptive pain. *(Used with permission from Pasero C, Portenoy R. Neurophysiology of pain and analgesia and the pathophysiology of neuropathic pain. Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Conduction

Receptor activation, involving voltage-gated sodium channels, leads to the generation of action potentials that are conducted along afferent A-*δ* and C-nerve fibers to the spinal cord.[11,12] Stimulation of large-diameter, sparsely myelinated A-*δ* fibers evokes sharp, well-localized pain, whereas stimulation of unmyelinated, small-diameter C fibers produces aching, poorly localized pain.[10]

Transmission

These afferent, nociceptive pain fibers synapse in various layers (laminae) of the spinal cord's dorsal horn, releasing excitatory neurotransmitters, such as glutamate and substance P. N-type voltage-gated calcium channels regulate the release of these excitatory neurotransmitters. The complex array of events that influence pain can be explained in part by the interactions between neuroreceptors and neurotransmitters that take place in this synapse. Pain signals reach the brain through a host of ascending spinal cord pathways, which include the spinothalamic tract.[10] Other sensory information is also carried along these pathways. Thus, pain is influenced by many factors supplemental to nociception, which prevents simple schematic representation. The thalamus acts as a relay station within the brain. As these pathways ascend and pass the impulses to higher cortical structures, pain can be processed further.[10]

Perception

At this point in transmission, pain is thought to become a conscious experience that takes place in higher cortical structures. The physiology surrounding perception is complex and not well understood, but we know cognitive and behavioral functions can modify pain. Thus relaxation, distraction, meditation, and guided mental imagery may strongly influence pain perception and decrease pain.[11,12] In contrast conditions such as depression or anxiety often worsens pain.[13]

Modulation

The brain and spinal cord modulate pain through a number of intricate processes. Pain transmission may be facilitated by neurotransmitters such as glutamate or substance P to make the signals stronger and pain more intense. The signal can also be attenuated/inhibited by descending pathways that consist of endogenous opioids (eg, enkephalins, and β-endorphins) γ-aminobutyric acid (GABA), norepinephrine, or serotonin.[14,15] Like exogenous opioids, endogenous peptides bind to opioid receptor sites and modulate the transmission of pain impulses.[14] Blockade of *N*-methyl-D-aspartate (NMDA) receptors may increase the μ-receptors' responsiveness to opiates.[16]

Immune System Impact on Pain Signaling

Over the past two decades research has demonstrated that a two-way communication exists between neurons and immune cells within the CNS, especially astrocytes and microglia. Microglia are the equivalent of a macrophage within the CNS.[16,17] Activation of microglia within the CNS in response to nerve injury (both in the periphery and CNS) leads to a complex cascade of events that appears to be responsible for the ongoing pain seen in neuropathic pain conditions. Activated microglia may also play a partial role in the development of opioid tolerance and opioid-induced hyperalgesia. Evidence is emerging that the interface between immune cells and neurons in the CNS plays a significant role in the maintenance of chronic pain and offers a new frontier of potential therapeutic targets in active research.[18]

Maladaptive (Pathophysiologic) Pain

Pathophysiologic pain is distinctly different from nociceptive pain in that it becomes disengaged from noxious stimuli or healing and often is described in terms of chronic pain. This type of pain is a result of damage or abnormal functioning of the peripheral nervous system (PNS) and/or CNS.[11] Maladaptive pain can be neuropathic, in which there is ongoing peripheral nerve injury (eg, postherpetic neuralgia, diabetic neuropathy or chemotherapy-induced neuropathy) or in the CNS (eg, following an ischemic stroke or with multiple sclerosis). Maladaptive pain may also be centralized, where no nerve injury or inflammation exists, but a centrally mediated disturbance in pain processing within the CNS leads to pain hypersensitivity and subsequently spontaneous pain. Classic examples are fibromyalgia, irritable bowel syndrome, temporomandibular joint disorder and chronic tension headaches. Chronic pain states are often mixed with all three mechanisms (nociceptive, neuropathic, and centralized) present within the same patient.[19] These pain syndromes are frequently under-recognized and difficult to treat. Additionally, reported pain is often not commensurate with physical examination findings or imaging results, which may result in undertreatment and ultimately inadequate pain relief.

The mechanism responsible for pain of this nature may be the nervous system's endogenous dynamic nature. Nerve damage or certain disease states may cause both peripheral (eg, alteration in nociceptive nerve fiber sensitivity, alteration of sodium channels, collateral sprouting of nerve fibers) and central (eg, hyperexcitability of central neurons or central sensitization, NMDA-glutamate receptor activation, central disinhibition) changes in neurotransmission leading to increased pain.[14,16] Pain circuits rewire themselves both anatomically and biochemically (often referred to as neural plasticity), and this produces a mismatch between pain stimulation and inhibition, potentially resulting in a progressive increase in the discharge of dorsal horn neurons.[20] The end result is chronic pain, where patients may present with episodic or continuous pain transmission (often described as burning, tingling, shock like, or shooting), exaggerated painful response to normally noxious stimuli (hyperalgesia), and/or painful response to normally non-noxious stimuli (allodynia).[9,10,21] This change over time may help to explain why this type of pain often manifests long after the actual nerve-related injury or when no actual injury is identified.

CLASSIFICATION OF PAIN

1 It is helpful in guiding assessment and treatment of pain to classify or subdivide the presenting symptoms into types of pain. There are numerous ways of classifying pain, such as by type of pain (eg, nociceptive, neuropathic, inflammatory), by pain intensity (eg, mild, moderate, or severe), or most commonly by duration of pain (eg, acute, subacute, or chronic pain).

Acute Pain

Acute pain can be a useful physiologic process, serving its adaptive purpose by warning individuals of disease states and potentially harmful situations. Unfortunately, severe, unremitting, undertreated acute pain may outlive its biologic usefulness, and produce many deleterious effects. Aside from

unnecessary suffering, untreated and undertreated acute pain has also been associated with numerous metabolic, hemodynamic and hemostatic changes and has been shown to increase one's risk for the development of chronic pain syndromes.[22] Acute pain is typically short in duration, lasting less than 3 to 6 months. It is often due to an identifiable cause and is usually nociceptive in nature with common causes including surgery, acute illness, trauma, labor, medical procedures, and cancer or cancer treatment.[23]

Chronic Pain

Under normal conditions, acute pain subsides quickly as the healing process decreases the pain-producing stimuli; however, in some instances, pain persists for months to years, leading to a chronic pathophysiologic pain state with features quite different from those of acute pain (**Table 60-1**).[23] In many cases, the exact etiology of pain may not always be identifiable. Chronic pain can be classified as either being associated with cancer (cancer pain) or from noncancer etiologies (chronic noncancer pain). Chronic noncancer pain is often a result of changes to nerve function and transmission thus making treatment more challenging.[24]

TABLE 60-1 Characteristics of Acute and Chronic Pain

Characteristic	Acute Pain	Chronic Pain
Relief of pain	Highly desirable	Highly desirable
Dependence and tolerance to medication	Unusual	Common
Psychological component	Usually not present	Often a major problem
Organic cause	Common	May not be present
Environmental/family issues	Small	Significant
Insomnia	Unusual	Common component
Treatment goal	Cure	Functionality
Depression	Uncommon	Common

Data from references 23 and 27.

Cancer Pain

Pain associated with potentially life-threatening conditions is often called malignant pain or in the case of cancer, cancer pain.[25] This type of pain includes both chronic and acute (eg, breakthrough pain) components and often has multiple etiologies. It is pain caused by the disease itself (eg, tumor invasion and organ obstruction), treatment (eg, chemotherapy, radiation, and surgical incisions), or diagnostic procedures (eg, biopsy).[25] Regardless of pain duration, or suspected underlying etiology, a standardized approach to evaluation of a pain complaint is imperative.

CLINICAL PRESENTATION

A patient-oriented approach is essential, and pain evaluation methods should not differ from those

used in other medical conditions.[26]

Therefore, a comprehensive history and physical examination are imperative to evaluate underlying diseases and other possible contributing factors.[23] This includes asking if the patient has pain and identifying the source when possible; however, the absence of a discreet etiology should not preclude appropriate treatment.[23] A baseline characterization of pain can be obtained by assessing the attributes outlined in **Table 60-2**.[27]

TABLE 60-2 Assessment of Pain

Onset and duration	When did pain begin and how long has it been since the pain began?
Palliative factors	What makes the pain better?
Provocative factors	What makes the pain worse?
Quality	Describe the pain.
Location	Where is the pain?
Severity/intensity	How does this pain compare with other pain you have experienced?
Temporal factors	Does the intensity of the pain change with time?

Data from reference 23.

TREATMENT

Desired pain management outcomes include both nonpharmacologic and pharmacologic strategies.

Desired Outcomes

The primary goal of pain treatment depends on the type of pain present and should be tailored to individual patients and circumstances. For example, a desired outcome in the acute postoperative setting may be to achieve a level of pain relief that allows the patient to attain certain functional goals, such as deep breathing or participation in physical therapy. In comparison, the goals in chronic noncancer pain are to improve or maintain the patient's level of functioning, decrease pain perception, reduce the use of medications when possible, and improve the patient's quality of life. And finally, in cancer pain or other forms of malignant pain, the goal is to provide patients with adequate pain relief such that they can tolerate diagnostic and therapeutic manipulation and permit the patient to function at a level that will allow freedom of movement and choice while minimizing adverse effects of chosen analgesics.[25]

CLINICAL PRESENTATION Pain Acute Pain General

- Look for obvious distress (eg, trauma). In infants, presentation may include changes in feeding habits and/or increased fussiness. Those with dementia may exhibit changes in eating habits, increased agitation, calling out, and/or facial grimacing. Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear, in particular, are noted to lower this threshold, whereas rest, mood elevation, sympathy,

diversion, and understanding raise the pain threshold

Symptoms

- Can be described as sharp, dull, shock like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these occur in a timely relationship with an obvious noxious stimuli)

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor, but these signs are *not diagnostic*
- In some cases there are no obvious physical signs
- Comorbid conditions usually not present
- Outcome of treatment generally predictable

Laboratory Tests

- Pain is always subjective
- There are no specific laboratory tests for pain
- Pain is best diagnosed based on patient description and history

Chronic Pain General

- Can appear to have no noticeable suffering. Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear, in particular, are noted to lower this threshold; whereas rest, mood elevation, sympathy, diversion, and understanding raise the pain threshold

Symptoms

- Can be described as sharp, dull, shock-like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these often occur *without* a temporal relationship with an obvious noxious stimuli)
- Over time, the pain stimulus may cause symptoms that completely change (eg, sharp to dull and obvious to vague)

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor are seldom present
- In most cases there are *no* obvious signs
- Comorbid conditions often present (eg, insomnia, depression, and anxiety)
- Outcome of treatment often unpredictable

Laboratory Tests

- Pain is always subjective
- Pain is best diagnosed based on patient description and history
- There are *no* specific laboratory tests for pain; however, history and/or diagnostic proof of past trauma (eg, computed tomography) may be helpful in diagnosing etiology. General labs that may be considered include vitamin D, thyroid stimulating hormone (generalized or widespread pain), and B12 (neuropathic pain)

Data from reference 23.

Nonpharmacologic Therapy

The use of nonpharmacologic therapies in the management of pain should always be considered first line therapy, either alone or in combination with appropriate analgesics. Physical manipulation, application of heat or cold, massage, biofeedback, cognitive behavioral therapy, relaxation, acupuncture, and exercise are all modalities with variable efficacy for both acute and chronic pain.[28] Implanted spinal cord stimulators have also been found to be somewhat beneficial in some chronic neuropathic pain conditions.[29] The evidence basis for many of the nonpharmacologic approaches is evolving and the results of these approaches can have varied efficacy based on the skill of the individual applying the modality, as well as the type of pain being treated.

Transcutaneous electrical nerve stimulation (TENS), a commonly used nonpharmacologic therapy, may reduce pain by enhancing natural descending inhibitory pathways within the CNS. Evidence to date suggests that the frequency of the electrical stimulation delivered, presence or absence of systemic analgesics and the type of underlying pain may affect the overall efficacy of this treatment.[30]

Simple interventions (eg, education or introductory information about expected discomfort or pain after certain procedures) reduce patient distress and help to reduce postprocedure pain.[31] Psychological techniques (eg, cognitive-behavioral therapy, relaxation training, and mindfulness-based stress reduction) have proven effective in reducing pain-related disability and improving global functioning in patients with numerous types of chronic pain.[32] Partnering with other clinicians who are familiar with the use of effective nonpharmacologic modalities should always be considered whenever possible to help reduce the overall reliance on pharmacologic approaches, especially opioids.

Pharmacologic Treatment—Appropriate Patient Selection

Pharmacologic treatment is often considered the cornerstone of pain management. Proper agent selection using a benefit-to-risk assessment is crucial when determining the optimal therapeutic plan for an individual patient. The potential for benefit with each pharmacologic option as well as the risk of adverse effects must be assessed.

Patient Selection Considerations in Acute Pain

The World Health Organization (WHO) recommends a three-step ladder approach using nonopioids as initial treatment and escalating to either "weak" or "strong" opioids based on mild, moderate, or severe pain intensity ratings, respectively. However, patient specific factors (e.g., renal or liver dysfunction which may limit nonopioid alternatives), may lead clinicians to initiate therapy with an opioid to optimize pain relief while minimizing adverse effects.

Patient Selection Considerations in Chronic Noncancer Pain

In all cases of chronic noncancer pain, an integrated systematic approach (such as that often provided by specialty pain providers), with a strong emphasis on patient–clinician relationships, is essential. Patients and clinicians must realize that optimal treatment may take months or even years to achieve. Although opioids continue to be commonly utilized in the management of chronic noncancer pain and can be effective for individual patients, limited data is available supporting the long-term safety and efficacy of these agents.[33] Thus, there is significant debate regarding the benefit of chronic opioid therapy for chronic pain. Chronic opioid therapy in this setting requires careful patient selection to evaluate whether the benefit of therapy outweighs the potential risks in the individual patient. Steps should be taken to identify and manage risks (eg, misuse and abuse) prior to initiating opioid therapy and risk mitigation strategies (eg, treatment agreements that outline patient and provider responsibilities and expectations, urine drug testing) should commonly be employed.[34] "Universal precautions" for pain have been suggested as a method to standardize the assessment and ongoing management of chronic pain with opioids and incorporate many of these principles.[7] Placebo should never be considered as a reasonable option for the management of pain regardless of risk factors.

Pharmacologic Treatment

Nonopioid Agents

Analgesia should be initiated with the most effective analgesic agent having the fewest side effects. Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) are often preferred first-line therapies in the treatment of mild-to-moderate pain, although the efficacy of acetaminophen has recently been called into question (**Table 60-3**).[35,36] The exact mechanism of acetaminophen is not completely understood but likely involves central prostaglandin modulation.[37] NSAIDs inhibit formation of varying prostaglandins produced in response to noxious stimuli, thereby decreasing the pain impulses received by the CNS.[29] Acetaminophen is generally indicated as a first-line therapy in some pain-related disease states, such as osteoarthritis, although prompt reassessment should occur to evaluate effectiveness. NSAIDs may be particularly useful in the management of cancer-related bone pain and for short-term relief in the management of chronic low back pain.[38]

TABLE 60-3 Adult FDA-Approved Nonopioid Analgesics (Includes Only FDA-Approved Agents for Pain)

Class and Generic Name (Brand Name)	Approximate Half-Life (h)	Usual Dosage Range (mg)	Maximal Dose (mg/day)
Salicylates			
Acetylsalicylic acid[a]—aspirin (various)	0.25	325-1,000 every 4-6 h	4,000
Choline and magnesium trisalicylate (various)	9-17	1,000-1,500 every 12 h 750 every 8 h (elderly)	3,000
Diflunisal (Dolobid, various)	8-12	500-1,000 initial 250-500 every 8-12 h	1,500
Salsalate (various)	1	1,000 every 12 h or 500 every 6 h	3,000
Para-aminophenol			
Acetaminophen[a] (Oral—Tylenol, various; Parenteral—Ofirmev)	2-3	325-1,000 every 4-6 h	4,000[b] Dosing for peds lower based on weight
Fenamates			
Meclofenamate (various)	0.8-3.3	50-100 every 4-6 h	400
Mefenamic acid (Ponstel)	2	Initial 500, 250 every 6 h (max. 7 days)	1,000[c]
Pyranocarboxylic acid			
Etodolac (various) (immediate release)	7.3	200-400 every 6-8 h	1,000 1,200 with extended-release product
Acetic acid			
Diclofenac potassium (Cataflam, various, Flector [patch] Voltaren Gel, Pennsaid [solution])	1.9	In some patients, initial 100, 50 three times per day Patch available—to be applied twice daily to painful area (intact skin only), Gel and solution dosing joint specific	150[d]
Propionic acids			
Ibuprofen[a] (Motrin, Caldolor, various)	2-2.5	200-400 every 4-6 h Injectable, 400-800 every 6 h (infused over 30 min)	3,200[e] 2,400[e] 1,200[f]
Fenoprofen (Nalfon, various)	3	200 every 4-6 h	3,200

Class and Generic Name (Brand Name)	Approximate Half-Life (h)	Usual Dosage Range (mg)	Maximal Dose (mg/day)
			300
Ketoprofen (various)	2	25-50 every 6-8 h	200 with extended-release product
Naproxen (Naprosyn, Anaprox, various)	12-17	500 initial	1,000[c]
		500 every 12 h or 250 every 6-8 h	
Naproxen sodium[a] (Aleve, various, combined with esomeprazole [Vimovo])	12-17	In some patients, 440 initial[f] 220 every 8-12 h[f]	660[f]
Pyrrolizine carboxylic acid			
Ketorolac—parenteral (Toradol, various)	5-6	30[g]-60 (single IM dose only)	30[g]-60
		15[g]-30 (single IV dose only)	15[g]-30
		15[g]-30 every 6 h (IV dose) (max. 5 days)	60[g]-120
Ketorolac—oral, indicated for continuation with parenteral only (various)	5-6	10 every 4-6 h (max. 5 days, which includes parenteral doses)	40
		In non-elderly patients, initial oral dose of 20	
Ketorolac—nasal spray, indicated for acute, moderate to moderately severe pain		1 spray (15.75 mg) in each nostril every 6-8 h in adults < 65 yr and weight ≥ 50 kg	126
Pyrazoles			
		Initial 400 followed by another 200 on first day, then 200 twice daily	
Celecoxib (Celebrex)	11	(note some recommend maintenance doses of 200 mg/day due to cardiovascular concerns)	400

FDA (Food and Drug Administration); h (hours); IM (intramuscular); IV (intravenous).

[a]Available both as an over-the-counter preparation and as a prescription drug.

[b]Some experts believe 4,000 mg may be too high. OTC max dose 3,000 mg daily, lower with weight based dosing in pediatric patients.

[c]Up to 1,250 mg on the first day.

[d]Up to 200 mg on the first day.

[e]Some individuals may respond better to 3,200 mg as opposed to 2,400 mg, although well-controlled trials show no better response; consider risk versus benefits when using 3,200 mg/day.

[f]Over-the-counter dose.

[g]Dose for elderly and those under 50 kg (110 lb).

Data from references 39 and 42.

Studies comparing the efficacy of individual NSAIDs have failed to identify greater efficacy of any NSAID compared to another. Therefore, the choice of a particular agent often depends on availability, cost, pharmacokinetics, pharmacologic characteristics, and the side-effect profile. Because of the large interpatient variability in response to individual NSAIDs, it is considered rational therapy to switch to another member of this class if there is inadequate response after a sufficient therapeutic trial of any single agent.[39] The duration of a sufficient trial has not been well defined; however, typically, an NSAID should be continued for a minimum of 1 month prior to evaluating the need to switch agents. Chronic use of NSAIDs may result in gastrointestinal (GI), renal, and cardiac toxicity. Topical NSAIDs may offer similar efficacy as oral NSAIDs with improved safety and tolerability in the treatment of small or superficial joint arthritis.[40] Appropriate patient selection for NSAID therapy is critical to ensure optimal benefit while minimizing potential adverse effects.

Opioid Agents

Opioids are often the next step in the management of acute pain and cancer-related chronic pain (Figure 60-3). This medication class may also be an effective treatment option in the management of chronic noncancer pain; however, this continues to be increasingly controversial. When a trial of opioids is warranted, each trial should not be done without a complete assessment of the pain complaint, including an assessment of the patient's functionality and risk factors for opioid misuse and abuse.[34,41]

Opioid choice should be based on patient acceptance; analgesic effectiveness; as well as pharmacokinetic, pharmacodynamic, and side-effect profiles with these attributes provided in **Tables 60-4 and 60-5**.[42]

TABLE 60-4 Opioid Analgesics, Central Analgesics, Opioid Antagonist

Class and Generic Name (Brand Name)	Chemical Source	Relative Histamine Release	Route*	Equianalgesic Dose in Adults (mg)	Approximate Onset (min)/Half-Life

					(h)
Phenanthrenes (morphine-like agonists)					
Morphine (Embeda[i] various)	Naturally occurring	+++	IM/IV	10	10-20/2
			PO	30	
Hydromorphone (Dilaudid, Exalgo, various)	Semisynthetic	+	IM	1.5	10-20/2-3
			PO	7.5	
Oxymorphone (Numorphan, Opana)	Semisynthetic	+	IM	1	10-20/2-3
			PO	10	
Levorphanol (various)	Semisynthetic	+	IM	Variable	10-20/12-16
			PO	Variable	
Codeine (various)	Naturally occurring	+++	IM	15-30[a]	
			PO	15-30[a]	10-30/3
Hydrocodone (available as combination, single entity extended release—Hysingla ER, Zohydro ER)	Semisynthetic	N/A	PO	5-10[a]	30-60/4
Oxycodone (OxyContin[i], Oxecta[i], Xtampza, Xartemis XR [oxycodone & acetaminophen])	Semisynthetic	+	PO	15-30[b]	30-60/2-3
Phenylpiperidines (meperidine-like agonists)					
Meperidine (Demerol, various)	Synthetic	+++	IM/IV	75	10-20/3-5
			PO	300[b]; not recommended	
Fentanyl (Sublimaze, Duragesic, Lazanda, Abstral, Fentora, Subsys, OTFC, Ionsys, various)	Synthetic	+	IM	0.125[c]	7-15/3-4
			Transdermal Buccal,	Variable[d]	

			transmucosal, sublingual, nasal inhaled		
				Variable[d]	
Diphenylheptanes (methadone-like agonists)					
Methadone	Synthetic	+	IM/IV	Variable[e] (acute)	
(Dolophine, various)			PO	Variable[e] (acute)	30-60/12-190
			IM	Variable[e] (chronic)	
			PO	Variable[e] (chronic)	
Agonist–antagonist derivatives					
Pentazocine (Talwin, various)	Synthetic	N/A	IM	Not recommended	
			PO	50[a]	15-30/2-3
Butorphanol (Stadol, various)	Synthetic	N/A	IM	2	10-20/3-4
			Intranasal	1[a] (one spray)	
Nalbuphine (Nubain, various)	Synthetic	N/A	IM/IV	10	<15/5
Buprenorphine (Buprenex, Butrans, Suboxone, Belbuca, Subutex, various)	Synthetic	N/A	IM	0.3	
			Transdermal	Variable	10-20/2-3
			Sublingual	Variable	
Antagonist					
Naloxone (Narcan, various)	Synthetic	N/A	IV	0.4-2*f*	1-2 (IV), 2-5 (IM)/0.5-1.3
Methylnaltrexone (Relistor)	Synthetic	N/A	SC	Variable	
Naltrexone (Revia)	Synthetic	N/A	PO		
Alvimopan (Entereg)	Synthetic	N/A	PO	12 mg QD-Q12	15 doses
Naloxegol (Movantik)	Synthetic	N/A	PO	12.5-25 mg QD	120/6-11
Central analgesics					
Tramadol (Ultram, Rybix, Ryzolt, ConZip, various)	Synthetic	N/A	PO	50-100[a,g,h]	<60/5-7

Tapentadol (Nucynta)	Synthetic	N/A	PO	50-100[a,g,h]	Within 60/4

IM, intramuscular; IV, intravenous; N/A, not available; PO, oral.

[*]The IM route should be avoided whenever possible—produces significant pain with administration and rate and extent of absorption is highly variable. If IV route is unavailable then administer subcutaneously (SC).

[a]Starting dose only (equianalgesia not shown).

[b]Starting doses lower (oxycodone 5-10 mg, meperidine 50-150 mg).

[c]Equivalent PO morphine dose = variable.

[d]For breakthrough pain only. Equianalgesic dose conversion should be avoided for Transmucosal Immediate Release Fentanyl (TIRF) products.

[e]The equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose. Caution should be exercised when initiating in opioid naïve patients.

[f]Starting doses to be used in cases of opioid overdose.

[g]First day of dosing may administer second dose 1 hour after first dose.

[h]Onset of action may differ for long-acting formulations. Ceiling dose recommendations exist and may differ from immediate release dosing recommendations.

[i]FDA approved as abuse-deterrent formulation.

Data from reference 42.

TABLE 60-5 Dosing Guidelines

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
NSAIDs/acetaminophen/aspirin	Use lowest effective dose for the shortest duration possible (see Table 69-3)	Used in mild-to-moderate pain May use in conjunction with opioid agents to decrease doses of each Regular alcohol use and acetaminophen may result in liver toxicity

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
		Care must be exercised to avoid overdose when combination products containing these agents are used
		Underlying renal impairment, hypovolemia, and heart failure may predispose to nephrotoxicity
Morphine	PO 5-30 mg every 4 h[a]	Drug of choice in severe pain
	IM 5-20 mg every 4 h[a]	Use immediate-release product with SR product to control breakthrough pain in cancer patients
	IV 5-15 mg every 4 h[a]	Typical patient controlled analgesia IV dose is 1 mg with a 10-minute lock out interval
	SR 15-30 mg every 12 h (may need to be every 8 h in some patients)	Every 24-hour products availableuse caution in renally-compromised patients
	Rectal 10-20 mg every 4 h[a]	
Hydromorphone	PO 2-4 mg every 4-6 h[a]	Use in severe pain
	XR 8 mg to 64 mg every 24 h	More potent than morphine; otherwise, no advantages
	IM 1-2 mg every 4-6 h[a]	
	IV 0.5-2 mg every 4 h[a]	Typical patient controlled analgesia IV dose is 0.2 mg with a 10-minute lock out interval
	Rectal 3 mg every 6-8 h[a]	Every 24-hour product (Exalgo) available
Oxymorphone	IM 1-1.5 mg every 4-6 h[a]	Use in severe pain
	IV 0.5 mg every 4-6 h[a]	No advantages over morphine
	PO immediate-release 5-10 mg every 4-6 h[a]	Use immediate-release product with controlled-release product to control breakthrough pain in cancer or chronic pain patients
	PO extended-release 5-10 mg every 12 h[a]	Manufacturer recommends 5 mg every 12 h in opioid-naïve patients
		Take ER on empty stomach

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
Levorphanol	PO 2-3 mg every 6-8 h[a] (Levo-Dromoran)	Use in severe pain
	PO 2 mg every 3-6 h[a] (Levorphanol Tartrate)	Extended half-life useful in cancer patients
	IM 1-2 mg every 6-8 h[a]	In chronic pain, wait 3 days between dosage adjustments
	IV 1 mg every 3-6 h[a]	
Codeine	PO 15-60 mg every 4-6 h[a]	Use in mild to moderate pain
	IM 15-60 mg every 4-6 h[a]	Weak analgesic; analgesic prodrug
Hydrocodone	PO 5-10 mg every 4-6 h[a]	Use in moderate/severe pain
Oxycodone	PO 5-15 mg every 4-6 h[a]	Use in moderate/severe pain
	Controlled release 10-20 mg every 12 h	
		Use immediate-release product with controlled-release product to control breakthrough pain in cancer or chronic pain patients
		CR reformulated to deter abuse
Meperidine	IM 50-150 mg every 3-4 h[a]	Use in severe pain
	IV 5-10 mg every 5 min prn[a]	Oral not recommended
		Do not use in renal failure
		May precipitate tremors, myoclonus, and seizures
		Monoamine oxidase inhibitors can induce hyperpyrexia and/or seizures or opioid overdose symptoms
Fentanyl	IV 25-50 mcg/h	Used in severe pain
	IM 50-100 mcg every 1-2 h[a]	**Do not use transdermal in acute pain**
	Transdermal 25 mcg/h every 72 h	Transmucosal for breakthrough cancer pain in patients already receiving or tolerant to opioids
	Transmucosal (Actiq/OTFC Lozenge and Onsolis buccal	**Always start with lowest dose despite daily opioid intake. Product specific**

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
	film) 200 mcg may repeat × 1, 30 min after first dose is started, then titrate	**titration recommendations exist**
	Transmucosal (Fentora Buccal Tablet) 100 mcg, may repeat × 1, 30 min after first dose is started, then titrate	
	Intranasal (Lazanda Spray) 100 mcg (one spray) in one nostril. Wait 2 h prior to redosing	
	Sublingual (Subsys Spray) 100 mcg (1 spray). Wait 4 h prior to redosing	
	Sublingual (Abstral Tablet) 100 mcg tablets placed sublingually. Must wait 2 h prior to redosing	
Methadone	PO 2.5-10 mg every 8-12 h[a]	Effective in severe chronic pain
	IM 2.5-10 mg every 8-12 h[a]	
		Some chronic pain patients can be dosed every 12 h
		Equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose. Avoid dose titrations more frequently than weekly in chronic pain maintenance
Pentazocine	PO 50-100 mg every 3-4 h[b] (max. 600 mg daily, for those 50 mg tablet containing 0.5 mg of naloxone)	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients Parenteral doses not recommended
	PO 25 mg every 4 h[b] (max. 150 mg daily, for those 25 mg tablet containing 325 mg of acetaminophen)	

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
Butorphanol	IM 1-4 mg every 3-4 h[b]	Second-line agent for moderate-to-severe pain
	IV 0.5-2 mg every 3-4 h[b]	May precipitate withdrawal in opiate-dependent patients
	Intranasal 1 mg (1 spray) every 3-4 h[b]	
	If inadequate relief after initial spray, may repeat in other nostril × 1 in 60-90 min	
	Max. 2 sprays (one per nostril) every 3-4 h[b]	
Nalbuphine	IM/IV 10 mg every 3-6 h[b] (max. 20 mg dose, 160 mg daily)	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients
		Used frequently in low doses to treat/prevent opioid-induced pruritus
Buprenorphine	IM 0.3 mg every 6 h[b]	Second-line agent for moderate-to-severe pain
	Slow IV 0.3 mg every 6 h[b]	May precipitate withdrawal in opiate-dependent patients
		Transdermal delivery systems (5, 7.5, 10, 15, 20 mcg/h) available for every 7 day administration. Detailed manufacturer dosing conversion recommendations exist
	May repeat × 1, 30-60 min after initial dose	Naloxone may not be effective in reversing respiratory depression
Naloxone	IV IM 0.4-2 mg	When reversing opiate side effects in patients needing analgesia, dilute and titrate (0.1-0.2 mg every 2-3 min) so as not to reverse analgesia
Tramadol	PO 50-100 mg every 4-6 h[a]	Maximum dose for nonextended-release, 400 mg/24 h; maximum for extended release, 300 mg/24 h
	If rapid onset not required, start 25 mg/day and titrate over	Decrease dose in patient with renal impairment and in the elderly

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid Tolerant Patients May Need Dose Modification)	Notes
	several days Extended release PO 100 mg every 24 h	
Tapentadol	PO 50-100 mg every 4-6 h[a]	First day of therapy may administer second dose after the first within 1 h Maximum dose first day 700 mg, max. dose thereafter 600 mg (max. dose for CR 500 mg)

CR, controlled release; ER, extended release; IM, intramuscular; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; PO, oral; prn, as needed; SR, sustained release; HCL, hydrochloride.

[a]May start with an around-the-clock regimen and switch to prn if/when the painful signal subsides or is episodic.

[b]May reach a ceiling analgesic effect.

Data from references 39, 42, and 46.

The pharmacologic activity of opioids depends on their affinity for and action at central and peripheral opiate receptors.[43] Therapeutic activities and side effects for this medication class range from those exhibited by the opiate agonists (eg, morphine) to those seen with the opiate antagonists (eg, naloxone). Partial agonists and antagonists (eg, nalbuphine) compete with agonists for opiate receptor sites and, depending on the inherent agonist and antagonist properties, exhibit mixed agonist–antagonist activity.[43] This may result in analgesia with fewer undesirable side effects. Efficacy and side effects also may further differ among opioid agents because of receptor subtype variability.[44] This μ-receptor (MOR) subtype variability may explain why some patients respond differently to certain opioids, specifically MOR agonists.[44]

The effects of the opioid analgesics are relatively selective, and at normal therapeutic concentrations, do not affect other sensory modalities.[43] While sensations of touch and proprioception are preserved; undesirable side effects may increase as the dose is escalated (**Table 60-6**).[43] Patients in severe pain may receive high doses of opioids with relatively no unwanted side effects, but as the pain subsides, even very low doses may not be tolerated.[45] Frequently, when opioids are administered, pain is not eliminated, but its unpleasantness is decreased.[43] Patients report that although their pain is still present, it no longer bothers them.

TABLE 60-6 Major Adverse Effects of the Opioid Analgesics

Effect	Manifestation
Mood changes	Dysphoria, euphoria
Somnolence	Sedation, inability to concentrate
Stimulation of chemoreceptor trigger zone	Nausea, vomiting
Respiratory depression	Decreased respiratory rate
Decreased gastrointestinal motility	Constipation
Increase in sphincter tone	Biliary spasm, urinary retention (varies among agents)
Histamine release	Urticaria, pruritus, rarely exacerbation of asthma due to bronchospasm (varies among agents)
Tolerance	Larger doses for same effect
Dependence	Withdrawal symptoms upon abrupt discontinuation
Addiction	Genetic predisposition leads to loss of control of drug use, continued use despite harm, compulsion to use, cravings
Hypogonadism	Fatigue, depression, loss of analgesia, sexual dysfunction, amenorrhea (women)
Sleep	Disrupts sleep-wake cycle, causes dose-dependent rapid eye movement (REM) suppression

Data from references 39 and 42.

Opioids share related pharmacologic attributes and exert a profound effect on the CNS and GI tract.[43] Mood changes, sedation, nausea, vomiting, decreased GI motility, constipation, respiratory depression, dependence, and tolerance are evident in varying degrees with all agents.[39,45] Tolerance to side effects (except to constipation) often develops over time.[43,45] Some differences exist between the opioids in regards to incidence of side effects, which may assist in selection of the most appropriate agent. 3 4 5 The route of administration depends on individual patient needs, with the oral route being preferred. However, the onset of analgesic effect for oral medications is approximately 45 minutes, and the peak effect usually occurs 1 to 2 hours after administration.[39] This delay must be considered when immediate relief is needed in the management of acute pain. Therefore, in some scenarios, such as acute severe pain (eg, pain crisis) or when the patient is unable to take oral medications, alternative routes of therapy, such as intravenous (IV) administration, may be preferred. The relative potency, defined by the equianalgesic dose, of opioids differs greatly (see Table 60-4). 4 5 Equianalgesic dose tables are often based on single-dose studies without regard for patient variability and should be used only as a guide, with further dose titration frequently required.[46]

Although true opioid allergies are rare, Table 60-4 can also be used when treating a patient who has a documented hypersensitivity to opioids. Most reactions, such as itching or rash, are due to the associated histamine release from cutaneous mast cells and not a true allergic or immunoglobulin-E

(IgE) or T-cell response.[47] Although caution is always advised, a decrease in potential cross-sensitivity is thought to exist when moving from one opioid structural class to another.[48] The classes are phenanthrenes (morphine-like agonists), phenylpiperidines (meperidine-like agonists), and diphenylheptanes (methadone-like agonists). When considering cross-sensitivity, the mixed agonist–antagonist and partial agonist class acts much like the morphine-like agonists.[49]

2 5 In the initial stages of acute pain, analgesics should be given around the clock. This should commence after administering a typical starting dose and titrating up or down, depending on the patient's degree of pain and demonstrated side effects (eg, sedation). As needed schedules may produce wide swings in analgesic plasma concentrations resulting in alternating states of uncontrolled pain and sedation. This may initiate a vicious cycle where increasing amounts of pain medications are needed for relief. 5 As the painful state subsides and the need for medication decreases, as needed schedules may be appropriate, which may also be useful in patients who present with pain that is intermittent or sporadic in nature (**Fig. 60-2**). As the painful state subsides and the need for medication decreases, as-needed schedules may be appropriate, which may also be useful in patients who present with pain that is intermittent or sporadic in nature (Fig. 60-2). When opioids are used in the management of persistent chronic pain, such as in oncology, around-the-clock administration schedules should be utilized (**Fig 60-3**). As needed opioids should be used in conjunction with around-the-clock regimens for times when patients experience breakthrough pain, which is a brief, transitory, exacerbation of moderate to severe pain typically occurring in patients with underlying persistent pain that may otherwise be controlled.[25,39,46]

FIGURE 60-2

Algorithm for acute pain. *(Data from Omnicare, Inc., Acute Pain Pathway.)*

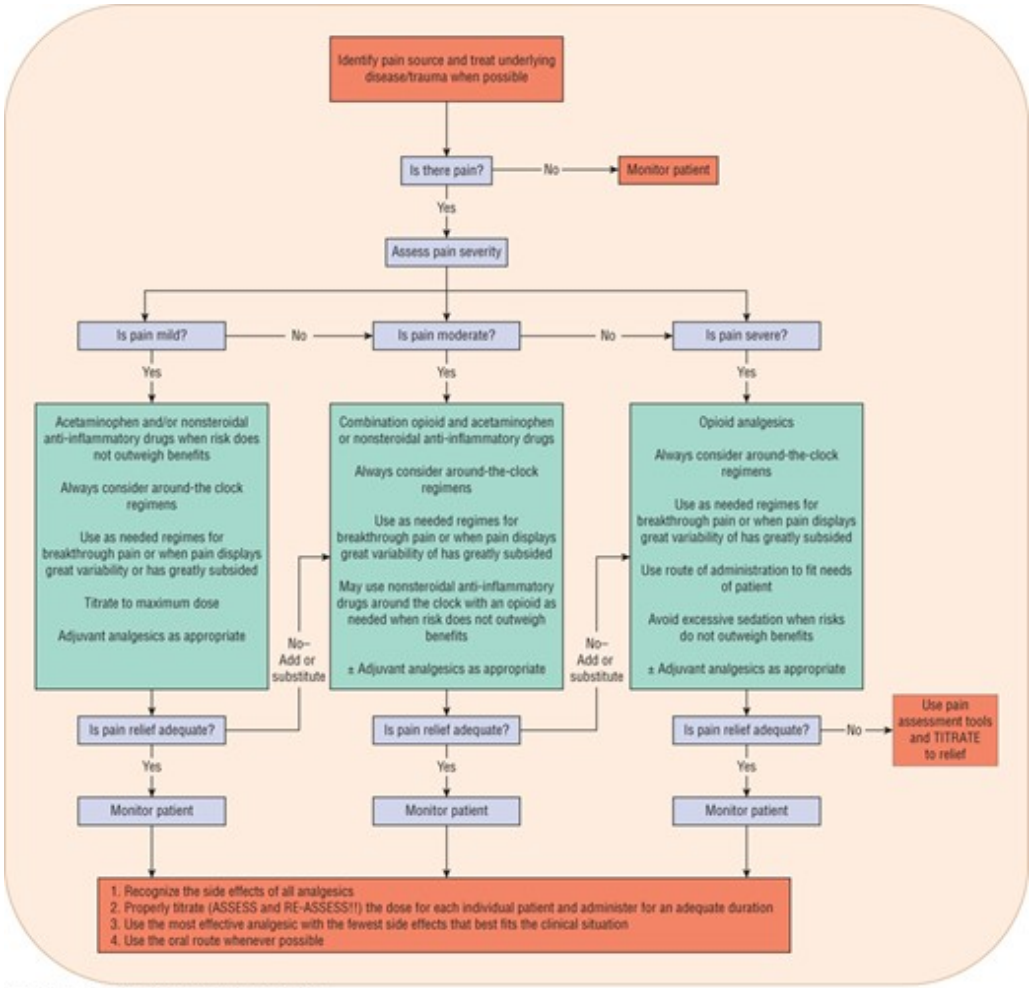

FIGURE 60-3

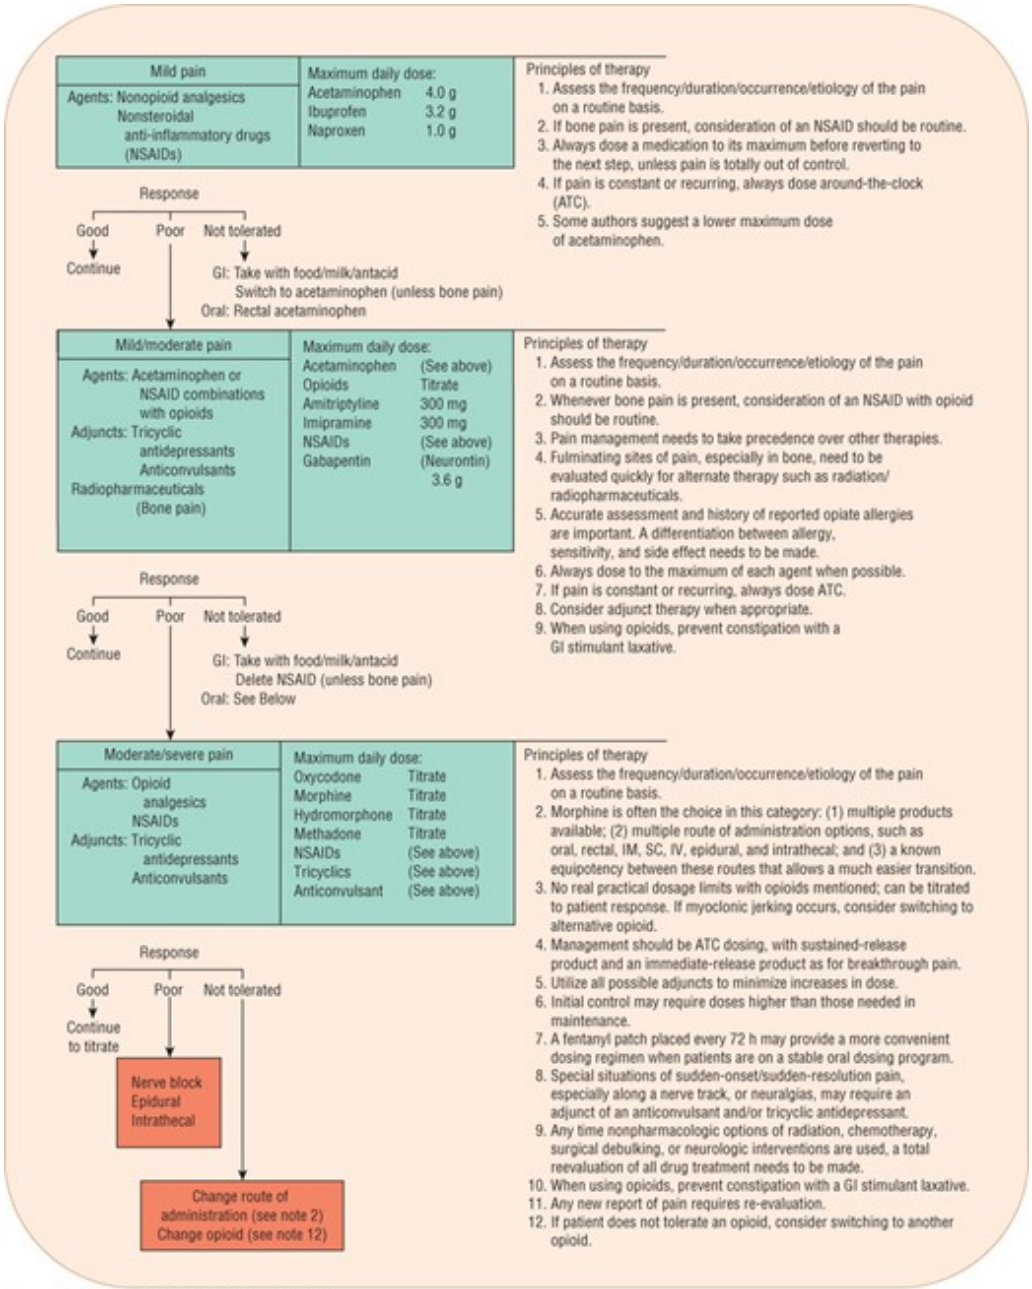
Algorithm for pain management in oncology patients. *(Data from the Kaiser Permanente Algorithm for Pain Management in Patients with Advanced Malignant Disease.)*



Continuous IV infusion of opioids should be reserved for opioid-tolerant patients.[50] An alternative method is patient-controlled analgesia (PCA), which is a technique in which patients can self-administer a preset dose of an IV opioid via a pump electronically interfaced with a timing device. Compared with traditional as needed opioid dosing, PCA yields better pain control, improved patient satisfaction, and relatively few differences in side effects.[50,51]

Administration of opioids directly into the CNS (eg, epidural and intrathecal/subarachnoid routes) may also be used by anesthesiology pain consult services in the control of acute, chronic noncancer, and cancer pain (**Table 60-7**); and is useful in more difficult to control pain states.[52] Due to reports of respiratory depression, pruritus, nausea, vomiting, urinary retention, and hypotension, these methods of analgesia require careful monitoring and are best used by experienced practitioners. Respiratory depression is of concern and can occur within minutes with intrathecal fentanyl or manifest as late as

19 hours after a single dose of intrathecal morphine. Guidelines mandate respiratory monitoring for at least 24 hours after a single dose of intrathecal or epidural morphine with standing orders for naloxone (opioid antagonist) for full or partial reversal.[53] Analgesia and side effects are evident at even lower doses when opioids are administered intrathecally instead of epidurally. This form of analgesia is often administered as a continuous-infusion and/or on a patient-controlled basis. When given simultaneously with intrathecal or epidural local anesthetics such as bupivacaine, opioid analgesics have been proven relatively safe and effective. All agents administered directly into the CNS should be preservative free.

TABLE 60-7 Intraspinal Opioids

Agent	Single Dose (mg)	Onset of Pain Relief (min)	Duration of Pain Relief (h)	Continual Infusion Dose (mg/h)
Epidural route				
Morphine	1-6	30	6-24	0.1-1
Hydromorphone	0.8-1.5	5-8	4-8	0.1-0.3
Fentanyl	0.025-0.1	5	2-8	0.025-0.1
Sufentanil	0.01-0.06	5	2-4	0.01-0.05
Subarachnoid route				
Morphine	0.1-0.3	15	8-34	–
Fentanyl	0.005-0.025	5	3-6	–

Note: Doses above should not be interpreted as equianalgesic doses for conversion to or from the specific opioid or route of administration.

Data from reference 39.

Opioids

Morphine and Congeners

Despite the availability of several newer agents, morphine remains the prototype opiate analgesic. As new opioid and nonopioid compounds are developed, their efficacy and side-effect profiles are typically compared against morphine as the standard. Using the equianalgesic tables, clinicians often refer to "oral morphine equivalents" when describing efficacy of other opioids. Many clinicians consider morphine the first-line agent when treating moderate-to-severe pain due to its relative low cost, broad clinical experience, and abundant dosage forms/strengths.

2 Side effects can be numerous, particularly when morphine is first initiated or when doses are significantly increased. Morphine causes nausea and vomiting through direct stimulation of the chemoreceptor trigger zone, decreased peristalsis, and a vestibular mechanism.[43] Opioid-induced nausea typically subsides over time with continued dosing, although this side-effect may be incredibly troublesome to patients, especially following surgery.[54] Although euphoria and dysphoria have been reported, morphine's unpleasant effects are more prominent when administered to

patients not experiencing pain.[43,45] As doses of morphine are increased, the respiratory center becomes less responsive to carbon dioxide, causing progressive respiratory depression.[45] This effect is less pronounced in patients being treated for severe or chronic pain, although concurrent administration with other respiratory depressants, such as benzodiazepines, may greatly enhance this adverse effect.[41] Respiratory depression often manifests as a decrease in respiratory rate (although minute volume and tidal exchange also are affected) and is further compounded because the cough reflex is also depressed.[43] More recently, end-tidal capnography has become commonplace as a means to monitor opioid-induced respiratory depression, especially in those at increased risk.[55] Morphine-induced respiratory depression can be reversed by the opioid antagonist, naloxone. In patients with underlying pulmonary dysfunction or sleep disordered breathing, caution must be exercised when opioids are used, as these patients are already using compensatory breathing mechanisms and are at risk for further respiratory compromise. Caution is also urged when combining opiate analgesics with alcohol or other CNS depressants (ie, benzodiazepines), because this combination is potentially harmful and possibly lethal.[43]

Therapeutic doses of morphine have minimal effects on blood pressure, cardiac rate, or cardiac rhythm when patients are supine; however, morphine does produce venous and arteriolar vessel dilation, potentially resulting in orthostatic hypotension, and hypovolemic patients may be more susceptible to morphine-induced cardiovascular changes (eg, decreases in blood pressure).[45] Because morphine prompts a decrease in myocardial oxygen demand in ischemic cardiac patients, it is often used to treat pain associated with myocardial infarction, although this practice has been called into question due to the potential for increased mortality.[56]

Morphine decreases the propulsive contractions of the GI tract resulting in constipation.[57] Morphine-induced spasms of the sphincter of Oddi have also been observed; however, the clinical significance of this is unclear. Urinary retention is another significant side effect of morphine and should be routinely assessed. Morphine-induced histamine release often manifests as pruritus, and may even exacerbate bronchospasm in patients with a history of asthma.[39] Therapeutic doses of morphine are not contraindicated in head injury, but drug-induced respiratory depression can increase intracranial pressure. Thus, caution is advised in head trauma patients who are not mechanically ventilated because morphine may increase intracranial pressures and cloud the neurologic examination results.[43]

Morphine is metabolized to two major metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). M6G contributes to analgesia, whereas M3G may contribute to unwanted side effects. The metabolites are renally cleared and can accumulate in patients with renal impairment, contributing to greater side effects.[43] Most clinicians recommend avoiding morphine in renally compromised patients (ie, creatinine clearance less than or equal to 30 mL/min [less than or equal to 0.5 mL/s]). Morphine also inhibits the release of gonadotropin-releasing hormone from the hypothalamus, thus decreasing plasma testosterone and cortisol (opioid-induced hypogonadism), whereas male patients may present with symptoms of erectile dysfunction, decreased libido, and decreased analgesic efficacy.[58] Women may experience alopecia, amenorrhea, and depressed mood, as well as decreased analgesic efficacy. Recommendations for clinical replacement of these hormones

in patients using chronic opioid therapy are not well defined.[58] While the clinical meaning has not clearly been elucidated, morphine and other opioids, depending on the situation being used, may either enhance or inhibit the immune system.[39,43]

4 Hydromorphone is more potent than morphine, but its overall pharmacologic profile parallels that of morphine. Some clinicians believe hydromorphone is associated with fewer side effects, especially pruritus, compared with other opioids. However, the research is limited and does not conclusively demonstrate this difference. Oxymorphone can be administered orally and by injection. Although extended-release and immediate-release oral products are available, it offers no pharmacologic advantage over morphine. Patients must be counseled to take the extended-release oxymorphone without food as high fat meals may greatly increase absorption, resulting in an increased risk of toxicity. Levorphanol has an extended half-life, but its overall therapeutic effects are similar to the other agents in this class.

Codeine is a commonly used opiate for the treatment of mild-to-moderate pain. It often is combined with other analgesic products (eg, acetaminophen). Unfortunately, it has the same propensity to produce side effects as morphine. Hydrocodone is perhaps the most commonly prescribed opiate and is available orally as immediate-release combined with nonopioid analgesics, as well as extended-release formulations. Its pharmacologic properties are similar to those of morphine. Oxycodone is a useful oral analgesic for moderate-to-severe pain. This is especially true when the product is used in combination with nonopioids. Although oxycodone shares basic morphine characteristics, the availability of an immediate-release and controlled-release oral dosage form also makes it very useful in chronic pain as well as acute pain.

Meperidine and Congeners (Phenylpiperidines)

The prototype phenylpiperidine, meperidine, has a pharmacologic profile comparable with that of morphine; however, it is not as potent and has a shorter analgesic duration. Meperidine offers no analgesic advantage over morphine, has greater toxicity (CNS hyperirritability caused by its renally eliminated metabolite normeperidine), and should be limited in use, especially in elderly patients, those with renal dysfunction, or for prolonged treatment durations.[39] In particular, avoid long-term usage and use in patients at greatest risk for toxicity (eg, elderly patients and those with renal dysfunction).[59]

Fentanyl is a synthetic opioid structurally related to meperidine that is used often in anesthesiology as an adjunct to general anesthesia. This agent is significantly more potent and faster acting than meperidine (see Table 60-4). It can be administered parenterally, transmucosally, sublingually, intranasally, and transdermally.[46]

Methadone and Congeners

Methadone has gained considerable popularity as an analgesic due to its oral efficacy, extended duration of action, and low cost. Properties unique to methadone, compared with other opioids, include the S-isomer's ability to antagonize NMDA receptors, agonist effects at the kappa opioid

receptor (KOR) and delta opioid receptor (DOR), as well as the blockade of serotonin and norepinephrine reuptake.[60] These properties may prove useful in the treatment of neuropathic and chronic pain. However, few trials have thoroughly evaluated methadone's risks versus benefits.[41,60] Epidemiologic studies suggest a growing number of methadone-related deaths, and cardiac arrhythmias have been associated with this medication, particularly at higher doses or when used concurrently with other agents that prolong QTc intervals. Recommendations exist for specific echocardiogram monitoring for methadone; however, concerns exist regarding their applicability.[60] The equianalgesic dose of methadone may decrease with higher doses of the comparator opioid, complicating conversions from other opioids to methadone. Methadone should not be titrated more frequently than every 5 to 7 days due to its unpredictable potency and variable half-live.[46,60]

Clinical Controversy…

Some clinicians believe that methadone should be tried before other opioids in many chronic pain conditions where an opioid is warranted because they believe that neuropathic pain is often a component. Other clinicians believe that sustained-released morphine or oxycodone is better first choice.

Opioid Agonist–Antagonist Derivatives

This analgesic class produces analgesia and has the potential for less respiratory depression than opioid agonists as they exert their analgesic activity via the KOR and either block or act as partial agonists at the MOR.[43] Agents in this class are considered to have a lower abuse potential than morphine, but psychotomimetic responses (eg, hallucinations and dysphoria), limited analgesic effect, and a propensity to initiate withdrawal in opioid-dependent populations have precluded their widespread clinical use. Both butorphanol and nalbuphine are available parenterally, with butorphanol also available as an intranasal spray. Nalbuphine is gaining popularity as a treatment for MOR agonist associated pruritus.[61]

Buprenorphine is a pharmacologically rich opioid, which exhibits KOR antagonism, and several MOR related actions, including partial agonism. Buprenorphine also displays agonist properties at the opioid receptor-like 1 receptor (ORL-1) which may have clinical ramifications in prevention of tolerance, euphoria/reward, and hyperalgesia.[62] Buprenorphine is available as a sublingual tablet, a once-weekly transdermal patch, or in combination with naloxone as a sublingual film. When buprenorphine/naloxone sublingual film is prescribed for opioid use disorder, a special DEA license is required by the prescriber.[63]

Central-Acting Opioids

Tramadol and tapentadol are the only centrally acting analgesics currently available in the United States. Tramadol binds to MOR receptors and inhibits serotonin, and, to a lesser extent, norepinephrine reuptake.[64] Tapentadol also binds the MOR receptor, but inhibits largely norepinephrine reuptake. Tramadol is indicated for the relief of moderate to moderately severe pain, while tapentadol is indicated for moderate-to-severe acute pain and diabetic peripheral

neuropathy.[14,43]

Both tramadol and tapentadol have side-effect profiles similar to that of the previously mentioned opioid analgesics (eg, dizziness, nausea, somnolence, and constipation). Tapentadol has not been systematically evaluated in patients with seizures, and it should be used with caution in these patients. Seizure risk may be elevated in patients taking tramadol.[65] In general, tramadol may have a place in treating patients with chronic pain, especially neuropathic pain, while tapentadol may be useful in the management of acute pain and the controlled release product may have a role in chronic pain treatment (eg, diabetes-related nerve pain).[66,67] It is important to note that tapentadol is significantly more potent than tramadol and these agents should not be used interchangeably.

Opioid Antagonists

The opioid antagonist naloxone binds competitively to opioid receptors but does not produce an analgesic or opioid side-effect response. Therefore, it is used most often to reverse the toxic effects of agonist- and agonist–antagonist-derived opioids. Other opioid antagonists exist, including naltrexone, naloxegol, and methylnaltrexone. Naltrexone's use is primarily limited to addiction medicine, while naloxegol and methylnaltrexone are peripherally acting only and used for opioid-induced constipation.[68]

With the growing prevalence of heroin and prescription opioid abuse related overdoses, pharmacists are increasingly being called upon to assist in the prevention of these deaths. Several States have legislation pending allowing for pharmacists to both prescribe and administer naloxone to those suspected of experiencing an opioid overdose. Naloxone may be administered intranasally or intramuscularly in these situations, and an intramuscular autoinjector, similar to that of the epinephrine devices, has recently become available.[69]

Tolerance, Hyperalgesia, Physical Dependence, Addiction, and Pseudoaddiction

A barrier that consistently causes clinicians to misjudge and mistreat pain is the misunderstanding of opioid tolerance, hyperalgesia, physical dependence, addiction, and pseudoaddiction. Tolerance is the reduction of drug effect over time as a result of exposure to the drug.[45] It develops at different rates and with great patient variability. However, with stable disease, opioid dose may stabilize over time. Hyperalgesia is an increased sensitivity to pain secondary to increased opioid doses that can be seen with rapid opioid escalation or high dose administration.[70] The mechanism or true clinical impact of this phenomenon is not currently understood. Opioid physical dependence is characterized by an abstinence syndrome following administration of an antagonist drug or abrupt dose reduction/discontinuation of an opioid.[45] Clinicians must understand that physical dependence and tolerance are not equivalent to addiction; and with chronic opioid use, physical dependence is expected.[45] Many definitions and classifications exist to describe the biopsychosocial phenomenon of addiction. The American Society of Addiction Medicine (ASAM) defines addiction as a "primary, chronic disease of brain reward, motivation, memory, and related circuitry" leading to biological, psychological, social and spiritual manifestations.[71] Addiction is characterized by cravings, resulting in

an inability to abstain from continued drug use despite harm and impairment in behavioral control. Individually, these behaviors are often described as aberrant, although patients may display aberrant behaviors (eg, medication-related behaviors that are inconsistent with strict adherence to the prescribed treatment) that are not a result of an underlying addiction.[7] A baseline assessment and ongoing evaluation of these behaviors and an individual's risk of misuse, abuse, and addiction is critical to mitigate risks of chronic opioid therapy and ensure patient safety.[72] Higher risk for opioid misuse or abuse is associated with a personal substance abuse, misuse, addiction, or diversion history, a significant family history of substance abuse, and presence of underlying psychiatric diagnosis.[41] Modifications to the treatment plan should be stratified based on patient risk, including baseline and random drug screens, patient–provider treatment agreements, pill counts, a smaller prescription supply, and regular assessment of aberrant behaviors. Combining these approaches with regular and ongoing assessments of pain and functionality may result in improved outcomes.[41]

Coanalgesics

Coanalgesics represent a diverse group of pharmacologic agents with individual characteristics that make them useful in the management of pain, but typically are not classified as analgesics. Examples of coanalgesics include antidepressants and anticonvulsants. Chronic pain that has a neuropathic component (eg, diabetic neuropathy) often requires coanalgesic therapy (**Table 60-8**). Anticonvulsants (eg, gabapentin, pregabalin, which may decrease neuronal excitability), tricyclic antidepressants and serotonin and norepinephrine reuptake inhibitor antidepressants (eg, nortriptyline, duloxetine, venlafaxine—which block the reuptake of serotonin and norepinephrine, thus enhancing pain inhibition), and topically applied local anesthetics (which decrease nerve stimulation) all have demonstrated efficacy in managing various chronic pain conditions.[73]

TABLE 60-8 Opioids to Avoid/Exercise Caution

Drug	Caution	Notes
Codeine	Do not use—especially in children and breastfeeding	Codeine is a prod rug, must be converted by CYP 2D6 to morphine to produce analgesia. High degree of polymorphism of 2D6, ultra-rapid metabolism = toxicity, poor metabolism = no analgesia
Meperidine	Do not use	Short duration of analgesia requiring frequent dosing Produces non-analgesic, toxic metabolite normeperidine, accumulation results in seizures, risk of accumulation increased in renal insufficiency
Agonist/Antagonist agents	Caution	Can produce opioid withdrawal in patients chronically taking opioid. Higher rate of psychomimetic reactions compared to other opioids
Tramadol	Caution—especially in elderly or in renal dysfunction	Tramadol is a pro-drug, must be converted by CYP 2D6 to desmethyl-tramadol (M1) to produce analgesia. High degree of polymorphism of 2D6, ultra-rapid metabolism = toxicity, poor metabolism = no analgesia

Drug	Caution	Notes
		Risk of seizure, risk of serotonin syndrome, risk of hypoglycemia

Data from references 59, 64, 65 and 80.

Clinical Controversy…

Many clinicians believe that some chronic painful conditions (eg, osteoarthritis) should never be treated with opioids; whereas others believe that when other modalities are not effective or seem to pose more of a risk to that particular patient than does conventional therapy (eg, NSAIDs), then opioids are necessary.

In the management of cancer pain, radiopharmaceuticals (eg, strontium-89 or samarium), corticosteroids, and bisphosphonates are useful coanalgesics in treating bone pain (Fig. 60-3).[74] Although antihistamines and amphetamines have been used as coanalgesics, they have demonstrated only limited success.

Multimodal Therapy

Commonly, multimodal therapy may be employed to optimize either acute or chronic pain management. Multimodal therapy is the concomitant use of different therapeutic interventions with the intent of obtaining additive therapeutic effects. Multimodal analgesia, one type of multimodal therapy, includes combining medications from different analgesic classes (eg, combination therapy with opioids and nonopioids or coanalgesics).[14,45] This often results in analgesia superior to that produced by either agent alone. Multimodal analgesia may also permit the use of lower doses and provide a more favorable side-effect profile, for example when NSAIDs are prescribed with opioids yielding an "opioid sparing" effect.

Regional Analgesia

Regional analgesia with properly administered local anesthetics can provide relief of both acute and chronic pain (**Table 60-9**).[75] These agents can be positioned by injection (eg, in joints, in the epidural or intrathecal space, along nerve roots, or in a nerve plexus) or topically. Lidocaine in the form of a patch has proven effective in treating focal neuropathic pain.[76] Regional nerve blocks with local anesthetics may effectively relieve pain. Although rare, elevated plasma concentrations of local anesthetics can cause CNS excitation and depression, including dizziness, tinnitus, drowsiness, disorientation, muscle twitching, seizures, and respiratory arrest.[75] Cardiovascular adverse effects include myocardial depression, hypotension, decreased cardiac output, heart block, bradycardia, arrhythmias, and cardiac arrest. Disadvantages of such methods include the need for skillful technical application, need for frequent administration, and highly specialized follow-up procedures.

TABLE 60-9 Local Anesthetics[a]

Agent (Brand Name)	Onset (min)	Duration (h)

Agent (Brand Name)	Onset (min)	Duration (h)
Esters		
Procaine (Novocain, various)	2-5	0.25-1
Chloroprocaine (Nesacaine, various)	6-12	0.5
Tetracaine (Pontocaine)	≤15	2-3
Amides		
Mepivacaine (Polocaine, various)	3-5	0.75-1.5
Bupivacaine (Marcaine, various)	5	2-4
Bupivacaine liposomal (Exparel—wound infiltration only)	variable	24 local 96 systemic
Lidocaine (Xylocaine, various)	<2	0.5-1
Prilocaine (Citanest)	<2	1-2
Ropivacaine[b] (Naropin)	10-30	0.5-6

[a]Unless otherwise indicated, values are for infiltrative anesthesia.

[b]Epidural administration.

Data from reference 42.

Clinical Controversy…

Some clinicians believe that daily opioid doses in chronic noncancer patients should be limited because the risk of potential abuse and that the adverse effects may out-weigh the benefits. In fact, some guidelines have even incorporated recommendations to limit doses to less than 90 mg of morphine or its daily equivalent (Centers for Disease Control). Other clinicians believe that by carefully screening patients for risks of abuse, frequent monitoring, identifying targeted pain symptoms, utilizing pain treatment "agreements," and distinctly outlining the treatment plans with patients, opioids can be titrated to effect, based on symptoms with no defined maximum dose.

SPECIAL POPULATIONS

The elderly and the young are at a higher risk for undertreatment because of inability to communicate or rate their pain. It is in these cases that parent or caregiver input becomes paramount to identify changes in behavior, which might suggest pain (eg, fussy, inconsolable, changes in eating patterns, crying out, or agitation). When patients cannot verbalize their pain (eg, coma), monitoring behaviors (eg, agitation) and physiologic signs and symptoms (eg, heart rate) is appropriate.

7 In addition, those living with chronic, debilitating, and life-threatening illnesses need specialized pain control and care that is palliative in nature.[77] Although care must be taken in these populations to ensure that proper individualized treatment plans follow accepted guidelines, the key concepts in

pain management as outlined in this chapter are the guiding tenets in maximizing pain control.[78,79]

PERSONALIZED PHARMACOTHERAPY

Recent research has illustrated genetic differences in pain transmission and response inter-individually as well as between genders, ages, and ethnicity. More interesting is the pharmacogenomic variability of analgesic response to both opioid and nonopioid analgesics. Genotyping (eg, CYP 2D6, CYP 2B6) may be useful when considering the addition of an opioid metabolized via one of these enzymes.

Codeine, oxycodone, hydrocodone, and methadone, as well as several of the SSRIs and SNRIs, are all either converted to active or inactive metabolites via one of these enzyme pathways.[80] Individuals who possess a variant allele for one or more of these enzymes may have unexpected outcomes, including greater than expected toxicity or side effects and lower than expected efficacy, depending on the individual genotype and phenotype. Frequency of genetic variation differs by ethnicity and gene. For example, up to 10% to 15% of the general population may be phenotypically poor metabolizers of CYP2D6, while 20% of Africans may be poor metabolizers and 30% of Arabs are ultra-rapid metabolizers.[81] This may be especially relevant for opioids in which much of the analgesic activity relies on conversion to an active metabolite from a relatively inactive parent (ie, codeine and tramadol). Recent data suggests high rates of variant metabolism in patients evaluated for genetic variation in CYP2C9, CYP2C19, and CYP2D6, with over 50% of patients expressing a variant in two or more genes.[82]

In some cases, genotype results may further help to explain cases where patients require higher doses to achieve adequate analgesia. For example, early published data suggests that variants in opioid-receptor subtypes, specifically MOR-1 (OPRM1 gene), may predict efficacy and dosing requirements for some opioids such as morphine or hydromorphone.[83,84]

EVALUATION OF THERAPEUTIC OUTCOMES

2 5 Consistent monitoring for effectiveness (eg, pain relief and adequate functionality) and adverse effects (eg, sedation) is critical in optimizing therapeutic outcomes. Numerous validated scoring tools exist (eg, numeric rating scale, visual analog scale, etc.); however, the tools need to be appropriate for the type of pain being evaluated, used consistently, and with good clinical judgment.[23,26] Pain management efficacy, any change in pain, and medication side effects (eg, opioid-induced sedation or constipation) must be assessed and reassessed on a regular basis. Frequency of reassessment should be dictated by the medication's route of administration, duration of action, various pharmacokinetic factors, or other concomitant therapies. Postoperative pain and acute exacerbation of cancer pain may need to be assessed hourly, whereas chronic noncancer pain may require only daily or less frequent assessment. Pain intensity assessment is vital in acute pain, whereas functionality becomes more of an issue in chronic pain. Quality of life must be assessed on a regular basis in all patients. Many advocate using the four "A"s (analgesia, activity, aberrant drug behavior, and adverse effects) as key assessment measures for any patient with chronic pain.

It is important to note that often objective signs are lacking for pain evaluation. Acute pain may result in increased sympathetic tone (eg, hypertension, tachycardia, and tachypnea); however, this response is usually diminished as acute pain progresses to chronic pain. The clinician must rely on the patient's description of their pain.

[2] All opioids can cause constipation. The best management of constipation is prevention. Patients should be counseled on the proper intake of fluids and fiber. A stimulating laxative should be added with chronic opioid use. [7] CNS depressants (eg, alcohol and benzodiazepines) amplify CNS depression when used with opioid analgesics, and use of these combinations should be discouraged when possible. When the combinations are used, patients should be monitored closely.

Clinical Controversy...

Some clinicians believe that opioid risk evaluation and mitigation strategies, which consist of mandatory care-giver enrollment, prescriber training, patient medication guides, and patient prescriber agreements, as outlined by the Federal Food and Drug Administration will decrease opioid misuse and lead to better patient care. Others feel this leads to increased costs and becomes a barrier to effective pain therapy.

Chapter 61: Headache Disorders

Deborah S. Minor; T. Kristopher Harrell

INTRODUCTION

KEY CONCEPTS

- 1 Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work.
- 2 A stratified care approach, in which the selection of initial treatment is based on headache-related disability and symptom severity, is the preferred treatment strategy for the migraineur.
- 3 Strict adherence to maximum daily and weekly doses of anti-migraine medications is essential.
- 4 Preventive therapy should be considered in the setting of recurring migraines that produce significant disability; frequent attacks requiring symptomatic medication more than twice per week; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury.
- 5 The selection of an agent for headache prophylaxis should be based on individual patient response, tolerability, convenience of the drug formulation, and coexisting conditions.
- 6 Each prophylactic medication should be given an adequate therapeutic trial (usually 6 months) to judge its maximal efficacy.
- 7 A general wellness program and consideration of headache triggers should be included in the management plan.
- 8 After an effective abortive agent and dose have been identified, subsequent treatments should begin with that same regimen.

Headache is one of the most common complaints encountered by healthcare practitioners and among the top five principal reasons given by adults 18 to 44 years of age for visiting US emergency

departments.[1] It can be symptomatic of a distinct pathologic process or can occur without an underlying cause. In 2013, the International Headache Society (IHS) updated its classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain[2] (**Table 61-1**). Designed to facilitate headache diagnosis in clinical practice and research, the IHS classification provides more precise definitions and standardized nomenclature for both the primary (tension-type, migraine, and cluster headache) and secondary (symptomatic of organic disease) headache disorders. This chapter focuses on the management of the primary headache disorders.

TABLE 61-1 International Headache Society Classification System: Focus on Migraine Headache

Migraine
Migraine without aura
Migraine with aura
Migraine with typical aura (lasting less than 1 hour) with or without headache
Migraine with brainstem aura
Hemiplegic migraine (familial, sporadic)
Retinal migraine (repeated attacks of monocular visual disturbance)
Chronic migraine (occurring on 15 or more days/mo for more than 3 months)
Complications of migraine
Status migrainous (debilitating attack lasting for more than 72 hours)
Persistent aura without infarction (symptoms persisting for more than 1 week)
Migrainous infarction (aura symptoms associated with an ischemic brain lesion)
Migraine aura-triggered seizure
Probable migraine with or without aura
Episodic syndromes that may be associated with migraine
Recurrent gastrointestinal disturbance (cyclical vomiting syndrome or abdominal migraine)
Benign paroxysmal vertigo
Benign paroxysmal torticollis
Tension-type headache
Cluster headache and other trigeminal autonomic cephalalgias
Other primary headaches
Headache attributed to head and/or neck trauma
Headache attributed to cranial or cervical vascular disorder
Headache attributed to nonvascular intracranial disorder
Headache attributed to a substance or its withdrawal
Headache attributed to infection
Headache attributed to disorder of homeostasis
Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cervical structure
Headache attributed to psychiatric disorder

Cranial neuropathies and facial pains

Other headache disorders, not elsewhere classified or unspecified

Adapted from Headache Classification Committee of the International Headache Society. The international classification of headache disorders, 3rd ed. Cephalalgia 2013;33(9):629-808.

Most recurrent headaches are the result of a benign chronic primary headache disorder.[3] Less often, headaches are symptomatic of a serious underlying medical condition, such as infection, cerebral hemorrhage, or brain mass lesion. The peak prevalence of tension-type and migraine headache, the most common of the primary headache disorders, occurs during the most productive years of life (18-54 years of age).[3,4] Despite the prevalence of these disorders and their associated disability, studies indicate that most headache sufferers do not obtain appropriate medical care for their headaches.[4,6] An improved understanding of the diagnosis and pathophysiologic mechanisms of the primary headache disorders, particularly migraine, has led to the development of medications capable of providing rapid relief from moderate to severe attacks. However, a thorough evaluation of the headache history is essential to establish an accurate headache diagnosis and identify patients who can benefit from these specific therapeutic options.

MIGRAINE HEADACHE

Epidemiology

Results of the American Migraine Prevalence and Prevention Study indicate that 17.1% of women and 5.6% of men in the United States experience one or more migraine headaches per year. The prevalence of migraine varies considerably by age and gender, but the epidemiologic profile has remained stable over the past 8 years. Gender differences in migraine prevalence have been linked to menstruation, but these differences persist beyond menopause. Prevalence is highest in both men and women between the ages of 18 and 44 years and is inversely related to income and educational attainment. In the American Migraine Prevalence and Prevention Study, 93% of those with migraine reported some headache-related disability, and 54% were severely disabled or needed bedrest during an attack.[4,5] A number of neurologic and psychiatric disorders as well as cardiovascular diseases, including stroke, epilepsy, major depression, sleep apnea, obesity, and anxiety disorder, show increased comorbidity with migraine.[6,7] Whether this relationship is causal or representative of a common pathophysiologic mechanism is unknown. The economic burden of migraine is substantial; however, the indirect costs from work-related disability far exceed the direct costs associated with treatment.[8,9]

Etiology And Pathophysiology

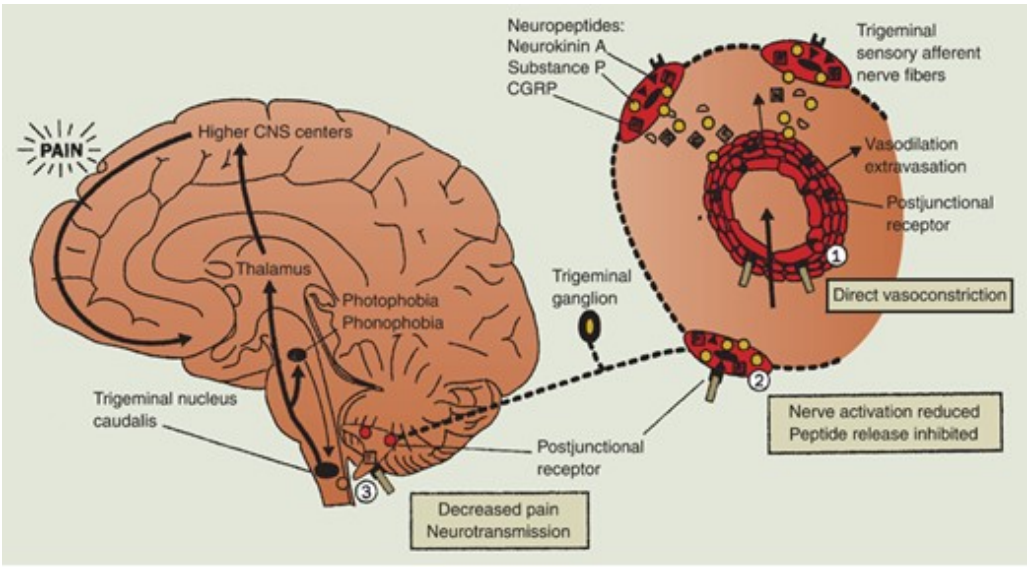
The etiologic and pathophysiologic mechanisms of migraine are not completely understood. According to earlier theories, the migraine aura was caused by intracerebral arterial vasoconstriction followed by reactive extracranial vasodilation and associated headache. Studies of regional blood flow in the brain do not support this hypothesis, and previous vascular and neural theories of

migraine development have merged into a combined theory of neurovascular mechanisms. Most clinicians now believe that the pathogenesis of migraine may be related to complex dysfunctions in neuronal and broad sensory processing.[2,6,10]

The pain and symptoms of migraine may be understood as a combination of altered perceptions resulting from neural suppression and activation of subcortical structures and trigeminal systems. Migraine pain is believed to result from activity within the trigeminovascular system, a network of visceral afferent fibers that arises from the trigeminal ganglia and projects peripherally to innervate the pain-sensitive intracranial extracerebral blood vessels, dura mater, and large venous sinuses[11] (**Fig. 61-1**). These fibers also project centrally, terminating in the trigeminal nucleus caudalis in the brain stem and upper cervical spinal cord, and thus provide a pathway for nociceptive transmission from meningeal blood vessels into higher centers of the central nervous system (CNS). Activation of trigeminal sensory nerves triggers the release of vasoactive neuropeptides, including calcitonin gene-related peptide (CGRP), neurokinin A, and substance P, from perivascular axons. The released neuropeptides interact with dural blood vessels to promote vasodilation and dural plasma extravasation, resulting in neurogenic inflammation. Orthodromic conduction along trigeminovascular fibers transmits pain impulses to the trigeminal nucleus caudalis, where information is relayed further to higher cortical pain centers. Continued afferent input can result in sensitization of these central sensory neurons, producing a hyperalgesic state that responds to previously innocuous stimuli and maintains the headache.[6,10,11,12]

FIGURE 61-1

The pathophysiology of migraine headache. Vasodilation of intracranial extracerebral blood vessels (possibly the result of an imbalance in the brainstem) results in the activation of the perivascular trigeminal nerves that release vasoactive neuropeptides to promote neurogenic inflammation. Central pain transmission may activate other brainstem nuclei, resulting in associated symptoms (nausea, vomiting, photophobia, and phonophobia). The antimigraine effects of the 5-$HT_{1B/ID}$ receptor agonists are highlighted at areas 1, 2, and 3. (CGRP, calcitonin gene-related peptide.) *(Reprinted from the Lancet, Vol. 351, Ferrari MD, Migraine, 1043-1051, Copyright © 1998, with permission from Elsevier.)*



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Aura occurs in a subgroup of migraineurs and also with the other primary headache disorders. The neurologic changes of the aura parallel those that occur during cortical spreading depression, a neuronal event characterized by a wave of depressed electrical activity that advances across the brain cortex at a rate consistent with the spread of aura symptoms.[6,10] Cortical spreading depression can cause inflammation and activation of the trigeminal nucleus caudalis. It is not clear whether this cortical spreading depression and the aura are the substrate of pain or actually trigger the presentation of migraine.[6,12]

Genetic factors seem to play an important role in susceptibility to migraine attacks. Studies in monozygotic twins suggest approximately 50% heritability of migraine with a multifactorial polygenic basis.[13] Although it is possible for any individual to experience a migraine attack, it is recurrence in the migraineur that is abnormal. Attack occurrence and frequency are governed by CNS sensitivity to migraine-specific triggers or environmental factors. Migraineurs appear to have a lowered threshold of response to specific environmental circumstances as a result of genetic factors that govern the balance of CNS excitation and inhibition at various levels. Thus, trigger factors can be viewed as modulators of the genetic set point that predisposes to migraine headache.[13,14] The hyperresponsiveness of the migrainous brain may be the result of an inherited abnormality in calcium and/or sodium channels and sodium/potassium pumps that regulate cortical excitability through the release of serotonin (5-hydroxytryptamine [5-HT]) and other neurotransmitters. Increased levels of excitatory amino acids such as glutamate and alterations in levels of extracellular potassium also can affect the migraine threshold and initiate and propagate the phenomenon of cortical spreading depression.[6,13,14,15,16]

5-HT has long been implicated as an important mediator of migraine headache. Specific populations of 5-HT receptor subfamilies appear to be involved in the pathophysiology and treatment of migraine headache. Acute antimigraine drugs such as the ergot alkaloids and triptan derivatives are agonists of vascular and neuronal 5-HT_1 receptor subtypes, resulting in vasoconstriction of meningeal blood vessels and inhibition of vasoactive neuropeptide release and pain signal

transmission.[6,15] Drugs used for migraine prophylaxis also modulate neurotransmitter systems.[10] These actions and benefits in migraine management are consistent with the current understanding of migraine pathophysiology and neurovascular disorders.

Clinical Presentation

The migraine attack has been divided into several phases. *Premonitory symptoms* are experienced by 12% to 79% of migraineurs in the hours or days before the onset of headache.[2,6] The previously popular terms *prodrome* and *warning symptoms* should be avoided because these are often used mistakenly to include aura.[2] Premonitory symptoms vary widely among migraineurs but usually are consistent within an individual. Neurologic symptoms (eg, allodynia, phonophobia, photophobia, hyperosmia, and difficulty concentrating) are common, but psychological (eg, anxiety, depression, euphoria, irritability, drowsiness, fatigue, hyperactivity, and restlessness), autonomic (eg, polyuria, diarrhea, and constipation), and constitutional (eg, stiff neck, yawning, thirst, food cravings, and anorexia) symptoms also are reported.[2,6,16]

The migraine *aura*, a complex of positive and negative focal neurologic symptoms that precedes or accompanies an attack, is experienced by approximately 25% of migraineurs on some occasions.[2,16] The aura typically evolves over 5 minutes or longer and lasts less than 60 minutes. Headache usually occurs within 60 minutes of the end of the aura. Occasionally, aura symptoms begin at the onset of headache or during the attack. The aura is most often visual and frequently affects half the visual field.[2] Visual auras vary in their complexity and can include both positive (scintillations, photopsia, teichopsia, or fortification spectrum) and negative (scotoma and hemianopsia) features. Sensory and motor aura symptoms, such as paresthesias or numbness involving the arms and face, dysphasia or aphasia, weakness, and hemiparesis, also are reported.[2,16]

CLINICAL PRESENTATION Migraine Headache General

- Migraine is a common, recurrent, severe headache that interferes with normal functioning. It is a primary headache disorder divided into two major subtypes, migraine without aura and migraine with aura.

Symptoms

- Migraine is characterized by recurring episodes of throbbing head pain, frequently unilateral, that when untreated can last from 4 to 72 hours. Migraine headaches can be severe and associated with nausea, vomiting, and sensitivity to light, sound, and/or movement. Not all symptoms are present in every attack.

- In the headache evaluation, diagnostic alarms should be identified. These include: acute onset of the “first” or “worst” headache ever, accelerating pattern of headache following subacute onset, onset of headache after age 50 years, headache associated with systemic illness (eg, fever, nausea, vomiting, stiff neck, and rash), headache with focal neurologic symptoms or papilledema, and new-onset headache in a patient with cancer or human immunodeficiency virus (HIV) infection.

Signs

- A stable pattern, absence of daily headache, positive family history for migraine, normal neurologic examination, presence of food triggers, menstrual association, long-standing history, improvement with sleep, and subacute evolution are all signs of migraine headache. Aura can signal the migraine headache but is not required for diagnosis.

Laboratory Tests

- In selected circumstances and secondary headache presentation, serum chemistries, urine toxicology profiles, thyroid function tests, Lyme disease studies, and other blood tests such as a complete blood count, antinuclear antibody titer, erythrocyte sedimentation rate, and antiphospholipid antibody titer can be considered.

Diagnostic Tests

- Perform a general medical and neurologic physical examination. Check for abnormalities: vital signs (fever, hypertension), funduscopy (papilledema, hemorrhage, and exudates), palpation and auscultation of the head and neck (sinus tenderness, hardened or tender temporal arteries, trigger points, temporomandibular joint tenderness, bruits, nuchal rigidity, and cervical spine tenderness), and neurologic examination (identify abnormalities or deficits in mental status, cranial nerves, deep tendon reflexes, motor strength, coordination, gait, and cerebellar function). Consider neuroimaging studies in patients with abnormal neurologic examination findings of unknown etiology and in those with additional risk factors warranting imaging.

Migraine *headache* pain is usually gradual in onset, peaking in intensity over a period of minutes to hours and lasting between 4 and 72 hours. Pain can occur anywhere in the face or head but most often involves the frontotemporal region. The headache is typically unilateral and throbbing or pulsating in nature; however, pain can be bilateral at onset or become generalized during the course of an attack.[2,16] Gastrointestinal (GI) symptoms almost invariably accompany the headache. During an attack, migraineurs frequently experience nausea, and emesis sometimes occurs. Other systemic symptoms associated with the headache phase include anorexia, food cravings, constipation, diarrhea, abdominal cramps, nasal stuffiness, blurred vision, diaphoresis, facial pallor, and localized facial, scalp, or periorbital edema. Sensory hyperacuity, manifested as photophobia, phonophobia, or osmophobia, is reported frequently. Because headache pain usually is aggravated by physical activity, most migraineurs seek a dark, quiet room for rest and relief. Impaired concentration, depression, irritability, fatigue, or anxiety often accompanies the headache. Once headache pain wanes, patients may experience a *resolution phase* characterized by feeling tired, exhausted, irritable, or listless. Impaired concentration may continue, as well as scalp tenderness or mood changes. Some patients experience depression and malaise, whereas others can feel unusually refreshed or euphoric.[2,16] The reader is referred to the IHS classification and recent reviews for descriptions of the classic migraine variants and other migraine subtypes[2,16] (see Table 61-1).

Although headaches have many potential causes, most are considered to be primary headache disorders. A comprehensive headache history is the most important element in establishing the

clinical diagnosis of migraine.[2,6,17] A thorough headache history always should be obtained, and information collected should include age at onset, attack frequency and timing, duration of attacks, precipitating or aggravating factors, ameliorating factors, description of neurologic symptoms, characteristics of the headache pain (quality, intensity, location, and radiation), associated signs and symptoms, treatment history, family and social history, and the impact of headaches on daily life.

Secondary headache can be identified or excluded based on the headache history, as well as the results of general medical and neurologic examinations. Diagnostic and laboratory testing also can be warranted in the setting of suspicious headache features or an abnormal examination. The routine use of neuroimaging (computed tomography or magnetic resonance imaging) generally is not indicated in patients with migraine and a normal neurologic examination, but should be considered in patients with an unexplained abnormal neurologic examination or an atypical headache history. Because migraine headaches usually begin by the second or third decade of life, headaches beginning after age 50 years suggest an organic etiology such as a mass lesion, cerebrovascular disease, or temporal arteritis.[2,3,16] **Table 61-2** lists the IHS diagnostic criteria for migraine with and without aura.[2]

TABLE 61-2 IHS Diagnostic Criteria for Migraine

Migraine without aura

At least five attacks

Headache attack lasts 4-72 hours (untreated or unsuccessfully treated)

Headache has at least two of the following characteristics:

- Unilateral location
- Pulsating quality
- Moderate or severe intensity
- Aggravation by or avoidance of routine physical activity (ie, walking or climbing stairs)

During headache at least one of the following:

- Nausea, vomiting, or both
- Photophobia and phonophobia
- Not attributed to another disorder

Migraine with aura (classic migraine)

At least two attacks

Migraine aura fulfills criteria for typical aura, hemiplegic migraine, retinal migraine or brainstem aura

Not attributed to another disorder

Typical aura

Fully reversible visual, sensory, or speech symptoms (or any combination) but no motor weakness

Homonymous or bilateral visual symptoms including positive features (eg, flickering lights, spot, lines) or negative features (eg, loss of vision) or unilateral sensory symptoms including positive features (eg, pins and needles) or negative features (ie, numbness), or any combination

At least two of the following:

- At least one symptom that develops gradually over a minimum of 5 minutes or different symptoms that occur in succession or both
- Each symptom lasts for at least 5 minutes and for no longer than 60 minutes
- Headache that meets criteria for migraine without aura begins during the aura or follows aura within 60 minutes

TREATMENT

Migraines

Desired Outcome

Clinicians who care for migraineurs must appreciate the impact of this painful and debilitating disorder on the life of the patient, the patient's family, and the patient's employer. Treatment strategies must address both immediate and long-term goals. [1] Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work. Recurrence of symptoms and treatment-related adverse effects should be minimal. Ideally, patients should be able to manage their own headaches effectively without a medical visit. In addition, migraineurs should take an active role in the creation of a long-term formal management plan. An individualized approach to treatment can result in a reduction in attack frequency and severity, thus minimizing headache-related disability and emotional distress and improving the patient's quality of life. Goals of long-term and acute treatment of migraine are listed in **Table 61-3**.[15,17,18]

TABLE 61-3 Goals of Therapy in Migraine Management

Goals of long-term migraine treatment

Reduce migraine frequency, severity, and disability

Reduce reliance on poorly tolerated, ineffective, or unwanted acute pharmacotherapies

Improve quality of life

Prevent headache

Avoid escalation of headache medication use

Educate and enable patients to manage their disease

Reduce headache-related distress and psychological symptoms

Goals for acute migraine treatment

Treat migraine attacks rapidly and consistently without recurrence

Restore the patient's ability to function

Minimize the use of backup and rescue medications[a]

Optimize self-care for overall management

Be cost-effective in overall management

Cause minimal or no adverse effects

[a]Rescue medications are defined as medications used at home when other treatments fail that permit the patient to get relief without a visit to the physician's office or emergency department.

Data from references 15, 17, and 18.

General Approach To Treatment

Nonpharmacologic and pharmacologic interventions are available for the management of migraine headache; however, drug therapy remains the mainstay of treatment for most patients. Pharmacotherapeutic management of migraine can be acute (ie, symptomatic or abortive) or preventive (ie, prophylactic). When choosing acute or preventive therapies, the clinician should consider the patient's response to specific medications and their tolerability, as well as coexisting illnesses that can limit treatment choices. Abortive or acute therapies can be migraine-specific (eg, ergots and triptans) or nonspecific (eg, analgesics, antiemetics, nonsteroidal antiinflammatory drugs [NSAIDs], and corticosteroids) and are most effective at relieving pain and associated symptoms when administered at the onset of migraine[15,17,18] (**Table 61-4**). A stratified care approach in which the selection of initial treatment is based on headache-related disability and symptom severity is the preferred treatment strategy for the migraineur.[15,17] Because attack severity varies in individuals, patients may be advised to use nonspecific agents for mild to moderate headache not causing disability while reserving migraine-specific medications for more severe attacks. The absorption and efficacy of orally administered drugs can be compromised by gastric stasis or nausea and vomiting that accompany migraine. Pretreatment with antiemetic agents or the use of nonoral treatment (eg, suppositories, nasal sprays, or injections) is advisable when nausea and vomiting are severe.[15,19]

TABLE 61-4 Dosing of Acute Migraine Therapies[a]

Drug	Dose	Usual Range/Comments

Drug	Dose	Usual Range/Comments
Analgesics		
Acetaminophen (Tylenol)	1,000 mg at onset; repeat every 4-6 hours as needed	Max. daily dose is 4 g
Acetaminophen 250 mg/aspirin 250 mg/caffeine 65 mg (Excedrin Migraine)	2 tablets at onset and every 6 hours	Available over-the-counter as Excedrin Migraine
Nonsteroidal antiinflammatory drugs		
Aspirin	500-1,000 mg every 4-6 hours	Max. daily dose is 4 g
Ibuprofen (Motrin)	200-800 mg every 6 hours	Avoid doses >2.4 g/day
Naproxen sodium (Aleve, Anaprox)	550-825 mg at onset; can repeat 220 mg in 3-4 hours	Avoid doses >1.375 g/day
Diclofenac (Cataflam, Voltaren)	50-100 mg at onset; can repeat 50 mg in 8 hours	Avoid doses >150 mg/day
Ergotamine tartrate		
Oral tablet (1 mg) with caffeine 100 mg (Cafergot)	2 mg at onset; then 1-2 mg every 30 minutes as needed	Max. dose is 6 mg/day or 10 mg/wk; consider pretreatment with an antiemetic
Sublingual tablet (2 mg) (Ergomar)		
Rectal suppository (2 mg) with caffeine 100 mg (Cafergot, Migergot)	Insert 1/2 to 1 suppository at onset; repeat after 1 hour as needed	Max. dose is 4 mg/day or 10 mg/wk; consider pretreatment with an antiemetic
Dihydroergotamine		
Injection 1 mg/mL (D.H.E. 45)	0.25-1 mg at onset IM, IV or subcutaneous; repeat every hour as needed	Max. dose is 3 mg/day or 6 mg/wk
Nasal spray 4 mg/mL (Migranal)	One spray (0.5 mg) in each nostril at onset; repeat sequence 15 minutes later (total dose is 2 mg or 4 sprays)	Max. dose is 3 mg/day; prime sprayer 4 times before using; do not tilt head back or inhale through nose while spraying; discard open ampules after 8 hours
Serotonin agonists (triptans)		
Sumatriptan (Imitrex)		
Injection	6 mg subcutaneous at onset; can repeat after 1 hour if needed	Max. daily dose is 12 mg

Drug	Dose	Usual Range/Comments
Oral tablets	25, 50, 85 or 100 mg at onset; can repeat after 2 hours if needed	Optimal dose is 50-100 mg; max. daily dose is 200 mg; combination product with naproxen, 85 mg/500 mg
Nasal spray	5, 10, or 20 mg at onset; can repeat after 2 hours if needed	Optimal dose is 20 mg; max. daily dose is 40 mg; single-dose device delivering 5 or 20 mg; administer one spray in one nostril
Zolmitriptan (Zomig, Zomig-ZMT)		
Oral tablets	2.5 or 5 mg at onset as regular or orally disintegrating tablet; can repeat after 2 hours if needed	Optimal dose is 2.5 mg; max. dose is 10 mg/day Do not divide ODT dosage form
Nasal spray	5 mg (one spray) at onset; can repeat after 2 hours if needed	Max. daily dose is 10 mg/day
Naratriptan (Amerge)	1 or 2.5 mg at onset; can repeat after 4 hours if needed	Optimal dose is 2.5 mg; max. daily dose is 5 mg
Rizatriptan (Maxalt, Maxalt-MLT)	5 or 10 mg at onset as regular or orally disintegrating tablet; can repeat after 2 hours if needed	Optimal dose is 10 mg; max. daily dose is 30 mg; onset of effect is similar with standard and orally disintegrating tablets; use 5-mg dose (15 mg/day max.) in patients receiving propranolol
Almotriptan (Axert)	6.25 or 12.5 mg at onset; can repeat after 2 hours if needed	Optimal dose is 12.5 mg; max. daily dose is 25 mg
Frovatriptan (Frova)	2.5 or 5 mg at onset; can repeat in 2 hours if needed	Optimal dose 2.5-5 mg; max. daily dose is 7.5 mg (3 tablets)
Eletriptan (Relpax)	20 or 40 mg at onset; can repeat after 2 hours if needed	Max. single dose is 40 mg; max. daily dose is 80 mg
Miscellaneous		
Metoclopramide (Reglan)	10 mg IV at onset	Useful for acute relief in the office or emergency department setting
Prochlorperazine (Compazine)	10 mg IV or IM at onset	Useful for acute relief in the office or emergency department setting

ODT, orally disintegrating tablet.

[a]Limit use of symptomatic medications to fewer than 10 days/mo when possible to avoid medication-overuse headache.

Data from references 15, 19, and 31.

The frequent or excessive use of acute migraine medications can result in a pattern of increasing headache frequency and drug consumption known as *medication-overuse headache* (or *rebound headache*).[2,6] The syndrome appears to evolve as a self-sustaining headache-medication cycle in which the headache returns as the medication wears off, leading to the consumption of more drug for relief. The headache history often reflects the gradual onset of an atypical daily or near-daily headache with superimposed episodic migraine attacks. Medication overuse is one of the most common causes of chronic daily headache.[20,21] Agents most commonly implicated in this syndrome include simple and combination analgesics and opiates. Triptans are also implicated.[2,6,22] Discontinuation of the offending agent leads to a gradual decrease in headache frequency and severity and a return of the original headache characteristics. Although detoxification usually can be accomplished on an outpatient basis, hospitalization can be necessary for the control of refractory rebound headache and other withdrawal symptoms (eg, nausea, vomiting, asthenia, restlessness, and agitation).[20,21] 3 Regulation of nociceptive systems and renewed responsiveness to therapy usually occur within 2 months following medication withdrawal.[2] Most experts recommend limiting use of acute migraine therapies to *fewer than 10 days per month* to avoid the development of medication-overuse headache.[2,22,23]

Preventive migraine therapies are administered on a daily basis to reduce the frequency, severity, and duration of attacks and improve responsiveness to symptomatic migraine therapies[8,24,25] (**Table 61-5**). 4 Preventive therapy should be considered in the setting of recurring migraines that produce significant disability despite acute therapy; frequent attacks occurring more than twice per week with the risk of developing medication-overuse headache; symptomatic therapies that are ineffective or contraindicated, or produce serious side effects; uncommon migraine variants that cause profound disruption and/or risk of permanent neurologic injury (eg, hemiplegic migraine, basilar migraine, and migraine with prolonged aura); and patient preference to limit the number of attacks.[22,26] Preventive therapy also may be administered preemptively or intermittently when headaches recur in a predictable pattern (eg, exercise-induced migraine or menstrual migraine).[26] The evidence to support the various agents used for migraine prophylaxis has recently been reviewed. Only propranolol, timolol, divalproex sodium, and topiramate are currently approved by the FDA for the indication, although other agents have established or probable efficacy. 5 Guidelines identify which agents might be effective, but there is insufficient evidence as to how to choose one therapy over another. Thus, the selection of an agent typically is based on its side effect profile and the patient's coexisting/comorbid conditions.[17,24,25] 6 A therapeutic trial of 2 to 3 months is necessary to achieve clinical benefit, but some reduction in attack frequency can be evident by the first month of therapy. Maximal benefits are typically observed by 6 months of treatment.[14,24,26] Drug therapy should be initiated with low doses and gradually increased until a therapeutic effect is achieved or side effects become intolerable. Drug doses for migraine prophylaxis are often lower than those necessary for other indications.[25,26] Overuse of acute headache medications will interfere with the effects of preventive treatment.[2,17] Prophylactic treatment usually is continued for at least 6 to 12 months after the frequency and severity of headaches have diminished. After that time, based on

discussions with the patient, gradual tapering or discontinuation may be reasonable.[22,24] Many migraineurs experience fewer and less severe attacks for lengthy periods following discontinuation of prophylactic medications or taper to a lower dose. **Figures 61-2** and **61-3** identify treatment and management algorithms for migraine headache.

TABLE 61-5 Dosing of Prophylactic Migraine Therapies

Drug	Initial Dose	Usual Range	Comments
β-Adrenergic antagonists			
Atenolol[a] (Tenormin)	50 mg/day	50-200 mg/day	
Metoprolol[b] (Toprol, Toprol XL)	100 mg/day in divided doses	100-200 mg/day in divided doses	Dose short-acting 4 times a day and long-acting 2 times a day; available as extended release
Nadolol[a] (Corgard)	40-80 mg/day	80-240 mg/day	
Propranolol[b] (Inderal, Inderal LA)	40 mg/day in divided doses	40-160 mg/day in divided doses	Dose short-acting 2-3 times a day and long-acting 1-2 times a day; available as extended release
Timolol[b] (Blocadren)	20 mg/day in divided doses	20-60 mg/day in divided doses	
Antidepressants			
Amitriptyline[a] (Elavil)	10 mg at bedtime	20-50 mg at bedtime	
Venlafaxine[a] (Effexor, Effexor-XR)	37.5 mg/day	75-150 mg/day	Available as extended release; increase dose after 1 week
Anticonvulsants			
Topiramate[b] (Topamax)	25 mg/day	50-200 mg/day in divided doses	As effective as amitriptyline, propranolol or valproate; increase by 25 mg/wk
Valproic acid/divalproex sodium[b] (Depakene, Depakote, Depakote ER)	250-500 mg/day in divided doses, or daily for extended release	500-1,500 mg/day in divided doses, or daily for extended release	Monitor levels if compliance is an issue
Nonsteroidal antiinflammatory drugs			
Ibuprofen[a] (Motrin)	400-1,200 mg/day in divided doses	Same as initial dose	Use intermittently, such as for menstrual migraine prevention; daily or prolonged use may lead to medication-overuse headache and is limited by potential toxicity
Ketoprofen[a] (Orudis)	150 mg/day in divided doses	Same as initial dose	
Naproxen sodium[a] (Aleve, Anaprox)	550-1,100 mg/day in divided doses	Same as initial dose	
Serotonin agonists (triptans)			

Drug	Initial Dose	Usual Range	Comments
Frovatriptan[b] (Frova)	2.5 mg/day or 5 mg/day in divided doses	Same as initial dose	Taken in the perimenstrual period to prevent menstrual migraine
Naratriptan[a] (Amerge)	2 mg/day in divided doses	Same as initial dose	
Zolmitriptan[a] (Zomig)	5-7.5 mg/day in divided doses	Same as initial dose	
Miscellaneous			
Histamine[a] (Histatrol)	1-10 ng two times/wk	Same as initial dose	May cause transient itching and burning at injection site
Magnesium[a]	400 mg/day	800 mg/day in divided doses	May be more helpful in migraine with aura and menstrual migraine
MIG-99[a] (feverfew)	10-100 mg/day in divided doses	Same as initial dose	Withdrawal may be associated with increased headaches
Petasites[b]	100-150 mg/day in divided doses	150 mg/day in divided doses	Use only commercial preparations, plant is carcinogenic
Riboflavin[a]	400 mg/day in divided doses	400 mg/day in divided doses	Benefit only after 3 months

[a]Level B—probably effective (1 Class I or 2 Class II studies).

[b]Level A—established efficacy (≥2 Class I studies).

As per Ameican Academy of Neurology therapeutic classification of evidence, Silberstein and Holland, et al. and Holland and Silberstein, et al. Neurology 2012;78:1337-1345 and 78:1346-1353.

FIGURE 61-2

Treatment algorithm for migraine headaches.

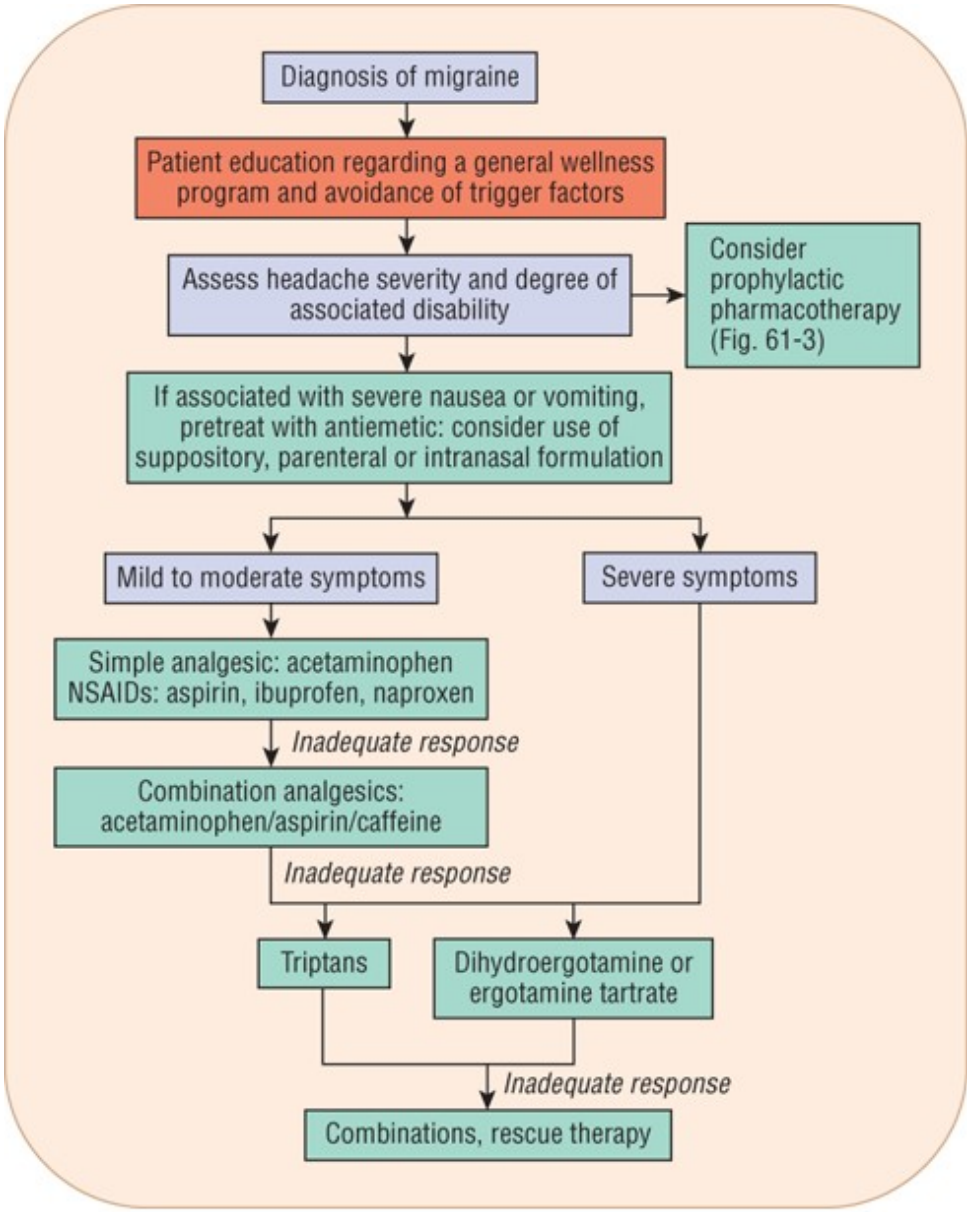

FIGURE 61-3

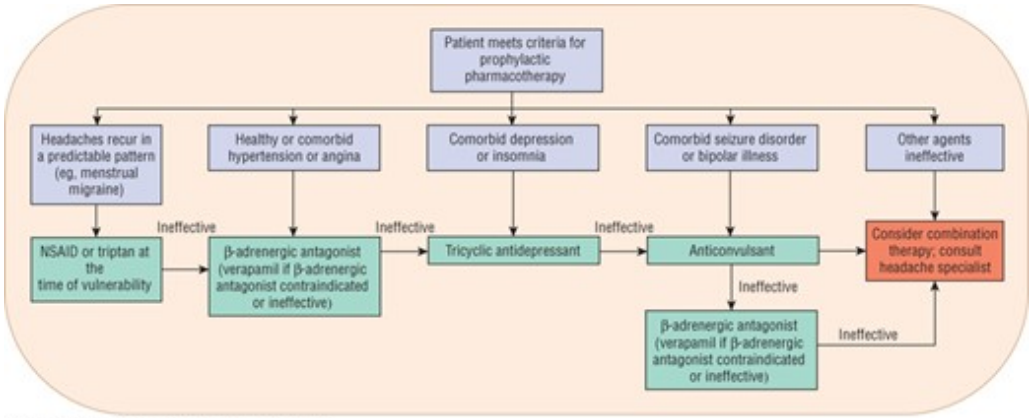
Treatment algorithm for prophylactic management of migraine headaches. (NSAID, nonsteroidal antiinflammatory drug.)



Nonpharmacologic Therapy

Nonpharmacologic therapy of acute migraine headache is limited but can include application of ice to the head and periods of rest or sleep, usually in a dark, quiet environment. Recommendations for the preventive management of migraine typically suggest that patients identify and avoid individual factors or triggers that consistently provoke migraine attacks[2,3,17,27] (**Table 61-6**). Changes in estrogen levels associated with menarche, menstruation, pregnancy, menopause, oral contraceptive use, and other hormone therapies can trigger, intensify, or alleviate migraine.[3] A headache diary that records the frequency, severity, and duration of attacks can facilitate identification of migraine triggers. 7 In appropriate situations, some patients may learn to cope with triggers after a process of controlled exposure and approach/confront strategies.[27,28] Patients also can benefit from adherence to a wellness program that includes regular sleep, exercise, and eating habits, smoking cessation, and limited caffeine intake. Behavioral interventions, such as relaxation therapy, biofeedback (often used in combination with relaxation therapy), and cognitive therapy, are preventive treatment options for patients who prefer nondrug therapy or when symptomatic therapies are poorly tolerated, contraindicated, or ineffective.[17]

TABLE 61-6 Commonly Reported Triggers of Migraine

Food triggers
Alcohol
Caffeine/caffeine withdrawal
Chocolate
Fermented and pickled foods
Monosodium glutamate (eg, in Chinese food, seasoned salt, and instant foods)
Nitrate-containing foods (eg, processed meats)
Saccharin/aspartame (eg, diet foods or diet sodas)
Tyramine-containing foods
Environmental triggers
Glare or flickering lights

High altitude
Loud noises
Strong smells and fumes
Tobacco smoke
Weather changes

Behavioral–physiologic triggers

Excess or insufficient sleep
Fatigue
Menstruation, menopause
Sexual activity
Skipped meals
Strenuous physical activity (eg, prolonged overexertion)
Stress or post-stress

Data from references 3, 17, 27, and 28.

Clinical Controversy …

Most migraineurs have triggers for the acute attack, at least occasionally, and are generally advised to avoid these as part of management to reduce the frequency of attacks. However, research evaluating the efficacy and usefulness of trigger avoidance is almost nonexistent. Triggers may change over time in the life of the migraineur and be modified by preventive medication. Trigger avoidance can also impose severe lifestyle restrictions and more stress. Avoidance may ultimately not allow for desensitization from the trigger and the subsequent development of relative immunity.[27,28]

PHARMACOLOGIC MANAGEMENT OF ACUTE MIGRAINE

Analgesics and NSAIDs

Simple analgesics and NSAIDs are effective medications for the management of many migraine attacks (see Table 61-4). They offer a reasonable first-line choice for treatment of mild to moderate migraine attacks or severe attacks that have been responsive in the past to similar NSAIDs or nonopiate analgesics. Of the NSAIDs, aspirin, diclofenac, ibuprofen, ketorolac, naproxen sodium, tolfenamic acid, and the combination of acetaminophen plus aspirin and caffeine have demonstrated the most consistent evidence of efficacy.[15,19] Evidence for other NSAIDs is either limited or inconsistent. Although some patients may observe benefits, acetaminophen alone is not generally recommended for migraine because the scientific support is not optimal.[18] Comparisons with other pharmacotherapeutic classes are limited; however, studies support the comparable efficacy of NSAIDs and triptans in acute migraine. Baseline headache intensity does not predict the success or failure of aspirin or other NSAIDs.[29,30] There are no studies comparing the relative efficacy of different NSAIDs.[19]

Clinical Controversy ...

A stratified care approach, in which the selection of initial treatment is based on headache-related disability and symptom severity, is the most recommended treatment strategy for the migraineur. This approach assumes that greater severity is a risk factor for failure of symptomatic treatments and reflects the need for more specific treatment, such as a triptan. However, recent reviews support the efficacy of aspirin and other NSAIDs in acute migraine, regardless of pre-treatment headache intensity, and with efficacy comparable to oral triptans.[29,30]

Nonsteroidal antiinflammatory drugs appear to prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of prostaglandin synthesis. Metoclopramide can speed the absorption of analgesics and alleviate migraine-related nausea and vomiting.[15] Suppository analgesic preparations are an option when nausea and vomiting are severe.[19] Acute NSAID therapy is associated with gastrointestinal (GI) (eg, dyspepsia, nausea, vomiting, and diarrhea) and CNS (eg, somnolence, dizziness) side effects. NSAIDs should be avoided or used cautiously in patients with previous ulcer disease, renal disease, or hypersensitivity to aspirin.[18,19]

The nonprescription combination of acetaminophen, aspirin, and caffeine was approved for the treatment of migraine in the United States because of its proven efficacy in relieving migraine pain and associated symptoms.[15,18] Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine). No randomized, placebo-controlled studies support the efficacy of butalbital-containing products in the treatment of migraine. The use of butalbital-containing analgesics or narcotics should be limited because of concerns about overuse, medication-overuse headache, and withdrawal.[18,19,23] Although frequent consumption of aspirin or acetaminophen alone can result in medication-overuse headache, combination analgesics appear to pose a greater risk.[19,23]

Opiate Analgesics

The use of narcotic analgesic drugs (eg, meperidine, butorphanol, oxycodone, and hydromorphone) in migraine treatment is controversial, and evidence for use is generally negative. Opiates have no vasopressor or antiinflammatory effects and can cause central sensitization, increasing the risk of medication-overuse headache and interfering with the efficacy of other treatments even with intermittent use.[15,23] Use should generally be reserved for patients with moderate to severe infrequent headaches in whom conventional therapies are contraindicated or as “rescue medication” after patients have failed to respond to conventional therapies.[18] Opioid therapy should be supervised closely because of the risk of sedation and the potential for abuse.[15,23]

Antiemetics

Adjunctive antiemetic therapy is useful for combating the nausea and vomiting that accompany migraine headaches and the medications used to treat attacks (eg, ergotamine tartrate). A single dose of an antiemetic, such as metoclopramide, chlorpromazine, or prochlorperazine, administered 15 to 30 minutes before ingestion of oral abortive migraine medications is often sufficient.

Suppository preparations are available when nausea and vomiting are particularly prominent. Metoclopramide is also useful to reverse gastroparesis and improve absorption from the GI tract during severe attacks.[15,18]

In addition to antiemetic effects, dopamine antagonist drugs also have been used successfully as monotherapy for the treatment of intractable headache (see Table 61-4). Prochlorperazine administered by the IV and intramuscular routes and IV metoclopramide provided more effective pain relief than placebo. Chlorpromazine and droperidol also have provided relief of migraine headache when administered parenterally at doses of 12.5 to 37.5 and 2.5 to 5 mg, respectively. The precise mechanism of action for these agents is unknown. The dopamine antagonists offer an alternative to the narcotic analgesics for the treatment of refractory migraine. Drowsiness and dizziness were reported occasionally, and extrapyramidal side effects were reported infrequently in migraine trials. Droperidol has a risk for QT prolongation.[18,19,23]

Miscellaneous Nonspecific Medications

Corticosteroids can be considered as rescue therapy for status migrainous (a severe, continuous migraine that can last up to 1 week).[18] IV or intramuscular dexamethasone at a dose of 10 to 25 mg has also been used as an adjunct to abortive therapy.[19]

Limited studies suggest a role for intranasal lidocaine in the treatment of acute migraine headache. Intranasal lidocaine, one to four drops of a 4% solution, provides rapid pain relief within 15 minutes of administration, but headache recurrence is common. Adverse effects generally are limited to local irritation, an unpleasant taste, and numbness of the throat.[18]

IV valproate 500 to 1,000 mg and magnesium sulfate 1,000 mg are nonsedating options for use in acute migraine treatment.[23] Future studies might establish a more defined role for these agents in migraine management.

Ergot Alkaloids and Derivatives

Ergotamine tartrate and dihydroergotamine can be considered for the treatment of moderate to severe migraine attacks (see Table 61-4). These drugs are nonselective 5-HT_1 receptor agonists that constrict intracranial blood vessels and inhibit the development of neurogenic inflammation in the trigeminovascular system.[15] Central inhibition of the trigeminovascular pathway is also reported as well as agonist activity at dopaminergic receptors. Venous and arterial constriction occur with therapeutic doses, but ergotamine tartrate exerts more potent arterial effects than dihydroergotamine.[15,19,23]

Ergotamine tartrate is available for oral, sublingual, and rectal administration. Oral and rectal preparations contain caffeine to enhance absorption and potentiate analgesia. Ergotamine use is limited because of issues of efficacy and side effects. Dosage requirements should be titrated strictly to establish an effective but subnauseating dose for future attacks. Despite clinical use since 1926, evidence supporting the efficacy of ergotamine in migraine is inconsistent.[19]

Dihydroergotamine is available for intranasal and parenteral administration by the intramuscular, subcutaneous, and IV routes.[23] Parenteral dihydroergotamine was viewed previously as inpatient or emergency department treatment for moderate to severe migraine or intractable headache, but patients can be trained to self-administer dihydroergotamine intramuscularly or subcutaneously. Mixing with 1% or 2% lidocaine can reduce burning at the injection site. Clinical opinion suggests its use is relatively safe and effective when compared with other migraine therapies.[15,18]

Nausea and vomiting (resulting from stimulation of the chemoreceptor trigger zone) are among the most common adverse effects of the ergotamine derivatives. Pretreatment with an antiemetic agent should be considered with ergotamine and IV dihydroergotamine therapy. Other common side effects include abdominal pain, weakness, fatigue, paresthesias, muscle pain, diarrhea, and chest tightness. Rarely, symptoms of severe peripheral ischemia (ergotism), including cold, numb, painful extremities, continuous paresthesias, diminished peripheral pulses, and claudication, can result from the vasoconstrictor effects of the ergot alkaloids. Gangrenous extremities, myocardial infarction, hepatic necrosis, and bowel and brain ischemia have also been reported. Dihydroergotamine is rarely associated with such side effects. Triptans and ergot derivatives should not be used within 24 hours of each other.[15,19] Ergotamine derivatives are contraindicated in patients with renal or hepatic failure; coronary, cerebral, or peripheral vascular disease; uncontrolled hypertension; and sepsis; and in women who are pregnant or nursing. Dihydroergotamine does not appear to cause rebound headache, but dosage restrictions for ergotamine tartrate should be observed strictly to prevent this complication.[19,23]

Serotonin Receptor Agonists (Triptans)

Introduction of the 5-HT receptor agonists, or triptans, represented a significant advance in migraine pharmacotherapy. The first member of this class, sumatriptan, and the second-generation agents zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan are selective agonists of the 5-HT_{1B} and 5-HT_{1D} receptors. Relief of migraine headache is the result of three key actions: normalization of dilated intracranial arteries through enhanced vasoconstriction, inhibition of vasoactive peptide release from perivascular trigeminal neurons, and inhibition of transmission through second-order neurons ascending to the thalamus.[15,31] These agents also display varying affinity for 5-HT_{1A}, 5-HT_{1E}, and 5-HT_{1F} receptors. The triptans are appropriate first-line therapy for patients with mild to severe migraine and are used for rescue therapy when nonspecific medications are ineffective.[31]

Sumatriptan, the most extensively studied acute therapy, is available for subcutaneous, oral, and intranasal administration. Subcutaneous sumatriptan is consistently superior to placebo in alleviating migraine headache and associated symptoms, with relief reported in 70% of patients at 2 hours in a meta-analysis of placebo-controlled studies.[31] In addition to enhanced efficacy, subcutaneous sumatriptan has a more rapid onset of action when compared with the oral formulation. The subcutaneous injection is packaged as an autoinjector device for self-administration by patients. Intranasal sumatriptan provides a faster onset of effect than the oral formulation and produces similar rates of response in placebo-controlled studies.[19,31]

Selection of a triptan is based on characteristics of the headache, convenience of dosing, and the patient's preference. At all marketed doses, the oral triptans are effective and well tolerated. The triptans differ in their pharmacokinetic and pharmacodynamic profiles (**Table 61-7**). In general, triptans can be divided into those with a faster onset and higher efficacy and those with a slower onset and lower efficacy. A recent meta-analysis summarizes the efficacy and tolerability of the oral triptans across published and unpublished studies. Using 100 mg of sumatriptan as the reference dose and based on 2-hour response rates, at doses recommended by the manufacturer, most of the triptans evaluated had similar therapeutic gains; frovatriptan and naratriptan were the exceptions with lower efficacy. Compared with other triptans, frovatriptan and naratriptan have the longest half-lives, the slowest onset of action, and less headache recurrence. This may make them more suitable for patients who have migraine attacks of a slow onset and longer duration. Faster-acting triptans are more efficacious when a rapid onset is necessary. Subcutaneous, intranasal, or orally dissolving tablets may be useful in patients with prominent early nausea or vomiting or those who have difficulty in swallowing tablets. Despite the fact that oral absorption can be delayed during migraine attacks, most patients prefer oral formulations.[15,23,29,31]

TABLE 61-7 Pharmacokinetic Characteristics of Triptans

Drug	Half-Life (hours)	Time to Maximal Concentration (t_{max})	Bioavailability (%)	Elimination
Almotriptan	3-4	1.4-3.8 hours	80	MAO-A, CYP3A4, CYP2D6
Eletriptan	4-5	1-2 hours	50	CYP3A4
Frovatriptan	25	2-4 hours	24-30	Mostly unchanged, CYP1A2
Naratriptan	5-6	2-3 hours	63-74	Largely unchanged, CYP450 (various isoenzymes)
Rizatriptan	2-3		45	MAO-A
Oral tablets		1-1.2 hours		
Disintegrating		1.6-2.5 hours		
Sumatriptan	2			MAO-A
SC injection		12-15 minutes	97	
Oral tablets		2.5 hours	14	
Nasal spray		1-2.5 hours	17	
Zolmitriptan	3		40-48	CYP1A2, MAO-A
Oral		2 hours		
Disintegrating		3.3 hours		
Nasal		4 hours		

CYP, cytochrome P450; MAO-A, monoamine oxidase type A.

Data from references 15, 23, and 31.

Clinical response to the triptans can vary considerably among individual patients. Individual responses cannot be predicted, and if one triptan fails, a patient can be switched successfully to another triptan.[15] After an effective agent and dose have been identified, subsequent treatments should begin with that same regimen. Combination therapy may also improve response rates and diminish migraine recurrence. A proprietary formulation of sumatriptan 85 mg plus naproxen 500 mg in a single tablet was more effective in clinical trials for headache relief and sustained pain-free response than either agent as monotherapy.[15,19]

Side effects to the triptans are common but usually mild to moderate in nature and of short duration. Adverse effects are consistent among the class and include paresthesias, fatigue, dizziness, flushing, warm sensations, and somnolence. Local side effects are reported with the subcutaneous (minor injection site reactions) and intranasal (taste perversion, nasal discomfort) routes. Up to 25% of patients receiving a triptan consistently report "triptan sensations," including tightness, pressure, heaviness, or pain in the chest, neck, or throat. The mechanism of these symptoms is unknown, but a cardiac source of pain seems unlikely in most patients.[31] However, all triptans are partial agonists of human 5-HT coronary artery receptors in vitro, resulting in a small but significant vasoconstrictor response. Adverse cardiac events are rare with only isolated cases of myocardial infarction and coronary vasospasm with ischemia reported. The triptans are contraindicated in patients with a history of ischemic heart disease (eg, angina pectoris, Prinzmetal's angina, or previous myocardial infarction), uncontrolled hypertension, and cerebrovascular disease. Patients at risk for unrecognized coronary artery disease should use triptans with caution. Postmenopausal women, men older than 40 years of age, and patients with uncontrolled risk factors should receive a cardiovascular assessment prior to triptan use and have initial doses administered under medical supervision. Triptans are also contraindicated in patients with hemiplegic and basilar migraine and should not be used routinely in pregnancy.[19,31] The triptans should not be given within 24 hours of the ergotamine derivatives. Administration of sumatriptan, rizatriptan, and zolmitriptan within 2 weeks of therapy with monoamine oxidase inhibitors (MAOIs) is not recommended. Eletriptan should not be administered with cytochrome P450 3A4 inhibitors such as macrolide antibiotics, antifungals, and some antiviral therapies. Concomitant therapy with the selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) (eg, duloxetine, venlafaxine, and mirtazapine) can potentially cause 5-HT syndrome. Regulatory agencies caution against concurrent administration, although it appears the likelihood of CNS adverse events is extremely low. The potential risk of these combinations should be carefully considered and discussed with the patient.[15,19,32] Frequent use of the triptans has been associated with the development of medication-overuse headache.[18,31]

Prophylactic Pharmacolgic Therapy

β-Adrenergic Antagonists

β-Adrenergic antagonists are among the most widely used drugs for migraine prophylaxis. Metoprolol, propranolol, and timolol have established efficacy in controlled clinical trials, reducing the frequency of attacks by 50% in greater than 50% of patients.[24,26] Atenolol and nadolol are also probably effective, while nebivolol and pindolol are possibly effective (see Table 61-5).[24] Because the

relative efficacy of the individual agents has not been established, selection of a β-blocker can be based on β-selectivity, convenience of the formulation, and tolerability. Although their precise mechanism of antimigraine action is unknown, β-blockers may raise the migraine threshold by modulating adrenergic or serotonergic neurotransmission in cortical or subcortical pathways. Although not first-line treatment for hypertension, β-blockers may be useful along with other therapy in patients with comorbid hypertension or angina. Side effects can include drowsiness, fatigue, sleep disturbances, vivid dreams, memory disturbance, depression, impotence, bradycardia, and hypotension. β-Blockers should be used with caution in patients with congestive heart failure, peripheral vascular disease, atrioventricular conduction disturbances, asthma, depression, and diabetes.[24,26]

Clinical Controversy …

To determine maximal clinical benefits, a therapeutic trial of 6 months is recommended when initiating treatment for episodic migraine prevention. Despite this recommendation, most migraine prevention studies have relatively brief treatment durations of only 12 to 16 weeks. Long-term scientifically sound assessments and evaluations of migraine preventive treatments are needed to further define their role in clinical care.[24]

Antidepressants

The beneficial effects of antidepressants in migraine are independent of their antidepressant activity and may be related to downregulation of central 5-HT_2 receptors, increased levels of synaptic norepinephrine, and enhanced endogenous opioid receptor actions.[33] The tricyclic antidepressant (TCA) amitriptyline and SNRI venlafaxine have demonstrated efficacy in placebo-controlled and comparative studies and are classified as probably effective for migraine prophylaxis (see Table 61-5).[24,26] Use of other antidepressants is based primarily on clinical and anecdotal experience. There are insufficient or conflicting data to support or refute the efficacy of other antidepressants, such as protriptyline, fluoxetine, or fluvoxamine, for migraine prophylaxis.[24]

Anticholinergic side effects are common with TCAs and limit use of these agents in patients with benign prostatic hyperplasia and glaucoma. Evening doses are preferred because of associated sedation. Increased appetite and weight gain can occur. Orthostatic hypotension and cardiac toxicity (slowed atrioventricular conduction) also are reported occasionally.[24,26] The most common side effects reported with venlafaxine are nausea, vomiting, and drowsiness. Again, the potential risk of 5-HT syndrome should be considered in patients using SSRIs or SNRIs along with a triptan.[24,32]

Anticonvulsants

Anticonvulsant medications have emerged as important therapeutic options for migraine prophylaxis with valproate, divalproex, and topiramate all having established efficacy.[24] The beneficial effects of these agents are likely caused by multiple mechanisms of action, including enhancement of γ-aminobutyric acid (GABA)-mediated inhibition, modulation of the excitatory neurotransmitter glutamate, and inhibition of sodium and calcium ion channel activity.[33] Anticonvulsants are

particularly useful in migraineurs with comorbid seizures, anxiety disorder, or bipolar illness.[24,26] The efficacy of sodium valproate and divalproex sodium (a 1:1 molar combination of valproate sodium and valproic acid) has been demonstrated in multiple placebo-controlled studies. In most trials for headache prophylaxis, there were no significant differences in treatment-emergent side effects between these agents and placebo. Nausea and vomiting, the most common early side effects, are self-limited and appear to be less common with divalproex sodium and gradual titration of doses. Alopecia, tremor, asthenia, somnolence, and weight gain are also complaints.[24,26] The extended-release formulation of divalproex sodium is administered once daily and is better tolerated than the enteric-coated formulation. Hepatotoxicity is the most serious side effect of valproate therapy, but the risk appears to be low in migraineurs (eg, patients older than 10 years of age who are receiving monotherapy and have no underlying metabolic or neurologic disorder). Baseline liver function tests should be obtained, but routine followup studies are not necessary in asymptomatic adults on monotherapy. Regular followup is necessary, however, for dosage adjustments and monitoring of effects. Valproate is contraindicated in pregnant women (owing to potential teratogenicity) and patients with a history of pancreatitis or chronic liver disease.[24,26]

Topiramate is the most extensively studied medication to date for migraine prophylaxis. Efficacy and improvements in health-related quality of life including daily work, home, and social activities have been demonstrated in several placebo-controlled studies.[17] To minimize adverse effects, topiramate should be initiated at a low dose and slowly titrated upward. The benefits of topiramate are observed as early as 2 weeks after initiation of therapy, with significant reductions in migraine frequency within the first month. Approximately 50% of patients treated to target doses are responders (50% or greater reduction in mean headache frequency). Treatment-emergent adverse events associated with topiramate include paresthesia, fatigue, anorexia, diarrhea, weight loss, hypesthesia, difficulty with memory, language problems, taste perversion, and nausea. Paresthesia is the most common adverse event, occurring in about half of patients at target doses. Weight loss, occurring in 9% to 12% of patients, is a unique adverse effect, as weight gain is a common reason to discontinue other preventive medications. Topiramate should be used with caution or avoided in patients with a history of kidney stones or cognitive impairment.[24,26]

Preliminary studies suggest a role for other anticonvulsants for migraine prevention. Carbamazepine is possibly effective, and a recent study evaluated gabapentin, but data are insufficient to determine efficacy. Lamotrigine is classified as possibly or probably ineffective.[24]

Nonsteroidal antiinflammatory drugs

Nonsteroidal antiinflammatory drugs are modestly effective for reducing the frequency, severity, and duration of migraine attacks, but potential GI and renal toxicity limit the daily or prolonged use of these agents. Consequently, NSAIDs have been used intermittently to prevent headaches that recur in a predictable pattern, such as menstrual migraine. Administration of NSAIDs in the perimenstrual period can be beneficial in women with true menstrual migraine. NSAIDs should be initiated up to 1 week prior to the expected onset of headache and continued for no more than 10 days.[26,34] If long-term NSAID therapy is initiated, monitoring of renal function and occult blood loss is necessary. For migraine prevention, the evidence for efficacy is strongest for naproxen and weakest for

aspirin.[24,26]

Triptans

Triptans are also useful for the prevention of menstrual migraine. Frovatriptan has established efficacy, while naratriptan and zolmitriptan are probably effective. The triptan is usually started 1 or 2 days before the expected onset of headache and continued during the period of vulnerability.[24,26] A separate indication for pure menstrual migraine is currently being deliberated by regulatory authorities.[24]

Miscellaneous Prophylatic Agents

At least two placebo-controlled studies show that petasites, an extract from the butterbur plant *Petasites hybridus*, is an effective preventive treatment for migraine.[26,35] A double-blind, placebo-controlled study demonstrated the probable efficacy of riboflavin (vitamin B_2) 400 mg daily in migraine prophylaxis. Riboflavin was well tolerated and associated with 50% or greater improvement in attack frequency in 54% of patients. However, the benefits of therapy became significant only after 3 months.[26,35] The relatively stable extract of feverfew (*Tanacetum parthenium*), MIG-99, is the most studied herbal preparation for migraine prevention. MIG-99 is classified as probably effective, reducing migraine frequency by 1.9 attacks per month.[35] Clinical trials evaluating various formulations of magnesium for migraine prevention have yielded mixed results, but there is probable efficacy.[26,35] CNS levels of magnesium are known to be significantly low during migraine attacks. Magnesium supplementation may be particularly effective for prevention of menstrual migraine.[34] Subcutaneous histamine has been compared with placebo, sodium valproate, and topiramate, with favorable results indicating probable efficacy in improving headache frequency, duration, and intensity. Transient burning and itching at the injection site were the only reported side effects with histamine administration.[35]

Other agents are possibly effective and may be considered for migraine prevention.[24,35] The angiotensin-converting enzyme inhibitor lisinopril and the angiotensin II receptor blocker candesartan provided effective migraine prophylaxis in recent double-blind, placebo-controlled, crossover studies of these agents.[24,26] Although use is limited by side effects, clonidine and guanfacine have also demonstrated possible efficacy.[24] Coenzyme Q10 was effective for migraine prevention and well tolerated in a small, randomized, double-blind, controlled study.[26,35] In one study, cyproheptadine (4 mg/day) was as effective as propranolol (80 mg/day) in reducing migraine frequency, duration, and severity, while the combination was more effective in attack frequency reduction.[24,35]

The calcium channel blockers, primarily verapamil, have been widely used for preventive treatment, although evidence supporting their use is inadequate or conflicting.[24,26] Extensive clinical experience and the ease of use of verapamil suggest a possible role in migraine prevention. Side effects of verapamil can include constipation, hypotension, bradycardia, atrioventricular block, and exacerbation of congestive heart failure.[24]

Localized injections of botulinum toxin type A have been used for various conditions and pain syndromes, including migraine headache. However, no consistent, statistically significant benefits have been found with migraine. The American Academy of Neurology concludes that botulinum toxin is probably ineffective.[26] Further study is needed to confirm the clinical utility and comparative efficacy for many of these miscellaneous agents in the prevention of migraine.

Personalized Pharmacotherapy

Although migraine is widely recognized as a disease that exacts an enormous toll on the sufferer, healthcare providers often do not recognize the degree and scope of functional impairment imposed by migraine on the individual.[17] Approximately 1 out of every 6 healthcare visits for migraine occurs in the emergency department, though management in this setting is often suboptimal. The use of opioids for the acute treatment of migraine in the emergency department is increasing, and the likelihood of unnecessary radiation exposure is greater.[5] Although most episodic migraine sufferers take medications for their headaches, only 2 in 3 patients who have been diagnosed and consulted with a healthcare provider use migraine-specific treatments. Just 11% of those eligible for use of medications to prevent migraine currently use them, although approximately 38% would benefit from prophylaxis.[14] Because many migraineurs who receive inadequate care experience substantial levels of pain and disability, improvement in migraine diagnosis, care, and treatment potentially could result in lower direct and indirect costs of the disease.

Effective communication and education of headache patients regarding required behavior changes and appropriate use of acute and prophylactic pharmacotherapy is essential. Healthcare professionals should inquire about and address coexisting conditions that may contribute to headache presentation or successful acute and preventive management. Decisions for treatment should be individualized, with consideration of frequency and severity of headache episodes, level of disability, trigger factors, coexisting conditions, tolerability of the available agents, and the patient's lifestyle and preferences.[17,24]

Medications with the highest level of efficacy should be used for treatment. Migraine management should be individualized on the basis of the patient's clinical presentation and medical history. Therapy should usually be initiated with the lowest effective dose and then titrated upward until clinical benefits are achieved, in the absence of adverse events. Medications that increase headache frequency or severity should be avoided. Many patients try nonpharmacologic or nonprescription treatments for headache management either before or concurrently with other drug therapy. Patients may not know how to take these products optimally and often need instructions and dosing limits.

Analgesics and NSAIDs can be considered the drugs of choice if effective for infrequent mild to moderately severe attacks. The triptans or dihydroergotamine can be used if initial therapies prove ineffective or as first-line therapy in moderate to severe migraine headache. Abortive therapy should be instituted early in the course of the attack to optimize efficacy and minimize migraine-related pain and disability. Preventive therapy should be considered in the setting of recurring migraines that produce significant disability; frequent attacks requiring symptomatic medication more than twice per week; symptomatic therapies that are ineffective or contraindicated, or produce serious side

effects; and uncommon migraine variants that cause risk of neurologic injury. Efficacy of any prescribed prophylactic regimen should be reassessed periodically. Therapeutic interventions require an adequate trial to achieve clinical benefit and often as long as 6 months for assessment of maximal benefit. A prolonged headache-free interval could allow for gradual dosage reduction and discontinuation of therapy.

A formal management plan and maintaining a headache diary are necessary for the patient and provider to evaluate therapy, headache impact, and medication consumption. Oversights can lead to decreased efficacy of medications resulting in repeat dosing and polypharmacy, decreased compliance, increased emergency visits, increased "doctor shopping," and, perhaps, increased use of expensive diagnostic procedures and inpatient services. Patients with stratified care targeted to their needs have higher headache response rates, shorter disability times, less health service utilization, and less loss of productivity.[19,26,35]

TENSION-TYPE HEADACHE

Epidemiology

Tension-type headache is the most common type of primary headache, with an estimated 1-year prevalence ranging from 38% to 86%.[3,36] Prevalence peaks in the fourth decade and is higher among women. The incidence decreases with age.[36] Although most tension-type headache sufferers experience some degree of functional impairment during their attacks, few sufferers seek medical attention, likely because they have infrequent attacks. Infrequent episodic tension-type headache (defined as fewer than one episode per month) is experienced by 64% of sufferers, while 22% have frequent episodic tension-type headache (episodes on 1-14 days/mo). The prevalence of chronic tension-type headache (15 or more days/mo, perhaps without recognizable episodes) is estimated at 0.9% to 2.2%.[2,36] Risk factors associated with a poor outcome in tension-type headache include coexisting migraine, sleep problems, anxiety, poor stress management, and the presence of chronic tension-type headache.[36]

Pathophysiology

Although tension-type headache is the most common type of headache, it is the least studied of the primary headache disorders, and there is limited understanding of key pathophysiologic concepts.[2,36] Some evidence supports that migraine and tension-type headaches represent a continuum of headache severity with similarities in mechanisms and pathophysiology. However, more recently, tension-type headache has been recognized as a distinct disorder.[2] The mechanism of pain in chronic tension-type headache is thought to originate from myofascial factors and peripheral sensitization of nociceptors. Central mechanisms also are involved, with heightened sensitivity of pain pathways in the CNS.[36] Mental stress, nonphysiologic motor stress, a local myofascial release of irritants, or a combination of these may be the initiating stimulus. Following activation of supraspinal pain perception structures, a self-limiting headache results in most individuals owing to central modulation of the incoming peripheral stimuli. Chronic tension-type headache can evolve from

episodic tension-type headache in predisposed individuals due to a change in central circuits and nociceptive processing along the brain stem reflex pathway and subsequent sensitization of the CNS.[36] It is likely that other pathophysiologic mechanisms also contribute to the development of tension-type headache.

Clinical Presentation

Premonitory symptoms and aura are absent with tension-type headache. The pain usually is mild to moderate in intensity and often is described as a dull, nonpulsatile tightness or pressure.[2,36] Bilateral pain is most common, classically described as having a "hatband" pattern. Associated symptoms generally are absent, but mild photophobia or phonophobia may be reported. The disability associated with tension-type headache typically is minor in comparison with migraine headache, and routine physical activity does not affect headache severity.[2,36] Palpation of the pericranial or cervical muscles can reveal tender spots or localized nodules in some patients.[2] Tension-type headache is classified as either episodic (infrequent or frequent) or chronic based on the frequency and duration of the attacks.[2]

TREATMENT

Tension-Type Headaches

General Approach To Treatment

The vast majority of episodic tension-type headache sufferers self-medicate with nonprescription medications and do not consult a healthcare professional. Although pharmacologic and nonpharmacologic treatments are available, simple analgesics and NSAIDs are the mainstay of acute therapy. Most agents used for tension-type headache have not been studied in controlled clinical trials.[37,38]

Nonpharmacologic Therapy

Psychophysiologic therapy and physical therapy have been used in the management of tension-type headache. Behavioral treatments can consist of cognitive-behavioral therapy (ie, stress management), relaxation training, and biofeedback.[37] These therapies (alone or in combination with pharmacotherapy) can result in a 33% to 64% reduction in headache activity. Relaxation training combined with biofeedback is more effective than other behavioral therapy options.[39] Evidence supporting physical therapeutic options, such as heat or cold packs, ultrasound, electrical nerve stimulation, stretching, exercise, massage, acupuncture, manipulations, ergonomic instruction, and trigger point injections or occipital nerve blocks, is somewhat inconsistent. However, individual patients may benefit from selected modalities in reducing the frequency of tension-type headache or during an acute episode.[38,39]

Pharmacologic Therapy

Simple analgesics (alone or in combination with caffeine) and NSAIDs are effective for the acute treatment of most mild to moderate tension-type headaches. Acetaminophen, aspirin, diclofenac, ibuprofen, naproxen, ketoprofen, and ketorolac have demonstrated efficacy in placebo-controlled and comparative studies.[38] Failure of nonprescription agents can warrant therapy with prescription drugs. The combination of aspirin or acetaminophen with butalbital or, rarely, codeine can be effective options in selected patients; however, use of butalbital and codeine combinations should be avoided when possible owing to the high potential for overuse and dependency. Acute medications should be taken for episodic tension-type headache not more than 3 days (butalbital-containing), 9 days (combination analgesics), or 15 days (NSAIDs) per month to prevent the development of medication-overuse or chronic tension-type headache.[38] There is no evidence to support the efficacy of muscle relaxants in the management of episodic tension-type headache.[38] Preventive treatment is appropriate for most patients with chronic tension-type headache and should be considered in those with frequent episodic tension-type headache if frequency (more than 2 per week), duration (greater than 3-4 hours), or severity results in medication overuse or substantial disability.[39] The principles of preventive treatment for tension-type headache are similar to those for migraine headache. TCAs are prescribed most often for prophylaxis, but other drugs also can be selected after consideration of comorbid medical conditions and respective side effect profiles. SSRIs are not effective in patients with tension-type headache who do not have depression. Limited studies support the use of the SNRIs mirtazapine and venlafaxine in patients with chronic tension-type headache and without depression.[37,39] Topiramate, gabapentin, and tizanidine may have benefits in chronic tension-type headache; however, confirmation is needed from randomized clinical trials. Data from small randomized studies suggest that trigger point injections of lidocaine may reduce headache frequency with frequent episodic or chronic tension-type headache. Injection of botulinum toxin into pericranial muscles has demonstrated inconsistent efficacy in the prophylaxis of tension-type headache and because of this, it is of uncertain benefit.[39]

CLUSTER HEADACHE

Epidemiology

Cluster headache, the most severe of the primary headache disorders, is characterized by attacks of excruciating, unilateral head pain that occur in series lasting for weeks or months (ie, cluster periods) separated by remission periods usually lasting months or years.[2,40] Cluster headaches can be episodic or chronic.[2] Cluster headache is relatively uncommon among the primary headache disorders, but the exact prevalence is uncertain. Estimates from pooled population studies show a lifetime prevalence of 124 per 100,000 or 0.12%.[40,41] The male-to-female ratio for cluster headache is approximately 4:1 with age of onset typically in the third to fifth decade. Greater than 65% of patients with cluster headache are tobacco smokers or have a history of smoking. Tobacco cessation does not, however, seem to improve the course of cluster headaches. Recent genetic epidemiologic surveys support a predisposition for cluster headache can exist in certain families.[40,41]

Pathophysiology

The etiologic and pathophysiologic mechanisms of cluster headache are not completely understood. Neuroimaging studies performed during acute attacks have demonstrated activation of the ipsilateral hypothalamic gray area, implicating the hypothalamus as a modulator of cluster headaches. The hypothalamus secondarily activates trigeminal-autonomic reflexes, leading to the ipsilateral pain and cranial autonomic features characteristic of cluster headache.[40,41] The cyclic and circadian rhythmicity of attacks also implicates a pathogenesis of hypothalamic dysfunction.[41] There is some evidence that cluster headache may result from inflammation of the nerves traversing the cavernous sinus resulting in injury to sympathetic fibers of the internal carotid artery.[41]

Clinical Presentation

One hallmark of cluster headaches is the circadian rhythm of painful attacks. Episodic cluster headaches are the most common cluster headache subtype in both men and women, occurring in up to 90% of patients.[41] In episodic cluster headaches, attacks occur daily for a week to several months, followed by long pain-free intervals.[40,41] Periods of remission average 2 years in length but have been reported to be from 2 months to 20 years in duration. Approximately 10% of patients have chronic symptoms with attacks recurring for over 1 year without remission or with remission periods of less than 1 month.[40,41]

Cluster headache attacks occur commonly at night and more commonly in the spring and fall. Attacks occur suddenly, with pain peaking quickly after onset and generally lasting 15 to 180 minutes.[40] The pain is excruciating, penetrating, and of a boring intensity in orbital, supraorbital, and temporal unilateral locations.[40,41] The headache is accompanied by cranial autonomic symptoms such as conjunctival injection, lacrimation, nasal stuffiness, rhinorrhea, eyelid edema, facial sweating, and miosis/ptosis, which resolve with resolution of the headache. Most sufferers of cluster headaches also describe restlessness or agitation. Whereas migraine patients retreat to a quiet, dark room, cluster headache patients generally sit and rock or pace about the room clutching their head.[40,41] Auras are not present with cluster headaches. During the cluster period, attacks occur from once every other day to eight times per day.[40,41] Specific diagnostic criteria for cluster headaches are provided within the IHS classification system.[2]

TREATMENT

Cluster Headaches

As in migraine, therapy for cluster headaches involves both abortive and prophylactic therapy. Abortive therapy is directed at managing the acute attack. Prophylactic therapies are started early in the cluster period in an attempt to induce remission. Patients with chronic cluster headache can require prophylactic medications indefinitely.

Abortive Therapy

Oxygen

The standard acute treatment of cluster headache is inhalation of 100% oxygen by nonbreather facial mask at a rate of at least 12 L/min for 15 minutes.[42,43,44] Repeat or frequent administration over a short period of time should be avoided, as overuse may increase the frequency or merely delay rather than abort the attack in some patients.[42,43] No side effects have been reported with the use of oxygen, but caution should be used for those who smoke or have chronic obstructive pulmonary disease.

Triptans

The quick onset of subcutaneous and intranasal triptans makes them safe and effective abortive agents for cluster headaches. Subcutaneous sumatriptan (6 mg) is the most effective agent. Nasal sprays are less effective but may be better tolerated in some patients. Adverse events reported in cluster headache patients are similar to those seen in migraineurs. Orally administered triptans have limited use in cluster attacks because of their relatively slow onset of action; oral zolmitriptan (10 mg), however, was beneficial in patients with episodic cluster headache, with 60% experiencing mild or no pain at 30 minutes.[42,44]

Ergotamine Derivatives

All forms of ergotamine have been used in cluster headaches, although no controlled clinical trials support their use.[42,44] In clinical use, IV dihydroergotamine may be given as a bolus followed by repeated administration over several days to break the cycle of frequent attacks.[42] Ergotamine tartrate also has provided effective relief of cluster headache attacks when administered sublingually or rectally.[42] Dosing guidelines are similar to those for migraine headache therapy.

Prophylactic Therapy

Verapamil

The preferred first-line treatment for prevention of cluster headaches is verapamil, a calcium channel blocker with antianginal and antiarrhythmic properties.[43,44] The beneficial effects of verapamil often appear within 2 to 3 weeks of therapy. A typical suggested dosage range is from 360 to 960 mg/day, starting with a dose of 240 mg/day. Rarely, patients with refractory cluster headaches are treated with doses as high as 1,200 mg/day. In such patients, an electrocardiogram should be obtained as the dose is increased, due to concerns for bradycardia or heart block.[42,44]

Lithium

Lithium carbonate is effective for episodic and chronic cluster headache attacks and can be used as an alternative to or in combination with verapamil.[44] A positive response is seen in up to 78% of patients with chronic cluster headache, and in up to 63% of patients with episodic cluster headache.[42] The usual dose is 600 to 1,200 mg/day, with a suggested starting dose of 300 mg twice daily.[44] Optimal plasma lithium levels for prevention of cluster headache have not been established,

but levels should be monitored and maintained between 0.6 and 1.2 mEq/L (0.6 and 1.2 mmol/L).[42]

Initial side effects are mild and include tremor, lethargy, nausea, diarrhea, and abdominal discomfort. Thyroid and renal function must be monitored during lithium therapy. Lithium should be administered with caution to patients with significant renal or cardiovascular disease, dehydration, pregnancy, or concomitant diuretic or NSAID use.[42,44]

Corticosteroids

Although there are few clinical trials evaluating the use of corticosteroids in cluster headache management, they have been used effectively for inducing remission.[42] Therapy is initiated with at least 5 days of 60 to 100 mg/day prednisone and then tapered by a dose reduction of approximately 10 mg/day. To avoid steroid-induced complications, long-term use is generally not recommended. Headaches can recur when therapy is tapered or discontinued.[42,44]

Miscellaneous Agents

Other therapies that have been used in the acute management of cluster headache include intranasal lidocaine and subcutaneous octreotide. Limited studies or case reports also support the use of divalproex sodium, topiramate, indomethacin, and intranasal capsaicin.[42,43,44]

Neurosurgical interventions to relieve chronic cluster headaches in patients refractory to pharmacologic therapy should be considered for some with debilitating headaches.[40,44] Neurostimulation has gained attention in the last several years.[42,45] Deep brain stimulation of the posterior hypothalamus and occipital nerve stimulation studies have shown positive results in small clinical trials.[42,45]

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored for frequency, intensity, and duration of headaches, as well as any change in the headache pattern. To this end, patients should be encouraged to keep a headache diary to document the frequency, severity, and duration of attacks, as well as response to medication and potential trigger factors. Careful monitoring is essential to initiate the most appropriate pharmacotherapy, document therapeutic successes and failures, identify medication contraindications, and prevent or minimize adverse events. Patients using acute therapies should be monitored for frequency of use of prescription and nonprescription medications to identify potential medication-overuse headache. Patient counseling is necessary to allow for proper medication use (eg, self-injection with sumatriptan), to encourage early use of medications in the headache cycle, and to enhance patient compliance. Strict adherence to dosing guidelines should be stressed to minimize potential toxicity. Patterns of abortive medication use can be documented to establish the need for prophylactic therapy. Prophylactic therapies also should be monitored closely (every 3-6 months until stable) for adverse reactions, abortive therapy needs, adequate dosing, and compliance. Consultation with other healthcare practitioners should be encouraged when changes in headache

patterns or medication use occur.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

CGRP	calcitonin gene-related peptide
CNS	central nervous system
FDA	Food and Drug Administration
GABA	γ-aminobutyric acid
GI	gastrointestinal
5-HT	serotonin, 5-hydroxytryptamine
IHS	International Headache Society
MAOI	monoamine oxidase inhibitor
NSAIDs	nonsteroidal antiinflammatory drugs
SNRI	serotonin-norepinephrine reuptake inhibitor
SSRI	selective serotonin reuptake inhibitor
TCA	tricyclic antidepressant

Chapter e62: Assessment of Psychiatric Disorders

Mark E. Schneiderhan; Leigh Anne Nelson; Steven Bauer

INTRODUCTION

KEY CONCEPTS

- 1 Patients with psychiatric conditions are treated in all healthcare settings. All clinicians can apply the basic skills of the psychiatric assessment to provide the best care for their patients.
- 2 The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* and the *Pocket Guide to the DSM-5 Diagnostic Exam* provides clinicians with a standardized approach for the initial assessment and follow up of patients with mental health conditions.
- 3 The World Health Organization's *International Classification of Diseases and Related Health Problems (ICD)* classification is currently used in both mental health and nonmental health settings for billing purposes.
- 4 Clinicians should be prepared to gather both the mental and physical health history from their patients. Obtaining a release of information (ROI) from patients to communicate with other healthcare providers or significant others is necessary when there are multiple providers.
- 5 Patient interviews should be conducted in an atmosphere that ensures the comfort, privacy, and safety of both the patient and the clinician. Effective listening skills and the application of open-ended questions are essential in the interview process and therapeutic relationship. Motivational interviewing (MI) can empower patients to participate and design achievable treatment goals.
- 6 If a patient is in crisis, the clinician may feel some apprehension about asking certain assessment questions. Knowing what specific questions to ask can help facilitate inquiry about sensitive areas, such as delusional thinking and suicidality.
- 7 A thorough current and past medication history, including allergies and side effects, is a

cornerstone of effective medication management. The medication history should be assessed for safety (eg, contraindications and drug interactions), tolerability (eg, side effects), efficacy (eg, response of target symptoms and adequate dosage and duration), and adherence (eg, affordability).

- 8 Baseline mental status examination (MSE), psychiatric rating scales, and psychological/neuropsychological tests are useful tools in diagnosing and monitoring the severity of symptoms and response to treatments of psychiatric disorders.

- 9 Although there are no diagnostic tests for psychiatric disorders, physical and laboratory assessments can help the rule out drug-induced or medical causes that may produce similar or overlapping symptoms.

- 10 Psychiatric rating scales, cognitive testing (neuropsychiatric rating scales), and psychological testing provide objective measures of psychiatric symptoms, adverse side effects, memory, and intellectual capacity and are often used in research and clinical settings.

1 Patients with mental health conditions often have comorbid physical illnesses, therefore, communication between multiple providers is necessary to prevent serious medical and/or medication-related consequences. Often care coordination between mental health and primary care services is required.[1] A good psychiatric assessment can identify the need for coordinated care and should be included as part of the full patient assessment in all healthcare settings. A psychiatric assessment should not be limited to the clinical setting. In many communities, basic mental health assessment education programs are being offered in efforts to reduce stigma and to help the public understand and even respond to signs of psychiatric illness and substance use disorders.[2] Along with traditional assessments used across all medical specialties (eg, laboratory tests, medical history, physical examination), mental health clinicians rely on communication skills and use validated assessments that are perhaps less objective in nature and less familiar to nonmental health practitioners. This chapter provides a basic overview of appropriate assessment techniques used by clinicians to develop individualized treatment plans for patients with psychiatric conditions. Readers needing greater depth than the materials provided in this chapter are referred to other sources.[3,4,5,6,7,8,9,10]

OVERVIEW OF DIAGNOSTIC CLASSIFICATION SYSTEMS USED IN PSYCHIATRY

2 The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) has been the most widely accepted diagnostic reference in the United States for the care of individuals with mental disorders. DSM provides a common language for practitioners to describe and diagnose psychiatric disorders. Common language is essential because there is considerable overlap of symptoms across many diagnoses.

3 In contrast, the World Health Organization's *International Classification of Disease and Related*

Health Problems (ICD) primary function was to provide scientists a means of collecting all disease and health information across populations. The ICD classification is currently used in both mental health and nonmental health settings for billing purposes in the United States.

Introduced in 1952, the *Diagnostic and Statistical Manual of Mental Disorders*, *First Edition (DSM-I)* was the first manual on mental disorders to focus on clinical utility.[11] The second edition (DSM-II), released in 1968, was largely an expansion of the number of psychiatric disorders included in the manual, but otherwise did not represent a shift in diagnostic methodology.

A paradigm shift was observed first in the DSM-III (1980) whose major structural changes and contributions included: the development of a multiaxial system, the use of empirically derived diagnostic criteria, and the use of an etiologically neutral descriptive approach.[11] The DSM-III was a categorical diagnostic approach which remained in place for the next three editions of the DSM (ie, DSM-III-R [1987], DSM-IV [1994], and *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* [DSM-IV-TR] [2000]), and was designed to produce homogeneous groups who could be both easily treated and easily researched. Unfortunately, it became clear over time, that at least for some diagnoses, the older DSM editions tended to obscure the clinical reality that people with complex comorbid conditions often have overlapping symptoms and bio-psychosocial risk factors.[9]

The DSM-5, published in 2013, marks the second and most recent paradigm shift in diagnostic methodology. Specifically, DSM-5 represents the first step away from a categorical system of classification to a dimensional one.[9] It has reorganized diagnostic categories as well as specific diagnoses within categories using a developmental lifespan approach. Changes in specific diagnoses or their classification reflect advancements in our understanding of those disorders that are empirically supported. More specifiers have been added which allows the clinician to pinpoint qualifiers (eg, with anxious distress) course (eg, early/late onset, partial/full remission), pattern of presentation (eg, with intermittent major depression) and severity. Most notably, DSM-5 has abandoned the use of the multiaxial system, in favor of a single list which includes those disorders formerly listed on Axis I, II and III. This "non-axial" system is meant to acknowledge that mental and physical disorders not only coexist, but affect, and are affected by one another. DSM-5 continues to distinguish mental disorders from "psychosocial and environmental problems. While previously listed on Axis IV, DSM-5 adopted already established and related ICD codes to classify those psychosocial conditions which both need attention and likely affect the mental disorder. Finally, functional status formerly coded on Axis V using the Global Assessment of Functioning (GAF) was discontinued due to its lack of reliability and "conceptual clarity".[9] The *WHO Disability Assessment Schedule 2.0* (WHODAS) is under investigation as a replacement and in use in some states (eg, Minnesota) as a marker of functional impairment (**Table e62-1**).[10] Finally, more emphasis is placed in DSM-5 on objective diagnostic and follow-up assessments, utilization of severity rating scales, screening tools, and cultural assessments. A complete list of the suggested patient assessment measures is available for clinical use and can be found in Section III of the DSM-5 entitled "Emerging Measures and Models" or online at http://www.psychiatry.org/dsm5 (ie, "Online Assessment Measures").[8] For a complete listing of all changes, please refer to section entitled "Changes from DSM-IV-TR to DSM-5" at http://www.psychiatry.org/dsm5.[9]

TABLE e62-1 Global Illness and Disability Assessment Scales

Rating Scale	Type	Scoring	Comments
Clinical Global Impressions (CGI) Scale CGI (S): Severity of Illness CGI (I): Global Improvement CGI: Efficacy Index	Clinician rated	1-item, CGI-S and CGI-I with a 7-point symptom severity and improvement score. 1-item CGI Efficacy index: Total score: 1-4 marked improvement; 5-8 moderate; 9-12 minimal; 13-16 unchanged or worse	Observational and nonsymptom-specific for assessing three global subsets: severity of illness, global improvement, and efficacy index measures both therapeutic and side effects. CGI rating scales (Last accessed 08/24/16) found at http://www.psywellness.com.sg/docs/CGI.pdf
WHO Disability Assessment Schedule WHODAS 2.0	Patient, Proxy, or Clinician (interviewer) rated	Assessment options include: 12 item, 12 + 24 item, and 36 item; Total score is the summative score. Complex scoring "item-response theory". Uses an algorithm to determine a range of disability 0 = No disability and 100 = full disability	Covers 6 Domains of functioning including: Cognition, Mobility, Self-Care, Getting along, Life activities, and Participation.

Data from references 10, 52 and 53. (Accessed September 9, 2015)

Diagnostic and Statistical Manual of Mental Disorders, *Fifth Edition* has retained the descriptive approach found in earlier editions of the manual with updates to the exact content. The descriptive text provides information for all mental disorders regarding diagnostic features, prevalence, development and course, risk and prognostic factors, functional consequences of the disorder, differential diagnosis, comorbidity and, where applicable, culture and gender related diagnostic considerations.

Diagnosing mental disorders and developing an appropriate treatment plan for patients requires the clinician to engage in a comprehensive interview that not only assesses the patient's presenting problem(s), but also provides the bio-psychosocial context for understanding those problems. *The Pocket Guide to the DSM-5 Diagnostic Exam*, includes examples of screening and follow-up questions used in a diagnostic interview for each of the mental disorder categories in DSM-5.[8] It also discusses approaches to establishing a therapeutic alliance with patients, conducting a 30-minute diagnostic interview, a stepwise approach to differential diagnosis, and evaluations in special populations (ie, cultural assessments).

Currently, both DSM-5 and WHO ICD-10 will continue to exist as companions in the diagnostic coding classification of psychiatric disorders. In the United States, the ICD, as it is used in reference to psychiatric disorders, is mandated by insurance companies to secure payments; whereas globally it is used to secure information regarding the epidemiology of the disorders. Broad differences currently exist between DSM-5 and ICD-10. However, ICD-11, due in 2018, is reportedly scheduled to be more in line, at least organizationally, with DSM-5. It will be important during these transitions to understand both systems and be fluent with integration.

In summary the DSM-5 and ICD provide clinicians with a systematic approach towards evaluating patients, thereby allowing for the development and implementation of better treatment plans and a more consistent way to evaluate treatment outcomes.

Clinical Controversy…

In 2015, clinicians who can submit patient claims to Medicare are now required to use a certified electronic health record (EHR) to avoid Medicare insurance reimbursement penalties. The transition from paper health records to the EHR has been challenging for mental healthcare providers. For example, there are multiple EHR vendors/systems with cost-based options for medical/mental health clinics. Often a clinic's EHR system is incompatible with other mental health and primary care health EHR systems and creates another barrier to exchanging patient health records. In addition, lower-cost EHRs are often not designed by clinicians, time-consuming to use, incompatible with clinical workflow, lack the latest diagnostic codes (ie, DSM-5), and may not be linked with the latest ICD codes for billing purposes. To meet Medicare requirements, clinicians have been forced to adapt to overcome these EHR programing limitations. For more information see http://www.healthit.gov/providers-professionals/faqs/are-there-penalties-providers-who-don%E2%80%99t-switch-electronic-health-record (Last accessed 09/24/2015) and http://www.healthcaredatasolutions.com/wp-content/uploads/2015/03/HDS-Whitepaper-6-EHR-Trends-to-Watch-in-2015.pdf (Last accessed 09/24/2015).

THE CLINICAL INTERVIEW

The psychiatric clinical assessment is more than a verbal communication exchange. Although the focus of the interview may be on mental health, the clinician should be prepared to assess both the mental and physical health conditions of their patients. Clinicians need to be aware that patients with psychiatric disorders often lack coordination of their healthcare.[1] Often multiple prescribers are involved resulting in poly-drug therapy. Communication exchanges between psychiatry and primary care services are often fragmented, even if they are co-located, due to siloes of practices.[12,13] Moreover, patients with severe and persistent mental illness (SPMI) have a shortened life span and are less likely to receive the same level of primary medical care compared with patients without psychiatric disorders.[14,15,16,17,18] Barriers to medical care include patient paranoia, ambivalence, and disorganization; which account for missed appointments and stigma toward psychiatric disorders.[19,20] For example, a significant number of patients who take antipsychotics are not adequately monitored for adverse effects, such as, emergent diabetes and dyslipidemia.[21,22,23,24] Therefore, the interviewer should be aware of the significant health disparity in this population

because best practices for medical monitoring has become the standard of care.[18,22,25,26,27]

Release of Information

4 Because coordination of care is often lacking, permission from the patient to obtain "collateral information," such as psychiatric and medical diagnoses, laboratory test results, medication lists, and other verbal or written records, should be obtained before the interview is completed. Collateral information can be obtained by asking the patient to sign a "Release of Information" (ROI), which is mandatory in order to contact significant others, family members, and other clinicians.[28]

In summary, the clinician should be prepared to assess the mental and physical health of the patient, which is discussed in more detail in the Mental Status Examination and Physical Examination and Laboratory Assessment sections later in this chapter.

Interview Techniques

5 Interviews should be conducted in a quiet, non-stimulating, private, and comfortable area where the patient and the interviewer feel at ease.[8] The interview setting should be appropriate to the patient's level of acuity and the potential for risk to the patient and clinician. The interviewer should introduce him- or herself and explain what is about to happen in order to establish a trusting relationship (ie, therapeutic alliance). Generally, open-ended questions come first followed by questions focused on more specific or personal data. Open-ended questions allow the patient to provide descriptions and other information in his or her own words. Even though more specific questions may then be necessary to fill in the gaps, beginning in this manner minimizes the risk of "leading" the patient. Patients can respond to specific questions and "yes" or "no" questions with answers they think the interviewer wants to hear. The interviewer must listen carefully and remain nonjudgmental about the information offered by the patient to develop trust and rapport and to ensure completeness and accuracy of the information. Motivational interviewing (MI) is another technique that can be useful for engaging the patient if conflicting issues arise such as discussions around tobacco, drugs, or alcohol use.[29] The MI approach to patient interactions is described by the acronym OARS (open-ended questions, affirmations, reflective listening, and summary).[29,30,31] More comprehensive descriptions and training opportunities for MI are available in other sources.[29,31,32]

Whether a clinician takes notes or just listens during the interview is an individual decision; the primary considerations are accurately recalling the details of the examination and assuring that the patient is comfortable with the note taking. **Table e62-2** provides examples of questions useful for gathering information toward the completion of the clinical interview. Before any conclusions are made during a patient interview, the impact of culture on the patient's presentation should be considered. Something that sounds delusional in one culture can be the norm in another culture. If a clinician is unclear whether culture of origin accounts for some of the patient's symptoms, he or she should obtain a ROI to consult with a family member or someone else familiar with the patient's culture of origin. The Cultural Formulation Interview (CFI) found in the assessment tools of DSM-5 can also be used to assist the clinician who suspects that cultural influences may be affecting the

diagnostic assessment.[9,10]

TABLE e62-2 Examples of Interview Questions for Assessing Psychiatric Disorders[a]

Mania

1. Tell me what your typical day is like.[b]
2. Do your thoughts go faster than you can say them?
3. Have you noticed a change in the amount of sleep that you require?
4. Have you spent a lot of money lately, and what did you spend it on?
5. Do you have a lot of extra energy?

   (To assess hallucinations and delusions, see Schizophrenia section below.)

Depression

1. How do you spend your time?[b]
2. Do you cry without any reason?
3. Do you still enjoy the same hobbies or activities that you once did?
4. Has your weight changed recently?
5. Have you had changes in your energy level recently?
6. Do you have any guilty feelings?
7. Do you find it difficult to remember phone numbers, names of friends, appointments, and so on? (To assess sleep and suicidal potential, see Sleep and Suicide sections below.)

Schizophrenia

Delusions

1. How do people treat you?
2. Do you feel that people plot against you?
3. Do you ever feel that you are watched or spied on?
4. Do you have any special abilities?
5. Does anyone ever try to mess with you or bother you?
6. Do others read your thoughts?

[a]For all of these example questions, try to get the patient to expand on their answers.

[b]These assessment questions or inquiries may be used early in the interview to assess other psychiatric disorders as well.

Clinical Controversy…

Patients diagnosed with borderline personality disorder (BPD) are often negatively affected by stigma from mental health providers. "Surplus Stigma" is a term that describes discrimination, misunderstanding, and fear of BPD among healthcare providers including: 1. Blaming the patient's parents that BPD was caused by parental neglect; 2. Refusal by the clinician to provide mental health services; 3. Negative portrayal by the media; and 4. Inability for patients to obtain medical insurance coverage when diagnosed only with BPD. Clinicians should be aware of their own emotional reactions towards a person diagnosed with BPD; since, this can have a negative effect on the quality of care. Consumer advocacy organizations such as the National Alliance on Mental Illness (*www.nami.org*) are committed to help increase awareness about the issues and perceptions surrounding all forms of mental illness including BPD. For additional information see: (http://www2.nami.org/Template.cfm?Section=20075&Template=/ContentManagement/ContentDisplay.cfm&ContentID=44745) (Last accessed 09/24/2015).

The Challenging Patient

6 Patient assessments can be challenging when symptoms of the condition prevent effective engagement with the clinician. Whereas excited patients may exhibit speech that is rapid and unorganized, depressed patients may respond with few words. Patients in the manic phases of bipolar disorder may not pause as they speak (ie, pressured speech), making it difficult for the interviewer to interject. In all cases, the interviewer can regain control by politely redirecting the patient back toward the question.

The interviewer should always be prepared to adjust his or her communication approach based on the responses or reactions of the patient. Often, as in the disease of schizophrenia, a patient may demonstrate *poor* insight and judgment. It can be common for the clinician to react negatively with anger if the patient seems to be manipulating and not adherent with treatment. Instead of reacting negatively, one principle in MI is to "roll with resistance" in which the clinician accepts the patient's perspective and encourages the patient to explore his or her own solutions.[29] In another situation, patients with psychosis may be paranoid and appear guarded or frightened by the interviewer's questions. During any patient encounter, clinicians should be aware of strong emotions such as fear, anger, or frustration and be careful not to judge or react to the patient. Overall, the best approach is to remain calm, speak softly, be respectful, use shorter or closed-ended questions, and seek only essential information. Sometimes, patients can become agitated and occasionally violent. Often violence is preceded by increased psychomotor agitation as evidenced by pacing, shaking, speaking in a loud voice, crossing arms, or gripping an object (ie, chair or table). When there is concern about safety, the interviewer should remain at safe distance from the patient and avoid any behavior that could be misconstrued as threatening, such as, being overly friendly (eg, touching) or unnecessary

staring. In these circumstances, it is best to keep the encounter brief and interview the patient in the presence of another healthcare provider. Both the patient and interviewer should have equal access to leave the room if either becomes too uncomfortable. If a patient becomes threatening to the interviewer, the interviewer should not hesitate to leave the room and call for help. If a patient describes suicidal thoughts and plans, the patient should be further assessed using the questions outlined in Table e62-2. Asking a patient about suicidal thoughts or plans will not increase the risk. The risk is greater if these questions are never asked or signs of distress are ignored. If concerns about the patient's safety persist, further assessments should be directed to the appropriate type of care, including either an emergency department visit or direct hospitalization for patients at immediate risk of harming themselves. In summary, applying MI skills or just remaining calm, quiet, and respectful may deescalate the agitated patient, preserve the therapeutic alliance, and improve overall treatment adherence.[29]

Psychiatric History

History of psychiatric disorders in patients and their families provide important information when formulating a diagnosis and treatment plan. Information collected should include the current and previous psychiatric diagnoses, clinical presentation of each mental disorder, time frame between episodes, level of functioning between episodes, length of each episode, total duration of the mental disorder, and treatment given during each episode as well as response to those treatments. Baseline functioning or the highest level of functioning achieved in the last few years is important because it helps to define a treatment goal. Information on the history of the current episode and reasons for presenting to the clinician should also be gathered. A family history should include a medication history of the immediate relatives because a family member's response to a given medication might predict an individual patient's response to that same medication.

Social History

A social history contains educational and occupational background; religion; marital status; substance-use, including tobacco, caffeine, illicit drugs, and alcohol; and current living situation. By understanding a patient's living environment and social situation, strategies to foster treatment adherence, reduce stress, and increase social support can be developed. To probe this area initially, the clinician can ask patients to describe their social support network. This can be followed by more specific questions such as: "To whom are you closest?" or "In whom do you confide?"

Medication History

7 A thorough medication history is one of the most important contributions a clinician can make to treatment planning. The history should include medications for both psychiatric and medical conditions and list all medications, including over-the-counter and herbals, taken by the patient. The history should also report how each drug was tolerated and describe the responses to a single drug or combination of drugs. All allergies must be noted. Because most psychiatric medications have a delayed onset of effect, it is important to determine whether an adequate trial (dose and duration) was provided before the patient is deemed "nonresponsive" to that drug. If a patient has a history of

nonadherence, specific causes should be investigated. Causes of non-adherence may include, but are not limited to, drug cost, complicated dosing schedules, lack of insight, failed efficacy, and adverse effects.

Mental Status Examination

8 The mental status examination (MSE) is a key patient assessment tool in psychiatry and is analogous to the physical examination in medicine. The MSE is completed through a direct patient interview and provides a systematic method of organizing and reporting current behaviors, thoughts, perceptions, and functioning. The MSE has several components (eg, Appearance, Attitude, Activity, Speech and Language, Mood and Affect) and is combined with other aspects of the patient workup (history of present illness, physical examination, appropriate laboratory tests, and medical and psychiatric history) to give a full picture of the presenting problem and factors contributing to the mental disorder.[7,8,9] The addition of symptom rating scales incorporated into the MSE can greatly enhance the clinical assessment. Consistent identification and tracking of symptoms with rating scales can even enable both the clinician and patient to mutually construct specific treatment goals and measure clinical progress such as changes in symptom frequency or severity over weeks or months.[33] Although terminologies can be misleading, the MSE should not be confused with the Mini Mental Status Exam (MMSE), which is discussed in the Neuropsychiatric Rating Scales section later. The components of the MSE include:

Appearance and Attitude toward the Examiner

The appearance of the patient throughout the interview should be noted, including age, dress, grooming and hygiene, use of cosmetics, and facial expressions. A description of appearance also should include unusual physical characteristics and the general state of physical health. The interviewer should note whether the patient is cooperative, mute, hostile, paranoid, guarded, or withdrawn.

Activity

Motor activity may be excessive or diminished. Overactivity during the interview can range from hand wringing; restless leg movements; and picking at clothing, skin, or hair to severe pacing in the room. Underactive patients move less than expected. Patients with rigid posture, an absence of movement, and failure to communicate may be catatonic or paranoid or experiencing medication-induced adverse effects.

Speech and Language

The quantity, flow, and speed of speech and the amount of eye contact should be noted. The appropriateness and degree of eye contact varies significantly among cultures, and before poor eye contact is interpreted, the patient's cultural background should be considered. Speech should be assessed as to whether it proceeds logically in a goal-directed manner or whether the content is vague and poorly organized. Abnormal speech characteristics include thought blocking, whereby the

person suddenly stops speaking without any obvious reason. *Thought blocking* usually occurs when hallucinations or delusions intrude into the person's thinking or when upsetting issues are discussed. Conversely, *pressured speech* is observed in conditions such as bipolar disorder. *Flight of ideas* is over-productive, rapid speech during which the patient jumps rapidly from one idea to the next. *Circumstantial* and *tangential speeches* are evidence of disorganized thoughts. C*ircumstantial speech*, whether pressured or not, lacks a clear direction because of excessive unrelated information, but the circumstantial patient eventually makes full "circle" back to his or her point. In tangential speech, however, the ultimate point is never made. *Perseveration* is repetition of an original answer to subsequent questions. *Mutism* is identified when the patient does not respond even though he or she is aware of the discussion.

Affect and Mood

Affect describes the patient's current emotional tone, as expressed through facial expression, body posture, and tone of voice, all of which can be objectively observed by the clinician. Mood describes feelings, which are subjectively reported by the patient. Changes in facial expression and the presence of tears, flushing, sweating, or tremors should be noted. Affect can be described further by its range, appropriateness, intensity, and stability. For example, in individuals with schizophrenia or depression, the affect can be *flat*, whereby no change in expression occurs throughout the interview. In contrast, during a manic episode, the affect is very intense and often *excited*. *Blunted affect* denotes that the range of emotional expression is reduced but not absent. An example of *inappropriate* or *incongruent affect* is when a patient laughs in a situation that would be expected to produce sadness. A rapidly shifting affect from one extreme to the other is described as *labile*.

Thought and Perceptual Disturbances

A variety of thought disturbances can occur in mental disorders. Many of these disturbances generally indicate the presence of psychosis or impaired reality testing. *Delusions* are fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be paranoid, somatic, or grandiose in nature. Delusions are often unshakable, and although the clinician can challenge the delusional thinking, one should not attempt to talk to a patient out of a delusion. The lack of awareness of a mental disorder (anosognosia) can often accompany delusions. *Thought broadcasting* is the belief that one's thoughts are audible to others. *Hallucinations* are false sensory impressions or perceptions that occur in the absence of an external stimulus. Hallucinations can be auditory, visual, olfactory, tactile, or gustatory and can be continuous or intermittent. In contrast, *illusions* are visual misperceptions involving a misinterpretation of a real sensory stimulus. For example, a person experiencing an illusion may react in fear if he or she momentarily misperceives the wind moving a curtain to be an intruder. This phenomenon does not always indicate a psychiatric disorder and can be seen in persons without mental disorders. Not all thought disturbances are indicative of psychosis. For example, the couplet of obsessions and compulsions can indicate the presence of obsessive-compulsive disorder, which is not considered to be a psychotic disorder. *Obsessions* are unwanted thoughts or ideas that intrude into a person's thinking. *Compulsions* are actions performed in response to the obsessions or to control anxiety associated with the obsession.

Evaluation of Cognition

The MSE assesses sensorium, attention, concentration, memory, and higher cognitive functions such as orientation and abstraction. If deficits in memory and concentration are primary or secondary complaints of the patient or these deficits are apparent during the interview, more formal or standardized mental status testing (eg, MMSE) may be required. The clinician should document whether the patient has received medications with sedative properties because the outcome of the examination can be altered if central nervous system depressants were recently taken.

Sensorium, or level of consciousness, refers to the alertness of the patient, and if he or she is not fully alert, the amount of stimulation needed to awaken the patient. Attention and concentration can be further assessed using serial subtraction by 7s ("serial 7s") or 3s or by having the patient spell a five-letter word backward (eg, d-l-r-o-w). General intelligence can be assessed loosely by asking factual information about current news items, recent presidents, or popular television shows or sporting events. *Memory* is the ability to recall prior information and experiences. There are many descriptors referring to specific types of memory such as working memory (ie, the capacity to hold information such as a phone number in mind for a few seconds), short-term memory (ie, the ability to recall newly acquired information after several minutes), and long-term or remote memory (historical facts) that are commonly assessed as part of the MSE. Orientation to time, place, person, and situation assesses short-term memory. Asking a patient to recall three objects 5 minutes after they are learned is the definitive test for short-term memory. Although, deficits in short-term memory may be seen in depression and anxiety, this finding is the hallmark feature of dementia. Asking the patient to do a certain task (eg, pick up a pen with his or her right hand and then fold a piece of paper and pass it to the examiner) or spelling a five-letter word in reverse are examples of testing working memory. Patients with cognitive deficits, such as those seen in dementias and schizophrenia, can exhibit deficits in working memory. Remote memory is assessed by asking patients to recall old facts about their lives, such as where they were born or where they went to school. Whereas remote memory usually remains intact the longest in patients with intellectual decline, the inability to create new memories is generally the first sign of a memory deficit. *Abstraction* is the ability to interpret information such as a proverb (eg, "People in glass houses shouldn't throw stones") or identify similarities or differences between words (eg, apple and orange). Abstraction is influenced by education, cultures, and linguistic fluency; thus, an inability to abstract is not always a sign of a psychiatric disorder. Persons with schizophrenia often provide *concrete* (literal or superficial interpretations) or *bizarre* responses to probes of abstraction.

Insight and Judgment

Insight refers to patient awareness that he or she has a mental disorder and the impact of that disorder on his or her life. *Anosognosia* is a term used to define the complete lack of insight or awareness of a mental disorder. Because lack of insight is associated with high morbidity and mortality rates among patients with mental disorders, there is much interest in this area as a focus of research.[34] For example, the symptom of *poor* insight is thought to be the main cause of *poor* judgment such as non-adherence with prescribed medications.[29,34,35] Levels of insight may be variable based on the level of acuity of the mental disorder.

Judgment is the ability to make decisions appropriate to the situation and can be impaired in people with a variety of mental disorders. Judgment can be assessed by asking patients how they would handle either their current or a hypothetical situation. As with insight, judgment also can be fluid. For example, intoxicated patients can demonstrate *poor* insight and judgment only to improve over several hours as their blood alcohol concentration decreases.

In summary, the MSE is the clinician's observations and expert opinion based on the patient's history, verbal responses, nonverbal reactions, appearance, and behaviors. The MSE is primarily used to establish the patient's diagnosis, target symptoms, response, and treatment plan. In addition to the MSE and based on the discretion of the clinician, a physical examination, laboratory assessments, objective rating scales, and psychological testing may be needed for a comprehensive mental health assessment and follow-up. These assessment tools are described in the following sections.

PHYSICAL EXAMINATION AND LABORATORY ASSESSMENT

9 There is no consensus about specific laboratory tests for diagnosing or evaluating mental disorders.[4,7] An emerging area of interest is the identification of biologic markers (eg, pharmacogenomics) as diagnostic tools, predictors, or indicators of drug response. Recent developments in brain imaging (functional magnetic resonance imaging [fMRI]) using computer algorithms are being studied and show promise in diagnostics. For example, a recent meta-analysis of fMRI studies found evidence for diagnostic specificity for emotional processing in schizophrenia and bipolar disorder.[36] Although, there are no diagnostic tests to definitively indicate that a patient has a specific mental disorder (eg, schizophrenia or bipolar disorder), physical assessments and laboratory tests are important to clarify the etiology of presenting symptoms.

Physical Assessment

Patients who present with psychiatric symptoms need a careful medical assessment because of overlapping symptoms from differing causes.[3,4,5,9] A complete physical examination, along with a detailed medical and medication history, vital signs, body mass index (BMI), a pregnancy test when indicated, and routine blood chemistry are commonly part of the workup of persons with a mental disorder. In most cases, a physical examination should be chaperoned in the mental health setting.

Presenting symptoms can have multiple etiologies (ie, medical, medications, and mental disorders). Medical conditions, psychiatric disorders, medication side effects, and illicit drug use can cause symptoms that are often indistinguishable. Patients with psychiatric disorders, especially depression and anxiety disorders, may present to primary care providers with only physical or somatic complaints (eg, gastrointestinal) and thus receive unnecessary medical treatment, while the root psychiatric cause is overlooked.

In contrast, psychiatric disorders may predispose a person to medical complications. For example, patients with SPMI have a high prevalence of modifiable risk factors such as poor nutrition, obesity, substance use disorders (eg, tobacco, alcohol, and illicit drugs), and sedentary lifestyles, leading to increased morbidity and mortality.[14,16] As a result, these patients die on average 25 years earlier than

the general population, with 60% of these premature deaths caused by comorbid medical conditions, including cardiovascular disease, diabetes, respiratory disease (eg, influenza, pneumonia), and infectious disease (eg, HIV/AIDS).[17,37]

Psychotropic medications can also cause or exacerbate medical conditions, such as diabetes mellitus, hyperlipidemia, or cardiac arrhythmias, necessitating an initial assessment and ongoing monitoring for these conditions while continuing treatment.[38,39] Baseline and follow-up assessments are needed to help document future adverse effects from medications. For example, the 2004 expert consensus guidelines recommend that patients taking antipsychotic agents should be periodically screened for symptoms of metabolic syndrome, including body weight, waist circumference, blood pressure, and fasting serum lipids and glucose.[38,39,40,41] Please refer to the chapter on Schizophrenia (Chapter 67) for in-depth information on antipsychotic adverse effects.

Abrupt onset of psychiatric symptoms can be an important clue that a medical cause (eg, delirium from an encephalopathy) may be present. Whereas, most chronic psychiatric disorders (eg, schizophrenia) may have a prodromal period prior to an acute episode. Patients older than 40 years at first presentation are more likely to have a medical cause for their psychiatric symptoms, because major mental disorders, such as schizophrenia and bipolar disorder, usually first present in adolescence or early adulthood. Family history can provide additional clues. Patients with fluctuating levels of consciousness; disorientation; memory impairment; or visual, tactile, or olfactory hallucinations are more likely to have a medical basis for their presentation that can be diagnosed by medical diagnostics (eg, laboratory tests, computed tomography [CT], magnetic resonance imaging [MRI]).

Laboratory Assessment

General laboratory screenings are useful for medication monitoring and ruling-out medical causes of mental disorders. Urine drug screens and blood alcohol tests play an important role in identifying the contribution of alcohol and illicit substances to the presenting symptoms. Additional testing can include an electroencephalogram (EEG) to evaluate for the presence of seizure activity and other neurologic conditions; CT or MRI scans to detect structural abnormalities; sedimentation rate and antinuclear antibodies for autoimmune disorders; vitamin B_{12} and folate concentrations for anemias; endocrine tests (eg, thyroid function) for identifying hormonal and metabolic disorders; and others work-ups as needed.[4] Laboratory tests should be individualized to the patient's age, medical/medication history, cooperativeness, and physical health; however, extensive testing is usually unnecessary and not cost effective.

Clinicians also use diagnostic tests to evaluate the relative safety of specific medications, such as pregnancy monitoring with divalproex, renal status when using lithium, or an electrocardiogram (ECG) when using medications that prolong the QT interval (eg, tricyclic antidepressants such as amitriptyline). Serum concentration monitoring is recommended for medications with a narrow therapeutic index (eg, lithium, divalproex, and carbamazepine). Serum concentration monitoring can also be useful for assessing medication adherence when there is an inadequate response. With the exceptions of lithium, divalproex, clozapine, and nortriptyline there are minimal data to support

obtaining serum concentrations for optimizing medication efficacy in patients with psychiatric disorders. Finally, clinicians must also be aware of pharmacokinetic and pharmacodynamic drug–drug and drug–food interactions that occur with many medications, which raise the probability of adverse effects, toxicity, or loss of efficacy. Pharmacogenomics may help clinicians predict and minimize drug and disease interaction risks and adverse drug reactions (eg, cardiovascular disease and hyperprolactinemia with antipsychotic agents).[42,43]

In summary, a range of assessments aid clinicians in conducting problem-focused workups to verify diagnoses and identify underlying or potential drug-related problems.[44] Although the MSE remains the cornerstone of the psychiatric workup, experts in the field recommend selective medical tests; a good medical, psychiatric, and medication history; and a thorough physical examination or referral to primary care. Awareness of overlapping chronic medical diseases, mental disorders, and psychiatric medications requires a more collaborative care approach to both the mental and physical health needs of the patient.

MEASUREMENTS OF PSYCHIATRIC SYMPTOMS AND COGNITIVE FUNCTION

10 In addition to the MSE, symptom-based rating scales are useful tools to provide an objective way to measure subjective data (eg, feelings, thoughts, and perceptions) and to screen or diagnose specific disorders. Because there are many types of scales from which to choose, the clinician rater needs training and experience to select and effectively use the most appropriate scale. Rating scales are used in a variety of settings, including research and patient care, and can serve an administrative purpose, such as quality control.[6]

Some rating scales are self-administered ("patient-rated") and do not require a staff member to collect the data; thus, they require minimal resources to administer and can provide valuable information, although some patients may be unable to self-administer a questionnaire for a variety of reasons, including limited literacy, instrument length (ie, number of items), and severity of symptoms.

In contrast, "clinician-rated" scales may provide a more consistent measure of target symptoms or behaviors. However, a major drawback includes the substantial time commitment for staff to administer the tests and the inability of some patients to tolerate these interviews, especially patients who are severely paranoid or agitated. In addition, repeated ratings are usually necessary to objectively describe longitudinal changes over a defined treatment period as opposed to a snapshot of a complex clinical situation.

Sensitivity, specificity, reliability, and validity are important considerations when selecting a rating scale. *Sensitivity* refers to a test's ability to detect a symptom or illness given that the symptom or illness is present. *Specificity* refers to a test's ability to correctly determine that a symptom or illness is absent when the person does not have the illness.[45]

Reliability is the extent to which the score on the scale reflects the hypothetical "true" score and how much interference occurs from outside influences.[46,47] Reliability is reported by the correlation

coefficient, which represents a chance correlation (0.00) or perfect correlation (1.00). Rating scales with correlation coefficients of less than 0.7 are usually considered unreliable for clinical studies. *Interrater reliability*—agreement in rating scores among clinician raters—is important to achieve when multiple clinicians rate the same patient or population. Interrater reliability is established by having all raters independently rate individual patients at the same time to determine the correlation of their scores.

Validity, in contrast, is the ability of a scale to measure what it was designed to measure. Various validity tests are performed on a rating scale to ensure that the scale assesses the appropriate aspects of the illness (*content validity*), the correlation with diagnoses or clinical change (*criterion-related validity*), and the extent to which the scale measures symptom traits in contrast to a specific symptom (*construct validity*).[47] Before administering any rating scale, the clinician should be trained or observed using the rating scale and have thorough knowledge of the rating scale's strengths and limitations.

Psychiatric Rating Scales

Psychiatric rating scales provide the clinician or researcher with a consistent measure of medication side effects and symptoms that are present in psychiatric disorders (eg, extrapyramidal side effects and tardive dyskinesia [TD] [**Table e62-3**], psychosis [**Table e62-4**], depression and mood disorders [**Table e62-5**], anxiety and obsessive compulsive disorders [**Table e62-6**]). *Symptom-based rating scales* (eg, Positive and Negative Syndrome Scale [PANSS], Hamilton Depression Rating Scale, and Abnormal Involuntary Movement Scale [AIMS]) are used to measure the presence or severity of symptoms and assist in the diagnostic formulation.[48,49,50,51,52,53.54,55,56] In contrast, *global assessment scales* can be used to identify the overall severity of psychiatric symptoms and impact on function (see Table 62-1) based on the patient's and/or clinician's experience (ie, Clinical Global Impressions Scales and WHODAS).[51,53]

TABLE e62-3 Adverse Effects Measuring Instruments

Rating Scale	Type	Scoring	Comments
Abnormal Involuntary Movement Scale (AIMS)	Tardive dyskinesia (TD) assessment	12-item, 5-point severity scale. Items 1-4 orofacial movement; 5-7 extremity and truncal movement; 8-10 global severity; 11 and 12 problems with teeth or dentures (yes or no)	5-10 minutes to complete. Most commonly used. Diagnostic criteria: at least 3 months of antipsychotic treatment. Mild severity score (2) in two discrete areas or moderate severity (3) in one area (eg, orofacial) indicates TD. Tremor is not counted. https://cpnp.org/_docs/ed/movement-disorders/scale/aims.pdf (Last accessed 09/24/2015)
Dyskinesia Identification System: Condensed User	Tardive dyskinesia assessment	15-item, 5-point severity scale. Items 1, 2 face; 3 eyes; 4, 5 oral; 6-9 lingual; 10, 11	5-10 minutes to complete. More descriptive criteria for scoring severity than the AIMS. Scoring based on three dimensions: frequency, detectability, and

Rating Scale	Type	Scoring	Comments
Scale (DISCUS)		head, neck, or trunk; 12, 13 upper limb; 14, 15 lower limb	intensity. Tremor is not counted. https://cpnp.org/_docs/ed/movement-disorders/scale/discus.pdf (Last accessed 09/24/2015)
Modified Simpson—Angus Scale (MSAS)	Drug-induced Parkinson and dystonia assessments	10-item, 5-point anchored severity scale. Mean score is obtained by adding all scores and dividing by 10. A mean score of 0.3 is the upper limit for no EPS	5-10 minutes to complete. Item domains include gait, arm dropping, shoulder shaking, elbow rigidity, wrist rigidity, leg pendulousness, head dropping, eye blinking, tremor, and salivation. https://cpnp.org/_docs/ed/movement-disorders/scale/msas.pdf (Last accessed 09/24/2015)
Barnes Akathisia Rating Scale (BARS)	Drug-induced akathisia	4-item, including three 4-point anchored severity scored items and a 5-point global rating score item. Total score of 12 possible	10 minutes to complete. Items 1-3: objective observation of restlessness, subjective awareness of restlessness, and subjective distress related to restlessness. Diagnostic criteria: require both objective and subjective ratings of at least one in either two subjective items. https://cpnp.org/_docs/ed/movement-disorders/scale/bars.pdf (Last accessed 09/24/2015)

EPS, extrapyramidal symptoms.

Data from references 49, 51 and 52.

TABLE e62-4 Psychosis Rating Scales

Rating Scale	Type	Scoring	Comments
Brief Psychiatric Rating Scale–Anchored (BPRS-A)	Clinician rated	18-item, 7-point severity scale: mildly ill A ≈ 32, moderately ill ≈ 44, markedly ill ≈ 55, and severely ill ≈ 70 when correlated to the CGI (Clinical Global Impressions Scale; see Table e62-1)	The anchored BPRS provides descriptions of each severity rating to increase the interrater reliability. The BPRS has four clusters of symptoms: thinking disturbance, anxious depression, withdrawal-retardation, and hostility-suspiciousness.
Positive and Negative Syndrome Scale (PANSS)	Clinician rated	30-item, 7-point severity scale: mildly ill ≈ 57, moderately ill ≈ 75, markedly ill ≈ 95, and severely ill 116 when correlated to the CGI	Based on the 18-item BPRS for assessing the presence or absence of positive and negative symptoms, and psychopathology of schizophrenia.

Data from references 48, 50 and 52.

TABLE e62-5 Depression and Bipolar Disorder Rating Scales

Rating Scale	Type	Scoring	Comments
Hamilton Depression Rating Scale (HAM-D or HDRS)	Clinician rated	17-item, 0-7 no depression; 8-16 = mild depression; 17-23 = moderate depression; >23 = severe depression	Used to screen patients for drug studies and to determine severity of symptoms and treatment outcome. HDRS is the standard to compare other depression rating scales against.
Montgomery–Asberg Depression Rating Scale (MADRS)	Clinician rated	10-item, 7-point scale. For each item: 0 = no symptoms; 6 = severe symptoms	Differentiates among all the intermediate grades of depression. Decreases bias in patients with other medical illnesses and increased somatization (varied unexplained physical symptoms).
Beck Depression Inventory (BDI)	Patient rated	21-item, 0-9 = normal; 10-15 = mild depression; 16-19 = mild-moderate; 20-29 = moderate-severe; 30-63 = severe depression	The standard for depression self-rating scales and an objective measure of change in symptoms as a result of treatment.
Zung Self-Rating Depression Scale (ZSDS)	Patient rated	20-item, 4-point severity scale: <50 = normal; 50-59 = minimal-mild; 60-69 = moderate-marked; ≥70 severe depression	Severity rated by frequency of occurrence of symptoms. May not be as sensitive in measuring changes in severity of symptoms.
Patient Health Questionnaire (PHQ-9)	Patient rated	9-item, 4-point scale. For each *DSM-IV* depression criteria item: 0 = not at all; 3 = nearly every day. Score <10 = minimal depression symptoms	Commonly used in primary care to establish a diagnosis of depression and assess severity of depressive symptoms.
Quick Inventory of Depressive Symptomatology (QIDS-C [Clinician] and QIDS-SR [Patient])	Clinician and patient rated	16-item, scores range from 0-27; 0-5 = none; 6-10 = mild; 11-15 = moderate; 16-20 = severe; 21-27 = very severe	Used to assess symptom severity and symptomatic change. QIDS-SR found to be as sensitive to symptom change as the HDRS. Has usefulness in both clinical and research settings.
Young Mania Rating Scale (YMRS)	Clinician rated	11-item, 5-point severity scale: 13 = minimal; 20 = mild; 26 = moderate; 38 = severe	Used to screen patients for drug studies and to determine severity of symptoms and treatment outcome. YMRS is the

Rating Scale	Type	Scoring	Comments
			standard to compare other mania rating scales against.
Mood Disorder Questionnaire (MDQ)	Patient rated	15-item, score of ≥7 suggestive of bipolar spectrum disorder	Screens for a lifetime history of mania or hypomania. Does not assess severity of illness.

Data from references 52, 54 and 55.

TABLE e62-6 Anxiety and Obsessive Compulsive Disorder Rating Scales

Rating Scale	Type	Scoring	Comments
Hamilton Anxiety Scale (HAM-A or HAM-AS or HAMRS)	Clinician rated	14-item, 5-point scale. scores of ≥ 18-20 for moderate anxiety	Consists of subscales to measure somatic and psychic anxiety
Self-Rating Anxiety Scale (Zung SAS)	Patient rated	20-item, 4-point intensity scale	Correlates to the clinician-rated Anxiety Status Inventory (ASI); however, there is little information on the validity of either test
Sheehan Panic and Anticipatory Anxiety Scale (SPAAS)	Patient and clinician rated	Three-part scale	Measures panic attacks, anticipatory anxiety, and limited symptom attacks
Yale–Brown Obsessive-Compulsive Scale (YBOCS)	Clinician rated	Semi-structured interview	Consists of several clusters of obsessions and compulsions; used to assess baseline severity and change in treatment studies

Data from references 52, 56 and 57.

In summary, patient-and clinician-rated scales are widely used in psychiatric research and recommended in clinical settings to monitor schizophrenia, depression, bipolar disorder, and anxiety disorders.[9,11,48,49,50,54,55,56,57]

Neuropsychiatric Rating Scales

Neuropsychiatric rating scales provide specific information, such as the rate of change and severity of cognitive decline or improvement. They are useful when repeated measurements of a patient's mental status are needed because they allow the clinician to determine response to an intervention (eg, medication) in a more systematic manner. In addition, some cognitive function measures are useful screens for neurocognitive disorders (eg, Alzheimer disease). A number of cognitive rating scales are available, the most common being the MMSE.

The MMSE is a structured interview that globally assesses many cognitive domains, including orientation, visuospatial organization, memory, and reasoning, to determine an overall score of cognitive function. The maximum score is 30, and a score of 23 or less is indicative of significant

cognitive impairment. The MMSE takes 5 to 10 minutes to administer and is used routinely in the clinical setting.[58] Other examples of cognitive rating scales include the Blessed Information Memory Concentration test (BIMC), the Dementia Rating Scale (DRS-2), the Clock Drawing test (CDT), and Alzheimer's Disease Assessment Scale (ADAS).[59,60,61,62]

Most of the rating scales involve a structured interview that requires clinician training to ensure accurate administration. Noise and distraction can affect the patient's performance ability; therefore, the interview should be conducted in a quiet area with adequate lighting. The interviewer should speak slowly and clearly to the patient when providing instructions and asking questions.

PSYCHOLOGICAL TESTING

Although most clinicians do not administer psychological testing, they can use the results to evaluate the role of medication in relationship to the diagnosis. Psychological testing alone cannot establish a firm diagnosis but can be a useful diagnostic tool when coupled with clinical judgment. Types of psychological testing include personality tests (eg, Minnesota Multiphasic Personality Inventory-2), intelligence tests (eg, Wechsler Adult Intelligence Scale—Revised, Wechsler Intelligence Scale for Children—Revised), projective tests (eg, Rorschach), and neuropsychological tests (eg, Bender Visual Motor Gestalt Test).[3] Neuropsychological and intellectual assessments generally require special training or a patient referral to a specialist, such as a licensed psychologist or neuropsychologist, and should not be confused with psychiatric rating scales, which can be administered by most clinicians. As with physical examinations, laboratory results, and rating scale scores, psychological test results are best used as only one part of a comprehensive diagnostic plan.

ACKNOWLEDGMENTS

The authors are grateful to Timothy Dellenbaugh MD, Associate Professor of Psychiatry and Residency Director, School of Medicine—University of Missouri–Kansas City for his significant contributions to this chapter in the previous edition.

Chapter 63: Attention Deficit/Hyperactivity Disorder

FIGURE 63-1

Julie A. Dopheide; Steven R. Pliszka

INTRODUCTION

KEY CONCEPTS

- 1 Untreated or ineffectively treated childhood attention deficit/hyperactivity disorder (ADHD) can lead to poor school performance, poor socialization, and increased risk for traffic accidents, psychiatric comorbidities, unemployment, and incarceration during adolescence and adulthood.
- 2 ADHD is 40% to 90% genetic in origin, and it is associated with decreased brain volume, a delay in cortical thickening, and dysregulation of the "default mode network," a brain system that regulates attention, prioritization of information, memory, and impulse control.
- 3 Symptoms of inattention or hyperactivity and impulsivity or all three must be present during childhood and cause functional impairment in two different settings for 6 months to meet diagnostic criteria for ADHD.
- 4 Prior to initiating pharmacotherapy, overall physical and mental health and psychiatric comorbidities must be assessed, and goals of treatment must be set.
- 5 Preschoolers, school-age children, adolescents, and adults with ADHD all can benefit from nonpharmacologic interventions that include a healthy diet, education on ADHD, and potentially effective cognitive and behavioral treatments.
- 6 The psychostimulants, methylphenidate, dexmethylphenidate, lisdexamfetamine or amphetamine salts, are the most effective pharmacologic treatment options for all ages with a rapid therapeutic effect, typically within 1 or 2 hours of an effective dose.

- 7 α_2-Adrenergic agonists such as extended-release preparations of guanfacine and clonidine are less effective than stimulants as monotherapy and are used as stimulants in youth to improve symptom control, particularly oppositional behaviors and insomnia.

- 8 When ADHD coexists with other neuropsychiatric conditions, such as anxiety disorders, major depression, autism spectrum disorder (ASD) or Tourette's disorder, it is optimal to treat the most functionally impairing disorder first (whether it is ADHD or the co-occurring condition) and then treat the second disorder.

- 9 When ADHD coexists with bipolar disorder, it is necessary to first stabilize the mood with lithium, an anticonvulsant, or an atypical antipsychotic before adding an ADHD-specific medication such as a psychostimulant.

- 10 Atomoxetine is a good option to manage ADHD symptoms in adolescents and adults with substance use disorders. It has a delayed onset of effect (2-4 weeks), but it has no abuse potential.

Once considered primarily a childhood disorder, attention deficit/hyperactivity disorder (ADHD) is now known to persist into adolescence for 75% and into adulthood for approximately 50% of individuals.[1,2,3] The American Academy of Pediatrics (AAP) considers ADHD a chronic condition that requires ongoing management.[1,2] Functionally impairing inattention, impulsivity, and hyperactivity in the ADHD brain have been correlated with neuroanatomical and functional brain changes.[4,5] It is unusual for an individual to display signs of the disorder in all settings or even in the same setting at all times; however, there is a persistent pattern of symptoms that persists for 6 months or more.[4,6] Co-occurring anxiety, mood disorders, learning disabilities, medical conditions, and substance abuse must be considered in assessment and treatment. Behavioral interventions and medications are effective for all ages, but there are special considerations for treatment plan development and monitoring in each age group.[1,23,4,7]

The psychiatric assessment of a child requires obtaining information from the child, parents, caregivers, and teachers.[1,4,8] Treating children with psychotropic drugs requires a very different approach than treating adults. Children undergo neurologic, physiologic, and psychosocial changes throughout development. Age-related pharmacodynamic and pharmacokinetic differences can alter drug disposition and response. Psychotropic drug treatment of children is intended to control symptoms or behaviors that impair learning and development.[1,2,4,5] Children may not be able to articulate symptom response or adverse effects of a medication. 1 Adolescents and adults with ADHD may not have been diagnosed and treated during childhood, putting them at greater risk for the psychosocial consequences of ADHD including unemployment, unstable relationships, substance abuse, and incarceration.[1,2,3,4,9,10,11]

EPIDEMIOLOGY

ADHD is the most well-known and researched neurodevelopmental disorder of childhood. It is

present in approximately 5% to 6% of children and approximately 2% to 3% of adults.[6,12] A 30-year epidemiological study showed that the actual prevalence of ADHD has not increased during the past 10 years, despite U.S. Centers for Disease Control (CDC) reports of increasing diagnosis.[12,13] When consistent diagnostic criteria from the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) are applied, the prevalence of ADHD for children and adolescents is similar among countries globally, at approximately 5.5%.12,13 ADHD is more prevalent in males than females with a ratio of 2:1 in children and 1.6:1 in adults.[6] In 2012, 5 million children in the United States or 10% of those aged 3 to 17 years were diagnosed with ADHD; almost twice the actual rate according to worldwide prevalence studies. Non-Hispanic Caucasian and black children were more likely diagnosed with ADHD compared with children of Hispanic or Asian descent.[13]

Increasing rates of ADHD diagnosis in the United States is likely a factor associated with the observed increased prescribing of ADHD medications. A Food and Drug Administration (FDA) study analyzed pediatric prescribing records from 59,000 retail pharmacies to compare prescribing rates in 2010 with those in 2002 in children aged 0 to 17 years for several therapeutic areas including antibiotics, proton-pump inhibitors, antidepressants, and ADHD medications. Overall pediatric prescribing decreased 7% over the 8 years studied, but prescriptions for ADHD medications increased by 46%. Methylphenidate was the most commonly prescribed drug in the ADHD category, but usage remained constant from 2002 to 2010, whereas usage of amphetamine products dropped by 15%.[14] Usage of dexmethylphenidate, lisdexamfetamine, and guanfacine increased from 2002 to 2010, while usage of atomoxetine in youth decreased.[14] The 2011 National survey of children's health queried parents and found that 11% of youth aged 4 to 17 years had ever been given the diagnosis of ADHD, and two-thirds were currently taking ADHD medication.[15]

A large U.S. pharmacy benefits management company, Express Script's, analysis of pharmacy claims representing 400,000 privately insured individuals younger than 65 years showed that ADHD medication use increased by 35.5% for all age groups between 2008 and 2012. The number of adults using ADHD medications was up 53.4% from 2008 to 2012. Children still received a higher percentage of ADHD prescriptions compared to adults; 80% of these were stimulants. Geography significantly impacted ADHD medication prescribing. In 2012, the number of U.S. citizens on ADHD medications was highest in the South at 3.6% and lowest in the West at 2.2%. South Carolina had the highest utilization with 5% of residents taking ADHD medications.[16] Health care professionals and teachers should recommend thorough assessment of ADHD by an experienced clinician using standardized criteria and investigating all possible causes of inattention, impulsivity, and hyperactivity in order to avoid overdiagnosis and potentially inappropriate treatment.

ETIOLOGY AND PATHOPHYSIOLOGY

2 Both genetic and environmental factors are implicated in the pathogenesis of ADHD. Children with fetal alcohol syndrome, lead poisoning, and meningitis have a higher incidence of ADHD compared to nonaffected children.[4,17] Obstetric adversity, maternal smoking, and adverse parent–child relationships are factors known to increase the risk of ADHD.[4,17]

Genetic studies show ADHD runs in families, with heritability estimated to be between 40% and 90%.[18,19] ADHD is considered a polygenic disorder meaning risk is not transferred on just a few key genes but rather hundreds or even thousands of genetic variants are thought to be involved modulating risk for symptom expression. Patients may have copies or deletions in the genome that cover multiple genes called copy number variants (CNV). These CNV studies have implicated a number of systems in ADHD: cholinergic receptors, and genes for central nervous system (CNS) development,[19] on an area of chromosome 15q13,[20,21] as well as glutamate metabotropic receptors.[18,22] Thus, the pathophysiology of ADHD may go well beyond the catecholamine systems that have been the focus of most studies to date. There is a continuum of genetic risk for ADHD, as some individuals inherit just a few symptoms and are considered clinically "subthreshold" while others present with more severe symptomatology meeting full DSM-5 criteria for ADHD.[19]

Some of the same genes that code for ADHD are involved in the heritability of autism spectrum disorder (ASD) and Tourette's disorder supported by the clinical observation that 30% to 80% of youth with ASD meet criteria for ADHD and 50% to 60% of patients with Tourette's disorder have impairing ADHD symptoms.[23,24]

Structural and functional brain changes are part of the pathophysiology of ADHD. Smaller brain volumes and a delay in cortical thickening have been documented in children with ADHD and in those who still meet criteria for the symptoms of ADHD in adulthood.[25,26] This delay in cortical thickening is thought to contribute to the difficulty with prioritizing attention and tasks; while a lack of connectivity between the prefrontal cortex and precuneus (located in the midline of the parietal lobe) is associated with the failure of suppression of the default mode network, causing lapses in attention and poor impulse control.[18,25]

2 Alterations in the "default mode" attention network have been found in adults with ADHD.[18] The default mode network consists of the medial prefrontal cortex, medial parietal lobe or precuneus, as well as the posterior cingulate. These areas are active during the "resting state" when attention is not engaged; this system is actively suppressed during active attention. A lack of connectivity between the prefrontal cortex and precuneus is associated with failure of suppression of the default mode network, causing lapses in attention and inhibitory control.[18] Therapeutic doses of stimulants that are recommended for the treatment of ADHD have been shown to normalize these structural and functional brain deficits, while improving symptoms of inattention and impulsivity.[5,25] By explaining the biological basis of ADHD as a brain disorder with genetic causes and some modifiable risk factors, clinicians can help families to better understand ADHD and minimize its negative impact on outcomes.

Clinical Presentation ADHD General

- Onset of symptoms must be before 12 years of age.

Symptoms

- Six or more of the symptoms must be present for 6 months; significant impairment must be

seen in two or more settings (eg, home and school); symptoms must be documented by parent, teacher, and clinician. Only five symptoms are required in older adolescents and adults (age 17 and older).

- *Inattention:*
    - Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (eg, overlooks or misses details, or work is inaccurate)
    - Often has difficulty sustaining attention in play activities or tasks (eg, has difficulty remaining focused during lectures, conversations, or lengthy reading)
    - Often has difficulty organizing tasks and activities (eg, poor time management, disorganized work, fails to meet deadlines)
    - Avoids tasks that require sustained mental effort (eg, schoolwork, reviewing lengthy papers or preparing reports)
    - Often does not seem to listen when spoken to directly (eg, mind seems to wander)
    - Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace
    - Is easily distracted by extraneous stimuli (may include unrelated thoughts)
    - Is often forgetful in daily activities (eg, doing chores, returning calls, paying bills)
    - Loses things necessary for activities (eg, school materials, keys, wallet)
- *Hyperactivity and impulsivity:*
    - Often fidgets with hands or feet or squirms in seat
    - Often leaves seat when remaining seated is expected
    - Often runs about or climbs excessively at inappropriate times (in adolescents or adults may be limited to feeling restless)
    - Often has difficulty playing quietly
    - Often blurts out answers before a question is completed (also finishes the sentences of others; cannot wait for turn in conversation)
    - Often interrupts or intrudes on others; may take over what others are doing

Data from American Psychiatric Association. Disorders usually first evident in infancy, childhood or adolescence. In: Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition. Arlington, VA, American Psychiatric Association, 2013:59-66.*

CLINICAL PRESENTATION

The AAP guideline for the diagnosis, evaluation, and treatment of ADHD in children and adolescents recommends an evaluation for any child between ages 4 and 18 years who presents with academic or behavioral problems and symptoms of inattention, hyperactivity, or impulsivity.[AAP11] 3 At least six symptoms of inattention or hyperactivity and impulsivity causing impairment in more than one major setting (eg, home, school) for 6 months and an onset of symptoms before age 12 are currently required by the DSM-5 for a diagnosis of ADHD in children 4 to 12 years only. Only five symptoms are required for older adolescents and adults (age 17 and over).[6] Validated rating scales, such as the Connors Rating Scales—revised (CRS-revised), and the Vanderbilt ADHD diagnostic scale are recommended for objective symptom ratings from parents and teachers in different age groups.[1,2,4,5,27] To make a diagnosis of ADHD, the clinician should rule out alternative causes of symptoms (learning disability, situational stressor) and assess for other conditions that may coexist with ADHD including oppositional defiant and conduct disorders, tics, ASD, sleep and mood disorders.[4,6,28]

Preschoolers (3 to 5 Years)

The DSM-5 diagnostic criteria for ADHD can be applied to preschool-age children, although it may be difficult to document symptoms in multiple settings with different caregivers if the child does not attend preschool.[1,6,9] Enrollment in a qualified preschool and a parent training program is often recommended. Both can help parents develop reasonable expectations for their child's development and foster the development of management skills for problem behaviors. Although methylphenidate has been found safe and effective for ADHD in 4- and 5-year-olds, behavioral interventions are recommended first. Medications can be considered when the child has moderate to severe symptoms unresponsive to behavioral interventions. The clinician needs to weigh the risks of starting medication at an early age against the harm of delaying diagnosis and treatment.[1,2,29]

School Age (6 to 11 Years)

Most cases of ADHD are first realized during ages 6 to 9 years, with the child having difficulty academically and/or socially in school and at home. Most children have combined inattentive and hyperactive or impulsive symptoms that cause functional impairment. This period is crucial to the child's success in school, socialization, and the development of his or her sense of self; therefore, accurate diagnosis and treatment is critical. Comorbid oppositional defiant disorder (ODD), conduct disorder, and aggression are indicators that the child is at greater risk for delinquency and substance abuse in adolescence.[9,30] This is the most well-studied age group, with strong data showing benefits of recognition and treatment with behavioral interventions and medications.[2,4]

Adolescents (12 to 18 Years)

Hyperactivity decreases in adolescents, and inattention and impulsivity are the more prominent functionally impairing symptoms. There may be fewer numbers of symptoms of ADHD in

adolescence, but the symptoms present cause significant functional impairment.[6,7,94] Higher rates of delinquency, drug and alcohol use, and psychiatric comorbidity have been documented in adolescents with ADHD compared with those without ADHD.[1,2,9,11] Assessment for substance abuse and risk of diversion must be considered before starting stimulant medications. Speeding and increased motor vehicle accidents occur at higher rates in teens with ADHD compared with those without the disorder.[1,2,3,7,9]

Adults

The presence of multiple comorbid conditions, particularly conduct or mood disorder, can increase the likelihood of ADHD chronicity into adulthood. DSM-5 criteria for ADHD in childhood also apply to adults. Inattentive symptoms are the most common and functionally impairing in adults, but hyperactive/restless and impulsive symptoms are experienced by many and are associated with higher rates of bipolar disorder and psychosis.[3] Cognitive deficits (eg, executive functioning, working memory, task prioritization, lower IQ) have been documented in adults with ADHD in addition to a greater risk for unstable relationships, unemployment, psychiatric hospitalization, and incarceration compared with those without ADHD.[3,10,11] The Adult ADHD Self-Report Scale (ASRS.v1.1) can be a useful screening tool as a first step to a more thorough diagnosis with an experienced clinician. Gathering collateral information from family and friends is recommended to either support or refute the diagnosis.[31,32]

TREATMENT

ADHD-specific cognitive and behavioral interventions are increasingly recognized as necessary components of an overall treatment plan aimed at symptom relief and optimal functioning. Several studies show combining medications with behavioral interventions produces the greatest symptom relief and the best outcomes.[2,33,34,35,36]

Desired Outcomes

4 Specific goals of treatment or desired outcomes must be identified (eg, able to sit in chair for 20 minutes; completes homework assignments, or no longer blurts out comments in class without being called upon). For adults, the desired outcome may be to read an entire newspaper before starting another project, improving safety while driving, or successfully completing tasks on time at work.[36,36,37]

Nonpharmacologic Therapy

Educational, Cognitive, and Behavioral Interventions

5 Education on ADHD as a biologic disorder with brain-derived causes is essential for destigmatizing ADHD and improving treatment acceptance. Parent training and behavioral interventions such as positive rewards for good behavior and structured limit setting are

recommended as first-line interventions before medication trials in preschoolers (3- to 5-year-olds) with ADHD. Behavioral interventions for ADHD are described in **Table 63-1**. It is crucial to get parents, teachers, and clinicians involved to coordinate care and provide consistent behavioral management for the child at home and at school. School-age children (6-11 years) also benefit from these behavioral interventions in addition to strategies, such as breaking up homework assignments into shorter, manageable segments. Although it varies by state, children and adolescents with ADHD may qualify for an individualized educational program (IEP) that allows for more time to take an exam, preferred seating, and modified work assignments.[1,2,31] It is noteworthy that most studies comparing behavioral intervention with stimulant therapy in youth found a much stronger effect on ADHD core symptoms from stimulants.[1,2,5,31] Combined behavioral and stimulant therapy resulted in greater improvements on academic and conduct measures in some studies with greater parent and teacher satisfaction ratings. Lower doses of stimulant were effective when behavioral interventions were administered according to several studies.[2,35]

TABLE 63-1 Behavioral Interventions for ADHD

Age	Description of Intervention	Typical Outcomes
Preschool and school age	Parent and family education on ADHD	Improved parental understanding and satisfaction
	Training on behavioral modification	Improved compliance with parental commands
	Classroom management instruction for teachers	Improved teacher satisfaction
Adolescent	Break up homework assignments into manageable segments. Structured schedule; organizer	Completion of assignments improves; improved self-esteem and sense of self
Adolescent and adult	ADHD-specific cognitive behavioral therapy	Improved productivity and vocational success
	Metacognitive therapy	Improved relationships

ADHD, attention deficit/hyperactivity disorder.

Data from references 2, 24, 27, 29 and 33.

5 Recommended behavioral interventions for adolescents and adults include keeping an external organizer (eg, smart phone, notebook with "to-do" lists) and breaking up activities into short, manageable tasks. Recognizing triggers for distraction and making a point of thinking before acting are useful interventions and are recommended during cognitive behavioral therapy (CBT) sessions designed to manage adult ADHD.[34,38] Controlled studies have shown that ADHD-specific CBT was more effective than psychoeducation and relaxation in adults with ADHD whose symptoms were only partially responsive to medication.[34] Similarly, adults with ADHD who partially responded to medications benefited more from a group-administered metacognition program (2 h/wk over 12 weeks) compared with supportive therapy sessions administered for the same amount of time.[38]

Yoga, meditation, and some dietary supplements have been recommended for ADHD as well, but they should not take the place of more established effective treatments, such as medications and cognitive interventions.[39]

Dietary Interventions

Extensive research has evaluated dietary interventions for ADHD, primarily in children with some adolescent data. When iron and zinc are supplemented in youth with known deficiencies, the therapeutic benefit of stimulant therapy can be enhanced, frequently allowing lower effective doses.[40,41] Omega-3 supplements can benefit some individuals with few side effects, but results are not consistently better than placebo. Although scientific evidence is lacking, there is a universal belief among families that the avoidance of sugar and artificial sweeteners improves ADHD symptoms. The attention paid to sugar avoidance and healthy diet is the more likely reason for improved behavior. An overall healthy diet with the proper balance of protein, fresh produce, and fiber is recommended.[41]

Clinical Controversy…

Studies are mixed regarding the long-term outcome of ADHD-specific pharmacotherapy. Do the long-term benefits in academic performance, health, occupational, psychosocial, and quality of life outcomes outweigh the risks? The longest U.S. naturalistic study over 8 years, the multimodal treatment study of children with ADHD (MTA) study, found that there was no long-term benefit in those who continued pharmacotherapy compared to those who did not [42,43] yet a German study showed 34% decrease in accidental severe brain injury in those treated with stimulant or atomoxetine for an average of 3.5 years compared to youth with ADHD who were untreated.[44] A 9-year Danish study showed lower rates of hospital contacts in youth who began treatment for ADHD before age 10 and slightly lower criminality.[45]

Pharmacologic Therapy

Figure 63-1 is an algorithm for drug selection in the treatment of ADHD.

FIGURE 63-1

Algorithm for drug selection in the management of attention deficit/hyperactivity disorder (ADHD). Treat predominant disorder first, reassess, and consider alternative or adjunct medications for optimal symptom control. (DEX, dextroamphetamine; DMPH, dexmethylphenidate; MPH, methylphenidate; MXA, mixed amphetamine salts; AMPH, amphetamine; TCA, tricyclic antidepressant.) (*Data from References 2, 4, 5, 47, and 79.*)

Stimulants

Stimulants are considered first-line therapy in most cases of ADHD; however, comorbid conditions impact the drug selection process. Pharmacotherapy should be considered whenever a thorough diagnostic assessment results in a diagnosis of ADHD. Several studies demonstrate the superiority of stimulants over behavioral interventions in alleviating core symptoms of ADHD.[4,37]

Treatment for ADHD may decrease the rate of some serious injuries in youth. Investigators evaluated a large German healthcare database (reflecting 20% of the population) and found no difference in overall injury rates in children between ages 3 and 17 years with ADHD treated with stimulant or atomoxetine compared with those not treated; however, there was a 34% decrease in severe brain injury in the treated group.[44]

Improvement in academic performance has been associated with stimulant treatment of ADHD. A National Institutes of Health (NIH) study of 594 fifth graders with ADHD showed those medicated (greater than 90% took stimulants) had 2.9 points higher math scores and 5.4 points higher reading scores compared with unmedicated children.[46] Another study involving 363 children between ages 10 and 18 years with ADHD showed medication improved but did not normalize cognition.[47]

6 Stimulants (eg, methylphenidate, dexmethylphenidate, mixed amphetamine salts, and dextroamphetamine) are the most effective drug treatment options, with an effect size of 0.9 compared with nonstimulant drug treatment options whose effect sizes range from 0.5 to 0.7 signifying lower efficacy.[2,4,48] Methylphenidate and amphetamines block dopamine and norepinephrine reuptake; amphetamines also increase catecholamine release.[49] Both drugs inhibit monoamine oxidase (MAO), amphetamines more potently than methylphenidate.[49] Because different stimulants work through slightly different mechanisms, the lack of response to one chemical class of stimulant (eg, methylphenidate or dexmethylphenidate) does not preclude response to another class

(eg, dextroamphetamine including lisdexamfetamine or mixed amphetamine salts).[5,37]

Stimulant dosing should be titrated for maximum individual efficacy and minimum side effects (**Table 63-2**).[2,4,5,50]

TABLE 63-2 Dosing of Stimulant Drugs Used in the Treatment of ADHD

Stimulant	Duration of Effect	Initial Dose and Available Strengths	Usual Dosing Range; Maximum Dose
Methylphenidate C-II[a]			
Short-acting IR			
Ritalin, methylin, generics[b]	3-5 hours	5 mg two or three times daily; increase by 5-10 or 20 mg/day at weekly intervals	5-20 mg two or three times a day; maximum dose: 60 mg/day
Intermediate-acting			
Ritalin SR[b]	3-8 hours	SR, ER doses; corresponds to the IR dose	20-40 mg every am or 40 mg every am and 20 mg in the early afternoon; maximum dose: 60 mg/day
Methylphenidate SR[b]			
Metadate ER[b]			
Methylin ER[b]			
Long-acting			
Ritalin LA 50% IR, 50% ER beads[b]	8-10 hours	20 mg every am; available as 10, 20, and 30 mg	20-40 mg every am and 20 mg in the early afternoon; maximum dose: 60 mg/day
Metadate CD 30% IR, 70% ER beads[b]	10-12 hours		20-60 mg/day, given every am; maximum dose: 60 mg/day
Concerta (OROS controlled-release delivery)[b]	10-12 hours	20 mg every am; available as 20, 30, and 40 mg	27-72 mg/day, given every am; maximum dose: 72 mg/day
ER inner compartments coated with IR methylphenidate	12 hours when worn for 9 hours		10-30 mg (12.5-37.5 cm^2). Drug active for 3 hours after patch removal
Daytrana methylphenidate transdermal system[b]	10-12 hours	18 mg every am; available as 18, 27, 36, and 54 mg; 90% bioavailability of IR	Max: 60 mg daily
Aptensio XR 40% IR, 60% ER	10-12 hours		Max: 60 mg daily
Extended release			Stable for 4 months after reconstituted

Stimulant	Duration of Effect	Initial Dose and Available Strengths	Usual Dosing Range; Maximum Dose
		10 mg (12.5 cm^2) applied to clean, dry area on hip each morning and removed after 9 hours	
methylphenidate[b]			
Quillavant extended release suspension 20% IR/80% ER[b]		10 mg; available as 10, 20, 30, 40, 50, and 60 mg capsules	
Must be reconstituted by pharmacist to 25 mg/5 mL concentration		10-20 mg in am suspension	
		Only studied in 6- to 12-year-olds	
Dexmethylphenidate (Focalin) C-II[b]	3-5 hours	2.5 mg every am or twice daily; available as 2.5, 5, and 10 mg tablets	5-10 mg/day given twice a day; maximum initial dose: 7.5 mg/day; maximum dose: 20 mg/day
Focalin XR 50% IR, 50% ER beads[b]	10-12 hours	5 mg every am; available as 5, 10, 15, 25, 30, 35, and 40 mg capsules	5-40 mg/day, given every am maximum dose: 30 mg/day for children and adolescents; maximum 40 mg/day for adults
Mixed amphetamine salts C-II (dextroamphetamine and levoamphetamine 3:1 ratio)			
Short-acting IR (Adderall, mixed amphetamine generics)[c]	4-6 hours	2.5 – 5mg every am to twice daily; Available in 5, 10, 7.5, 12.5, 15, 20, 30mg tablet	5-40mg; Max: 40mg/day
Amphetamine C-II (dextroamphetamine and levoamphetamine ratio 1:1)[c]	6-10 hours	2.5 -5mg every am to twice daily; Available in 5 and 10mg tablets	5-20mg; Max: 40mg/day
Evekeo,			

Stimulant	Duration of Effect	Initial Dose and Available Strengths	Usual Dosing Range; Maximum Dose
Long-acting XR (Adzenys XR-ODT) dextroamphetamine and levoamphetamine ratio 3:1[d]	10-12 hours	3.1, 6.3, 9.4, 12.5, 15.7, 18.8, extended release oral disintegrating tablets 3.1mg Adzenys ODT ~ 5mg of Adderall XR	3.1 – 18.8mg/day; Max: 18.8mg/day
Dyanavel XR 2.5mg/ml		2.5mg/1ml oral suspension	
Dextroamphetamine and levoamphetamine ratio 3.2:1[d]	10-12 hours	2.5mg of suspension ~ 4mg of mixed amphetamine salts	5 – 20mg/day; Max: 20mg/day
Mixed amphetamine salts C-II	10-12 hours	5 – 10mg every am; available as 5, 10, 20, 30mg extended release capsule	5 - 30mg; Max: 30mg/day
Extended release capsule (Adderall XR) dextroamphetamine and levoamphetamine ratio 3:1[d]			
Dextroamphetamine C-II		2.5 mg every am once- or twice-daily dosing	10-40 mg/day (divided in two doses)
Short-acting	4-6 hours		10-40 mg/day given twice daily
Dextroamphetamine generics[c]	3-5 hours	2.5 mg every am to two or three times daily dosing	5-30 mg every day or 5-15 mg twice daily; maximum: 40 mg/day
Dexedrine, Zenzedi[c]			
Intermediate-acting	5-8 hours	Available as 5, 10, and 15 mg	
Dexedrine Spansule[d]			
Long-acting		5 mg every am; available as 5 and 10 mg	Start at low end; titrate weekly to response; give in am
Lisdexamfetamine (Vyvanse)[d] (prodrug converted to dextroamphetamine)	10-12 hours	Available as 20, 30, 40, 50, 60, and 70 mg capsules	Slower onset compared with other dextroamphetamine products

ER, extended release; IR, immediate release; OROS, osmotically released oral delivery system; SR, sustained release; XR, extended release.

[a]The Drug Enforcement Administration label C-II, schedule II refers to significant abuse potential.

[b]Methylphenidate and dexmethylphenidate products are FDA approved in ≥6 years old.

[c]Immediate release amphetamine and dextroamphetamine products are FDA approved in ≥3 years old.

[d]Extended release amphetamine and dextroamphetamine products are FDA approved in ≥6 years old.

Data from references 2, 4, 5, 27, 52 and stimulant product package inserts or Daily Med.

Clinical Controversy…

Stimulants are regularly prescribed for ADHD beyond the FDA's recommended daily maximum dose. This practice has not been studied, and therefore the clinical impact of such a practice is unknown. Short-term studies evaluating therapeutic benefits of doses at the high end of the FDA-approved therapeutic range show greater efficacy in managing aggression for example.[66] Conversely, a 9-year study shows 1.8x greater risk of adverse cardiac events in patients taking stimulants at the high end of the dosing range.[65]

With immediate-release stimulants, most patients require a two or three times daily dosing schedule because of the short half-lives and duration of action of these drugs (2-4 hours for methylphenidate and dexmethylphenidate and ~4 to 6 hours for dextroamphetamine or mixed amphetamine salts).[2,4,5] Drug response is maximal during the absorption phase, is evident in 15 to 30 minutes, and lasts 2 to 6 hours.[4,5]

Drug delivery systems of once-daily products (amphetamine aspartate, amphetamine sulfate, dextroamphetamine sulfate, and dextroamphetamine saccharate [Adderall XR]; methylphenidate [Concerta]; methylphenidate [Daytrana]; dexmethylphenidate [Focalin XR]; methylphenidate [Metadate CD]; and methylphenidate long-acting [Ritalin LA]) provide 8 to 12 hours of symptom control.[2,4,5,48,51] Concerta uses an oral osmotic (OROS) controlled-release delivery system, whereas other oral preparations use combinations of immediate-release and extended-release beads.[2,4,5] Concerta is a nondeformable tablet, and it should not be given to children with gastrointestinal (GI) narrowing because of the risk of obstruction. Methylphenidate transdermal system provides 12 hours of symptom control when worn for 9 hours.[2,48,51] Methylphenidate extended release suspension was only studied in 6- to 12-year-olds, and it can be an advantage for children with trouble swallowing pills.[52] Older wax-matrix sustained-release (SR) products (eg, Ritalin SR) are less effective and infrequently used.[4,5] Once-daily stimulant formulations are the preferred treatment for ADHD in most individuals due to convenience and better medication adherence.[4,5,53] Immediate-release formulations have the advantage of lower cost, less insomnia, and potentially fewer growth effects versus extended-release products.[4,30] Adolescents and adults with ADHD are also responsive to stimulants.[2,4,37] Methylphenidate is effective in adolescents and adults in doses up to 1.5 mg/kg daily.[3,5,37] Lisdexamfetamine is a prodrug conjugated to an amino acid that requires cleavage during metabolism to the active dextroamphetamine. It has a longer time to onset of effect but may provide a smoother blood level compared with extended-release formulations. It is intended to pose less

abuse potential.[48]

Administration of stimulant medications with food can delay the absorption and subsequently delay the onset of therapeutic effect by 30 minutes to 1 hour for immediate-release preparations, and 1 to 2 hours for extended-release preparations.[50] Total bioavailability of stimulant can be decreased by 10% to 30% with coadministration of food, more so for beaded formulations of extended-release stimulant compared with OROS methylphenidate or lisdexamfetamine.[50]

Adverse Effects

The most common adverse effects of stimulants and their management strategies are listed in **Table 63-3**.[54] At least 15 cases of priapism, (painful prolonged erection) associated with stimulant use have been reported to the FDA in boys with a mean age of 12.5 years. A few cases of priapism have been reported with atomoxetine, and all cases require immediate medical attention.[55a] FDA has received at least 51 reports of skin discoloration, also known as chemical leukoderma that may not be reversible.[55b]

Psychiatric, cardiac, and growth effects of stimulants have been extensively studied and are compared to other treatment options in the sections below.

TABLE 63-3 Stimulant Adverse Effects and Their Management

Adverse Effect	Recommendation/Management Strategy
Common	
Reduced appetite, weight loss	Give high-calorie meal when stimulant effects are low (at breakfast or at bedtime), or consider cyproheptadine at bedtime
Stomachache	Administer stimulant on a full stomach; lower dose if possible
Insomnia	Give dose earlier in the day; lower the last dose of the day or give it earlier; consider a sedating medication at bedtime (guanfacine, clonidine, melatonin, or cyproheptadine)
Headache	Divide dose, give with food, or give an analgesic (eg, acetaminophen or ibuprofen)
Rebound symptoms	Consider longer-acting stimulant trial, atomoxetine, or antidepressant
Irritability/jitteriness	Assess for comorbid condition (eg, bipolar disorder); reduce dosage; consider mood stabilizer or atypical antipsychotic
Uncommon to Rare	
Dysphoria	Reduce dosage; reassess diagnosis; consider alternative therapy
Skin discoloration (chemical leukoderma)	Counsel regarding risk before using methylphenidate patch
Zombie-like state	Reduce dosage or change stimulant medication
Tics or abnormal movements	Reduce dosage; consider alternative medication

Adverse Effect	Recommendation/Management Strategy
Priapism (painful erection)	Obtain medical assistance immediately; consider alternative treatment
Hypertension, pulse fluctuations	Reduce dosage; change medication
Hallucinations	Discontinue stimulant; reassess diagnosis; mood stabilizer and/or antipsychotic may be needed

Data from references 3, 4, 27, 30, 55, 84.

Psychiatric

Although considered rare, the FDA has added warnings to the labeling of all ADHD medications (ie, stimulants, atomoxetine, α_2-adrenergic agonists) regarding three broad categories of psychiatric adverse effects: psychosis, mood disturbance (ie, irritability, lability, or depression), and severe anxiety or panic attacks. Treatment-emergent psychosis is estimated to occur in approximately 1.5% of youth treated with stimulant medications based on placebo-controlled trials.[30,56] Hallucinations involving visual or tactile sensations of insects, snakes, or worms were typical in children, with adolescents and adults experiencing hallucinations and delusions.[57] Sadness from stimulants may in part be genetically mediated, as an association was found between two (CES1) (SNP) markers and the occurrence of sadness in 77 youth taking immediate-release methylphenidate for ADHD.[58] There is also evidence to suggest that preschool-aged youth are more susceptible to sadness, irritability, and mood lability with stimulant treatment compared with adolescents and adults.[30,54]

Case reports of atomoxetine-associated mania and psychosis exist, but the risk is less well-characterized versus stimulants. Both stimulant and atomoxetine have the potential to cause or exacerbate mania, anxiety, panic attacks, or depression. Stimulants and atomoxetine should not be given to manage attention in individuals with primary psychotic illnesses such as schizophrenia or schizoaffective disorder due to the high risk of worsening psychosis.[30,57]

Clonidine and guanfacine are much less likely than stimulants or atomoxetine to cause psychosis, mania, or anxiety, but treatment-emergent irritability, depression, and nightmares have been reported.[59,60,61] When psychiatric adverse effects occur, dose reduction or cessation of therapy and supportive treatment is recommended.[30]

Cardiac

Stimulants, atomoxetine, and α_2-adrenergic agonists have well-described cardiac and cardiovascular side effects that are not significant for most youth but can be intolerable in some, particularly in those with existing cardiac/cardiovascular disease. Clinical trial data show that children who take stimulants for ADHD can have an increased heart rate by 3 to 10 beats/min and/or increased systolic blood pressure by 3 to 8 mm Hg, and increased diastolic blood pressure by 2 to 14 mm Hg.[30] Atomoxetine treatment has been associated with increased heart rate at an average of approximately

4 beats/min and increased systolic or diastolic blood pressure of 2 to 4 mm Hg.[62] Clonidine and guanfacine may cause dose-related bradycardia and lowered blood pressure in youth that may prevent upward titration in addition to modest widening of the QTc interval (5-7 msec) that warrants monitoring, particularly if the child takes another agent known to prolong QTc such as an antidepressant or antipsychotic.[30,60]

Reports of sudden unexplained death associated with stimulant treatment for ADHD prompted the U.S. Agency for Healthcare Research and Quality to conduct two studies of large healthcare databases in order to compare rates of sudden cardiac death, heart attack, and stroke in those taking stimulants with those not taking stimulants. The first study of 1.2 million 2- to 24-year-olds (mean age at baseline 11.1 years) taking stimulants for an average of 2.1 years showed that 3.1 per 100,000 experienced a serious cardiac event. This was no greater than rates in the general population.[63] The second study included 150,000 users of stimulants aged 25 to 64 years each matched to two nonusers of stimulants (443,000). This study in adults found no greater risk of sudden death, heart attack, or stroke in stimulant users versus nonstimulant users.[64] The relatively short duration of use and overall good health of those studied may have biased the results. These studies add to earlier findings showing no increased risk of serious cardiac events with stimulant use, and, therefore, no restriction in stimulant use has been recommended.[63,64]

Stimulant products should be used with caution in pediatrics and in adults with known structural cardiac abnormalities. The American Heart Association recommends careful screening of all children and adolescents prior to initiating pharmacologic therapy for ADHD, including a medical and family history and physical examination.[30] The physician should consider a baseline electrocardiogram (ECG) if history suggests cardiovascular disease.[30]

A 9.5-year prospective cohort study of children with ADHD found that although rare, adverse cardiovascular events were twice as likely to occur in stimulant users as in nonusers.[65] There were 111 cardiovascular events in the 8,300 children with ADHD. Hypertension, heart disease not otherwise specified, and cardiovascular disease not otherwise specified comprised 62% of adverse cardiac events, arrhythmias comprised 23%, while cardiac arrest accounted for less than 1% of events.[30] The same investigators looked at national rates of stimulant use (n = 714,258) and found 1.8 times greater risk of a cardiovascular events in those taking stimulant with greater risk of adverse cardiac events on higher doses of stimulant compared with lower doses.[65]

Growth

Two reviews that analyzed approximately 32 studies indicated that stimulant treatment of ADHD can affect growth, but the effects are minimal or insignificant for most children. A study of 579 children showed a decrease of approximately 1 cm/y (~0.5 in) in height over 1 to 3 years of continuous treatment with methylphenidate and a weight deficit of 3 kg (6.6 lb) in the first year of treatment and 1.2 kg (2.6 lb) in the second year of treatment.[4,5] Amphetamine products may be associated with more growth effects than methylphenidate according to separate studies.[4,5] Proposed mechanisms of stimulant effects on growth include alterations in growth hormone or growth factor, decreased thyroxine secretion, and suppression of appetite leading to reduced caloric intake.[4,30] Two

case–control studies, with approximately 140 boys and 110 girls, assessed growth effects after taking stimulant medication over a 10-year period and found no significant effect on growth in boys or girls taking stimulants compared with matched controls not taking stimulant. The average duration of stimulant use was 7.5 years.[30]

In most cases, children should be given a drug-free trial every year.[4,30] Time off stimulant appears to lessen stimulant growth suppressant effects, but evidence is lacking to firmly determine the impact of drug holidays on growth.[4,37] Consideration must be given to the risks of negative effects on learning, socialization, and self-image while off stimulant therapy when determining the frequency and duration of the drug-free trial.[4,30] Drug dosage often varies from year to year, largely because of age-related pharmacokinetic changes. As a child develops, hepatic metabolism slows, and volume of distribution increases.[50]

Nonstimulants

Extended-release guanfacine and extended-release clonidine are less effective alternatives to the stimulants for treatment of ADHD in children and adolescents. Clonidine and guanfacine are approved by the FDA as monotherapy and as adjuncts to stimulants for improving overall response and for managing behavioral symptoms and insomnia associated with ADHD. Unlike guanfacine and clonidine, atomoxetine is also approved in adults. Atomoxetine is generally considered less effective than stimulants, but there is evidence to show that some patients preferentially respond to atomoxetine over stimulants.[37] Potential advantages of atomoxetine and α_2-adrenergic agonists relative to stimulants include no abuse potential, less potential for growth effects, and less sleep disturbance.[4,30] See **Table 63-4** for dosing.

TABLE 63-4 Dosing and Adverse Effect Monitoring of Nonstimulant Drugs for ADHD

Drug	Dosing Range and Titration Schedule	Adverse Effect Monitoring
Atomoxetine (Strattera)	≤70 kg (≤154 lb): start at 0.3-0.5 mg/kg every am or twice daily, maximum: 1.4 mg/kg/day; ≥70 kg (≥154 lb): start at 40 mg every am or divided twice daily, maximum: 100 mg/day	Nausea, anorexia, ↑ blood pressure, ↑ pulse, insomnia, fatigue, sedation, severe liver injury (rare), suicidality
Bupropion (Wellbutrin SR, XL)	50-300 mg/day; 3 mg/kg/day by end of week 1; can increase to 6 mg/kg/day or maximum of 300 mg/day as tolerated	Nausea, insomnia, rash, tics; dose-related risk of seizures
Antipsychotics (for comorbid aggression, mood disorders, tics, or irritability associated with ASD)		
Aripiprazole[a] (Abilify)	2-5 mg daily; can titrate weekly as tolerated to response (usual range: 5-20 mg/day)	Nausea, restlessness, insomnia extrapyramidal symptoms, dizziness, sedation
Haloperidol[a] (Haldol)	0.5-1 mg twice daily; can titrate every 3-4 days as tolerated to response (usual range: 0.5-5 mg/day)	Extrapyramidal symptoms, dizziness, ↑ serum prolactin, sedation

Drug	Dosing Range and Titration Schedule	Adverse Effect Monitoring
Olanzapine[a] (Zyprexa)	2.5-5 mg every day; can titrate every 3-4 days as tolerated to response (usual range: 7.5-15 mg/day)	Sedation, severe weight gain, restlessness, extrapyramidal symptoms Diabetes, marked hyperlipidemia (never a first-line treatment)
Quetiapine[a] (Seroquel)	25-50 mg twice daily; can titrate every 3-4 days as tolerated to response (usual range: 200-600 mg/day)	Sedation, dizziness, weight gain, diabetes, hyperlipidemia
Risperidone[a] (Risperdal)	0.25-0.5 mg twice daily; can titrate every 3-4 days as tolerated to response (1-4 mg/day)	Extrapyramidal symptoms, dizziness, ↑ serum prolactin, decreased skeletal bone mass, hepatotoxicity, weight gain Diabetes, hyperlipidemia
Ziprasidone[a] (Geodon)	10-20 mg twice daily; can titrate every 3-4 days as tolerated to response (usual range: 40-160 mg/day)	Nausea, restlessness, insomnia extrapyramidal symptoms, sedation, QTc prolongation
Other		
Clonidine (Catapres) or clonidine extended release XR (Kapvay)	0.05 mg two or four times daily; can increase as tolerated to 0.1-0.4 mg/day. For XR, give 0.1 mg at bedtime; may increase by 0.1 mg weekly; maximum: 0.4 mg/day given twice a day if dose >0.2 mg/day	Sedation, dizziness, heart block (check ECG), constipation, headache, upper abdominal pain
Guanfacine (Tenex) or guanfacine extended release XR (Intuniv)	0.5 once or twice daily; can increase as tolerated to 1-4 mg/day. Max: 4 mg/day in children/adolescents For XR, give 1 mg in the am; titrate weekly to response Max: 4 mg/day in children; 7 mg/day in adolescents	Same as above with potentially lower risk of sedation. Effective dose higher in heavier children

ADHD, attention deficit/hyperactivity disorder; ASD, autism spectrum disorder; ECG, electrocardiogram; SR, sustained release; XL, extended length.

[a]Short-term use (1–4 months) only for severe aggression associated with ADHD; may be longer if comorbidity such as bipolar disorder, Tourette's disorder, or autism spectrum disorder.

Data from references 4,30,60,61,75,76,78.

Atomoxetine

Atomoxetine is a selective norepinephrine reuptake inhibitor that should be taken in divided doses in the morning or late afternoon by children for improved tolerability.[67] Adults can take it once daily, usually in the morning.[3,67] Placebo-controlled, short-term trials (6-12 weeks) have shown that atomoxetine is effective in reducing ADHD symptoms in children, teens, and adults, and long-term studies show ongoing benefit and safety for children and adolescent responders out to 4 years.[68] A controlled trial comparing atomoxetine, OROS methylphenidate, and placebo over 6 weeks in 6 to 16-year-old patients showed that both drugs were significantly better than placebo at improving ADHD symptoms, but OROS methylphenidate was superior to atomoxetine.[4,37] There was evidence for a preferential response to atomoxetine in some individuals.[37]

Atomoxetine has a significantly slower onset of therapeutic effect than stimulants (2-4 weeks vs 1-2 hours with an effective stimulant dose), and full benefit may not be seen for 6 to 12 weeks.[4,37] Atomoxetine is sometimes combined with a stimulant in partially responsive patients based on limited data from open trials and case series describing fewer late-day rebound effects and better sleep when atomoxetine is given in the evening; however, adverse effects are additive.[4,37,67] A new norepinephrine reuptake inhibitor, edivoxetine has shown some benefit for managing ADHD in children; more studies are needed.[69]

Atomoxetine Adverse Effects

Possible adverse effects of atomoxetine and their management are similar to those of stimulants, including upset stomach and psychiatric and cardiac adverse effects (see Table 63-4). Atomoxetine has less growth suppression risk compared with stimulants, but it has a greater risk of fatigue, sedation, and dizziness compared with stimulants or bupropion. Studies show that adults experience overall similar adverse effects as youth but they are less likely to report decreased appetite and are more likely to report urinary hesitation/retention and sexual side effects (decreased libido and erectile disturbances) compared to youth.[37,67] Unlike stimulants, atomoxetine labeling includes a bolded warning of potential for severe liver injury following reports in two patients. Continuation studies have not shown evidence for liver toxicity with long-term use; however, a case of idiosyncratic liver toxicity requiring liver transplantation in a 10-year-old boy was reported.[68,70]

Atomoxetine is the only FDA-approved ADHD medication with a labeled warning for new-onset suicidality, 0.4% in atomoxetine-treated patients versus 0% in patients receiving placebo.[30] Despite this statistic, atomoxetine treatment is not thought to increase the risk of suicidality beyond the increased risk associated with having ADHD.[30]

α_2-Adrenergic Agonists

Guanfacine and clonidine are central α_2-adrenergic agonists, acting both presynaptically to inhibit norepinephrine release and postsynaptically to increase blood flow in the prefrontal cortex. Increased blood flow in the prefrontal cortex has been shown to enhance working memory and executive functioning. Both interact with a multitude of neurotransmitter systems, including catecholamine,

indolamine, and α_2-receptors on parasympathetic neurons, opioids, imidazole, and amino acid systems.[49]

Guanfacine has a longer elimination half-life and duration of action (18 hours) compared with clonidine (12 hours), and its greater selectivity for the α_{2a}-receptor, compared with clonidine, imparts less sedation and dizziness.[60] Clonidine and guanfacine are not as effective as stimulants for monotherapy treatment (effect size 0.22-0.58 vs 0.8-1.2 for stimulants).[60] In addition to being approved as monotherapy, extended-release clonidine and guanfacine are FDA approved as adjuncts to stimulants. Both are prescribed frequently as adjuncts to reduce disruptive behavior, control aggression, or improve sleep in youth.[4,60] Neither have been studied sufficiently for ADHD in adults.

Guanfacine XR can be given once daily during monotherapy while clonidine XR should be given twice daily for optimal symptom coverage. Both are considered acceptable second-line agents for children and adolescents unresponsive to or unable to tolerate stomach upset or insomnia with stimulant medications. Extended-release guanfacine and clonidine are more sedating than stimulants or atomoxetine; therefore, sleepiness during the school day requires careful monitoring.[60]

α_2-Adrenergic Agonist Adverse Effects

The most common side effects of clonidine and guanfacine are dose-dependent sedation, hypotension, and constipation.[2,4,60] Sedation usually subsides after 2 to 3 weeks of therapy.[4,60] Clinical trials show a mean decrease of 3 to 5 mm Hg in blood pressure with mean heart rate decrease of 3 to 5 beats/min. Heart block and sudden death have been reported rarely with α_2-adrenergic agonists. Further analysis revealed that these events occurred in the context of polypharmacy and/or congenital heart malformation. Prescreening for existing cardiac problems and increased monitoring when combining medications is warranted.[30,60]

Bupropion

Bupropion, a monocyclic antidepressant, is a weak dopamine and norepinephrine reuptake inhibitor with no significant direct effect on serotonin or MAO. Its active metabolites augment noradrenergic and dopaminergic function. Investigations with bupropion in children demonstrated efficacy greater than placebo in two controlled trials and efficacy comparable with methylphenidate (n = 15 children) in another controlled trial.[4,5] Bupropion has been found beneficial for adolescents with depression and ADHD. For adults with ADHD, the number needed to treat (NNT) is between 4 and 5 compared with "2" with stimulant therapy.[51] Bupropion causes less appetite suppression and weight loss compared with stimulants but has a greater risk of seizures.[4,51]

Bupropion Adverse Effects

Bupropion's adverse effects include nausea, which can resolve over time or with slower dosage titration, and rash, which can require discontinuation of therapy if severe (see Table 63-4). Bupropion should not be used in children with a seizure or eating disorder because of unacceptable risk of seizures in these patients. It can cause or exacerbate tics.[4,37,71]

Lithium and Anticonvulsants

Lithium and anticonvulsants are used increasingly to control aggression and explosive behavior in patients with a diagnosis of ADHD who are not responsive or are only partially responsive to treatment with a stimulant. Some patients actually can have childhood-onset bipolar disorder or combined ADHD–bipolar disorder.[4,72,73] Valproate is the most well-studied anticonvulsant for aggression associated with ADHD. Dosing starts in low divided doses with titration over 1 to 2 weeks to therapeutic response.[72,74]

Antipsychotics

Conventional antipsychotics such as chlorpromazine and haloperidol can improve symptoms of hyperactivity and impulsivity, but their negative effects on learning, cognitive functioning, and the significant risk of extrapyramidal side effects (eg, dystonia and tardive dyskinesia) limit their usefulness.[75]

Second-generation antipsychotics such as risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole have been used to control severe aggression in refractory cases of ADHD, particularly if conduct disorder (CD) or bipolar disorder coexists.[72,73] They pose a lower risk of extrapyramidal side effects compared with conventional agents, but they can cause metabolic side effects such as hyperlipidemia, hyperglycemia, and weight gain in addition to hyperprolactinemia.[75,76,77] Ziprasidone has the lowest risk of metabolic side effects among these second-generation antipsychotics. Risperidone is the most well studied for aggression associated with ADHD,[77] but because it has the most potent dopamine antagonism, it poses the highest risk of hyperprolactinemia and associated early puberty, gynecomastia, galactorrhea, amenorrhea, and decreased bone density.[75,78] Aripiprazole is least likely to elevate prolactin due to its dopamine agonist effects.[75]

Comorbidity

8 Individuals with ADHD often present with comorbid conditions (Fig. 63-1). If multiple drugs are started simultaneously, it is impossible to determine the impact of each drug. The predominance and urgency of symptoms guide the drug selection process. For example, if a child presents as severely anxious or depressed with associated attentional problems, then an antidepressant should be initiated first with monitoring to determine if attentional symptoms improve.[2,4,71] When a child presents with severe ADHD and associated anxiety or depression, a stimulant should be initiated to treat the more severe ADHD. If ADHD symptoms improve significantly, but anxiety or depression persists, then an antidepressant can be added.[2,4,37,71] Studies show that stimulants do not routinely make anxiety disorders worse, but they might not improve symptoms either.[5,37] 9 Bipolar disorder may be difficult to distinguish from ADHD because inattention, hyperactivity, and impulsivity are common with both conditions. When ADHD is diagnosed in an individual with bipolar disorder, the mood must be stabilized first with lithium, an anticonvulsant, or an atypical antipsychotic before considering an ADHD-specific treatment.[72,73]

ADHD and ASD

ASD is estimated to occur in 20% to 50% of youth with ADHD and 30% to 80% of youth with ASD exhibit symptoms of inattention.[79] Impairments can range from mild to severe with poor language development, poor social skills, sensory over-responsivity, emotional dysregulation, inattention, impulsivity, irritability, oppositional behavior, and aggression.[79] There are few studies to guide treatment of ADHD in individuals with ASD. Only one double-blind, 4-week crossover trial showed methylphenidate improved ADHD symptoms in 34 of 66 children with ASD (51%); however, 18% of these children discontinued during the 8-week open-continuation phase because of irritability. Sleep changes, poor appetite, diarrhea, anxiety, depression, and headache were also reported.[79]

Available evidence shows that stimulants are less effective and less well-tolerated for managing ADHD in youth with more severe forms of ASD.[79] If a stimulant trial is initiated, the child with ASD should be monitored carefully for worsening stereotypies, obsessional symptoms, sleep difficulties, poor appetite, irritability, or the emergence of seizures. Atomoxetine was only slightly better than placebo in managing ADHD symptoms in children with ASD according to a controlled trial in 97 children, ages between 6 and 17 years, during 8 weeks.[79] Clonidine and guanfacine have small, uncontrolled studies only showing benefit for improving attention and decreasing aggressive/impulsive behavior in children with ASD.[79]

ADHD and Epilepsy

Patients with ADHD are two to three times more likely to experience seizures than age-matched peers, and ADHD is the most common comorbidity in youth with epilepsy.[30] Fortunately, while there are a few reports of worsening seizure frequency, most studies show methylphenidate is safe and effective for managing ADHD in youth with epilepsy. The child should be stabilized and seizure-free on an anticonvulsant prior to initiation of the stimulant as stimulants are known to lower the seizure threshold. The impact of atomoxetine, clonidine, and guanfacine on seizure frequency requires further study.[30]

ADHD and Substance Abuse

Genetics, age (14- to 25-year-olds), psychosocial factors, and comorbidities all influence one's risk for drug and alcohol abuse.[9,80] ADHD itself is a known risk factor for the development of a substance use disorder. A review of 27 longitudinal studies that followed children with and without ADHD into adolescence or adulthood found that compared with control subjects without ADHD, children with ADHD were (1) nearly three times more likely to report nicotine dependence in adolescence/adulthood, (2) almost two times more likely to meet diagnostic criteria for alcohol abuse or dependence, (3) approximately 1.5 times more likely to meet criteria for marijuana use disorder, (4) twice as likely to develop cocaine abuse or dependence, and (5) more than 2.5 times more likely to develop a substance use disorder overall.

Parents frequently express concern that treating their child with a stimulant, particularly early

treatment, may increase the risk of substance abuse. Follow-up studies show that stimulant therapy for ADHD neither increases nor decreases the risk of subsequent drug or alcohol abuse.[9,80] There is evidence that individuals initiating treatment early (before age 8), are less likely to use substances than those who have delayed onset of treatment. Behavioral therapy may also confer some protection against substance use and delinquency.[9,80] Atomoxetine, an α_2-agonist, or bupropion are preferred agents for individuals with ADHD and active substance use disorders.

Comorbid conditions including depression, anxiety, low self-esteem, conduct disorder, and antisocial personality disorder all increase the risk for developing a substance use disorder in an individual with ADHD.[9,80] These comorbidities also increase the risk for delinquency and incarceration that can prevent treatment and lead to ongoing substance abuse. As youth with ADHD transition to adolescence, parents and clinicians should pay attention to whether the teen could be at risk for substance abuse or inappropriate use of their prescribed medication.[5,81,82]

Several studies have evaluated protective factors against substance abuse and delinquency for youth both with and without ADHD. These studies found that a quality parent-youth relationship, involving good communication, regular time together, consistent rules, and sharing of information (eg, how the child or adolescent spends free time and who his or her friends are) can be effective in deterring alcohol and substance abuse in youth with or without ADHD.[9,80,83] Youth support groups at high schools, such as the Gay/Straight Alliance (GSA), are credited with assisting schools with achieving lower rates of illicit drug use and the misuse of prescription ADHD medications compared with schools without GSAs.[83]

ADHD and ODD/CD

Causes of ODD, CD, and associated severe aggression in youth are multifactorial with psychosocial adversity factors contributing along with comorbidities that could include a learning disability, ADHD, disruptive mood dysregulation disorder (DMDD), or bipolar disorder.[73,76,77,80] Experts consider psychosocial interventions that include parent training and support for the child's family an essential part of the treatment plan for youth with ADHD, co-occurring with ODD or CD.[27]

Effectively managing ADHD with stimulant or atomoxetine has the most evidence for improving associated ODD symptoms in youth, although clonidine or guanfacine may also be effective.[7,27,60] Once treated, ODD may be less likely to develop into the more severe CD. A study in aggressive 6- to 13-year-olds with ADHD found that systematic weekly methylphenidate titration to an average dose of 52 mg/day along with behavioral therapy resulted in optimal symptom control without the need for antiaggressive medications such as risperidone or quetiapine.[66] This prevents exposure to the risk of atypical antipsychotic side effects such as weight gain, diabetes, hyperprolactinemia, and extrapyramidal side effects. Studies in adolescents taking OROS methylphenidate found most of them needed between 54 and 72 mg/day for optimal therapeutic benefit.[66]

Studies in adolescents and adults with ADHD show that doses of stimulant above the recommended daily maximum are frequently needed for optimal symptom control prompting the American

Academy of Child and Adolescent Psychiatry to publish an "off-label maximum dosage of 100 mg/day for methylphenidate and 60 mg/day for dextroamphetamine and mixed amphetamine salts." These dosage ranges appear in the academy's practice parameter on the treatment of ADHD.[3,27]

Unfortunately optimizing ADHD-specific medication such as stimulant or atomoxetine is not universally effective for aggression and over half of youth with ADHD and ODD/CD need more than one medication for optimal symptom control.[77] The treatment of severe childhood aggression (TOSCA) study showed that adding risperidone 1 to 3 mg daily to parent training, behavioral therapy, and optimized stimulant in 168 youth (mean age 9) with ADHD and either ODD or CD resulted in moderate improvement in aggression. Adverse effects documented over the 9-week study included nausea, elevation in prolactin, and weight gain.[77]

ADHD and Tourette's Disorder

ADHD occurs in 50% to 60% of youth with chronic tics or Tourette's disorder, and 20% of children with ADHD go on to develop chronic tics or Tourette's disorder.[24,84] Until recently, experts cautioned that stimulants should not be first-line treatments for ADHD in youth with tic disorders due to the stimulant's ability to increase central dopaminergic and noradrenergic activity, potentially exacerbating tics. There is less need for concern according to investigators who conducted a meta-analysis of 22 placebo-controlled trials involving 2,385 children with ADHD and Tourette's disorder. The analysis showed that stimulants were not more likely to worsen tics than placebo, and the association between stimulants and new-onset tics was more coincidental than a cause and effect relationship.[84] The timing of tic development in the context of ADHD may have led clinicians to inappropriately attribute new onset tics to stimulant treatment. Epidemiologic studies show that when ADHD and Tourette's co-occur, symptoms of ADHD present 2 to 3 years before tics emerge. Tourette's disorder is known for fluctuating symptom severity with tics worsening and remitting in an unpredictable pattern, further diminishing the ability to accurately attribute tic causality.[24,84]

A double-blind, placebo-controlled trial compared methylphenidate or clonidine monotherapy with combination methylphenidate and clonidine in patients with ADHD and Tourette's disorder. Combination therapy demonstrated the greatest benefit in reducing symptoms of ADHD and tics (*P* less than 0.0001).[4] Clonidine appeared most helpful for impulsivity and hyperactivity, whereas methylphenidate was most helpful for inattention. All treatments were well tolerated, but sedation was common (28%) in those receiving clonidine.[4]

Clonidine or guanfacine alone is a less effective alternative to stimulants in the treatment of children with Tourette's disorder and ADHD. Guanfacine was administered to 34 children (mean age 10.4 years), with ADHD and tic disorder during an 8-week, placebo-controlled trial at a dose of 1.5 to 3 mg/day. Tic severity decreased by 31% in the guanfacine group compared with 0% in the placebo group.[4] There was a mean improvement of 37% on the teacher-rated ADHD scale compared with 8% improvement with placebo.

Atomoxetine, when studied for 16 to 18 weeks, appears to be an effective treatment for ADHD and tics in pediatric patients with comorbid Tourette syndrome or chronic motor tic disorder. For instance,

in 148 children and adolescents, randomized to up to 18 weeks of atomoxetine (0.5-1.5 mg/kg/day) or placebo, improvements were observed both in the severity of ADHD (effect size = 0.6) and tics (effect size = 0.3).[68]

Individuals with Tourette's disorder and ADHD are more prone to disruptive behaviors including poor frustration tolerance, aggression, and impulsivity, often requiring behavioral interventions and medications that may include second-generation antipsychotics.[24] Second-generation antipsychotics such as risperidone, aripiprazole, and ziprasidone have evidence from controlled trials to support their use in managing motor and vocal tics associated with Tourette disorder, however, aripiprazole is the only agent currently FDA-approved for managing Tourette's disorder.[24]

Personalized Pharmacotherapy

Factors that should be taken into account to personalize pharmacotherapy for ADHD include age, co-occurring conditions including substance abuse, effectiveness of treatment, side-effect sensitivities, and patient or family preference. An individual's ability to metabolize a drug and the drug's pharmacokinetic profile and drug-interaction potential should also be considered. To date, genomic studies have not provided information to guide clinical practice.

Pharmacokinetic and Drug Interactions

Methylphenidate is de-esterified prior to elimination and is less likely to have metabolic drug interactions compared with mixed amphetamine salts. Gender has been shown to influence the absorption of methylphenidate, with males having increased bioavailability compared with females.[50] Variability in dosage requirements for amphetamine salts, atomoxetine, and bupropion, can be due to interpatient variability in plasma concentration achieved at a given dose. All are metabolized via cytochrome P450 (CYP) 2D6, and bioavailability and half-life can be four to eight times greater in those taking a CYP2D6 inhibitor (eg, bupropion, fluoxetine, or paroxetine) or in poor metabolizers. For example, atomoxetine's half-life is 5 hours in extensive metabolizers and 19 hours in poor metabolizers.[4] Over time, dosage adjustments may be necessary for any medication in order to compensate for age-related changes in distribution and metabolism.

EVALUATION OF THERAPEUTIC OUTCOMES

Careful documentation of baseline symptoms and complaints over a 1-month predrug period is essential to the evaluation of therapeutic and adverse outcomes. Investigation regarding family history of psychiatric disorders and cardiac disease is essential to determine risk for related adverse drug reactions and to implement appropriate monitoring.[2,30] Baseline symptoms can be measured using videotapes, clinician rating scales (eg, ADHD Rating Scale IV, Vanderbilt ADHD Diagnostic Scale), or both. In addition, height, weight, and eating and sleeping patterns should be recorded at baseline and every 3 months.[4,27,30]

After the initiation and titration of any drug treatment, it is necessary that parents, teachers, and

clinicians assess the overall functioning of the child or adult using standardized rating scales to determine if significant therapeutic benefit justifies continuing medication.[2,4,27] Therapeutic effects of the stimulants include decreased motor activity and impulsivity and increased attention span.[2,4,5,27] This suggests that stimulants are indicated for ADHD symptoms and not for primary learning disorders. The benefits of drug therapy must outweigh the potential for adverse effects to justify continued treatment.[2,4,27]

There is a lack of standardized assessment tools for adults; however, the adult ADHD screening tool can be useful.[32] Short-term studies (1 year or less) in adults with ADHD show that treatment with stimulants improves subjective quality of life. Long-term studies are needed to better assess the risk versus benefit of stimulant therapy on psychosocial and health outcomes.[85]

Atomoxetine, α_2-adrenergic agonists, and bupropion also require monitoring to detect changes in appetite, weight, and sleep patterns, as well as pulse and blood pressure. A therapeutic trial of atomoxetine or bupropion consists of 6 weeks at maximum tolerated doses unless response occurs at a lower dose.[2,4,27] Atomoxetine's full therapeutic benefit may continue to build over weeks to months, but if there is no significant benefit in the initial 6 weeks, it is unlikely that atomoxetine will be effective; therefore it can be tapered off.[68]

When guanfacine or clonidine is given, careful clinical monitoring for fatigue, dizziness, and autonomic changes (eg, blood pressure and pulse) is recommended.[30,60] The American Heart Association has stated that ECG monitoring is not required for α_2-adrenergic agonists treatment in children, although many clinicians continue to assess for ECG changes, particularly if there is a family history of cardiac disease, if the patient is taking other agents that impact cardiac function, or if clinical symptoms warrant.[30,45] When discontinuing treatment, clonidine and guanfacine should be withdrawn slowly (0.05 mg clonidine/0.5 mg guanfacine reductions every 3-7 days) to prevent rebound hypertension or behavioral dyscontrol.[59,60] A therapeutic trial requires 1 to 2 months to assess therapeutic response, although increased sleep usually occurs immediately.[59,60]

Evaluation of therapeutic outcomes is particularly important when antipsychotics are used in youth as the U.S. Office of Inspector general's peer review psychiatrists found quality of care concerns in 67% of 475 medical records of youth receiving antipsychotics through Medicaid.[86] Among the biggest problems were lack of appropriate indications and lack of appropriate monitoring to ensure safety. Baseline weight, lipids, and fasting glucose should be monitored every 6 months in addition to the need to monitor for extrapyramidal symptoms and hyperprolactinemia.[8,75,86]

Chapter 64: Eating Disorders

Steven C. Stoner; Valerie L. Ruehter

INTRODUCTION

KEY CONCEPTS

- 1 Eating disorders, while no longer considered a controversial psychiatric illness, remain difficult to treat, as comparative effectiveness trials are limited, study methods and outcome measures vary, and patients are often resistant to accepting treatment.
- 2 The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) separates binge-eating disorder (BED) as an individual eating disorder diagnosis and replaces the category of Eating Disorders Not Otherwise Specified with Specified and Unspecified Feeding andEating Disorders.
- 3 Despite strong genetic associations for the development of eating disorders as established in monozygotic and dizygotic twin studies, a clear association with a specific genetic linkage or mutation has not been identified.
- 4 Shifting between eating disorder diagnostic categories is possible, especially when symptom remission is not achieved with treatment.
- 5 Psychiatric comorbidities are common with all forms of eating disorders, and the differential diagnosis should generally include evaluation for depression, schizophrenia, generalized anxiety, obsessive–compulsive disorder (OCD), and personality disorders.
- 6 During the process of caloric restoration, calories must be gradually introduced to prevent the potentially fatal complication known as refeeding syndrome. Failure to restore calories quickly enough may result in an unfeeding syndrome.
- 7 Mortality resulting from suicide in individuals with eating disorders is not uncommon, and clinicians must monitor closely for suicidality and educate appropriately as they would during the treatment of patients with major depressive disorder taking antidepressants.

- 8 The current preferred treatment approach for anorexia nervosa (AN) includes a minimum of 6 months of psychotherapy, preferably cognitive behavioral therapy (CBT) in adults and family-based therapy in children.
- 9 Despite limited data, antidepressants are the preferred pharmacologic intervention for the acute and maintenance phases of bullemia nervosa (BN) in combination with nonpharmacologic treatments.
- 10 There is growing sentiment that severe and enduring AN exists and that the focus should be on the impact of the disorder and improving quality of life instead of on treating medical symptoms.

Eating disorders are widely accepted as serious mental illnesses. The spectrum of eating disorders encompasses several complex diseases, with most sharing the pathologic feature of over-evaluation of body shape and weight. Eating disorders arise from the complex interaction between environmental, societal, developmental, psychosocial, genetic, and biologic factors. It is estimated that 5 to 10 million women and 1 million men in the United States alone have an eating disorder. The urbanization of society, social pressure, and obsession with perfection and being thin have led to an increasing prevalence of eating disorders, with a median age of onset between 18 and 21 years, though estimates in adolescent studies suggest median ages of onset between 12 and 13 years.[1,2] Anorexia nervosa (AN), bulimia nervosa (BN), and binge-eating disorder (BED) are the most prevalent forms of eating disorders.[3]

1 Despite an improved understanding of these cognitively and emotionally disabling and potentially fatal disorders, treatment remains difficult. Pharmacologic intervention is a small part of a comprehensive treatment plan that emphasizes psychotherapy, notably cognitive behavioral therapy (CBT) in adults and family therapy in younger patients.

EPIDEMIOLOGY

Anorexia Nervosa

Anorexia nervosa impacts an estimated 0.9% to 2% of women in the United States, occurring predominantly in girls and young women (90%), and usually presenting during adolescent years (median onset 12.3 years of age).[1,2] The estimated 12-month prevalence of the disorder in the general population is 0.4% of females with a smaller percentage in males.[2,3] Longitudinal management of AN is difficult, as patients are often resistant to weight restoration plans, and psychiatric comorbidities exist in over 50% of those with AN.[2] Rates of relapse requiring hospitalization within 1 year exceed 30%, and crude mortality rates are estimated at 5%.[3,4,5]

The promotion of the virtues of being thin is also a potentially negative environmental factor. Many internet and online communities inappropriately promote healthy lifestyle aspects of anorexia and being thin as a means of being in control and successful, while also serving as a means of support.[6]

Bulimia Nervosa

Bulimia Nervosa also occurs predominantly in girls and young women (90%) and usually presents in later adolescence or early adult life.[2] Between 1% and 4.6% of adolescent and young adult females meet the diagnostic criteria for BN, with lifetime prevalence estimates of 1.5% of females and 0.5% of men.[1,2,3,7,8]

Binge-Eating Disorder

Binge-Eating Disorder often presents in adolescence but can also present later in life.[3] BED is more common in females with a lifetime prevalence of 2.8% in adults and 1.6% in adolescents.[1,9] The 12-month prevalence rate is an estimated 1.6% in females and 0.8% in males.[3,10] CBT and interpersonal psychotherapy are the preferred treatments, although antidepressants and lisdexamfetamine have demonstrated benefits.[11]

Other Specified and Unspecified Feeding and Eating Disorders

2 According to the DSM-5, the new categories of Specified and Unspecified Feeding and Eating Disorders apply to cases where symptoms result in distress, but do not meet full diagnostic criteria for any feeding or eating disorders.[3] Examples listed within these categories include atypical AN, BN (lower frequency), BED (lower frequency), purging disorder, and night eating syndrome (NES).[3]

Night eating syndrome is common in obesity clinic populations, often accompanied by depressive symptoms. The syndrome is defined by repetitive night eating that includes eating after having been asleep or excessive food consumption following evening meals.[3,12] NES affects an estimated 1.5% of the general population with a high prevalence of obesity and psychiatric comorbidities.[13] Patients with NES are reported to benefit from antidepressant therapy, most notably sertraline 50 to 200 mg daily or escitalopram 5 to 20 mg daily.[12,14]

Additionally, DSM-5 includes Pica, Avoidant/Restrictive Food Intake Disorder, and Rumination Disorder as stand-alone diagnoses' within Feeding and Eating Disorders.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

The exact etiology of eating disorders remains unknown; however it is most likely a combination of genetic, biologic, developmental, and environmental factors. The biologic basis for eating disorders is difficult to delineate because it is unclear if the biologic changes are caused by or are a result of the aberrant eating behavior.

Structural and functional brain imaging studies utilizing computerized tomography (CT) and magnetic resonance imaging (MRI) have yielded a number of inconclusive findings. AN has been linked with the development of enlarged cortical sulci, ventricles, inter-hemispheric fissure and reductions in grey matter (amygdala, hippocampus, cingulate cortex, and putamen). Findings

examining white matter volume changes have not produced consistent results.[15] Dystrophic abnormalities in the cerebrum have also been noted with weight loss, though normalization occurs with weight gain.[15] Abnormalities of the hypothalamic–pituitary–gonadal, hypothalamic–pituitary–adrenal, and hypothalamic–pituitary–thyroid axes are described as potential causes of AN. Amenorrhea is found in the majority of females with anorexia, providing support for the association with gonadotropin; however amenorrhea as a required symptom was removed with the release of DSM-5.[3,8]

Serotonin, norepinephrine, and dopamine have been studied extensively with well-described roles in controlling eating behaviors. Special emphasis has been placed on the role of serotonin (5-HT), specifically noting reduced cerebrospinal fluid (CSF) basal concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the principle metabolite of 5-HT, as well as increased binding of 5-HT_{1A} receptors and reduced binding of 5-HT_{2A} receptors in different regions within the central nervous system (CNS). Reduced dietary intake of certain foods leads to reduced levels of tryptophan, which is required for the development of 5-HT.[16,17,18] There is evidence suggesting that 5-HT and dopamine function remain abnormal after weight restoration, with 5-HT activity being abnormally high in patients recovered from AN, while 5-HT_{2A} receptors are reduced and dopamine receptors are increased following recovery.[16,17,18]

Complicating the study of these abnormalities is that their dysfunction is thought to be secondary to weight loss. Another molecular genetic target of study is brain-derived neurotrophic factor (BDNF), which is also being studied in other diseases such as depression.[18]

3 There are strong genetic influences in AN and likely associations in both BN and BED. In addition, there is a high degree of premorbid anxiety and obsessive tendencies, which are also symptoms of disorders with suspected genetic associations. Twin studies have shown concordance of ~55% and 35% in monozygotic twins and 5% and 30% in dizygotic twins for AN and BN, respectively.

Genetic-based linkage studies have examined multiple single nucleotide peptides to identify predictors for developing AN, which may subsequently help identify appropriate pharmacologic treatments. Studies to date have identified possible associations with chromosomes #1, #2, #3, #4, and #13; however, there are no consistent findings to date, and studies are limited by low sample size.[16,19,20] Genetic mutation studies have focused on polymorphisms of the 5-HT_{2A} receptor.[21] One acquired hereditary abnormality being studied is the presence of low-function alleles associated with the 5-HT transporter (*5-HTTLPR*) and 5-HT_{2A} receptor gene (*–1438G/A*), with findings suggesting an association with poor treatment response.[22] Recent work has also associated estrogen receptor I gene (ESRI) with the restrictive form of AN.[23]

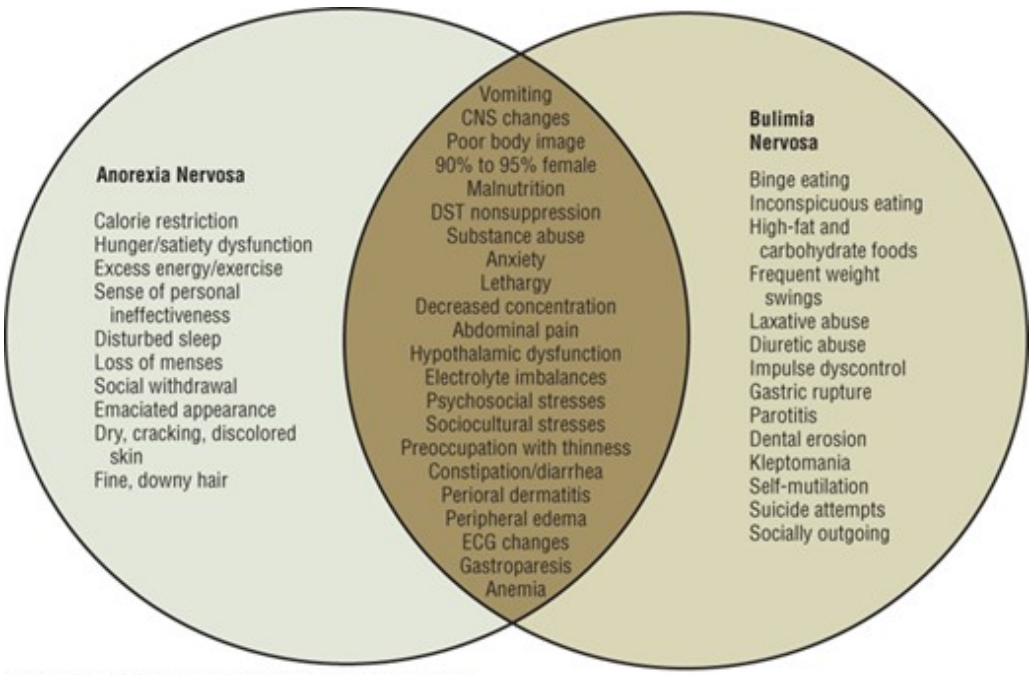
Emphasis is also placed on environmental factors such as social stress and psychological and developmental issues related to dysfunctional family relationships that may trigger abnormal eating behaviors. Athletes are at risk for eating disorders, especially female gymnasts, ballet dancers, figure skaters, distance runners, swimmers, male wrestlers, and body builders.[24]

DIAGNOSTIC CRITERIA AND CLINICAL PRESENTATION

Anorexia nervosa and BN occur together in ~30% to 64% of patients with eating disorders, thus appearing as a continuum of symptoms making careful medical and psychiatric assessment at baseline essential.[25] Patients who initially present with either AN or BN may alternate from one to the other, especially in cases where remission is not achieved. **Figure 64-1** demonstrates similar and unique features of both disorders.

FIGURE 64-1

Signs and symptoms of anorexia nervosa and bulimia nervosa. (DST, dexamethasone suppression test; ECG, electrocardiogram.)



The use of purging methods is not limited to BN. Self-induced vomiting is the most common form of purging behavior.[26] Laxative abuse is another form of purging common in both AN and BN, used by an estimated 3% to 70% of patients.[26,27,28] Although ineffective as a weight-loss strategy, laxative abuse is often used in combination with other behaviors, including exercise, diuretics, enemas, and saunas. Within the diagnostic framework of AN, laxative abuse is most common in those identified with the purging subtype.[26] Psychiatric symptoms of depression, anxiety, and borderline personality disorder are also reported in those who abuse laxatives.[26,27,28]

Depression, schizophrenia, obsessive–compulsive disorder (OCD), and conversion disorders should be included in the differential diagnosis of AN, BN, and BED as eating abnormalities can be a component or share similar symptoms of these illnesses. The salient differences are the overriding drive for thinness, disturbed body image, increased energy directed at losing weight, and binge eating

episodes that are relatively specific for eating disorders. Most patients with eating disorders experience relief of psychiatric symptoms on refeeding.[10]

Anorexia Nervosa

The presentation of AN includes a recent period of weight loss as well as associated behaviors to promote this such as vomiting, limiting food intake, and excessive exercise. Current diagnostic criteria for AN include the restriction of energy intake relative to requirements that leads to low body weight contextually as it relates to age, sex, developmental trajectory, and physical health.[3] The *DSM-5* further classifies AN as restricting type (restricting food intake with no binge eating or purging behavior over the past 3 months) or binge eating/purging type, in which patients regularly participate in bingeing or purging over the prior 3 months.[3] The severity of AN is based upon body mass index (BMI) in adults and BMI percentiles in children and adolescents. Comorbid psychiatric conditions, such as major depression, are frequent but should initially be considered secondary to starvation and not a true mood disorder. Specific risk factors for AN include being female, having a sibling with AN, the presence of mood disorders in family members, and co-morbid anxiety, personality, or substance use disorders.[29]

5 Psychiatric comorbidity is common, as up to 75% of patients have a primary mood disorder, and there is also an association with personality disorders (eg, oppositional defiant disorder) and anxiety disorders, such as social phobia and OCD.[2,30] The lifetime prevalence of OCD in patients with AN is reported to be as high as 40% compared to 2.5% in the general population.[30,31,32] The impact that psychiatric comorbidity has on treatment outcomes of AN is unknown, but it is important to understand that deprivation of food may contribute to both mood and cognitive fluctuations.

Bulimia Nervosa

The core feature of BN is recurrent episodes of binge eating (an excessive intake of calorie-laden food over a short period of time). Most have normal weight, although they might fluctuate between being underweight and overweight. Patients lack control over their eating and participate in recurrent compensatory behavior to prevent weight gain. These behaviors may include self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; strict dieting or fasting; or excessive exercise. To meet *DSM-5* criteria, the binges and compensatory behaviors must occur on average at least once weekly for 3 months.[3] BN can further be differentiated by purging type (regularly engages in self-induced vomiting or the misuse of laxatives, diuretics, or enemas) or non-purging type (uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but does not engage in purging activities).[3]

CLINICAL PRESENTATION Anorexia Nervosa General

- Restriction of energy intake that leads to low body weight and self-evaluation that is influenced by perceptions of weight and body shape.

Symptoms

- Patients have obsessions and fears about eating and gaining weight.
- They complain about feeling full even when they have eaten very little food.
- Denial of symptoms, failure to recognize low body weight, and low self-esteem.
- Patients often feel ineffective and have a lack of self-control.

Signs

- Weakness, lethargy, cachexia, amenorrhea, vomiting, restricted food intake, inappropriate exercise, delayed sexual development, edema, delayed gastric emptying, constipation, abdominal pain, bradycardia, hypotension, osteoporosis, dry cracking skin, lanugo, callus on dorsum of hand, cold intolerance, perioral dermatitis, and erosion of dental enamel.

Laboratory Abnormalities

- Hypokalemia, hypochloremia, hypothyroidism, hypophosphatemia, hypokalemic alkalosis, hypomagnesemia, metabolic acidosis, blood urea nitrogen, hepatic enzymes, leukopenia, thrombocytopenia, anemia, QT interval prolongation, bradycardia, hypercholesterolemia, and bone mineral density.

Other Diagnostic Tests

- Nonspecific electroencephalogram (EEG) changes.

CLINICAL PRESENTATION Bulimia Nervosa General

- Patients binge eat and stop when they have abdominal pain or self-induced vomiting or are interrupted by another person.
- They have a pattern of severe dieting followed by binge eating episodes.
- They are concerned about their body image but do not have the drive to thinness, which is a characteristic of AN.

Symptoms

- Patients do not eat regular meals and do not feel satiety at the end of a meal.
- They may use purging methods such as laxatives for weight control.
- They have guilt, depression, and self-disparagement after binges.
- Social isolation can result from frequent bingeing.
- Chaotic and troubled personal relationships and substance abuse are common.

Signs

- Bingeing, vomiting, salivary gland inflammation, erosion of dental enamel, callus on dorsum of hand, perioral dermatitis, dental caries, parotid gland enlargement, abdominal pain, upper end of normal body weight or slightly overweight, frequent weight fluctuations, and diminished masticatory ability.

Laboratory Abnormalities

- Hypokalemia, hypochloremic metabolic acidosis, and elevated serum amylase.

Other Diagnostic Tests

- None

Patients typically binge and vomit at least once daily. Caloric intake varies, but patients can consume between 5,000 and 20,000 cal (20,920 and 83,680 J) during a single binge. Patients tend to consume foods that are easy to ingest, do not require much chewing or preparation, and are high in carbohydrates or fat. Binge eating is typically secretive and precipitated by a stressful event, followed by post-binge remorse. Binges often last less than 2 hours but can extend to more than 8 hours. To compensate for the excessive caloric intake, many patients fast for prolonged periods, exercise compulsively, purge, or abuse laxatives.

Psychiatric comorbidity includes depression (up to 80%), poor impulse control, and substance abuse. Approximately 30% to 37% of bulimic patients have a personal history of substance abuse.[33] Kleptomania and borderline and avoidant personality disorders are also frequently observed.[30,34] Patients also commonly steal laxatives and comfort items, such as candies and clothes.[8]

Binge-Eating Disorder

Patients with BED present with recurrent episodes of bingeing without the compensatory behaviors associated with AN or BN. It is estimated that 5% to 10% of patients seeking treatment for obesity have BED. Comorbid psychotic disorders are common and reported in greater than 70% of BED patients. Depression and low self-esteem are common, but self-deprecating focus on body image is less severe than in AN or BN.[32,35] Diagnostic criteria for BED requires recurrent episodes of binge eating (eating an amount of food in a specific period of time that is larger than what most people would eat in a similar situation and a sense of lack of control over eating during the episode).[3] The binge-eating episodes are required to be associated with at least three of the following: eating more rapidly than normal; eating until feeling uncomfortably full; eating large amounts of food when not physically hungry; eating alone because of embarrassment of how much is being eaten; and feeling disgusted with oneself, depressed, or guilty after the episode. The severity of BED is determined by the number of binge-eating episodes per week (1-3 = mild; 4-7 = moderate; 8-13 = severe; 14 or more = extreme).[3]

MEDICAL COMPLICATIONS OF EATING DISORDERS

The potential medical complications of eating disorders involve multiple organ systems. The type of medical complication encountered is dependent on the type and frequency of the eating disorder behavior. Cardiac complications may occur and can include arrhythmias such as sinus bradycardia, cardiac muscle atrophy, orthostatic hypotension, decreased cardiac output, arrhythmia, and QTc interval prolongation.[36,37] During caloric restoration, there is a potential risk for developing refeeding syndrome, which can progress to fatal cardiovascular collapse. This risk is reduced by the gradual versus rapid reintroduction of calories.

Metabolic (metabolic acidosis and metabolic alkalosis) and electrolyte disturbances (eg, hypokalemia, hypomagnesemia, and hypocalcemia) and dehydration are often seen. Elevations in bicarbonate levels during periods of hypokalemia can be an indication that the patient is inducing vomiting or using dietary weight-loss medications. Non-anion-gap acidosis has also been reported with the abuse of laxative agents. Additionally, both acute and chronic renal failures have been reported.

Gastrointestinal (GI), oropharyngeal, and dental complications are frequent, as are general complaints of lethargy and fatigue. Evidence of Russell's sign may be present signified by skin lesions on the fingers used to induce vomiting.

Hormonal changes related to the hypothalamic–pituitary–gonadal axis resulting from starvation are seen. These abnormalities include effects on estradiol, the gonadotropins (eg, luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing hormone), thyroid function, adrenal function, and growth hormone.[8,36] Specific to female athletes is the female athlete triad, defined by the development of irregular menses, osteoporosis, and disordered eating.[36,38] An athlete may experience only one or two components of the triad, or all three.[39] Osteopenia and osteoporosis are potential long-term complications of suppressed estrogen. The restoration of weight, specifically in AN, reverses the bone loss, although estrogen supplementation does not appear to be effective.[40] In all cases, the preferred method to address these issues is the normalization of nutrition. The impact on female fertility is not well studied, although the ability to carry a pregnancy to term or to give birth to a child of average birth weight appears reduced.

CLINICAL PRESENTATION Binge-Eating Disorder General

- Repeated episodes of binge-eating that includes a lack of self-control and eating an amount of food that is beyond what most people would eat.
- Episodes of binge-eating may include rapid eating, a sense of fullness to the point of being uncomfortable, eating when not hungry, eating alone secondary to feeling embarrassed, and a sense of self-disgust, depression, or guilt.

Symptoms

- Episodes of binge-eating
- Lack of self-control
- Rapid consumption of food

- Feeling full and eating when not hungry
- Isolation and guilt/depression

Signs

- Obesity
- History of weight loss followed by weight gain
- Binge-eating without compensatory purging
- Psychiatric (eg, depression, anxiety) and medical complications (eg, GERD, hypertension) are not uncommon.

Laboratory Abnormalities

- Elevated lipids, glucose, and hemoglobin A1C, abnormal electrolytes, increased weight.

Other Diagnostic Tests

- None

Chronic starvation can contribute to brain atrophy. Decreases in white matter and CSF volumes return to normal after a healthy weight is achieved, but gray matter loss can persist.[10,41,42]

Obesity is common in patients with binge eating disorder and may also be present in patients with BN, placing these patients at an increased risk of medical co-morbidities including Type II diabetes mellitus and hypertension.[25] Assessment should include measurement of weight, height, pulse rate, blood pressure, and calculation of BMI. Random glucose and ECG should be done as medically indicated.[25]

A thorough physical and laboratory evaluation, as described in **Table 64-1**, is essential to determine the severity of medical complications.[3,10,25,54]

TABLE 64-1 Physical and Laboratory Assessment of Eating Disorders

Evaluation	Target Symptoms
Pulse	Bradycardia, Tachycardia
Blood pressure	Hypotension, orthostasis
Height/weight	Underweight for size and age/body mass index
Respiratory rate	Rapid if heart failure occurs during refeeding
Temperature	Hypothermia, cold intolerance
Electrocardiogram	ST depression, flat T waves, U waves, increased QT interval, atrioventricular block
GI	Hypoactive bowel sounds, gastritis, abdominal distention

Evaluation	Target Symptoms
Skin	Dryness, scaling, lanugo, hair loss, calluses on fingers and hands
Menses	Amenorrhea
Complete blood count	Leukopenia, anemias, thrombocytopenia
Electrolytes	Hypokalemia, hypomagnesemia, hyponatremia, hypophosphatemia, or hyperphosphatemia
pH	Metabolic alkalosis (acidosis if laxative abuse)
Amylase	Elevated; pancreatitis rare
Liver	Hypoalbuminemia, elevated γ-glutamyl transferase if alcohol abuse, elevated AST
Thyroid	Low to low normal, but not true thyroid disease
Cortisol	Elevated with lack of suppression on dexamethasone suppression test
Bone density	Osteoporosis, Osteopenia
Renal	Reduced eGFR (< 60 mL/min [1 mL/s])
Endocrine	Hypoglycemia

Data from references 3, 10, 25, and 54.

TREATMENT

Desired Outcomes

The goals for patients with eating disorders are to reduce distorted body image; restore and maintain healthy body weight; establish normal eating patterns; improve psychological, psychosocial, and physical problems; resolve contributory family problems; enhance compliance; and prevent relapse.[10] Specific to BED is the additional goal of weight loss.

Prognosis

Anorexia Nervosa

The long-term prognosis of patients with AN is not clear, as the majority of studies focus only on patients receiving treatment. The course of the disorder most commonly consists of a single episode with subsequent return to normal weight, although patients can still experience issues with disturbed body image, disordered eating, and other psychiatric problems.[10] Some patients experience an unremitting course leading to death, whereas others suffer episodically. Remission rates appear to be a function of time in treatment, as the lowest rates of remission are reported in shorter-duration follow-up trials, while remission rates near 80% have been reported in longer-term follow-up studies at 8 and 16 years.[43] Despite this, it is estimated that up to 20% remain chronically ill despite weight normalization, return of menses, and improved eating behaviors.[44] The prognosis is more favorable with longer follow-up care and younger age of onset, whereas a poorer prognosis is associated with

chronic illness, lower initial weight, poor family relationships, obsessive–compulsive personality symptoms, and the presence of bulimia or purging behavior.[21,44,45,46] Crude mortality rates appear to be lower than historically projected; the estimated mortality rate is 2.8% to 4%. When death occurs, it is most often the result of cardiac arrest or suicide.[3,43,44]

Bulimia Nervosa

The prognosis of BN, although not well studied, appears to be better than that of AN. Patients with milder presenting symptoms who are treated as outpatients tend to do better, whereas those with electrolyte imbalances, esophagitis, dental caries, and salivary gland enlargement have a more complicated course.[8] The presence of psychiatric comorbidity and greater general psychiatric symptom severity has been determined to be poor prognostic indicators. Longer rates of follow-up tend to have higher rates of remission, reaching 70% or higher with 5 to 20 years of follow-up. However, it is important to note that even in cases in which patients respond, they continue to exhibit symptoms that wax and wane, sometimes meeting full criteria for diagnosis of BN or sub-threshold forms of BN on the basis of insufficient frequency and/or duration of disordered eating behavior. Total absence of symptoms is an uncommon outcome, and residual symptoms predispose the patient to relapse.[43] The actual definition of recovery varies, as once-a-month binge–purge episodes are considered by some to be recovery if their episodes were previously more frequent, whereas other clinicians consider a patient recovered only when there is complete absence of these behaviors.[46]

Binge Eating Disorder

Of all of the eating disorders, BED has the least amount of long-term follow-up data associated with it. Studies to date suggest higher remission rates (25%-80%) in 1- and 4-year follow-up studies compared with findings in AN and BN longitudinal studies. These numbers are irrespective of treatment selected and treatment during the follow-up time frame studied. Estimated crude mortality rates range from 0% to 3% with a cumulative mortality rate reported at 0.5%.[43]

General Approach to Treatment

Treatment plans are individualized based on the severity of specific core features of the eating disorder and comorbid medical and psychiatric conditions. Psychiatrists, physician assistants, nurses, nutrition specialists, psychologists, and pharmacists play a role in the care of these complex patients. The absence of an adequate support system of family and friends can contribute to failed treatment. A critical first step is to determine the severity of illness, as that drives both the intensity and the setting for delivery of care. Hospitalization is generally reserved for the most severely ill patients. Some criteria for hospitalization are outlined in **Table 64-2**.[3,10,21,24,53] Medications are part of the comprehensive treatment strategy for eating disorders, but are rarely recommended as the sole treatment.[47,48,49] Comparative, double-blind, placebo-controlled trials are sparse, and most are limited by small sample sizes, ambivalent patient attitudes toward treatment, medical complications, and high dropout rates.[50]

TABLE 64-2 Considerations for Hospitalization of Patients with Eating Disorders

- Rapid weight loss or BMI <12
- Reduced oral intake of food (sudden and persistent)
- Medical complications (eg, edema) and metabolic abnormalities (eg, hypoproteinemia) from bingeing, purging, and starvation (eg, heart rate <40 beats/min, heart rate >120 beats/min, blood pressure <90/60 mm Hg, glucose <60 mg/dL [<3.3 mmol/L], potassium <3 mEq/L [<3 mmol/L], or inability to maintain core temperature)
- Co-occurring psychiatric symptoms, notably suicidal ideation, self-harm, psychotic depression, or substance abuse and dependence
- Nonresponsive to outpatient treatment (after 3-4 months) and poor motivation to recover
- Demoralization or nonfunctional family
- Denial of severity of abnormal eating behaviors
- Continuous supervision required to prevent purging (vomiting or laxative abuse)

Data from references 3, 10, 21, 24, and 54.

Anorexia Nervosa

Nonpharmacologic Treatments

8 Evidence supports that psychotherapy based treatments have the greatest likelihood of eliciting a response in AN patients.[10,25,51,52] However, the specific type of psychotherapy that is preferred varies and may include CBT, dialectical behavioral therapy, focal psychodynamic therapy, behavioral management, specialist supportive clinical management, interpersonal psychotherapy, nutritional counseling, and family therapy.[10,25,30,51,52,53,54,55] In younger patients, family therapy is the preferred first-line therapy.[56] Patients of lower age, those with shorter duration of illness, with restrictive type AN, who are employed, who are not taking psychotropic medications, and with better social adjustment may have improved outcomes.[55] Current guidelines suggest at least 6 months of psychotherapy is preferred, though studies of at least 1 year in duration have demonstrated favorable outcomes by reducing relapse rates.[25,52,53] CBT helps the patient overcome distorted thinking, including self-worth as measured by body image, feelings of being fat despite evidence to the contrary, and denial. CBT also teaches patients how to use strategies besides eating to cope.

Interpersonal psychotherapy focuses on interpersonal relationships and functioning, whereas CBT provides positive reinforcement for weight gain.[31] A combined approach of interpersonal psychotherapy and CBT is also a reasonable treatment approach.[51] Many psychiatric symptoms in an acutely ill patient, such as depression and anxiety, diminish or disappear with weight restoration.

Initial treatment is directed toward restoring a healthy weight, especially in inpatient settings where target weights are often more rapidly achieved.[30] After medical stability and appropriate weight are reached, therapy can be redirected toward addressing ongoing interpersonal problems, weight maintenance, cognitive restructuring, and skill development for relapse prevention.[25] Oral refeeding, initially with liquid formulas if necessary, is the most common approach to weight restoration.

In severe cases when a patient refuses to eat, nasogastric refeeding is preferred over IV bolus dosing in part because it can allow for higher initial caloric intake and has been associated with reductions in length of inpatient hospitalizations and increased rate of weight gain without an increase in complications.[57] Total parenteral nutrition is reserved only for the management of severely malnourished patients and if other refeeding methods fail. The decision to administer total parenteral nutrition must be made carefully, because of the potentially devastating psychological effect on patients who do not wish to gain weight.

Current clinical evidence suggests a controlled weight gain of 0.9 to 1.4 kg (2-3 lb) per week in inpatient settings and 0.2 to 0.5 kg (0.5-1 lb) per week in outpatient settings.[3,49,58] Refeeding recommendations vary between younger patients and adults and are considered controversial. An acceptable approach for younger patients is to begin refeeding at 800 to 1,000 cal/day (3347-4184 J/day), while others suggests a more aggressive approach.[59] Adults may be considered for refeeding initiation in the range of 1,000 to 1,600 cal/day (4184-6694 J/day) (30-40 cal/kg/day [126-167 J/kg/day]) with slow titration (every other day) upwards (100-200 cal/day [419-837 J/day]) until they begin to demonstrate sustained weight gain or achieve target weights.[10,53,60] This can require the intake of an additional 3,500 to 7,000 cal (14,644-29,288 J) per week.[53] Slow refeeding has long been considered important to prevent psychological and medical consequences, including the severe electrolyte disturbance that results from insulin surges known as refeeding syndrome, which can result in death. A criticism is that too conservative of an approach results in further weight loss early in treatment (unfeeding syndrome), contributing to a failure to achieve nutritional recovery goals.[61]

Pharmacologic Therapy

Antidepressants

Although many studies examined the role of antidepressants in the treatment of AN, they often have small sample sizes and large confidence intervals.[63] Antidepressants currently have no role in the acute treatment of AN, unless there is another clinical indication present.[10,21,47]

Data suggest that medication is ineffective, especially in cases where the patient is below their expected weight. Thus, antidepressants should be initiated only if depression, anxiety, obsessions, or compulsions persist after the target weight is achieved.[21,58] The duration of treatment when antidepressants are used in this manner is unclear, but one study showed benefit in treated patients for 1 year, and current guidelines suggest 9 to 12 months of therapy.[10,25,51,52,53] Antidepressants, along with psychotherapy, have been used to help maintain weight and prevent relapse, but data supporting this are limited.[63] Most clinicians prefer the selective serotonin reuptake inhibitor (SSRI)

antidepressants because they are better tolerated and have greater cardiovascular safety than tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs).[10,25,51,52] Because these patients are sensitive to anticholinergic and cardiovascular effects, if TCAs or MAOIs are used, low starting doses and slow titration toward an effective dose are appropriate. The risk of cardiotoxicity in a malnourished population must not be underestimated, and a baseline electrocardiogram (ECG) should be obtained before initiation of these agents.

Fluoxetine continues to be the most widely studied SSRI in AN. Most clinicians initiate at low doses, for example, 20 mg/day, and increase to a maximum of 60 mg/day based on response and tolerability.[60,62,63] Some controversy exists regarding when antidepressant therapy should be initiated. During the starvation phases of anorexia, the majority of clinical trials suggest that antidepressants are ineffective, partly due to reduced tryptophan levels, though debate remains as to their effectiveness once weight restoration has occurred. Evidence from a 52-week, randomized, placebo-controlled clinical trial of 93 patients with the treatment arm receiving doses from 20 to 80 mg/day after weight restoration showed no difference between fluoxetine and placebo for time to relapse.[64]

Antipsychotics

First- and second-generation antipsychotics have been utilized as a treatment for AN, specifically targeting anxiety and obsessive and paranoid thoughts related to weight gain. First-generation antipsychotics contributed to BMI gains, but provided little benefit overall at reducing other core symptoms, and the associated adverse events were considered to outweigh the benefits. Second-generation antipsychotics have provided an additional alternative for treating AN, with reports of improvement in weight gain and reductions in symptoms such as depression, anxiety, and obsessive–compulsiveness. Most of the data are from case reports or small trials in both adolescents and adults using risperidone 0.5 to 2.5 mg daily, olanzapine 2.5 to 10 mg daily, and quetiapine 50 to 800 mg daily.[65,66,67,68,69] Olanzapine in combination with day hospital treatment has been shown to be more effective than day hospital treatment alone in achieving greater weight gain and reducing obsessive symptoms.[68] In addition, an outpatient study examining olanzapine versus placebo, independent of concurrent psychotherapy, demonstrated significant improvement in BMI.[70] While some benefits have been reported, not all positive findings have been replicated, and caution is urged, as there is likely an increased susceptibility to some of the physiologic effects of antipsychotic medications. Optimal treatment duration is unknown, as most of the larger studies are less than or equal to 3 months in duration.

Miscellaneous Agents

Metoclopramide can be helpful in reducing bloating, early satiety, and abdominal pain commonly found in AN, but it does not affect weight gain.[10] Low-dose, short-acting benzodiazepines (0.25 mg alprazolam or 0.5 mg lorazepam) given before meals are useful when severe anxiety limits eating.[10] Estrogen replacement has been used, but restoring menses through refeeding is a preferred approach to minimize bone density loss. Supplementation with zinc is also being studied to assist

with weight restoration.[51]

Clinical Controversy…

There is widespread disagreement about the most appropriate rate of refeeding. An approach that is too aggressive may increase the risk of developing "refeeding syndrome" while utilizing a conservative approach may result in delays in patients achieving proper weight restoration.

Bulimia Nervosa

Nonpharmacologic Therapy

Outpatient-based treatment is most often recommended except in extreme cases (see Table 64-2). The nondrug strategies used in BN are similar to those used with AN, and they are equally critical to success. CBT has the strongest evidence supporting its benefit in managing BN.[25,51,53] Current treatment guidelines suggest that CBT should consist of 16 to 20 sessions over a 4- to 5-month period.[25,53] Data suggests that 30% to 50% of individuals who receive CBT for BN are abstinent from binge eating and purging behaviors by conclusion of the treatment.[71] Interpersonal psychotherapy also plays a role and has a moderate degree of evidence to support its use, but it is considered less effective than CBT.[10,22] A 2014 study demonstrated that CBT was more effective in relieving binging and purging than psychoanalytic psychotherapy and was generally faster in alleviating eating disorder features and general psychopathology.[72] Nutritional counseling, planned meals, and self-monitoring can help interrupt the binge–purge cycle. Family therapy in bulimic patients is less critical than with AN, as these patients tend to be older. A recent study suggested that CBT-guided self-care was a more effective treatment approach in adolescents than family therapy. Programs using motivational teaching and self-help guides based on CBT have shown promise.[31,75,76,77] When such programs have been combined with medication, for example, fluoxetine, enhanced response has been reported.[78] Online delivery of CBT may provide an acceptable treatment alternative for patients who have limited access.[73,74] Data support the use of 12-step programs, but they should not be used as monotherapy.[10,21] Adjunctive interventions, such as acupuncture and yoga, targeting symptoms of anxiety and depression need further study.[79,80]

Pharmacologic Therapy

Antidepressants

9 Antidepressants are used in the acute and maintenance phases of BN adjunctively with nonpharmacologic approaches. A wide array of antidepressants, including TCAs, MAOIs, trazodone, serotonin–norepinephrine reuptake inhibitors (SNRIs), bupropion, and SSRIs, have been studied. Additionally, several reviews analyzing this body of literature have been published, although there continues to be limited placebo-controlled, randomized, double-blind clinical studies.[21,47,81] Antidepressants are reported to reduce depression, anxiety, obsessions, and impulsive behaviors, such as binge eating and purging, and improve eating habits, although their impact on body

dissatisfaction remains unclear. The presence of comorbid mood disorders is not necessary for a response in patients with BN.

The benefit appears to be more robust in the acute phase of the illness, as relapse despite continued antidepressant use is common in patients who are in or near remission.[21,49] Antidepressant response usually occurs in 6 to 8 weeks, and reduction in frequency of binge–purge behavior has been as high as 73% and as low as zero.[47] Abstinence rates (elimination of bingeing and purging behaviors) with short-term use range from 0% to 68%. More data are needed to determine the long-term benefits of antidepressants for preventing relapse of bulimia symptoms. One trial evaluating the impact of fluoxetine versus placebo in the maintenance phase showed a better outcome in patients receiving fluoxetine 60 mg/day, although high dropout rates in both groups blurred the overall benefit.[82]

Selective serotonin reuptake inhibitors are the preferred agents because of their tolerability and because they have been studied in the largest number of patients. Fluoxetine remains the only medication with FDA approval for BN. Efficacy of other SSRI agents is still lacking, but an alternative SSRI may be considered in clinical practice for patients who do not respond to fluoxetine.[81] Tolerability is the primary criterion for selecting an antidepressant in the treatment of BN because of patients' heightened sensitivity to adverse effects and the lack of a clear difference in efficacy between the classes. Even though there is a suggestion that MAOIs produce the most robust effect, the risk of using these medications in impulsive patients limits their use.[49] SNRIs have shown promising results; however, the data supporting their use are limited to case reports. Bupropion, a norepinephrine–dopamine reuptake inhibitor, is contraindicated in bulimic patients because of the increased risk of seizures.

Before initiating pharmacologic therapy, a careful baseline physical examination, ECG, and laboratory workup are essential. Underlying ECG changes secondary to hypokalemia or bradycardia and atrioventricular block from starvation can be present. There is potential for fatal outcomes secondary to cardiac arrest or suicide. All antidepressants can cause seizures; thus, a careful risk–benefit assessment is warranted if the patient has predisposing factors such as a personal or family history of seizures, cerebrovascular disease, or alcohol or sedative–hypnotic withdrawal.

Doses in the treatment of BN are similar to those in patients treated for depression, although at the higher end of the range. Readers are referred to Chapter 68 for antidepressant dosing ranges. For fluoxetine, the higher end of the dosing range, 60 mg/day, can be necessary for response.[83] With all agents, most clinicians initially target the bottom to the middle of the dosing range and increase the dose if there is an inadequate response. Slow titration is needed to allow time to develop tolerance to adverse effects. If TCAs are used, serum concentration monitoring is recommended to ensure that absorption is not compromised by purging.

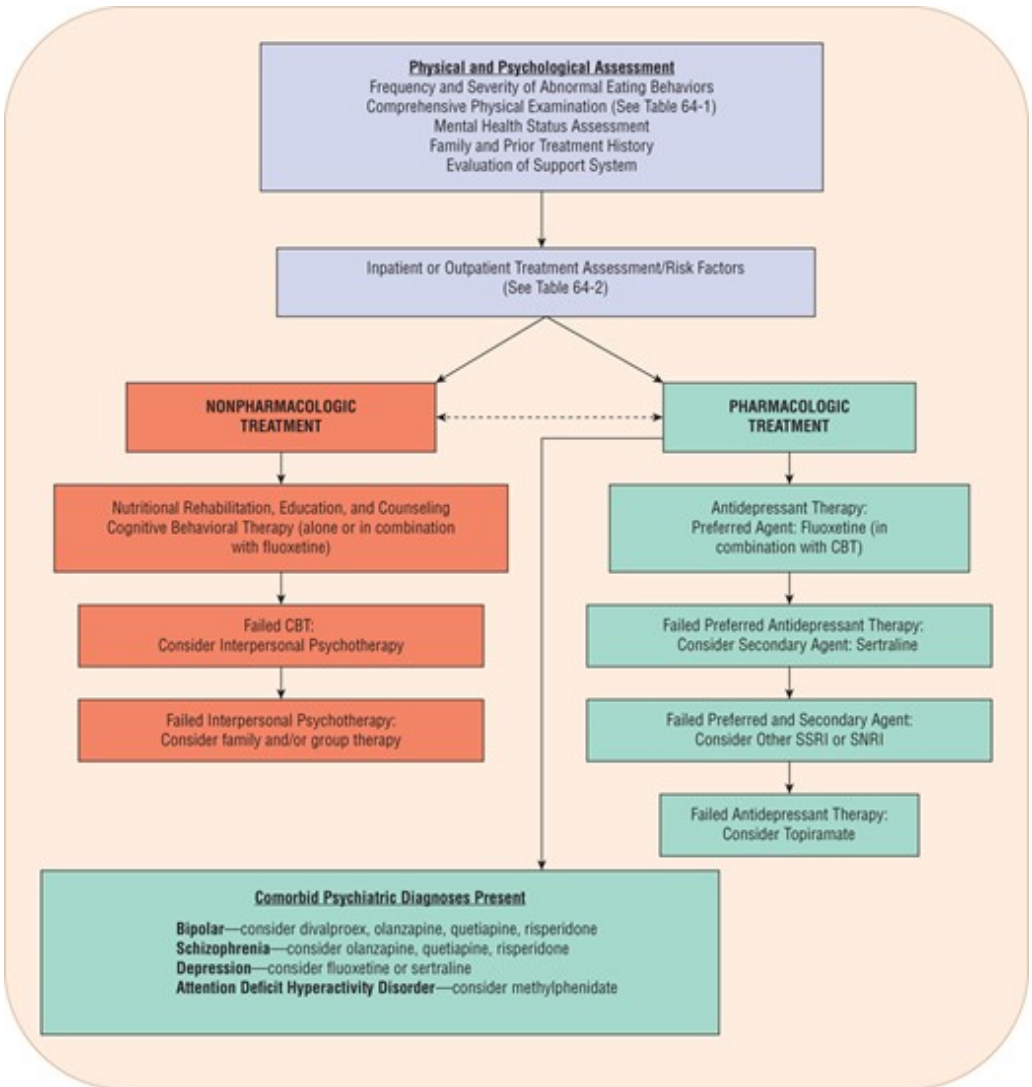
The time for antidepressant onset of effect in BN is unclear. In the absence of data, the definition of a therapeutic trial from the depression literature (4-8 weeks at a therapeutic dose) should be used. A 2010 report by Sysko et al. identified that response (defined as greater than 60% reduction in binge eating or vomiting frequency) by week 3 is a positive predictor of eventual treatment response.[84] Because the majority of subjects will not experience a complete remission, and there are few data on

predictors of response or whether switching to another class will improve response, a clear and specific target should be stated initially.[17]

Optimal duration of treatment after response is poorly defined, although most clinicians treat for 9 months to 1 year and then reevaluate. The evidence is mixed as to whether any early benefit is sustained; hence, the decision to continue treatment should be made based on both initial response and the maintenance of that benefit. If the symptoms return within a few months after antidepressant discontinuation, then the treatment may need to be reinitiated. **Figure 64-2** describes criteria for medication use in BN.

FIGURE 64-2

Bulimia nervosa treatment algorithm. (CBT, cognitive behavioral therapy; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.)



Miscellaneous Agents

Because of the lack of evidence demonstrating their benefit, lithium and traditional anticonvulsants are reserved for bulimic patients with comorbid bipolar disorder.[10,85] Randomized, placebo-controlled trials with topiramate have demonstrated reduced binge/purge frequency and weight loss versus placebo, although side effects including cognitive impairment and paresthesia may hinder medication adherence.[86,87] Low-dose benzodiazepines before meals can help reduce anxiety associated with refeeding, although long-term use is not warranted because of the risk of abuse and dependence. One double-blind trial with ondansetron has shown benefit, but there are insufficient data to recommend a specific role for this agent.[88] One small, open-label, pilot study of zonisamide showed it to be effective in BN, but due to study limitations, the results should be considered preliminary, and further data are needed to confirm its role in treatment.[89] Data are conflicting on the opiate antagonist naltrexone with only modest improvement seen at high doses, but naltrexone is not recommended due to risk of elevated hepatic transaminases.[65] Antipsychotics and appetite suppressants do not play a role in managing core symptoms of BN.[21]

Nonpharmacologic versus Pharmacologic Approaches

The combination of pharmacologic and nonpharmacologic measures appears to produce the best chance for a positive outcome for patients with BN.[53] Antidepressants, specifically SSRIs, are the drug class of choice in bulimic patients, whereas other medications are reserved for patients with comorbid psychiatric conditions. Only in unusual circumstances should patients be treated with antidepressants alone. Evidence suggests the greatest benefit is during the acute phase of treatment, whereas data are mixed regarding their role in the prevention of relapse.

Binge Eating Disorder

Nonpharmacologic Therapy

Individual and group CBT are universally accepted as the non-pharmacologic treatment interventions of choice, specifically aimed at reducing the number binge eating episodes though not likely to significantly improve weight loss.[52,90] Interpersonal therapy (IPT) has recently demonstrated comparable efficacy to CBT at 1-, 2-, and 5-year follow-up reviews.[91,92] Dialectical behavior therapy (DBT) is also an appropriate psychotherapy treatment intervention, though not considered first-line.[91,92] Weight loss focused treatment programs are generally considered to be the most effective nonpharmacologic intervention to reduce weight, specifically in those who are obese.[93]

Pharmacologic Therapy

The stimulant lisdexamfetamine, antidepressants, and anticonvulsants are the pharmacologic agents that are most extensively studied in BED. Antidepressants have demonstrated efficacy as monotherapy at reducing binge eating, decreasing BMI, and improving depressed mood during the acute phases of the illness compared with placebo, but they can also be used in combination with CBT to augment response.[25,65,94,95,96] The SSRIs citalopram (20 mg-60 mg in clinical trials, however doses above 40 mg are not recommended), escitalopram (10 mg-30 mg), fluvoxamine (up to 200

mg), fluoxetine (40 mg-80 mg), sertraline (100 mg-200 mg), are associated with some level of improvement in BED related symptoms.[94,95,96,97] This includes a reduction in binge frequency, a reduction in BMI, improved mood symptoms, and reduced obsessive compulsive symptoms, though not all studies have included each of these outcome measures in their methodology.[97] The results from two different meta-analyses suggest that antidepressants have higher remission rates when compared with placebo.[81] The majority of the data are with SSRIs given at antidepressant doses.[97]

Atomoxetine (40 mg-120 mg) and venlafaxine (75 mg-300 mg) have evidence to support improvement in BED symptoms. Specific benefit was reduction in binge frequency, reduced BMI, weight loss, and improved mood symptoms.[97]

Lisdexamfetamine is a prodrug of dextroamphetamine and is FDA approved for the treatment of moderate to severe BED (30 mg initially and titrated to 50 mg-70 mg daily). Clinical trials demonstrated reductions in numbers of binge days per week, a greater percentage of patients with global clinical improvement, a higher percentage achieving a 4-week cessation of binge episodes, and improvement in obsessive compulsive psychometric measures.[98]

Clinical Controversy…

Lisdexamfetamine has recently gained FDA approval for the treatment of BED; however, in many cases it is not utilized as a first-line therapy. The limitations to its use as a first-line agent for BED relate to safety concerns (eg, possible abuse, cardiac arrhythymia).

Topiramate 25 to 300 mg daily reduced binge frequency, body weight, and BMI, and remission rates were higher when combined with CBT.[99,100] Zonisamide (100-600 mg/day) alone and in combination with CBT over the course of 16-week and 1-year studies demonstrated efficacy at reducing binge eating and weight loss; however, there were high dropout rates due to intolerability.[81]

Orlistat 120 mg given three times daily, along with calorie-restricted diet, produced weight reduction in obese patients with BED.[101] Other medications used to treat obesity, such as phentermine and the combination of phentermine with topiramate lack current clinical evidence to support their use in BED.

Another alternative, chromium picolinate (600-1,000 mcg/day) was investigated in BED patients. Results from a small, 6-month trial found that blood glucose was reduced, though there were non-significant improvements in reducing binge frequency, weight, and depressed mood.[102]

In summary, the question of where BED fits on the diagnostic spectrum continues to be explored. Current literature suggests that two different types of pharmacologic agents (SSRIs and topiramate) hold promise in the short term, but long-term data are lacking. As with other eating disorders, nonpharmacologic treatments are the key to a successful outcome.

Personalized Pharmacotherapy

Results from genetic variation studies are largely inconclusive. While serotonin is the most widely

studied neurotransmitter, there is not an overwhelmingly consistent response to the serotonin-enhancing medications. Often response is simply a reduction in behaviors such as bingeing and purging, but not a complete amelioration of symptoms. To date, there is no widely accepted pharmacogenomic or pharmacokinetic predictors of medication response in patients with eating disorders.

EVALUATION OF THERAPEUTIC OUTCOMES

Anorexia Nervosa

A combination of subjective and objective measures is used to assess response in patients with AN. A reduction in the frequency and severity of abnormal eating habits, normalized exercise patterns and laboratory tests, and a sustained weight close to age-matched normals are key indicators of response. A diary recording exercise frequency, menses, food intake, patterns of eating, and associated feelings while eating is a useful tool to track progress, especially in the outpatient setting. Weekly weigh-ins on the same scale, preferably at a clinician's office, help monitor progress early in treatment and reduce the focus on weight and anxiety caused by the variability found among different scales. Follow-up laboratory tests and ECGs are not part of routine monitoring unless the patient is restricting food intake, is purging, or continues to lose weight despite treatment. Inpatients require daily assessment of weight and caloric intake, vital signs, and urine output because of the severity of their illness. They also can need monitoring of bathroom privileges early in their care. A healthy weight gain of not more than 0.2 to 0.5 kg (0.4-1.1 lb) per week toward a goal of 90% to 95% of normal weight or a BMI greater than 18.5 kg/m^2 is a critical sign of treatment success. A patient's use of coping skills and contingencies for dealing with stress, other than manipulating food consumption, also should be assessed. Antidepressants can assist in alleviation of persistent depression, anxiety, and obsessions, after weight restoration. Improvement in mood is expected to occur within 8 weeks. Patients receiving TCAs should be evaluated for dry mouth, constipation, hypotension, and sedation. Patients receiving SSRIs should be monitored for agitation, drug-induced anorexia, nausea, weight loss, and insomnia. The decision to use long-term medication must be based on specific and sustained improvement in the target symptoms, balanced against adverse effects.

10 Recent research focused on quality of life as a primary outcome measure compared to targeting specific symptoms of AN. Quality of life is generally lower in individuals with a history or clinical presence of an eating disorder. The belief behind this change in focus suggests that patients who are otherwise not interested in changing behaviors may be more invested in improving their perceived quality of life. Preliminary findings, however, suggest that improvement in quality of life is in part dependent on symptom improvement and weight gain, thus weight gain and behavioral change should remain the focus of treatment.[103]

Bulimia Nervosa

An individualized treatment and monitoring plan begins with a thorough assessment describing the

baseline frequency and severity of treatment-responsive target symptoms and other associated findings. The assessment must be comprehensive, as a patient can hide his or her illness by shifting from one type of behavior to another (eg, exercise to purging).

A comprehensive assessment includes a description of psychiatric symptoms, physical findings, frequency and severity of binge–purge episodes, laxative and ipecac use, exercise patterns, and laboratory and ECG abnormalities. Interpersonal and relationship problems should also be evaluated. Some findings indicating a more chronic course of illness, such as salivary gland inflammation and erosion of dental enamel, can take months to reverse or might never normalize. Hence, these are not sensitive indicators of early treatment response. Data describing a patient's baseline level of functioning and previous response to treatment should be used to set goals in the current treatment plan.

Response to an antidepressant usually occurs within 4 to 8 weeks after the onset of treatment. If response does not occur, binge–purge behavior should be considered as a factor potentially contributing to the malabsorption of medication. If this behavior is not present, then every attempt should be made to maximize the dose. Serum concentration monitoring, when appropriate as with TCAs, should be done periodically (every 3-6 months if a patient is responding and tolerating the medication, or more frequently if clinically indicated). Evaluation of previously described adverse effects also should be part of the monitoring plan. If the patient responds, he or she should be followed for 6 to 12 months, and then reassessed for the need for ongoing medication. If the patient relapses after medication discontinuation, then the medication should be restarted. There is an increased risk of suicidality associated with antidepressant use in major depression, thus suicidality assessments should be included following their initiation, especially early in therapy. Please refer to Chapter 68 for further details and more comprehensive information related to antidepressant use.

Eating disorder patients who are outpatients present a particular challenge to clinicians. Impulsivity associated with BN can increase the risk for suicide. Prescriptions should be limited to small supplies. In addition, pharmacists should be alert to persons who make large or frequent purchases of laxatives or ipecac syrup, as this is an indicator of possible bulimic behaviors.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

5-HIAA	5-hydroxyindoleacetic acid
5-HT	serotonin
5-HTTLPR	serotonin transporter
AN	anorexia nervosa
BDNF	brain-derived neurotrophic factor
BED	binge-eating disorder
BMI	body mass index
BN	bulimia nervosa
CBT	cognitive behavioral therapy

CNS	central nervous system
CSF	cerebrospinal fluid
CT	computerized tomography
DBT	dialectical behavior therapy
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders* (fifth edition)
ECG	electrocardiogram
EEG	electroencephalogram
ESRI	estrogen receptor I gene
GI	gastrointestinal
IPT	interpersonal therapy
MAOI	monoamine oxidase inhibitor
MRI	magnetic resonance imaging
NES	night eating syndrome
OCD	obsessive–compulsive disorder
SNRI	serotonin–norepinephrine reuptake inhibitor
SSRI	selective serotonin reuptake inhibitor
TCA	tricyclic antidepressant

Chapter 65: Substance-Related Disorders I: Overview and Depressants, Stimulants, and Hallucinogens

FIGURE 65-1

Paul L. Doering; Robin Moorman Li

INTRODUCTION

KEY CONCEPTS

- 1 Problems related to abuse of chemical substances can occur acutely (eg, respiratory arrest from using heroin) or after some length of time (eg, dependence or withdrawal from continued use of an opiate). The treatment approach is distinctly different depending on the type of problem.
- 2 Certain drugs of abuse are marketed via the Internet and other unregulated outlets using names that would not immediately identify the substance as a dangerous drug. Health professionals must stay abreast of the latest marketing ruse to conceal the true nature of the substance.
- 3 Synthetic chemists are constantly developing new drugs of abuse with pharmacology that mimics that of established controlled substances. Often, the dangers of these substances are greater than that of the parent compound.
- 4 For a few drugs, there is a specific antidote that can be used in cases of overdoses. For others, treatment is symptomatic and supportive. Early recognition and treatment of acute drug intoxications can make a huge difference in the ultimate outcome for the patient.
- 5 Withdrawal from certain classes of drugs (eg, benzodiazepines or barbiturates) can be life-threatening, and steps must be taken to ensure that discontinuation or dose reduction is

gradual and that it takes place in closely supervised settings.

- 6 While there is much research focusing on drugs to treat the underlying addictive processes, to date the successes have been few. Whereas methadone, levo-α-acetylmethadol (LAAM), and buprenorphine are used for narcotic maintenance, the logical approach at present should center on prevention and using pharmacotherapies like buprenorphine to wean patients off of opioids altogether.

- 7 While the goal of therapy for substance dependence is to wean patients from a drug or drug category altogether, this is often difficult to do. For some, the treatment strategy is to manage the chemical dependency to allow the patient to lead as normal a life as is possible. This may require the substitution of one drug for the primary drug of dependency.

- 8 Pharmacotherapy of substance-related disorders is most often adjunctive to other modes of therapy such as counseling and intense psychotherapy.

The book of *Ecclesiastes* wisely reminds us that "[W]hat has been will be again, what has been done will be done again; there is nothing new under the sun."[1] It is doubtful that the author of these sage words was referring to the repeating cycle of substance abuse, but when it comes to this subject there rarely *is* anything new under the sun, and this metaphor aptly applies.

Psychoactive drug use dates back to prehistoric times and the Neolithic era (8,500-4,000 BC) where the earliest human use of psychoactive substances consisted almost exclusively of plants and fruits whose mood-altering qualities were accidentally discovered but subsequently deliberately grown.[2]

Ancient civilizations (4,000 BC-400 AD) such as the Sumerians, Egyptians, Indians, Chinese, and South Americans used opium, alcohol, cannabis, peyote, psychedelic mushrooms, and coca leaves. The Middle Ages (400-1,400) saw the use of psychoactive plants, such as belladonna and psilocybin mushroom, used by witches and shamans for healing and spiritual purposes, and distilled alcohol, coffee, tea, and opium spread along the trade routes.[2]

Almost 5,000 years ago at the Temple of Imhotep, a center for treating mental illness, opium was used in an attempt to cure the mentally ill by inducing vision, performing rituals, and praying to the gods.[2] Hippocrates, the father of medicine, recommended opium as a painkiller and as a treatment of female hysteria.[2] Evidence of the inhalation of cannabis smoke can be found in the 3rd millennium BC, as indicated by charred cannabis seeds found in a ritual fire at an ancient burial site in present-day Romania.[3] In 2003, a leather basket filled with cannabis leaf fragments and seeds was found next to a 2,500- to 2,800-year-old mummified shaman in the northwestern Xinjiang Uygur Autonomous Region of China.[4] Thousands of years later, nearly every one of these drugs is still used today in one form or another for their mind-altering effects.

For any textbook to remain relevant, it must give emphasis to *current* information in any given content area. This means that space previously budgeted to one subject must give way to more recent trends. For example, if this chapter was written in the late 1960s, great attention would be

given to the use and abuse of lysergic acid diethylamide (LSD) or methamphetamine.[5,6] If it was written in the late 1970s, the epidemic abuse of hydromorphone (Dilaudid) would be featured.[7] Sadly, hydromorphone has regained a prominent position in the sprawling landscape of drug abuse and addiction.

In the mid-to late-1970s great attention would be given to the abuse of methaqualone (Quaalude).[8] Somewhere along the way, the abuse of pentazocine would take center stage.[9] Amphetamine abuse has come, gone, and come back again.[10] γ-Hydroxybutyric acid (GHB) made a sudden and dramatic appearance on the scene, but its use has lessened in the past years.[11] The current epidemic of prescription drug abuse has skyrocketed its way into prominence. Hallucinogens such as dimethyltryptamine (DMT) and phenylethylamine derivatives are making a strong comeback.

By no means does this suggest that these above-mentioned drugs have disappeared, but instead many have taken a back seat to other, more commonly encountered drugs. For this reason, this rewrite of the present chapter and the one to follow will leave out some of the information from previous editions. The interested reader should consult prior editions of this textbook for information about these substances.

TERMINOLOGY USED IN SUBSTANCE ABUSE

The lack of a common vocabulary in substance abuse treatment and prevention leads to several problems. Wide arrays of terms are in common use, many without precise meaning. This lack of universal agreement on language hampers effective communication among professionals and leads to difficulties in formulating public policy and administering third-party reimbursement programs.

In 2003, the Liaison Committee on Pain and Addiction, a collaborative effort of the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine (ASAM), developed definitions related to the use of medications for the treatment of pain consistent with current understanding of relevant neurobiology, pharmacology, and appropriate clinical practice. While other classification systems are currently in use, the following definitions have been approved by each of the three collaborating organizations. The following definitions resulted from this consensus development committee[12]:

1. *Addiction* is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following five Cs: *c*hronicity, impaired *c*ontrol over drug use, *c*ompulsive use, *c*ontinued use despite harm, and *c*raving.

2. *Drug abuse* is a maladaptive pattern of substance use characterized by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use creating physical danger, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.

3. *Physical dependence* is a state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

4. *Tolerance* is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.

EPIDEMIOLOGY

Illicit drug use, including the misuse of prescription medications, affects the health and well-being of millions of Americans. Cardiovascular disease, stroke, cancer, infection with the human immunodeficiency virus (HIV), hepatitis, and lung disease can all be affected by drug use. Some of these effects occur when drugs are used at high doses or after prolonged use. However, other adverse effects can occur after only one or a few occasions of use. Addressing the impact of substance use alone is estimated to cost Americans more than $600 billion each year.

National Survey On Drug Use and Health

The National Survey on Drug Use and Health (NSDUH)[13] is the primary source of statistical information on the use of illegal drugs by the U.S. population. Conducted by the federal government since 1971, the survey collects data from a representative sample of the population at their place of residence.

The National Survey on Drug Use and Health obtains information on nine categories of illicit drugs: marijuana (including hashish), cocaine (including crack), heroin, hallucinogens, and inhalants, as well as the nonmedical use of prescription-type pain relievers, tranquilizers, stimulants, and sedatives.

In 2014, an estimated 27.0 million Americans aged 12 or older were current (past month) illicit drug users, meaning that they had used an illicit drug during the month prior to the survey interview. This corresponds to about 1 in 10 Americans (10.2%). The most commonly used illicit drug in the past month was marijuana, which was used by 22.2 million people aged 12 or older. An estimated 6.5 million people reported nonmedical use of psychotherapeutic drugs in the past month, including 4.3 million nonmedical users of prescription pain relievers.

Although nonmedical pain reliever use continued to be the second most common type of illicit drug use in 2014, the percentage of people aged 12 or older in 2014 who were current nonmedical users of pain relievers (1.6%) was lower than the percentages in most years from 2002 to 2012, but it was similar to the percentage in 2013.

The use of many types of other illicit drugs has not increased in recent years. However, the percentage of people aged 12 or older in 2014 who were current heroin users was higher than the percentages in most years from 2002 to 2013.

Approximately 21.5 million people aged 12 or older in 2014 had a substance use disorder (SUD) in the past year, including 17.0 million people with an alcohol use disorder, 7.1 million with an illicit

drug use disorder, and 2.6 million who had both an alcohol use and an illicit drug use disorder.

Monitoring The Future Study

Every year the Institute for Social Research at the University of Michigan conducts its Monitoring the Future Study (MTFS), supported under a series of research grants from the National Institute on Drug Abuse.[14]

A main purpose of this research is to study changes in the beliefs, attitudes, and behavior of young people in the United States which requires frequent reassessment to identify the rapidly changing patterns.[14]

The 2014 MTF survey encompassed about 41,600 8th-, 10th-, and 12th-grade students in 377 secondary schools nationwide.[14] Annual marijuana prevalence peaked among 12th graders in 1979 at 51%, following a rise that began during the 1960s. In the ensuing years rates have gone up and down in 8th, 10th, and 12th graders. Daily use increased in all three grades after 2007, reaching peaks in 2011 (at 1.3% in 8th), 2013 (at 4.0% in 10th), and 2011 (at 6.6% in 12th), before declining modestly since. Daily prevalence rates in 2014 were 1.0%, 3.4%, and 5.8%, respectively. Researchers postulate that the increase of smoking marijuana is partly attributable to the national debate over medical use of cannabis which may make the drugs seem safer to teenagers.[14]

Synthetic marijuana (see below) which contains designer chemicals included in the cannabinoid family (common names are K-2, Spice, and Blaze) has been of increasing concern both because of its adverse effects and its high rates of use, first documented by this study in 2011. Annual prevalence at that time was found to be 11.4%, making synthetic marijuana the second most widely used class of illicit drug after marijuana among 12th graders. Despite the Drug Enforcement Administration's (DEA) intervention, use among 12th graders remained unchanged in 2012 at 11.3%, which suggests either that compliance with the new scheduling had been limited or that producers of these products succeeded in continuing to change their chemical formulas to avoid using the ingredients that had been scheduled. In 2012, for the first time, 8th and 10th graders were asked about their use of synthetic marijuana; annual prevalence rates were 4.4% and 8.8%, respectively. Use in all 3 grades dropped in 2013, and the decline was sharp and significant among 12th graders. The declines continued into 2014 and were significant for both 10th and 12th graders.

ECONOMIC IMPACT OF SUBSTANCE ABUSE

Substance abuse and addiction have an enormous impact on the economy. Annual costs of illicit drug use are estimated at more than $11 billion for health care and $182 billion for crime and lost productivity.[15]

ACUTE VERSUS CHRONIC PROBLEMS

1 Misuse of chemical substances causes problems of two types: those that occur acutely and those

that arise after continued use of a drug. Acute problems are usually predictable, given the pharmacology of the drug. Chronic abuse of chemical substances can cause a wide array of physical, psychological, and psychiatric morbities. The substance-induced disorders discussed here mainly include intoxication and withdrawal.

1 The essential feature of substance dependence is the continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug. Patients who take prescribed drugs for appropriate medical indications and in correct doses may still show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than being tapered. Tolerance and physical dependence are inevitable consequences of chronic treatment with opioids and certain other drugs, but by themselves, tolerance and physical dependence do not imply "addiction." According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, (*DSM-5*)[16] the overall category of substance-induced disorders includes intoxication, withdrawal, and other substance/medication-induced mental disorders (eg, substance-induced psychotic disorder, substance-induced depressive disorder). To meet *DSM-5* criteria for the diagnosis of SUD, at least two of the following must occur within a 12-month period:

1. The specific substance is often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control use of the substance.
3. A great deal of time is spent in activities necessary to obtain, use, or recover from the effects of the substance.
4. Craving, or a strong desire or urge to use the substance.
5. Recurrent use of the substance resulting in a failure to fulfill major role obligations at work, school, or home.
6. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of substance.
7. Important social, occupational, or recreational activities are given up or reduced because of the use of the substance.
8. Recurrent substance use in situations in which it is physically hazardous.
9. Use of the substance is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.
10. Tolerance, as defined by either of the following:
    a. A need for markedly increased amounts of the substance to achieve intoxication or desired effect.

b. Markedly diminished effect with continued use of the same amount of the substance.

11. Withdrawal, as manifested by either of the following:

    a. The characteristic withdrawal syndrome for the substance of the criteria set for a given substance.

    b. The substance (or a closely related one) is taken to relieve or avoid withdrawal symptoms.

The DSM-5 does not use the word *addiction* in its classification scheme, although it is in common usage in many countries to describe severe problems related to compulsive and habitual use of substances. The more neutral term *SUD* is used to describe the wide range of the disorder, from a mild form to a severe state of chronically relapsing, compulsive drug taking. Some clinicians will choose to use the word addiction to describe more extreme presentations, but the word is omitted from the official DSM-5 SUD diagnostic terminology because of its uncertain definition and its potentially negative connotation.

Intoxication refers to the development of a substance-specific syndrome after recent ingestion and presence in the body of a substance, and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system (CNS). Examples include belligerence, mood lability, impaired judgment, and impaired social or occupational functioning. Evidence for recent intake of the substance can be obtained from the history, physical examination, or laboratory examination. The most common changes involve disturbances in perception, wakefulness, attention, thinking, judgment, motor behavior, and interpersonal behavior.

As with most illnesses, the course and prognosis of the disorders of substance use and dependence are variable. Getting patients who are drug dependent to stop using drugs is very difficult, and many patients return to drug use even after treatment. It has been reported that as many as 75% of treated, substance-dependent patients will relapse at least once. Many patients, however, are able to obtain recovery with treatment and continued care in 12-step programs such as Alcoholics Anonymous or Narcotics Anonymous. Substance dependence or addiction can be viewed as a chronic illness that can be controlled successfully with treatment but cannot be cured and is associated with a high relapse rate. Without treatment, the course can progress to life-threatening severity, resulting from the effects of the drug, drug contaminants, or medical complications of use.[18] Although an in-depth discussion of the mechanism of drug addiction is beyond the scope of this chapter, the interested reader is directed to a review article that presents the current understanding of the biology of drug addiction.[17]

CNS DEPRESSANTS

Opiates and Opioids

Deaths from prescription opioids have reached epidemic levels in the past decade. The number of overdose deaths is now greater than the number of deaths from heroin and cocaine combined. In 2014, an estimated 6.5 million Americans aged 12 or older were current nonmedical users of

psychotherapeutic drugs, representing 2.5% of the population aged 12 or older. Estimates of current nonmedical use of prescription psychotherapeutic drugs among the population aged 12 or older has largely been driven by the nonmedical use of prescription pain relievers. In 2014, about two thirds of the current nonmedical users of psychotherapeutic drugs who were aged 12 or older reported current nonmedical use of pain relievers. This represents 1.6% of the population aged 12 or older. Nonmedical users of pain relievers in 2014 were lower than the percentages in most years from 2002 to 2012, but it was similar to the percentage in 2013. A few years back, The Centers for Disease Control and Prevention (CDC) noted that, between 1997 and 2007, drug company distribution of prescription opioid analgesics increased 627%. The quantity of prescription painkillers sold to pharmacies, hospitals, and doctors' offices was 4 times larger in 2010 than in 1999. According to the CDC, enough of these drugs are currently distributed for every American to take 5 mg Vicodin every 4 hours for 3 weeks.[19,20] Stated differently, enough prescription opioids were prescribed in 2010 to medicate every American adult around-the-clock for a month.[21] Distribution by drug companies rose from 96 mg/person in 1997 to 698 mg/person in 2007. Although most of these drugs were prescribed for a medical purpose, many ended up in the hands of people who misused or abused them. Each day, almost 7,000 people are treated in emergency departments (ED's) for using these drugs in a manner other than as directed. Deaths from prescription painkillers have also quadrupled since 1999, killing more than 16,000 people in the United States in 2013.[21]

Many states report problems with "pill mills," where doctors prescribe large quantities of opioids to people without medical justification. Some people also obtain prescriptions from multiple prescribers by "doctor shopping."

Clinical Controversy…

There is considerable debate about the appropriate use of prescribed opiates and how this might contribute to the overuse or abuse of these same drugs for nonmedicinal purposes. Not all decisions that physicians and other prescribers make are going to be correct. Likewise, pharmacists are going to occasionally make the wrong decision by either declining to fill a prescription that is proper and appropriate or by filling one that is bogus. In the final analysis, mistakes in judgment are going to be made in both directions. Given this fact, in which direction should the health professional err? Should health practitioners give the patient the benefit of the doubt, writing or filling the prescription, even if their decision ultimately turns out to be wrong? Or should the mandate be in the other direction: refuse to prescribe pain medicines or refuse to fill the prescriptions, even when, in truth, the prescription is appropriate and valid? Most healthcare professional assume that complaints of pain are real and prescribe accordingly.

Nearly every state has authorized prescription drug monitoring programs (PDMPs), and most are operational at this time. PDMPs are electronic systems for the monitoring of controlled substances and drugs of concern dispensed in the state or dispensed to an address in the state. PDMPs aim to detect and prevent the diversion and abuse of prescription drugs at the retail level, where no other automated information collection system exists, and to allow for the collection and analysis of prescription data more efficiently than states without such a program can accomplish.

In 2011 NSDUH indicated that illicit drug use is 16.2% among pregnant teens and 7.4% among

pregnant women aged 18 to 25 years.[13] From 2009 to 2012, incidence of Neonatal Abstinence Syndrome (NAS), defined as a withdrawal syndrome that occurs in opioid-exposed infants shortly after birth, increased nationally from 3.4 (95% confidence interval [CI]: 3.2-3.6) to 5.8 (95% CI 5.5-6.1) per 1,000 hospital births, reaching a total of 21,732 infants with the diagnosis. Aggregate hospital charges for NAS increased from $732 million to $1.5 billion ($P<0.001$), with 81% attributed to state Medicaid programs in 2012.[23] NAS incidence varied by geographic census division, with the highest incidence rate (per 1,000 hospital births) of 16.2 (95% CI 12.4-18.9) in the East South Central Division (Kentucky, Tennessee, Mississippi and Alabama) and the lowest in West South Central Division Oklahoma, Texas, Arkansas and Louisiana 2.6 (95% CI 2.3-2.9).[24]

Methadone

More than 30% of prescription opioid deaths involve methadone, even though only 2% of painkiller prescriptions are for this drug. Six times as many people died of methadone overdoses in 2009 than a decade before.[25]

Studies using medical examiner data suggested that more than three-quarters of methadone overdoses involved persons who were not enrolled in programs treating opioid addiction with methadone and that most persons who overdosed were using it without a prescription.[26]

Still, more than 4 million methadone prescriptions were written for pain in 2009, despite US Food and Drug Administration (FDA) warnings about the risks associated with this drug.

Methadone has pharmacologic properties unique among opioids, and as a result, a lack of knowledge about methadone among practitioners and patients has been identified as a factor contributing to the increased number of deaths observed in recent years.[28] Methadone's elimination half-life (8-59 hours) is longer than its duration of analgesic action (4-8 hours). In an FDA advisory issued in November 2006,[29] healthcare professionals were reminded that methadone's peak respiratory depressant effects typically occur later, and persist longer than its peak analgesic effects. The advisory notes that during treatment initiation, methadone's full analgesic effect is usually not attained until 3 to 5 days of dosing.

Deaths have been reported during conversion from chronic, high-dose treatment with other opioid agonists to methadone. It is critical to understand the pharmacokinetics of methadone when converting patients from other opioids to methadone. Particular vigilance is necessary during treatment initiation, during conversion from one opioid to another, and during dose adjustments. Also, there are pharmacokinetic and pharmacodynamic drug interactions between methadone and many other drugs. Thus drugs administered concomitantly with methadone should be evaluated for interaction potential.[29]

Heroin

The threat posed by heroin in the United States is serious and has increased since 2007. Heroin is available in larger quantities, used by a larger number of people, and is causing an increasing number

of overdose deaths. In 2013, 8,620 Americans died from heroin-related overdoses, nearly triple the number in 2010. Increased demand for, and use of, heroin is being driven by both increasing availability of heroin in the U.S. market and by some controlled prescription drug (CPD) abusers using heroin. CPD abusers who begin using heroin do so chiefly because of price differences, but also because of availability, and the reformulation of OxyContin®, a commonly abused prescription opioid.

Also, high purity batches of heroin sold in certain markets are causing users to accidentally overdose. There is an increase in new heroin initiates, many of whom are young and inexperienced. Abusers of prescription opioids (drugs with known compositions and concentrations) initiating use of heroin may encounter, an illicitly-manufactured drug with varying purities, dosage amounts, and adulterants; and the use of highly toxic heroin adulterants such as fentanyl in certain markets (see below). Further, heroin addicts who have stopped using heroin for a period of time (due to rehabilitation programs, incarceration, etc.) and subsequently return to using heroin are particularly susceptible to overdose, because their tolerance for the drug has decreased.

Heroin availability is increasing in areas throughout the United States. Availability levels are highest in the Northeast and in areas of the Midwest, according to law enforcement reporting. According to National Seizure System (NSS) data, heroin seizures in the United States increased 81% over 5 years, from 2,763 kg in 2010 to 5,014 kg in 2014. Traffickers are also transporting heroin in larger amounts. The average size of a heroin seizure in 2010 was 0.86 kg; in 2014, the average heroin seizure was 1.74 kg.[30]

Between 1980s and 1990s, the purity of the heroin brought into the United States increased significantly. In 1981, the average retail-level purity of heroin was 10%. By 1999, that had increased to an average of 40%. During the same time, the price per gram decreased greatly. In 1981, the average price per gram of pure heroin was $3,260 in 2012 U.S. dollars (USD) at the retail-level; by 1999, that price had decreased to $622 (2012 USD). Since that time, heroin prices have remained low, and heroin purity levels, while fluctuating, have remained elevated.[30]

When heroin is higher in purity, it can be snorted or smoked, which broadens its appeal. Many people who would never consider injecting a drug were introduced to heroin by inhalation. In the 1990s, the drug largely lost the stigma associated with injecting, and a new population of heroin users emerged. High-purity heroin is still commonly inhaled and, according to treatment officials, remains a common method of administration by new heroin initiates.

Current cocaine users outnumbered heroin users by approximately 5 times in 2013, but heroin-involved overdose deaths were almost twice those of cocaine. Deaths involving heroin are also increasing at a much faster rate than for other illicit drugs, more than tripling between 2007 (2,402) and 2013 (8,260).

Fentanyl

Fentanyl, a synthetic and short-acting opioid analgesic, is 50-100 times more potent than morphine and approved for managing acute or chronic pain associated with advanced cancer. Although

pharmaceutical fentanyl can be diverted for misuse, most cases of fentanyl-related morbidity and mortality have been linked to illicitly manufactured fentanyl and fentanyl analogs, collectively referred to as non-pharmaceutical fentanyl (NPF). NPF is sold via illicit drug markets for its heroin-like effect and often mixed with heroin and/or cocaine as a combination product—with or without the user's knowledge—to increase its euphoric effects.

In March 2015, the DEA issued a nationwide alert identifying fentanyl as a threat to public health and safety. The National Heroin Threat Assessment Summary, noted that beginning in late 2013 and throughout 2014, several states have reported spikes in overdose deaths due to fentanyl and its analog acetyl-fentanyl.

Similar to previous fentanyl overdose outbreaks, most of the more than 700 fentanyl-related overdose deaths reported to DEA during this timeframe were attributable to illicitly-manufactured fentanyl—not diverted pharmaceutical fentanyl—and either mixed with heroin or other diluents and sold as a highly potent form (sometimes under the street name "China White"). The DEA report noted that the true number of fentanyl deaths is most likely higher because many coroners' offices and state crime laboratories do not test for fentanyl or its analogs unless given a specific reason to do so.[32]

Fentanyl poses a significant danger to public health workers, first responders, and law enforcement personnel that may unwittingly come into contact with it either by absorbing through the skin or accidental inhalation of airborne powder. In August 2015, New Jersey law enforcement officers conducting a narcotics field test on an illicit substance experienced shortness of breath, dizziness, and respiratory distress after coming into contact with an unknown substance, which forensic laboratory testing determined to be a mix of cocaine, heroin, and fentanyl.[32]

Benzodiazepines And Other Sedative-Hypnotics

Emergency department visits involving benzodiazepines clearly outnumber those involving any of the other types of psychotherapeutic agents. The Drug Abuse Warning Network (DAWN)[33] estimates that 408,021 ED visits associated with nonmedical use of pharmaceuticals involved benzodiazepines in 2010 (the last year such data is available).[15] This is a dramatic increase from 2004 in which there were 170,471 ED visits attributed to benzodiazepines.

Because all benzodiazepines have abuse and dependence liability, patients cannot be switched from one benzodiazepine to another in hopes of decreasing a pattern of drug abuse or dependence behavior. Zolpidem, a nonbenzodiazepine, nonbarbiturate sedative, has been suggested to have little liability for physical dependence, but tolerance and withdrawal have been reported in association with its use as well.[33] Recent reports in the lay press have linked use of zolpidem to sleep walking, erratic driving, binge eating, and other similarly bizarre activities.

Benzodiazepines generally do not cause life-threatening respiratory depression (unless taken with other sedatives), as do the barbiturate-like drugs.[34] Long-term use of even therapeutic doses of benzodiazepines can cause physical dependence and withdrawal symptoms after abrupt

discontinuation.[34] Occurrence of hallucinations or seizures would indicate severe physical withdrawal.

Gradual tapering of dosage is also associated with less withdrawal and rebound anxiety than abrupt discontinuation. Treatment of sedative-hypnotic and benzodiazepine intoxication is summarized in **Table 65-1**. For additional information on benzodiazepine withdrawal, refer to Chapter 70.

TABLE 65-1 Pharmacologic Treatment of Substance Intoxication

Drug Class	Nonpharmacologic Therapy	Pharmacologic Therapy	Level of Evidence[a,b]
Benzodiazepines	Support vital functions	Flumazenil 0.2 mg/min IV initially, repeat up to 3 mg max.	AI
Alcohol, barbiturates, and sedative-hypnotics (nonbenzodiazepines)	Support vital functions	None	B3
Opiates	Support vital functions	Naloxone 0.4-2 mg IV every 3 minutes	A1
Cocaine and other CNS stimulants	Monitor cardiac function	Lorazepam 2-4 mg IM every 30 minutes to 6 hours as needed for agitation	B2
		Haloperidol 2-5 mg (or other antipsychotic agent) every 30 minutes to 6 hours as needed for psychotic behavior	B3
Hallucinogens, marijuana, and inhalants	Reassurance; "talk-down therapy"; support vital functions	Lorazepam and/or haloperidol as above	B3
Phencyclidine	Minimize sensory input	Lorazepam and/or haloperidol as above	B3

[a]Strength of recommendations, evidence to support recommendation, A, good; B, moderate; C, poor.

[b]Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from references 91 and 111.

CLINICAL PRESENTATION Benzodiazepine Intoxication and Withdrawal General

- The intoxicated patient may be in acute distress in overdoses or when benzodiazapines are combined with alcohol.

- Patients in withdrawal may also be in acute distress and should be treated with a benzodiazepine taper to prevent seizures.

Symptoms

- The patient may experience memory impairment, drowsiness, visual disturbances, confusion, and gastrointestinal disturbances. Patients may appear intoxicated, with slurred speech, poor coordination, swaying, and bloodshot eyes, with or without the odor of alcohol.
- Withdrawal symptoms include agitation and restlessness, dizziness, flu-like symptoms, impaired memory and concentration, nausea and vomiting, nightmares, visual disturbances, convulsions, and hallucinations.

Signs

- Hypotension or nystagmus may be observed, and urinary retention may occur.

Laboratory Tests

- Qualitative testing to confirm presence of benzodiazepines is useful for diagnostic purposes, but quantitative plasma concentrations are usually not clinically useful.

Carisoprodol

Carisoprodol is a prescription drug marketed since 1959 and used in primary care settings for the treatment of musculoskeletal conditions associated with muscle spasms and back pain. Its effectiveness for this use has been questioned.[35]

It is marketed in the United States as Soma as well as many generic versions. It is both structurally and pharmacologically related to meprobamate, a schedule IV substance. In fact, a substantial percentage of the drug is metabolized to meprobamate,[35] a drug with barbiturate-like properties.

In legitimate medical practice carisoprodol is used as an adjunct to rest, physical therapy, and other measures for relief of acute, painful musculoskeletal conditions.[35] Adverse effects are mostly related to the CNS: drowsiness, dizziness, vertigo, ataxia, tremor, agitation, irritability, headache, depressive reactions, syncope, and insomnia. Carisoprodol may also adversely affect cardiovascular (tachycardia, postural hypotension, and facial flushing), gastrointestinal (nausea, vomiting, hiccup, and epigastric distress), and hematologic systems. Carisoprodol overdose has resulted in stupor, coma, shock, respiratory depression, and death.[35]

The number of carisoprodol-related ED visits involving misuse or abuse by patients aged 50 or older tripled between 2004 and 2009 (from 2,070 to 7,115 visits). The majority of ED visits involving carisoprodol also involved other pharmaceuticals (77%); the most common combinations involved narcotic pain relievers (55%) and benzodiazepines (47%).[33]

Recognizing that prolonged abuse of carisoprodol at high dosage can lead to tolerance, dependence,

and withdrawal,[35] DEA issued a final rule to classify carisoprodol as a Schedule IV controlled substance effective from January 11, 2012.[36]

Dextromethorphan

Dextromethorphan abuse is one of the most common (and most dangerous) examples of over-the-counter (OTC) drug abuse.[37] Intoxication from consuming large doses of cough syrup is known on the street as "robodosing" or "robotripping." Handfuls of cough and cold remedies are sometimes called "skittles" because they look similar to the popular fruit candy. Dextromethorphan creates a depressant and sometimes profound hallucinogenic effect when taken in large doses. Since the drug is available OTC, it is easily procured by adolescents. Those who use the cough syrup to get high are sometimes called "syrup heads."

High doses induce effects that include hyperexcitability, lethargy, ataxia, slurred speech, diaphoresis, hypertension, nystagmus, and mydriasis. When taken at much higher doses, it acts as a dissociative anesthetic, similar to phencyclidine (PCP, "angel dust") and ketamine ("Special K"). These are the effects sought by those who use the drug to get high. At these high doses, dextromethorphan also is a CNS depressant.[38]

The recommended treatment for acute overdoses of dextromethorphan is naloxone. Although reports of its efficacy are mixed, it may be helpful in reversing the CNS depressant and neurologic effects.[38]

CNS STIMULANTS

Cocaine

Cocaine is perhaps the most behaviorally reinforcing of all drugs of abuse. Clinicians estimate that approximately 10% of people who begin to use the drug recreationally will go on to serious, heavy use. Once having tried cocaine, an individual cannot predict or control the extent to which he or she will continue to use the drug.

The most characteristic pharmacologic effect of cocaine is stimulation of the CNS. In the CNS, cocaine appears to mediate its effects primarily by blocking reuptake of catecholamine neurotransmitters such as norepinephrine and dopamine.

Cocaine is absorbed rapidly from virtually all sites of application. For many years, cocaine has been administered as the hydrochloride salt form, usually by inhalation, but also by injection. In the last 18 to 20 years, as the purity of cocaine hydrochloride obtained on the street declined, many users converted the cocaine hydrochloride to cocaine base, also known as "crack" or "rock." Smoking the drug leads to almost instant absorption and intense euphoria. Peak plasma concentrations of more than 900 ng/mL (mcg/L; 3.0 µmol/L) have been achieved following inhalation of cocaine base vapors, compared with concentrations of only 150 to 200 ng/mL (mcg/L; 0.49-0.66 µmol/L) achieved after inhalation of similar amounts of pure cocaine hydrochloride powder.[39]

The high from snorting can last 15 to 30 minutes, whereas that from smoking can last 5 to 10 minutes. Increased use can reduce the period of stimulation. An appreciable tolerance to the high can develop, and many addicts report that they seek but fail to achieve as much pleasure as they did from their first exposure. Scientific evidence suggests that the powerful neuropsychologic reinforcing property of cocaine is responsible for an individual's continued use despite harmful physical and social consequences.

Research has helped clarify certain patterns of cocaine use, such as combining cocaine and alcohol. Such drug use would seem counterintuitive because cocaine is a CNS stimulant, and alcohol a CNS depressant. In the presence of alcohol, cocaine is metabolized to cocaethylene, a longer-acting but potent psychoactive compound compared to the parent drug.[40,41] The risk of death from cocaethylene is greater than from cocaine. The cocaine-alcohol combination is one of the most commonly identified among individuals who come to hospital EDs with acute substance abuse problems.

Cocaine is metabolized and eliminated rapidly. The elimination half-life of cocaine is approximately 1 hour, and the duration of effect is very short.[39] The short duration of effect provides a powerful incentive for repeated use of the drug. Many users experience intense drug use cycling, sometimes lasting days, characterized by rapidly repeating doses of cocaine until their supply is exhausted. Laboratory monkeys, given a choice between food and cocaine around the clock for 8 days, consistently choose cocaine.

Complications of cocaine use frequently involve cardiovascular events.[42,43] Cocaine is a psychotomimetic drug, sometimes even at nontoxic doses. A kindling phenomenon has been described with cocaine in which neuronal function becomes altered with each dose of the drug. The psychosis is qualitatively very similar to a paranoid schizophrenic psychosis.[44] Although there is some controversy as to whether cocaine is associated with physical withdrawal on abrupt discontinuation, most clinicians feel that there is a characteristic syndrome of withdrawal effects, although they are not life-threatening.

Amphetamine, Methamphetamine, and Other Stimulants

The physiologic and psychologic effects of amphetamines and other stimulants are qualitatively similar to those of cocaine—they diminish fatigue, increase alertness, and suppress appetite. Pharmacologically, amphetamines increase the activity of catecholamine neurotransmitters (eg, norepinephrine and dopamine) by increasing release and by inhibiting the degradative enzyme monoamine oxidase.

Methamphetamine is used orally, intranasally, rectally, by intravenous injection, and by smoking. Immediately after inhalation or intravenous injection, the methamphetamine user experiences an intense sensation, called a "rush" or "flash," that lasts only a few minutes and is described as extremely pleasurable.[45]

Because methamphetamine elevates mood, people who experiment with it tend to use it with increasing frequency and in increasing doses, although this was not their original intent. The timing

and intensity of the “rush” that accompanies the use of methamphetamine, which is a result of the release of high levels of dopamine in the brain, depend in part on the method of administration.[45] Specifically, the effect is almost instantaneous when smoked or injected, whereas it takes approximately 5 minutes after snorting or 20 minutes after oral ingestion.[39,45] Prolonged use of methamphetamine can result in a tolerance for the drug and increased use at higher dosage levels, creating dependence. Such continual use of the drug with little or no sleep may lead to an extremely irritable and paranoid state. Discontinuing use of methamphetamine often results in a state of depression, as well as fatigue, anergia, and some types of cognitive impairment that can last from 2 days to several months.[45]

Negative consequences of methamphetamine abuse range from anxiety and insomnia to convulsions, paranoia, and brain damage. Methamphetamine-induced caries, or “meth mouth” is a characteristic pattern of dental decay commonly observed in patients that smoke methamphetamine.[46]

In addition to the many direct effects on methamphetamine users are the indirect impacts on individuals and society. Flammable ingredients that include acetone, red phosphorous, ethyl alcohol, and lithium metal are used in methamphetamine cookers, often with disastrous results. Fires and explosions often ensue, resulting in severe burns and uncovering laboratories to local law enforcement. Children of methamphetamine abusers are at high risk of neglect and abuse, and pregnant women’s use of methamphetamine can cause growth retardation, premature birth, and developmental disorders in neonates. Treatment for methamphetamine dependence is very difficult, and has a low success rate.[45]

According to the 2014 National Drug Threat Survey,[46] 31.8% of responding agencies indicated methamphetamine was the greatest drug threat in their areas. Also, 40.6% of responding agencies indicated that methamphetamine is highly available, meaning the drug is easily obtained at any time. The majority of methamphetamine available in the United States is Mexico-produced.[46]

The vast majority of methamphetamine laboratories seized in the United States are the small capacity production laboratories, also known as “one-pot” or “shake-and-bake” or “mom-and-pop” laboratories. These laboratories produce small amounts of methamphetamine—generally one to three grams per laboratory—generally for personal use or use among a small group of people.[46]

CLINICAL PRESENTATION Amphetamine Intoxication and Withdrawal General

- Amphetamine intoxication is an acute condition that may result in death. Pharmacotherapy may be indicated for symptomatic control of seizures.
- Patients may experience withdrawal symptoms for several days, but are usually not in acute distress. Treatment of withdrawal is supportive in nature. Pharmacotherapy is not effective to treat the symptoms of amphetamine withdrawal.

Symptoms

- Depression, altered mental status, drug craving, dyssomnia, and fatigue are all symptoms of withdrawal.

- Amphetamine intoxication may present as increased wakefulness, increased physical activity, decreased appetite, increased respiration, hyperthermia, and euphoria. Other CNS effects include irritability, insomnia, confusion, tremors, convulsions, anxiety, paranoia, chest pain, and aggressiveness. Hyperthermia and convulsions can result in death.

Signs

- Patients with amphetamine intoxication may present with tachycardia, hypertension, or stroke.

Laboratory Tests

- A qualitative urine screening for drugs of abuse is used for diagnostic purposes. Confirmatory blood tests with gas chromatography and mass spectrophotometry or liquid chromatography coupled tandem mass spectrometry may be used for verification.

In this process, ephedrine or pseudoephedrine is extracted from OTC cold and allergy tablets. Producers mix pseudoephedrine and other household items in a plastic soda-type bottle. The chemical reaction that produces methamphetamine reduces the ephedrine. Indeed, a synonym for methamphetamine is desoxy-ephedrine.[46]

Pharmacists should be wary of persons wishing to purchase large quantities of products containing nonprescription sympathomimetic products. As a precaution, federal legislation now mandates that pseudoephedrine-containing products be kept behind a counter, and suitable identification must be shown before they can be purchased.

Because the reaction is exothermic, this method of production is highly volatile and dangerous, and is susceptible to error resulting in fires or explosions. It also exposes bystanders to dangerous, sometimes lethal, chemicals. Although these laboratories produce very small amounts of methamphetamine, they produce large amounts of toxic waste. The DEA estimates that one pound of methamphetamine produced by a small capacity lab can produce five to six pounds of toxic waste.

Ecstasy and Other Methamphetamine Analogs

Several dozen analogs of amphetamine and methamphetamine are mildly hallucinogenic. Two methamphetamine analogs of most concern are 3,4-methylenedioxyamphetamine and especially 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy). The annual prevalence of Ecstasy declined significantly in 2014 from the previous year in all three grades, dropping from 4.1% to 3.5%. Over the past dozen years, the use of Ecstasy has changed quite a bit, with peak incidence in 2001 at 6.7% and decreasing each year until 2014.[14]

The effects of MDMA usually last approximately 4 to 6 hours. Users of the drug say that it produces profoundly positive feelings, empathy for others, elimination of anxiety, and extreme relaxation. MDMA is also said to suppress the need to eat, drink, or sleep, enabling users to endure 2- to 3-day

parties. Consequently, MDMA use sometimes results in severe dehydration or exhaustion. MDMA generally reduces inhibitions and creates a sense of euphoria, but it also can evoke anxiety and paranoia. Heavier doses generate depression, irrationality, and psychosis. Users claim they experience feelings of closeness with others and a desire to touch them.

MDMA use can result in a variety of acute psychiatric disturbances, including panic, anxiety, depression, and paranoid thinking. Physical symptoms include muscle tension, nausea, blurred vision, faintness, chills, and sweating. MDMA also increases the heart rate and blood pressure. Other effects include hyperthermia, dehydration, vomiting, tremors, loss of control over body movements, insomnia, convulsions, rapid eye movements, and teeth and jaw clenching.[47]

MDMA is perceived to be a harmless drug by many of its users, based in part on the fact that the risk of death is low compared with other drugs such as heroin and cocaine. However, mounting evidence points to neurotoxic effects of MDMA, involving a complex and incompletely understood mechanism. MDMA has been shown to destroy serotonin-producing neurons in animals, but further research is needed to understand the mechanism behind this loss of serotonin following MDMA exposure.[47]

Researchers have found that heavy MDMA users have memory problems that persist for at least 2 weeks after they have stopped using the drug.[48,49] McCann and colleagues[50,51] conducted several studies to determine the effects of MDMA use on cognitive performance. MDMA users and controls were found to perform similarly on several cognitive tasks. However, MDMA subjects had significant performance deficits on a sustained-attention task requiring arithmetic calculations, a task requiring complex attention and incidental learning, a task requiring short-term memory, and a task of semantic recognition and verbal reasoning. The authors believe that their data provide further evidence that MDMA is neurotoxic to brain serotonin neurons in humans, and the behavioral data suggest that brain serotonin injury is associated with subtle but significant cognitive deficits.

Manufacturers of illicit drugs sometimes substitute other, potentially more dangerous substances for the one the buyer is expecting. Other suppliers produce products adulterated with chemical byproducts of the incomplete processing of active ingredients. One such chemical, *para*-methoxyamphetamine, is a drastically more potent hyperthermic agent than MDMA, and deaths have been attributed to this agent.[52]

“Molly” (for “molecular”) is a purified form of MDMA that is typically ingested orally, or may be added to marijuana and smoked.[53] This form of MDMA is popular due to a faster time to peak, a reported cleaner feeling of euphoria, and a reported more subtle “come down” period. “Molly” is also rumored as a safer form of MDMA, since it supposedly contains no adulterants commonly found in the tablet form of MDMA.[53]

A very engaging and insightful article on the possible medical uses of MDMA was published recently[54] and the interested reader is encouraged to read it.

Synthetic Cathinones (A.K.A., Bath Salts)

2 Bath salts are a family of structurally related sympathomimetic, synthetic, designer drugs, known collectively as cathinones. Despite being marketed as “bath salts” or “plant food” and labeled “not for human consumption,” people use these substances for their amphetamine or cocaine like effects. The name “bath salts” appears to have been selected to disguise the true nature of these substances. They are available in small quantities (milligram or one-half gram packages) and obviously are not the same as legitimate commercial bath products that are used for taking a soothing bath. Since the time of their appearance in the recreational drug market, there have been numerous confirmed cases of abuse, dependence, severe intoxication, and deaths related to the consumption of synthetic cathinones.[55]

Catha edulis (Khat) is an evergreen slow-growing shrub or tree native to Ethiopia and cultivated in East Africa and the South West Arabian Peninsula that in recent years has been grown widespread in Europe as well.[56]

In areas where it is grown people use the fresh vegetable material (leaves, stems, and flower buds) of this plant for its stimulant effects. The fresh khat leaves contain 62 alkaloids, and two of these, cathine and cathinone, have been demonstrated to have amphetamine-like effects. Like amphetamines, cathine and cathinone are CNS stimulants, but their potency is less. Several studies have shown that the chronic use of this plant may produce various harmful effects, such as increased incidence of acute coronary vasospasm and myocardial infarction, esophagitis, gastritis, oral keratotic lesions, and liver toxicity.[56]

Most of the synthetic cathinones, first appearing as recreational drugs in the mid-2000s, are a ring-substituted cathinone closely related to the phenethylamine family. The synthetic cathinones are the beta-keto analogues of natural cathinone and differ from amphetamines by the presence of a ketone oxygen group at the beta-position.[56]

3 The pharmacology of these substances has not been extensively studied, but available information shows that these molecules may also inhibit monoamine oxidase. Within the class of synthetic cathinones there are considerable differences in pharmacology. The synthetic cathinones, pyrovalerone and methylenedioxypyrovalerone (MDPV), are highly potent and selective catecholamine transporter inhibitors but not substrate releasers. Mephedrone, methylone, ethylone, butylone, and naphyrone act as nonselective monoamine uptake inhibitors, similar to cocaine and, with the exception of naphyrone, also release serotonin, similar to MDMA. Cathinone and methcathinone are selective catecholamine uptake inhibitors and releasers, similar to their non-β-keto analogs amphetamine and methamphetamine.[56]

Case reports have revealed a variety of adverse effects associated with the use of bath salts, including tachycardia, hypertension, diabetic ketoacidosis, delusions, paranoid psychosis, hyperthermia, dizziness, agitation, headaches, hyponatremia, acute liver failure, and suicide. Fatal intoxication has been associated with members of this class of drugs.[56] One report[57] by the Substance Abuse and Mental Health Services Administration (SAMHSA) reveals that bath salts were linked to an estimated 22,904 visits to hospital EDs in 2011.

The report shows that about two-thirds (67%) of ED visits involving bath salts also involved the use of another drug. Only 33% of the bath salts-related visits to EDs involved just the use of bath salts; 15% of the visits involved combined use with marijuana or synthetic forms of marijuana, and 52% involved the use of other drugs.[57]

A particularly potent synthetic cathinone burst upon the scene in late 2014 and early 2015.[58,59] Known by its street name, "flakka" a single dose is about a tenth of a gram and costs just $4 to $5. People who take more than this small amount—either accidentally or purposefully—risk powerful side effects that include accelerated heart rate, anxiety, paranoia, agitation, and psychosis.[58]

The drug is particularly prevalent in some counties in Florida, Submissions for testing to the Florida Department of Law Enforcement's crime labs have grown from 38 in 2013 to 228 in 2014.[59] At the Broward County Florida Sheriff's Office laboratory, flakka submissions grew from fewer than 200 in 2014 to 275 in just the first three months of 2015. By August, 2015 there had been at least 33 deaths linked to the substance in the preceding 10 months.[59]

On July 9, 2012, President Barack Obama signed a law that classified certain synthetic cathinones and classes of related chemicals as Schedule I Controlled Substances.[57] Flakka and 9 similar drugs were placed into Schedule I on March 7, 2014, pursuant to the temporary scheduling provisions of the Controlled Substances Act.

HALLUCINOGENS

Lysergic acid diethylamide

The drugs commonly classified as hallucinogens are LSD, psilocybin, DMT, mescaline, and other related compounds. LSD is one of the most potent mood-changing chemicals. It is manufactured from lysergic acid, which is found in ergot, a fungus that grows on rye and other grains.

Pharmacologically, LSD and related drugs stimulate both presynaptic (5-hydroxytryptamine [5-HT]$_{1A}$ and 5-HT$_{1B}$) and postsynaptic (5-HT$_2$) serotonin receptors in the brain, which functionally can cause either agonist or antagonist effects on serotonin activity. Precisely how the hallucinogens exert their effects remains unclear. LSD is an extraordinarily potent compound, producing observable CNS effects at doses as low as 25 mcg. For an in-depth review of LSD, the reader is directed to a review by Passie and colleagues.[61] An interesting article on the history, current status, and future uses of LSD has been recently published.[62]

Designer Drugs

2 The past few years have witnessed the (re)-emergence of a number of very potent substances from three categories of drugs: the phenethylamine, the piperazines, and the tryptamines.[63] These drugs are marketed largely through Internet sales, and are abused by people of all ages. They are illegally manufactured or synthesized in clandestine laboratories; many designer drugs are offered as

a “research chemical,” “not for human consumption.”

Phenethylamines are ingested for their stimulant and hallucinogenic effects on the CNS. One group of the phenethylamine category that has received attention in recent years contains 2,5-dimethyoxy or 2C derivatives, such as 4-bromo-2,5-dimethyoxyphenethylamine (2C-B) or 2,5-dimethyoxy-4-iodophenethylamine (2C-I).

Due to their stimulant and hallucinogenic effects, piperazines have entered the club or party scene. Piperazines of concern include N-benzylpiperazine (BZP), 1-(3-trifluoromethylphenyl)-piperazine (TFMPP), and 1-(3-chlorophenyl)-piperazine (meta-chlorophenylpiperazine, mCPP). While mCPP is found in the illicit market, it is also a metabolite and starting material for the synthesis of several prescription drugs (eg, trazodone and nefazadone).[63]

Many of these emerging drugs have been added to DEA’s drugs and chemicals of concern list, and two drugs—BZP and TFMPP—appeared on the list of top 25 drugs reported to National Forensic Laboratory Information System (NFLIS) in 2008 (BZP only), 2009, and 2010.[64] For example, N,N-dimethyltryptamine (DMT), occurs naturally. South American snuffs and brews like Ayahuasca, prepared from a jungle vine (*Banisteriopsis caapi*), have been used in ancient medicinal and ritualistic practices that continue today. Like piperazines, tryptamines are hallucinogenic substances that are taken orally, or more rarely by smoking, snorting, or injection. Commonly abused tryptamines include DMT and 5-methoxy-N,N-diisopropyltryptamine (5-MeO-DIPT). Several of the drugs presented in this NFLIS Special Report have been named and federally scheduled under the Controlled Substances Act.

MARIJUANA

Marijuana continues to be the most commonly used illicit drug in the United States. An estimated 22.2 million Americans aged 12 or older in 2014 were current users of marijuana.[13] This number of past month marijuana users corresponds to 8.4% of the population aged 12 or older. The percentage of people aged 12 or older who were current marijuana users in 2014 was higher than the percentages from 2002 to 2013. According to the most recent MTFS[14] current daily marijuana use, defined as use on 20 or more occasions in the last 30 days, has fluctuated widely since the MTFS began. Among 12th-grade respondents, it rose from 6.0% in 1975 to 10.7% in 1978, declined to 1.9% by 1992, and then began to increase again. Current daily use reached 6.6% in 2011, the highest prevalence seen in three decades (ie, since 1981). In 2014 daily use of marijuana was at 5.8%. It is estimated that 3.8% of the world’s population used cannabis in the last year.[65]

Most users smoke marijuana in hand-rolled cigarettes (joints), while some use pipes or water pipes (bongs). Marijuana cigars called blunts have also become popular.[14] To make blunts, users slice open cigars and replace the tobacco with marijuana.

Marijuana’s effects begin immediately after the drug enters the brain and last from 1 to 3 hours. If marijuana is consumed in food or drink, the short-term effects begin more slowly, usually within 30 minutes to 1 hour, and last longer, for as long as 4 hours. Smoking marijuana delivers several times more of its major active ingredient, Δ-9-tetrahydrocannabinol (THC) into the blood than does eating

or drinking the drug.

Marijuana Potency

The principal psychoactive component of marijuana is THC. Hashish, the dried resin of the top of the plant, is much more potent than the plant itself. Increasingly sophisticated growing techniques have resulted in plants of greater potency.

The Potency Monitoring Project, funded by the National Institute on Drug Abuse, studies samples of drugs that have been confiscated by law enforcement personnel. The Project issues a Quarterly Report that publishes average concentrations of THC for various types of cannabis specimens. The specimens of domestically eradicated cannabis are sent to the project from state and local drug labs. In addition, specimens of seized cannabis are sent from DEA's field forensic labs.

CLINICAL PRESENTATION Marijuana Intoxication General Symptoms

- Patients intoxicated with marijuana may experience euphoria, sensory intensification, increased appetite, apathy, hallucinations, and dry mouth. Occasionally, marijuana use produces anxiety, fear, distrust, or panic.

Signs

- Tachycardia and conjunctival congestion may be observed in patients intoxicated with marijuana.

Laboratory Tests

- Although the duration of effect of marijuana may be only several hours, THC is detectable on toxicologic screening for up to 4 to 5 weeks, especially in chronic users.

In 1995, the average THC potency of leaf marijuana was 3.96%; in 2013, the average THC potency was 12.55%. In the 1990s, the average THC content of hash oil, a type of marijuana concentrate, ranged from 13% to 16%; today the average THC content of hash oil is 52%; one recent sample tested at 82%.[46]

The abuse of marijuana concentrates ("wax," "butane honey oil," etc.) is increasing throughout the United States. These concentrates can be abused using e-cigarettes or consumed in edibles, and have significantly higher THC levels than leaf marijuana. Highly flammable butane gas is used to extract the THC from the marijuana leaf, and has resulted in explosions, injuries, and deaths.[46,66]

Harmful Effects of Marijuana

Marijuana has been used widely and is believed by many to be a relatively harmless, nonaddictive intoxicant. The DSM-5 has a classification called Cannabis Use Disorder.[16] New to DSM-5 is the recognition that abrupt cessation of daily or near-daily cannabis use often results in the onset of a cannabis withdrawal syndrome. Common symptoms of withdrawal include irritability, anger or

aggression, anxiety, depressed mood, restlessness, sleep difficulty, and decreased appetite or weight loss. Although typically not as severe as alcohol or opiate withdrawal, the cannabis withdrawal syndrome can cause significant distress and contribute to difficulty quitting or relapse among those trying to abstain.

Scientific research has found that 1 in 10 marijuana users will become addicted to the drug. And if one begins in adolescence, that number rises to 1 in 6.[67] Acutely, marijuana has many of the effects of alcohol—sedation, a decrease in reactivity and ability to perform complex tasks, and disinhibition. Endocrine effects including amenorrhea, decreased testosterone production, and inhibition of spermatogenesis have been demonstrated. Marijuana is associated with an amotivational syndrome characterized by a behavioral pattern of apathy, dullness, impaired judgment, decreased concentration and memory, loss of interest in personal hygiene, and a general reduction of goal-directed behavior.[68]

Science confirms that the adolescent brain, particularly the part of the brain that regulates the planning of complex cognitive behavior, personality expression, decision making, and social behavior, is not fully developed until the early to mid-20s. Developing brains are especially susceptible to all of the negative effects of marijuana and other drug use.[69]

One of the most well designed studies[70] on marijuana and intelligence, released in 2012, found that marijuana use reduces IQ by as much as eight points by age 38 among people who started using marijuana regularly before age 18 but then stopped. The purpose of the study was to test the association between persistent cannabis use and neuropsychological decline and determine whether decline is concentrated among adolescent-onset cannabis users. Participants were members of the Dunedin Study, a prospective study of a birth cohort of 1,037 individuals followed from birth (1972/1973) to age 38 years. Cannabis use was ascertained in interviews at ages 18, 21, 26, 32, and 38 years. Neuropsychological testing was conducted at age 13 years, before initiation of cannabis use, and again at age 38 years, after a pattern of persistent cannabis use had developed. Persistent cannabis use was associated with neuropsychological decline broadly across domains of functioning, even after controlling for years of education. Informants also reported noticing more cognitive problems for persistent cannabis users. Impairment was concentrated among adolescent-onset cannabis users, with more persistent use associated with greater decline. Further, cessation of cannabis use did not fully restore neuropsychological functioning among adolescent-onset cannabis users. Findings are suggestive of a neurotoxic effect of cannabis on the adolescent brain and highlight the importance of prevention and policy efforts targeting adolescents.[70]

A recent study found that the prevalence of marijuana use among U.S. adults doubled over the past decade.[71] Face-to-face interviews conducted in surveys of 2 nationally representative samples of U.S. adults: the National Epidemiologic Survey on Alcohol and Related Conditions (data collected April 2001-April 2002; *N* = 43,093) and the National Epidemiologic Survey on Alcohol and Related Conditions-III (data collected April 2012-June 2013; *N* = 36,309). In total, 79,000 people were interviewed on alcohol use, drug use and related psychiatric conditions during the 2001-2002 and 2012-2013 surveys.[71]

The percentage of Americans who reported using marijuana in the past year more than doubled between 2001-2002 and 2012-2013, and the increase in marijuana use disorder during that time was nearly as large. Past year marijuana use rose from 4.1% to 9.5% of the U.S. adult population, while the prevalence of marijuana use disorder rose from 1.5% to 2.9%.[71]

In this study, approximately 30% of people who used marijuana in the past year met criteria for marijuana use disorder during 2012 to 2013, as defined by the DSM-5. About 3 in 10 people who use marijuana met the criteria for addiction.[71]

When examined by age, young adults (ages 18-29) were found to be at highest risk for marijuana use and marijuana use disorder, with use increasing from 10.5% to 21.2% and disorder increasing from 4.4% to 7.5% over the past decade.[71]

Marijuana and Driving

Studies have shown that marijuana impairs driving performance, increasing lane weaving, and that since the legalization of medical marijuana in Colorado, drivers involved in fatal motor vehicle crashes are significantly more likely to test positive for marijuana use.[72,73]

As marijuana and alcohol are frequently used together, more research is needed to understand the effects of combined use. Studies suggest that using marijuana and alcohol together impairs driving more than either substance alone, and that alcohol use may increase the absorption of THC, the psychoactive chemical found in marijuana.[72]

Along with the increased prevalence of marijuana smoking, rates of driving under the influence of cannabis have also risen in recent years. Studies show that approximately 6% to 11% of fatal accident victims test positive for THC. In many of these cases alcohol is detected as well.[74] A systematic review and meta-analysis was conducted to determine whether the acute consumption of cannabis by drivers increases the risk of motor vehicle collisions.[75] The report included nine studies. The authors conclude that acute cannabis consumption is associated with an increased risk of a motor vehicle crash, especially for fatal collisions. Another meta-analysis showed an estimated odds ratios relating marijuana use to crash risk reported in included studies ranged from 0.85 to 7.16.[76]

Medical Marijuana

Since 1996, 23 states now have medical marijuana laws, and four states, as well as the District of Columbia, have legalized marijuana for recreational use. Some believe that the widespread use of medical marijuana is a thinly veiled strategy for the future legalization of recreational as well as medicinal use. Vague state laws governing medical marijuana have allowed recreational users of the drug to take advantage of marijuana dispensaries. Obtaining a license to use marijuana is not difficult. For example, on the boardwalk of Venice Beach, California, pitchmen dressed in marijuana green clothing approach passers-by with offers of a $35, 10-minute evaluation for a medical marijuana recommendation for everything from cancer to appetite loss.[77]

Clinical Controversy...

The mere mention of the words "medical marijuana" is bound to evoke strong emotions among laypersons and healthcare professionals alike. While the federal government continues to enforce laws that make possession and use of marijuana illegal, regardless of the intended purpose, at last count twenty-three states now have medical marijuana laws and four states, as well as the District of Columbia, have legalized marijuana for recreational use. While the safety and efficacy of marijuana to treat certain identifiable medical conditions has been confirmed, many other uses are supported by anecdote or limited clinical experience. However, the debate involves much more than whether cannabis works or not to treat illness. Instead, there are political, social, economic, and religious considerations that cloud the controversy over whether marijuana should be legalized for medical purposes. This debate is bound to continue for years to come.

Designing and conducting adequate research studies of the beneficial effects of marijuana present some methodological challenges.[78] Smoked marijuana varies by dose, due to individual differences in absorption and metabolism in the liver, as well as puff frequency, depth of inhalation, and retention of inhaled smoke. Two comprehensive and dispassionate reviews[79,80] of medical marijuana have been published, and the reader is encouraged to consult these for further information.

Synthetic Cannabinoids

3 Over the past several years, recreational use of synthetic cannabinoid compounds has been increasing in the United States. Known colloquially as "K2," "Spice," "Aroma," "Mr. Smiley," "Zohai," "Eclipse," "Black Mamba," "Red X Dawn," "Blaze," and "Dream," these products were not listed as controlled substances until somewhat recently. As a result, they were available at gas stations, convenience stores, and on the Internet.

Following identification of THC in 1964 and the CB l and CB 2 cannabinoid receptors in the 1980s, there was a pharmaceutical effort to synthesize cannabinoid receptor agonists for potential therapeutic indications like nausea and pain. The largest structural group of synthetic cannabinoid receptor agonists is the JWH compounds named after John W. Huffman, an organic chemist at Clemson University, who synthesized many of these compounds.[81] The vast majority of these efforts never reached commercial fruition. However, independent chemists now use this publicly available research to produce synthetic cannabinoids.

Synthetic cannabinoids produce a combination of adverse effects that resemble intoxication from Δ-9-THC, the psychoactive component of marijuana. However, synthetic cannabinoids appear to be more potent and may stay active in the body longer than Δ-9-THC. The adverse effects of synthetic cannabinoids include severe agitation, anxiety, nausea, vomiting, tachycardia, elevated blood pressure, tremors, seizures, hallucinations, paranoid behavior, and nonresponsiveness. After regular consumption, withdrawal signs and symptoms have been observed. Death after use of synthetic cannabinoids has also been reported.[76]

3 Currently there are over 100 compounds referred to as "synthetic marijuana."[82] The finished

salable products consist of psychoactively inert dry plant material sprayed or otherwise mixed with these synthetic cannabinoid receptor agonists.[83,84]

Symptoms of synthetic cannabinoid toxicity are similar to the euphoric and psychoactive effects of marijuana with additional sympathomimetic symptoms, including severe agitation and anxiety, extreme tachycardia, hypertension, nausea and vomiting, muscle spasms, seizures, tremors, diaphoresis, and restlessness. Intense hallucinations and psychotic episodes, and suicidal and other harmful thoughts and/or actions have also been reported.[85,86] Cohen et al. published one of the first articles in the medical literature describing the effects of synthetic cannabinoid intoxication.[87]

Gunderson et al. have published a systematic review of the effects of synthetic cannabinoids and their psychosocial implications.[88] Additional information on synthetics can be found at the web site of the U.S. Office of National Drug Control Policy.[89]

INHALANTS

Inhalants are a diverse group of substances that include volatile solvents, gases, and nitrites that are sniffed, snorted, huffed, or bagged to produce intoxicating effects similar to those of alcohol. These substances are found in common household products such as glues, lighter fluid, cleaning fluids, paint products, nail polish remover, gasoline, rubber glue, waxes, and varnishes. Chemicals found in these products include toluene, benzene, methanol, methylene chloride, acetone, methylethyl ketone, methylbutyl ketone, trichloroethylene, and trichloroethane. The gas used as a propellant in canned whipped cream and in small metallic containers called “whippets” (used to make whipped cream) is nitrous oxide or “laughing gas.”

Space limitation prevents an in-depth discussion of inhalants, and the interested reader is referred to past editions of this text or at the NIDA website.[90]

TREATMENT

Acute Drug Intoxications

4 Treatment of drug intoxication, summarized in **Table 65-1**, is primarily supportive. Vital functions are maintained while waiting for the drug to be eliminated. Whenever possible, drug therapy should be avoided because psychotropic drug therapy has the potential for worsening a toxic reaction to another psychoactive agent; however, when patients are agitated, combative, assaultive, hallucinating, or delusional, drug therapy may be required. Toxicology screens are useful in the evaluation and treatment process, but knowledge of the metabolism of the suspected drug and its excretion patterns is important for proper interpretation of test results.

CLINICAL PRESENTATION Opioid Intoxication and Withdrawal General

- Onset of the acute phase of withdrawal ranges from a few hours after stopping heroin to 3 to 5 days after stopping methadone. The duration of withdrawal ranges from 3 to 14 days.

- Opioid withdrawal is not fatal unless there is a concurrent medical problem of major concern.
- The presence of delirium should raise the question of concurrent withdrawal from another drug, such as alcohol, or another cause of delirium possibly secondary to drug use.

Symptoms

- During withdrawal, patients can experience piloerection, insomnia, muscle aches, and yawning. While intoxicated, patients can experience euphoria, dysphoria, apathy, sedation, or attention impairment.

Signs

- Fever, lacrimation, diaphoresis, or diarrhea may be observed during withdrawal. Motor retardation, slurred speech, and miosis may be observed during intoxication.

Laboratory Tests

- Treatment is based more on clinical presentation because plasma opioid levels may not be clinically useful.

Other Diagnostic Tests

- Arterial blood gases, pulse oximetry, and pulmonary function tests are useful to assess respiratory depression.

Flumazenil can be used to reverse toxic effects of benzodiazepines. Naloxone can be used to reverse the effects of opiates. The usual dosage for naloxone in acute opiate toxicity is 0.4 to 2 mg intravenously, given approximately every 3 minutes as necessary. In some instances a naloxone infusion could be administered since the half-life of the opiate is likely to be longer than that of naloxone (**Table 65-2**). Although naloxone is effective in reversing opiate overdose, it also can precipitate physical withdrawal in physically dependent patients. An excellent comprehensive review of the management of opioid analgesic overdose was published in 2012.[91]

TABLE 65-2 How to Use a Naloxone Infusion

1. If a naloxone bolus (start with 0.04 mg IV and titrate) is successful, administer two thirds of the effective bolus dose per hour by IV infusion; frequently reassess the patient's respiratory status
2. If respiratory depression is not reversed after the bolus dose:

   Intubate the patient, as clinically indicated

   Administer up to 10 mg of naloxone as an IV bolus. If the patient does not respond, do not initiate an infusion
3. If the patient develops withdrawal after the bolus dose:

Allow the effects of the bolus to abate

If respiratory depression recurs, administer half of this new bolus dose and begin an IV infusion at two thirds of the initial bolus dose per hour. Frequently reassess the patient's respiratory status

4. If the patient develops withdrawal signs or symptoms during the infusion:

   Stop the infusion until the withdrawal symptoms abate

   Restart the infusion at half the initial rate; frequently reassess the patient's respiratory status

   Exclude withdrawal from other xenobiotics

5. If the patient develops respiratory depression during the infusion:

   Readminister half of the initial bolus and repeat until reversal occurs

   Increase the infusion by half of the initial rate; frequently reassess the patient's respiratory status

   Exclude continued absorption, readministration of opioid, and other etiologies as the cause of the respiratory depression

Data from reference 112.

Intoxication with stimulants, including cocaine, is treated pharmacologically only if the patient is overtly psychotic and agitated.[92,93] Injectable benzodiazepines, usually lorazepam 2 to 4 mg intramuscularly every 30 minutes to 6 hours as necessary, can be used for agitation. Antipsychotic drugs can be used on a short-term basis, primarily in patients with psychotic symptoms, and usually at relatively low doses, such as haloperidol 2 to 5 mg intramuscularly every 30 minutes to 6 hours as necessary, followed by 5 to 15 mg orally per day in single or divided doses if the patient is still psychotic after initial treatment.[92]

An evidence-based guideline gives precise recommendations for treating the cardiovascular complications of cocaine abuse and provides insight into the epidemiology, pathophysiology, treatment, and prognosis of the cardiac effects of cocaine.[94] Seizures generally are treated supportively. Intravenous lorazepam or diazepam can be used if seizures progress to status epilepticus.[92]

Hallucinogen intoxication is treated in a manner similar to stimulant intoxication. Drug therapy often can be avoided because patients can respond to careful reassurance, or so-called talk-down therapy. When necessary, short-term antianxiety and/or antipsychotic drug therapy can be used, as described previously.

Withdrawal

5 Treatment of drug withdrawal is the primary indication for drug therapy in substance-related disorders. Goals of drug therapy include prevention of progression of withdrawal to life-threatening severity and enabling the patient to be sufficiently comfortable and functional to participate in a behavioral treatment program and supportive drug therapy. The clinician should remember that withdrawal is usually part of a substance dependence disorder. In drug therapy for withdrawal, it is important to avoid reinforcing the patient's drug-seeking and drug-use behavior to the extent possible. Patients must be educated to deal with the stress of withdrawal without seeking drugs. Treatment of drug withdrawal is summarized in **Table 65-3**.

TABLE 65-3 Treatment of Withdrawal from Some Common Drugs of Abuse

Drug or Drug Class	Pharmacologic Therapy	Level of Evidence[a,b]
Benzodiazepines		
Short to intermediate acting	Lorazepam 2 mg three to four times a day; taper over 5-7 days	A1
Long-acting	Lorazepam 2 mg three to four times a day; taper over additional 5-7 days	A1
Barbiturates	Pentobarbital tolerance test; initial detoxification at upper limit of tolerance test; decrease dosage by 100 mg every 2-3 days	B3
Opiates	Methadone 20-80 mg orally daily; taper by 5-10 mg daily or buprenorphine 4-32 mg orally daily, or clonidine 2 mcg/kg three times a day × 7 days; taper over additional 3 days	A1 (methadone and buprenorphine) B1 (clonidine)
Mixed-substance withdrawal		
Drugs are cross-tolerant	Detoxify according to treatment for longer-acting drug used	B3
Drugs are not cross-tolerant	Detoxify from one drug while maintaining second drug (cross-tolerant drugs), then detoxify from second drug	B3
CNS stimulants	Supportive treatment only; pharmacotherapy often not used; bromocriptine 2.5 mg three times a day or higher may be used for severe craving associated with cocaine withdrawal	B2

[a]Strength of recommendations, evidence to support recommendation, A, good; B, moderate; C, poor.

[b]Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from reference 45, 91 and 111.

CLINICAL PRESENTATION Cocaine Intoxication and Withdrawal General

- In overdoses, cocaine is a CNS and cardiac stimulant. Cocaine-related deaths are often a result of cardiac arrest or seizures followed by respiratory arrest.

Symptoms

- Symptoms of intoxication include motor agitation, elation, euphoria, grandiosity, loquacity, hypervigilance, sweating or chills, nausea, and vomiting.
- Symptoms of withdrawal include fatigue, sleep disturbances, nightmares, depression, and changes in appetite.
- High doses of cocaine and/or prolonged use can trigger paranoia.

Signs

- Tachycardia, mydriasis, and either elevated or lowered blood pressure may be observed with overdose. Cardiac abnormalities (eg, arrhythmias) and respiratory depression may be observed with overdose. Bradyarrhythmias, myocardial infarction, and tremors may be observed in acute withdrawal. Prolonged cocaine snorting can result in ulceration of the mucous membranes of the nose and can damage the nasal septum enough to cause it to collapse.

Laboratory Tests

- Qualitative urine screening tests for drugs of abuse are useful, followed by confirmatory testing if necessary. Levels of the primary metabolite, benzoylecgonine, may help diagnose acute cocaine toxicity.

Other Diagnostic Tests

- Abnormal electroencephalograms may be observed with patients in acute withdrawal.

CNS Depressant Withdrawal

Benzodiazepines

5 Treatment of benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal. The major difference in management is the length of treatment.[95] The onset of withdrawal symptoms in patients physically dependent on the long-acting benzodiazepines can be delayed up to 7 days after discontinuation of the drug. A common approach in detoxification of such patients is to initiate treatment at usual dosages (chlordiazepoxide orally 50 mg 3 times a day; lorazepam orally 2 mg 3 times a day) and to maintain the initial dosage for 5 days, with gradual tapering over an additional 5 days. Detoxification in patients physically dependent on shorter-acting benzodiazepines is similar to treatment of alcohol withdrawal.[95]

Among the benzodiazepines, alprazolam has been suggested to be more difficult to taper and

discontinue than the other benzodiazepines.[95] A longer, more gradual taper of the benzodiazepine used for detoxification can be needed. With all benzodiazepines, protracted minor abstinence symptoms—such as anxiety, insomnia, irritability, sensitivity to light and sound, and muscle spasms—can remain for several weeks in patients with a history of long term exposure, even after the acute phase of benzodiazepine withdrawal is complete.[95]

Opiates

Opiate withdrawal syndrome is similar to a severe case of influenza. It is not life-threatening unless there is a concurrent life-threatening medical condition. Observable signs of withdrawal should be noted before initiation of drug therapy. Characteristic signs and symptoms of opiate withdrawal include pupillary dilatation, lacrimation, rhinorrhea, piloerection ("gooseflesh"), yawning, sneezing, anorexia, nausea, vomiting, and diarrhea. Seizures do not occur. Onset and duration of withdrawal symptoms and the time of peak occurrence depends on the half-life of the drug involved. Typically heroin withdrawal reaches a peak within 36 to 72 hours of discontinuation and can last for 7 to 10 days. For methadone, symptoms peak at 72 hours but can last for 2 weeks or more.

In the past, drug therapy for opioid withdrawal had typically been methadone, a synthetic opiate. Methadone is administered in decreasing doses over a period not exceeding 30 days (short-term detoxification) or 180 days (long-term detoxification). With methadone there were limited provisions for take-at-home dosing of methadone because of concern about the diversion of these drugs to illicit use.[96,97]

The American Society of Addiction Medicine recently published a practice guideline for the use of medication in the treatment of addiction involving opioid use.[98]

Use Of Buprenorphine In Opiate Withdrawal and Maintenance

6 In 2002, buprenorphine was approved for opioid withdrawal. Prior to the passage of the federal Drug Addiction Treatment Act (DATA) of 2000,[99] office-based management of opioid dependence was illegal because existing federal laws prohibited physicians from prescribing narcotics for the sole purpose of maintaining a patient in a narcotic-addicted state.

Sublingual buprenorphine is available in the United States in three formulations. When buprenorphine with naloxone is administered sublingually, the naloxone component produces no clinically significant effect; however, after parenteral administration, naloxone-induced opioid antagonism occurs resulting in symptoms of withdrawal.[100,101]

The single ingredient and naloxone combination tablet formulations were introduced in the United States in January 2003, and a mucoadhesive combination film formulation was introduced in September 2010. In the combination tablets and film, naloxone is incorporated in a fixed ratio (1 mg naloxone per 4 mg buprenorphine) to deter abuse by parenteral routes, such as nasal insufflation ("snorting") or injection.

To qualify to prescribe buprenorphine, physicians must be board certified in addiction medicine/psychiatry or hold other special credentials, and physicians are required to obtain 8 hours of authorized training before they can prescribe medications for office-based treatment of opioid dependence.[99] DATA 2000, as amended in December 2006, specifies that an individual physician may have a maximum of 30 patients on opioid therapy at any one time for the first year. One year after the date on which a physician submitted the initial notification, the physician may submit a second notification of the need and intent to treat up to 100 patients.[99]

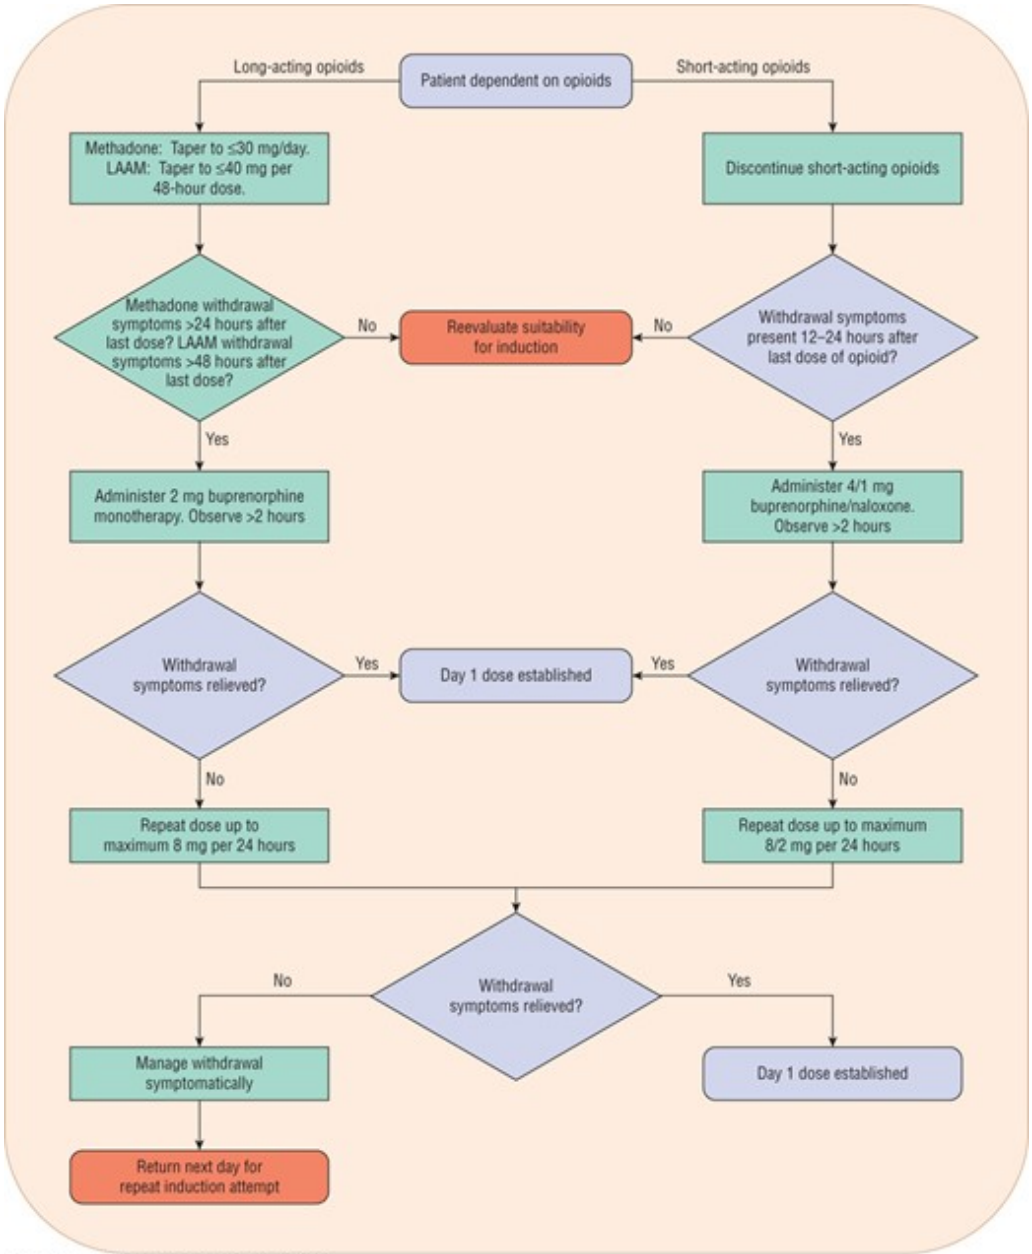
Medically supervised withdrawal with buprenorphine consists of an induction phase and a dose-reduction phase. Best practice guidelines collectively called Treatment Improvement Protocols (TIPs) are periodically issued for treatment of SUDs. TIP 40 (the guideline for the Use of Buprenorphine in the Treatment of Opioid Addiction),[102] provides consensus- and evidence-based guidance on the use of buprenorphine.

The statement recommends that patients dependent on short-acting opioids (eg, hydromorphone, oxycodone, and heroin) be inducted directly onto buprenorphine/naloxone tablets. The use of buprenorphine (either as buprenorphine monotherapy or buprenorphine/naloxone combination treatment) to taper off long-acting opioids should be considered only for those patients who have evidence of sustained medical and psychosocial stability, and should be undertaken in conjunction and in coordination with patients' overall opioid treatment programs (OTPs).[93]

6 7 Maintenance treatment with buprenorphine for opioid addiction consists of three phases: (1) induction, (2) stabilization, and (3) maintenance.[101] Induction is the first stage of buprenorphine treatment and involves helping patients begin the process of switching from the opioid of abuse to buprenorphine. The goal of the induction phase is to find the minimum dose of buprenorphine at which the patient discontinues or markedly diminishes use of other opioids and experiences no withdrawal symptoms, minimal or no side effects, and no craving for the drug of abuse. The consensus panel recommends that the buprenorphine/naloxone combination be used for induction treatment (and for stabilization and maintenance) for most patients. The consensus panel further recommends that initial induction doses be administered as observed treatment; further doses may be thereafter provided via prescription. To minimize the chances of precipitating withdrawal, patients who are transferring from long-acting opioids (eg, methadone, sustained-release morphine, and sustained-release oxycodone) to buprenorphine should be inducted using buprenorphine monotherapy, but switched to buprenorphine/naloxone soon thereafter. Induction protocols are shown in **Figure 65-1**.

FIGURE 65-1

Determining the induction dose for days 1 to 2 of buprenorphine therapy.



The stabilization phase begins when a patient is experiencing no withdrawal symptoms, is experiencing minimal or no side effects, and no longer has uncontrollable cravings for opioid agonists. Dosage adjustments may be necessary during early stabilization, and frequent contact with the patient increases the likelihood of compliance. The longest period that a patient is on buprenorphine is the maintenance phase. This period may be indefinite. During the maintenance phase, attention must be focused on the psychosocial and family issues that have been identified during the course of treatment as contributing to a patient's addiction.[102]

Some other issues related to opioid abuse that need to be addressed during maintenance treatment include, but are not limited to, the following:[102]

- Psychiatric comorbidity
- Somatic consequences of drug use

- Family and support issues
- Structuring of time in prosocial activities
- Employment and financial issues
- Legal consequences of drug use
- Other drug and alcohol abuse

A systematic review was published in 2009[94] evaluating the withdrawal component of buprenorphine treatment, including 21 studies involving 1,736 participants. The major comparisons for buprenorphine were with methadone (5 studies) and clonidine or lofexidine (12 studies). Five studies compared different rates of buprenorphine dose reduction.

The authors concluded that severity of withdrawal is similar for withdrawal managed with buprenorphine and withdrawal managed with methadone, but withdrawal symptoms may resolve more quickly with buprenorphine. It appears that completion of withdrawal treatment may be more likely with buprenorphine relative to methadone (RR 1.18; 95% CI, 0.93-1.49; $P = 0.18$) but more studies are required to confirm this.[103]

A more recent study[104] was published examining outcomes over 42 months in the Prescription Opioid Addiction Treatment Study (POATS). POATS was a multi-site clinical trial lasting up to 9 months, examining different durations of buprenorphine-naloxone treatment plus standard medical management for prescription opioid dependence, with participants randomized to receive or not receive additional opioid drug counseling. Telephone interviews were administered approximately 18, 30, and 42 months after main-trial enrollment.

At Month 42, 31.7% were abstinent from opioids and not on agonist therapy; 29.4% were receiving opioid agonist therapy, but met no symptom criteria for current opioid dependence; 7.5% were using illicit opioids while on agonist therapy; and the remaining 31.4% were using opioids without agonist therapy. Participants reporting a lifetime history of heroin use at baseline were more likely to meet DSM-IV criteria for opioid dependence at month 42 (OR = 4.56, 95% CI = 1.29-16.04, $p < .05$). Engagement in agonist therapy was associated with a greater likelihood of illicit-opioid abstinence. Eight percent ($n = 27/338$) used heroin for the first time during follow-up; 10.1% reported first-time injection heroin use.

The authors concluded that long-term outcomes for those dependent on prescription opioids demonstrated clear improvement from baseline. However, a subset exhibited a worsening course, by initiating heroin use and/or injection opioid use.

Unfortunately, buprenorphine itself can be abused, and in fact, abuse is common worldwide. In one study[105] rates of abuse and diversion of three sublingual buprenorphine formulations (single ingredient tablets; naloxone combination tablets and film) were compared. Data were obtained from the Researched Abuse, Diversion, and Addiction-Related Surveillance (RADARS®) System Poison Center, Drug Diversion, OTP, Survey of Key Informants' Patients (SKIP), and College Survey Programs

through December 2012.

Abuse rates in the OTP, SKIP, and College Survey Programs were greatest for single ingredient tablets, and abuse rates in the Poison Center Program and illicit diversion rates were greatest for the combination tablets. Abuse rates with combination film were significantly less than rates for either tablet formulation in all programs. In some instances, the film version can be abuse by injecting the soluble film.[105] Other studies have reported on the same phenomenon of injection of the soluble film.[97]

5 A rapid opioid detoxification (ROD) technique has been developed that is designed to shorten detoxification by precipitating withdrawal through the administration of opioid antagonists such as naloxone or naltrexone.[107] This approach is thought to have the advantage of getting patients through detoxification rapidly, minimizing the risk of relapse, and initiating treatment more quickly with naltrexone maintenance combined with suitable psychosocial interventions. Ultra-rapid opioid detoxification (UROD) represents a variant of this technique in which patients undergo opioid antagonist–precipitated withdrawal while under general anesthesia or heavy sedation. In the United States, there has been a rapid proliferation of programs offering ultrarapid detoxification, with some programs charging up to $15,000 per treatment. Rapid detoxification remains unproven and controversial.

Antagonist-induced withdrawal is more intense but less prolonged than withdrawal managed with reducing doses of methadone, and doses of naltrexone sufficient for blockade of opioid effects can be established significantly more quickly with antagonist-induced withdrawal than withdrawal managed with clonidine and symptomatic medications. The level of sedation does not affect the intensity and duration of withdrawal, although the duration of anesthesia may influence withdrawal severity. There is a significantly greater risk of adverse events with heavy, compared to light, sedation (RR 3.21, 95% CI 1.13-9.12, $P = 0.03$) and probably with this antagonist-induced withdrawal compared to other forms of detoxification.[107]

The ASAM has issued its policy statement regarding rapid and UROD.[108] The policy reads as follows:

1. Opioid detoxification alone is not a treatment of opioid addiction. ASAM does not support the initiation of acute opioid detoxification interventions unless they are part of an integrated continuum of services that promote ongoing recovery from addiction.

2. Ultra-rapid opioid detoxification is a procedure with uncertain risks and benefits, and its use in clinical settings is not supportable until a clearly positive risk-benefit relationship can be demonstrated. Further research on UROD should be conducted.

3. Although there is medical literature describing various techniques of ROD, further research into the physiology and consequences of ROD should be supported so that patients may be directed to the most effective treatment methods and practices.

4. Prior to participation in any particular modality of opioid detoxification, a patient should be provided with sufficient information to allow him/her to provide informed consent. This should

include information about the risks of termination of a treatment of prescribed agonist medications such as methadone or buprenorphine, as well as the need to comply with medical monitoring of their clinical status for a defined period of time following the procedure to ensure a safe outcome. Patients should also be informed of the risks, benefits and costs of alternative methods of available treatment.

DESIRED OUTCOMES

Substance Dependence

8 The treatment of drug dependence is primarily behavioral. The patient generally is taught that complete abstinence is the only realistic alternative to a life of uncontrollable drug use and despair that ultimately will end in death, and that there is no intermediate, controllable level of drinking or use of another drug. There may be an extremely few individuals who can return to controllable levels of drinking alcohol, but it is impossible to predict who these individuals are. The prospect of life without alcohol or other drugs is incomprehensible to many patients. Entry into treatment often is facilitated by some type of leverage that the drug-dependent person associates with negative consequences, such as potential loss of job, divorce, legal problems, or deteriorating physical health. Early treatment is directed at penetrating the denial of a problem that is always present. The patient must be educated as to the disease of addiction, the effects of drugs, and the permanence of the condition.

As evidenced by the approval of the two buprenorphine products, there has been a trend toward outpatient treatment for drug dependence, caused in part by cost-containment efforts. Inpatient treatment programs can cost as much as $20,000 for a 4-week stay. When withdrawal symptoms are mild to moderate and there are no other medical indications for hospitalization, outpatient treatment can be an attractive alternative to inpatient treatment. One critical criterion for outpatient treatment is the patient's compliance with complete abstinence from the dependence-producing drug during the treatment experience.

Families must be involved in treatment. The course of the patient's illness often has a devastating effect on other family members. Severely depleted self-esteem, denial of the family member's addiction, feelings of responsibility for the family member's drug use, and other behaviors that parallel the addiction process are often present.

8 Because at present there are no drugs to effectively treat the underlying addictive processes of drug dependence, treatment must be a lifelong process. Aftercare, or what is now being called *continued care,* should include regular and frequent treatment in some form. Most drug-dependence treatment programs embrace a treatment approach based on the 12 steps to recovery. Among chemically dependent healthcare professionals, treatment that incorporates both 12-step and peer-led self-help groups can be most effective.

PERSONALIZED PHARMACOTHERAPY

The notion of using pharmacogenetic testing to individualize the treatment of substance abuse disorders is relatively new, but studies of several genes have yielded significant findings.[100] Several gene variants have been shown to influence individual response to pharmacotherapy for drug addiction, notably in the μ opioid receptor gene OPRM1 A118G (rs561720), polymorphisms of CYP2A6, and ANKK1 Taq1A. It remains to be seen how this genetic information will be incorporated into clinical practice. Prospective studies evaluating the use of genetic testing in a clinical setting and the effect on treatment outcome are warranted to further evaluate the benefits and risks of this approach.[109,110]

Chapter 66: Substance-Related Disorders II: Alcohol, Nicotine, and Caffeine

Paul L. Doering; Robin Moorman Li

INTRODUCTION

KEY CONCEPTS

- 1 Tobacco is the number one preventable cause of death in the United States.
- 2 In the United States from 2010 to 2012, alcohol poisoning was attributed to an estimated 6 deaths per day in men between the ages of 35 to 64.
- 3 Pharmacogenomic studies have identified genotypic and functional phenotypic variants that either serve to protect patients or predispose them toward alcohol dependence.
- 4 Except at very high and very low blood concentrations, the metabolism of alcohol is considered to follow zero-order pharmacokinetics, and this has important implications for the time course in which alcohol can exert its effects.
- 5 Disulfiram, naltrexone, and acamprosate are FDA-approved drug therapies for the treatment of alcohol dependence. The clinical utility of these agents to improve sustained abstinence remains controversial. Relapse is common.
- 6 More than three quarters of smokers are nicotine dependent. Tobacco dependence is a chronic condition that requires repeated interventions.
- 7 A systematic Cochrane review completed in 2012 showed all forms of nicotine replacement therapy were effective in reducing the amount smoked and achieving abstinence.
- 8 It has been suggested a quit date should be set 1 week following initiating varenicline therapy. Studies now show a flexible quit date is efficacious and safe.
- 9 Caffeinism is the term coined to describe the clinical syndrome produced by acute or

chronic overuse of caffeine. As many as one in five adults consume doses of caffeine generally considered large enough to cause clinical symptoms.

- 10 Energy drinks are now popular particularly among adolescents and emerging adults. There are now safety concerns surrounding the use of these drinks due to the doubling of emergency room visits from 2000 to 2011 secondary to adverse reactions.

1 Alcohol, nicotine, and caffeine are considered by most to be socially acceptable drugs, yet they impose an enormous social and economic cost on our society. Approximately 480,000 deaths in the United States each year are attributable to tobacco use, making tobacco the number one preventable cause of death and disease the United States.[66] The three leading causes of death attributable to smoking include lung cancer, chronic obstructive pulmonary disease, and ischemic heart disease.[1]

2 In 2013, heavy drinking was reported by 6.3% of the population aged 12 or older, or 16.5 million people.[2] Approximately one quarter (22.9%) of persons aged 12 or older participated in binge drinking at least once in the 30 days prior to the National Survey on Drug Use and Health (NSDUH) in 2013 which is very similar to the 23% reported in 2012.[2] The World Health Organization estimates that in 2012, there were approximately 3.3 million people worldwide who died from alcohol consumption.[3] Long-term alcohol abuse often leads to chronic disease. A causal relationship between alcohol abuse and at least 200 types of chronic disease or injury has been established (eg, esophageal cancer, liver cancer, and cirrhosis of the liver, epileptic seizures, homicide, and motor vehicle accidents) worldwide.[3] Nationally, between the years of 2010 to 2012, there were approximately 2,200 deaths caused by alcohol poisoning in patients greater than 15 years old. It has been calculated that during this time period, there were an average of 6 deaths per day predominately in men between the ages of 35 to 64 caused by alcohol poisoning.[4]

Caffeine is currently the most widely used psychoactive substance in the world. In the United States, 80% to 90% of adults regularly consume behaviorally active doses of caffeine.

ALCOHOL

Epidemiology of Alcohol Use

Approximately half of Americans aged 12 or older reported being current drinkers of alcohol according to the NSDUH in 2013 (52.2%) which translates to an estimated 136.9 million people.[2] In 2013, heavy drinking was reported by 6.3% of the population aged 12 or older, meaning that they drank five or more drinks on the same occasion on at least 5 different days in the past month.[2]

The Disease Model of Addiction as Applied to Alcoholism

The disease concept of addiction, using alcoholism as a model, states that addiction is a disease, and that individuals who suffer from the disease do not choose to contract the disease any more than someone who suffers from heart disease or diabetes mellitus chooses to contract that illness. A

disease is defined as "any deviation from or interruption of the normal structure or function of any part, organ, or system (or combination thereof) of the body that is manifested by a characteristic set of symptoms and signs and whose etiology, pathology, and prognosis may be known or unknown."[5] Diagnostic criteria for alcoholism have changed in the recent release of the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5). The DSM-5 now refers to alcohol use disorder (AUD) rather than having 2 separate disorders, alcohol abuse and alcohol dependence, which were listed in the DSM-4.[6] Based on DSM-5, AUD requires meeting 2 of the 11 criteria during a 12-month period. Severity is determined based on the number of criteria met and subsequently classified as mild (2-3 symptoms), moderate (4-5 symptoms), or severe (6 or more symptoms). Comparison of the criteria between DSM-4 and DSM-5 shows most criteria are very similar with the exception of elimination of legal problems and addition of craving in the criteria for DSM-5.[7,8]

3 It has long been recognized that alcohol dependence is heritable, as 50% of first-degree relatives of alcoholics become alcohol-dependent themselves.[9,10] A recent quantitative meta-analysis evaluated heritability of AUD's on twin and adoption studies and determined similar results: 0.49 (95% confidence interval [CI] 0.47-0.54).[11] Pharmacogenomic research continues to work to identify genetic variations leading to not only variations in responses to alcohol, but also the responses to the effects of the pharmacological treatment of AUDs.[10] Large-scale pharmacoepidemiologic studies have further elucidated the environmental risk factors that are associated with either protective effects or predisposition toward alcoholism (**Table 66-1**).[12]

TABLE 66-1 Genotypic, Phenotypic, and Environmental Factors That Increase Alcohol-Dependence Risk

Susceptibility Genes	Phenotype	Environment
Regions on chromosomes 1 and 4 that code for the following receptors:	Personality traits that include:	Religious background
$GABA_A$	Novelty seeking	Urban residence (vs rural)
Serotonin 1b	Impulsivity	History of sexual abuse
DRD4	Aggression	Being single
Tryptophan hydroxylase	Depression	Having deceased parents
Neuropeptide Y	Maximum number of alcoholic drinks consumed per day	
Gene that codes for:		
ALDH2		
5HTTLPR		

ALDH2, aldehyde dehydrogenase 2; DRD4, type 4 dopamine receptor gene; GABA, γ-aminobutyric acid; 5HTTLPR, 5 hydroxytryptamine transporter.

Data from references 9 and 12.

Pharmacology and Pharmacokinetics of Alcohol

Alcohol as a Drug

Alcohol is a CNS depressant that affects the CNS in a dose-dependent fashion, producing sedation that progresses to sleep, unconsciousness, coma, surgical anesthesia, and finally fatal respiratory depression and cardiovascular collapse. Alcohol affects endogenous opiates and several neurotransmitter systems in the brain, including γ-aminobutyric acid (GABA), glutamine, and dopamine. Alcohol is available in a variety of concentrations in various alcoholic beverages. There is approximately 14 g of alcohol in a 12-oz (355 mL) can of beer (approximately 5%), 5 oz (148 mL) of nonfortified wine (approximately 12%), or one shot (1.5 oz [44 mL]) of 80-proof whiskey (40%).[13] Full consumption of this amount will cause an increase in blood alcohol level of approximately 20 to 25 mg/dL (4.3 to 5.4 mmol/L) in a healthy 70-kg (154 lb) male, although this varies with the time frame over which the alcohol is consumed, the type of alcoholic beverage, whether food is consumed along with it, and many patient variables. The lethal dose of alcohol in humans is variable, but deaths generally occur when blood alcohol levels are greater than 400 to 500 mg/dL (87-109 mmol/L).[14]

Pharmacokinetics

Absorption of alcohol begins in the stomach within 5 to 10 minutes of oral ingestion. The onset of clinical effects follows fairly rapidly. Peak serum concentrations of alcohol usually are achieved 30 to 90 minutes after finishing the last drink, although it is variable depending on the type of alcoholic beverage consumed, what and when the person last ate, and other factors.[15]

More than 90% of alcohol in the plasma is metabolized in the liver by 3 enzyme systems that operate within the hepatocyte. The remainder is excreted by the lungs and in urine and sweat. Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase in the cell. In turn, acetaldehyde is metabolized to carbon dioxide and water by the enzyme aldehyde dehydrogenase. A second pathway for oxidation of alcohol uses catalase, an enzyme located in the peroxisomes and microsomes. The third enzyme system, the microsomal alcohol oxidase system, has a role in the oxidation of alcohol to acetaldehyde. These last two mechanisms are of lesser importance than the alcohol dehydrogenase–aldehyde dehydrogenase system.[15,16]

4 The metabolism of alcohol generally is said to follow zero-order pharmacokinetics.[17] This can, in fact, be an oversimplification because at very high or very low concentrations of alcohol, the metabolism can follow first-order pharmacokinetics.[17] On average, the blood alcohol concentration (BAC) is lowered from 15 to 22.2 mg/dL (3.3-4.8 mmol/L) per hour in the nontolerant individual, assuming that the individual is in the postabsorptive state(**Table 66-2**). Alcohol has a volume of distribution of 0.6 to 0.8 L/kg, representing the total body water.[17]

TABLE 66-2 Specific Effects of Alcohol Related to BAC

BAC (%)[a]	Effect

(mmol/L)	
0.02-0.03 (4-8)	No loss of coordination, slight euphoria, and loss of shyness
0.04-0.06 (9-14)	Feeling of well-being, relaxation, lower inhibitions, sensation of warmth. Euphoria. Some minor impairment of reasoning and memory, lowering of caution
0.07-0.09 (15-21)	Slight impairment of balance, speech, vision, reaction time, and hearing. Euphoria. Judgment and self-control are reduced, and caution, reason, and memory are impaired. It is illegal to operate a motor vehicle in some states at this level
0.10-0.125 (22-27)	Significant impairment of motor coordination and loss of good judgment. Speech can be slurred; balance, vision, reaction time, and hearing impaired. Euphoria. It is illegal to operate a motor vehicle at this level of intoxication
0.13-0.15 (28-34)	Gross motor impairment and lack of physical control. Blurred vision and major loss of balance. Euphoria is reduced, and dysphoria is beginning to appear
0.16-0.20 (35-43)	Dysphoria (anxiety, restlessness) predominates; nausea can appear. The drinker has the appearance of a "sloppy drunk"
0.25 (54)	Needs assistance in walking; total mental confusion. Dysphoria with nausea and some vomiting
0.30 (65)	Loss of consciousness
≥0.40 (>87)	Onset of coma, possible death caused by respiratory arrest

BAC, blood alcohol concentration.

[a]Grams of ethyl alcohol per 100 mL of whole blood.

Data from references 20 and 21.

Clinical Indicators of Chronic Alcohol Abuse

The CAGE questionnaire is a commonly used tool for detecting individuals more likely to be abusing alcohol and therefore at greater risk for alcohol withdrawal. CAGE is a mnemonic for four questions: (a) Do you ever feel the need to *c*ut down on your alcohol use? (b) Have you ever been *a*nnoyed by others telling you that you drink too much? (c) Have you ever felt *g*uilty about your drinking or something you did while drinking? (d) Do you ever have an "*e*ye opener"? A positive response to two or more of these four questions suggests an increased likelihood of alcohol abuse with an average sensitivity of 0.71 (71%) and an average specificity of 0.90 (90%).[18]

The Alcohol Use Disorders Identification Test (AUDIT) is a validated 10-question screening tool originally developed to screen for alcohol dependence, problems associated with alcohol use, and the amount and frequency of alcohol consumption in adults in the primary care setting.[19] This screening tool can be completed by the patient or can be completed via an interview with a health care provider. AUDIT scores greater than 8 out of a possible 40 indicate moderate issues with alcohol, and anything greater than 16 indicates greater problems with alcohol requiring subsequent counseling and monitoring. If scores are higher than 20, then further evaluation for alcohol

dependence is indicated. The AUDIT tool, as well as a short version of AUDIT (AUDIT-C), has been used within a broad range of patient population samples and is an appropriate first step in identifying patients struggling with alcohol issues.[19]

Acute Effects of Alcohol

At lower serum concentrations, euphoria and disinhibition may be noted. Slurred speech, altered perception of the environment, impaired judgment, ataxia, incoordination, nystagmus, and hyperreflexia may occur. As plasma levels increase, combative and destructive behavior may occur. With higher levels still, somnolence and respiratory depression may ensue.[20] The typical effects of various BACs are shown in Table 66-2, although effects vary from individual to individual.

Alcohol Poisoning

Acute alcohol poisoning usually occurs with rapid consumption of large quantities of alcoholic beverages. With sustained drinking of moderate amounts of alcohol, the user passes out before a toxic dose of alcohol can be ingested, and/or the person vomits to rid the stomach of its toxic reservoir. With rapid drinking, the person may fall asleep or pass out without vomiting, allowing continued alcohol absorption from the gastrointestinal (GI) tract until fatal BACs are achieved.[21]

Laboratory Studies

In the emergency room, a BAC should be ordered in any patient in whom alcohol ingestion is suspected, regardless of the presenting complaint. For clinical purposes, most laboratories report BAC in units of mg/dL or mmol/L. In legal cases, results are reported in percentage (grams of ethyl alcohol per 100 mL of whole blood). Along with a BAC, a complete blood count to assess for anemia, complete metabolic panel, serum magnesium to assess electrolytes, serum glucose, and renal and liver function should be ordered. If the diagnosis is unclear, if the intoxication seems atypical, or when there is suspicion of multiple drug ingestions, a complete toxicologic screen to rule out the presence of other substances may be useful.[22]

Treatment

Alcohol-Related Disorders

Desired Outcomes

Goals for alcohol-dependent persons trying to decrease or discontinue alcohol intake include: (a) the prevention and treatment of withdrawal symptoms (including seizures and delirium tremens) and medical or psychiatric complications, (b) long-term abstinence after detoxification, and (c) entry into ongoing medical and alcohol-dependence treatment.

Alcohol Withdrawal

Following the completion of a baseline assessment by using a validated tool, such as the Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar),[23] symptom-triggered treatment with a benzodiazepine is the current standard of care in alcohol detoxification to manage and minimize symptoms and avoid progression to the more severe stages of withdrawal. Trials comparing different benzodiazepines demonstrated that all appear similarly efficacious in reducing signs and symptoms of withdrawal.[24,25]

Although benzodiazepines are the standard of care, other agents have been evaluated for efficacy in the treatment of alcohol withdrawal. A Cochrane review of the efficacy and safety of pharmacological options in treating alcohol withdrawal syndrome was published in 2011. A total of 7,333 patients were included in this review, and the medications evaluated included benzodiazepines, baclofen, anticonvulsants, psychotropic analgesic nitrous oxide (PAN), and gamma hydroxybutyrate. Efficacy was determined based on the impact on alcohol withdrawal seizures. Benzodiazepines were more efficacious when compared to both placebo (RR 0.16; 95% CI 0.04-0.69) and antipsychotics (RR 0.24; 95% CI 0.07-0.88). Within the benzodiazepine class comparison, no benzodiazepine was statistically shown to have better efficacy, although there was a trend for better efficacy with chloridazepoxide.[26]

CLINICAL PRESENTATION Alcohol Intoxication and Withdrawal General

- Acute alcohol detoxification and withdrawal after chronic alcohol abuse is a serious condition that can require hospitalization and adjunctive pharmacotherapy. At very high BAC, death is possible.

Symptoms

- The intoxicated patient can present with slurred speech and ataxia. The patient can be sedated or unconscious. As BACs decrease rapidly, nausea, vomiting, and hallucinations can ensue. Delirium and seizures are the most severe symptoms.
- An evaluation should be completed using the Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar) to document the patients baseline symptoms.

Signs

- The intoxicated patient can present with nystagmus.
- In withdrawal, the patient can present with tachycardia, diaphoresis, or hyperthermia.

Laboratory Tests

- In the emergency department, a BAC should be ordered when alcohol ingestion is suspected. Clinical laboratories typically report BAC in units of milligrams per deciliter or millimoles per liter. A whole blood alcohol level of 150 mg/dL (33 mmol/L) reported in the hospital corresponds to 0.15% BAC obtained by law enforcement.

- A complete blood count to assess for anemia, complete metabolic panel along with magnesium to assess electrolytes, glucose, renal, and liver function.
- A complete toxicologic screen to rule out the presence of other substances can be useful.

Other Diagnostic Tests

- Differentiate acute alcohol intoxication from other medical illnesses (eg, head trauma).
- Order computed tomography (CT) on any patient with focal neurologic findings, failure to improve, new-onset seizures, or mental status out of proportion to degree of intoxication.

Treatment Regimens

Front-Loading Therapy

One approach to managing alcohol withdrawal includes initially using a high dose of a long-acting benzodiazepine, such as diazepam 10 to 20 mg or chlordiazepoxide 100 mg, and administering repeat doses approximately every 1 to 2 hours until the patient is sedated.[22] It is reported that an average of three doses of these long-acting benzodiazepines is commonly utilized to achieve adequate sedation. It is important for providers to monitor the patients carefully for benzodiazepine toxicity such as over sedation, respiratory depression, and delirium. Additionally, this approach should be used with extreme caution in elderly patients or patients who have liver disease since the elimination rate will be extended leading to increased risk of toxicity.[22]

Symptom-Triggered Therapy

With symptom-triggered therapy, medication is given only when the patient has symptoms and CIWA-Ar score is 8 or above.[22] This approach results in treatment that is shorter, potentially avoiding oversedation and allowing the clinician to focus on specific therapy for alcohol dependence.[24,25] Various benzodiazepines have been used in this therapy including diazepam, chlordiazepoxide, and lorazepam depending on factors including the patient's age and liver function. The patient is then reassessed hourly utilizing the CIWA-Ar score. If the score remains above 8, the patient can continue to receive the dose of selected benzodiazepine. If the score is lower than 8 and the patient appears stable, the time frame for assessment and repeat treatment can extend to 4 to 8 hours (**Table 66-3**).[27]

TABLE 66-3 Dosing and Monitoring of Pharmacologic Agents Used in the Treatment of Alcohol Withdrawal

Drug	Dose Per Day (Unless Otherwise Stated)	Indication	Monitoring	Duration of Dosing	Level of Evidence for Efficacy[a]
Multivitamin	1 tablet	Malnutrition	Diet	At least until eating a	B3

Drug	Dose Per Day (Unless Otherwise Stated)	Indication	Monitoring	Duration of Dosing	Level of Evidence for Efficacy[a]
				balanced diet at caloric goal	
Thiamine	50-100 mg	Deficiency	CBC, WBC, nystagmus	Empiric × 5 days. More if evidence of deficiency	B2
Crystalloid fluids (typically D5–0.45 NS with 20 mEq (20 mmol) of KCl per liter)	50-100 mL/hour	Dehydration	Weight, electrolytes urine output, nystagmus if dextrose	Until intake and outputs stabilize and oral intake is adequate	A3
Clonidine oral (Catapres)	0.05-0.3 mg Consider dose reduction in the elderly	Autonomic tone rebound and hyperactivity	Shaking, tremor, sweating, blood pressure	3 days or less	B2
Clonidine transdermal (Catapres-TTS)	TTS-1 to TTS-3 Consider dose reduction in the elderly	Autonomic tone rebound and hyperactivity	Shaking, tremor, sweating, blood pressure	1 week or less. One patch only	B3
Labetalol	20 mg IV every 2 hours as needed; dosage reduction (eg, by about 50% for oral dosage) is advised in patients with hepatic impairment	Hypertensive urgencies and above	Blood pressure target	Individual doses as needed	B3
Antipsychotics, haloperidol (Haldol)	2.5 to 5 mg every 4 hours	Agitation unresponsive to benzodiazepines, hallucinations (tactile, visual, auditory, or otherwise), or	Subjective response plus rating scale (CIWA-AR or equivalent)	Individual doses as needed	B1

Drug	Dose Per Day (Unless Otherwise Stated)	Indication	Monitoring	Duration of Dosing	Level of Evidence for Efficacy[a]
		delusions			
Antipsychotics, atypical Quetiapine (Seroquel) Aripiprazole (Abilify)	25-200 mg; dosage adjustment is necessary in hepatic impairment 5-15 mg	Agitation unresponsive to benzodiazepines, hallucinations, or delusions in patients intolerant of conventional antipsychotics	Subjective response plus rating scale (CIWA-AR or equivalent)	Individual doses as needed in addition to scheduled antipsychotic	C3
Benzodiazepines Lorazepam (Ativan) Chlordiazepoxide (Librium) Clonazepam (Klonopin) Diazepam (Valium)	0.5-2 mg 5-100 mg 0.5-2 mg 2.5-10 mg	Tremor, anxiety, diaphoresis, tachypnea, dysphoria, seizures	Subjective response plus rating scale (CIWA-AR or equivalent)	Individual doses as needed. Underdosing is more common than overdosing	A2
Alcohol oral		Prevent withdrawal	Subjective signs of withdrawal	Wide variation	C3
Alcohol IV		Prevent withdrawal	Subjective signs of withdrawal	Wide variation	C3

CBC, complete blood count; CIWA-AR, Clinical Institute Withdrawal Assessment for Alcohol, Revised; D5, dextrose 5%; KCl, potassium chloride; NS, normal saline; WBC, white blood cell count.

[a]Strength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: 1, evidence from more than one properly randomized controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case–control analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from references 22, 28, and 29.

Fixed-Schedule Therapy

Over the years, benzodiazepines given regularly at a fixed dosing interval have been used for alcohol withdrawal. The major problem with this approach is under dosing of the benzodiazepine because of cross-tolerance (see Table 66-3). Current guidelines take exception with this rigid approach, urging clinicians to allow for some degree of individualization within fixed-schedule therapy.[24,25]

Treatment of Alcohol Withdrawal Seizures

Alcohol withdrawal seizures do not require treatment with an anticonvulsant drug unless they progress to status epilepticus, because seizures usually end before diazepam or another drug can be administered.[25] Phenytoin, which is not cross-tolerant to alcohol, does not prevent or treat withdrawal seizures, and without an IV loading dose, therapeutic blood levels of phenytoin are not reached until acute withdrawal is complete. Patients experiencing seizures should be treated supportively. An increase in the dosage and slowing of the tapering schedule of the benzodiazepine used in detoxification or a single injection of a benzodiazepine may be necessary to prevent further seizure activity. Patients with a history of withdrawal seizures can be predicted to experience an especially severe withdrawal syndrome. In such patients, a higher initial dosage of a benzodiazepine and a slower tapering period of 7 to 10 days are advisable.

Treatment of Nutritional Deficits and Electrolyte Abnormalities

Fluid status should be carefully assessed, and fluid, electrolyte, and vitamin abnormalities should be corrected. Hydration can be necessary in patients with vomiting, diarrhea, increased body temperature, or severe agitation. Alcoholics often have electrolyte imbalances because of inadequate nutrition and fluid volume related to antidiuretic hormone inhibition. Hypokalemia can be corrected with oral potassium supplementation as long as renal function is adequate. Thiamine (vitamin B_1) is often depleted in alcoholics, and supplementation is standard because it can prevent the development of the Wernicke-Korsakoff syndrome (eg, mental confusion, eye movement disorders, and ataxia [poor motor coordination]). An initial dose of 100 mg IV or IM is commonly used. In practice, thiamine is usually given 100 mg once daily orally, IV, or intramuscularly for 3 to 5 days (see Table 66-3).[25]

Alcohol hypoglycemia usually occurs in the absence of overt liver disease, and it is more likely if the patient is fasting or exercising or is sensitive to alcohol; it is less likely if the patient is obese. The alcohol directly interferes with hepatic gluconeogenesis, but not glycogenolysis. The energy required for metabolism of alcohol is diverted away from the energy needed to take up lactate and pyruvate —substrates for gluconeogenesis. So, patients who drink alcohol can become hypoglycemic once glycogen stores are depleted. Neurologic symptoms of hypoglycemia can be confused with alcohol intoxication, and in the inpatient setting, blood glucose should be monitored regularly.[25]

Treatment Settings

Alcohol withdrawal treatment can take place in hospitals, inpatient detoxification units, or outpatient

settings. Only patients with mild to moderate symptoms should be considered for outpatient treatment, and it is a good idea to have a responsible, sober person available to help the patient monitor symptoms and administer medications. Patients with a strong craving for alcohol, those concurrently using other drugs, and those with a history of seizures or delirium tremens are not good candidates for outpatient treatment. Pharmacologic agents used in the treatment of alcohol withdrawal are summarized in Table 66-3.[24,25]

Pharmacologic Management of Alcohol Dependence

5 In the United States, disulfiram, naltrexone, once-monthly injectable extended-release naltrexone, and acamprosate are the only four drugs that are FDA-approved for the treatment of alcohol dependence. Disulfiram acts as a deterrent to the resumption of drinking, and naltrexone is a competitive opioid antagonist that has been shown to reduce cravings for alcohol. Acamprosate is a GABA ergic agonist that modulates alcohol cravings (**Table 66-4**).[7] Other drugs, including nalmefene, baclofen, bupropion, various serotonergic agents (including selective serotonin reuptake inhibitors and vascular serotonin-3 [5-HT_3] receptor antagonists), topiramate, gabapentin, and lithium, also have been used either abroad or in the United States off-label for alcohol dependence. A Cochrane review of 25 studies with 2,641 patients was completed to evaluate a variety of anticonvulsants, including gabapentin, topiramate, oxcarbazepine, valproate, levetiracetam, pregabalin, and carbamazepine, to determine efficacy in the treatment of alcohol dependence. These agents did perform better than placebo when comparing the number of drinks per day and average heavy drinking days but there was insufficient evidence that these agents led to an increased number of patients abstaining from alcohol. The conclusion was there is insufficient evidence of efficacy to support the use of anticonvulsant treatment of alcohol dependence.[30]

TABLE 66-4 Dosing and Monitoring of Pharmacologic Agents Used in the Treatment of Alcohol Dependence

Drug	Dosage Range Per Day	Indication	Monitoring	Duration of Dosing	Level of Evidence for Efficacy[a]
Disulfiram (Antabuse)	250-500 mg; used with extreme caution in patients with hepatic cirrhosis or insufficiency	Deterrence	Facial flushing, liver enzymes	Indefinite	B2
Acamprosate (Campral)	999-1,998 mg and higher (333 mg tablets) Dosage adjustment necessary in renal impairment	Craving	Patient-reported craving, renal function	Indefinite	A1

Drug	Dosage Range Per Day	Indication	Monitoring	Duration of Dosing	Level of Evidence for Efficacy[a]
Naltrexone (ReVia)	50-100 mg; dosage adjustment may be needed in renal and liver impairment	Craving	Patient-reported craving	Indefinite	A1
Naltrexone (Vivitrol)	380 mg intramuscularly once every 4 weeks Risk of hepatotoxicity lower compared to oral formulation due to lack of first pass effect	Craving	Patient-reported craving	Indefinite	B2
Mood stabilizers (eg, lamotrigine [Lamictal], topiramate [Topamax], carbamazepine [Tegretol], valproic acid [Depakote])	Seizure disorder doses	Craving	Patient-reported craving, plasma drug levels	Indefinite	B2
Antidepressants (eg, clomipramine [Anafranil], bupropion [Wellbutrin], doxepin [Sinequan], fluoxetine [Prozac])	Depression doses	Craving, depression, anxiety	Patient-reported craving	Indefinite	B2

[a]Strength of recommendations: A, B, and C, good, moderate, and poor evidence to support recommendation, respectively.

Quality of evidence: 1, evidence from more than one properly randomized controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case–control analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from references 28 and 29.

Disulfiram

Disulfiram deters a patient from drinking by producing an aversive reaction if the patient drinks. In the absence of alcohol, disulfiram has minimal effects. It inhibits aldehyde dehydrogenase in the

biochemical pathway for alcohol metabolism, allowing acetaldehyde to accumulate. The resulting increase in acetaldehyde causes severe facial flushing, throbbing headache, nausea and vomiting, chest pain, palpitations, tachycardia, weakness, dizziness, blurred vision, confusion, and hypotension. Severe reactions including myocardial infarction, congestive heart failure, cardiac arrhythmia, respiratory depression, convulsions, and death can occur, particularly in vulnerable individuals.[7]

Naltrexone

Naltrexone, an opiate antagonist available in the United States since 1984 for the treatment of opioid dependence, blocks the effects of exogenous opioids. In 1994, the FDA approved its use in the treatment of alcohol dependence. Naltrexone is thought to attenuate the reinforcing effects of alcohol, and those who consume alcohol while taking naltrexone report feeling less intoxicated and having less craving for alcohol.[7] Evidence suggests that genetics plays a role in the clinical response to naltrexone, as the efficacy of naltrexone treatment varies greatly among individuals. In previous preliminary studies, Asp40 polymorphism in the μ-opioid receptor gene demonstrated increased response to naltrexone with lower rates of relapse to heavy drinking. In a recent double blind, randomized, controlled clinical trial evaluating naltrexone in comparison to placebo, 221 patients were stratified by genotype. It was found that Asp40 allele does not have a significant effect on the response rate for naltrexone treatment,[31] but further studies are needed.

Naltrexone should not be given to patients currently dependent on opiates because it can precipitate a severe withdrawal syndrome. Naltrexone should be used with caution in patients with moderate to severe renal impairment. Although naltrexone is associated with dose-related hepatotoxicity, this generally occurs at doses higher than those recommended for treatment of alcohol dependence, and elevated liver enzyme levels generally normalize upon discontinuation of naltrexone. It is recommended that baseline and periodic liver function tests should be completed one to three months after initiation of therapy and then continued annually.[32] Nevertheless, it is considered contraindicated in patients with hepatitis, liver failure, or serum aminotransferase levels greater than 5 times normal.[7]

A review of 50 randomized controlled studies, which included approximately 7,800 patients, showed the most common side effects were nausea and daytime sedation. Efficacy was measured by the decrease in drinking days and also the amount of heavy drinking. Results showed there was approximately a 4% decrease in drinking days, and the risk of heavy drinking decreased to 83% compared to placebo (NNT = 9). The usual starting dose of oral naltrexone is 50 mg/day, but doses of 100 mg/day have been used and studied.[33]

In April 2006, the FDA approved Vivitrol, a once-monthly intramuscular naltrexone formulation. The usual effective dose is 380 mg IM each month.[34] Extended-release formulations reduce the likelihood of forgetting or choosing not to take medication, assuring that once the patient receives an injection, he or she will be “adherent” for the next month.[34]

Criticism has been leveled at the extended-release dosage form, suggesting that naltrexone’s benefit may be limited to less severe alcohol dependence, and exclusively to reduction in heavy drinking

rather than abstinence. Pettinati et al[34] report the results of a study in alcohol-dependent patients who had higher baseline severity, as measured by: (a) the Alcohol Dependence Scale or (b) having been medically detoxified in the week before randomization. Higher severity alcohol-dependent patients, when receiving 380 mg (n = 50) of the extended-release compound compared with placebo (n = 47), had significantly fewer heavy-drinking days during the study (hazard ratio = 0.583; P= 0.0049) and showed an average reduction of 37.3% in heavy-drinking days compared with 27.4% for placebo-treated patients (P = 0.039). The authors contend that their data support the efficacy of extended-release naltrexone 380 mg in relatively higher severity alcohol dependence for both reduction in heavy drinking and maintenance of abstinence.[34]

Acamprosate

Acamprosate is a glutamate modulator at the *N*-methyl-d-aspartate receptor that reduces alcohol craving. Acamprosate, approved in the United States in 2004, had been available in Europe for many years. Patients treated with acamprosate are more successful in maintaining abstinence from alcohol versus placebo. Acamprosate is well tolerated, with GI adverse effects most common.

A Cochrane review of 24 randomized controlled trials (RCTs) with 6,915 participants[35] found that, compared with placebo, acamprosate significantly reduced the risk of any drinking (RR 0.86; 95% CI 0.81-0.91; NNT 9.09; 95% CI 6.66-14.28) and significantly increased the cumulative abstinence duration (mean difference 10.94 days [95% CI 5.08-16.81]), while secondary outcomes did not reach statistical significance. Diarrhea was the only side effect that was more frequently reported with acamprosate than placebo (risk difference 0.11 [95% CI 0.09-0.13]; NNTB 9.09 [95% CI 7.69-11.11]). Table 66-4 shows dosing information for this and the other options used in treating alcohol dependence.

NICOTINE

Since 1964 when the first Surgeon General's report on smoking was released, the number of adults who smoke has decreased from 42.4% in 1965[36] to 17.1% in March 2014,[37] and now there are more former smokers than current smokers.[1] This trend has been aided by the clinical guidelines for tobacco use and dependence which were released in 2000 and last updated in 2008.[38] Telephone quitlines are also available in every state, and more patients are increasingly referred to smoking cessations counseling services. There is also a growing number of Internet and mobile phone text messaging programs to reach the teenage and young adult population to promote smoking cessation.[39,40]

Despite proven effectiveness of pharmacological and counseling services to aid in sustained smoking cessation, cigarette smoking continues to be the leading cause of preventable morbidity and mortality in the United States. Data from the 2013 National Health Interview Survey[41] found that the overall percent of current smokers from the years 2005 to 2013 in adults (18 years old and older) decreased from 20.9 to 17.8. It was determined this represents 3 million fewer smokers in 2013 compared with 2005, but this decline has not been uniform across all subsets of the population.[42]

The Healthy People 2020 target is currently set for the prevalence of smoking to be less than or equal to 12%, and based on the current rate of decline, this target will not be met. Healthy People 2020 also calls for greater utilization of tobacco use counseling within ambulatory settings to improve smoking cessation rates with the goal of increasing the cessation attempts from 48% in 2008 to 80% by 2020.[43]

Epidemiology of Tobacco Use

The NSDUH reported in 2013 that an estimated 25.5% (66.9 million) of the US population's 12 years of age and older people used a tobacco product at least once in the month prior to being interviewed. In addition, 55.8 million Americans were current cigarette smokers, 12.4 million smoked cigars, 8.8 million used smokeless tobacco, and 2.3 million smoked pipes.[44] Comparing age groups, adults between the ages of 18 and 25 years have the highest rate of cigarette use (37%), but it is encouraging to see the rates continue to decrease each year since 2002 when 45.3% of young adults were using cigarettes. Within youth aged 12 to 17, use of cigarettes also continued to decline from 15.2% in 2002 to 7.8% in 2013.[44]

Data trends from the 2013 NSDUH continue to show smoking prevalence varies based on the level of education. The highest percentage of adults who admitted to smoking was adults who had not completed high school (33.6%). The lowest rate of smoking was seen in adults who graduated from college (11.2%). Results from the NSDUH also showed cigarette smoking was higher in unemployed adults (40.1%) in comparison to adults who were employed full time (22.8%).[44]

Economic Impact of Smoking

The direct healthcare expenditures associated with smoking range between $289 and $333 billion a year for both direct medical care of adults and indirect costs such as lost productivity.[1] Medicaid patients' smoking rates are substantially higher in comparison to the general population. Smoking-attributable medical expenditures are estimated at 11% of Medicaid program expenditures.[45]

Health Risks of Smoking

Cigarette smoking substantially increases the risk of (a) cardiovascular diseases, such as stroke, sudden death, and heart attack; (b) nonmalignant respiratory diseases including emphysema, asthma, chronic bronchitis, and chronic obstructive pulmonary disease; (c) lung cancer; and (d) other cancers.[1] Exposure to environmental tobacco smoke (*passive exposure*) has been cited as the cause of lung cancer, stroke, and coronary heart disease in adults.[46,47] Children who are exposed to environmental smoke have a higher risk of respiratory infection, asthma, and ear infections than those who are not exposed. Sudden infant death syndrome occurs more often in infants whose mothers smoked during pregnancy than in offspring of nonsmoking mothers. The harmful effects of smoking on reproduction and pregnancy include reduced fertility and fetal growth, as well as increased risk of ectopic pregnancy and spontaneous abortion.[46]

Pharmacology of Nicotine

Nicotine is a ganglionic cholinergic agonist with pharmacologic effects that are highly dependent on dose. These effects include central and peripheral nervous system stimulation and depression, respiratory stimulation, skeletal muscle relaxation, catecholamine release by the adrenal medulla, peripheral vasoconstriction, and increased blood pressure, heart rate, cardiac output, and oxygen consumption. Cigarette smoking or low doses of nicotine produce an increased alertness and increased cognitive functioning by stimulating the cerebral cortex. At higher doses, nicotine stimulates the "reward" center in the limbic system of the brain.[48]

When nicotine is ingested, a feeling of pleasure and relaxation can occur. Repetitive exposure to nicotine leads to neuroadaptation, which builds tolerance to the initial effects. An accumulation of nicotine in the body leads to a more substantial withdrawal reaction if cessation is attempted. Common symptoms experienced during withdrawal can include anxiety, difficulties concentrating, irritability, and strong cravings for tobacco.[49] Onset of these withdrawal symptoms usually occurs within 24 hours and can last for days, weeks, or longer. This powerful force of nicotine addiction is one reason smokers who attempt to achieve smoking cessation have a high rate of relapse, and only 3% remain abstinent 6 months following the quit date.[51]

Treatment

Desired Outcomes

Ideally, we would hope that all smokers quit, and that young people never take up the habit. Unfortunately, this is unlikely to happen. The Healthy People 2020 target setting the prevalence of smoking at less than or equal to 12% is a realistic and achievable goal.[43]

Nicotine Dependence

Agency for Healthcare Research and Quality Clinical Practice Guideline: Treating Tobacco Use and Dependence

The Agency for Healthcare Research and Quality (AHRQ) periodically convenes expert panels to develop clinical guidelines for healthcare practitioners. Because of the widespread prevalence of smoking-related illnesses, its related morbidity and mortality, and the economic burden imposed, the agency convened a panel of experts in 1994 to develop guidelines on the treatment of tobacco addiction. The resultant guideline for smoking cessation was updated in 2008,[38] and no further updates have been released at the time of this writing.

The guideline suggests strategies for appropriate treatments for every patient. Because effective treatments for tobacco dependence now exist, every patient should receive at least minimal treatment every time he or she visits a clinician (**Figs. 66-1** and **66-2**).

FIGURE 66-1

Model for treatment of tobacco use and dependence.

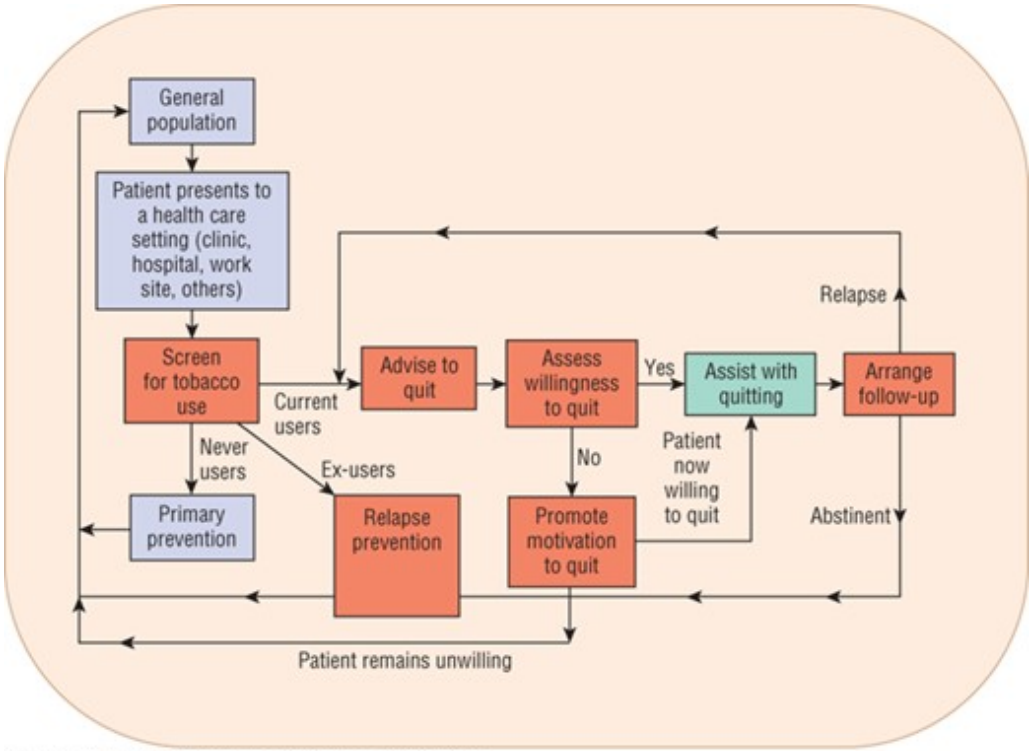

FIGURE 66-2

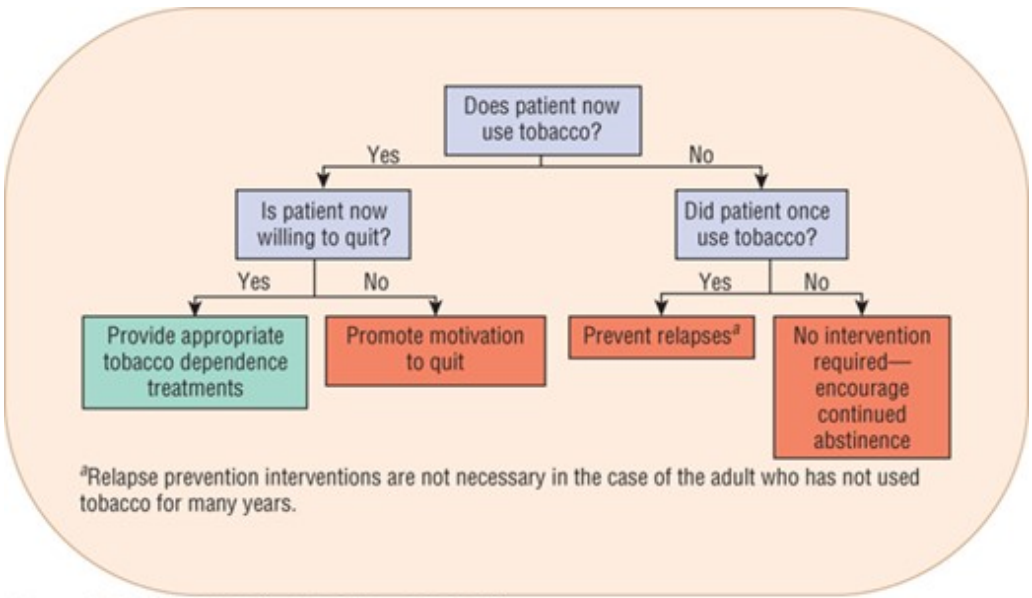
Algorithm for treating tobacco use.



The guideline identified a number of key findings that clinicians should use:

1. Tobacco dependence is a chronic condition that often requires repeated intervention. However, effective treatments exist that can produce long-term or permanent abstinence.

2. Because effective tobacco-dependence treatments are available, every patient who uses tobacco should be offered at least one of these treatments.

3. It is essential that clinicians and healthcare delivery systems (including administrators, insurers, and purchasers) institutionalize the consistent identification, documentation, and treatment of every tobacco user who is seen in a healthcare setting.

4. Brief tobacco-dependence treatment is effective, and every patient who uses tobacco should be offered at least brief treatment.

5. There is a strong dose–response relationship between the intensity of tobacco-dependence counseling and its effectiveness. Treatments involving person-to-person contact (via individual, group, or proactive telephone counseling) are consistently effective, and their effectiveness increases with treatment intensity (eg, minutes of contact).

6. Three types of counseling and behavioral therapies were found to be especially effective and should be used with all patients who are attempting tobacco cessation:

    - Provision of practical counseling (problem-solving/skills training)
    - Provision of social support as part of treatment (intratreatment social support)
    - Help in securing social support outside treatment (extratreatment social support)

CLINICAL PRESENTATION Nicotine Withdrawal General

- The patient may experience anxiety, but may not be in acute distress. Symptoms can wax and wane over time.

Symptoms

- The patient may complain of cravings, difficulty concentrating, frustration, irritability, and impatience. Hostility, insomnia, and restlessness can also occur.

Signs

- Increased skin temperature can be present.

Numerous effective pharmacotherapy options for smoking cessation now exist (**Table 66-5**). Seven first-line pharmacotherapy options reliably increase long-term smoking abstinence rates: sustained-release (SR) bupropion, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch, and varenicline. Combinations of these should be considered if a single agent has failed.

TABLE 66-5 Dosing and Monitoring of Pharmacologic Agents Used for Smoking Cessation

Drug	Place in	Dosage Range	Duration	Comments/Monitoring	LOEE[a]

	Therapy			Parameters	
Bupropion SR[b,c] (Zyban)	First-line	Titrate up to 150 mg orally twice daily. May require reduced initial dose in elderly	3-6 months	Patients receiving both bupropion and a nicotine patch should be monitored for hypertension	A1
Clonidine[c,d] (Catapres)	Second-line	Titrate to response; 0.2-0.75 mg/day. Consider dose reduction in the elderly	6-12 months	Monitor baseline electrolyte and lipid profiles, renal function, uric acid, complete blood count, and blood pressure	B2
Nicotine polacrilex (gum)[b] (Nicorette)	First-line	Initial dose depends on smoking history: 2-4 mg every 1-8 hours	12 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy	A1
Nicotine inhaler[b] (Nicotrol)	First-line	24-64 mg/day (total daily dose)	3-6 months (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy	A1
Nicotine nasal spray[b] (Nicotrol NS)	First-line	8-40 mg/day (total daily dose)	14 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy	A1
Nicotine patch[b] (NicoDerm, Nicotrol)	First-line	Initial dose depends on smoking history: 7-21 mg topically once daily	6 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy	A1
Nortriptyline[c,d] (Aventyl)	Second-line	Titrate up to 75-100 mg orally daily	6-12 months	Dry mouth, blurred vision, and constipation are dose-dependent adverse effects	B2
Varenicline[c] (Chantix)	First-line	Titrate up to 1 mg orally twice daily. If CrCl <30 mL/min (0.5 mL/s), 0.5 mg once per day	3-6 months	Monitor renal function, especially in elderly patients. Nausea, headache, insomnia are dose-dependent adverse effects	A1

LOEE, level of evidence for efficacy.

[a]Strength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: 1, evidence from more than one properly randomized controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case–control analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

[b]Nicotine replacement therapies can be combined with each other and/or bupropion to increase long-term abstinence rates.

[c]Do not abruptly discontinue. Taper up initially, and taper off once therapy is complete.

[d]Clonidine and nortriptyline are not FDA-approved for smoking cessation.

Data from reference 38.

Two second-line pharmacotherapy options are considered efficacious and can be considered by clinicians if first-line options are not effective: clonidine and nortriptyline.[38] Tobacco-dependence treatments are both clinically effective and cost-effective relative to other medical and disease prevention interventions. As such, insurers and purchasers should ensure all insurance plans include as a reimbursed benefit the counseling and pharmacotherapeutic treatments that are identified as effective in this guideline, as well as clinician reimbursement for providing tobacco-dependence treatment just as they are reimbursed for treating other chronic conditions.

Other Factors Important to the Success of a Smoking-Cessation Strategy

The AHRQ expert panel emphasized the importance of the type and intensity of the contact with the counselor to the success of the intervention. When interventions last for more than 10 minutes, the increase in cessation rates is much better than when interventions do not involve contact with a professional. Group and individual counseling are more effective than no intervention in increasing abstinence rates. Self-help materials (e.g., handouts, pamphlets, and brochures) without any direct physical contact are not effective.[52] Interventions are more successful when they include social support and training in general problem-solving skills, stress management, and relapse prevention. The number of treatment sessions offered is also important. Providing at least four or more sessions, longer than 10 minutes in length, and if possible providing treatments from multiple types of clinicians have proven higher success rates compared with less intensive interventions.[38] A Cochrane analysis reviewed 38 trials, which included approximately 15,000 patients who received a combination of pharmacotherapy treatment and behavioral support either in person or through telephone support. It was determined based on the results of these trials the addition of behavioral support could improve the chances of cessation from 10% to 25%.[53] Although comprehensive behavioral interventions have been shown to be more effective in helping people quit smoking and remain abstinent, less intensive treatments are beneficial as well. Even minimal contacts lasting less than 3

minutes including the steps known as the 5 A's: Ask, Advise, Assess, Assist, and Arrange are more successful in increasing cessation rates than intervention involving no contact.[38]

Motivational interviewing is a form of counseling to help patients identify barriers for making a behavior change. A meta-analysis[54] of 28 studies published between 1997 and 2014, including over 16,000 smokers who underwent motivational interviewing as part of the smoking cessation program, found that motivational interviewing with standard care or brief cessation advice did improve quit rates modestly. Subgroup analysis found that motivational interviewing was most effective when completed in shorter sessions by general practitioners.

Other forms of interventions have been identified as effective to improve smoking cessation rates. Telephone-based quitlines which are operated by the National Cancer Institute and offered in all 50 states, the District of Columbia, Puerto Rico, and Guam via 1-800-QUIT-NOW provide various options such as recorded messages, counseling services, mailed materials, counselor follow up services, and access to pharmacotherapy options for smoking cessation.[55] Physicians are also offered a referral process to the quitlines to improve time efficiency by suggesting the patients call the quitline, or by faxing or emailing a referral. Studies evaluating this process have identified combining the physician visit with a referral to a quit line has been effective in improving quit rates.[56] Quitlines are also now included with the graphic warning labels on the cigarette packages to help improve utilization of the counseling services. The use of technology to further enhance counseling opportunities has also increased over the years including websites, text messaging, social networking, and smart phone applications although further studies are needed to determine what format is the most effective.[57]

Counseling alone can be effective, but counseling efficacy is further augmented by the addition of pharmacotherapy. In a meta-analysis that included 150 trials with more than 50,000 participants using one or more of the five forms of nicotine replacement therapy (NRT) including nicotine gum, nasal spray, transdermal patches, sublingual tablets/lozenges, or inhaler, it was found that the use of NRT significantly increased the rate of cessation by 50% to 70% compared with placebo. Although counseling is suggested by guidelines, it was shown that NRT is effective independent of counseling services.[58]

Pharmacologic Therapy for Smoking Cessation

All patients attempting to quit should be encouraged to use effective pharmacotherapy agents for smoking cessation except in the presence of special circumstances. First line agents include NRT, sustained release bupropion hydrochloride, and varenicline tartrate.[38] As with other chronic diseases, the most effective treatment of tobacco dependence encompasses multiple modalities. Pharmacotherapy is a vital element of a multicomponent smoking cessation program that should always include nonpharmacologic components. The role of pharmacotherapy in smoking cessation is summarized in Table 66-5.

Nicotine Replacement Therapy

7 In 2012, a systematic review[58] was performed to determine the effectiveness of the different

forms of NRT (eg, chewing gum, transdermal patches, nasal spray, inhalers, and tablets) in achieving abstinence or a sustained reduction in the amount smoked. The review showed that all of the commercially available forms of NRT were effective for smoking cessation and increased quit rates by 50% to 70%.

Nicotine Gum

Clinicians should offer 4-mg rather than 2-mg nicotine gum to highly dependent smokers.[38] The 2-mg gum is recommended for patients smoking fewer than 25 cigarettes per day, whereas the 4-mg gum is recommended for patients smoking 25 or more cigarettes per day. Generally, the gum should be used for up to 12 weeks, no more than 24 pieces chewed per day. Gum should be chewed slowly until a peppery or minty taste emerges and then "parked" between cheek and gums to facilitate nicotine absorption through the oral mucosa. Acidic beverages (eg, coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing. Instructions to chew the gum on a fixed schedule (at least one piece every 1-2 hours) for at least 1 to 3 months can be more beneficial than ad libitum use.[38]

Nicotine Patch

The nicotine patch is available both as a nonprescription medication and as a prescription drug, and it approximately doubles long-term abstinence rates over those produced by placebo interventions.[58] Treatment of 8 weeks or less has been shown to be as efficacious as longer treatment periods. It has also been shown combining the nicotine patch with an oral formulation such as the nicotine gum which allows ad libitum nicotine delivery can improve the overall cessation without significant increased risk for harm.[59] Clinicians should consider starting treatment on a lower patch dose in patients smoking 10 or fewer cigarettes per day.[38] The 16- and 24-hour patches have shown a possible benefit in comparison to the standard dose patches which could be considered for heaviersmokers.[58] A patch should be applied as soon as the patient wakes on the quit day and at the start of each day thereafter. The patient should place a new patch on a relatively hairless location, typically between the neck and waist. There are no restrictions on activity while using the patch. Patients who experience sleep disruption should remove the 24-hour patch prior to bedtime or use the 16-hour patch.[38]

Nicotine Nasal Spray

Nicotine nasal spray more than doubles long-term abstinence rates when compared with a placebo spray. It is available exclusively as a prescription medication. A dose of nicotine nasal spray consists of one 0.5-mg delivery to each nostril (1 mg total). Initial dosing should be one to two doses per hour, increasing as needed for symptom relief. The minimum recommended treatment is 8 doses per day, with a maximum limit of 40 doses per day (5 doses per hour). Recommended duration of therapy is 3 to 6 months. Patients should not sniff, swallow, or inhale through the nose while administering doses because this increases irritating effects.[38]

Nicotine Lozenge

The nicotine lozenge is available as a 2-mg and a 4-mg dose. The 2-mg lozenge is recommended for patients who normally smoke their first cigarette later than 30 minutes after awakening, and the 4-mg lozenge is recommended for smokers who smoke within 30 minutes of waking. The duration of treatment is 12 weeks. It is recommended no more than 20 lozenges should be used in 1 day.[38] The most common side effect of the lozenge is nausea. As with the nicotine gum, acidic beverages (eg, coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during use of the lozenge.[38]

Instructing Patients in the Use of NRT

Compliance with NRT improves when the patient is presented a clear rationale for its use and a realistic expectation about the response. It should be explained to the patient that nicotine is responsible for addiction and discontinuation of the nicotine causes craving for cigarettes, tension, irritability, sadness, problems with sleep, and difficulty concentrating. The patient should be told using the patch results in less desire to smoke and provides an opportunity for a new nonsmoker to practice all the new nonsmoking skills without being burdened by craving. The patient should understand that with smoking, there are naturally peaks and valleys in the amount of nicotine in the bloodstream. With the patch, there is a steady gradual rise in the blood nicotine concentration that levels off and remains constant for much of the day, and then gradually decreases while the person is asleep.[38]

Side Effects

Nicotine-replacement products have relatively few side effects. Nausea and light-headedness are possible symptoms of nicotine overdose that warrant a reduction of the nicotine dose. The most frequent side effect with the nicotine patch is skin irritation related to the adhesive or the medium containing nicotine and not to the nicotine itself. Approximately 50% of patients report skin irritation during the course of treatment with the patch. The patch site can be rotated to diminish this problem. Switching to a different brand of patch can alleviate the problem because different products use different adhesives or media. The gum can be used instead of the patch when the skin irritation is severe. Less than 5% of patients were forced to discontinue therapy because of skin reactions.[38]

Duration

Those who commit to quitting smoking using NRT should be told that treatment for up to 3 months is common.[60] However, some patients will experience severe withdrawal even beyond this time period; thus, long-term use of NRT might be indicated. Long-term use of NRT has not been linked to any safety concerns and is supported by the 2008 updated US Public Health Service Guidelines.[38]

Non-Nicotine Options

Bupropion

Bupropion inhibits neuronal reuptake and potentiates the effects of norepinephrine and dopamine. Although its precise mechanism in smoking cessation is not well understood, dopamine has been associated with the rewarding effects of addictive substances. The AHRQ panel concluded that SR bupropion is an efficacious smoking cessation treatment that patients should be encouraged to use.[38]

Contraindications for bupropion use include current or past seizure disorders, a history of monoamine oxidase inhibitor use over the last 14 days, and a history of anorexia nervosa or bulimia. Along with multiple other precautions listed in the product labeling, current alcohol use, use of medications that lower seizure threshold (eg, antidepressants and antipsychotics), and depression are possible concerns when using this medication.[38] In 2009, the FDA required manufacturers of Zyban (bupropion) and generic manufacturers to add new boxed warnings and to develop a medication guide highlighting the risk of serious neuropsychiatric symptoms in patients using this product. Possible symptoms include depressed mood, agitation, anxiety, hostility, changes in behavior, suicidal thoughts and behavior, and attempted suicide.[38] A meta-analysis[61] involving 65 trials utilizing bupropion for smoking cessation showed that bupropion significantly increased the incidence of long-term cessation when used as a sole agent in 44 separate trials. Other trials that used bupropion as an add-on agent with NRT did not show additional benefit in improving cessation rates.[61]

For smoking cessation, the manufacturer recommends a dosage of 150 mg once daily for 3 days and then twice daily for 7 to 12 weeks or longer, with or without NRT. Patients are instructed to stop smoking during the second week of treatment and are encouraged to use counseling and support services along with the medication. For maintenance therapy, consider SR bupropion 150 mg twice daily for up to 6 months.[38]

Varenicline (Chantix)

Varenicline acts at sites in the nicotine-affected brain in two ways: by providing nicotine effects to ease withdrawal symptoms and by blocking the effects of nicotine from cigarettes if they resume smoking. Specifically, varenicline is a partial agonist that binds selectively to α_4-β_2-nicotinic acetylcholine receptors with a greater affinity than nicotine. When bound tothe receptor, the drug blocks nicotine from binding and also evokes a response but to a lesser degree than nicotine. The stimulation ofthe receptor results in release of dopamine and thus provides a type of “reward” that can decrease craving and withdrawal symptoms.[62]

8 The recommended dosage for varenicline is 0.5 mg daily for 3 days, increase to 0.5 mg twice daily for 3 days, and then increase to 1 mg twice daily for a standard 12-week treatment. It is suggested the quit date should be set for 1 week after initiating varenicline, but recent studies have shown allowing a flexible quit date is also efficacious and safe. If abstinence has not been achieved after the 12-week treatment, then a second 12-week treatment may be prescribed.[63]

Varenicline is listed as a first-line agent in the 2008 clinical guidelines on treating tobacco use and

dependence. Fourteen trials comparing varenicline with placebo, three of which also had a comparison with bupropion, were reviewed in a meta-analysis.[64] Varenicline resulted in an over two fold increased likelihood of long-term smoking cessation compared with counseling alone. The most common side effect seen in these studies was mild to moderate nausea over a short period of time following treatment initiation.

Since 2006, when varenicline was approved by the FDA, alarming numbers of adverse effects, including suicidal thoughts, erratic behavior, and aggressive behavior, have been reported. The large number of reports led to the release of a Public Health Advisory by the FDA in February 2008.[65] The advisory stressed the importance of screening for any type of psychiatric illness or any behavior changes after starting varenicline. A boxed warning along with an update of the medication guide from the manufacturer was required by the FDA.[66] The FDA sponsored two epidemiologic studies that evaluated the neuropsychiatric adverse events linked to the use of varenicline. These studies had multiple limitations, and although the studies did not show an increased risk of hospitalization secondary to neuropsychiatric events, it is important for both healthcare professionals and patients to be aware of the possible risks associated with the use of varenicline.[67] Specific warnings stress patients should report any history of psychiatric illness and any changes in behavior or mood immediately to their prescribing practitioner.[68] Since the addition of the boxed warning, there have been additional reports of adverse reactions when mixing varenicline with alcohol, including decreased tolerance to the effects of alcohol and unusual behavior. There have also been some rare reports of seizures predominately in the first month of treatment with varenicline in patients with well-controlled seizure disorder or no history of seizures.[68]

Additionally, in 2011, the FDA issued a safety communication reporting cardiovascular adverse events, including myocardial infarctions, which were seen in a higher number of patients receiving varenicline compared with placebo.[69] A meta-analysis[70] was completed which included over 7,000 patients enrolled in randomized, controlled, double-blind, placebo controlled trials greater than or equal to 12 weeks in duration. The goal of this meta-analysis was to study the cardiovascular safety by evaluating the number of occurrences of major adverse cardiac events and the timing of these events. Although a trend for increased risk of cardiac events was observed in this analysis, the increased risk was not found to be statistically significant.[70] The current recommendation from the FDA is to evaluate the risk versus benefit of using varenicline[71] since there is a greater than twofold increased likelihood of long-term smoking cessation compared with nonpharmacologic treatment when using varenicline.[64] It has been shown varenicline was more effective in helping patients to achieve smoking cessation and maintain abstinence for up to 1 year than placebo.[72]

Clinical Controversy…

It has been well established that smoking during pregnancy can lead to adverse outcomes during the pregnancy including miscarriage, placental abruption, preterm delivery, and low birth rate leading to a higher risk of infant morbidity and mortality.[38] In 2012, a Cochrane review of 6 trials utilizing NRT in 1,745 pregnant women concluded there was insufficient evidence to support efficacy or safety in using NRT in pregnancy. (RR 1.3; 95% CI 0.93-1.9).[73] In 2014, the SNIPP trial, a randomized, double

blind, placebo controlled, parallel group, multicenter trial included 402 pregnant women who were randomized into NRT with nicotine patches or placebo treatment from quit day until delivery. Nicotine patches did not improve cessation rates compared to placebo, although the incidences of serious adverse effects were not higher for the NRT treatment group.[74] The SNAPP trial evaluated 1,050 pregnant smokers who were randomized to NRT or placebo and followed at multiple endpoints including 1 month after starting therapy, at delivery, and at 6, 12, and 24 months following delivery.[75] NRT was effective during the first month, but subsequently efficacy was equal to placebo with regards to smoking cessation. Children involved in the study showed no difference in birth weight or respiratory issues, but the children randomized into the NRT group did have fewer developmental problems compared to the placebo group. In a 2015 retrospective population-based study, over 2,500 children with maternal exposure to NRT during pregnancy were shown not to have experienced adverse effects linked to NRT.[76] Although it is clear more research is needed, the current recommendations are similar to the 2008 guidelines. Behavioral therapy should be attempted, but if this fails then the risks and benefits of NRT should be discussed, and initiation of the NRT and proper monitoring should be considered if appropriate based on the individual patient.[38]

Comparison of NRT and Non-Nicotine Options

A systematic review and multiple treatment meta-analysis was performed using a Bayesian model to evaluate the effect of high-dose and standard-dose NRT, combination NRT, bupropion, and varenicline.[77] The primary outcome included smoking abstinence at 4, 12, 26, and 52 weeks following the set quit date. The standard- and high-dose NRT patch, bupropion, and varenicline were shown to be superior to placebo and controls on a consistent basis. Varenicline was shown to be statistically more effective in achieving smoking abstinence compared with the other agents except at 6 months when compared with high-dose NRT patches and combination therapy. It is difficult to identify which agent is more effective over another at this time, since other considerations, such as cost and specific patient factors must also be taken into account.[77] Furthermore, a meta-analysis was performed which included 12 Cochrane reviews between 2008 and 2012, 267 trials, and 101,000 smokers to evaluate benefits and risks associated with the first line pharmacotherapy agents including: NRT, varenicline, and bupropion. Additionally, other agents including nortriptyline and clonidine were also evaluated in this review. All first line smoking cessation agents were found to be superior to placebo, and varenicline was found to be superior to both single forms of NRT (OR 2.88; 95% CI 2.40-3.37) and to bupropion (OR 1.59; 95% CI 1.29-1.96) and is equally effective in comparison to combination NRT (OR 1.06; 95% CI 0.75-1.48). Bupropion and NRT were equal in efficacy. In regards to safety, there were no excessive neuropsychiatric events or cardiovascular events with bupropion (neuropsychiatric events data: RR 0.88; 95% CI 0.31-2.50; cardiovascular data: RR 0.77; 95% CI 0.37-1.59) and no excessive neuropsychiatric events with varenicline (RR 0.53; 95% CI 0.17-1.67) and no statistically significant cardiovascular events. (RR 1.26; 95% CI 0.62-2.56).[78]

Second-Line Medications

Second-line medications are pharmacotherapy options for which there is evidence of efficacy for treating tobacco dependence, but which have a more limited role than first-line medications because

(a) the FDA has not approved them for treatment of tobacco dependence and (b) there are more concerns about potential side effects than with first-line medications.[38] Second-line treatments should be considered for use on a case-by-case basis after first-line treatments have been used or considered.

Clonidine

It has been found that clonidine is efficacious as a smoking cessation treatment. It can be used off-label as a second-line agent to treat tobacco dependence. A meta-analysis of six trials showed that clonidine increased smoking cessation rates by 9% (RR 1.63, CI 1.22-2.18).[78] There are reports of dose-dependent side effects, particularly sedation and hypotension. It should be noted that abrupt discontinuation of clonidine can result in symptoms, such as nervousness, agitation, headache, and tremor, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine levels.[38] Doses have varied significantly, from 0.15 to 0.75 mg/day orally and from 0.1 to 0.2 mg/day transdermally, without a clear dose–response relationship to cessation. Most commonly reported side effects include dry mouth, drowsiness, dizziness, sedation, and constipation. Clonidine will lower blood pressure in most patients; thus, blood pressure should be monitored.[38]

Nortriptyline

It is also considered to be efficacious as a second-line agent for tobacco dependence. Therapy is initiated 10 to 28 days before the quit date to allow it to reach steady state at the target dose. Trials have initiated treatment at a dose of 25 mg/day, increasing gradually to a target dose of 75 to 100 mg/day. Duration of treatment used in smoking cessation trials has been approximately 12 weeks. A recent meta-analysis of 6 trials with 975 patients showed that nortriptyline as a sole agent does show similar efficacy to NRT and has also been effective in increasing long-term cessation rates.[61] Most commonly reported side effects include sedation, dry mouth, blurred vision, urinary retention, light-headedness, and tremor.[38]

Future Treatments

Work continues on the development of vaccines to treat nicotine addiction. Vaccines are designed to produce antibodies that bind to nicotine and prevent it from entering the brain. As a result, the positive stimulus in the brain that is normally caused by nicotine is no longer present, thereby taking away the physical motivation for smoking.[79]

Multiple vaccines have been in development including NicVAX, NicQb, and Niccine, but clinical trial results utilizing the first generation of nicotine vaccines have been disappointing. It is postulated the vaccines have not been able to produce the antibody levels needed to achieve clinical efficacy, and the challenges presented by patient individual variability have also been detrimental.[79] Research is needed to further develop next-generation vaccines in hopes that this will become a treatment option for smoking cessation in the future.

Personalized Pharmacotherapy

The genetics associated with nicotine addiction is very complex and continues to be studied with great interest. Many phenotypes and corresponding genes have been identified which affect smoking behavior, including nicotine dependence, daily cigarette consumption, onset of smoking, smoking cessation success, and withdrawal symptoms.[80] Studies continue to evaluate the effects of polymorphisms in various genes and the effect this has on the efficacy of pharmacotherapy treatment options. Additionally, genetic variability in nicotine metabolism continues to be evaluated since variations in Cytochrome P450 2A6 leads to different addiction rates to nicotine and responses to NRT.[80] Further understanding of these variations will prove helpful in creating a personalized pharmacotherapy plan to improve smoking cessation rates.

Electronic Nicotine Delivery Systems

The electronic nicotine delivery systems (ENDS; also known as e-cigarettes or electronic cigarettes) are designed to deliver a propylene glycol or glycerol product with a combination of nicotine, flavorings, and/or other chemicals through an aerosol. Using this device is commonly referred to as "vaping." It has been suggested that using the products instead of smoking traditional cigarettes can eliminate the exposure to most of the toxins commonly seen in traditional cigarettes.[81] The range of nicotine delivered to the user can vary according to the product type and brand, but can also be affected by the temperature and the specific delivery system.[82] At the time of this writing, no ENDS has been approved by the FDA as a cessation aid, although these products have gained popularity as a cessation aid. A review of 2 studies which included 600 people indicated the use of e-cigarettes with nicotine improved the chances of long term smoking cessation compared with e-cigarettes without nicotine. To date, there are not enough studies comparing e-cigarettes with nicotine to traditional NRT options for smoking cessation. The evidence for efficacy of e-cigarettes with nicotine for smoking cessation is low, and further studies are needed. Additionally, the safety of e-cigarettes has not been studied to determine the risks associated with the chemicals used in these devices, the amount of nicotine exposure delivered, nor the risk of second-hand exposure to the chemicals emitted while vaping. The popularity of these agents is also concerning since younger individuals might feel this is a safer alternative to smoking and become addicted to nicotine through this method.

Clinical Controversy…

A huge debate continues regarding e-cigarettes. The e-cigarettes are viewed as a better choice over traditional cigarettes by some since the user will not be exposed to the carcinogens associated with smoking traditional cigarettes. However, there are other concerns associated with e-cigarette including possible dangers associated with propylene glycol or glycerol and added flavorings that are included in these products. Additionally, e-cigarettes can appeal to adolescents due to the belief that e-cigarettes are safer and varieties of flavors offered in these products can be very appealing as well. Exposure of the developing brain to nicotine could increase the risk of developing a nicotine addiction. A recent study has shown that exposure to e-cigarettes did increase the likelihood of using other tobacco products including traditional cigarettes and other forms of tobacco within the

following year of e-cigarette exposure. Further studies are needed to clarify the benefits of e-cigarettes compared to the risks.[83]

CAFFEINE

Caffeine is the most widely consumed behaviorally active substance in the world, generating an increased sense of well-being, happiness, energy, alertness, and sociability.[84] Caffeinism is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine. The syndrome usually is characterized by CNS and peripheral manifestations, most notably anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiologic complaints. As many as one in five adults consumes doses of caffeine generally considered large enough to cause clinical symptoms.[84]

Pharmacologically, the risk of developing meaningful clinical manifestations becomes high when intake exceeds 500 mg/day. Drinking traditional coffee, it could be assumed this level of caffeine might not be reached. This helps explain why, up until recently, deaths from acute ingestions of caffeine were virtually nonexistent. However, pure caffeine powder has become available via the Internet,[85] and some individuals have been using it by the teaspoonful. One teaspoonful of the bulk powder is estimated to be equivalent to 25 to 30 cups of coffee. The "recommended dose" is 1/64th to 1/16th of a teaspoonful, which is equivalent to 2 cups of coffee, and exceeding this dose has led to toxicity including life threatening cardiac arrhythmias and death. Due to this risk, efforts are being made to regulate powdered caffeine, which currently is available for purchase without regulation.[85]

Caffeine has been proposed as a "model of drug abuse" despite the facts that its sale is largely unrestricted and that heavy consumption of caffeine-containing beverages is not considered to be drug abuse. The following information represents a broad overview of dependence, withdrawal, and tolerance. The reader interested in more information is urged to consult the exhaustive review by Juliano et al.[84]

Epidemiology of Caffeine Use and Abuse

Recently, data from the What We Eat in America/National Health and Nutrition Examination Survey (NHANES) was evaluated on caffeine consumption in the United States through caffeinated beverages, foods, and energy drinks. This data showed that 89% of men and women in the United States consume caffeine daily, predominantly through caffeinated beverages (98%). The most common caffeinated beverage was coffee (64%), tea, and soft drinks were less popular (16% and 18%, respectively). The intake of caffeine averaged 186 mg/day, and over half of the consumers ingested this amount in one consumption.[86] Caffeine intake among children, adolescents, and young adults is prevalent from foods and beverages based on the 1999 to 2010 NHANES data analyzing ages of participants from 2 years old to 22 years old. It was found that 73% consumed caffeine, although the caffeine consumption overall remained similar through the years, the choice of beverages has changed from predominately soda in 1999 to 2000 to a combination of soda, sweetened coffee, and energy drinks in 2009 to 2010.[87]

Energy Drinks

A number of energy drinks containing caffeine, taurine, vitamins, and sugar which are sold under brand names such as Red Bull, Monster Energy, Rockstar, NOS, and Amp, continue to gain popularity among adolescents and emerging adults. It is now estimated that 30% to 50% of this population are now using these products.[88] The amount of caffeine in 1 can of Red Bull (8.4 oz [250 mL]) includes77 mg of caffeine, although other products can contain higher amounts of caffeine depending on the size of the container. The energy shot, a 2 ounce (60 mL) product, claims to contain the "same amount of caffeine as a cup of coffee" and also includes a variety of B vitamins and other products claimed to improve energy.[89] Since these products commonly include natural ingredients such as ginkgo, they are regulated by the 1994 Dietary Supplement and Education Act and are not required to disclose how much caffeine is in the product.

10 Many questions on the safety of the use of these products have been raised due to the increase in emergency department visits which doubled from 2007 to 2011.[90] Reports submitted to the FDAs Center for Food Safety and Applied Nutrition from 2004 to 2012 included over 20 reports on adverse reactions to Red Bull, including cardiac symptoms, anxiety, aggression, and convulsions.[91] Additionally, there are multiple case reports of cardiovascular events including atrial fibrillation, ST-elevation myocardial infarctions, and fatal ventricular arrhythmias in adolescents following energy drink consumption.

Several manufacturers were marketing alcoholic beverages containing caffeine. In 2010, the FDA requested that the manufacturers remove the caffeine from their products. Unfortunately, mixing the energy drinks with alcohol remains popular and has been proven dangerous because the high levels of caffeine can reduce awareness and mask the typical depressant effects of alcohol, giving the consumer a false sense of competence leading to poor decision making such as drunk driving or other increased risky behavior.[92]

Differential Diagnosis

The DSM-5 has 4 caffeine-related diagnoses including: caffeine intoxication, caffeine withdrawal, other caffeine-induced disorders which include both caffeine induced sleep and anxiety disorders, and unspecified caffeine-related disorder which includes symptoms, which might be attributed to caffeine use, but does not fit in any of the other categories. DSM-5 does not currently list a diagnosis of caffeine use disorder (CUD), but it has been identified as an area which needs further research to determine if CUD should become an official diagnosis.[8]

The diagnostic criteria for caffeine intoxication include recent consumption of caffeine normally exceeding 250 mg and 5 or more symptoms during or shortly after consumption of caffeine. The symptoms of caffeine intoxication will usually decrease over 24 hours as the caffeine is eliminated from the body. Consumption of very high doses of caffeine could be dangerous and require immediate medical attention.[8]

Caffeine withdrawal is a new diagnosis in the DSM-5. It occurs after the abrupt cessation of chronic

caffeine use and can occur even with low doses of caffeine in some patients. The diagnosis of caffeine withdrawal requires 3 of the 5 listed symptoms, including headache (most common), marked fatigue or drowsiness, altered mood (depressed, irritable, and dysphoric), difficulty in concentrating, or flu-like symptoms including nausea, vomiting, muscle pain/stiffness (**Table 66-6**). The extent and severity of withdrawal can vary individually but normally will be more severe with higher chronic doses of caffeine.[8]

TABLE 66-6 DSM-5 Diagnostic Criteria for Caffeine Withdrawal

Criteria
Prolonged daily use of caffeine

Abrupt cessation or decreased use in caffeine leading to at least three of the following symptoms after 24 hours of cessation
• Concentration problems
• Mood changes: dysphoric mood, depressed mood, irritability
• Dramatic fatigue or drowsiness
• Headache
• Flu-like symptoms
  ○ Nausea
  ○ Vomiting
  ○ Muscle pain/stiffness

Symptoms negatively impact areas of functioning such as social or occupational functioning.
Symptoms experienced cannot be explained by other concurrent medical conditions.

Data from reference 8.

Pharmacology of Caffeine

Caffeine is rapidly and completely absorbed from the GI tract, reaching a peak blood level within 30 to 60 minutes after oral ingestion. It easily crosses the blood–brain barrier, and levels achieved in the brain are proportional to the dose administered.[93] The half-life of caffeine in humans is approximately 4 to 6 hours in healthy nonsmoking adults. Smoking will result in a shorter half-life, and liver dysfunction and pregnancy will extend the half-life.[93] Overdoses of caffeine are now more common due to the wide availability of energy drinks. Caffeine increases the heart rate and force of cardiac contraction and also has a strong diuretic effect. Due to the stimulating properties of caffeine, nervousness, agitation, and insomnia may occur. More serious reactions could include cardiac arrhythmias, hypotension, and convulsions.[94] The key factor promoting caffeine use and dosage

increases can be the drug's reinforcing effect on pleasure and reward centers of the brain. Caffeine's pharmacologic actions appear comparable (although less potent) with those of other stimulants, such as amphetamines and cocaine.[93]

Caffeine Dependence

Research has shown that abstinence from caffeine induces a distinct withdrawal syndrome.[95] In a structured psychiatric interview, subjects who self-identified as having problems with caffeine use were evaluated for features of a *DSM-IV-TR* diagnosis of drug dependence. Those judged to be caffeine dependent manifested at least three of four criteria (eg, tolerance, withdrawal, persistent desire, or an unsuccessful attempt to reduce consumption and persistent use despite adverse psychological or physical consequences). Of 99 people screened, 27 were evaluated by means of a structured psychiatric interview modified for the diagnosis of caffeine dependence; 16 of those subjects (59%) met the criteria. In a second phase of the study, 11 of the 16 caffeine-dependent individuals participated in a 2-day, double-blind, crossover study of caffeine deprivation. Nine showed evidence of caffeine withdrawal during the placebo phase.

CLINICAL PRESENTATION Caffeine Intoxication General

- The patient may not be in acute distress.

Symptoms

- The patient may complain of nausea, vomiting, diarrhea, and psychomotor agitation, and can appear restless, nervous, and excited.

Signs

- The patient can present with facial flushing, diuresis, and muscle twitching.
- Tachycardia or cardiac arrhythmias can also occur.

Laboratory Tests

- Caffeine serum concentrations are rarely used clinically.

Caffeine Withdrawal

The frequency of the caffeine withdrawal syndrome is not well known, but it may be common. Withdrawal can occur when individuals who previously consumed caffeine on a regular basis suddenly discontinue its intake or reduce the dose.[84] The syndrome is characterized by the occurrence of headache, drowsiness, fatigue, and sometimes impaired psychomotor performance, difficulty concentrating, nausea, excessive yawning, and craving. These symptoms usually appear within 18 to 24 hours after discontinuation, corresponding to the time required for the drug to be cleared from the body.

The caffeine withdrawal headache is somewhat unique, starting with a sense of fullness in the head and progressing to throbbing and diffuse pain that is made worse by movement. The maximum intensity of the pain occurs 3 to 6 hours after beginning.

When caffeine is reintroduced, relief of withdrawal symptoms tends to occur within 30 to 60 minutes. Reintroduction of caffeine appears to be the most effective "treatment" for the caffeine withdrawal syndrome.[84]

CLINICAL PRESENTATION Caffeine Withdrawal General

- The patient may not be in acute distress.

Symptoms

- The patient may complain of headache, nausea, vomiting, drowsiness, poor concentration, depressed mood.
- The patient reports the symptoms are adversely affecting overall social/occupational functioning and/or leading to distress.

Laboratory Tests

- Caffeine serum concentrations are rarely used clinically.

Effect on Sleep

Caffeine interferes with sleep in most nontolerant individuals.[84] Tolerant people are much less likely to self-report sleep abnormalities, or they may sense that the insomnia has disappeared altogether. To illustrate, 53% of those consuming less than 250 mg/day agreed that caffeine before bedtime would prevent sleep, compared with 43% of those consuming 250 to 749 mg/day and only 22% of those taking 750 mg/day or more. Even though the higher-level consumers denied that caffeine interferes with their sleep, studies done in the sleep laboratory confirm that caffeine consumers do have greater sleep latency, more frequent awakenings, and altered sleep architecture, and that these effects are dose related.

Caffeine during Pregnancy

Over the years, there has been much discussion on whether or not caffeine intake during pregnancy is harmful to the developing fetus. Results of research have been mixed, but in general, caffeine has not been shown to be a potent and consistent teratogen. Kuczkowski[96] published an evidence-based review highlighting the implications of caffeine intake in pregnancy and offering recommendations for practitioners providing peripartum care to expectant mothers who consume caffeine. The author concluded that, for the healthy pregnant adult, moderate daily caffeine intake at a dose level up to 400 mg/day is not associated with adverse effects, such as general toxicity, cardiovascular effects, effects on bone status and calcium balance, changes in adult behavior, increased incidence of cancer, or effects on fertility. The study did not identify any significant positive associations between

maternal caffeine consumption and cardiovascular malformations. The March of Dimes advises women to limit their caffeine intake to less than 200 mg/day. This recommendation was prompted by the results of a population-based prospective cohort study published in March 2008,[97] showing that pregnant women consuming 200 mg or more of caffeine a day had double the risk of miscarriage compared with those who had no caffeine. Criticism of this study was swift to follow, and its conclusions have been called into question. A Cochrane systematic review[98] points out that authors of some observational studies have concluded that caffeine intake is harmful to the fetus. The review concludes that there is insufficient evidence from RCTs to support any reason to avoid caffeine during pregnancy. Unfortunately, this review is based on only two published controlled trials.

Caffeine and Headaches

A Norwegian study[99] investigated the association between caffeine consumption and headache in the general adult population. Results were based on cross-sectional data from 50,483 (55%) out of 92,566 invited participants aged greater than or equal to 20 years. A weak but significant association (OR 1.16; 95% CI 1.09-1.23) was found between high caffeine consumption and infrequent headaches. In contrast, headache for greater than 14 days/mo was less likely among individuals with high caffeine consumption compared with those with low caffeine consumption. The authors speculate that their results may indicate that high caffeine consumption changes chronic headache into infrequent headache due to the analgesic properties of caffeine. Alternatively, chronic headache sufferers tend to avoid intake of caffeine to not aggravate their headaches, whereas individuals with infrequent headache are less aware that high caffeine use can be a cause.

Treatment

Desired Outcomes

Many people drink coffee, tea, and other caffeinated beverages without problems. When adverse health effects occur (eg, insomnia, headaches, anxiety, AND palpitations), it may be necessary to cut down on the amount of caffeine ingested or to eliminate it altogether to achieve the goal of elimination of these symptoms.

Caffeinism

Caffeinism is treated by reducing or discontinuing the drug. It may be necessary to wean the patient off the drug gradually because going “cold turkey” can produce such serious symptoms that the drug must be restarted. Decaffeinated beverages can be substituted slowly for the caffeinated type. However, relapses are less likely to occur when the drug is discontinued all at once, probably because of the considerable self-discipline required to continue weaning the drug when one knows that an increase in dose will cause the symptoms to abate.

Chapter 67: Schizophrenia

FIGURE 67-1

M. Lynn Crismon; Rania S. Kattura; Peter F. Buckley

INTRODUCTION

KEY CONCEPTS

- 1 Although multiple neurotransmitter dysfunctions are involved in schizophrenia, the etiology is more likely mediated by multiple subcellular processes that are influenced by different genetic polymorphisms.
- 2 The clinical presentation of schizophrenia is characterized by positive symptoms, negative symptoms, and impairment in cognitive functioning.
- 3 Comprehensive care for individuals with schizophrenia must occur in the context of a multidisciplinary mental healthcare environment that offers comprehensive psychosocial services in addition to psychotropic medication management.
- 4 A thorough patient evaluation (eg, history, mental status examination, physical examination, psychiatric diagnostic interview, and laboratory analysis) should occur to establish a diagnosis of schizophrenia and to identify potential co-occurring disorders, including substance abuse and general medical disorders.
- 5 Given that it is challenging to differentiate among antipsychotics based on efficacy, side effect profiles become important in choosing an antipsychotic for an individual patient.
- 6 Pharmacotherapy guidelines should emphasize antipsychotics monotherapies that optimize efficacy-to-side effect ratios before progressing to medications with greater side effect risks. Combination regimens should only be used in the most treatment-resistant patients.
- 7 Adequate time on a given medication at a therapeutic dose is the most important variable in predicting medication response.
- 8 Long-term maintenance antipsychotic treatment is necessary for the vast majority of patients with schizophrenia in order to prevent relapse.
- 9 Thorough patient and family psychoeducation should be implemented, utilizing motivational interviewing methods that focus on patient-driven outcomes in an effort to allow patients to achieve life goals.
- 10 Pharmacotherapy decisions should be guided by systematic monitoring of patient symptoms, preferably with the use of brief symptom rating scales and systematic assessment of potential adverse effects.

Schizophrenia is one of the most complex and challenging of psychiatric disorders. It represents a heterogeneous syndrome of disorganized and bizarre thoughts, delusions, hallucinations, inappropriate affect, and impaired psychosocial functioning. From the time that Kraepelin first described dementia praecox in 1896 until publication of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) in 2013, the description of this illness has continuously evolved.[1] Scientific advances that increase our knowledge of central nervous system (CNS) physiology, pathophysiology, and genetics will likely improve our understanding of schizophrenia in the future.

EPIDEMIOLOGY

The lifetime prevalence of schizophrenia ranges from 0.3% to 0.7%.[1] The worldwide prevalence of schizophrenia is fairly similar among

most cultures. Schizophrenia most commonly has its onset in late adolescence or early adulthood and rarely occurs before adolescence or after the age of 40 years. Although the prevalence of schizophrenia is equal in males and females, the onset of illness tends to be earlier in males. Males most frequently have their first episode during their early 20s, whereas with females it is usually during their late 20s.[1]

ETIOLOGY

Although the etiology of schizophrenia is unknown, research has demonstrated various abnormalities in brain structure and function.[2] However, these changes are not consistent among all individuals with schizophrenia. The cause of schizophrenia is likely multifactorial, that is, multiple pathophysiologic abnormalities can play a role in producing the similar but varying clinical phenotypes we refer to as schizophrenia.

A neurodevelopmental model has been evoked as one possible explanation for the etiology of schizophrenia.[2] This model proposes that schizophrenia has its origins in some as yet unknown in utero disturbance, possibly occurring during the second trimester of pregnancy. Evidence for this is provided by the abnormal neuronal migration demonstrated in studies of brains from people with a diagnosis of schizophrenia. This "schizophrenic lesion" can result in abnormalities in cell shape, position, symmetry, connectivity, and functionality to the development of abnormal brain circuits.[2] Changes are consistent with a cell migration abnormality during the second trimester of pregnancy, and some studies associate upper respiratory infections during the second trimester of pregnancy with a higher incidence of schizophrenia.[3] Other studies associate low birth weight (LBW; less than 2.5 kg [5.5 lb]), obstetric complications, or neonatal hypoxia with schizophrenia.[2] Maternal stress, perhaps related to the effects of circulating glucocorticoids in utero, may be a risk factor for schizophrenia. Maternal "stress" could derive from a variety of external and internal noxious events (malnutrition, infection, etc.). The resulting secondary "synaptic disorganization" associated with such insults is thought not to produce overt clinical manifestations of psychosis until adolescence or early adulthood because this is the corresponding time period of neuronal maturation. Recent attempts to link neurotramsitter abnormalities with a neurodevelopmental model are discussed under pathophysiology.[4]

Although studies show decreased cortical thickness and increased ventricular size in the brains of many patients with schizophrenia, this occurs in the absence of widespread gliosis.[2] One hypothesis is that obstetric complications and hypoxia, in combination with a genetic predisposition, could activate a glutamatergic cascade that results in increased neuronal pruning. It is hypothesized that this genetic predisposition may be related to genes controlling *N*-methyl-D-aspartate (NMDA) receptor activity. As a part of the normal neurodevelopmental process, pruning of dendrites occurs. In normal individuals, approximately 35% of the peak number of dendrites at 2 years of age has been pruned by the time the person reaches mid adolescence. Studies have shown a higher percentage of pruning in individuals with schizophrenia. Furthermore, synaptic pruning predominantly involves glutamatergic dendrites. Hypoxia or other prenatal insult can result in a decreased number of basal neurons from which to start, and glutamatergic activation can exaggerate the pruning process.[2,3] Studies have shown an increased susceptibility to immune/autoimmune disorders in schizophrenia, as well as abnormalities of autoantibodies and cytokine functioning.[5] The immune hypothesis of schizophrenia emphasizes integration of mental and physical well-being.

Numerous studies have shown neuropsychological abnormalities and impairment in reaching normal motor milestones and abnormal movements in young children who later develop schizophrenia.[2] Abnormalities in brain function occur long before the onset of psychotic symptomatology and provide empirical evidence for schizophrenia being a neurodevelopmental disorder.[2] However, the progressive clinical deterioration in many patients suggests that this illness can also have a neurodegenerative component. This is consistent with recent brain imaging studies that show deteriorative brain changes in patients with frequent relapses.[2,6] These changes may be most pronounced among adolescents with early onset schizophrenia.[7] Schizophrenia may be an illness exhibiting neurodegenerative propensity based on a vulnerable neurodevelopmental predisposition.[2,7] Although a specific abnormality has not been discovered, evidence suggests a genetic basis for schizophrenia, and at least part of this may be epigenetic. Although the risk of developing schizophrenia is 0.6% to 1.9% in the US population, the risk is approximately 10% if a first-degree relative has the illness and 3% if a second-degree relative has the illness.[2] If both parents have schizophrenia, the risk of producing an offspring with schizophrenia increases to approximately 40%. Twin studies in dizygotic twins report that the risk of the second twin developing schizophrenia, if one twin has the illness, is between 12% and 14%. However, in monozygotic twins the risk increases to 48%.[2] Adoption studies indicate that the risk for schizophrenia lies with the biologic parents, and environmental changes during the child's developmental stages do not alter this. If schizophrenia occurs in siblings, the onset of illness tends to occur at the same age in each, thus lessening the possibility of an environmental precipitant.

Numerous approaches have been utilized to study the genetics of schizophrenia, including genome-wide association studies (GWAS), copy number variant (CNV) studies, and gene candidate studies.[8] Genetic etiologies in schizophrenia are likely heterogeneous, but present with similar clinical phenotypes, and involve epigenetic interactions.[8] GWAS have identified nearly 20 genetic loci that reach genome-wide significance ($P = 5 \times 10^{-8}$), but only some of these have been replicated in multiple studies.[8] GWAS indicate susceptible genes for schizophrenia on chromosome 6, and common genes underlying psychosis on zinc finger protein 804A (*ZNF804A*), voltage-dependent Ca channel (*CACN1A2*), neurogranin *(NRGN)*, and polybromo 1 (*PBRM1*).[6,8] Of major interest is the finding that polymorphisms of the complement component 4 (*C4*) genes on chromosome 6 may be implicated in the abnormal dendritic pruning seen in individuals with

schizophrenia.[9] Risk for schizophrenia has been demonstrated in CNV studies for deletions on chromosomes 1, 15, and 22. Polymorphism in the 158 valine/methionine (158*Val/Met*) alleles of the catecholamine-*O*-methyl transferase (*COMT*) gene may explain some of the frontal lobe functional deficits in a subset of individuals with schizophrenia.[6] Other recent studies have shown abnormalities in several genes that code for neurodevelopment and for trophic factors.[10,11] For example, dysbindin is a neurodevelopmental protein gene that is found on chromosome 6, and it has been termed a *NMDA-related schizophrenia susceptibility gene*.[12] Alleles associated with decreased dysbindin ribonucleic acid (RNA) in the dorsolateral prefrontal cortex have been reported in patients with schizophrenia and their families.[12] Another recent GWAS of a large pedigree showed an increased signal at chromosome 8p, close to the gene that encodes for neuregulin—another neurodevelopmental gene. Interest is burgeoning regarding how genetic vulnerability might interact with environmental stressors.[6] It is also important to appreciate that there is an overlap—both clinically and biologically—between schizophrenia and mood disorders. Indeed, one "mega genome with association study" found broad overlap in single nucleotide polymorphisms (SNPs) from chromosomes 3, 10, and 12, across schizophrenia, bipolar disorder, and major depression. Two of these SNPs were at loci related to the pathophysiology calcium-channels.[10] Another study showed '108' potential risk loci associated with schizophrenia. Those related to calcium-channel genes as well as glutamatergic genes are immune-related genes.[11] Thus, the epigenetic risk in schizophrenia may be for a spectrum of mental disorders with other factors assisting in determining the clinical phenotype.

PATHOPHYSIOLOGY

Most recent studies have found decreases in gray matter and increases in ventricular size in individuals with schizophrenia. Although some of these changes may be associated with chronic antipsychotic use, particularly with first generation antipsychotics, studies in first break, treatment-naïve individuals also show decreased grey matter. A meta-analysis of systematic reviews conducted since the year 2000 found consistent decreases in gray matter in multiple brain areas, including the frontal lobes, cingulate gyri, and medial temporal regions among others. A corresponding increase in ventricular size was also observed as well as decreased white matter in the corpus callosum.[13] A recent longitudinal study of high-risk youth showed a substantially greater decrease in grey matter in high-risk youth who progressed to psychosis than in high-risk youth who did not progress to psychosis and in normal controls.[14] Changes in hippocampal volume may correspond with impairment in neuropsychological testing.[2,6] Rather than a decrease in the number of neurons in affected brain areas, a decrease in axonal and dendritic communications between cells can result in a loss of connectivity that can be important with respect to neuronal adaptivity and CNS homeostasis.[2,6] These changes are likely consistent with the evidence for abnormal neuronal pruning.[2]

Although a DA-receptor defect likely exists in schizophrenia, this is an over simplification. Presynaptic changes in dopaminergic neurons occur as well, and this is consistent with the neurodevelopmental model that has been proposed.[4, 6] Numerous positron emission tomography (PET) studies have shown regional brain abnormalities, including increased glucose metabolism in the caudate nucleus and decreased blood flow and glucose metabolism in the frontal lobe and left temporal lobe.[2] This may indicate dopaminergic hyperactivity in the head of the caudate nucleus and dopaminergic hypofunction in the frontotemporal regions. PET studies using dopamine-2 (D_2)-specific ligands suggest increased densities of D_2 receptors in the head of the caudate nucleus with decreased densities in the prefrontal cortex.[2,6] However, a meta-analysis showed an increase in presynaptic DA synthesis and release in the striatum with only a small increase in $D_{2/3}$ receptor availability.[15] PET studies assessing dopamine-1 (D_1) function suggest that subpopulations of patients with schizophrenia may have decreased densities of D_1 receptors in the caudate nucleus and the prefrontal cortex. Hypofrontality can be associated with lack of volition and cognitive dysfunction, core features of schizophrenia. It is unknown whether these changes represent a primary event or secondary processes related to other pathophysiologic abnormalities in schizophrenia. Because of the heterogeneity in the clinical presentation of schizophrenia, it has been suggested that the DA hypothesis may be more applicable to "neuroleptic-responsive psychosis," with multiple different etiologies possibly being responsible for causing schizophrenia.[2,4,6] Attempts have been made to develop relationships between these abnormal findings and behavioral symptoms present in patients with schizophrenia. The positive symptoms are possibly more closely associated with DA-receptor hyperactivity in the mesocaudate, whereas negative symptoms and cognitive impairment are most closely related to DA-receptor hypofunction in the prefrontal cortex. Presynaptic D_1 receptors in the prefrontal cortex are thought to be involved in modulating glutamatergic activity, and this can be important with regard to working memory in individuals with schizophrenia.[2,4,6]

A recent commentary attempts to link different neurotransmitter alterations with different phases of schizophrenia.[4] Krystal hypothesizes that a Predrome Phase is associated with glutamategic synaptic dysfunction resulting in a glutamate signaling defect. This deficit is partially compensated for by a down regulation of gamma-amino-butyric acid (GABA) and synaptic proliferation, producing the Prodromal Phase of Schizophrenia. The GABA deficit results in less inhibition of excitatory circuits to dopaminergic projections, producing dopaminergic dysfunction, the onset of psychosis and the Syndrome Phase. The degree of dopamine dysfunction may well be associated with more severe disease.[6] Associated loss of grey matter compounds the synaptic deficits, leading to the Chronic Phase.[4] Clinical support for this hypothesis is based on a recent exploratory analysis indicating that the glutamatergic receptor (mGluR2/3) agonist methionil improves symptoms of schizophrenia in early disease but not in later disease.[16]

The glutamatergic system is one of the most widespread excitatory neurotransmitter systems in the brain. Alterations in its function, either

hypoactivity or hyperactivity, can result in toxic neuronal reactions.[4] Dopaminergic innervation from the ventral striatum decreases the limbic system's inhibitory activity (perhaps through GABA interneurons); thus, dopaminergic stimulation increases arousal. The corticostriatal glutamate pathways have the opposite effect, inhibiting dopaminergic function from the ventral striatum, therefore allowing the limbic system to have increased inhibitory activity. Descending glutamatergic tracts interact with dopaminergic tracts directly as well as through GABA interneurons. Glutamatergic deficiency produces symptoms similar to those of dopaminergic hyperactivity and possibly those seen in schizophrenia. It is proposed that schizophrenia may involve some in utero assault that leads to a developmental defect in NMDA receptor function—so-called NMDA hypofunction. This defect is proposed to have latent clinical expression with the psychotic manifestations from NMDA hypofunction not being seen until late adolescence or early adulthood. MicroRNAs, small noncoding RNAs, are critical to neurodevelopment as well as to regulation of adult neuronal processes. NMDA-regulated microRNA miR-132 is significantly downregulated in individuals with schizophrenia as compared with controls. Several genes are regulated by miR-132, and this altered expression may be related to NMDA hypofunction and the abnormal synaptic pruning seen in the brains of individuals with schizophrenia.[17]

1 Schizophrenia is a complex disorder, and multiple etiologies likely exist. Based on current knowledge, it is naive to think that any currently proposed etiology can adequately explain the genesis of this complex disease. Molecular research involving genetically determined subtle changes in microRNA, G proteins, protein metabolism, and other subcellular processes can eventually identify the biologic disturbances associated with schizophrenia.[2,17] Moreover, the development of distinct biomarkers will help tease out specific phenocopies of schizophrenia as well as the boundaries between psychosis and mood disorders.[18] The advent of regenerative medicine and the application of stem cell research to schizophrenia also holds promise to disentangle the pathobiology of this enigmatic disorder.[19]

CLINICAL PRESENTATION

Schizophrenia is the most common functional psychosis, and great variability occurs in clinical presentation. Despite numerous attempts to portray a stereotype in movies and on television, the stereotypic person with schizophrenia essentially does not exist. Moreover, schizophrenia is not a "split personality." It is a chronic disorder of thought and affect with the individual having a significant disturbance in interpersonal relationships and ability to function in society.

The first psychotic episode can be sudden in onset with few premorbid symptoms, or commonly can be preceded by withdrawn, suspicious, peculiar behavior (schizoid). During acute psychotic episodes, the patient loses touch with reality, and in a sense, the brain creates a false reality to replace it. Acute psychotic symptoms can include hallucinations (especially hearing voices), delusions (fixed false beliefs), and ideas of influence (beliefs that one's actions are controlled by external influences). Thought processes are disconnected (loose associations), the patient may not be able to carry on logical conversation (alogia), and can have simultaneous contradictory thoughts (ambivalence). The patient's affect can be flat (no emotional expression), or it can be inappropriate and labile. The patient is often withdrawn and inwardly directed (autism). Uncooperativeness, hostility, and verbal or physical aggression can be seen because of the patient's misperception of reality. Self-care skills are impaired, and the patient is frequently dirty and unkempt, and in general has poor hygiene. Sleep and appetite are often disturbed. When the acute psychotic episode remits, the patient typically has residual features. This is an important point in differentiating schizophrenia from other psychotic disorders. Although residual symptoms and their severity vary, patients can have difficulty with anxiety management, suspiciousness, and lack of volition, motivation, insight, and judgment. Therefore, they often have difficulty living independently in the community. Because of poor anxiety management and suspiciousness, they are frequently withdrawn socially, and have difficulty forming close relationships with others. In addition, impaired volition and motivation contribute to poor self-care skills and make it difficult for the patient with schizophrenia to maintain employment.

Patients with schizophrenia frequently experience a lack of historicity, or difficulty in learning from their experiences. They can repeatedly make the same mistakes in social conduct and situations requiring judgment. They have difficulty understanding the importance of treatment, including medications, in maintaining their ability to function in society. Therefore, they tend to discontinue medications and other treatments, and this increases the risk of relapse and rehospitalization. The co-occurrence of substance abuse (predominantly alcohol or polysubstance—alcohol, cannabis, and cocaine) in patients with schizophrenia is very common and is another frequent reason for relapse and hospitalization.[1] This effect can be caused by direct toxic effects of these drugs on the brain,[20] but is also caused by the medication nonadherence that is associated with substance abuse. Some drugs of abuse—most notably cannabis—have been associated with a higher prevalence of schizophrenia.[20,21]

Although the course of schizophrenia is variable, the long-term prognosis for many patients is poor. It is marked by intermittent acute psychotic episodes and impaired psychosocial functioning between acute episodes, with most of the deterioration in psychosocial functioning occurring within 5 years after the first psychotic episode.[20] By late life, the patient can appear "burned out," that is, the patient ceases to have acute psychotic episodes, but residual symptoms persist. In a subpopulation of patients, probably 5% to 15%, psychotic symptoms are nearly continuous, and response to antipsychotics is poor.[20]

Schizophrenia is a chronic disorder, and the patient's history must be carefully assessed for dysfunction that has persisted for longer than 6 months. After their first episode, patients with schizophrenia rarely have a level of adaptive functioning as high as before the onset of the

disorder. The *DSM-5* should be consulted for the complete criteria for a diagnosis of schizophrenia.[1] The DSM-5 also asks the clinician to specify the episode severity for schizophrenia after having the diagnosis for at least 1 year and whether the patient is presenting with catatonia.[1]

2 The *DSM-5* classifies the symptoms of schizophrenia into two categories: positive and negative. Greater emphasis is being placed on a third symptom category, cognitive dysfunction (**Table 67-1**).[20] The areas of cognition found to be abnormal in schizophrenia include attention, working memory, and executive function. Positive symptoms have traditionally attracted the most attention and are the ones most improved by antipsychotics. However, negative symptoms and impairment in cognition are more closely associated with poor psychosocial function. Along with these characteristic features of schizophrenia, many patients also have comorbid psychiatric and general medical disorders.[20] These include depression, anxiety disorders, substance abuse, and general medical disorders such as respiratory disorders, cardiovascular disorders, and metabolic disturbances. These comorbidities substantially complicate the clinical presentation and course of schizophrenia.

It has been suggested that symptom complexes can correlate with prognosis, cognitive functioning, structural abnormalities in the brain, and response to antipsychotic drugs. Negative symptoms and cognitive impairment can be more closely associated with prefrontal lobe dysfunction and positive symptoms with temporolimbic abnormalities. Many patients demonstrate both positive and negative symptoms. Patients with negative symptoms frequently have more antecedent cognitive dysfunction, poor premorbid adjustment, low level of educational achievement, and a poorer overall prognosis.[20]

TREATMENT

Desired Outcome

Pharmacotherapy is a mainstay of treatment in schizophrenia, and it is impossible to effectively implement psychosocial rehabilitation programs without antipsychotic treatment in the majority of patients.[20] 3 A pharmacotherapeutic treatment plan should be developed that delineates drug-related aspects of therapy. Most deterioration in psychosocial functioning occurs during the first 5 years after the initial psychotic episode, and treatment should be particularly assertive during this period.[20] The individualized treatment plan created for each patient should have explicit end points defined, including realistic goals for the target symptoms most likely to respond, and the relative time course for response.[23] Other desired outcomes include avoiding unwanted side effects (SEs), integrating the patient back into the community, increasing adaptive functioning to the extent possible, and preventing relapse.

Nonpharmacologic Therapy

Psychosocial rehabilitation programs oriented toward improving patients' adaptive functioning are the mainstay of nondrug treatment for schizophrenia. These programs can include case management, psychoeducation, targeted cognitive therapy, basic living skills, social skills training, basic education, work programs, supported housing, and financial support. In particular, programs aimed at employment and housing have been the more effective interventions and are considered "best practices." Programs that involve families in the care and life of the patient have been shown to decrease rehospitalization and improve functioning in the community. For particularly low-functioning patients, assertive intervention programs, referred to as *active community treatment* (ACT), are effective in improving patients' functional outcomes. ACT teams are available on a 24-hour basis and work in the patient's home and place of employment to provide comprehensive treatment, including medication, crisis intervention, daily living skills, and supported employment and housing.[20] Medication treatment cannot be successful without proper attention to these other aspects of care. People with schizophrenia need comprehensive care, with coordination of services across psychiatric, addiction, medical, social, and rehabilitative services. The level of coordination in the United States is often insufficient, and patients become at risk to "fall through the cracks." National policy documents have called for greater coordination of care.[22] Other countries have highlighted more robust primary and secondary preventative approaches, highlighting early identification, ease of access to care, and staging of disease management.[23] The National Institute of Mental Health (NIMH) Recovery After Initial Schizophrenia Episode (RAISE) study found that four core interventions ("personalized medication management, family psychoeducation, resilience-focused individual therapy, and supported employment and education") significantly improved the quality of life over a 24 month period for individuals with early schizophrenia as compared to usual community care.[24]

Emphasis is growing on the role that the patient plays in a recovery-based system of care, where the person's lifetime aspirations and goals become the center of care, rather than symptom reduction being the primary focus. This recovery-based approach recognizes the strengths and resilience of people with schizophrenia.[24] It also acknowledges how people with schizophrenia can be a support to others who are coping with the illness.[24] It is important to frame clinical decision making in the context of a mutual process involving patient and

clinician—rather than a unilateral "here's a prescription … please take these tablets" approach. It is increasingly recognized that cognitive behavioral therapy can help some patients. Computer-based therapies and social media related approaches are emerging to help people with schizophrenia. Cognitive remediation—which uses computer-based cognitive retraining techniques—has been shown to be of benefit (not FDA approved at time of writing).[25] It is probable that social media and mobile technology strategies may be harnessed to improve communications, medication adherence, and potentially detect early warning signs of impending relapse in patients with schizophrenia. A list of psychotherapeutic approaches to the treatment of schizophrenia is given in **Table 67-2**.

TABLE 67-2 Psychotherapeutic Approaches to the Treatment of Schizophrenia

Individual	Group	Cognitive Behavioral
Supportive/counseling		
Personal therapy		Cognitive behavioral therapy
	Interactive/social	
Social skills therapies		Compliance therapy
Vocational sheltered employment rehabilitation therapies

Pharmacologic Therapy

4 The importance of initial accurate diagnostic assessment cannot be overemphasized. A thorough mental status examination (MSE), psychiatric diagnostic interview, physical, and neurologic examination, complete family and social history, and laboratory workup must be performed to confirm the diagnosis and exclude general medical or substance-induced causes of psychosis. Laboratory tests, biologic markers, and commonly available brain imaging techniques do not assist in the diagnosis of schizophrenia or selection of medication. A pretreatment patient workup not only is important in excluding other pathology, but also serves as a baseline for monitoring potential medication-related side effects, and should include vital signs, complete blood count, electrolytes, hepatic function, renal function, electrocardiogram (ECG), fasting serum glucose, hemoglobin A1c, serum lipids, thyroid function, and urine drug screen.

Both first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs) are used in the treatment of schizophrenia.[26,27,28] Since no absolute criterion distinguishes atypical (second-generation) from typical (traditional or FGA) antipsychotics, and no universally accepted definition exists for an atypical antipsychotic. *Second-generation antipsychotic* is a more appropriate term. Common to all definitions is the ability of the drug to produce antipsychotic response with few or no acutely occurring extrapyramidal side effects (EPS). Other attributes that have been ascribed to some SGAs include enhanced efficacy (particularly for negative symptoms and cognition), absence or near absence of propensity to cause tardive dyskinesia, and lack of effect on serum prolactin.[29] To date, the only approved SGA that fulfills all of these criteria is clozapine.[29] The major factor in distinguishing among antipsychotics is adverse effects.[26,27,29] The major advantage of SGAs is their lower risk of neurologic side effects, particularly effects on movement. However, this is offset by increased risk of metabolic side effects with some SGAs, including weight gain, hyperlipidemias, and diabetes mellitus. 5 Side effect profiles differ among antipsychotics, and this information in combination with individual patient characteristics should be used in deciding which drug to use in an individual patient.

Results from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, primarily in patients with chronic schizophrenia, indicate that olanzapine, compared with quetiapine, risperidone, ziprasidone, and the FGA perphenazine, had modest, but not statistically significant, superiority in maintenance therapy with treatment persistence as the primary clinical outcome.[30] However, increased metabolic adverse effects occurred with olanzapine. Another major study of patients early on in their illness also highlights the high rate of cardiometabolic disturbances and the need to tailor treatment early in the course of the illness.[31,32]

No known differences exist in efficacy between low- and high-potency FGAs. Previous patient or family history of response to an antipsychotic is helpful in the selection of an agent. **Table 67-3** lists antipsychotics and their usual dosage ranges.

TABLE 67-3 Available Antipsychotics and Dosage Ranges

Generic Name	Trade Name	Starting Dose (mg/day)	Usual Dosage Range (mg/day)	Comments
First-Generation Antipsychotics				
Chlorpromazine	Thorazine	50-150	300-1,000	Most weight gain among FGAs
Fluphenazine	Prolixin	5	5-20	
Haloperidol	Haldol	2-5	2-20	Higher dropout rate in first episode
Loxapine	Loxitane	20	50-150	

Generic Name	Trade Name	Starting Dose (mg/day)	Usual Dosage Range (mg/day)	Comments
Loxapine inhaled	Adasuve	10	10	Maximum 10 mg per 24 hours Approved REMS program only
Perphenazine	Trilafon	4-24	16-64	
Thioridazine	Mellaril	50-150	100-800	Significant QTc prolongation
Thiothixene	Navane	4-10	4-50	
Trifluoperazine	Stelazine	2-5	5-40	
Second-Generation Antipsychotics				
Aripiprazole	Abilify	5-15	15-30	
Asenapine	Saphris	5	10-20	Sublingual only, no food or drink for 10 minutes after administration of the dose
Brexpiprazole	Rexulti	1	2-4	
Cariprazine	Vraylar	1.5	1.5-6	Due to long half-life, steady-state is not reached for several weeks
Clozapine	Clozaril	25	100-800	Check plasma level before exceeding 600 mg
Iloperidone	Fanapt	1-2	6-24	Care with dosing in CYP2D6 slow metabolizers
Lurasidone	Latuda	20-40	40-120	Take with food; ≥350 calories (≥1,460 J)
Olanzapine	Zyprexa	5-10	10-20	Avoid in first episode because of weight gain
Paliperidone	Invega	3-6	3-12	Bioavailability increased when administered with food
Quetiapine	Seroquel	50	300-800	
Quetiapine XR	Seroquel XR	300 mg	400-800	
Risperidone	Risperdal	1-2	2-8	
Ziprasidone	Geodon	40	80-160	Take with food, ≥500 calories (≥2,100 J)

Note: In first-episode patients, starting dose and target dose should generally be 50% of the usual dose range. See Long-Acting Injectable Antipsychotics in text for dosing of these agents.

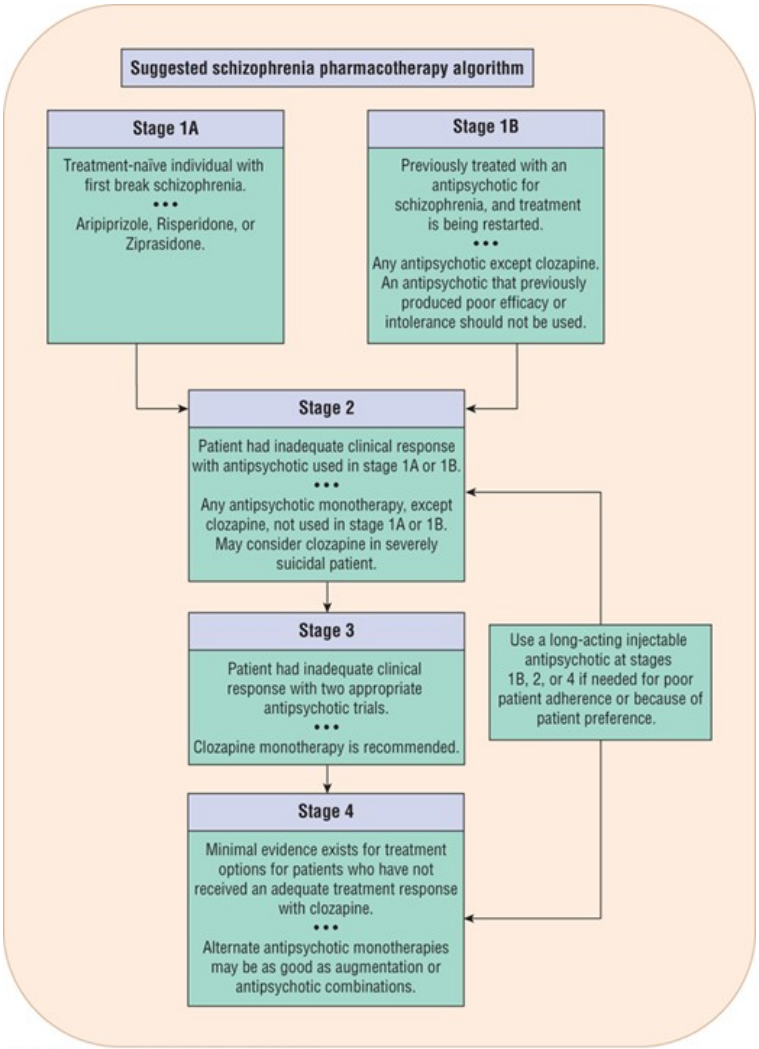
Data from reference 29, 40, 58,59,60, 63, 69, 116.

Published Guidelines and an Algorithm Example

Figure 67-1 outlines a suggested pharmacotherapeutic algorithm for schizophrenia. This algorithm is based on information from four evidence-based guidelines, the Psychopharmacology Algorithm Project at the Harvard Medical School Department of Psychiatry, South Shore Program,[27,28] the 2009 update of the practice guideline from the American Psychiatric Association (APA),[33] the 2009 update of the Patient Outcomes Research Team (PORT) guidelines,[26] and the 2012 update of the guidelines from the World Federation of Biological Psychiatry.[29] These sources were augmented with results from recent published clinical trials.

FIGURE 67-1

Suggested pharmacotherapy algorithm for treatment of schizophrenia. Schizophrenia should be treated in the context of an interprofessional model that addresses the psychosocial needs of the patient, necessary psychiatric pharmacotherapy, psychiatric co-occurring mental disorders, treatment adherence, and any medical problems the patient may have. See the text for a description of the algorithm stages. *(Data from references 26,27,28,29,30.)*



Stage 1A of the treatment algorithm applies to those patients experiencing their first acute episode of schizophrenia. Studies suggest that SGAs result in greater treatment retention and are more effective in preventing a second episode in first episode patients than FGAs. In addition, SGAs carry a reduced risk of EPS.[29] Among the SGAs, only aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone have evidence of efficacy in first episode patients. Olanzapine is not recommended in first episode because of weight gain and metabolic side effects.[26,27,28,29]

Quetiapine is associated with less time to rehospitalization than other compared SGAs and also causes greater weight gain so it is not recommended in Stage 1A. This leaves aripiprazole, risperidone, and ziprasidone as the evidence based options in first episode patients (Stage 1A).[27,28] Of these, aripiprazole and ziprasidone produce the least weight gain. Because of the sensitivity to antipsychotic-induced EPS in first-episode patients, antipsychotic dosing should be initiated at the lower end of the dose range.[39]

A recent study in first episode patients showed that long-acting risperidone injectable was more effective than oral risperidone in preventing relapse over a 1 year period.[34] In fact, the relapse rate was six times higher in the oral risperidone group than with the long-acting injectable. Based upon this study, long-acting risperidone can also be considered a treatment option for first episode patients. If long acting risperidone is going to be used, patients should first be stabilized on oral risperidone. As indicated in the nonpharmacological treatment section, it is critical that enriched psychosocial programs be implemented along with appropriate pharmacotherapy.

Clinical Controversy...

Although studies do not demonstrate a difference in acute response rates between SGAs and FGAs in first episode schizophrenia, better patient retention rates and a longer time to second episode are associated with the use of SGAs. While the World Federation of Psychiatry Guidelines and the Harvard guidelines favor the SGAs as first-line antipsychotics, the PORT guidelines offer no preference. All four sets of guidelines recommend not using olanzapine in patients with their first episode of schizophrenia.

Stage 1B addresses pharmacotherapy of a patient who was previously treated with an antipsychotic, and treatment is being restarted because the patient stopped taking the medication. If the patient experienced a robust improvement in symptoms, good tolerability, and the patient is positive about taking the previous antipsychotic, then that medication can be restarted. Otherwise, a medication from Stage 2 should be used. Stage 2 addresses pharmacotherapy in a patient who had inadequate clinical improvement with the antipsychotic used in stage 1A or 1B, or the patient responded but subsequently had a relapse while taking medication. Stage 2 recommends antipsychotic monotherapy with a FGA or SGA not used in Stage 1.[26,27,28,29] Because of safety concerns and the need for white blood cell (WBC) monitoring, clozapine is not generally recommended at Stage 2.[26,27,28,29] However, clozapine has superior efficacy in decreasing suicidal behavior, and it should be considered at stage 2 for the suicidal patient.[26] Clozapine can also be considered at stage 2 in patients with a history of violence or comorbid substance abuse.[26] If a patient has unacceptable side effects with the antipsychotic used during Stage 1A, Stage 1B, or Stage 2, then an alternate antipsychotic for that stage should be chosen.

Long acting injectable (LAIs) antipsychotics may be considered at Stage 2. LAIs have been traditionally used in patients with a pattern of poor medication adherence, but it has been suggested that their use may be more successful if used earlier in the course of schizophrenia before patients develop a pattern of nonadherence.[26,29,35]

In stage 3 the recommended treatment is clozapine.[26,27,28,29]

In stage 4, only minimal evidence exists for any treatment option for those patients who do not have adequate symptom improvement with clozapine. However, a recent placebo controlled trial showed that ziprasidone 80 mg/day added to clozapine significantly improved negative symptoms and general psychopathology as compared with placebo, and a recent small trial demonstrated efficacy for electroconvulsive therapy (ECT) augmentation of clozapine.[36,37] Additional treatment options that are tried, again with minimal evidence, include mood stabilizer augmentation, and another antipsychotic combined with clozapine.[26,29,38] The use of antipsychotic combinations is controversial, as limited evidence supports increased efficacy for combination antipsychotic treatment.[26,29,38]

Predictors of Response

Obtaining a thorough medication history is important, and previous antipsychotic treatment should help guide the selection of drug therapy, in that either a good prior response favors the use of the same agent or a negative prior response suggests the selection of a dissimilar drug. Nonprescription and illicit drug use can influence psychiatric presentation and thus diagnosis or antipsychotic response. Amphetamines and other CNS stimulants, cocaine, corticosteroids, digitalis glycosides, indomethacin, marijuana, pentazocine, phencyclidine, and other drugs can induce psychosis in susceptible individuals or exacerbate psychosis in patients with preexisting psychiatric illness.[1,20,21,29] Patients with schizophrenia who continue to abuse alcohol or drugs usually have a poor response to medications and a poor prognosis. Alcohol, caffeine, and nicotine use may potentially result in drug interactions with antipsychotics.

Individual differences in patient response have been either proposed or identified, which can be clinically useful predictors of response.[20] Acute onset and short duration of illness, presence of acute stressors or precipitating factors, later age of onset, family history of affective illness, and good premorbid adjustment as reflected in stable interpersonal relationships or employment are all predictors of good response.[20]

Although controversial, affective symptoms can correlate with an overall good response. Negative symptoms and neuropsychological deficits related to cognition and neurologic soft signs can correlate with poor antipsychotic response.[20] A patient's subjective response within the first 48 hours after being administered an FGA can be associated with drug responsiveness.[38] An initial dysphoric response, demonstrated by stating a dislike of the medication, or feeling worse or zombie-like, combined with anxiety or akathisia-like symptoms, is associated with poor drug response, adverse effects, and nonadherence.

The importance of developing a therapeutic alliance between the patient and the clinician cannot be underestimated. Patients who form positive therapeutic alliances are more likely to be adherent with all aspects of therapy, experience a better outcome at 2 years, and require smaller antipsychotic doses.[20]

A certain minority of patients fails to benefit from antipsychotic therapy, and their psychosocial functioning can actually worsen.

Initial Treatment in an Acute Psychotic Episode

The goals during the first 7 days of treatment should be decreased agitation, hostility, combativeness, anxiety, tension, and aggression, and normalization of sleep and eating patterns. The usual recommendation is to initiate therapy and to titrate dose over the first few days to an average effective dose, unless the patient's physiologic status or history indicates that this dose can result in unacceptable adverse effects. Because of its strong alpha one (α_1) receptor antagonism and resulting risk of hypotension, iloperidone and clozapine should be titrated more slowly than other antipsychotics. **Table 67-4** lists the usual dosage range, and an average dose is typically midrange. Because of increased sensitivity to side effects, particularly EPS, in first-episode psychotic patients, typical dosing ranges are approximately 50% of the doses used in chronically ill individuals.[26,29] If "cheeking" of medication is suspected, liquid formulations and orally disintegrating

tablets of different antipsychotics are available. If a patient has shown absolutely no improvement after 2 weeks at a therapeutic dose then later clinical response is unlikely, and moving to the next treatment stage in the algorithm is recommended.[20,39]

TABLE 67-4 Summary of Available Long Acting Injectable (LAI) Antipsychotics

Medication Name Parameter	Fluphenazine Decanoate	Haloperidol Decanoate	Risperidone LAI Risperdal Consta	Paliperidone Palmitate Invega Sustenna	Paliperidone Palmitate Invega Trinza	Olanzapine Pamoate Zyprexa Relprevv	Aripiprazole Monohydrate Abilify Maintena	Aripiprazole Lauroxil Aristada
FDA Approved Indication	Schizophrenia	Schizophrenia	Schizophrenia Bipolar I Disorder maintenance	Schizophrenia Schizoaffective Disorder	Schizophrenia	Schizophrenia	Schizophrenia	Schizophrenia
Dose Range (mg)	12.5-100	20-450	12.5-50	39-234	273-819	150-405	160-400	441-882
PO Overlap	None	4 weeks (none if loading); use PO dose patient was taking prior to injection	3 weeks after first injection Use PO dose patient was taking prior to injection	None	None	None	2 weeks PO dose ranges from 10 to 20 mg/day	21 days PO over lap after first injection
Recommended maximum dose	100 mg every 2-3 weeks	450 mg every 4 weeks	50 mg every 2 weeks	234 mg every 4 weeks	819 mg every 3 months	300 mg every 2 weeks or 405 mg every 4 weeks	400 mg monthly	882 mg monthly
Initiation or Loading	Can Load	Can Load	None	Initiation required	None required, dose used depends on last Invega Sustenna dose as follows: If 78 mg give 273 mg If 117 mg give 410 mg If 156 mg give 546 mg If 234 mg give 819 mg	Initiation required	None	None required, dose depends on PO dose as follows: If 10 mg/day PO give 441 mg per month IM If 15 mg/day PO give 662 mg per month IM If 20 mg PO give 882 mg per month
Time to peak	8-24 hours	4-11 days	4-5 weeks	13 days	30-33 days	<1 week	5-7 days	5-6 days
T_{ss}	2-3 months	2-3 months	6-8 weeks	36 days		3 months	3-4 months	4 mos.
Injection Site Gluteal	Yes	Yes	Yes	Yes after 2nd dose	Yes	Yes	Yes	Yes for all dose strengths
Deltoid	Yes	Yes	Yes	Yes	Yes	No	No	Yes, but only 441 mg dose
Injection Method/Technique		Z-Track	Standard					
Notes			A starting dose of 12.5 mg is recommended in patients	Avoid use in patients with moderate to severe renal impairment	Requires at least a 4 month trial with Invega Sustenna Not	Monitor for PDSS Subject to REMS	Maintenance dose reduced to 300 mg if patient experiences	May require up to 2 weeks of PO trial to establish tolerability to

Medication Name Parameter	Fluphenazine Decanoate	Haloperidol Decanoate	Risperidone LAI Risperdal Consta	Paliperidone Palmitate		Olanzapine Pamoate Zyprexa Relprevv	Aripiprazole Monohydrate Abilify Maintena	Aripiprazole Lauroxil Aristada
				Invega Sustenna	Invega Trinza			
			with hepatic or renal impairment	(CrCl <50 mL/min [<0.83 mL/s])	recommended in patients with moderate or severe renal impairment (CrCl <50 mL/min[<0.83 mL/s])		adverse events. Dose adjustment needed in CYP2D6 slow metabolizers. Avoid use in patients taking CYP 3A4 inhibitors >14 days	aripiprazole before initiating LAI Avoid use of strong CYP2D6 and 3A4 inhibitors on 662 mg and 882 mg dose, no adjustment needed for 441mg dose

PO, Oral; T_{ss}, Time to steady-state; CrCl, Creatine Clearance; IM, intramuscular; LAI, Long Acting Injectable.

Clinical Controversy…

Minimal research evidence supports the use of antipsychotic doses beyond the dose range in the FDA-approved product labeling. However, clinicians frequently titrate doses above the approved range, and frequently attest to symptom improvement when this is done. It is unclear whether the observed symptom improvement is due to the increased dose, time on the antipsychotic, or just pure chance. If higher than recommended doses are used, treatment should be time limited (eg, 6-12 weeks), and a brief clinical rating scale should be used to monitor for potential change in symptoms.

Although some clinicians believe that larger daily doses are necessary in more severely symptomatic patients, data are not available to support this practice. Some symptoms, such as agitation, tension, aggression, and increased motor activity, may respond more quickly, but side effects can be more common with higher doses. However, interindividual differences in dosage and patient response do occur. In partial but inadequate responders who are tolerating the chosen antipsychotic, it may be reasonable to titrate above usual dose ranges. However, this tactic should be time-limited (ie, 2-4 weeks), and if the patient does not achieve further improvement, either the dose should be decreased or an alternative treatment strategy should be tried. In general, rapid titration of antipsychotic dosage is not indicated.[20,26] However, intramuscular (IM) antipsychotic administration (eg, aripiprazole 5.25-9.75 mg IM, haloperidol 2-5 mg IM, olanzapine 2.5-10 mg IM, or ziprasidone 10-20 mg IM) can be used to assist in calming a severely agitated patient. Agitation can be manifested as loud, physically or verbally threatening behavior, motor hyperactivity, or physical aggression. Although this technique can assist in calming an acutely agitated psychotic patient, it does not improve the extent of remission, or time to remission, or the length of hospitalization. Haloperidol IM for treatment of acute aggression is associated with a higher incidence of EPS than using an injectable SGA. If the patient is receiving an antipsychotic within the usual therapeutic range, the use of lorazepam 2 mg IM as needed in combination with the maintenance antipsychotic is a rational alternative to an injectable antipsychotic. Hypotension, respiratory depression, CNS depression, and death have been reported with injectable lorazepam in combination with either olanzapine or clozapine; thus, parenteral lorazepam is not recommended in combination with either of these antipsychotics.[29,33]

The initial Risk Evaluation and Mitigation Strategy (REMS) for inhaled loxapine powder was approved by the Food and Drug Administration (FDA) with an indication of treatment of acute agitation associated with schizophrenia or bipolar disorder. Because of the risk of bronchospasm, pulmonary distress, and pulmonary arrest, the medication can only be administered in a healthcare facility and through the FDA-approved REMS. Before administration, patients must be screened for a history of asthma, chronic obstructive pulmonary disease, or other lung disease associated with bronchospasm, and use is limited to one 10 mg inhaled dose per 24-hour period.[40] It is not known whether inhaled loxapine offers any therapeutic advantages in acute agitation compared with currently available IM or oral products.

Stabilization Therapy

Improvement is usually a slow but steady process over 6 to 12 weeks or longer. During the first 2 to 3 weeks, goals should include increased socialization and improvement in self-care habits and mood. Improvement in formal thought disorder should follow and can take an additional 6 to 8 weeks to respond. Patients who are early in the course of their illness can experience a more rapid resolution of symptoms than individuals who are more chronically ill. In general, if a patient has shown no improvement after 2 weeks of treatment at therapeutic doses, or has achieved only a partial decrease in positive symptoms within 12 weeks at adequate doses, then the next

algorithm stage should be considered. In more chronically ill patients, symptoms may continue to improve over 3 to 6 months. During acute stabilization, usual FDA-labeled doses of SGAs are recommended (see Table 67-4).[26,27,28,29] An optimum dose of the chosen drug should be estimated in the initial treatment plan. If the patient begins to show adequate response at a particular dose, then the patient should remain at this dosage as long as symptoms continue to improve. 7 In general, adequate time on a therapeutic antipsychotic dose is the most important factor in predicting medication response. However, if necessary, dose titration can continue within the therapeutic range every 1 or 2 weeks as long as the patient has no side effects.

Before changing medications in a poorly responding patient, the following should be considered: Were the initial target symptoms indicative of schizophrenia or did they represent manifestations of a different diagnosis, a long-standing behavioral problem, a substance abuse disorder, or a general medical condition? Is the patient adherent with pharmacotherapy? Are the persistent symptoms poorly responsive to antipsychotics (eg, impaired insight or judgment, or fixed delusions)? How does the patient's current status compare with response during previous exacerbations? Would this patient potentially benefit from a change to a different treatment stage (**Fig. 67-1**)? Does this patient have a treatment-resistant schizophrenia?

The conclusion that a partially responding patient has achieved as much symptomatic improvement as possible is one that must be made with great care. Treatment goals must be realistic. Medications are effective at decreasing many of the symptoms of schizophrenia (and are thus referred to as palliative), but they are not curative, and all symptoms may not abate. Although one should aim to achieve none to minimal residual positive symptoms with effective treatment, it is still unclear what a realistic goal is with regard to maximum improvement in negative symptoms.

It is important to screen patients for co-occurring mental disorders, and their presence can become more apparent during the stabilization or maintenance phases of schizophrenia treatment. Examples include substance abuse disorders, depression, obsessive-compulsive disorder, and panic disorder. As co-occurring disorders will limit symptom and functional improvement and increase the risk of relapse, it is critical that treatment for the co-occurring disorder be implemented in combination with evidence-based treatment for schizophrenia.

Maintenance Treatment

Maintenance drug therapy prevents relapse, as shown in numerous double-blind studies. The average relapse rate after 1 year is 18% to 32% with active drug (including some nonadherent patients) versus 60% to 80% for placebo.[26,27,28,29] Thus avoiding relapses is a major goal of treatment.[26,27,28,29]

After treatment of the first psychotic episode in a patient with schizophrenia, medication should be continued for at least 12 months after remission.[26,27,28,29] 8 Many schizophrenia experts recommend that patients with robust medication response be treated for at least 5 years. In chronically ill individuals, continuous or lifetime pharmacotherapy is necessary in the majority of patients to prevent relapse. This should be approached with the lowest effective dose of the antipsychotic that is likely to be tolerated by the patient.[26,27,28,29]

Antipsychotics should be tapered slowly before discontinuation. Abrupt discontinuation of antipsychotics, especially clozapine, can result in withdrawal symptoms, felt to be a manifestation of rebound cholinergic outflow. Insomnia, nightmares, headaches, GI symptoms (eg, abdominal cramps, stomach pain, nausea, vomiting, and diarrhea), restlessness, increased salivation, and sweating are reported. Although available evidence does not indicate a best way to switch from one antipsychotic to another, it is often recommended to taper and discontinue the first antipsychotic over at least 1 to 2 weeks while the second antipsychotic is initiated and the dose titrated.[29] Tapering needs to occur more slowly with clozapine.[29]

Long-Acting Injectable Antipsychotics

Traditionally, long-acting antipsychotics have been primarily used for patients who are unreliable in taking oral medication on a daily basis. More recently, it has been suggested to offer LAIs to patients as a treatment option earlier in treatment before they develop a pattern of nonadherence.[35] As indicated earlier, one study showed LAI risperidone to be more effective in preventing relapse in patients with their first episode of schizophrenia.[34]

Before declaring a patient nonadherent, it should be determined whether the patient's medication nonadherence is because of side effects. If so, an alternative medication with a more favorable side effect profile should be considered before a long-acting injectable antipsychotic. The patient's motivation for treatment is a major factor influencing outcome. Conversion from oral therapy to a long-acting injectable is most successful in patients who have been stabilized on oral therapy.

Paliperidone palmitate is a long-acting injectable (LAI) that has the advantage of once-monthly injections and easy conversion from oral to IM treatment.[41] Similarly, aripiprazole monohydrate and aripiprazole lauroxil LAI are once monthly injections that require 2 and 3 weeks of oral antipsychotic overlap respectively.

Olanzapine pamoate monohydrate is a LAI administered every 2 or 4 weeks. It is associated with a postinjection delirium/sedation syndrome (PDSS) occurring in approximately 2% of patients.[42] The symptoms of PDSS are similar to those of an oral olanzapine overdose

and include delirium like symptoms, sedation, as well as changes in level of consciousness. Delirium is the most commonly reported symptom in PDSS cases. The risk of occurrence does not appear related to dose or duration of treatment. One hypothesis is that its occurrence may be associated with accidental entry of the drug into the bloodstream.[42] In 2013, the FDA issued a warning regarding sudden death of two patients who received olanzapine LAI.[43] A follow up to this report indicated that the cause of the sudden deaths was inconclusive.[44] The product labeling contains an FDA boxed warning regarding PDSS. Olanzapine pamoate is subject to REMS, and the FDA labeling limits the availability of olanzapine LAI to a restricted distribution program. The injection must be administered in a registered healthcare facility, and the patient must be observed by a health professional for at least 3 hours after administration and must not drive or operate machinery for that day.[42]

Conversion from an oral antipsychotic to a LAI medication should start with stabilization on an oral dosage form of the same agent, for a short trial (3-7 days), to determine whether the patient tolerates the medication without significant side effects. With long-acting risperidone, measurable serum concentrations are not seen until approximately 3 weeks after single-dose administration. Thus, it is important that the oral antipsychotic be administered for at least 3 weeks after beginning the injections. Dose adjustments are recommended to be made no more often than once every 4 weeks.[45] The recommended starting dose with risperidone LAI is 25 mg, and clinical experience suggests that titration to doses greater than or equal to 37.5 mg per injection may be necessary for maintenance treatment. Long-acting risperidone has demonstrated efficacy, with an optimal dose range between 25 and 50 mg given IM every 2 weeks. Doses above 50 mg every 2 weeks are not recommended, as research indicates no greater clinical efficacy but more EPS.[45]
