The usual dose of intracavernosal alprostadil is 10 to 20 mcg, with a maximum recommended dose of 60 mcg. Doses greater than 60 mcg have not produced any greater improvement in penile erection, but may cause hypotension or prolonged erections lasting more than 1 hour.[78] The dose should be administered 5 to 10 minutes before intercourse. The manufacturer recommends that patients be slowly titrated up to the minimally effective dosage to minimize the likelihood of hypotension. Under a physician's supervision, patients should be started with a 1.25-mcg dose, which can be increased in increments of 1.25 to 2.50 mcg at 30-minute intervals up to the lowest dose that produces a firm erection for 1 hour and does not produce adverse effects. In clinical practice, this process is rarely done because it is time consuming. Thus, many physicians start the patient on 10 mcg and move quickly up the dosage range to identify the best dose for the patient. To avoid adverse effects, patients should receive not more than one injection per day and not more than three injections per week with a 24-hour interval between doses (see Table 83-3).

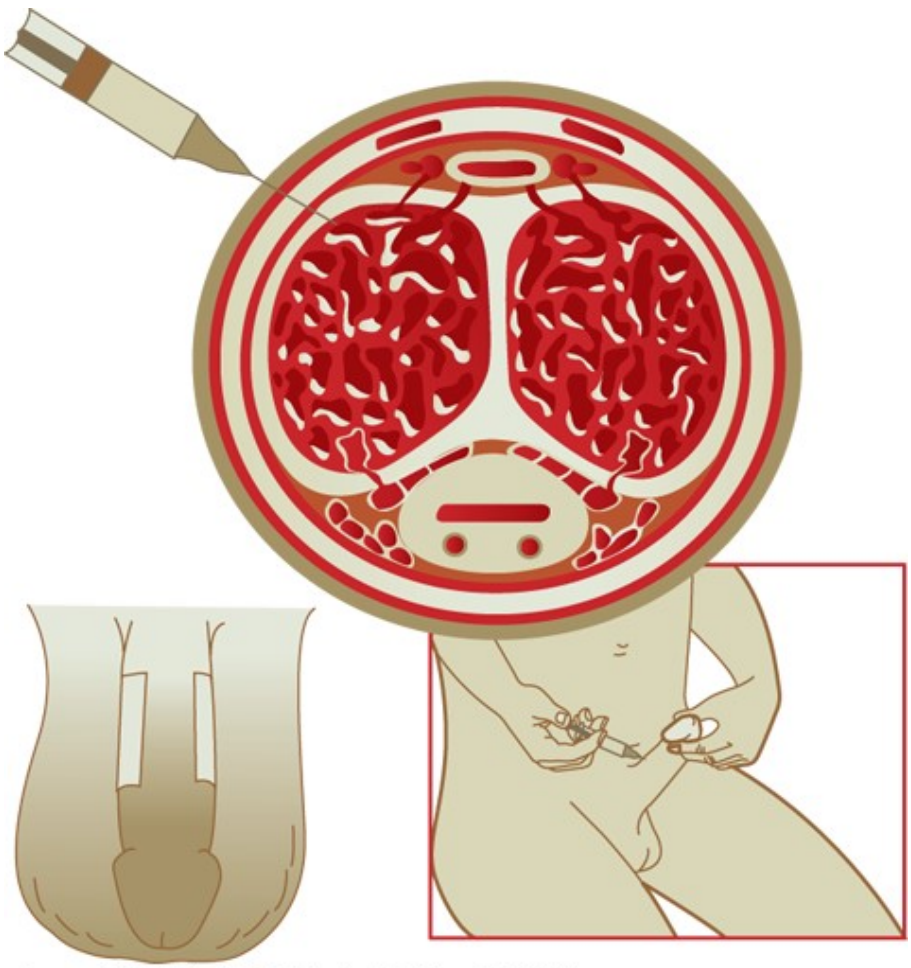
Intracavernosal injections should be performed using a 0.5-inch (1.3 cm), 27- or 30-gauge needle. A tuberculin syringe or a syringe prefilled with diluent as supplied by the manufacturer should be used to ensure precise measurement of doses. Patients with needle phobia, poor vision, or poor manual dexterity can use commercially available autoinjectors to facilitate administration of intracavernosal alprostadil.

Intracavernosal injections require that the patient or the sexual partner practice good aseptic techniques (to avoid infection), have good manual skills and visual ability, and be comfortable with injection techniques. When practicing self-injection, the patient should use one hand to firmly hold the glans penis

against his thigh to expose the lateral surface of the shaft. The injection should be made at right angles into one of the lateral surfaces of the proximal third of the penis. The injection should never be made into the dorsal or ventral surface of the penis. This will prevent inadvertent injection of the drug into arteries on the dorsal surface or the urethra on the ventral surface. After the injection, the penis should be massaged to help distribute the drug into the opposite corpus cavernosum. Injection sites should be rotated with each dose. Finally, manual pressure should be applied to the injection site for 5 minutes to reduce the likelihood of hematoma formation (**Fig. 83-5**).

FIGURE 83-5

Technique for administration of intracavernosal injections. *(From Caverject [package insert]. New York, NY: Pfizer Inc.; 1999. Data from http://media.pfizer.com/files/products/uspi_caverject_powder.pdf.)*



Once the optimal dosage of intracavernosal alprostadil is established, the patient should return for routine medical follow-up every 3 to 6 months. Some patients subsequently require dosage adjustment, largely attributed to worsening of the underlying disease that is contributing to the erectile dysfunction.

Adverse Effects

Intracavernosal alprostadil is most commonly associated with local adverse effects. Hematoma and

bruising at the injection site occurs most often during the first year of therapy. These effects are largely the result of poor injection technique. To minimize the risk of injection site hematomas, patients should apply pressure to the injection site for 5 minutes after each dose. Similarly, infection at the injection site has been reported. Meticulous aseptic technique is necessary to prevent this complication.

Cavernosal plaques or areas of fibrosis at injection sites form in approximately 2% to 12% of patients. When they occur, the patient should suspend further injections for 2 to 4 months or until the plaques resolve. These plaques may cause penile curvature, similar to Peyronie's disease, which makes sexual intercourse difficult or impossible. The cause of corporal fibrosis and plaque formation is unknown. This adverse effect may be caused by poor injection technique or by alprostadil itself. Although patients have developed corporal fibrosis, alprostadil may be less likely to cause this adverse effect compared to other intracavernosal drug combinations, such as phentolamine or papaverine. Unlike cavernosal fibrosis associated with large doses and repeated administration of papaverine, penile scarring secondary to alprostadil appears to be unpredictable.

Alprostadil causes penile pain in approximately 10% to 44% of patients. The pain has been described as a burning discomfort or dull pain near the injection site or during the erection, which generally does not persist after the penis becomes flaccid. The pain usually is mild, generally does not require discontinuation of therapy, and often abates even with continued treatment. However, 2% to 5% of patients discontinue taking alprostadil because of severe pain. The pain can be managed by oral analgesics (eg, acetaminophen), if necessary. One investigator has recommended adding procaine to intracavernosal alprostadil, but this may mask the signs of more serious adverse effects of the drug or of penile injury during intercourse and is not recommended.[79] The mechanism of this adverse reaction is poorly understood. Alprostadil may intrinsically produce pain. In addition, the pain may be a result of the pH of the parenteral solution. Alprostadil is acidic, and the commercially available Caverject formulation is buffered with sodium citrate, a weak base, to reduce pain on injection.

Priapism, a prolonged, painful erection lasting more than 1 hour, occurs in 1% to 15% of treated patients. It occurs most often during the dose titration period and is rare thereafter. Blood sludging in the corpora can lead to tissue hypoxia and irreversible cavernosal fibrosis and scarring. The risk for this complication is greatest for erections that persist beyond 4 to 6 hours. Patients are advised to seek medical attention immediately when drug-induced erections last more than 4 hours, as this may progress to a urologic emergency. Its management includes supportive care, including analgesics for pain and sedatives for anxiety. In addition, needle aspiration of sludged blood in the corpora or intracavernosal injection of α-adrenergic agonists (eg, phenylephrine) has been used. These procedures facilitate venous drainage of the corpora, allowing venous outflow to "catch up" with arterial inflow.

The likelihood of prolonged erections with intracavernosal alprostadil is dose related. Therefore, to prevent this adverse effect, the lowest effective dose should be used, and the dose should be titrated to ensure that the duration of the erection is not more than 1 hour.

Intracavernosal alprostadil rarely causes systemic adverse effects, owing to the agent's local catabolism in cavernosal tissue and rapid deactivation in pulmonary tissue (if any of the drug escapes into the systemic circulation). However, large doses greater than 20 mcg are associated with dizziness and hypotension in some patients and is one reason why such large doses are not commonly used.

Intracavernosal injection therapy should be used cautiously by patients at risk for priapism, including

patients with sickle cell disease, leukemia, or multiple myeloma. It should be used cautiously by patients who may develop bleeding complications secondary to injections, including patients with thrombocytopenia or those taking anticoagulants. It also should be used cautiously by patients who use poor-quality injection technique, including patients with psychiatric disorders, obese patients (who may not be able to reach or see the penile injection site), patients who are blind, patients with severe arthritis, or patients with abnormal penile anatomy.

Intraurethral alprostadil should be avoided in patients with urethral stricture or urethritis, or if the female partner is pregnant.

Intraurethral Alprostadil

Efficacy

10 Intraurethral alprostadil inserts are marketed as MUSE, which contains a medication pellet inside a prefilled urethral applicator. Multiple studies show this product has an overall effectiveness rate of 43% to 65%[92,93] compared with 70% to 90% for intracavernosal alprostadil. Its decreased effectiveness and inconvenient administration method have resulted in this product being considered a third-line treatment option for patients with erectile dysfunction. However, some patients have responded to intraurethral alprostadil even though they did not respond to intracavernosal alprostadil[94] or sildenafil.[95]

Intraurethral alprostadil has been combined with a VED to improve treatment response.[96]

The voluntary dropout rate is high and has been reported to be 57% and 75% after 3 and 15 months, respectively.[95]

Pharmacokinetics

Following intraurethral instillation, alprostadil is absorbed quickly through the urethra, into the corpus spongiosum, and then into the corpora cavernosum. As much as 80% of each dose is absorbed by the urethra and corpus spongiosum in less than 10 minutes, with peak absorption occurring in 20 to 25 minutes. An estimated 20% of each dose is delivered to the corpora cavernosum. As with intracavernosal injections of alprostadil, any drug absorbed into the systemic circulation is rapidly metabolized on first pass through the lungs.

The onset after intraurethral insertion is similar to that of intracavernosal injection, 5 to 10 minutes, and the duration is 30 to 60 minutes.

Dosing

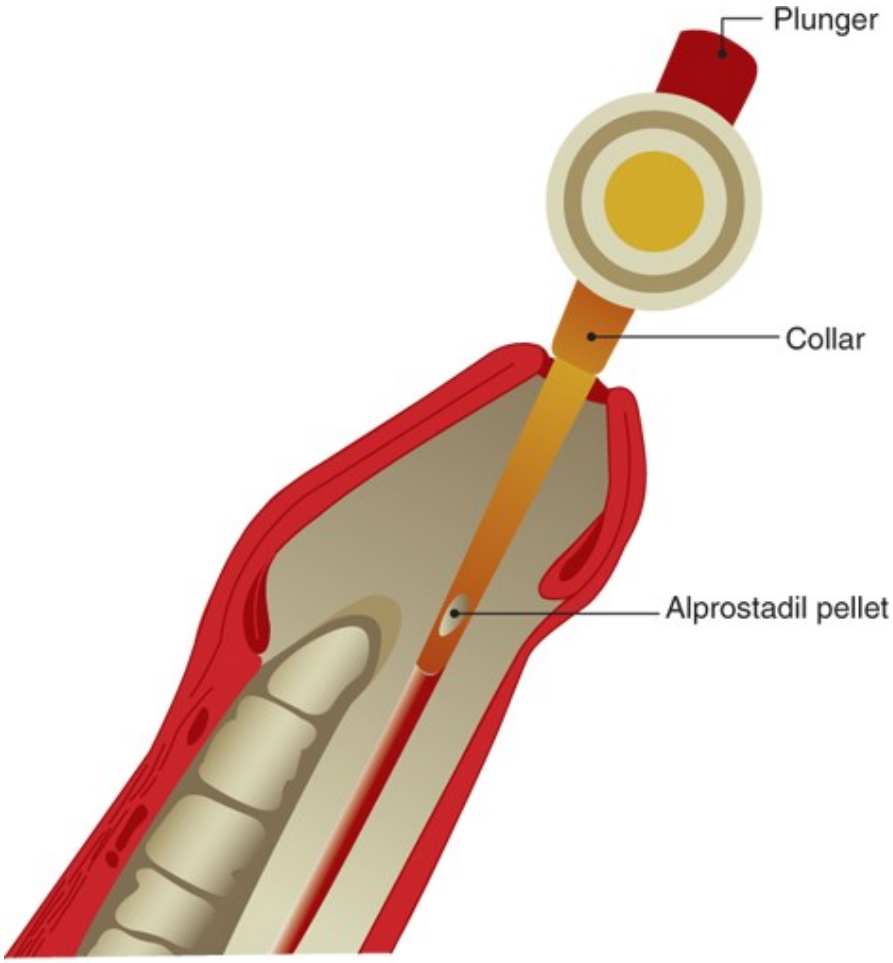
The usual dose of intraurethral alprostadil is 125 to 1,000 mcg. The dose should be administered 5 to 10 minutes before sexual intercourse. Not more than two doses per day are recommended. Before administration, the patient should be advised to empty his bladder, voiding completely (see Table 83-3).

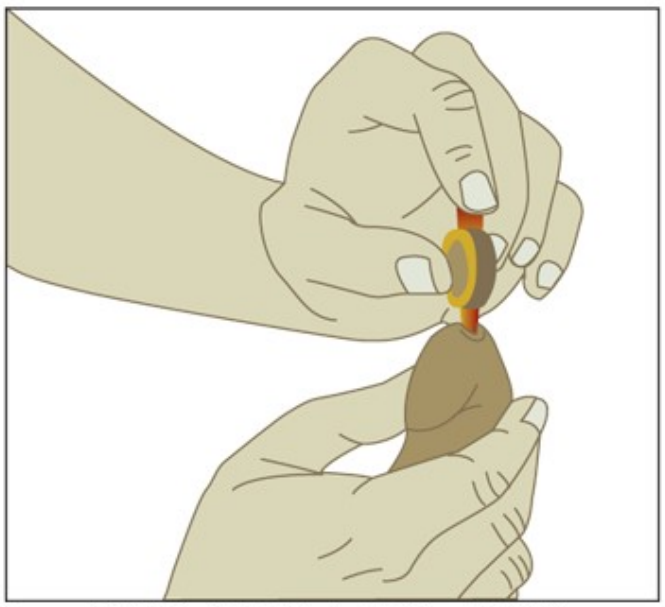
Similar to intracavernosal injection treatments, intraurethral insertion of alprostadil requires good manual and visual skills to minimize the risk of urethral injuries. Intraurethral alprostadil is supplied in a prefilled intraurethral applicator. The patient should void first to moisten the urethra. With one hand the patient

holds the glans penis, and with the other hand the patient inserts the intraurethral applicator 0.5 inch (1.3 cm) into the urethra. The drug pellet is then pushed into the urethra. The penis should be massaged to enhance drug dissolution in the urethral fluids and drug absorption (**Fig. 83-6**).

FIGURE 83-6

Technique for administration of intraurethral alprostadil with a medicated urethral system for erection applicator. *(From Muse [package insert]. Mountain View, CA: Vivus, Inc.; 2003.)*





Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Adverse Effects

The urethra can be injured because of an improper administration technique. Injuries can lead to urethral stricture and difficulty voiding. Patients should receive complete education about optimal administration procedures before starting treatment.

Urethral pain has been reported in 24% to 32% of patients. Usually it is mild and does not require discontinuation of treatment. Female sexual partners may experience vaginal burning, itching, or pain, which probably is related to transfer of alprostadil from the man's urethra to the woman's vagina during intercourse.

Prolonged painful erections (priapism) have been rarely reported. Syncope and dizziness have been reported rarely (only 2%-3% of patients) and likely are related to use of excessively large doses.

Clinical Controversy…

Although not recommended by the manufacturer, combinations of erectogenic medications or use of erectogenic medications with VEDs is a common practice. Published clinical trials of good research design are often lacking. Use of such combinations must take into consideration the published data available to support the use, potential adverse effects of the combination, and cost.

Unapproved Agents

A variety of other commercially available and investigational agents have been used for management of erectile dysfunction. Although it is beyond the scope of this chapter to discuss all of them, some of the more commonly used agents are discussed here.

Yohimbine

Yohimbine, a tree-bark derivative also known as *yohimbe*, is widely used as an aphrodisiac. Yohimbine is a central α_2-adrenergic antagonistic that increases catecholamines and improves mood. Some investigators believe that yohimbine has peripheral proerectogenic effects. Yohimbine may reduce peripheral α-adrenergic tone, thereby permitting a predominant cholinergic tone, which could result in a vasodilatory response.[21,96] The usual oral dose is 6 mg three times per day.

Based on a meta-analysis of published studies that concluded that yohimbine is only mildly efficacious for psychogenic erectile dysfunction,[96] the American Urological Association has cautioned against the use of yohimbine.[21] In addition, yohimbine can cause many systemic adverse effects, including anxiety, insomnia, tachycardia, and hypertension.

Papaverine

Papaverine is a nonspecific phosphodiesterase type 5 inhibitor that decreases metabolic catabolism of cAMP in cavernosal tissue. As a result of enhanced tissue levels of cAMP, smooth muscle relaxation occurs. Cavernosal sinusoids fill with blood, and a penile erection results.

Papaverine is not FDA approved for erectile dysfunction. Intracavernosal papaverine alone is not commonly used for management of erectile dysfunction because the large doses required produce dose-related adverse effects, such as priapism, corporal fibrosis, hypotension, and hepatotoxicity.[21,97]

Papaverine is more often administered in lower doses combined with phentolamine and/or alprostadil. A variety of formulas have been used, but no one mixture has been proven better than other mixtures. Combination formulations are considered safer and are associated with the potential for fewer serious adverse effects than high doses of any one of these agents.

A portion of each papaverine dose is systemically absorbed, and its prolonged plasma half-life of 1 hour contributes to adverse effects. The usual dose of papaverine is 7.5 to 60 mg when used as a single agent for intracavernosal injection. When used in combination, the dose decreases to 0.5 to 20 mg.

If treated with papaverine, patients with a history of underlying liver disease or alcohol abuse should undergo liver function testing at baseline and every 6 to 12 months during continued treatment.

Phentolamine

Phentolamine is a competitive nonselective α-adrenergic blocking agent. It reduces peripheral adrenergic tone and enhances cholinergic tone. As a result, it improves cavernosal filling and is proerectogenic.[21]

Phentolamine has most often been administered as an intracavernosal injection. Monotherapy is avoided because large doses are required for an erection, and at these large doses systemic hypotensive adverse effects would be prevalent. Most often, phentolamine has been used in combination with other vasoactive agents for intracavernosal administration. A ratio of 30 mg papaverine to 0.5 to 1 mg phentolamine is typical, and the usual dose ranges from 0.1 to 1 mL of the mixture. Such a mixture promotes local effects of phentolamine and minimizes systemic hypotensive adverse effects.

Hypotension is the most common adverse effect of intracavernosal phentolamine. It is more common and more severe with large doses or in patients with a poor injection technique who have injected into a vein (rather than the cavernosa). Prolonged erections have been reported in patients who used excessive doses of intracavernosal medications in combination.

Penile Prostheses

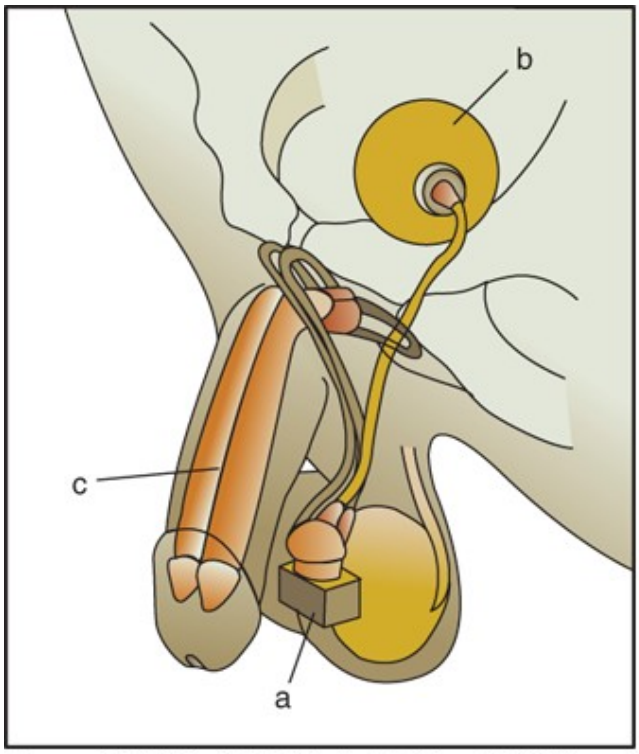
Surgical insertion of a penile prosthesis is the most invasive treatment of erectile dysfunction. It is reserved for patients who do not respond to or who are not candidates for less invasive oral or injectable treatments.

Prosthesis insertion requires anesthesia and skilled urologists. Two prostheses are widely used: malleable and inflatable. Malleable or semirigid prostheses consist of two bendable rods that are inserted into the corpora cavernosa. The patient appears to have a permanent erection after the procedure; the patient is able to bend the penis into position at the time of intercourse.

The inflatable prosthesis has several mechanical parts. The inflatable prosthesis produces a more natural erection. The patient develops an erection only when the device is activated. Some newer advances in inflatable prosthesis technology have resulted in devices with fewer mechanical parts. These devices can be placed during shorter surgical procedures and have a low 5-year mechanical failure rate (6%-10%) as compared with the original inflatable prostheses (**Fig. 83-7**).[21,98]

FIGURE 83-7

Example of surgically implanted penile prosthesis. (a, activation mechanism; b, reservoir with fluid for inflating prosthesis; c, inflatable rods in corpora.) *(From http://kidney.niddk.nih.gov/kudiseases/pubs/impotence.)*



Penile prostheses provide penile rigidity suitable for vaginal intercourse and are associated with a greater than 90% patient satisfaction rate, which is generally higher than that observed with any other drug treatment or VED.[99] The surgical success rate after insertion is 82% to 98%.[21]

Adverse effects of prosthesis insertion can occur early or late after the surgical procedure. The most common early complication is infection. Late complications include mechanical failure of the prosthesis, particularly when an inflatable prosthesis has been inserted. With improved technology, the mechanical failure rate has decreased to 5%.[99] Other late complications include erosion of the rods through the penis or late-onset infection. Although some salvage procedures have been devised, in many cases the prosthesis requires removal.

Personalized Pharmacotherapy

For the management of erectile dysfunction, treatment selection must be individualized based on the patient's preferences for and perception of the effectiveness of various treatment options, out-of-pocket costs for treatment, and potential adverse effects.

In general, patients prefer a discreet form of treatment that is not obvious to the sexual partner and that does not require careful attention to timing of administration relative to sexual intercourse. Because treatment for erectile dysfunction is not included as a covered item on many insurance plans, the cost of treatment is likely to be a consideration for most patients.

For patients with both moderately symptomatic benign prostatic hyperplasia and erectile dysfunction, a reasonable approach is the use of daily tadalafil, which should be effective for both conditions.

For patients who fail treatment with a single medication, a VED, a combination drug regimen, or surgical intervention are options.

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcomes of specific treatments for erectile dysfunction include (a) improvement in the quantity and quality of penile erections suitable for intercourse and (b) avoidance of adverse drug reactions and drug interactions.

At baseline and after the patient has completed a clinical trial period of several weeks with a specific treatment for erectile dysfunction, the physician should conduct assessments to determine whether the quality and quantity of penile erections has improved. A patient's level of satisfaction is highly individualized, depending on his lifestyle and expectations. Therefore, a patient who has successful intercourse once per week might be completely satisfied, whereas another patient might judge this to be unsatisfactory. Patients with unrealistic expectations in this regard must be identified and counseled by clinicians to avoid adverse effects of excessive use of erectogenic agents.

Failure to improve the quality and quantity of penile erections suitable for intercourse after an appropriate clinical trial period with a specific treatment for erectile dysfunction occurs in a significant percentage of patients. In this case, physicians generally take the following steps in order:

1. Ensure that the patient has been prescribed a maximum tolerated dose and has an adequate clinical trial of a specific treatment before discarding it as ineffective.

2. Switch to another drug (see Fig. 83-2).

3. Reserve surgical treatment for patients who do not respond to drug treatment.

CONCLUSION

Erectile dysfunction is a common disorder of aging men. Its incidence is higher in patients with underlying medical disorders that compromise the vascular, neurologic, hormonal, or psychogenic systems necessary for a normal penile erection. Medications are common causes of erectile dysfunction. By correcting the underlying etiology, erectile dysfunction can often be reversed without the use of specific treatments.

When treatment of erectile dysfunction is needed, the least invasive options should be used first because they produce the lowest incidence of serious adverse effects. Phosphodiesterase type 5 inhibitors are first-line treatment. If this fails or if the patient cannot use a phosphodiesterase type 5 inhibitor, a VED or intracavernosal alprostadil injection therapy can be initiated. If this treatment fails, the patient can attempt a combination of intracavernosal alprostadil plus VED, combination intracavernosal therapy, or intraurethral alprostadil. If this treatment fails, the patient may require insertion of a penile prosthesis.

Some insurance companies do not reimburse for drug treatments for erectile dysfunction, so cost is an

important issue for patients.

Clinicians should provide clear and simple advice. Patient confidentiality and privacy, which are extremely important to men with erectile dysfunction, should be maintained at all times.

Chapter 84: Benign Prostatic Hyperplasia

Mary Lee; Roohollah Sharifi

INTRODUCTION

KEY CONCEPTS

- 1 Although symptomatic benign prostatic hyperplasia (BPH) is rare in men younger than 50 years, it is common in men 60 years and older. Prostate growth is androgen-dependent. Symptoms commonly result from both static and dynamic factors.
- 2 BPH symptoms may be exacerbated by medications, including antihistamines, phenothiazines, tricyclic antidepressants, and anticholinergic agents. In these cases, discontinuing the causative agent can relieve symptoms.
- 3 For patients with mild disease who are asymptomatic or have mildly bothersome symptoms and no complications of BPH disease, watchful waiting is indicated. Watchful waiting includes behavior modification, lifestyle modification, discontinuation of medications that contribute to voiding symptoms, and return visits to the physician at 6- or 12-month intervals for assessment of worsening symptoms or signs of bladder outlet obstruction.
- 4 If symptoms progress to a moderate or severe level, drug therapy or surgery is indicated. α_1-Adrenergic antagonists quickly relieve voiding symptoms, but do not prevent disease progression. 5α-Reductase inhibitors delay symptom progression and reduce the incidence of BPH-related complications in patients with prostates of at least 30 to 40 g, but may not reduce voiding symptoms for 3 to 6 months.
- 5 All α_1-adrenergic antagonists are equally effective in relieving BPH symptoms. Older second-generation immediate-release formulations of α_1-adrenergic antagonists (eg, terazosin, doxazosin) can cause adverse cardiovascular effects, mainly first-dose syncope, orthostatic hypotension, and dizziness. For patients who cannot tolerate these hypotensive adverse effects, the third-generation, pharmacologically uroselective agents α_{1A}-adrenergic antagonists (eg, tamsulosin, silodosin) or an extended-release formulation of alfuzosin, a second-generation, functionally uroselective agent, are good alternatives.

- 6 5α-Reductase inhibitors are useful primarily for patients with large prostates greater than 30 to 40 g who wish to avoid surgery and cannot tolerate the side effects of α_1-adrenergic antagonists. 5α-Reductase inhibitors have a slow onset of action, taking up to 6 months to exert maximal clinical effects, which is a disadvantage of their use, especially when used as single drug therapy for BPH. In addition, decreased libido, erectile dysfunction, and ejaculation disorders are common adverse effects, which may be troublesome problems in sexually active patients.

- 7 Phosphodiesterase inhibitors can be used in patients with moderate to severe BPH and erectile dysfunction. They improve irritative voiding symptoms, but do not produce significant increases in urinary flow rate or reductions in postvoid residual (PVR) urine volume. Hence, a phosphodiesterase inhibitor is considered less effective than an α-adrenergic antagonist for BPH. A phosphodiesterase inhibitor may be used alone; however, symptom improvement and an increase in peak urinary flow rate has been demonstrated when the phosphodiesterase inhibitor is used along with an α-adrenergic antagonist or a 5α-reductase inhibitor.

- 8 Anticholinergic agents are indicated in patients with moderate to severe lower urinary tract symptoms (LUTS) with a predominance of irritative voiding symptoms. In this case, the drugs are commonly added on to an existing regimen of an α_1-adrenergic antagonist or a 5α-reductase inhibitor. Because older patients are at high risk of systemic and central nervous system anticholinergic adverse effects, uroselective anticholinergic agents may be preferred over nonuroselective agents. To minimize the risk of acute urinary retention, anticholinergics should be used cautiously in patients when the PVR urine volume is greater than 100 to 150 mL before initiating treatment with an anticholinergic agent. In addition, the potential anticholinergic medication burden should be assessed before starting an anticholinergic agent.

- 9 Mirabegron is a β_3-adrenergic agonist that relaxes the detrusor muscle to increase the bladder's storage capacity and prolong the interval between voidings. Although not FDA-approved for management of BPH, it is indicated for treatment of overactive bladder symptoms, including urgency and nocturia. These symptoms mimic irritative lower urinary tract voiding symptoms. Thus, mirabegron is used as an alternative to anticholinergic agents in patients with irritative voiding symptoms that do not respond to α_1-adrenergic antagonists or in patients who cannot tolerate anticholinergic adverse effects.

- 10 Surgery is indicated for moderate to severe symptoms of BPH for patients who do not respond to or do not tolerate drug therapy, or for patients with complications of BPH. It is the most effective mode of treatment because it relieves symptoms and increases peak urinary flow rate in the greatest number of men with BPH. However, the two standard techniques, transurethral resection of the prostate (TURP) and open prostatectomy, are associated with the highest rates of complications, including retrograde ejaculation and erectile dysfunction. Therefore, minimally invasive surgical procedures are often desired by patients. These relieve symptoms and are associated with a lower rate of adverse effects and do not require hospitalization, but they have higher reoperation rates than the standard procedures.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm of American men. A nearly ubiquitous condition among elderly men, BPH is of major societal concern, given the large number of men affected, the progressive nature of the condition, and the healthcare costs associated with it.

This chapter discusses BPH and its available treatments: watchful waiting, α_1-adrenergic antagonists, 5α-reductase inhibitors, phosphodiesterase inhibitors, anticholinergic agents, mirabegron, and surgery. The limitations of phytotherapy are described.

EPIDEMIOLOGY

According to the results of autopsy studies, approximately 80% of older men develop histologic evidence of BPH. About half of the patients with microscopic changes develop an enlarged prostate gland, and as a result, they may develop symptoms including difficulty emptying urine from the urinary bladder. Approximately half of symptomatic patients eventually require treatment. Thus, the disease can be characterized by three stages: BPH, benign prostatic enlargement (BPE), and benign prostatic obstruction (BPO). While BPH itself may not require treatment, some patients with BPE, depending on the size of the prostate, will be at risk of developing complications of BPH. In these patients, 5α-reductase inhibitors can reduce disease complications and delay the need for prostate surgery. In patients with moderate to severe BPO, bothersome voiding symptoms require medical or surgical treatment.

1 The peak incidence of clinical BPH occurs between ages 63 and 65 years. Symptomatic disease is uncommon in men younger than 50 years, but some urinary voiding symptoms are present by the time men turn 60 years. The Boston Area Normative Aging Study estimated that the cumulative incidence of clinical BPH was 78% for patients at age 80 years.[1] Similarly, the Baltimore Longitudinal Study of Aging projected that approximately 60% of men at least 60 years old develop clinical BPH.[2]

NORMAL PROSTATE PHYSIOLOGY

Located anterior to the rectum, the prostate is a small heart-shaped, chestnut-sized gland located below the urinary bladder. It surrounds the proximal urethra like a doughnut.

Soft, symmetric, and mobile on palpation, a normal prostate gland in an adult man weighs 15 to 20 g. Physical examination of the prostate must be done by digital rectal examination (ie, the prostate is manually palpated by inserting a finger into the rectum). Thus, the prostate is examined through the rectal wall.

The prostate has two major functions: (a) to secrete fluids that make up a portion (20%-40%) of the ejaculate volume and (b) to provide secretions with antibacterial effect possibly related to its high concentration of zinc.[2]

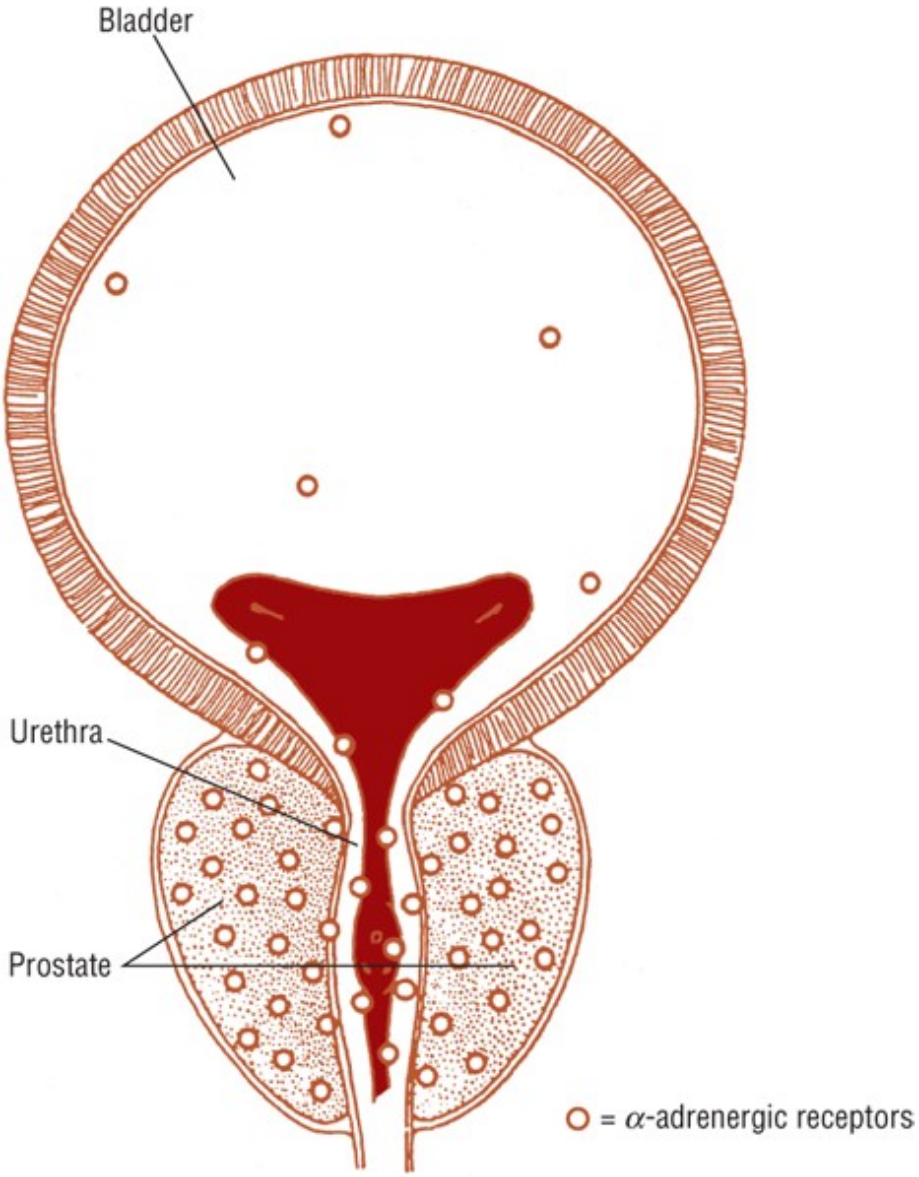
At birth, the prostate is the size of a pea and weighs approximately 1 g. The prostate remains that size until the boy reaches puberty. At that time, the prostate undergoes its first growth spurt, growing to its normal adult size of 15 to 20 g by the time the young man is 25 to 30 years old. The prostate

remains this size until the patient reaches age 40 years, when a second growth spurt begins and continues for the rest of his lifetime. During this period, the prostate can quadruple in size or grow even larger.

The prostate gland comprises three types of tissue: epithelial tissue, stromal tissue, and the capsule. Epithelial tissue, also known as *glandular tissue*, produces prostatic secretions. These secretions are delivered into the urethra during ejaculation and contribute to the total ejaculate volume. Androgens stimulate epithelial tissue growth. Stromal tissue, also known as *smooth muscle tissue*, is embedded predominantly with α_1-adrenergic receptors. Of the α_1-adrenergic receptors, 65% to 75% of them are of the α_{1A} subtype.[3] Stimulation of these receptors by norepinephrine causes smooth muscle contraction, which results in an extrinsic compression of the urethra, reduction of the urethral lumen, and decreased urinary bladder emptying. The normal prostate is composed of a higher amount of stromal tissue than epithelial tissue, as reflected by a stromal-to-epithelial tissue ratio of 2:1. This ratio is exaggerated to 5:1 for patients with BPH, which explains why α_1-adrenergic antagonists are quickly effective in symptomatic management and why 5α-reductase inhibitors reduce an enlarged prostate gland by only 25%.[2,4] The capsule, or outer shell of the prostate, is composed of fibrous connective tissue and smooth muscle, which also is embedded with α_1-adrenergic receptors. When stimulated with norepinephrine, the capsule contracts around the prostatic urethra (**Fig. 84-1**).

FIGURE 84-1

Representation of the anatomy of and α-adrenergic receptor distribution in the prostate, urethra, and bladder. *(Narayan P, Indudhara R. Pharmacotherapy for benign prostatic hyperplasia. Western Journal of Medicine. 1994;161(5):495-506. Copyright © 1994 with permission from BMJ Publishing Group Ltd.)*



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Testosterone is the principal testicular androgen in males, whereas androstenedione is the principal adrenal androgen. These two hormones are responsible for penile and scrotal enlargement, increased muscle mass, and maintenance of the normal male libido. These androgens are converted by 5α-reductase in target cells to dihydrotestosterone (DHT), an active metabolite. Two types of 5α-reductase exist. Type I enzyme is localized to sebaceous glands in the frontal scalp, liver, and skin, although a small amount is in the prostate. DHT produced at these target tissues causes acne and increased body and facial hair. Type II enzyme is localized to the prostate, genital tissue, and hair follicles of the scalp. In the prostate, DHT induces growth and enlargement of the gland.[3]

In prostate cells, DHT has greater affinity for intraprostatic androgen receptors than testosterone, and DHT forms a more stable complex with the androgen receptor. Thus, DHT is considered a more potent androgen than testosterone in the prostate. Of note, despite the decrease in testicular androgen production in the aging male, intracellular DHT levels in the prostate remain normal,

probably due to increased activity of intraprostatic 5α-reductase.[3]

Estrogen, a product of peripheral metabolism of androgens, is believed to stimulate the growth of the stromal portion of the prostate gland. Estrogens are produced when testosterone and androstenedione are converted by aromatase enzymes in peripheral adipose tissues. In addition, estrogens may induce the androgen receptor.[2] As men age, the ratio of serum levels of testosterone to estrogen decreases as a result of a decline in testosterone production by the testes and increased adipose tissue conversion of androgen to estrogen.

PATHOPHYSIOLOGY

Although the precise pathophysiologic mechanisms causing BPH remain unclear, the role of intraprostatic DHT and type II 5α-reductase in the development of BPH is evidenced by several observations:

1. BPH does not develop in men who are castrated before puberty.
2. Patients with type II 5α-reductase enzyme deficiency do not develop BPH.
3. Castration causes an enlarged prostate to shrink.
4. Administration of testosterone to orchiectomized dogs of advanced age produces BPH.

The pathogenesis of BPH is often described as resulting from both static and dynamic factors. Static factors relate to anatomic enlargement of the prostate gland, which produces a physical block at the bladder neck and thereby obstructs urinary outflow. Enlargement of the gland depends on androgen stimulation of epithelial tissue and estrogen stimulation of stromal tissue in the prostate. Dynamic factors relate to excessive α-adrenergic tone of the stromal component of the prostate gland, bladder neck, and posterior urethra, which results in contraction of the prostate gland around the urethra and narrowing of the urethral lumen.

Symptoms of BPH disease may result from static and/or dynamic factors, and this must be recognized when drug therapy is considered. For instance, some patients may present with obstructive voiding symptoms, but have prostates of normal size. In these patients, dynamic factors likely are responsible for the symptoms. However, for patients with enlarged prostate glands, static and dynamic factors likely are working in concert to produce the observed symptoms. Moreover, the likelihood of developing moderate to severe obstructive voiding symptoms is directly related to the increasing size of the prostate gland.[5]

Static factors may be accentuated if the patient becomes stressed or is in pain. In these situations, increased α-adrenergic tone may precipitate excessive contraction of prostatic stromal tissue. When the stressful event resolves, voiding symptoms often improve.[2]

MEDICATION-RELATED SYMPTOMS

2 Medications in several pharmacologic categories should be avoided for patients with BPH because they may exacerbate symptoms.[6] Testosterone replacement regimens, used to treat primary or secondary hypogonadism, deliver additional substrate that can be metabolized to DHT by the prostate. Although no cases of BPH have been reported because of exogenous testosterone administration, cautious use is advised for older patients with prostatic enlargement. α-Adrenergic agonists, used as oral or intranasal decongestants (eg, pseudoephedrine, ephedrine, or phenylephrine), can stimulate α-adrenergic receptors in the prostate, resulting in muscle contraction. By decreasing the caliber of the urethral lumen, bladder emptying may be compromised. β-Adrenergic agonists (eg, terbutaline) may cause relaxation of the bladder detrusor muscle, which prevents bladder emptying.[7] Drugs with significant anticholinergic adverse effects (eg, antihistamines, phenothiazines, tricyclic antidepressants, or anticholinergic drugs used as antispasmodics or to treat Parkinson disease) may decrease contractility of the urinary bladder detrusor muscle. For patients with BPH who have a narrowed urethral lumen, loss of effective detrusor contraction could result in acute urinary retention, particularly for patients with significantly enlarged prostate glands and a PVR urine volume greater than 150 mL. Diuretics, particularly in large doses, can produce polyuria, which may present as urinary frequency, similar to that experienced by patients with BPH.

CLINICAL PRESENTATION

Patients with BPH can present with a variety of symptoms and signs of disease. All symptoms of BPH can be divided into two categories: obstructive and irritative.

Obstructive symptoms, also known as *prostatism* or *bladder outlet obstruction*, result when dynamic and/or static factors reduce bladder emptying. The force of the urinary stream becomes diminished, urinary flow rate decreases, and bladder emptying is incomplete and slow. Patients report urinary hesitancy and straining and a weak urine stream. Urine dribbles out of the penis, and the urinary bladder always feels full, even after patients have voided. Some patients state that they need to press on their bladder to force out the urine. In severe cases, patients may go into urinary retention when bladder emptying is not possible. In these cases, suprapubic pain can result from bladder overdistension.

Approximately 50% to 80% of patients have irritative voiding symptoms, which typically occur late in the disease course. Irritative voiding symptoms result from long-standing obstruction of the bladder neck. The detrusor muscle cholinergic receptors become supersensitive to small volumes of urine in the bladder. Involuntary bladder contractions are triggered resulting in urinary urgency and frequency.[8] Patients report waking up every 1 to 2 hours at night to void (nocturia), which significantly reduces quality of life. As BPH progresses, the bladder muscle undergoes hypertrophy so that it can generate a greater contractile force to empty urine past the anatomic obstruction at the bladder neck. Decompensation eventually occurs, and the hypertrophied bladder muscle is no longer able to generate adequate contractile force; the bladder becomes ineffective in emptying urine. Acute urinary retention and recurrent urinary tract infections, and renal failure complicate progressive, untreated disease.

Other factors implicated in the pathophysiology of BPH include chronic prostatic inflammation,

advanced atherosclerosis of the blood supply to the pelvis, and decreased release of nitric oxide and decreased production of cyclic guanosine monophosphate (cGMP) at the bladder neck and in the prostate.[9]

CLINICAL PRESENTATION Benign Prostatic Hyperplasia General

- A patient is in no acute distress unless he has moderate to severe symptoms or complications of BPH.

Symptoms

- Obstructive symptoms: Slow urinary stream, intermittency, hesitancy, straining to urinate, incomplete emptying, dribbling
- Irritative symptoms: Urgency, frequency, nocturia

Signs

- Digital rectal examination reveals an enlarged prostate (>20 g) with no nodules or indurations; prostate is soft, symmetric, and mobile.

Laboratory Tests

- Increased blood urea nitrogen (BUN) and serum creatinine with long-standing, untreated bladder outlet obstruction, elevated prostate-specific antigen (PSA) level.

Other Diagnostic Tests

- Increased American Urological Association (AUA) Symptom Score, decreased urinary flow rate (<10 mL/s), and increased PVR urine volume

Symptoms of BPH vary over time. Symptoms may improve, remain stable, or worsen spontaneously. Thus, BPH is not necessarily a progressive disease; approximately 85% of patients with BPH have stable symptoms when evaluated 4 years after initial diagnosis.[10] Between one and two-thirds of men with mild disease stabilize or improve without treatment over 2.5 to 5 years.[2,6] However, worsening symptoms and complications of BPH develop in patients, particularly those with a prostate gland size 30 to 40 mL or PSA of 1.4 ng/mL (µg/L) or greater.[2,6]

Collectively, obstructive and irritative voiding symptoms and their negative impact on a patient's quality of life are referred to as *lower urinary tract symptoms* (LUTS). However, LUTS is not pathognomonic for BPH and may be caused by other diseases, such as neurogenic bladder and urinary tract infection.[2]

Another presentation of BPH is silent prostatism. Patients have LUTS, but adapt to the symptoms and do not voluntarily complain about them. Such patients do not present for medical treatment until complications of BPH disease arise or a spouse brings in the symptomatic patient for medical care.

When BPH progresses, it can produce complications that include the following:

1. Acute, painful urinary retention, which can lead to acute renal failure.
2. Persistent or intermittent gross hematuria when tissue growth exceeds its blood supply.
3. Overflow urinary incontinence or unstable bladder.
4. Recurrent urinary tract infection that results from urinary stasis.
5. Bladder diverticula.
6. Bladder stones.
7. Chronic renal failure from long-standing bladder outlet obstruction.

Approximately 17% to 20% of patients with symptomatic BPH require treatment because of disease complications.[11] Men older than 70 years with large prostates greater than 40 g and a PVR urine volume greater than 100 mL are three times more likely to have severe symptoms or suffer from acute urinary retention and to require prostatectomy than patients with smaller prostates.[12] Thus, a serum PSA level of 1.4 ng/mL (µg/L) has been used as a surrogate marker for an enlarged prostate gland to identify patients at risk for developing complications of BPH disease and has been used to guide selection of the most appropriate treatment modality in some patients.[12,13]

DIAGNOSTIC EVALUATION

Because the obstructive and irritative voiding symptoms associated with BPH are not unique to the disease and can be presenting symptoms of other genitourinary tract disorders, including prostate or bladder cancer, neurogenic bladder, prostatic calculi, or urinary tract infection, the patient presenting with signs and symptoms of BPH must be thoroughly evaluated.

A careful medical history should be taken to ensure that a complete listing of symptoms is collected to identify concomitant disorders that may be contributing to voiding symptoms. The medical history should be followed by a thorough medication history, including all prescription and nonprescription medications and dietary supplements that the patient is taking. Any drugs that could be causing or exacerbating the patient's symptoms should be identified. If possible, the suspected drugs should be discontinued or the dosing regimen modified to ameliorate the voiding symptoms.

The patient should undergo a physical examination, including a digital rectal examination, although the size of the prostate gland may not correspond to symptoms. BPH usually presents as an enlarged, soft, smooth, symmetric gland, greater than 20 g in size. Some patients have only a slightly enlarged gland and yet have bothersome or even serious voiding difficulties. Other patients have intravesical enlargement of the prostate gland (ie, the gland grows into the urinary bladder and produces a ball-valve blockage of the bladder neck). This type of prostate enlargement is not palpable on digital examination.

The patient's perception of the severity of BPH symptoms guides selection of a particular treatment modality in a patient. To evaluate the patient's perceptions objectively, validated instruments, such as the AUA Symptom Score (**Table 84-1**), are commonly used. Using the AUA Symptom Score, the patient rates the "bothersomeness" of seven obstructive and irritative voiding symptoms.[14] Each item is rated for severity on a scale from 0 to 5, such that 35 is the maximum score and is consistent with the most severe symptoms. Patients usually are stratified into the three groups shown in the table based on disease severity for the purposes of deciding a treatment approach.

TABLE 84-1 Categories of BPH Disease Severity Based on Symptoms and Signs

Disease Severity	AUA Symptom Score	Typical Symptoms and Signs
		Asymptomatic
Mild	≤7	Peak urinary flow rate <10 mL/s PVR urine volume >25-50 mL
Moderate	8-19	All of the above signs plus obstructive voiding symptoms and irritative voiding symptoms (signs of detrusor instability)
Severe	≥20	All of the above plus one or more complications of BPH

AUA, American Urological Association; BPH, benign prostatic hyperplasia; BUN, blood urea nitrogen; PVR, postvoid residual.

In addition, the patient can complete a voiding diary in which he records the number of voids, the volume of each void, and voiding symptoms for several days. This information is used to evaluate symptom severity and tailor recommendations for lifestyle modifications that may ameliorate symptoms.

The only clinical laboratory test that must be performed is a urinalysis. Because many of the voiding symptoms of BPH could be caused by other urologic disorders, a urinalysis can help screen for hematuria, urolithiasis, and infection. To screen for prostate cancer, another common cause of glandular enlargement, a PSA test should be performed for patients aged 40 years or more, with at least a 10-year life expectancy in whom the potential benefit of diagnosing the disorder will be outweighed by the cost of the test.[14]

Objective measures of bladder emptying include peak and average urinary flow rate (normal is at least 10 mL/s). These measures are determined using an uroflowmeter, which checks the rate of urine flow out of the bladder. This is a quick noninvasive outpatient procedure in which the patient is instructed to drink water until his bladder feels full and then the patient's urinary flow is clocked during voiding. A low urinary flow rate (<10-12 mL/s) implies failure of bladder emptying due to obstruction or a functional disorder of the detrusor muscle. Thus, the degree of bladder outlet obstruction may not correlate with peak urinary flow rate.[14]

Another objective measure is PVR urine volume (normal is 0 mL), which is assessed using a transabdominal ultrasound. A high PVR urine volume (>25-50 mL) implies failure of bladder

emptying and a predisposition for urinary tract infections. Because of a weak correlation among voiding symptoms, prostate size, and urinary flow rate, most physicians use a combination of measures, including the patient's assessment of symptoms along with objective evaluation of urinary outflow, PVR, and presence of complications of BPH to determine the need for treatment.

Many other tests can be performed if additional information is needed to assess the severity of BPH disease and its complications, to assist in the preoperative assessment of the patient, or to distinguish prostate enlargement due to BPH from that caused by prostate cancer. Tests include a serum BUN and creatinine, voiding cystometrogram, transrectal ultrasound of the prostate, IV pyelogram, renal ultrasound, and prostate biopsy.

TREATMENT

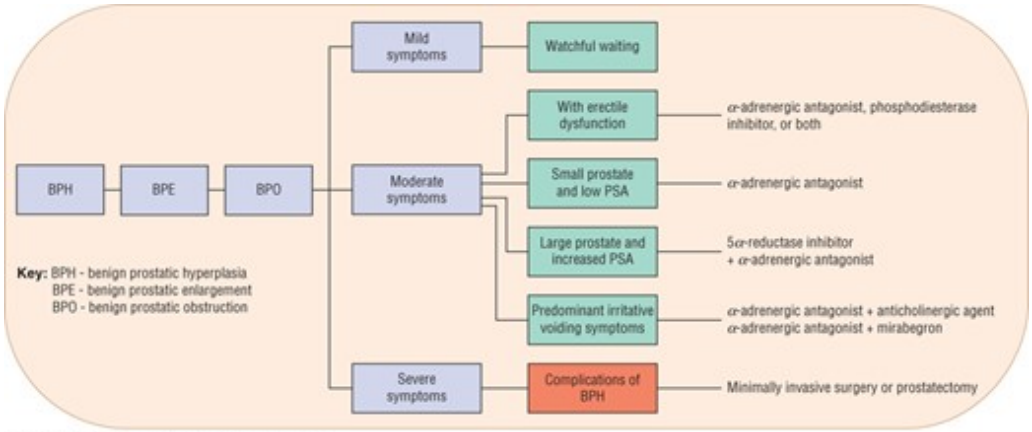
The goals of treatment are to control symptoms, as evidenced by a minimum of a 3-point decrease in the AUA symptom index, prevent progression of BPH disease by reducing the risk of developing complications, and delay the need for surgical intervention

As a disease of symptoms, BPH is treated by relieving bothersome symptoms. However, selection of a single best treatment for a patient must consider the variable costs and adverse effects of treatment options, the inability to predict the course of the disease in an individual patient, and the potential benefit that may occur in a comparatively small number of treated patients.

The AUA Guidelines on Management of Benign Prostatic Hyperplasia is the principal tool used in the United States[14] and is similar to the European Guidelines[15] (**Fig. 84-2**) with the exception that the European Guidelines recommend tadalafil for moderate to severe LUTS in younger male patients (who are likely to be sexually active) who are physically trim and that 5α-reductase inhibitors are recommended for long-term treatment of patients with BPH who have a prostate volume greater than 40 mL and a PSA greater than 1.4 ng/mL (µg/L). The AUA Guidelines were originally published in 2010, and although reaffirmed in 2014, were not revised. The European Guidelines were updated and published in 2013.

FIGURE 84-2

Management algorithm for benign prostatic hyperplasia (BPH).



All patients should be encouraged to initiate and maintain a heart healthy lifestyle, including a low-fat diet, high intake of plenty of fresh fruits and vegetables, regular physical exercise, and no smoking.[16,17] If the patient is overweight, he should be encouraged to lose weight. If the patient has diabetes mellitus, dyslipidemia, or hypertension, he should be advised to optimize management of those disorders.

Specific treatment options include watchful waiting, pharmacologic therapy, and surgical intervention. Although phytotherapy is used by some patients alone or along with conventional medications for BPH, head-to-head comparisons with FDA-approved treatments are lacking; consequently, such herbals cannot be recommended at this time.[14]

3 Patients with mild disease are asymptomatic or have mildly bothersome symptoms and have no complications of BPH disease. These patients can be managed with watchful waiting, which entails having the patient return for reassessment at intervals of 6 to 12 months. At each return visit, the patient should complete a standardized, validated survey tool to assess severity of symptoms and objective signs of disease should be assessed using measurement of urinary flow rate and PVR urine volume. Watchful waiting should be accompanied by patient education about the disease and behavior modification to avoid practices that exacerbate voiding symptoms. Behavior modification includes restricting fluids close to bedtime, minimizing caffeine and alcohol intake, frequent emptying of the bladder during waking hours or before long trips (to avoid overflow incontinence and urgency), and avoiding drugs that could exacerbate voiding symptoms.[17] At each visit, physicians should assess the patient's risk of developing acute urinary retention by evaluating the patient's prostate size or using PSA as a surrogate marker of prostate enlargement.[14]

4 If symptoms progress to the moderate or severe level, or the patient perceives his symptoms to be bothersome, the patient should be offered specific treatment. In these patients, watchful waiting delays—but does not decrease—the need for prostatectomy. In symptomatic patients, watchful waiting can lead to intractable urinary retention, increased PVR urine volumes, and significant voiding symptoms.[18,19] Recommended treatment options include drug therapy with an α_1-adrenergic antagonist or 5α-reductase inhibitor, a combination of an α_1-adrenergic antagonist and a 5α-reductase inhibitor, a phosphodiesterase inhibitor alone or combined with an α_1-adrenergic

antagonist or 5α-reductase inhibitor, or the addition of an anticholinergic agent to an α_1-adrenergic antagonist or 5α-reductase inhibitor; or surgery.

Patients with serious complications of BPH should be offered surgical correction (transurethral or open prostatectomy, or a minimally invasive surgical procedure). Drug therapy is considered an interim measure for such patients because it only delays worsening of complications and the need for surgical intervention.[6,14,18]

Desired Outcomes

The desired outcomes of treatment include reducing LUTS as evidenced by an improvement of AUA Symptom Score by at least three points, an increase in the peak urinary flow rate, and a normalization of PVR to less than 50 mL. In addition, treatment should prevent the development of disease complications and reduce the need for surgical intervention. Treatment should be well tolerated and be cost-effective.

Personalized Pharmacotherapy

In selecting the most appropriate treatment for an individual patient, consideration should be given to the severity and quality of the patient's LUTS, the likelihood of developing complications of BPH (based on size of the prostate gland or the PSA level), the patient's preference for medical versus surgical intervention, and the cost of treatment.

Concurrent medical illnesses of the patient should also be considered. For example, if the patient has erectile dysfunction and moderate LUTS, then a phosphodiesterase inhibitor might be preferred over an α_1-adrenergic antagonist. If the patient has overactive bladder syndrome and BPH, irritative voiding symptoms may require the addition of an anticholinergic agent or mirabegron. If medical treatment is initiated, the patient's level of renal function should be assessed, as the daily dose of some α-adrenergic antagonists and some anticholinergics require modification to avoid accumulation.

Pharmacologic Therapy

Drug therapy for BPH can be categorized into three types: agents that relax prostatic smooth muscle (reducing the dynamic factor), agents that interfere with testosterone's stimulatory effect on prostate gland enlargement (reducing the static factor), and agents that relax bladder detrusor muscle (improving the urine storage capacity of the bladder) (**Tables 84-2** and **84-3**). Of the agents that relax prostatic smooth muscle, second- and third-generation α_1-adrenergic antagonists have been most widely used. These agents relax the intrinsic urethral sphincter and prostatic smooth muscle, thereby enhancing urinary outflow from the bladder. Phosphodiesterase inhibitors also relax bladder neck and prostatic smooth muscle. α_1-Adrenergic antagonists and phosphodiesterase inhibitors do not reduce prostate size. Of the agents that interfere with testosterone's stimulatory effect on prostate gland size, the only agents approved by the FDA are 5α-reductase inhibitors (eg, finasteride, dutasteride). Other agents that interfere with androgen stimulation of the prostate have not been

popular in the United States because of the many adverse effects associated with their use. The luteinizing hormone-releasing hormone superagonists leuprolide and goserelin decrease libido and can cause erectile dysfunction, gynecomastia, and hot flashes. Antiandrogens (eg, bicalutamide, flutamide) produce nausea, diarrhea, gynecomastia, and hepatotoxicity. Finally, antimuscarinic agents relax detrusor muscle contraction, which reduces irritable voiding symptoms in some patients with BPH. Antimuscarinic agents and mirabegron both reduce irritative voiding symptoms, improve urine storage capacity of the bladder, and increase the interval between voidings.[18,19]

TABLE 84-2 Medical Treatment Options for Benign Prostatic Hyperplasia

Category	Mechanism	Drug (Brand Name)
Reduces dynamic factor	Blocks α_1-adrenergic receptors in prostatic stromal tissue Blocks α_{1A}-receptors in the prostate Causes smooth muscle relaxation of prostate, bladder neck, and prostatic urethra	Prazosin (Minipress) Alfuzosin (Uroxatral) Terazosin (Hytrin) Doxazosin (Cardura) Tamsulosin (Flomax) Silodosin (Rapaflo) Tadalafil (Cialis)
Reduce static factor	Blocks 5α-reductase enzyme Blocks dihydrotestosterone at its intracellular receptor Blocks pituitary release of luteinizing hormone Blocks pituitary release of luteinizing hormone and blocks androgen receptor	Finasteride (Proscar) Dutasteride (Avodart) Bicalutamide (Casodex)[a] Flutamide (Eulexin)[a] Leuprolide (Lupron)[a] Goserelin (Zoladex)[a] Megestrol acetate (Megace)[a]
Other	Relaxes detrusor muscle of bladder	Tolterodine (Detrol) Oxybutynin (Ditropan) Trospium (Sanctura) Solifenacin (Vesicare) Darifenacin (Enablex)

Category	Mechanism	Drug (Brand Name)
		Fesoterodine (Toviaz)
		Tadalafil (Cialis)
		Mirabegron (Myrbetriq)

[a]Not FDA approved for treatment of benign prostatic hyperplasia.

TABLE 84-3 Comparison of α_1-Adrenergic Antagonists, 5α-Reductase Inhibitors, Phosphodiesterase Inhibitors, and Anticholinergic Agents for Benign Prostatic Hyperplasia

	α_1-Adrenergic Antagonists	**5α-Reductase Inhibitors**
Relaxes prostatic smooth muscle	Yes	No
Decreases prostate size	No	Yes
Halts disease progression	No	Yes
Peak onset	1-6 weeks	3-6 months
Efficacy in relieving BOO	++	++ (for patients with enlarged prostates)
Frequency of dosing	One to two times per day, depending on the agent and dosage formulation	Once per day
Decreases PSA	No	Yes
Sexual dysfunction adverse effects	EJD	Decreased libido, ED, EJD
Cardiovascular adverse effects	Yes	No
	Phosphodiesterase Inhibitors	**Anticholinergic Agents**
Relaxes prostatic smooth muscle	Yes	No
Decreases prostate size	No	No
Halts disease progression	No	No
Peak onset	4 weeks	1-2 weeks
Efficacy in relieving BOO	+	0 (irritative symptoms only)
Frequency of dosing	Once per day	Once per day
Decreases prostate-specific antigen	No	No
Sexual dysfunction adverse effects	No	ED

	α_1-Adrenergic Antagonists	5α-Reductase Inhibitors
Cardiovascular adverse effects	Yes (mild hypotension)	Yes (tachycardia)
	β_3-Adrenergic Agonists	
Relaxes prostatic smooth muscle	No	
Decreases prostate size	No	
Halts disease progression	No	
Peak onset	2 weeks, but may take up to 8 weeks	
Efficacy in relieving BOO	0 (irritative symptoms only)	
Frequency of dosing	Once per day	
Decreases prostate-specific antigen	No	
Sexual dysfunction adverse effects	No	
Cardiovascular adverse effects	Yes (hypertension)	

BPH, benign prostatic hyperplasia; ED, erectile dysfunction; EJD, ejaculation disorder; PSA, prostate-specific antigen.

+Notation is a quantitative assessment.

Selection of a medical treatment for a patient should be determined on a case-by-case basis after the patient and provider discuss the risks, benefits, and costs of various treatments. With drug therapy for BPH, patients must understand that the benefits continue only as long as the medication is taken.

If possible, drug therapy should be initiated with a single agent, usually an α_1-adrenergic antagonist, which is faster acting and more effective than a 5α-reductase inhibitor. In addition, α_1-adrenergic antagonists are effective in reducing LUTS independent of prostate size, have no effect on PSA, and are associated with less sexual dysfunction than are 5α-reductase inhibitors. A 5α-reductase inhibitor is a good first-choice agent for a symptomatic patient with a significantly enlarged prostate (>40 g) who cannot tolerate the cardiovascular adverse effects of α_1-adrenergic antagonists.

For patients at risk for developing complications of BPH, specifically patients with an enlarged prostate gland greater than 40 g,[11] and an elevated PSA greater than or equal to 1.4 ng/mL (µg/L), combination drug therapy with an α_1-adrenergic antagonist and a 5α-reductase inhibitor is more beneficial than single drug therapy. The pharmacologic rationale for such a combination is that using two drugs with different mechanisms of action can be more effective than either drug alone. The clinical benefit of combination drug therapy is that it quickly relieves symptoms, delays disease progression, and reduces the need for surgical intervention. Since combination drug therapy is

expensive and associated with more adverse effects than single drug therapy, it should be reserved for those patients who will benefit the most from it.

For patients with both erectile dysfunction and BPH, a phosphodiesterase inhibitor alone or in combination with an α-adrenergic antagonist may be used. However, it should be noted that a phosphodiesterase inhibitor alone will only relieve LUTS, and will produce a clinically insignificant urinary flow rate increase or postvoid urine volume decrease. Therefore, a phosphodiesterase inhibitor is generally considered less effective than an α-adrenergic antagonist.

For patients with LUTS with a predominance of irritative voiding symptoms, an anticholinergic agent could be added to an existing drug regimen for BPH. To reduce the risk of developing systemic anticholinergic adverse effects, an uroselective anticholinergic agent or mirabegron may be prescribed. To avoid the risk of developing acute urinary retention with an anticholinergic agent, anticholinergics should be used cautiously when the patient's PVR volume is greater than 250 to 300 mL.

α-Adrenergic Antagonists

Three generations of α-adrenergic antagonists have been used to treat BPH. They all relax smooth muscle in the prostate and bladder neck. Because of their antagonism of presynaptic α_2-adrenergic receptors that results in tachycardia and arrhythmias, first-generation agents such as phenoxybenzamine have been replaced by the second-generation postsynaptic α_1-adrenergic antagonists and third-generation uroselective postsynaptic α_{1A}-adrenergic antagonists.

5 The second- and third-generation α_1-adrenergic antagonists are considered equally effective for treatment of BPH.[14,19,20] These agents generally improve the AUA Symptom Score by 30% to 40%, decreasing the AUA Symptom Index by three to six points, within 2 to 6 weeks, depending on the need for dose titration; increase urinary flow rate by 2 to 3 mL/s in 60% to 70% of treated patients; and reduce PVR urine volume. With continued use, durable clinical benefit has been demonstrated for years.[20] Their effectiveness in reducing BPH symptoms and the severity of adverse effects appear to be dose-dependent.[20] They have no effect on prostate volume. α_1-Adrenergic antagonists do not reduce PSA levels, preserving the utility of this prostate cancer marker in this high-risk population.[14]

α-Adrenergic antagonists differ in their propensity to cause hypotensive adverse effects and ejaculation disorders. Modified- or extended-release formulations and third-generation α_{1A}-adrenergic antagonists produce a lower prevalence of hypotension than immediate-release, second-generation agents. α_{1A}-Adrenergic antagonists are more likely to produce ejaculation disorders than α_1-adrenergic antagonists. Finally, older, immediate-release, second-generation α-adrenergic antagonists and tamsulosin are available as inexpensive generic formulations, which may be desirable in selected patients.[14,20,21]

Second-generation agents include prazosin, terazosin, doxazosin, and alfuzosin. At the usual doses used to treat BPH, immediate-release formulations of prazosin, terazosin, and doxazosin antagonize peripheral vascular α_1-adrenergic receptors in addition to those in the prostate. As a result, first-dose

syncope, orthostatic hypotension, and dizziness are characteristic adverse effects. To improve tolerance to these adverse effects, therapy should start with a low dose of 1 mg daily and then should be slowly titrated up to a full therapeutic dose over several weeks.[19,20,21] Additive blood-pressure-lowering effects commonly occur when these agents are used with antihypertensive agents, which limit the use of these agents for some patients.[14] These agents differ in terms of duration of action and dosage formulation. Whereas prazosin requires dosing two to three times per day, terazosin, doxazosin, and alfuzosin offer more convenient once-daily dosing. Because prazosin requires twice- to thrice-daily dosing and has significant cardiovascular adverse effects, it is not recommended in the current AUA guidelines for treatment of BPH.[14] Extended-release dosage formulations are available for doxazosin and alfuzosin. These offer the convenience of once-daily dosing, treatment initiation with a full therapeutic dose, and decreased dose-related hypotension as the formulation produces lower peak serum concentrations than immediate-release products. An α_1-adrenergic antagonist is not preferred as single-drug therapy for treatment of both BPH and hypertension in a patient. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) of 24,000 patients with hypertension, doxazosin produced more congestive heart failure than amlodipine, lisinopril, or chlorthalidone.[22] Thus, both the AUA and the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure[14,23] recommend that patients with BPH and hypertension be treated with separate and appropriate drug treatment for each medical condition.

Alfuzosin is considered functionally and clinically uroselective in that usual doses used to treat BPH are less likely than other second-generation agents to cause cardiovascular adverse effects in animal or human models.[24] This clinical observation has been observed more often with the once-daily, extended-release formulation of alfuzosin, which is the only commercially available formulation in the United States, as compared with the immediate-release formulation that is dosed three times per day, which is available in Europe.[24] Its clinical uroselectivity has been postulated to be due to higher concentrations of alfuzosin achieved in the prostate versus serum after usual doses,[25] absence of high peak serum levels with the extended-release formulation, and the fixed dosing schedule of the extended-release formulation. The extended-release alfuzosin dosing is FDA approved for 10 mg daily, with no dose titration increase. This formulation is particularly convenient for patients who are starting to take the medication.

Tamsulosin and silodosin are the only third-generation α_1-adrenergic antagonists available in the United States. They are pharmacologically selective for prostatic α_{1A}-adrenergic receptors, which comprise approximately 70% to 75% of the adrenergic receptors in the prostate gland, prostatic urethra, and bladder neck.[20,21,26] Blockade of these receptors relaxes smooth muscle of the prostate and bladder neck and improves bladder emptying in patients with BPH. In addition, both of these agents have low affinity for vascular α_{1B}-adrenergic receptors, which explains why hypotension is not as frequent with usual daily doses as compared with second-generation agents.[26,27]

Silodosin has 50-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1D}-adrenergic receptor and has 100-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1B}-adrenergic receptor.[28] Silodosin demonstrates greater pharmacologic uroselectivity than tamsulosin, which has a

10-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1D}-adrenergic receptor and has 2.5-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1B}-adrenergic receptor.[28] However, these pharmacologic differences are not associated with a clinically significant difference in efficacy or adverse effects, as reported in one direct comparison clinical trial.[29]

The uroselectivity of α_{1A}-adrenergic receptors has multiple implications. Dose titration is minimal; therefore, patients can begin tamsulosin 0.4 mg daily or silodosin 8 mg daily. Patients can be instructed to take the dose anytime during the day, unlike immediate-release formulations of terazosin and doxazosin, which should be taken at bedtime so that patients can sleep through the time when peak cardiovascular adverse effects are most likely to occur. Tamsulosin and silodosin should be taken 30 minutes after the same meal every day because food decreases their bioavailability, reduces the peak serum concentration of the drug, and lowers the risk of hypotensive adverse effects. The onset of peak action is quick, in the range of 1 week. Increasing the daily dose of tamsulosin to 0.8 mg daily produces inconsistent improvements in effectiveness, but does increase adverse effects.[30] These agents are well tolerated in patients with well-controlled hypertension; and the addition of tamsulosin to furosemide, enalapril, nifedipine, and atenolol does result in hypotension.[31]

As compared with tamsulosin, silodosin requires dosage reduction in patients with hepatic impairment or when the creatinine clearance is 30 to 50 mL/min (0.5-0.83 mL/s), is contraindicated in patients with severe hepatic insufficiency or a creatinine clearance less than 30 mL/min (0.5 mL/s), and has the potential to produce more adverse effects because of elevated plasma concentrations if used concurrently with potent CYP 3A4 inhibitors (eg, clarithromycin, itraconazole, ketoconazole, ritonavir) or P-glycoprotein inhibitors (eg, cyclosporine). Silodosin also causes more ejaculatory dysfunction than tamsulosin.[27] Finally, silodosin is commercially available from only one source, whereas tamsulosin is available as a generic formulation.

The usual doses of α_1-adrenergic antagonists are summarized in **Table 84-4**.

TABLE 84-4 Dosing of Drugs Used in Treatment of Benign Prostatic Hyperplasia

Drug	Brand Name	Initial Dose	Usual Dose	Special Population Dose
***α*-Adrenergic Antagonists**				
Prazosin	Minipress	0.5 mg twice a day orally	1-5 mg twice a day orally	For uptitrating the dose, double the dose every 2 weeks
Terazosin	Hytrin	1 mg at bedtime orally	10-20 mg daily orally	For uptitrating the dose, increase slowly to 2 mg, 5 mg, and then 10 mg daily in a stepwise fashion. Take extra care if the patient is taking other drugs that lower blood pressure
Doxazosin	Cardura Cardura	1 mg daily orally	8 mg daily orally	For the immediate-release formulation, doses of 16 mg daily have been used for hypertension. For the XL formulation,

Drug	Brand Name	Initial Dose	Usual Dose	Special Population Dose
	XL	4 mg daily orally	4-8 mg daily	increase from 4 to 8 mg daily after a 3- to 4-week interval. When switching from the immediate- to the extended-release formulation, start at 4 mg of the extended-release formulation no matter what maintenance dose of immediate-release doxazosin the patient is taking
Alfuzosin	Uroxatral	10 mg daily orally	10 mg daily orally (no dose titration)	This is an extended-release formulation, and it should not be chewed or crushed. The drug should be taken after meals and used cautiously in patients with creatinine clearance is less than 30 mL/min (0.5 mL/s)
Tamsulosin	Flomax	0.4 mg daily orally	0.4-0.8 mg daily orally	This is an extended-release formulation, and it should not be chewed or crushed. The drug should be taken after meals. No dosage adjustment is needed in patients with renal or liver dysfunction. Allow several weeks after starting a dose before increasing to a higher dose
Silodosin	Rapaflo	8 mg daily orally	8 mg daily orally (no dose titration)	This drug is contraindicated when creatinine clearance is less than 30 mL/min (0.5 mL/s). If creatinine clearance is 30-50 mL/min (0.5-0.83 mL/s), use 4 mg daily orally, preferably after the same meal each day. Should not be given to patients on potent CYP 3A4 inhibitors or to patients known to be poor metabolizers of CYP 2D6.
5α-Reductase Inhibitors				
Finasteride	Proscar	5 mg daily orally	5 mg daily orally	No dosage adjustment in patients with renal impairment. Use cautiously in patients with hepatic impairment
		0.5 mg daily orally		
Dutasteride	Avodart	1 tablet (equivalent to 0.5 mg dutasteride + 0.4 mg tamsulosin) daily orally	0.5 mg daily orally	No dosage adjustment in patients with renal impairment. Use cautiously in patients with hepatic impairment
Dutasteride + tamsulosin	Jalyn		1 tablet daily orally	No dosage adjustment needed in patients with renal or hepatic impairment

Drug	Brand Name	Initial Dose	Usual Dose	Special Population Dose
Phosphodiesterase Inhibitor				
Tadalafil	Cialis	5 mg daily orally	5 mg daily orally	If creatinine clearance is 30-50 mL/min (0.5-0.83 mL/s), use 2.5 mg daily orally. Do not use if creatinine clearance is less than 30 mL/min (0.5 mL/s)
Anticholinergic Agents				
Darifenacin	Enablex	7.5 mg daily orally	7.5-15 mg daily orally	For uptitrating the dose, double the dose after 2 weeks. If the patient is taking a potent CYP3A4 inhibitor (eg, ketoconazole, itraconazole, ritonavir, nelfinavir, and clarithromycin), do not exceed 7.5 mg daily orally
Fesoterodine	Toviaz	4 mg daily orally	4-8 mg daily orally	This is an extended-release formulation, and it should not be chewed or crushed. If the patient is taking a potent CYP3A4 inhibitor (eg, ketoconazole, itraconazole, ritonavir, nelfinavir, and clarithromycin), do not exceed 4 mg daily orally. If the creatinine clearance is less than 30 mL/min (0.5 mL/s), do not exceed 4 mg daily orally
Oxybutynin	Ditropan	5 mg two to three times a day orally	5-10 mg two to three times a day orally	Increase daily dose at 5-mg increments at weekly intervals. No specific dosing modifications available for patients with renal impairment, however use cautiously in these patients.
	Ditropan XL	5 mg daily orally	5-30 mg daily orally	This is an extended release formulation, and it should not be crushed or chewed. Increase daily dose at 5-mg increments at weekly intervals. No specific dosing modifications available for patients with renal impairment, but use cautiously in these patients.
	Oxytrol TDS	1 patch (3.9 mg oxybutynin) twice weekly	1 patch (3.9 mg) twice weekly	This is a transdermal patch. Apply to abdomen, hip, or buttock. Rotate application site. Do not expose patch to sunlight. No specific dosing modifications available for patients with renal impairment, however use cautiously in these patients.
	Gelnique 10% gel	1 g gel (100 mg oxybutynin) daily	1 g gel (100 mg oxybutynin) daily	

Drug	Brand Name	Initial Dose	Usual Dose	Special Population Dose
				This is available as premeasured dose packets. Apply to abdomen, thighs, upper arms or shoulders. Wash hands after application. Do not bathe, shower, or swim for 1 hour after application. Cover application site with clothing until medication dries on skin. Rotate application site daily. No specific dosing modifications available for patients with renal impairment, but use cautiously in these patients.
Solifenacin	Vesicare	5 mg daily orally	5-10 mg daily orally	If the creatinine clearance is less than 30 mL/min (0.5 mL/s) or the patient has moderate hepatic impairment, do not exceed 5 mg daily orally. If the patient is taking a potent CYP3A4 inhibitor (eg, ketoconazole, itraconazole, ritonavir, nelfinavir, and clarithromycin), do not exceed 5 mg daily orally If the patient has significant renal impairment, limit dose to 1 mg twice a day
Tolterodine	Detrol	2 mg twice daily orally	2 mg twice daily orally	The LA formulation is an extended-release formulation, and it should not be chewed or crushed. If the creatinine clearance is 10-30 mL/min (0.17-0.5 mL/s) or the patient has mild/moderate hepatic impairment, do not exceed 2 mg daily orally. If the creatinine clearance is less than 10 mL/min (0.17 mL/s), do not use Detrol LA
	Detrol LA	4 mg daily orally	4 mg daily orally	
Trospium	Sanctura	20 mg twice daily orally	20 mg twice daily orally	Avoid alcohol ingestion for 2 hours after a dose. Use cautiously in patients with moderate or severe hepatic impairment. In patients older than 75 years, use the immediate-release formulation and start with 20 mg daily orally. If the creatinine clearance is less than 30 mL/min (0.5 mL/s), use 20-mg immediate-release formulation
	Sanctura XR	60 mg daily orally	60 mg daily orally	The XR is an extended-release formulation,

Drug	Brand Name	Initial Dose	Usual Dose	Special Population Dose
				and it should not be chewed or crushed. This is not recommended in patients with creatinine clearance less than 30 mL/min (0.5 mL/s)
β_3-Adrenergic Agonist				
Mirabegron	Myrbetriq	25 mg daily orally	25-50 mg daily orally	This is an extended-release formulation. Do not chew, crush, or divide tablet. In patients with a creatinine clearance of 15-29 mL/min (0.25-0.48 mL/s) or those with moderate hepatic impairment, the maximum daily dose should be 25 mg daily. This drug is not recommended in patients with creatinine clearance less than 15 mL/min (0.25 mL/s).

When using immediate-release formulations of the second-generation α_1-adrenergic antagonists terazosin and doxazosin, slow titration up to a therapeutic maintenance dose is necessary to minimize orthostatic hypotension and first-dose syncope. Conservatively, dosages should be increased in an orderly stepwise process, at 2- to 7-day intervals, depending on the patient's response to the medication. A faster titration schedule can be used as long as the patient does not develop orthostatic hypotension or dizziness. Two sample titration schedules for terazosin are as follows:

1. Schedule 1: Slow titration
    - Days 4 to 14: 2 mg at bedtime
    - Weeks 2 to 6: 5 mg at bedtime
    - Weeks 7 and on: 10 mg at bedtime
2. Schedule 2: Quicker titration
    - Days 1 to 3: 1 mg at bedtime
    - Days 4 to 14: 2 mg at bedtime
    - Weeks 2 to 3: 5 mg at bedtime
    - Weeks 4 and on: 10 mg at bedtime

Patients should continue taking the drug as long as they continue to respond to it. Durable responses for 6 and 10 years have been reported for tamsulosin[32] and doxazosin,[33] respectively.

With the exception of silodosin and alfuzosin, no dosage adjustments are recommended for α_1-adrenergic antagonists for patients with renal failure. A reduced starting dose of 4 mg daily of silodosin is recommended for patients with moderate renal impairment (creatinine clearance 30-50 mL/min [0.5-0.83 mL/s]). Alfuzosin should be avoided when the creatinine clearance is less than 30 mL/min (0.5 mL/s).

Because these drugs are hepatically catabolized, the lowest effective dose should be used for patients with hepatic dysfunction, and patients should be monitored carefully for adverse effects. Approximately 10% to 12% of patients discontinue taking second-generation α_1-adrenergic antagonists because of adverse effects, especially those that affect the cardiovascular system (eg, syncope, dizziness, hypotension).[34] Patients who tolerate hypotension poorly should avoid immediate-release formulations of second-generation α_1-adrenergic antagonists. This includes patients with poorly controlled angina, serious cardiac arrhythmias, patients with reduced circulating volume, patients with untreated hypertension, and patients taking multiple antihypertensives.[21,34] These patients are candidates for a third-generation α_1-adrenergic antagonists or alfuzosin.

Tiredness and asthenia, anejaculation, flu-like symptoms, and nasal congestion are the most common dose-related adverse effects of tamsulosin and silodosin. These adverse effects are extensions of their α-adrenergic antagonist activity and are dose-related, but with proper education patients likely will not discontinue treatment.[34,35]

Floppy iris syndrome has been associated with doxazosin, silodosin, and tamsulosin use, although the number of reported cases is highest with tamsulosin.[36] The mechanism for this adverse reaction is related to blockade of α_{1A}-adrenergic receptors in iris dilator muscles. As a result, during cataract surgery, pupillary constriction occurs despite the use of mydriatic agents and the iris billows out (floppy iris), both of which complicate the procedure or can increase the likelihood of postoperative complications, including posterior capsular rupture, retinal detachment, residual retained lens material, or endophthalmitis.[37,38] Permanent loss of vision can result.

Patients who are taking α_1-adrenergic antagonists and who plan to undergo cataract surgery should inform their ophthalmologist that they are taking this medication so that appropriate measures can be taken during eye surgery, for example, use of iris retractors, pupillary expansion rings, or potent mydriatic agents.[36,37,38] No benefit has been demonstrated with holding the α_1-adrenergic antagonist preoperatively.

For patients who are scheduled to have cataract surgery, and who have not yet started an α_1-adrenergic antagonist, they should be advised to delay the start of the α_1-adrenergic antagonist until surgery has been completed. Patients with severe sulfa allergy should avoid tamsulosin.

Caution is needed when CYP 3A4 inhibitors, for example cimetidine and diltiazem, are used with α_1-adrenergic antagonists because a drug–drug interaction could lead to decreased metabolism of the latter agents. In contrast, concurrent use of potent CYP 3A4 stimulators, for example carbamazepine and phenytoin, may increase hepatic catabolism of α_1-adrenergic antagonists.

Phosphodiesterase inhibitors (eg, sildenafil, vardenafil, tadalafil) may produce hypotension if used in large doses along with α_1-adrenergic antagonists. The mechanisms for this interaction are related to the intrinsic vasodilatory effects of phosphodiesterase inhibitors and the higher susceptibility of elderly patients to venous pooling because of autonomic incompetence.[24,39] The prevalence of hypotension depends on the specific phosphodiesterase inhibitor and α_1-adrenergic antagonist agent, specifically the combination of tadalafil and tamsulosin is least likely to produce a clinically significant drug interaction, as compared with other combinations.[39] Therefore, a patient's blood pressure should be stabilized on the α_1-adrenergic antagonist before starting a phosphodiesterase inhibitor. In addition, patients who are taking phosphodiesterase inhibitors with α_1-adrenergic antagonists should have their blood pressure monitored closely when initiating combined drug use.

Clinical Controversy...

Among the α_1-adrenergic antagonists, agents that are pharmacologically or clinically uroselective appear to have a lower potential to cause hypotension than nonuroselective agents. However, it is unclear if there is any distinct clinical advantage of using alfuzosin, over tamsulosin or silodosin.

5α-Reductase Inhibitors

6 Finasteride competitively inhibits type II 5α-reductase, the predominant isoform of the enzyme in the prostate, suppresses intraprostatic DHT by 80% to 90%, and decreases serum DHT levels by 70%.[14,40] Dutasteride is a nonselective inhibitor of type I and II 5α-reductase. It more quickly and completely suppresses intraprostatic DHT production and decreases serum DHT levels by 90%.[41] However, direct comparison clinical trials show no advantages of these pharmacodynamic actions of dutasteride when compared with finasteride.[41] These agents are indicated for management of moderate to severe BPH disease for patients with enlarged prostate glands of at least 40 g.[14,15,41] For such patients, 5α-reductase inhibitors may slow disease progression and decrease the risk of disease complications, thereby decreasing the ultimate need for surgical intervention. When taken continuously for 4 years or 6 years, dutasteride or finasteride, respectively, has been shown to decrease the risk of acute urinary retention and prostatectomy.[43,44] For patients with severe disease, these agents generally can be used with a 6-month short course of an α_1-adrenergic antagonist, which will provide fast symptom relief until the 5α-reductase inhibitor starts to work. 5α-Reductase inhibitors may be preferred for patients with BPH and an enlarged prostate gland who have uncontrolled arrhythmias, have poorly controlled angina, are taking multiple antihypertensive agents, or are unable to tolerate hypotensive adverse effects of α_1-adrenergic antagonists.

5α-Reductase inhibitors also reduce or stop prostate-related bleeding by inhibiting prostatic vascular endothelial growth factor. Thus, the prevalence of gross hematuria in patients with BPH may be reduced with treatment of 5α-reductase inhibitors.[14]

5α-Reductase inhibitors reduce prostate size by 25%, increase peak urinary flow rate by 1.6 to 2.0 mL/s, improve voiding symptoms in approximately 30% of treated patients, and produce few serious adverse effects. Compared with α_1-adrenergic antagonists, 5α-reductase inhibitors have several

disadvantages. 5α-Reductase inhibitors have a delayed peak onset of clinical effect, which is undesirable for patients with bothersome symptoms, and an adequate clinical trial is 6 to 12 months. In addition, patients experience less objective improvement of the AUA Symptom Score and urinary flow rate with 5α-reductase inhibitors than with α_1-adrenergic antagonists.[14] 5α-Reductase inhibitors cause more sexual dysfunction than α_1-adrenergic receptor antagonists; therefore, physicians consider 5α-reductase inhibitors to be the second-line agents for treatment of BPH in sexually active males (**Tables 84-3** and **84-5**).[14,44]

TABLE 84-5 Monitoring of Drugs Used in Treatment of Benign Prostatic Hyperplasia

Drug	Adverse Reaction	Monitoring Parameter	Comment
α-Adrenergic antagonists	Syncope Lightheadedness Orthostatic hypotension Tachycardia Nasal congestion Ejaculatory dysfunction Priapism Floppy iris syndrome	Blood pressure Heart rate	If prescribing an immediate-release formulation, start the patient on the lowest possible dose and instruct the patient to take the first dose at bedtime. Slowly uptitrate the dose over several weeks. Stabilize the patient's blood pressure on the α-adrenergic antagonist before adding any other hypotensive agent. If the patient needs cataract surgery, instruct the patient to inform the ophthalmologist so that appropriate measures can be taken during the procedure to prevent intraoperative complications. If the patient has a painful erection lasting longer than 4 hours, the patient should seek immediate medical attention
5α-Reductase inhibitors	ED Decreased libido Ejaculatory dysfunction Gynecomastia	PSA	The patient's PSA level should decrease by 50% if he is adherent to therapy
Phosphodiesterase inhibitor	Headache Dizziness Nasal congestion Dyspepsia Back pain	Blood pressure Pulse Hearing loss	If the patient experiences hearing loss, discontinue tadalafil

Drug	Adverse Reaction	Monitoring Parameter	Comment
Anticholinergic agents	Myalgia Hearing loss Dry mouth Constipation Headache Tachycardia Blurry vision Acute urinary retention Drowsiness Confusion Angioedema Anaphylaxis ED	Mental status Bowel habits Ability to urinate	Adverse effects are dose-related and generally reversible. Patients with signs of severe allergic reaction need immediate medical attention
β_3-adrenergic agonist	Hypertension Tachycardia Dry mouth Nausa Constipation Diarrhea Headache Nasopharyngitis Impaired cognition	Blood pressure Bowel habits	Adverse effects are dose-related and generally reversible.

ED, erectile dysfunction; PSA, prostate-specific antigen.

In the Prostate Cancer Prevention Trial, patients with BPH who had large prostate glands and a PSA

level less than 3 ng/mL (µg/L) were prescribed finasteride 5 mg daily for up to 7 years. Finasteride reduced the 7-year prevalence of prostate cancer by 25%.[45] However, finasteride was associated with a 27% increase in the number of patients who developed high-grade prostate cancer, which usually is invasive. Although originally thought to be a disadvantage of finasteride use, it is now thought that the higher incidence of prostate cancer was due to biopsy sampling bias. That is, since finasteride reduces the size of the prostate gland, this results in increased sensitivity of sampling biopsies to detect prostate cancer.[46]

Another clinical trial produced similar results. The Reduction by Dutasteride in Prostate Cancer Events (REDUCE) study compared the effect of 4 years of continuous use of dutasteride versus placebo on reducing the incidence of prostate cancer in more than 6,700 men at high risk for developing prostate cancer. At the end of the study, dutasteride-treated patients had a 22.8% decreased relative risk of prostate cancer. Of the patients with biopsy-positive prostate cancer, a similar number of patients in each treatment group developed high grade tumors of Gleason grade 7 to 10 with no statistical difference between the groups.[47]

Thus, when finasteride is administered long-term to patients with BPH, it could be useful as chemoprophylaxis in patients with a family history of prostate cancer or in men of African descent who have an increased risk of developing prostate cancer. The possibility of developing a high-grade prostate cancer should be discussed with the patient before treatment is initiated with a 5α-reductase inhibitor for prevention of prostate cancer.[45,48]

Finasteride is well absorbed from the gastrointestinal (GI) tract (95%), and its absorption is unaffected by food. Peak serum concentrations are reached 1 to 2 hours after the dose. Finasteride is highly protein bound. The liver extensively metabolizes finasteride to inactive metabolites, which are largely excreted in stool. The plasma half-life is 4.7 to 7.1 hours, but its biologic half-life probably is longer, as decreased serum DHT levels persist for up to 2 weeks after finasteride dosing is stopped.

For BPH, finasteride is given in doses of 5 mg by mouth daily. The dose can be taken with meals or on an empty stomach. No dosage adjustment is needed for patients with renal dysfunction. Although no dosage reduction is recommended for patients with hepatic insufficiency, patients should be monitored carefully. Maximal reductions in prostate volume or symptom improvement may not be evident for 12 months, but noticeable changes from baseline should occur after 6 months of continuous treatment. No clinically relevant drug interactions have been reported with 5α-reductase inhibitors.

Patients must continue to take 5α-reductase inhibitors as long as they respond. Durable responses to finasteride and dutasteride have been reported with continued treatment for 6 years[43] and 4 years,[41] respectively. Upon discontinuation of the drug, prostate size and voiding symptoms generally return to baseline.

5α-Reductase inhibitors can produce sexual dysfunction, and this has led to discontinuation of therapy in up to 12% of treated patients in one pooled analysis.[41] Ejaculation disorders (dry sex or delayed ejaculation) have been reported in 3% to 8% of treated patients.[44] These disorders, which are possible results of decreased prostatic secretion, are reversible with drug discontinuation.

Erectile dysfunction has been reported in 3% to 16% of patients.[41,44] It may be secondary to ejaculation disorders or may be due to drug-induced inhibition of nitric oxide synthase (which is needed to produce nitric oxide, a vasodilatory substance) in cavernosal tissue. The role of 5α-reductase inhibitors in causing erectile dysfunction is not clear, as elderly men with BPH commonly develop erectile dysfunction as they age or have concurrent medical illnesses or concomitant drug therapies that may predispose to the development of sexual dysfunction.[49] Decreased libido has been reported in 2% to 10% of treated patients.[44]

Other minor adverse effects include nausea, abdominal pain, asthenia, dizziness, flatulence, headache, rash, muscle weakness, and gynecomastia.

5α-Reductase inhibitors are in FDA pregnancy category X, which means that they are contraindicated in pregnant females. Exposure of the male fetus to finasteride may produce pseudohermaphroditic offspring with ambiguous genitalia, similar to those of patients with a rare genetic deficiency of type II 5α-reductase. Because of this teratogenic effect, women who are pregnant or seeking to become pregnant should not handle 5α-reductase inhibitor tablets and should not have contact with semen from men being treated with 5α-reductase inhibitors. Women health professionals of childbearing age should handle this product with protective gloves if there is any chance that they are pregnant.

Usual doses of 5α-reductase inhibitors produce a median reduction of serum PSA levels by 50% at months 6 to 12 after the start of treatment. To interpret a PSA level in a patient being treated with a 5α-reductase inhibitor, it is generally recommended that the actual measured level be doubled to get an estimate of the true level.[14] For this reason, PSA levels must be measured before treatment begins, and the patient should have a digital rectal examination. After 6 months of therapy, the patient should have a repeat PSA. This PSA level can be used as the new baseline for the patient.[50] Alternatively, when compared to the pretreatment PSA, if the during treatment level does not decline by 50% and the patient has been adherent to the 5α-reductase inhibitor regimen, he should be evaluated for prostate cancer. Annually thereafter, the patient should have a PSA assay and digital rectal examination. Patients with an increase in PSA level of 0.3 ng/mL (µg/L) or more above the baseline nadir level should be evaluated for prostate cancer[50] or noncompliance to the prescribed regimen.

Clinical Controversy...

Whether or not a 5α-reductase inhibitor should be initiated in an asymptomatic patient with BPH who has risk factors for disease complications is unclear. Treatment would shrink an enlarged prostate, however, it is also costly and associated with sexual dysfunction, gynecomastia, and other adverse effects.[51]

Phosphodiesterase Type 5 Inhibitors

7 Several observations led to the use of phosphodiesterase type 5 inhibitors for management of BPH. BPH and erectile dysfunction are often present concurrently in the same patient.[35,52] The pathophysiology of BPH and erectile dysfunction may be common in so far as both disorders may be

associated with increased smooth muscle contraction and pelvic atherosclerosis.[49,52] Improvement of BPH symptoms has been reported to ameliorate erectile dysfunction; and vice versa.[35,52] Adverse effects of α-adrenergic antagonists and 5α-reductase inhibitors include erectile dysfunction, which responds to a phosphodiesterase type 5 inhibitor.[35]

Phosphodiesterase type 5 inhibitors relax smooth muscle in the prostate and bladder neck, probably by increasing cGMP. By so doing, phosphodiesterase type 5 inhibitors interrupt the Rho-protein kinase pathway, which normally regulates smooth muscle contraction mediated by endothelin and α-adrenergic stimulation, and reduces LUTS.[35,54,55,56]

In multiple clinical trials of patients with moderate LUTS, tadalafil caused significant improvements in voiding symptoms as measured by the AUA Symptom Index score or International Prostate Symptom Score (IPSS), with the level of improvement similar to that observed with α-adrenergic antagonists.[56,57] However, no or minimal increase in urinary flow rate or reduction in PVR urine volume occurred with tadalafil alone.[58,59,60] Tadalafil 2.5 mg was inferior to 5 mg, and doses of 10 mg or 20 mg were not superior to 5 mg.[53,54,55,56,57,58,59,60,61] This is the basis of the current product labeling dose of tadalafil 5 mg daily for BPH. The onset of clinical symptom improvement is within 4 weeks.[56,62]

The most common adverse effects observed are headache, flushing, gastroesophageal reflux, sinusitis, visual disturbances, and back pain, which are generally reversible and do not require discontinuation of therapy. When tadalafil was combined with an α-adrenergic antagonist, patients experienced significant improvements in LUTS, increased urinary flow rates, and decreased PVR volume[59]; however, the improvement was similar to that observed with an α-adrenergic antagonist alone.[63]

A few other BPH studies have employed sildenafil 50 mg or 100 mg daily or vardenafil 10 mg twice a day.[59,63] However, most of the clinical trials have evaluated tadalafil for treatment of BPH. This is probably because BPH is viewed as a chronic disease; tadalafil has been FDA-approved for once-daily dosing; and tadalafil has the longest half-life and duration of action among the phosphodiesterase inhibitors.[64] The recommended tadalafil dose is 5 mg daily. Based on the limited clinical benefit, cost, and potential adverse effects of tadalafil, it would be prudent to reserve its use for patients with both BPH and erectile dysfunction.[58,59,64] Patients with known cardiovascular disease should be assessed and stratified according to the Princeton Consensus Panel guidelines[65] to identify those patients who can safely use tadalafil. If used in combination with an α-adrenergic antagonist, precautions should be taken to minimize hypotension, specifically, stabilize the patient's blood pressure on the α-adrenergic antagonist before adding tadalafil.[39] If used in combination with a 5α-reductase inhibitor, tadalafil may be used instead of an α-adrenergic antagonist, and the combination may be associated with less sexual dysfunction, particularly in younger, sexually active patients.

Anticholinergic Agents

8 Treatment with an α_1-adrenergic antagonist, 5α-reductase inhibitor, or surgery may improve

urinary flow rate and bladder emptying; however, the patient may still complain of irritative voiding symptoms (eg, urinary frequency, urgency, and nocturia), which mimic those of overactive bladder syndrome. A variety of anticholinergic agents, including oxybutynin or tolterodine, have been added to an α-adrenergic antagonist regimen to relieve these symptoms.[66]

By blocking muscarinic receptors in the detrusor muscle, anticholinergic agents can reduce uninhibited detrusor contractions, a sequela of prolonged bladder outlet obstruction. Thus, irritative voiding symptoms are reduced. The peak clinical effect is observable in several weeks. It is recommended that a patient should be reevaluated 4 to 6 weeks after starting an anticholinergic agent for BPH. Because older patients are sensitive to the central nervous system adverse effects and dry mouth, such patients should be started on the lowest effective dose and then slowly titrated up.[66,67] Anticholinergic agents are contraindicated in patients with narrow angle glaucoma, urinary or gastric retention, or severely decreased intestinal motility. The total anticholinergic burden should be considered prior to making the decision to initiate an anticholinergic agent if the patient is already taking other anticholinergic agents (eg, antipsychotic, antidepressant, antihistamine, antiparkinsonian agents). When multiple anticholinergic agents are taken concurrently, anticholinergic adverse effects, including dry mouth, nausea, constipation, blurred vision, and confusion, will more likely occur and be more severe.

Uroselective anticholinergic agents, which preferentially inhibit M_3 receptors (eg, darifenacin or solifenacin), or transdermal (oxybutynin), or extended-release formulations of anticholinergic agents (eg, tolterodine) are recommended for patients who poorly tolerate systemic adverse effects of other anticholinergic agents. In the presence of BPH, anticholinergic agents can cause acute urinary retention in patients with poor detrusor contractility. Therefore, before prescribing an anticholinergic agent, a PVR urine volume should be measured and should be 150 mL or less[14,67]

Mirabegron

Approximately 95% of the β-adrenergic receptors in the urinary bladder are of the β_3 subtype. When stimulated, β_3-adrenergic receptors increase production of cyclic adenosine monophosphate (cAMP), which relaxes the detrusor muscle.[68]

9 Mirabegron is a β_3-adrenergic agonist. As a result of relaxing the detrusor muscle during the storage phase of the micturition cycle, mirabegron reduces irritative voiding symptoms, increases urinary bladder capacity, and increases the interval between voidings. Mirabegron does not inhibit voiding or reduce urinary flow rate, nor does it increase PVR urine volume or cause acute urinary retention.[8,69,70] The clinical effect of mirabegron for LUTS is similar to that of anticholinergic agents, but mirabegron is better tolerated.[8,70] Mirabegron does not produce anticholinergic adverse effects, nor does it cause acute urinary retention.

Mirabegron is indicated for symptomatic management of overactive bladder syndrome. Its symptoms overlap with the irritative component of LUTS. For this reason, mirabegron is used as an alternative to anticholinergic agents in patients with LUTS, when irritative symptoms persist despite treatment with an α_1-adrenergic antagonist or 5α-reductase inhibitors.[8] The usual starting dose of mirabegron is 25

mg daily, increasing to 50 mg daily if needed. A usual daily dose of 25 mg daily is recommended for patients with impaired renal function (creatinine clearance of 15-20 mL/min [0.25-0.33 mL/s]) or mild hepatic impairment. Mirabegron should not be used in patients with moderate to severe hepatic dysfunction or a creatinine clearance less than 15 mL/min (0.25 mL/s). Adverse effects include increased blood pressure, headache, dry mouth, constipation, and nasopharyngitis.

Combination Drug Therapy

Many drug combinations have been used for BPH. With an α_1-adrenergic antagonist as initial therapy, medications are often added when the patient's symptoms are still bothersome. For example, α_1-adrenergic antagonists seem to be more effective in reducing obstructive voiding symptoms than irritative symptoms. To reduce irritative symptoms, an anticholinergic agent[71,72] mirabegron, or a phosphodiesterase type 5 inhibitor[59] may be added. Similarly, a 5α-reductase inhibitors has a slow onset of action. To achieve faster symptom relief, an α_1-adrenergic antagonist, mirabegron,[70] or a phosphodiesterase inhibitor[73] has been added on. These combinations do not reduce the need for prostate surgery or reduce the risk of disease progression. When such combinations are used, the benefit of reducing bothersome symptoms must be balanced by the increased risk of adverse effects and drug interactions and the higher cost of treatment.

However, the combination of an α_1-adrenergic antagonist and a 5α-reductase inhibitor is ideal for patients with both severe symptoms and an enlarged prostate gland of at least 40 g and PSA of at least 1.4 ng/mL (µg/L), a surrogate marker for an enlarged prostate gland.[11,14] Such patients appear to be at high risk for disease progression, as evidenced by symptom worsening and development of disease complications, including acute urinary retention, recurrent urinary tract infection, or need for surgical intervention.[11]

In the landmark Multiple Treatment of Prostate Symptoms Study (MTOPS), a regimen of finasteride and doxazosin for 5 years was shown to prevent symptom progression by 66%, decrease the risk of developing acute urinary retention by 81%, and decrease the need for prostate surgery by 67%. Moreover, urinary symptom improvement and higher urinary flow rates at 15 to 18 months were observed in patients treated with combination therapy, as compared with monotherapy with finasteride alone or doxazosin alone.[11] In another key clinical trial, the Combination of Avodart and Tamsulosin (COMBAT) study, dutasteride versus tamsulosin versus a combination of dutasteride and tamsulosin were evaluated in patients with large prostate glands and a mean PSA of 4 ng/mL (µg/L). The combination regimen was more effective in reducing symptoms 9 months after the start of treatment than dutasteride alone or tamsulosin alone. Whether the combination of dutasteride and tamsulosin prevents disease progression after 4 years awaits long-term study results, although preliminary subgroup analysis has shown that combination therapy reduces the percentage of patients who develop disease progression.[74,75]

Although not proven by direct comparison trials, any combination of 5α-reductase inhibitor and α_1-adrenergic antagonist probably is similarly effective for patients with the aforementioned characteristics.[76] The disadvantages of a combination regimen include increased medication cost to

the patient and an increased incidence of adverse drug effects (ie, 18%-27% of patients discontinued treatment because of hypotension).

Clinical Controversy...

The combination of an α_1-adrenergic antagonist and 5α-reductase inhibitor can relieve LUTS, slow progression of BPH, and reduce the need for prostate surgery for patients with moderate to severe symptoms and a prostate of 40 g or larger. It may be possible to discontinue the α_1-adrenergic antagonist after 6 to 9 months; however, this potentially cost-saving measure requires further clinical study. A preliminary clinical trial showed BPH disease progression when either drug was discontinued after 2 years of continuous use.[77,78]

Surgical Intervention

10 The gold standard for treatment of patients with complications of BPH is prostatectomy performed either transurethrally or as an open surgical procedure.[14,15] Surgical intervention is also used for patients with moderate to severe symptoms, who are not responsive to drug therapy, who are noncompliant with drug therapy, or who prefer surgical intervention. Surgical intervention is always indicated for patients with complications of BPH, including acute urinary retention not responsive to drug treatment, chronic urinary retention associated with decreased renal function or overflow urinary incontinence, urolithiasis, or recurrent hematuria.[79] Surgical removal of the prostatic adenoma offers the highest rate of symptom improvement, but it also has the highest complication rate.

With TURP, an endoscopic resectoscope inserted through the urethra is used to remove the inside core of the prostatic adenoma. This enlarges the opening at the bladder neck and prostatic urethra. Often performed as outpatient surgery, this procedure produces on average a peak urinary flow rate increase of 125%, improves the AUA Symptom Score by 10 to 18 points, and improves voiding symptoms by almost 90% in approximately 90% of patients.[6] A common complication of TURP is retrograde ejaculation, occurring in up to 75% of patients. Bleeding, urinary incontinence, and erectile dysfunction occur in smaller, but significant numbers of patients (2%-15%).[79] Approximately 2% to 10% and 12% to 15% of patients require second surgeries within 5 and 8 years, respectively.[79]

Alternatively, an open surgical procedure (open prostatectomy) can be performed retropubically or suprapubically. This procedure is usually reserved for men with prostate glands larger than 80 mL. This necessitates hospitalization for at least a few days, anesthesia, and a longer recuperation time. Adverse effects of open prostatectomy include bleeding, urinary and soft-tissue infection, retrograde ejaculation in 77% of patients, erectile dysfunction in 16% to 33% of patients, and urinary incontinence in 2% of patients. The reoperation rate is 3% to 5% at 10 years.[14]

Transurethral incision of the prostate (TUIP) is an alternative surgical procedure for patients with moderate to severe voiding symptoms who have an enlarged prostate gland less than 30 g in size. In the short term TUIP is as effective as TURP but requires less operation time, causes less blood loss, and produces fewer adverse effects.[14] TUIP involves using an endoscopic resectoscope to make one

or two incisions at the bladder neck to widen the opening. In limited long-term studies, the reoperation rate for TUIP is slightly higher than with TURP.

Minimally invasive surgical procedures are highly desirable by patients. The procedures do not require hospitalization, are associated with less blood loss, have a lower potential to produce adverse effects, are less expensive than continuous drug therapy regimens lasting years, and may be particularly useful for debilitated patients with moderate to severe voiding symptoms and smaller-sized prostate glands, or for patients who are taking anticoagulants. These procedures typically use heat energy from microwaves, water, or laser (holmium, potassium titanyl phosphate, or thulium) to destroy prostate tissue.[14,15] Commonly used procedures include transurethral needle ablation of the prostate, green light laser ablation, and transurethral microwave thermotherapy of the prostate.[80,81,82] A disadvantage of all minimally invasive surgical procedures is the high percentage of patients who may develop acute urinary retention in the immediate postoperative period. In addition, patients who undergo minimally invasive procedures generally experience smaller improvements in voiding symptoms and urinary flow rates, and are more likely to require reoperation after an initial improvement in symptoms than patients who undergo TURP or open prostatectomy.[80,81,82]

Phytotherapy

Although phytotherapy is widely used in Europe for the management of BPH, the published data on herbal agents are largely inconclusive and conflicting. Studies often lack placebo controls, which are essential for assessing treatments for BPH because spontaneous regression of mild symptoms can occur. Furthermore, because these agents are marketed under the Dietary Supplements Health and Education Act, their efficacy, safety, and quality are not regulated by the FDA. For these reasons, herbal products—including saw palmetto berry (*Serenoa repens*), stinging nettle (*Urtica dioica*), South African star grass (*Hypoxis rooperi*), pumpkin seed (*Cucurbita pepo*), and African plum (*Pygeum africanum*)—are not recommended for treatment of BPH.[14] Excellent reviews on phytotherapy for BPH have been published.[83,84]

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcome of BPH therapy is improvement of voiding symptoms with minimal treatment-related adverse effects. As a disease for which therapy is directed at the voiding symptoms that the patient finds most bothersome, assessment of outcomes depends on the patient's perceptions of the effectiveness of therapy. Use of a validated, standardized instrument, such as the AUA Symptom Score, for assessing patient's voiding symptoms is important in this process.[14]

For patients being considered for surgical treatment, objective measures of bladder emptying are useful and include the urinary flow rate and PVR urine volume (see "Diagnostic Evaluation").

Because this patient population is at high risk for prostate cancer, PSA should be measured and a digital rectal examination performed annually if the patient has a life expectancy of at least 10 years. For patients taking 5α-reductase inhibitors, a second PSA taken after 6 months of treatment should

be compared with baseline measurements. If the patient is suspected of having developed renal impairment as a consequence of long-standing bladder outlet obstruction, then BUN and serum creatinine should be evaluated at regular intervals.

SUMMARY

A ubiquitous disease of aging men, symptomatic BPH requires medical attention to preserve the patient's quality of life and to prevent disease complications, many of which can be life-threatening in this patient population. In men who have no or mildly bothersome symptoms, watchful waiting and behavior modification are the best treatment approach, as BPH remains stable or even regresses in approximately half of these men.

For patients with voiding symptoms that are moderate to severely bothersome, pharmacotherapy is indicated. An α_1-adrenergic antagonist is the agent of first choice. Second-generation agents include terazosin, doxazosin, and alfuzosin, and third-generation agents include tamsulosin and silodosin. Immediate-release formulations of terazosin and doxazosin cause more cardiovascular adverse effects than do extended-release formulations (eg, doxazosin or alfuzosin), or uroselective α_{1A}-adrenergic agents (eg, tamsulosin, silodosin, or alfuzosin). 5α-Reductase inhibitors are preferred drug treatment for patients with enlarged prostates who poorly tolerate the hypotensive adverse effects of α_1-adrenergic antagonists. However, 5α-reductase inhibitors have a slow onset of action. For patients who do not respond to monotherapy, combination drug therapy could be attempted. Such regimens have been found to be most effective for patients with enlarged prostates greater than 40 g. Alternatively, surgery is an option.

For patients with both moderate to severe BPH and erectile dysfunction, a phosphodiesterase inhibitor alone or combined with an α-adrenergic antagonist may be prescribed. For patients with moderate to severe BPH with a predominance of irritative voiding symptoms, an anticholinergic agent, mirabegron, or a phosphodiesterase inhibitor may be added to an existing drug treatment regimen for BPH. Before starting an anticholinergic agent in a patient with BPH, the patient's PVR should be documented at less than 150 mL.

For patients who have complications of BPH, surgery is required. Although it has more adverse complications than does pharmacotherapy or watchful waiting, TURP is considered the gold standard.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ALLHAT	Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial
AUA	American Urological Association
BPE	benign prostatic enlargement
BPO	benign prostatic obstruction
BPH	benign prostatic hyperplasia

BUN	blood urea nitrogen
cAMP	cyclic adenosine monophosphate
cGMP	cyclic guanosine monophosphate
COMBAT	Combination of Avodart and Tamsulosin (Study)
CYP	cytochrome P-450
DHT	dihydrotestosterone
GI	gastrointestinal
IPSS	International Prostate Symptom Score
LUTS	lower urinary tract symptoms
MTOPS	Multiple Treatment of Prostate Symptoms (Study)
PSA	prostate-specific antigen
PVR	postvoid residual (pertains to urine volume)
REDUCE	Reduction by Dutasteride in Prostate Cancer Events
TURP	transurethral resection of the prostate
TUIP	transurethral incision of the prostate

Chapter 85: Urinary Incontinence

Eric S. Rovner; Jean Wyman; Sum Lam

INTRODUCTION

KEY CONCEPTS

- 1 In evaluating urinary incontinence (UI), drug-induced or drug-aggravated etiologies must be ruled out.
- 2 Accurate diagnosis and classification of UI type are critical to the selection of appropriate pharmacotherapy.
- 3 Goals of treatment for UI are reduction of symptoms, minimization of adverse effects, and improvement in quality of life.
- 4 Nonpharmacologic, nonsurgical treatment is the first-line treatment for several types of UI, and should be continued even when drug therapy is initiated.
- 5 Antimuscarinic agents are second-line treatments for urge incontinence. Choice of agent should be based on patient characteristics (eg, age, comorbidities, concurrent medications, and ability to adhere to the prescribed regimen).
- 6 Mirabegron, a β_3-adrenergic agonist, is another second-line treatment for urge incontinence, and can be considered in patients who failed to achieve optimal efficacy or cannot tolerate adverse effects of antimuscarinic agents.
- 7 Duloxetine (approved in Europe only), α-adrenergic receptor agonists, and topical (vaginal) estrogens (alone or together) are the drugs of choice for urethral underactivity (stress incontinence).
- 8 Assessment of patient outcomes should include efficacy, adverse effects, adherence, and quality of life.
- 9 Management of UI should target individualized goals, which may change over time. If

therapeutic goals are not achieved with a given agent at optimal dosage for an adequate duration of trial, consider switching to an alternative agent.

Urinary incontinence (UI) is defined as involuntary leakage of urine.[1] It is frequently accompanied by other bothersome lower urinary tract symptoms, such as urgency, increased daytime frequency, and nocturia. It is among the most common medical condition occurring in humans and yet it is an underdetected and underreported health problem that can significantly affect quality of life. Patients with UI may have depression as a result of the perceived lack of self-control, loss of independence, and lack of self-esteem, and they often curtail their activities for fear of an "accident." UI may also have serious medical and economic ramifications for untreated or undertreated patients, including perineal dermatitis, worsening of pressure ulcers, urinary tract infections, and falls.

This chapter highlights the epidemiology, etiology, pathophysiology, treatment of stress, urge, mixed, and overflow UI in men and women.

EPIDEMIOLOGY

UI is highly prevalent, and the impact of this condition is substantial, crossing all racial, ethnic, and geographic boundaries. In addition, lower urinary tract symptoms (eg, urgency, urinary frequency, and nocturia) associated with overactive bladder (OAB) are also quite debilitating.[2] Several studies have objectively shown that UI is associated with reduced levels of social and personal activities, increased psychological distress, and overall decreased quality of life as measured by numerous indices.[3] The condition can affect people of all age groups, but the peak incidence of UI, at least in women, appears to occur around the age of menopause, with a slight decrease in the age group 55 to 60 years, and then a steadily increasing prevalence after age 65 years.

Determining the true prevalence of UI is difficult because of problems with definition, reporting bias, and other methodological issues. The Medical, Epidemiologic, and Social Aspects of Aging survey found that the prevalence of UI in noninstitutionalized women at age 60 years and older was approximately 38%. Almost one-third of those surveyed noted urine loss at least once weekly, and 16% noted UI daily. A publication from a National Institutes of Health working group conference estimated the median level of UI prevalence to be approximately 20% to 30% during young adult life, with a broad peak around middle age (30%-40% prevalence) and an increase in the elderly (30%-50% prevalence).[4]

In the United States, chronic UI is one of the most common reasons cited for institutionalization of the elderly, and the condition is frequently encountered in the nursing home setting. Little is known about the basic differences in clinical and epidemiologic characteristics of incontinence across racial or ethnic groups. Some studies report a higher incidence of UI overall in white populations as compared with African Americans, but differences in access to healthcare as well as cultural attitudes and mores may contribute to these differences.[5,6]

Consistent across all studies of unselected, noninstitutionalized populations is that UI is at least half as common in men as in women.[7] Overall, the prevalence of UI in men has been estimated to be

approximately 9%.[8] The prevalence of UI in men increases steadily with age across most studies, with the highest prevalence recorded in the oldest patient cohorts.[9]

ETIOLOGY AND PATHOPHYSIOLOGY

Anatomy

The lower urinary tract consists of the bladder, urethra, urinary or urethral sphincter, and surrounding musculofascial structures, including connective tissue, nerves, and blood vessels. The urinary bladder is a hollow organ composed of smooth muscle and connective tissue located deep in the bony pelvis in men and women. The urethra is a hollow tube that acts as a conduit for urine flow out of the bladder. An epithelial cell layer termed the *urothelium,* which is in constant contact with urine, lines the interior surface of both the bladder and the urethra. Previously considered inert and inactive, the urothelium may play an active role in the pathophysiology of many lower urinary tract disorders, including interstitial cystitis/bladder pain syndrome and UI[8] and may be a targeted location for future pharmacologic therapeutic interventions for some types of lower urinary tract dysfunction.[10] The urinary or urethral sphincter is a combination of smooth and striated muscle within and surrounding the proximal portion of the urethra adjacent to the bladder. In the male, the prostate gland lies just beyond the bladder outlet and is intimately associated with the urethral sphincter. Its location accounts for both the favorable effects of pharmacological manipulation on male lower symptoms as well as the risk of UI in males following some types of prostate surgery.

To understand the principles of pharmacotherapy for UI, an understanding of the neuroanatomy and neurophysiology of the bladder and urethra is needed. The primary motor (efferent) input to the detrusor muscle of the bladder is parasympathetic and travels along the pelvic nerves emanating from spinal cord segments S2 to S4. Acetylcholine appears to be the primary neurotransmitter at the neuromuscular junction in the human lower urinary tract. Both volitional and involuntary detrusor contractions are mediated by activation of postsynaptic muscarinic receptors by acetylcholine. Of the five known subtypes of muscarinic receptors, the majority of bladder smooth muscle cholinergic receptors are of the M_2 variety. In humans, the ratio of M_2/M_3 receptor numbers is approximately 3:1. However, M_3 receptors are the subtype responsible for both emptying contractions of normal micturition as well as involuntary bladder contractions that may result in UI.[8] Thus, most pharmacologic antimuscarinic therapy is primarily anti-M_3 based. Administration of such agents results in detrusor smooth muscle relaxation and a reduction of bladder overactivity.

Beta-3-adrenergic receptors are found in the lower urinary tract at the level of the detrusor muscle and the urothelium.[8] Although found elsewhere, stimulation of these receptors in the detrusor results in smooth muscle relaxation. Clinically, administration of β_3-agonists is associated with attenuation of bladder contractility and, similarly to antimuscarinics, is used clinically to treat overactive bladder and related urge incontinence. β-Receptors are also located on the urethra but their clinical significance is considered to be negligible.

Clinically relevant a-adrenergic receptors are located at the level of the bladder outlet on the smooth

and striated muscle of the urethra.[8] Stimulation of these receptors with α-adrenergic agonists results in increased urethral closure pressure. Such effects are usually not pronounced enough to treat stress urinary incontinence; however, use of these agents may result in unwanted adverse effects such as aggravation of bladder outlet obstruction and result in poor bladder emptying (urinary retention).

Other potentially relevant motor and sensory pathways, neurotransmitters, and receptors have been identified in the lower urinary tract (eg, transient receptor potential channels, E-series prostaglandin receptors). However, the exact role of such targets, as well as ways of modulating their activity pharmacologically in humans has yet to be elucidated and further discussion is beyond the scope of this chapter.

Urinary Continence

To prevent incontinence during the bladder filling and storage phase of the micturition cycle, the urethra, or more accurately the urethral sphincter, must maintain adequate closure in order to resist the flow of urine from the bladder at all times until voluntary voiding is initiated. Urethral closure or resistance to flow is maintained to a large degree by the proximal (under involuntary control) and distal (under both voluntary and involuntary control) urinary sphincters. Variable contributions to urethral closure may also come from the urethral mucosa, submucosal spongy tissue, and the overall length of the urethra. During bladder filling and urinary storage, the bladder accommodates to increasing volumes of urine flowing in from the upper urinary tract without a significant increase in bladder (intravesical) pressure. The maintenance of a low intravesical pressure despite increasing volumes of urine is a unique property of the bladder and is termed *compliance*. In addition, bladder or detrusor smooth muscle activity is normally suppressed during the filling phase by centrally mediated neural reflexes. Normal bladder emptying occurs with opening of the urethral sphincters concomitant with a volitional bladder contraction. Bladder contraction occurs in a coordinated fashion, resulting in a rise in intravesical pressure. The rise in intravesical pressure is ideally of adequate magnitude and duration to empty the bladder to completion. Opening and funneling of the bladder outlet results in urine flow into the urethra until the bladder is emptied to near completion.

The bladder and urethra normally operate in unison during the bladder filling and storage phase, as well as the bladder emptying phase of the micturition cycle. The smooth and striated muscles of the bladder and urethra are organized during the micturition cycle by a number of reflexes coordinated at the pontine micturition center in the midbrain. Disturbances in the neural regulation of micturition at any level (brain, spinal cord, or pelvic nerves) often lead to characteristic changes in lower urinary tract function that may result in UI.[11,12]

Mechanisms of Urinary Incontinence

Simply stated, UI may occur as a result of abnormalities of only the urethra (including the bladder outlet and urinary sphincter) or only the bladder or as a combination of abnormalities in both. Abnormalities may result in either overactivity or underactivity of the bladder and/or urethra, with resulting development of UI. Although this simple classification scheme excludes extremely rare

causes of UI such as congenital ectopic ureters and urinary fistulas, it is useful for gaining a working understanding of the condition and understanding the basis for therapeutic intervention including pharmacotherapy of various lower urinary tract disorders.

Urethral Underactivity (Stress Urinary Incontinence)

This type of incontinence is characterized by brief bursts of UI concomitant with exertional activities such as exercise, running, lifting, coughing, and sneezing. The pathophysiology of *stress urinary incontinence* (SUI) is related to decreased or inadequate urethral closure forces. In individuals with SUI, the muscular tissues surrounding the urethra that form the urethral sphincter are compromised and thus not able to resist the expulsive forces resulting from transient increases in intra-abdominal pressure during physical activity. Such forces are transmitted to the bladder (an intra-abdominal organ), compressing it to such an extent as to cause the egress of urine through the urethra. SUI is characterized by episodic, usually low volume urinary leakage but is clearly proportional to the amount of physical exertion or other increases in abdominal pressure such as that related to coughing and sneezing as well as the ambient urethral closure forces.

Risk factors for SUI in the woman include pregnancy, childbirth, menopause, cognitive impairment, obesity, and aging.[13,14] In men, SUI is most commonly the result of prior lower urinary tract surgery and injury to the sphincter mechanism within and external to the urethra. Radical prostatectomy for treatment of adenocarcinoma of the prostate and transurethral resection of the prostate (TURP) are probably the most common proximate causes of SUI in the man. Notably, compared with its prevalence in women, SUI in men is actually quite rare.

SUI may be caused or aggravated by some pharmacologic agents such as α-antagonists and angiotensin-converting enzyme (ACE) inhibitors.[15] α-Antagonists may relax the smooth muscle at the level of the urethral sphincter, resulting in a weakened closure mechanism and the onset of SUI. Alternatively, some α-agonists, such as those used clinically for nasal congestion or weight loss, may improve SUI in some individuals, and may even potentially aggravate some types of voiding problems such as those related to bladder outlet obstruction from an enlarged prostate. An adverse effect of some ACE inhibitors is chronic cough, which can also aggravate existing SUI.

Bladder Overactivity (Urge Urinary Incontinence)

Urge incontinence is defined as the leakage of urine associated with urgency, a compelling desire to void.[1] This is most often related to detrusor (bladder) overactivity due to involuntary bladder contractions. Bladder overactivity describes the condition in which the detrusor muscle contracts inappropriately during urinary storage that, in the neurologically normal individual, results in a sense of urinary urgency. The terms *overactive bladder* and *detrusor (bladder) overactivity* are distinct and should not be used interchangeably.

The International Continence Society defines OAB as a symptom syndrome characterized by urinary urgency, with frequency and nocturia, with/without associated UI in the absence of a known pathologic condition that may result in similar symptoms (eg, urinary tract infection, bladder cancer).[8]

Frequency is defined as micturition more than eight times per day. *Urgency* is described as a sudden compelling desire to urinate that is difficult to delay.[1] People suffering from OAB typically have to empty their bladder frequently, and, when they experience a sensation of urgency, they may leak urine if they are unable to reach the toilet quickly. Many patients have associated nocturia (>1 micturition per night) and/or nocturnal incontinence (enuresis). Patients with urge urinary incontinence (UUI) often, but invariably experience high-volume urine leakage when it occurs. Although detrusor overactivity may be related to OAB, the former diagnosis requires urodynamic testing while the latter is symptomatically defined.

Most patients with OAB and UUI have no identifiable underlying etiology and thus are classified as "idiopathic." Patients with a relevant neurologic condition and with UI related to involuntary bladder contractions demonstrated on urodynamic testing are classified as having neurogenic detrusor overactivity. Clearly identifiable risk factors for UUI include normal aging, neurologic disease (including stroke, Parkinson disease, multiple sclerosis, and spinal cord injury), and bladder outlet obstruction (eg, due to benign prostatic hyperplasia [BPH] or prostate cancer).

The pathophysiology of OAB and UUI is not well understood but is likely related to either neurogenic or myogenic factors or combination of both.[16] A full discussion of these differences is complex and beyond the scope of this chapter. However, in practice, although the cause of UUI is difficult to define, the treatment is identical regardless of etiology and pathophysiology.

Some pharmacologic agents may cause or aggravate UUI. Diuretics will cause the rapid accumulation of urine in the bladder with resulting urinary urgency and frequency that can result in UUI. Alcohol will have similar effects. Anticholinesterase inhibitors may also produce urgency and frequency.

Urethral Overactivity and/or Bladder Underactivity (Overflow Incontinence)

Overflow incontinence is urinary leakage resulting from an overfilled and distended bladder that is unable to empty. This type of UI occurs when the bladder is filled to capacity at all times but is unable to empty, causing urine to leak from a distended bladder past a normal or even overactive sphincter. Another term related to overflow incontinence is *chronic urinary retention*.[16]

Overflow incontinence is the result of urethral overactivity, bladder underactivity, or a variable combination of both. Clinically and practically, the most common causes of urethral overactivity in men are anatomic urethral obstruction, including that due to BPH and prostate cancer. In women, urethral overactivity is rare but may result from cystocele formation (with resultant kinking or obstruction of the urethra) or surgical overcorrection following surgery for the repair of SUI (iatrogenic obstruction). In both men and women, overflow UI may be associated with systemic neurologic dysfunction or diseases, such as spinal cord injury or multiple sclerosis.

Bladder underactivity occurs as a result of the detrusor muscle of the bladder becoming progressively weakened and eventually losing the ability to voluntarily contract and expel urine during voiding. In the absence of adequate contractility, the bladder is unable to empty completely, and large volumes of residual urine are left after voiding. Both myogenic and neurogenic factors have been implicated in producing the impaired contractility seen in this condition. Clinically, overflow incontinence is most

commonly seen in the setting of long-term chronic bladder outlet obstruction in men, such as that due to BPH or prostate cancer, diabetes mellitus, or denervation due to radical pelvic surgery, such as abdominopelvic resection or radical hysterectomy.

There are numerous pharmacologic agents that can result in urinary retention and overflow incontinence. Agents that increase urethral resistance or closure pressure include α-agonists and tricyclic antidepressants. Over-the-counter cold and cough remedies as well as diet pills may contain agents with α-adrenergic properties and/or antihistaminic properties that can result in voiding dysfunction and urinary retentions. Agents that can decrease bladder contractility include anticholinergics, tricyclic antidepressants, calcium channel blockers, narcotic analgesics, and antipsychotics.

Mixed Incontinence and Other Types of Urinary Incontinence

Various types of UI may coexist in the same patient. The combination of bladder overactivity resulting in urinary incontinence (UUI or urinary urge incontinence) and urethral underactivity resulting in urinary incontinence (SUI or stress urinary incontinence) is termed *mixed incontinence*. The diagnosis is often difficult because of the confusing array of presenting symptoms. Bladder overactivity may also coexist with impaired bladder contractility. This occurs most commonly in the elderly and is termed *detrusor hyperactivity with impaired contractility*.[17]

Functional incontinence is not caused by bladder- or urethra-specific factors. Rather, in patients with conditions such as dementia or cognitive or mobility deficits, the UI is linked to the primary disease process more than any extrinsic or intrinsic deficit of the lower urinary tract. An example of functional incontinence occurs in the postoperative orthopedic surgery patient. Following extensive orthopedic reconstructions such as total hip arthroplasty, patients are often immobile secondary to pain or traction. Therefore, patients may be unable to access toileting facilities in a reasonable amount of time and may become incontinent as a result. Treatment of this type of UI may involve simple interventions such as placing a urinal or commode at the bedside that allows for uncomplicated access to toileting. Pharmacologically, functional incontinence can be induced by sedative-hypnotics, narcotic analgesics, and other medications with cognitive adverse effects.

Many localized or systemic illnesses may result in UI because of their effects on the lower urinary tract or the surrounding structures:

1. Dementia/delirium
2. Depression
3. Urinary tract infection (cystitis)
4. Postmenopausal atrophic urethritis or vaginitis
5. Diabetes mellitus
6. Neurologic disease (eg, stroke, Parkinson disease, multiple sclerosis, spinal cord injury)

7. Pelvic malignancy

8. Constipation

9. Congenital malformations of the urinary tract

1 As noted above, many commonly used medications may precipitate or aggravate existing voiding dysfunction and UI (**Table 85-1**).[18]

TABLE 85-1 Medications That Influence Lower Urinary Tract Function

Medication	Effect
Diuretics, acetylcholinesterase inhibitors	Polyuria resulting in urinary frequency, urgency
α-Receptor antagonists	Urethral muscle relaxation and stress urinary incontinence
α-Receptor agonists	Urethral muscle contraction (increased urethral closure forces) resulting in urinary retention (more common in men)
Calcium channel blockers	Urinary retention due to reduced bladder contractility
Narcotic analgesics	Urinary retention due to reduced bladder contractility
Sedative hypnotics	Functional incontinence caused by delirium, immobility
Antipsychotic agents	Anticholinergic effects resulting in reduced bladder contractility and urinary retention
Anticholinergics	Urinary retention due to reduced bladder contractility
Antidepressants, tricyclic	Anticholinergic effects resulting in reduced bladder contractility, and α-antagonist effects resulting in urethral smooth muscle contraction (increased urethral closure forces) both contributing to urinary retention
Alcohol	Polyuria resulting in urinary frequency, urgency
ACEIs	Cough as a result of ACEIs may aggravate stress urinary incontinence

ACEIs, angiotensin-converting enzyme inhibitors.

Generally, SUI is considered the most common type of UI and probably accounts for at least a portion of UI in more than half of all incontinent women. Some studies have found that mixed UI (SUI plus UUI) is the most common type of UI. However, the proportions of SUI, UUI, and mixed UI vary considerably with age group and gender of patients studied, study methodology, and a variety of other factors.

CLINICAL PRESENTATION

2 UI may present in a number of ways, depending on the underlying pathophysiology. A complete medical and medication history, including an assessment of symptoms and a physical examination, is essential for correctly classifying the type of incontinence and thereby assuring appropriate therapy.

CLINICAL PRESENTATION Urinary Incontinence Related to Urethral Underactivity (SUI) General

- The patient usually notes UI during activities such as exercise, running, lifting, coughing, and sneezing. Occurs much more commonly in women (generally seen only in men with prior lower urinary tract surgery, neurologic disease, or other injury compromising the sphincter).

Symptoms

- Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (minimal or no nocturia). May develop urgency and frequency as a compensatory mechanism (or as a separate component of bladder overactivity).

Diagnostic Tests

- Observation of urethral meatus while patient coughs or strains.

Urine Leakage

UI represents a spectrum of severity in terms of both volume of leakage and degree of bother to the patient. It is important to carefully consider the level of patient discomfort and bother when discussing urine leakage as each individual may or may not desire therapy. A careful and complete history during the patient interview is essential to accurately determine the precise nature of the problem. The onset, nature, timing, and volume of incontinence are recorded as is the use of pads. Use of absorbent products, such as panty liners, pads, or briefs, is an important point of discussion, but the clinician must keep in mind that use of these products varies among patients. The number and type of pads may not relate to the amount or type of incontinence, as their use is a function of personal preference and hygiene. A high number of absorbent pads may be used every day by a patient with severe, high-volume UI or, alternatively, by a fastidiously hygienic patient with low-volume leakage who simply changes pads often to prevent wetness or odor. Nevertheless, a large number of pads that are described by the patient as “soaked” is indicative of high-volume urine loss.

Regardless of the volume of urine loss, the desire to seek evaluation for UI in the majority of patients is most commonly elective and therapy is often contingent on the degree of bother to the individual patient. As with the use of absorbent products, patients differ with regard to the amount of urine loss they will tolerate before considering the condition bothersome enough to seek assistance. However, it is critically important that in some individuals new-onset UI may be the first manifestation of an undiagnosed illness (eg, diabetes, multiple sclerosis), or may occur as a result of treatment or drug therapy of an unrelated condition. It is these individuals who mandate a full evaluation and treatment.

Symptoms

Under the best of circumstances, UI is difficult to categorize based on symptoms alone (**Table 85-2**).[19] In a study of patients who appeared to have SUI based on symptoms and patient history,

urodynamics showed that only 72% of patients had SUI as the sole cause of incontinence.[20]

CLINICAL PRESENTATION Urinary Incontinence Related to Bladder Overactivity (UUI) General

- Can have bladder overactivity and UI without urgency if sensory input from the lower urinary tract is absent.

Symptoms

- Urinary frequency (>8 micturitions per day), urgency with or without UI; nocturia (≥1 micturition per night) and enuresis may be present.

Diagnostic Tests

- Urodynamic studies are the gold standard for diagnosis for the diagnosis of detrusor overactivity. Urinalysis and urine culture should be negative (rule out urinary tract infection as the cause of frequency).

TABLE 85-2 Differentiating Bladder Overactivity-Related UI (Urge Urinary Incontinence) from Urethral Underactivity Related UI (Stress Urinary Incontinence)

Symptoms	Bladder Overactivity (UUI)	Urethral Underactivity (SUI)
Urgency (strong, sudden desire to void)	Yes	Not common
Frequency with urgency	Yes	Rarely
Leaking during physical activity (eg, coughing, sneezing, lifting)	No	Yes
Amount of urinary leakage with each episode of incontinence	Large if present	Usually small
Ability to reach the toilet in time following an urge to void	No or just barely	Yes
Nocturnal incontinence (presence of wet pads or undergarments in bed)	Yes	Rare
Nocturia (waking to pass urine at night)	Usually	Seldom

Patients with SUI characteristically complain of urinary leakage with physical activity. Volume of leakage is proportional to the level of activity. They will often leak urine during periods of exercise, coughing, sneezing, lifting, or even when rising from a seated to a standing position. Patients with pure SUI will not have leakage when physically inactive, especially when they are supine. Often they will have little or no UI at night, will not awaken to void during the night (nocturia), will not wet the bed, and often do not even wear absorbent products during the night. Urinary urgency and frequency may be associated with SUI, either as a separate component caused by bladder overactivity (mixed incontinence) or as a compensatory mechanism wherein the patient with SUI learns to toilet frequently to prevent large-volume urine loss during physical activity.

CLINICAL PRESENTATION Overflow Incontinence (Chronic Urinary Retention) General

- Important but uncommon type of UI in both men and women. Urethral overactivity is usually due to prostatic enlargement (men) or cystocele formation or surgical overcorrection following stress incontinence surgery in women. Bladder underactivity resulting in overflow incontinence can result from many causes including neurogenic disease, diabetes, and postoperatively from pelvic surgery (eg, radical hysterectomy).

Symptoms

- Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency. Abdominal pain if acute urinary retention is present.

Signs

- Increased postvoid residual urine volume.

Diagnostic Tests

- Assessment of postvoid residual urine either by imaging (ultrasound, etc) or catheterization. Renal function tests to rule out renal failure due to chronic urinary retention.

Typical symptoms of UUI and bladder overactivity include frequency, urgency, and high-volume incontinence. Nocturia and nocturnal incontinence are often present. Urine leakage is unpredictable, and the volume loss may be quite large. Patients often wear protection both day and night. Urinary frequency can be affected by a number of factors unrelated to bladder overactivity, including excessive fluid intake (polydipsia) and bladder hypersensitivity states such as interstitial cystitis and urinary tract infection. In some patients, bladder overactivity manifests as UI without awareness in the absence of a sense of urinary urgency or frequency. *Urinary urgency*, a sensation of impending micturition, requires intact sensory input from the lower urinary tract. In patients with spinal cord injury, sensory neuropathies, and other neurologic diseases, a diminished ability to perceive or process sensory input from the lower urinary tract may result in bladder overactivity and UI without urgency or urinary frequency. When bladder contraction occurs without warning and sensation is absent, the condition is referred to as *reflex incontinence*.

Patients with overflow incontinence may present with lower abdominal fullness as well as considerable obstructive urinary symptoms, including hesitancy, straining to void, decreased force of urinary stream, interrupted stream, and a vague sense of incomplete bladder emptying. These patients may also have a significant component of urinary frequency and urgency. In patients with acute urinary retention and overflow incontinence, lower abdominal pain may be present. Although these symptoms are not specific for overflow incontinence, they may warrant further investigation, including an assessment of postvoid residual urine volume.

Signs

A presenting complaint of UI mandates a directed physical examination and a brief neurologic assessment. The workup ideally includes an abdominal examination to exclude a distended bladder,

neurologic assessment of the perineum and lower extremities, pelvic examination in women (looking especially for evidence of prolapse or hormonal deficiency), and genital and prostate examination in men. Perineal skin maceration, erythema, breakdown, and ulceration may be indicative of chronic, severe UI. Patients with chronic incontinence may also manifest fungal infections of the skin of the perineum and upper thighs.

SUI can usually be objectively demonstrated by having the patient cough or strain during the examination and observing the urethral meatus for a sudden spurt of urine. In women, SUI may be associated with varying degrees of vaginal prolapse, including cystourethrocele (bladder and urethral prolapse).

In both men and women, digital rectal examination provides an opportunity to check ambient rectal tone and the integrity of the sacral reflex arc (eg, anal wink) as well as assess the patient's ability to perform a voluntary pelvic floor muscle contraction (ie, Kegel exercise), which may be an important factor in deciding on appropriate therapy. In men, a digital examination of the prostate assesses for the presence of prostate cancer, inflammation, and BPH.

A targeted neurologic examination includes assessment of reflexes, rectal tone, and sensory or motor deficits in the lower extremities, which might be indicative of systemic or localized neurologic disease. Neurologic diseases have the potential to affect bladder and sphincter function and thus may have significant implications in the incontinent patient.

Prior Medical or Surgical Illness

UI may present in the setting of concurrent, seemingly unrelated illnesses. New-onset UI may be the initial manifestation of systemic illnesses such as diabetes mellitus, metastatic malignancies, and neurologic diseases such as Parkinson disease, brain tumors, and multiple sclerosis. Central nervous system (CNS) disease, or injury above the level of the pons, generally results in symptoms of bladder overactivity and UUI. Spinal cord injury or disease may manifest as bladder overactivity and UUI or as overflow incontinence, depending on the spinal level and completeness of the injury or disease.

Medications may have wide-ranging effects on lower urinary tract function (see Table 85-1). A thorough inquiry into the use of new medications in the setting of recent-onset UI may show a relationship.

Acute UI manifesting in the immediate postoperative setting may be secondary to a number of factors, including surgical manipulation and immobility, and to a number of medications, especially opioid analgesics and sedative-hypnotics.

Prior surgery may have effects on lower urinary tract function. UI following prostate surgery in men is highly suggestive of injury to the sphincter and resultant SUI. Pelvic surgery for benign and malignant conditions may result in denervation or injury to the lower urinary tract. This includes bowel surgery and gynecologic procedures. For example, new-onset total UI following gynecologic surgery suggests intraoperative bladder injury and subsequent development of a postoperative vesicovaginal fistula. Radiation therapy to the pelvis for malignant disease (eg, prostate cancer or cervical cancer) may result in injury to the bladder or urethra and subsequent UI.

In women, UI may be related to several gynecologic factors, including childbirth, hormonal status, and prior gynecologic surgery although recently the relationship of some of these factors to UI has come under debate.[21] Pregnancy and childbirth, particularly vaginal delivery, are associated with SUI and pelvic prolapse. Significant SUI in the nulliparous woman is uncommon. UI that becomes progressive at or around menopause suggests a hormonal component that may be responsive to estrogen or hormone replacement therapy.

UI may present in the setting of other significant pelvic floor disorders, signs, and symptoms. Constipation, diarrhea, fecal incontinence, dyspareunia, sexual dysfunction, and pelvic pain may be related to UI. A history of gross hematuria in the setting of UI mandates further urologic investigation, including radiologic imaging of the upper urinary tract and cystoscopy. Acute dysuria with or without hematuria in the setting of UI suggests cystitis. Urinalysis and urine culture should be performed in these patients.

TREATMENT

Desired Outcomes

3 The efficacy goals for the management of UI include restoration of continence, reduction of the number of UI episodes, and prevention of complications (pressure ulcers, nursing home placement, etc). Other desired outcomes are minimization of adverse treatment consequences and cost, as well as improvement in the patient's quality of life.

General Approach to Treatment

Nonsurgical, nonpharmacologic intervention is the first-line treatment for UI. Drug therapy may be considered in patients whose UI is not adequately controlled by nonpharmacologic therapies and in those who have no major contraindications to drug treatment. In general, pharmacotherapy provides a better response when combined with behavioral interventions. Selection of agent should be based on the type of UI, and patient characteristics (eg, age, comorbidities, concurrent drug therapies, ability to maintain medication adherence). Surgery can be considered when the degree of bother or lifestyle compromise is sufficient and other nonsurgical interventions are undesired or ineffective.

Antimuscarinic agents have been the mainstay of pharmacotherapy for OAB and UUI. According to the American Urological Association (AUA) guideline,[22] clinicians should avoid antimuscarinic agents in patients with narrow-angle glaucoma unless approved by the treating ophthalmologist. Antimuscarinic agents should be cautiously used in patients with frailty, impaired gastric emptying, or a history of urinary retention, or in those who are taking other drugs with anticholinergic properties. When one agent offers inadequate symptom control and/or unacceptable adverse drug events, consider a dose modification or switching to another agent. Before initiating antimuscarinic therapy, patients should be informed of adverse effects and strategies to minimize them. Before abandoning effective antimuscarinic therapy, clinicians should manage constipation and dry mouth (bowel regimen, fluid management, dose modification, or alternative antimuscarinics).[22]

Nonpharmacologic Therapy

Nonsurgical Treatment

4 Nonpharmacologic, nonsurgical treatment of UI is recommended as the first-line treatment at a primary care level. It is the only option for patients in whom pharmacologic and/or surgical management is inappropriate or undesired. Examples of patients who fulfill these criteria for nonpharmacologic treatment include those with mild to moderate symptoms and who do not want to take medication; those with comorbid conditions that place them at high risk for adverse effects from drug therapy; those who are not medically fit for surgery; those who plan future pregnancies (which may adversely affect long-term surgical outcomes); those with overflow incontinence whose condition is not amenable to surgery or drug therapy; and those who are delaying surgery or do not want to undergo surgery.[23,24]

Nondrug interventions for UI include behavioral interventions, external neuromodulation, anti-incontinence devices, and supportive interventions (**Table 85-3**).[23,24] Behavioral interventions are generally the first-line treatment for SUI, UUI, and mixed UI. Interventions include lifestyle modifications, voiding schedule regimens, and pelvic floor muscle rehabilitation. Because the key to success with any type of behavioral intervention is motivation of patients or caregivers, these individuals must be active participants in developing a treatment plan. Regular follow-up is needed to help motivate patients and caregivers, provide reassurance and support, and monitor treatment outcomes.

TABLE 85-3 Nonpharmacologic Management of Urinary Incontinence

Intervention	Description	Patient Characteristics
Lifestyle Modifications		
Behavioral changes (eg, fluid and caffeine modifications, smoking cessation, weight loss, constipation prevention)	Self-management strategies targeted toward reducing or eliminating risk factors that cause or exacerbate UI	Used as first-line therapies or in combination with pharmacological treatment in patients with stress, urgency, and mixed incontinence
Scheduling Regimens		
Timed voiding	Toileting on a fixed schedule where interval does not change, typically every 2 hours during waking hours	Used for patients with cognitive or physical impairments
Habit retraining	Scheduled toiletings with adjustments of voiding intervals (longer or shorter) based on patient's voiding pattern	Used for institutionalized or homebound patients with cognitive or physical impairments

Intervention	Description	Patient Characteristics
Prompted voiding	Scheduled toiletings that require prompts to void from a caregiver, typically every 2 hours; patient assisted in toileting only if response is positive; used in conjunction with operant conditioning techniques for rewarding patients for maintaining continence and appropriate toileting	Used for patients who are functionally able to use toilet or toilet substitute, able to feel urge sensation, and able to request toileting assistance appropriately; primarily used in institutional settings or in homebound patients with an available caregiver
Bladder training	Scheduled toiletings with progressive voiding intervals; includes teaching urgency suppression strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques; sometimes combined with drug therapy	Used for stress, urgency, and mixed incontinence in patients who are cognitively intact, able to toilet, and motivated to comply with training program
Pelvic Floor Muscle Rehabilitation		
Pelvic floor muscle exercises (eg, Kegel exercises)	Regular practice of pelvic floor muscle contractions; may involve use of pelvic floor muscle contraction for prevention of stress leakage and urge inhibition	Used for stress, urgency, and mixed incontinence in patients who can isolate and correctly contract pelvic floor muscles; requires cognitively intact and highly motivated patient
Biofeedback	Use of electronic or mechanical instruments to display visual or auditory information about neuromuscular or bladder activity; used to teach correct pelvic floor muscle contraction or urge inhibition; home trainers available	Used for stress, urgency, and mixed incontinence in patients who have the capability to learn voluntary control through observation and are motivated; used in conjunction with pelvic floor muscle exercises
Vaginal weight training	Active retention of increasing vaginal weights; typically used in combination with pelvic floor muscle exercises at least twice per day	Women with stress incontinence who are cognitively intact, can correctly contract pelvic floor muscles, able to stand, and have sufficient vaginal vault and introitus to retain cone, and are highly motivated; contraindicated in patients with moderate to severe pelvic organ prolapse
External Neuromodulation		

Intervention	Description	Patient Characteristics
Nonimplantable electrical stimulation	Application of electrical current through vaginal, anal, surface, or fine needle electrodes; used to inhibit bladder overactivity and improve awareness, contractility, and efficacy of pelvic floor muscle contraction; handheld stimulators for home use are available	Used for stress, urgency, and mixed incontinence in patients who are highly motivated; contraindicated in patients with diminished sensory perception; urinary retention, history of cardiac arrhythmia, cardiac pacemakers, implantable defibrillators, pregnant or attempting pregnancy; vaginal or anal electrodes are contraindicated in moderate or severe pelvic organ prolapse
Percutaneous tibial nerve stimulation	Application of a pulsed electrical current through a fine needle electrode placed externally near the tibial nerve	Used for treatment of overactive bladder with urinary urgency, frequency, and urgency incontinence; contraindicated in patients with pacemakers or implantable defibrillators, prone to excessive bleeding, or women who are pregnant
Extracorporeal magnetic electrical stimulation	Pulsed magnetic stimulation to pelvic floor musculature causing depolarization of motor neurons, thus inducing pelvic floor muscle contraction; stimulation is provided through a specially designed chair that contains a device for producing a pulsing magnetic field	Used for treatment of stress, urgency, and mixed incontinence; contraindicated in patients with demand cardiac pacemakers or metallic joint replacements; may be useful treatment option when other approaches fail or are not feasible
Alternative Medicine Therapies		
Acupuncture	Involves insertion of disposable sterile fine stainless steel needles into points on the skin that are thought to suppress or stimulate spinal and/or supraspinal reflexes to the bladder and/or urethra	Used for stress, urgency, and mixed incontinence and UI due to spinal cord injury
Anti-Incontinence Devices		
Bed or pant alarms	Sensor devices that respond to wetness; used to awaken or alert individuals via noise or vibrating mechanism	Primarily used for nocturnal enuresis in children; system available for monitoring incontinence in home care and institutional environments
Pessaries	Intravaginal devices designed to support the bladder neck, relieve minor to moderate pelvic organ prolapse, and change pressure	Used for female stress incontinence and mild to moderate pelvic organ prolapse; in postmenopausal women, topical estrogen therapy is typically prescribed

Intervention	Description	Patient Characteristics
	transmission to the urethra	to prevent ulceration and breakdown of vaginal tissue; requires good manual dexterity to manipulate device
Urethral insert (women only)	Intraurethral device	Used in female stress incontinence with stress incontinence who are cognitively intact and have good manual dexterity
Urethral compression device (men only)	Penile clamp	Used in men patients with stress incontinence who are cognitively intact and have good manual dexterity
External collection devices (men only)	Condom catheter with leg bag	Used in men with urgency, stress, and overflow incontinence and in those with functional impairments
Catheters	Disposable, intermittent urethral catheters and indwelling urethral and suprapubic catheters	Used for overflow incontinence; used in patients who are bed-bound or with significant mobility impairments and severe incontinence; those with terminal illness; those with sacral pressure ulcers until healing occurs
Supportive Interventions		
Toileting substitutes and other environmental modifications	Female and male urinals, bedside commodes, elevated toilet seats	Used for patients with mobility impairments that make reaching toilet in timely fashion difficult
Absorbent products	Variety of reusable and disposable liners, pads, male drip collectors, male guard, collector undergarment, fitted brief, and pant systems; some products contain a polymer that absorbs and wicks urine away from the body	Used for all types of incontinence
Physical therapy	Gait and/or strength training	Used for older patients with mobility impairments that make reaching a toilet in timely fashion difficult

External neuromodulation may include nonimplantable electrical stimulation (EStim), percutaneous tibial nerve stimulation (PTNS), or extracorporeal magnetic stimulation (MStim). Neuromodulation is typically prescribed when traditional pelvic floor muscle rehabilitation has failed. Anti-incontinence devices such as bed alarms, catheters, pessaries, penile clamps, and external collection devices are reserved for special situations depending on patients' UI symptoms, cognitive and mobility status, and overall health status. Supportive interventions such as physical therapy may be beneficial for patients with muscle weakness and slow gait to reach the toilet in a timelier manner, and absorbent

products will provide greater confidence in dealing with unpredictable urine loss.

Surgical Treatment

Only rarely does surgery play a role in the initial management of UI. In the absence of secondary complications from UI (eg, skin breakdown or infection), the decision to surgically treat symptomatic UI should be based on the premise that the degree of bother or lifestyle compromise to the patient is great enough to warrant an elective operation, and that nonsurgical therapy either is undesired or has been ineffective.

Successful application of surgery depends mostly on defining the underlying abnormalities responsible for UI (bladder vs urethra, underactivity vs overactivity). Once the underlying factors are determined, other considerations include renal function, sexual function, severity of leakage, history of abdominal or pelvic surgery, presence of concurrent abdominal or pelvic pathology requiring surgical correction, and finally the patient's suitability for the procedure and willingness to accept the risks of surgery.

If patients with uncomplicated SUI become dissatisfied with the initial management approaches of pelvic floor exercises, medications, and/or behavioral modification, surgical treatment assumes the primary role.

Surgical correction of female SUI (urethral underactivity) is directed toward either (a) repositioning the urethra and/or creating a backboard of support, or otherwise stabilizing the urethra and bladder neck in a well-supported retropubic (intra-abdominal) position that is receptive to changes in intra-abdominal pressure; or (b) improving the sealing mechanism and/or creating compression or otherwise augmenting the urethral resistance provided by the intrinsic sphincteric unit, with (ie, sling) or without (ie, periurethral injectable bulking agents) urethral and bladder neck support.

Bulking agents are injected into the urethra at the level of the urinary sphincter as an office-based procedure and are generally considered quite safe. However, their durability and efficacy are likely inferior to other options.[25]

Midurethral synthetic slings have become the most common approach to the treatment of SUI in women in the United States.[26] These can be inserted as outpatient procedures that have shorter convalescence periods and allow faster return to usual activities compared with many of the older procedures. These procedures are generally felt to be highly durable and efficacious. However, safety concerns have been expressed regarding the implantation of surgical mesh in some patients, the implications of which are yet to be fully clarified.[27]

SUI in men is very rare in the absence of prior pelvic surgery, injury, or neurologic disease. When it occurs, SUI in men can be treated in a number of ways.[28] Bulking agents can be injected periurethrally and submucosally into the region of the external urinary sphincter. This approach is less effective and far less durable than alternative surgical procedures, although it can be performed in the office setting without the need for general anesthesia.

The artificial urinary sphincter is generally considered to be the gold standard for treatment of male SUI.[28] Placement of this manually operated silicone device has been associated with very high long-term success and satisfaction rates.[29] Male slings placed through a perineal incision are an alternative to the artificial urinary sphincter. However, long-term efficacy and safety data are lacking.[30]

Most patients with UUI are managed nonsurgically with a combination of behavioral modification, pelvic floor exercises, and pharmacologic therapy. However, for patients refractory to such measures, invasive therapy can be beneficial. Posterior tibial nerve stimulation is an office-based percutaneous treatment for UUI or OAB. Therapy consists of weekly 30-minute treatments with a needle placed posteriorly to the medial malleolus of the ankle for 3 months. Efficacy appears similar to or slightly better than oral pharmacotherapy.[31] However, long-term efficacy and safety data are lacking.[32]

Surgery for the treatment of UUI generally consists of implantation of a sacral nerve stimulator (neuromodulation) or endoscopic office-based injection of botulinum toxin directly into the detrusor muscle.[33,34] Neuromodulation is a staged surgical procedure in which a neurostimulator lead is placed transforaminally at the level of sacral spinal cord root S3. Its exact mechanism is unknown, but the device may exert its favorable effects on urination and UUI by rebalancing the afferent and efferent nerve impulses to the lower urinary tract and pelvic floor. The injection of botulinum toxin is performed in the office generally with local anesthesia. Following transurethral injection directly into the detrusor muscle using a small needle in a template fashion, the toxin is taken up by the local neurons. The intracellular toxin cleaves SNAP-25, a cystoplasmic protein critical for the attachment of neurotransmitter containing vesicles to the cell membrane at the nerve terminal. As the vesicles containing neurotransmitter are unable to fuse to the cell membrane and release its contents into the synaptic cleft, neural transmission to the postsynaptic muscle fascicle is interrupted. This results in a graded, initially irreversible but transient weakness and paralysis of the affected muscle. The duration of effect of the toxin is about 4 to 8 months, after which repeat injection is necessary to maintain effect. The therapeutic algorithm involving these two choices for treatment of refractory UUI is evolving and is determined largely by patient preference.[35]

Few surgical treatments for bladder underactivity are effective. After an appropriate evaluation for reversible causes, the most effective management of this condition is intermittent self-catheterization performed by the patient or a caregiver three or four times per day. Sacral nerve stimulation (neuromodulation) has shown some efficacy in this patient population, but success rates for detrusor underactivity (nonobstructive urinary retention) are inferior to those seen with urinary frequency and urgency.[36] Proper patient selection for this therapy remains poorly defined. Alternative methods of management that are less satisfactory or more invasive include indwelling urethral or suprapubic catheters and urinary diversion.

Urethral overactivity is most commonly caused by anatomic obstruction. Anatomic obstruction in men is most often caused by benign prostatic enlargement. Treatments may include transurethral surgical resection of the prostate (see Chapter 84).

Rarely, bladder outlet obstruction is caused by a functional obstruction at the level of the bladder

neck or external sphincter. Hypertrophy of the smooth muscle fibers at the level of the bladder neck in men and women may result in obstruction to the flow of urine. In patients who do not respond to pharmacologic therapy with α-adrenergic receptor antagonists, endoscopic incision using the cystoscope is highly effective in treating this very uncommon condition.

Pharmacologic Therapy

Urge Urinary Incontinence

5 Antimuscarinic agents and β_3-adrenergic agonist (mirabegron) are the second-line drug treatments for relieving UUI symptoms and preventing its complications. **Table 85-4** summarizes AUA recommendations for treating OAB in adults.[22] **Table 85-5** lists the usual dosage for approved agents for OAB or UUI. **Table 85-6** suggests common monitoring parameters for these agents.

TABLE 85-4 AUA Guideline for Treatment of Overactive Bladder in Adults

Recommendation	Evidence Strength Grade[b]
First-Line Treatments	
Behavioral therapies (eg, bladder training, bladder control strategies, pelvic floor muscle training, fluid management)	B
Behavioral therapies may be combined with antimuscarinic therapies	C
Second-Line Treatments	
Oral antimuscarinics or β_3-adrenergic agonist as second-line therapy	B
If an IR and an ER formulation are available, prefer ER formulations because of lower rates of dry mouth	B
Transdermal oxybutynin (patch or gel) may be offered	C
Third-Line Treatments	
Intradetrusor onabotulinum toxin A (100 units) in carefully selected patients who have been refractory to first- and second-line OAB treatments[a]	B/C
Peripheral tibial nerve stimulation in a carefully selected patient population	C
Sacral neuromodulation in carefully selected patients with severe refractory OAB symptoms or in those who are not candidates for second-line therapy and are willing to undergo a surgical procedure	C

AUA, American Urological Association; ER, extended-release; IR, immediate-release; OAB, overactive bladder.

[a]The patient must be able and willing to return for frequent postvoid residual evaluation and able and willing to perform self-catheterization if necessary.

[b]When sufficient evidence existed, the body of evidence for a particular treatment was assigned a

strength rating of A (high), B (moderate), or C (low). Both B and C indicate that benefits outweigh risks/burdens.

TABLE 85-5 Dosing of Medications Approved for OAB or UUI

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Anticholinergics/Antimuscarinics					
Oxybutynin IR	Ditropan	2.5 mg twice daily	2.5-5 mg two to four times daily		Titrate in increments of 2.5 mg/day every 1-2 months; available in oral solution
Oxybutynin XL	Ditropan XL	5-10 mg once daily	5-30 mg once daily		Adjust dose in 5-mg increments at weekly interval; swallow whole
Oxybutynin TDS	Oxytrol Oxytrol for Women (OTC)		3.9 mg/day apply one patch twice weekly		Apply every 3-4 days; rotate application site
Oxybutynin gel 10%	Gelnique		One sachet (100 mg) topically daily		Apply to clean and dry, intact skin on abdomen, thighs or upper arms/shoulders; contains alcohol
Oxybutynin gel 3%	Gelnique 3%		Three pumps (84 mg) topically daily		Same as above
Tolterodine IR	Detrol		1-2 mg twice daily	1 mg twice daily if patient is taking CYP3A4 inhibitors, or with renal/hepatic impairment	
Tolterodine LA	Detrol LA		2-4 mg once daily	2 mg once daily in those who are taking CYP3A4 inhibitors or with renal/hepatic impairment	Swallow whole; avoid in patients with creatinine clearance ≤10 mL/min (≤0.17 mL/s)
Trospium chloride IR	Sanctura		20 mg twice daily	20 mg once daily in patient age ≥75 years or creatinine clearance ≤30 mL/min (≤0.5 mL/s)	Take 1 hour before meals or on empty stomach; patient age ≥75 years should take at

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
					bedtime
Trospium chloride ER	Sanctura XR		60 mg once daily	Avoid in patient age ≥75 years or creatinine clearance ≤30 mL/min (≤0.5 mL/s)	Take 1 hour before meals or on empty stomach; swallow whole
Solifenacin	VESIcare	5 mg daily	5-10 mg once daily	5 mg daily if patient is taking CYP3A4 inhibitors or with creatinine clearance ≤30 mL/min (≤0.5 mL/s) or moderate hepatic impairment; avoid in severe hepatic impairment	Swallow whole
Darifenacin ER	Enablex	7.5 mg once daily	7.5-15 mg once daily	7.5 mg daily if patient is taking potent CYP3A4 inhibitors or with moderate hepatic impairment; avoid in severe hepatic impairment	Titrate dose after at least 2 weeks; swallow whole
Fesoterodine ER	Toviaz	4 mg once daily	4-8 mg once daily	4 mg daily if patient is taking potent CYP3A4 inhibitors or with creatinine clearance ≤30 mL/min (≤0.5 mL/s); avoid in severe hepatic impairment	Prodrug (metabolized to 5-hydroxymethyl tolterodine); swallow whole
β_3-Adrenergic Agonist					
Mirabegron ER	Myrbetriq	25 mg once daily	25-50 mg once daily	25 mg once daily if creatinine clearance 15-29 mL/min (0.25-0.49 mL/s) or moderate hepatic impairment; avoid in patients with ESRD or severe hepatic impairment	Swallow whole

CYP, cytochrome P450 enzyme; ER, extended-release; ESRD, end-stage renal disease; IR, immediate release; LA, long acting; OAB, overactive bladder; OTC, over-the-counter; TDS, transdermal system; UUI, urge urinary incontinence; XL, extended release.

TABLE 85-6 Monitoring of Medications Approved for OAB or UUI

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Antimuscarinic			
Oxybutynin IR	Anticholinergic adverse effects: dry mouth,	Contraindications and precautions: urinary retention,	In general, ER, LA, XL, and topical products

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Oxybutynin XL Oxybutynin TDS Oxybutynin gel 10% Oxybutynin gel 3% Tolterodine IR Tolterodine LA Trospium chloride IR Trospium chloride ER Solifenacin Darifenacin ER Fesoterodine ER	constipation, headache, dyspepsia, dry eyes, blurred vision, cognitive impairment, tachycardia, sedation, orthostatic hypotension Application site reactions (topical agents): pruritus, erythema	gastric retention, severely decreased GI motility, angioedema, myasthenia gravis, uncontrolled narrow-angle glaucoma Worsening of renal/hepatic condition or concomitant drug therapy, which may necessitate dosage reduction or drug cessation Mental status change or risk for falls in elderly or frail patients	are associated with fewer anticholinergic adverse effects, particularly dry mouth Possible transference of drug from topical application Avoid open fire or smoke until alcohol-based gel has dried
β_3-Adrenergic Agonist			
Mirabegron ER	Hypertension, nasopharyngitis, urinary tract infection, headache	Precautions: urinary retention, severe uncontrolled hypertension Worsening of renal/hepatic condition, which may necessitate dosage reduction or drug cessation Increased effect of narrow therapeutic index drugs that are CYP2D6 substrates	Mirabegron is a CYP2D6 inhibitor

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
		QT prolongation	

CYP, cytochrome P450 enzyme; ER, extended-release; IR, immediate release; LA, long acting; OAB, overactive bladder; TDS, transdermal system; UUI, urge urinary incontinence; XL, extended release.

Antimuscarinic agents (see Table 85-5) antagonize muscarinic receptors and suppress premature detrusor contractions, thereby enhance bladder storage. They have similar contraindications, precautions, and side-effect profiles, with incidence/severity varies with each individual agent.[37] Choice of therapy should be based on patient characteristics (eg, age, comorbidities, concurrent medications, and ability to adhere to the prescribed regimen). These agents improve quality of life in patients with UUI, and are considered equally effective based on statistical superiority over placebo or active controls. In clinical trials, major efficacy outcomes for these agents in the management of UI are reduction of the mean number of UI episodes, decrease in the number of micturitions per day, and increase of urine volume voided per micturition.[38]

Oxybutynin Immediate Release

Oxybutynin immediate release (IR) is the oldest and least expensive treatment for UUI. It has the disadvantage of giving substantial nonurinary antimuscarinic effects (see Table 85-6). It also causes orthostatic hypotension, and sedation/weight gain, due to the blockage of α-adrenergic-, and histamine H_1-receptors, respectively.[39] Overall, significant adverse effects of this agent jeopardize medication adherence and can prevent dose escalation to achieve optimal benefit. Its multiple daily dosing may be too complicated for patients with cognitive impairment or those who are taking multiple medications. Oral solution formulation may be easier to administer to patients who have difficulty in swallowing.

To optimize tolerability, initiate dose at no more than 2.5 mg twice daily, increase to 2.5 mg three times daily after 1 month, then titrate in increments of 2.5 mg/day every 1 to 2 months until the desired response or the maximum recommended dosage. Side effects may be managed by dose reduction. Dry mouth may be relieved by use of sugarless hard candy, gum, or a saliva substitute. Constipation can be minimized by increasing the intake of water, dietary fiber, physical activity, or laxative therapy.

Oxybutynin Extended-Release

An extended-release (XL) formulation of oxybutynin can be considered an alternative therapy in patients who cannot tolerate IR formulation. It delivers a controlled amount of oxybutynin over a 24-hour period, and has a reduced first-pass metabolism. The lower plasma concentration of active metabolite, *N*-desethyloxybutynin, due to reduced first-pass metabolism, may explain the lower dry mouth incidence associated with the XL product.[40] In short-term studies of up to 12 weeks' duration, oxybutynin XL was better tolerated than oxybutynin IR, with approximately 7% of patients discontinuing treatment because of adverse effects (compared with approximately 27% of those taking oxybutynin IR).[40]

In short-term studies, oxybutynin XL was at least as effective as tolterodine IR or long acting (LA) in managing urinary symptoms. Pooled results of two open-label studies suggested that oxybutynin XL was inferior in patient-perceived improvement in bladder control and adverse effects profile to tolterodine LA. However, both agents provided similar patients' or physicians' perception of benefit over baseline and proportions of withdrawals due to lack of efficacy. A major limitation of this study was lack of blinding, which may lead to patient and observer bias.[41]

Oxybutynin XL should be administered once daily, and should not be crushed or chewed. Elderly patients should start with a dose of 5 mg once daily and titrate gradually to desired effects, which may take at least 4 weeks after dose initiation or escalation. Drug interactions may occur when oxybutynin is used with other anticholinergic drugs, potent CYP3A4 inhibitors (eg, itraconazole, miconazole, erythromycin, and clarithromycin), and acetylcholinesterase inhibitors via pharmacodynamic antagonism.[40]

Transdermal Oxybutynin

The oxybutynin transdermal system (TDS) is another option for patients who cannot tolerate IR oxybutynin or who prefer topical drug delivery route. In 2013, the US Food and Drug Administration (FDA) approved the oxybutynin TDS as the first over-the-counter treatment for OAB in women aged 18 years and over. The patch allows oxybutynin to bypass first-pass hepatic and gut metabolism, and gives a more tolerable adverse effect profile compared with oral formulations.[42] It is as effective as oxybutynin IR in reducing the frequency of UUI episodes and improving patient-perceived urinary leakage.[42,43] Compared with tolterodine LA, oxybutynin TDS provided similar efficacy outcomes, including attaining complete continence and improving quality of life.[41] A large multicenter trial reported improved quality of life and good tolerability in patients 65 years or older; increase in work productivity was noted among younger patients.[44,45]

Patients should apply oxybutynin TDS to dry, intact skin on the abdomen, hip, or buttocks every 3 to 4 days (twice weekly). Rotating application site at least weekly may help minimize local side effects. The most common adverse effects are pruritus (14%-17%) and erythema (6%-9%) at the application site, dry mouth (5%-10%), constipation (3%), and abnormal vision (2.5%).[42]

Oxybutynin Topical Gel

This formulation (available in 10% or in 3%) causes significantly less dry mouth than oxybutynin (6.1% vs 73.1%).[46,47,48] In short-term studies, it is more effective than placebo, but gives dry mouth and application site reactions as the most common adverse effects.[49] Although it did not cause cognitive impairment in older adults in short-term studies, clinicians should monitor for anticholinergic effects during long-term therapy, particularly in frail patients.[50]

The most common adverse events include dry mouth (8%-12%), application site reactions (5%-11%), and dizziness (3%).[46,47] Clinicians should counsel patients to avoid applying sunscreen within half an hour before or after application and to avoid showering within 1 hour after application. The transfer of gel between individuals may occur if vigorous skin contact is made at the application site; patients

should avoid open fires or exposure to smoking until this alcohol-based gel has dried.[46,47]

Tolterodine Immediate Release

Tolterodine is a competitive muscarinic receptor antagonist that is as effective as oxybutynin IR, and is associated with lower drug discontinuation rates (8% vs 27% oxybutynin IR).[41,51] It may have better medication adherence than oxybutynin due to better tolerability.[52]

Tolterodine is predominantly eliminated by hepatic metabolism, which is partially under the control of genetic polymorphism.[51] The principal metabolic pathway in extensive metabolizers involves oxidation of the parent drug by CYP isoenzyme 2D6 to the active 5-hydroxymethyl metabolite (DD01). In CYP2D6 poor metabolizers (approximately 7% of the US population), the principal metabolic pathway involves CYP3A4. Because tolterodine is principally metabolized by CYP3A4 in this case, its elimination may be impaired by CYP3A4 inhibitors (eg, fluoxetine, sertraline, fluvoxamine, macrolide antibiotics, azole antifungals, and grapefruit juice). For example, fluoxetine, an inhibitor of CYP2D6 and 3A4, decreases the metabolism of tolterodine to DD01, and results in significant increase of drug exposure to tolterodine.[51] Whether tolterodine significantly alters the pharmacokinetics of drugs metabolized by CYP2D6 is unknown, so caution is advised with concurrent use with agents metabolized by CYP2D6.[51]

Tolterodine IR can be given 1 to 2 mg twice daily with or without food. It is not recommended in patients with creatinine clearance less than 10 mL/min (<0.17 mL/s) or severe hepatic impairment. The dose should be reduced to 2 mg in patients with mild to moderate hepatic impairment, or creatinine clearance 10 to 30 mL/min (0.17-0.5 mL/s), or in those taking potent CYP3A4 inhibitors. The maximum benefit from tolterodine may take up to 8 weeks after therapy initiation or dose escalation.[51]

The most common adverse effects of tolterodine are dry mouth, dyspepsia, headache, constipation, and dry eyes. Of note, patients who have known hypersensitivity to fesoterodine fumarate should not receive tolterodine because both agents are metabolized to DD01. Monitoring of QT prolongation is advisable in patients who are also taking Class IA (eg, quinidine, procainamide) or Class III (eg, amiodarone, sotalol) antiarrhythmic medications.[51]

Tolterodine Long Acting

Tolterodine LA offers a convenient once-daily dosing, and causes less dry mouth than taking IR products. It is better than placebo in efficacy outcomes, including ability to complete tasks before voiding and patient perception of benefit.[53] It also improves OAB symptoms in men who were taking α-adrenergic blockers.[54]

Tolterodine LA should be given once daily, and should not be crushed or chewed. The dose should be limited to 2 mg once daily in patients with mild to moderate hepatic impairment (Child-Pugh class A or B), severe renal impairment creatinine clearance 10 to 30 mL/min (0.17-0.50 mL/s), or taking drugs that are potent CYP3A4 inhibitors (ketoconazole, itraconazole, clarithromycin, or ritonavir).

Patients with creatinine clearance less than 10 mL/min (<0.17 mL/s) or severe hepatic impairment (Child-Pugh class C) should avoid taking the drug. Patients should be counseled that it takes up to 8 weeks to see maximum benefit after starting therapy or dose escalation. Common adverse effects and monitoring parameters for tolterodine LA are similar to its IR product.[53]

Fesoterodine Fumarate

Fesoterodine fumarate is also indicated for symptoms of urinary frequency, urgency, or urge incontinence. It is a prodrug that is metabolized to its active metabolite, 5-hydroxymethyl tolterodine (also a metabolite of tolterodine), by nonspecific plasma esterases.[55]

In a short-term study, fesoterodine was better than tolterodine ER 4 mg and placebo on reducing UUI episodes, micturitions, urgency and improving health-related quality of life. However, fesoterodine caused more dry mouth (28% vs 13%), and constipation (4% vs 3%) than tolterodine ER. It has been associated with higher discontinuation rates due to adverse events (5% vs 3%).[56]

The usual starting dose is 4 mg daily, increasing to 8 mg daily, as needed and tolerated. The dose of fesoterodine should not exceed 4 mg daily in the presence of severe renal impairment (creatinine clearance <30 mL/min [≤0.50 mL/s]) or in patients also taking potent CYP3A4 inhibitors. Fesoterodine is not recommended in patients with severe hepatic impairment. It is available in XL tablets, which should be swallowed whole; patients should not chew, crush, or divide the product.[55]

The most common adverse effects of fesoterodine are dry mouth (27%), constipation (5.1%), dyspepsia (2%), and dry eyes (1.6%). Anticholinergic adverse effects associated with fesoterodine are dose-related.[55]

Trospium Chloride Immediate Release

Trospium chloride, a quaternary ammonium anticholinergic, is a second-generation antimuscarinic agent for UUI. Trospium chloride is poorly absorbed after oral administration (<10%), and food reduces bioavailability by 70% to 80%. It is principally cleared by the renal route (60%). Metabolites account for approximately 40% of the excreted dose following oral administration. The major metabolic pathway is hypothesized as ester hydrolysis with subsequent conjugation. CYP is not expected to contribute significantly to the elimination of trospium. The plasma half-life is approximately 20 hours; with renal clearance about 30 L/h. Active tubular secretion is a major route of elimination for trospium. When creatinine clearance is less than 30 mL/min (0.50 mL/s), drug exposure and drug concentration are significantly increased.[57]

In a study involving a large proportion of elders (mean age, 63 years), trospium chloride was better than placebo in efficacy outcomes of UUI. In a 12-week, controlled study, trospium chloride IR was noninferior to oxybutynin IR in managing UUI, but was associated with less dry mouth.[58]

The frequency of anticholinergic side effects of trospium was higher in patients 75 years and older than younger subjects. This occurrence is believed to be pharmacodynamic (ie, increased sensitivity).

No data at present support the hypothesis that trospium chloride is less neurotoxic than nonquaternary ammonium anticholinergics (based on the hypothesis of reduced transit across the blood–brain barrier of trospium chloride due to its positive electrical charge on the quaternary nitrogen). Trospium may interact with other drugs that are eliminated by active tubular secretion via competition (eg, procainamide, pancuronium, morphine, vancomycin, and tenofovir).[57] Trospium IR is dosed 20 mg twice daily, and should be taken on an empty stomach. Dosage reduction (by 50% of the daily dose) is recommended when creatinine clearance is less than 30 mL/min (0.50 mL/s). In older patients (75 years and older), dose reduction to 20 mg once daily should be considered based upon tolerability.[57]

Trospium Chloride Extended-Release

Trospium chloride ER offers once-daily dosing. Its efficacy and safety have been demonstrated in patients with OAB, including those who are older and taking multiple medications.[59,60]

Trospium is eliminated primarily unchanged in the urine. It is not recommended in patients with severe renal impairment (creatinine clearance <30 mL/min [≤0.50 mL/s]). Alcohol should not be consumed within 2 hours of trospium ER administration. Coadministration with antacid may increase or decrease trospium exposure, but the clinical relevance of these findings is unknown. In addition, coadministration of immediate-release (IR) metformin 500 mg twice daily reduced the steady-state systemic exposure of trospium by approximately 29% and peak concentration by 34%.[60]

The usual dosage of trospium ER is 60 mg daily. Because food decreases the bioavailability by 35% to 60%, XL trospium chloride must be taken on an empty stomach (1 hour before or 2 hours after meals).[60] Common adverse effects with trospium chloride ER have been dry mouth (11%), constipation (9%), dizziness (2%), dry eyes (1.6%), flatulence (1.6%), nausea (1.4%), and abdominal pain (1.4%). Patients should be informed that alcohol may enhance the drowsiness caused by anticholinergic agents.[60]

Solifenacin Succinate

Solifenacin succinate is a second-generation antimuscarinic agent indicated for the treatment of OAB with urge incontinence, urgency, and urinary frequency.[61] Solifenacin was better than tolterodine ER in terms of reducing the number of UUI episodes and pad usage and in improving patients' perception of their bladder condition.[62] Clinical data showed that solifenacin recipients had significant improvement in 5 of 10 quality-of-life domains from baseline compared with placebo recipients.[63] Compared with oxybutynin IR, solifenacin was associated with fewer episodes (35% vs 83%) and lower severity of dry mouth.[64,65]

Solifenacin is well absorbed (mean absolute bioavailability, 88%), and food has no clinically relevant effect on absorption. It is principally eliminated via metabolism and renal excretion of metabolites, with renal excretion of parent compound less than 10% of the dose. With a mean terminal disposition half-life of 50 to 60 hours, the drug can be dosed once daily.[61] The primary pathway for elimination

of solifenacin is via CYP3A4. Adverse effects, including dry mouth, occurred similarly between younger and older patients.[64]

The recommended dose of solifenacin is 5 mg once daily. If the drug is well tolerated but the effectiveness is not optimal, the dose can be increased to 10 mg once daily. Little additional benefit is generally achieved with doses exceeding 5 mg daily. Solifenacin can be administered with or without food. For patients with creatinine clearance rates less than 30 mL/min (0.50 mL/s) or with moderate hepatic impairment (Child-Pugh class B), the daily dosage should not exceed 5 mg. Patients who have severe hepatic impairment (Child-Pugh class C) should avoid using this drug. If the patient is receiving concurrent therapy with one or more potent CYP3A4 inhibitors, the daily dose should not exceed 5 mg.

The most common adverse reactions of solifenacin are dry mouth (11%-28%), constipation (5%-13%), urinary tract infection (4%-5%), and blurred vision (3%-5%). It interacts with CYP3A4 inhibitors and inducers; close patient monitoring is required. Prolonged corrected QT intervals have been reported with high-dose solifenacin.[61]

Darifenacin

Darifenacin is another second-generation antimuscarinic for the management of OAB or UUI. It improves urinary symptoms, and quality of life.[66,67] It may be considered in patients who are dissatisfied with previous antimuscarinic treatments.

The mean absolute bioavailabilities of the 7.5-, 15-, and 30-mg extended-release (ER) formulations are 15%, 19%, and 25%, respectively. Bioavailability is affected by formulation, CYP2D6 genotype, dose, and race. Bioavailability is enhanced using an ER formulation (70%-110% higher than IR), in heterozygous CYP2D6 extensive metabolizers and poor metabolizers (40%-90% higher than homozygous extensive metabolizers), and white race (56% higher than Japanese). Darifenacin is extensively metabolized, with cumulative urinary excretion of the parent compound less than 10%. The 2D6 and 3A4 isoenzymes of CYP are responsible for darifenacin metabolism. With a mean terminal disposition half-life of 3 to 5 hours (depending on CYP2D6 metabolizer status), an ER formulation is needed to allow once-daily dosing.[68]

Darifenacin ER should be initiated at 7.5 mg once daily, and may be increased to 15 mg once daily after 2 weeks to target clinical response. The dosage should be limited to 7.5 mg daily in patients with moderate hepatic impairment (Child-Pugh B), taking potent CYP3A4 inhibitors. It should be avoided in patients with severe hepatic impairment (Child-Pugh C). It must be swallowed whole without chewing, dividing, or crushing. The most frequently reported adverse reactions are constipation (21%), dry mouth (19%), headache (7%), dyspepsia (5%), and nausea (4%). Darifenacin may interact with substrates of CYP2D6 (flecainide, thioridazine, and tricyclic antidepressants).[68]

Clinical Controversy…

Should antimuscarinic pharmacotherapy be used to treat UUI in patients with mild cognitive impairment or dementia? Antimuscarinic agents may worsen cognitive function, especially in older

adults. Caution should be exercised as these agents may antagonize the therapeutic effects of acetylcholine esterase inhibitors indicated for dementia.

Mirabegron

Mirabegron has been approved by FDA in June 2012 for the treatment of OAB with symptoms of UUI, urgency, and urinary frequency.

6 Mirabegron is another second-line treatment for managing UUI. It increases bladder capacity by relaxing the detrusor smooth muscle during the storage phase of the urinary bladder fill-void cycle by the activation of β_3-adrenergic receptors. Similar to antimuscarinic agents, it is only modestly effective and reduces urinary frequency and incontinence episodes by less than one per day. It is associated with nonsignificant improvements in UUI, urgency episodes, and quality-of-life measures. It has been shown to have similar efficacy as with tolterodine ER.[22,69] It reduces mean number of incontinence episodes per 24 hours, mean number of micturitions per 24 hours, and increased mean volume voided per micturition. The efficacy is usually seen during 4 to 8 weeks of therapy.[69]

Mirabegron reaches its peak plasma concentrations at approximately 3.5 hours, and has an oral bioavailability of 29% to 35%. It achieves steady state within 7 days of therapy. It can be taken with or without food. Mirabegron is extensively distributed in the body, with a volume of distribution of approximately 1,670 L. It has protein binding of approximately 71% to both albumin and α_1-acid glycoprotein. Mirabegron is metabolized via multiple pathways involving dealkylation, oxidation, glucuronidation, and amide hydrolysis. It has two inactive metabolites (16% and 11% of total exposure), respectively. Isoenzymes CYP2D6 and 3A4 play a limited role in its elimination. Poor metabolizers of CYP2D6 had an increased mean peak concentration and drug exposure compared to extensive metabolizers of CYP2D6 (16% and 17%, respectively). Other enzymes that are involved in mirabegron metabolism include butylcholinesterase, uridine diphospho-glucuronosyltransferases (UGT), and possibly alcohol dehydrogenase.

Total body clearance of mirabegron is about 57 L/h, with a terminal elimination half-life of 50 hours. Renal clearance equals approximately 13 L/h, primarily through active tubular secretion along with glomerular filtration. The urinary elimination of unchanged mirabegron is dose-dependent and ranges from 6% to 12% after a daily dose of 25 to 100 mg.[69]

Mirabegron should be initiated at 25 mg once daily, and may titrate upward to 50 mg once daily after 8 weeks, based on individual efficacy and tolerability; limit dose to 25 mg once daily in patients with severe renal impairment or moderate hepatic disease. Mirabegron is available in ER tablets, and should be swallowed whole with water without chewing, dividing, or crushing. It should be avoided in patients with end-stage renal disease, severe hepatic impairment, or severe uncontrolled hypertension (≥180/110 mm Hg). Most commonly reported adverse reactions were hypertension (7%-11%), nasopharyngitis (4%), urinary tract infection (3%-6%), and headache (3%-4%). Patient should be monitored for increased blood pressure and urinary retention, particularly in patients with bladder outlet obstruction or those who are taking anticholinergic drugs.[69] Mirabegron has similar adverse effects (except less dry mouth) when compared with tolterodine ER. Blood pressure and

heart rate changes were minimal (<1 mm Hg and <2 beats per minutes, respectively).[22] Mirabegron is a moderate inhibitor of CYP2D6, and may affect the dosage requirement for some 2D6 substrates (eg, metoprolol and desipramine). Thus, drug level monitoring for certain medications with a narrow therapeutic range, such as thioridazine, flecainide, and propafenone, is advised. When initiating a combination of mirabegron and digoxin, start with the lowest possible dose of digoxin and titrate based on drug level and clinical effect.[69]

Other Anticholinergics and Antimuscarinics

Other drugs for treatment of UUI are less effective, are not safer, or have not been adequately studied.[23] Tricyclic antidepressants are generally no more effective than oxybutynin IR, and give bothersome and potentially serious adverse effects (eg, orthostatic hypotension, cardiac conduction abnormalities, dizziness, and confusion). They are also potentially life-threatening in overdose. Therefore, their use should be limited to individuals who have one or more additional medical indications for these agents (eg, depression or neuropathic pain); patients with mixed UI (because of their effect of decreasing bladder contractility and increasing outlet resistance); and possibly those with nocturnal incontinence associated with altered sleep patterns. Because of the lower incidence of adverse effects, desipramine and nortriptyline may be preferred over imipramine and doxepin. However, due to their lower anticholinergic activity, they may not be as effective. Other agents that are not recommended for UUI include propantheline, flavoxate, dicyclomine and hyoscyamine.

Clinical Controversy…

Which approved agent should be used as first-line pharmacotherapy of UUI (oxybutynin, tolterodine, trospium chloride, solifenacin, darifenacin, fesoterodine, or mirabegron)? Financial considerations currently favor generic oxybutynin IR. Choice of an initial agent should be individualized based on tolerability, affordability, and adherence issues. Patient comorbidities may favor the use of more expensive branded agents.

Comparative Data

Several systematic reviews with meta-analyses have examined the comparative effectiveness and adverse effects of antimuscarinic drugs for UI and OAB.[37,70,71] In general, higher doses of a particular drug were associated with greater adverse effects, particularly dry mouth. LA products (oxybutynin and tolterodine) had less dry mouth as compared to IR formulations.

In one meta-analysis of 86 randomized controlled trials, clinical effects of different doses of muscarinic drugs (tolterodine, solifenacin, fesoterodine) were compared.[70] For tolterodine, daily regimens of 1 mg, 2 mg, and 4 mg had similar effects for UI episodes and micturitions in 24 hours. For solifenacin, frequency and urgency were better with 10 mg when compared with 5 mg. For fesoterodine, some outcomes (patient-reported cure, UI episodes, micturitions per 24 hours) were better for 8 mg versus 4 mg; however, there were no differences in efficacy between 4 mg and 12 mg, although dry mouth was significantly higher with 12 mg. Comparing of the IR products of oxybutynin and tolterodine found similar in efficacy. Oxybutynin IR was associated with lower tolerability,

particularly dry mouth, than tolterodine IR or LA. Oxybutynin IR, TDS (patch), and tolterodine LA produced similar reductions in the number of incontinence episodes. However, the oral agents were associated with higher frequencies of dry mouth and constipation. In contrast, the patch formulation was associated with higher frequencies of local (application site) reactions.[70]

Solifenacin had greater clinical efficacy (patient-reported cure or improvement, UI episodes, urgency episodes, and quality of life) than did tolterodine, although constipation was more common. Darifenacin 15 mg daily dose had similar efficacy to oxybutynin in reducing OAB symptoms but a lower occurrence of dry mouth. When comparing darifenacin 30 mg with oxybutynin 30 mg, dry mouth rates were similar, but constipation was more frequent in patients treated with darifenacin 30 mg.[70,71]

In a systematic review of 94 randomized controlled trials involving drugs for UUI, all drugs showed similar small benefits.[37] Per 1,000 treated women, continence was restored in this decreasing order: fesoterodine, oxybutynin or trospium, solifenacin, and tolterodine. Rates of treatment discontinuation due to adverse effects in this decreasing order: oxybutynin, fesoterodine, trospium, and solifenacin.[37] Tolterodine was found to be better tolerated than fesoterodine or oxybutynin. More data are needed to assess long-term adherence and drug safety, quality-of-life improvements, and comparative effectiveness among drugs.[37]

Currently, there is no direct comparison between antimuscarinics and mirabegron. In a meta-analysis of 44 trials examining the effects of mirabegron 50 mg versus antimuscarinics in patients with OAB, mirabegron and antimuscarinics had similar efficacy in reducing UI and UUI, with the exception of solifenacin 10 mg that was more efficacious in improving micturition frequency and frequency of UUI. However, mirabegron had a similar incidence of dry mouth as placebo, and significantly lower incidence than antimuscarinics.[38] Selection of an initial drug therapy most likely depends on side-effect profile, comorbidities, concurrent drug therapy, and patient preference in drug delivery methods. **Table 85-7** lists the frequencies for the most common adverse events for all approved treatment agents based on manufacturers' product information.

TABLE 85-7 Adverse Event Incidence Rates with Approved Drugs for Bladder Overactivity[a]

Drug	Dry Mouth	Constipation	Dizziness	Vision Disturbance
Oxybutynin IR	71	15	17	10
Oxybutynin XL	61	13	6	14
Oxybutynin TDS	7	3	NR	3
Oxybutynin gel	10	1	3	3
Tolterodine	35	7	5	3
Tolterodine LA	23	6	2	4
Trospium chloride IR	20	10	NR	1
Trospium chloride XR	11	9	NR	2
Solifenacin	20	9	2	5
Darifenacin ER	24	18	2	2

Drug	Dry Mouth	Constipation	Dizziness	Vision Disturbance
Fesoterodine ER	27	5	NR	3
Mirabegron ER	3	3	3	NR

IR, immediate release; LA, long acting; TDS, transdermal system; XL, extended release; XR/ER, extended release; NR, not reported.

Botulinum Toxin A

Enthusiasm is considerable for the application of botulinum toxin A for treatment of voiding dysfunction. Botulinum toxin is a naturally occurring powerful muscle relaxant produced by *Clostridium botulinum*.

Injected into smooth or striated muscle, botulinum toxin acts as a neurotoxin by temporarily paralyzing the muscle. The mechanism of action of the paralytic effect is generally ascribed to prevention of the release of the neurotransmitter acetylcholine into the synapse at the neuromuscular junction, although other pathways in neurotransduction may also be affected.

This compound is commercially produced for medical use in a number of conditions such as muscle spasticity, hyperhidrosis, and cosmetic reduction of skin wrinkles. It is currently indicated for the treatment of detrusor overactivity associated with neurologic condition and OAB.[72,73,74] Intradetrusor onabotulinumtoxin A is recommended by AUA as the third-line treatment in adult patients with refractory OAB.[22] In the lower urinary tract, it has also been used to treat external urethral sphincter spasticity by direct injection into the external urethral sphincter.

Botulinum toxin is delivered into the detrusor muscle (intravesical injection) using a cystoscope equipped with a needle. The usual dosage is between 100 and 300 units per session. It is injected through the needle directly into the bladder muscle in 10 to 30 injections spaced over 5 to 10 minutes. The procedure is carried out as an outpatient procedure without general anesthesia. The duration of therapeutic effect varies, lasting usually from 4 to 8 months. Repeat injections are necessary to maintain the beneficial effects.[74]

The adverse effects of botulinum toxin A when used in the urinary tract most frequently include dysuria, hematuria, urinary tract infection, and urinary retention. Urinary retention occurs in up to 20% of treated individuals and persists until the paralytic effects have worn off (up to 6-8 months). Therapeutic and adverse effects may not become evident for 3 to 7 days, presumably because this period of time is required for uptake of the toxin following injection.[73,74]

Intravesical (ie, bladder) injection of botulinum toxin A in patients with refractory OAB resulted in increased bladder capacity, increased bladder compliance, and improved quality of life.[73,74] Adverse effects include urinary tract infection and urinary retention.[73] Comparative data with placebo and other interventions, long-term safety and efficacy outcomes, and data regarding the optimal dose of

botulinum toxin for idiopathic OAB are needed.

An alternative mechanism of delivery other than intravesical injection would greatly improve the appeal of this agent as needle injection can be painful in some individuals. Results of an open-label trial of intravesical botulinum toxin A in dimethylsulfoxide in 21 women with refractory idiopathic detrusor overactivity demonstrated a significant reduction in the frequency of incontinence episodes without any effect on postvoid residual urine volumes.[75] Further studies are needed in this regard.

Catheterization Combined with Medications

Patients with UUI and an elevated postvoid residual urine volume due to retention may require intermittent self-catheterization along with frequent voiding between catheterizations. If intermittent catheterization is not possible, surgical placement of a suprapubic catheter may be necessary. Use of a chronic indwelling catheter should be avoided because of the increased occurrence of urinary tract infections and nephrolithiasis.

Regardless of catheterization status, patients may experience symptom relief with judicious use of oxybutynin (IR, XL, or TDS formulations), tolterodine (IR or LA formulations), trospium chloride, solifenacin, fesoterodine, darifenacin, or mirabegron, as these agents relax the detrusor muscle and enhance bladder storage. Patients with UUI and symptoms of urinary retention may also benefit from an α-adrenergic receptor antagonist that relaxes the internal bladder sphincter (eg, prazosin, terazosin, doxazosin, tamsulosin, silodosin, and alfuzosin). Although theoretically of benefit, bethanechol, a cholinergic agonist, has not been demonstrated effective in improving bladder emptying in well-done trials. In addition, it causes numerous bothersome (eg, muscle and abdominal cramping and diarrhea) and potentially life-threatening adverse effects and should not be used in patients with asthma or heart disease.[23]

Urethral Underactivity

7 Urethral underactivity, or SUI, may be aggravated by agents with α-adrenergic receptor blocking activity, including prazosin, terazosin, doxazosin, tamsulosin, alfuzosin, silodosin, methyldopa, clonidine, guanfacine, guanadrel, and labetalol. The goal of therapy for SUI is to improve the urethral closure mechanism by stimulating α-adrenergic receptors in the smooth muscle of the bladder neck and proximal urethra, enhancing the supportive structures underlying the urethral epithelium, or enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex.[76]

Estrogens

Local and systemic estrogens have been used extensively for the pharmacologic management of SUI since the 1940s. Estrogens are believed to work via several mechanisms, including enhancement of the proliferation of urethral epithelium, local circulation, and numbers and/or sensitivity of urogenital α-adrenergic receptors. However, a trial has questioned whether estrogens exert a stimulatory effect on vaginal collagen production, at least over the short-term.[77]

A meta-analysis of 34 trials evaluating the use of local or systemic estrogen therapy on UI in postmenopausal women found that systematic administration of estrogen alone or in combination with progesterone resulted in UI worsening.[78] In fact, observational studies have documented that oral or systemic estrogen use is associated with an increased risk of UI compared with that in nonusers.[79] There was some evidence that vaginal estrogen (vaginal cream or pessaries) may improve UI, and reduce urgency and frequency. The long-term effects of this therapy in older women are unknown. A recent meta-analysis of 17 trials of local estrogen compared to placebo or no treatment found beneficial effects on UI and OAB symptoms and some urodynamic parameters.[80] Different forms of vaginal estrogen (ring, pessary) appear to have similar improvements in urinary symptoms (SUI, UUI, frequency, urgency). Studies comparing vaginal estrogen alone or in combination with antimuscarinic drugs (tolterodine or oxybutynin) or pelvic floor muscle exercises found greater improvement in subjective measures of UI in the combination approach. If estrogens are to be used for treatment of UI or OAB in postmenopausal women, only topical products should be administered, potentially combined with other treatment modalities such as pelvic floor muscle exercises or antimuscarinic drugs.

α-Adrenergic Receptor Agonists

Numerous open trials have supported the use of a variety of α-adrenergic receptor agonists in SUI, including ephedrine, norfenefrine, phenylpropanolamine, and midodrine. Phenylpropanolamine was withdrawn from the US market in 2000 because of a risk for stroke in women using the agent.[80] Some patients may have left over supplies of this agent or may obtain it from international sources. If so, individuals with the contraindications listed later in the chapter (especially coronary artery disease and/or cardiac arrhythmias) should be warned against self-treatment with this or other α-adrenergic receptor agonists.

Placebo-controlled comparative trials with phenylpropanolamine, norfenefrine, and norephedrine support the modest efficacy of these agents for treatment of mild or moderate SUI.[81,82] These agents have been found to variably affect maximum urethral closure pressure and functional urethral length.

Adverse effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness. Contraindications to the use of these agents include the presence of hypertension, tachyarrhythmias, coronary artery disease, myocardial infarction, cor pulmonale, hyperthyroidism, renal failure, and narrow-angle glaucoma.

Several studies have evaluated whether the clinical and urodynamic effects of a combination of estrogen and an α-adrenergic receptor agonist exceed those of the individual therapies in SUI.[82] In general, combination therapy has resulted in somewhat superior clinical and urodynamic responses compared with monotherapy, including severity of complaints, amount of urine lost per episode, number of daily voluntary micturitions, number of leakage episodes per day, patient preference, pad use, maximum urethral closure pressure, functional urethral length, and pressure transmission ratio.

Duloxetine

Duloxetine, a dual inhibitor of serotonin and norepinephrine reuptake (SNRI), was approved in 2004 for treatment of depression and painful diabetic neuropathy in the United States.[83] It is approved for SUI in Europe only. It is believed to affect central serotoninergic and noradrenergic regions, which are involved in ascending and descending control of urethral smooth muscle and the external urethral sphincter. These mechanisms facilitate the bladder-to-sympathetic reflex pathway, increasing urethral and external urethral sphincter muscle tone during the storage phase.

The mean terminal disposition half-life, clearance, and volume of distribution of duloxetine in healthy volunteers are 10 to 12 hours, 114 to 119 L/h, and 1,787 to 1,943 L, respectively. Duloxetine is metabolized by CYP2D6 and 1A2 enzymes to form multiple metabolites and then eliminated in the urine. Duloxetine may increase the concentrations, drug exposure and half-lives of CYP2D6 substrates (eg, desipramine). Meanwhile, the drug concentration of duloxetine can be increased by CYP2D6 inhibitors (eg, paroxetine) and CYP1A2 inhibitors (eg, fluvoxamine).[83]

Moderate hepatic dysfunction (Child-Pugh class B) significantly increases mean AUC and terminal disposition half-life of duloxetine. Mild or moderate renal impairment (creatinine clearance 30-80 mL/min [0.50-1.33 mL/s]) does not affect drug disposition. In severe renal impairment (hemodialysis patients), mean peak plasma concentration and AUC are both increased 100%, whereas metabolite concentrations are increased up to 900%.[83]

In six large double-blinded, randomized, placebo-controlled clinical trials that evaluated duloxetine for SUI, duloxetine therapy produced significant reductions in UI episode frequency and number of micturitions per day, improvement in incontinence quality-of-life questionnaire scores and patient self-assessment, and increase in mean micturition interval. Results were independent of baseline UI severity (severity based on incontinent episode frequency). Significant intergroup differences were seen by week 4. However, cure rates were generally not improved by duloxetine. When evaluating the absolute differences between treatments, the actual benefit of duloxetine was generally quite modest.[83] Duloxetine also reduced incontinence episodes and improved quality of life in men with SUI after radical prostatectomy.[84]

A randomized, placebo-controlled clinical trial evaluated the effects of duloxetine (80 mg daily), pelvic floor muscle training (PFMT), and the combination of both modalities on incontinent episode frequency, incontinence-related quality of life, pad use, and patient global impression of change. Sham PFMT was used in the placebo group. Results indicated that duloxetine plus PFMT were probably additive in effect and that combination therapy afforded greater improvement than either monotherapy.[85]

The adverse events associated with duloxetine may make adherence problematic. In the SUI trials, treatment-emergent adverse events occurred in 68% to 93% of duloxetine and 50% to 72% of placebo recipients. Premature study withdrawal rates (due to adverse events) were as high as up to 33%. The most common adverse events reported with duloxetine were nausea (≤46%), headache (≤27%), constipation (≤27%), dry mouth (≤22%), and insomnia (≤14%). Of interest, the drug may be associated with small increases in blood pressure (such as venlafaxine, another SNRI) and withdrawal symptoms (sleep disturbances). Unfortunately, adherence to long-term therapy is quite poor due to a

combination of adverse events and lack of efficacy.[86]

Despite these negatives, duloxetine is the first drug approved by a regulatory agency for treating SUI in Europe. Based on studies conducted to date, a dosage regimen of 40 to 80 mg/day (in one or two doses) appears reasonable. Gradual dose titration (40 mg daily for 2 weeks, then 80 mg daily) helps reduce the risks of nausea, dizziness, and premature drug discontinuation. If cessation of duloxetine is desired, consider tapering the dosage by 50% for 2 weeks before discontinuation to avoid withdrawal symptoms.

Venlafaxine

Venalfaxine is another SNRI. A double-blind, randomized, placebo-controlled clinical trial has demonstrated the benefit of venlafaxine 75 mg once daily for 12 weeks over placebo in terms of incontinence episode frequency, voiding interval, quality of life, and patient global impression of improvement. Nausea occurred in 40% of the venlafaxine group compared with 15% of the placebo group.[87]

Overflow Incontinence

Overflow incontinence secondary to benign or malignant prostatic hyperplasia may be amenable to pharmacotherapy. For management of malignant prostatic disease, see Chapter 131. The pharmacotherapy of BPH is discussed in Chapter 84.

Clinical Controversy…

The optimal approach to pharmacotherapy of SUI is unclear. Although not supported by evidence-based medicine, many clinicians initiate a trial of topical estrogen, followed by addition of an α-adrenergic receptor agonist in estrogen nonresponders unless contraindicated. No drugs, except duloxetine in Europe, have been approved for the management of SUI. However, long-term tolerability issues may hinder chronic use.

PERSONALIZED PHARMACOTHERAPY

Patient factors (age, comorbidities, concurrent drug therapies, ability to adhere to prescribed regimen, etc) should be considered when selecting pharmacotherapy for patients with UI.

All anticholinergic/antimuscarinic drugs have similar contraindications and precautions, including urinary retention, gastric retention, uncontrolled narrow-angle glaucoma, CNS effects, angioedema, and myasthenia gravis. IR formulations of older agents (oxybutynin and tolterodine) have been associated with higher rates of anticholinergic adverse effects (dry mouth, constipation, headache, dyspepsia, dry eyes, cognitive impairment, tachycardia, and urinary retention). Older patients are particularly susceptible to these adverse events, thus require close monitoring. Significant dry mouth may lead to dental caries, ill-fitting dentures, and swallowing difficulty. Orthostatic hypotension and sedation may lead to falls in patients with baseline cognitive or cardiac conditions. Constipation is prevalent among the older patients because of polypharmacy and age-related physiologic changes.

All patients on anticholinergics should be warned about risk of somnolence and advised not to drive or operate heavy machinery until they know how the drugs affect them. Women with mixed UI or UUI plus urethritis or vaginitis may benefit from a topical estrogen (alone or in combination with an anticholinergic drug). Men with irritative symptoms of BPH that are nonresponsive to drug therapy may benefit from anticholinergic therapy while being closely monitored for the risk of precipitating acute urinary retention.

Antimuscarnic drugs should be considered for the management of UUI as monotherapy or in combination with nonpharmacologic interventions. None of the currently available antimuscarnic agents appears to have a clear advantage in efficacy over others. Selection of an agent should be based on drug tolerability, dosing convenience, cost considerations, and patient preference. In general, LA or ER products given once daily are preferable over IR ones because of better tolerability. Dose escalation of IR formulations may result in improved efficacy, albeit limited, at the cost of an increase in adverse event frequency and severity. Newer antimuscarnic agents and mirabegron may be good choices for patients who are intolerable of CNS adverse effects associated with older agents. Topical formulations, such as oxybutynin TDS or gel, may offer favorable systemic adverse effect profiles and convenient dosing. Selection of an agent should also be based on patient factors, such as renal/hepatic function, concomitant diseases, concurrent drug therapy, and medication adherence. It is advisable to review concomitant medications for any possibility of additive, synergistic, antagonistic drug interactions in cholinergic system and liver enzymes (CYP3A4 and 2D6).

EVALUATION OF THERAPEUTIC OUTCOMES

8 Assessment of patient outcomes should include efficacy, side effects, adherence, and quality of life. During long-term management of UI, patient-specific clinical signs and symptoms of most distress (“bother”) to the individual must be monitored. A daily diary may be useful in this regard. Some of the short-form instruments used in incontinence research for measuring symptom impact and condition-specific quality of life can be used in clinical monitoring. In addition, quantitating the use of ancillary supplies, such as pads, may be useful.

9 The main goal of therapy is to minimize the signs and symptoms most bothersome to the patient, as well as the use of pads and other ancillary supplies or devices. Total elimination of UI signs and symptoms may not be possible, and patients and practitioners need to mutually establish realistic goals of therapy. Because the therapies for UI frequently have nuisance adverse effects (eg, anticholinergic effects such as dry mouth, constipation, sedation, etc) that may compromise regimen adherence, the presence and severity of adverse effects must be carefully elicited at each visit to the healthcare practitioner. Queries of the patient and caregiver regarding CNS effects are important in elderly or frail patient as these effects can be severe enough to cause loss of independent living skills. Emergence of adverse effects may necessitate drug dosage adjustment or use of alternative strategies (eg, chewing sugarless gum, sucking on hard sugarless candy, or use of saliva substitutes in xerostomia) or even drug discontinuation. Patient should be encouraged to persist with a particular treatment for 4 to 8 weeks before declaring treatment failure. Nonresponders to an antimuscarinic should be offered at least one other antimuscarinic and/or dose modification attempted to obtain a better balance between efficacy and side effects.

Chapter e86: Function and Evaluation of the Immune System

Daniel A. Zlott; Nicole Weimert Pilch; Geoffrey M. Thiele

INTRODUCTION

KEY CONCEPTS

- 1 Cells of the immune system are derived from the pluripotent stem cell. Hematopoiesis is closely regulated to assure adequate numbers of different cell types. The development of these different cells or cell lineages depends on cell-to-cell interactions and hematopoietic growth factors.
- 2 Upon activation, dendritic cells (DCs) express higher concentrations of major histocompatibility complex class II molecules, B7-1, B7-2, CD40, ICAM-1, and LFA-3 molecules than other antigen-presenting cells (APCs). They also produce more IL-12. These differences may explain why, in vitro, DCs are the most efficient APC.
- 3 A T lymphocyte expresses hundreds of T-cell receptors (TCRs). All the TCRs expressed on the surface of an individual T lymphocyte have the same antigen specificity.
- 4 An immature B lymphocyte expresses thousands of membrane-bound surface immunoglobulin (sIg) as IgM (monomeric) or IgD, all with the same specificity (ie, antigen-binding site). Upon antigen stimulation and T cell help, the immature B lymphocyte matures (proliferates, class-switches and becomes a plasma cell) to secrete different isotypes (eg, IgM [pentamer], IgA, immunoglobulin G [IgG], and IgE) with the same specificity as the original membrane-bound sIg.
- 5 Serum protein electrophoresis determines the total concentration of all circulating proteins, including the immunoglobulins (ie, IgG, IgA, IgM, IgD, and IgE). The concentration of the individual isotypes can be determined with isotype-specific quantification methods. Most clinical laboratories quantitate only IgG, IgM, and IgA because they are the most prevalent isotypes in the bloodstream. In patients with allergic disorders, quantification of IgE is rarely useful.

- 6 An understanding of the mechanism of action of immunomodulators allows a clinician to anticipate potential adverse effects. The benefit of manipulating immune responses must be balanced with the potential consequences and long-term sequela (eg, tumor growth, infections, etc) of such manipulation.

The immune system is a complex network of barriers, organs, cellular elements, and molecules that interact to defend the body against invading pathogens. The *immune system* is actually composed of two distinct systems of immunity: innate immunity and adaptive immunity. In brief, innate immunity includes a series of nonspecific barriers (physical and chemical), along with cellular and molecular elements strategically deployed and positioned to prevent or quickly neutralize infection. Adaptive immunity works in concert with the innate immune system. In contrast to innate immunity, adaptive immunity constantly evolves and adapts to the invading pathogens. The hallmarks of the adaptive immune response are; *diversity*, *memory*, *mobility*, *self-versus nonself-discrimination*, *redundancy*, *replication*, and *specificity*.[1] *Diversity* indicates the capability of the immune system to respond to many different pathogens or strains of pathogens. Immunological *memory* ensures a quicker and more vigorous response to a subsequent encounter with the same pathogen. If an individual has seen something before, the odds are good that he or she will see it again. So the individual will make more of these cells and have them ready. *Mobility* of components of the immune system enables local reactions to provide systemic protection. *Discrimination of self versus nonself* helps prevent the immune response from responding to ourselves, and thus results in tolerance to our own materials. *Redundancy* refers to the ability of the immune system to produce components with similar biological effects from multiple cells lines, such as inflammatory cytokines. *Replication* of the cellular components of the immune system amplifies the immune response. *Specificity* describes the ability of the immune system to distinguish between dissimilar antigens.

MAJOR TISSUES AND ORGANS OF THE IMMUNE SYSTEM

While numerous cells of the immune system have the ability to migrate to most body tissues, some tissues and organs serve as key members of the immune system. These include primary and secondary lymphoid tissues and organs. *Primary lymphoid tissues and organs*, the bone marrow and thymus, provide an environment for the development and maturation of select cells of the immune system. It is here that these select cells of the immune system mature and become tolerant of self and competent to respond to foreign antigens. Importantly, no immune response occurs in these sites. *Secondary lymphoid organs* provide an environment where various cells of the immune system interact with and respond to antigens.[2]

Primary Lymphoid Tissues

Bone Marrow

The bone marrow is the predominant primary lymphoid tissue of the body because it is the source of all cellular elements of the blood (erythrocytes, leukocytes, and thrombocytes [ie, platelets]). The few exceptions to this rule are mostly confined to fetal development when some blood cells are

transiently produced in the yolk sac, liver, spleen, thymus, and lymph nodes.[3] Regardless of where they are formed, all blood cells arise from common self-renewing pluripotent stem cells via the process of *hematopoiesis* (**Figure e86-1**). During hematopoiesis, pluripotent stem cells differentiate along particular myeloid and lymphoid lineages to produce the leukocytes of the immune system, erythrocytes, and thrombocytes.[4,5] Hematopoiesis is controlled by soluble mediators called hematopoietic growth factors/cytokines or colony-stimulating factors (CSFs) that are multifunctional and drive responses, such as growth, survival, proliferation, differentiation, maturation, and functional activation.[6] The destiny of the leukocytes (if they survive the maturation process) is to become mature cells of the immune system directly from the bone marrow (all leukocytes except T lymphocytes), or to migrate out of the bone marrow to continue their maturation elsewhere (T lymphocytes in the thymus). Selected hematopoietic growth factors are identified in Figure e86-1, and a more comprehensive list appears in **Table e86-1**. Currently, four human hematopoietic cytokines have one or more recombinant products that are FDA-approved for clinical use: erythropoietin (EPO); granulocyte colony-stimulating factor (G-CSF); granulocyte-macrophage colony-stimulating factor (GM-CSF); and interleukin 11 (IL-11).[7] In addition, 2 small-molecule thrombopoietin receptor agonists, eltrombopag and romiplostim, are FDA-approved for the treatment of various autoimmune-mediated platelet disorders.[8,9]

FIGURE e86-1

Basic model of hematopoiesis, outlining the various pathways blood cells taken from their origin as bone marrow stem cells through stages in which they are progressively selected to become monopotent mature cells with specific functions. Selected hematopoietic growth factors include: EPO, erythropoietin; FLT-3L, fms-like tyrosine kinase ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; NK, natural killer; SCF, stem cell factor; TPO, thrombopoietin.

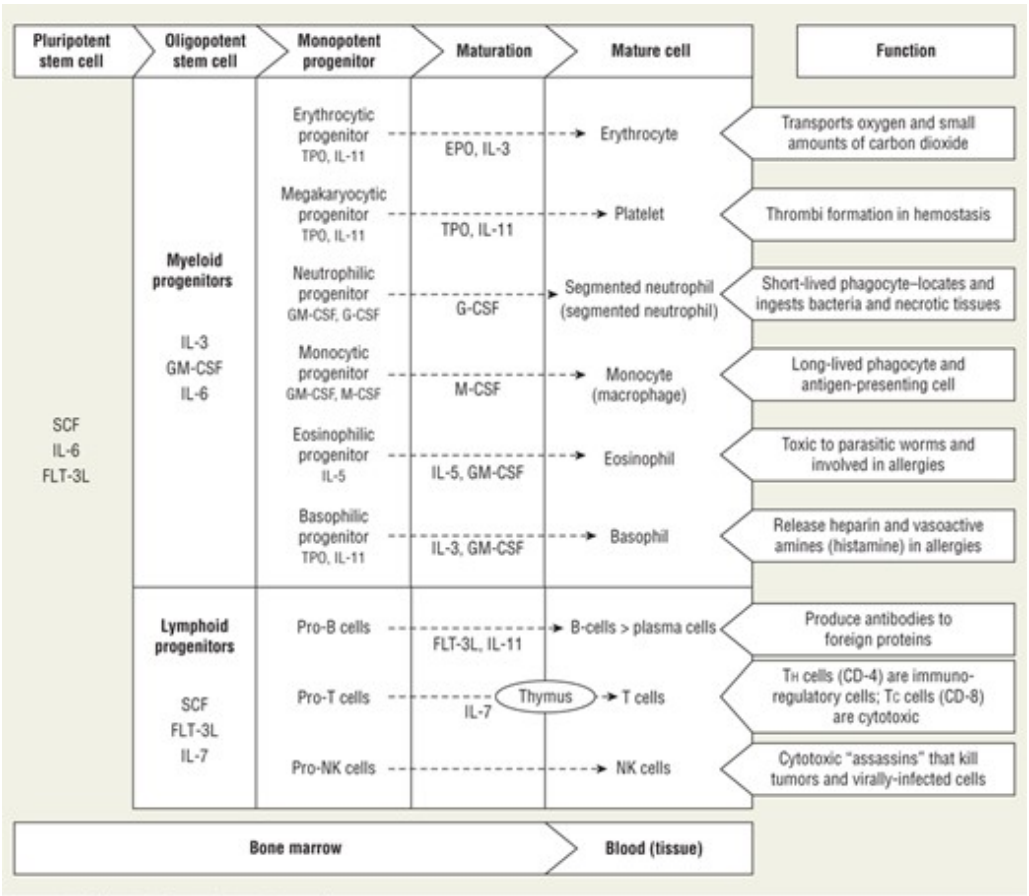

TABLE e86-1 Hematopoietic Growth Factors or Colony-Stimulating Factors

Cytokine	Sources	Principal Effects
EPO	Kidney, liver	Erythrocyte production and maturation
GM-CSF	T lymphocytes, macrophages, bone marrow stromal cells	Maturation and activation of granulocytes, monocytes/macrophages, and eosinophils
G-CSF	Macrophages, bone marrow stromal cells	Maturation and activation of neutrophils
M-CSF	Macrophages, bone marrow stromal cells	Maturation and activation of monocytes/macrophages
TPO	Liver, kidney	Platelet production
SCF	Bone marrow stromal cells, constitutively	Stem cell and progenitor cells activation
FLT-3L	Bone marrow stromal cells	Early-acting growth factor
IL-3	T lymphocytes, macrophages	Maturation and differentiation of hematopoietic and mast cells
IL-5	Activated T lymphocytes	Eosinophil production
IL-6	Activated T lymphocytes, bone marrow stromal cells	Progenitor cell stimulation
IL-7	Bone marrow stromal cells	T-cell maturation/survival

Cytokine	Sources	Principal Effects
IL-11	Bone marrow stromal cells	Growth factor for B lymphocytes and megakaryocytes

EPO, erythropoietin; FLT-3L, fms-like tyrosine kinase ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; TPO, thrombopoietin.

Thymus

The thymus is a bilobed primary lymphoid organ located in the superior mediastinum between the aorta and the sternum. Its primary function is to produce mature T cells (thymus-dependent lymphocytes), which are the leukocytes responsible for cell-mediated immunity, including cytotoxic actions and immunoregulation. Through an intricate multistep process called thymic education, T cells that do not react to self and have all of the appropriate receptors are considered beneficial to the immune system and leave the thymus. T cells that fail the thymic education test (estimated at > 99% of all T cells) are eliminated via apoptosis.[1]

Secondary Lymphoid Tissues

Spleen

The spleen is a slender elongated secondary lymphoid organ located in the upper left quadrant of the abdomen that receives blood from the splenic artery. Although it is not a vital organ, it functions as an immunological filter of the blood and destroys defective and old erythrocytes. It contains compartments designated as red pulp and white pulp. The white pulp provides an environment for the interaction of B cells and T cells where debris in the blood is able to interact with antigen-presenting cells (APCs), T cells, and B cells to initiate cell-mediated immune responses (T cells) and antibody production (B cells). The red pulp serves as a site of red blood cell degradation. The spleen sequesters many cellular elements (leukocytes, erythrocytes, and platelets) and can become dangerously congested during a strong inflammatory response to result in a condition termed *splenomegaly*.

Lymph Nodes

Lymph nodes are normally small BB-sized lymphoid organs widely distributed between the groin and the neck. While the spleen filters blood, lymph nodes act as immunological filters for interstitial lymphatic fluid from the body's tissues. Lymph nodes provide an environment for the interaction of debris with APCs and other immune cells (T cells and B cells).[2] Lymph nodes may sequester activated immune cells (or tumor cells) and become inflamed and engorged causing lymphadenopathy.

Mucosa-Associated Lymphoid Tissue

Mucosa-associated lymphoid tissue (MALT) is the most extensive component of human lymphoid tissue and is distributed along mucosal linings of the body.[10] MALT may consist of well-defined

networks of primary lymphoid follicles and other associated immunocompetent cells (adenoids, appendix, intestinal Peyer's patches, and tonsils), small solitary lymph nodes, or loosely organized clusters of lymphoid cells that are found in intestinal villi. The primary function of these tissues is to filter, trap, and remove pathogens that breach mucosal surfaces. In addition to neutralizing pathogens, MALT generates plasma cells (activated B cells) that secrete antibodies, some of which are of the secretory IgA class of immunoglobulins with unique components to enable increased longevity in mucosal sites.

As mentioned earlier, the immune system includes two functional divisions: (a) The *innate* or nonspecific immune response which encodes evolutionary genes aimed at providing rapid responses against non-mammalian targets; and (b) the *adaptive* or specific immune response which uses cells that can rearrange their DNA in order to create specific structures on the T cell receptor (on T cells) and surface immunoglobulin (sIg) (on B cells) which bind individual antigens or proteins (**Table e86-2**).[11] While we tend to teach these as two separate models for simplicity, these divisions extensively interact with the adaptive immune response driving the innate immune response.[12] Awareness of each component of the immune system and the consequences of disrupting homeostasis must be understood in order to appropriately dose, administer, and monitor the effect of medications given to manipulate immune responses.

TABLE e86-2 Functional Divisions of the Immune System

	Innate	Adaptive
Exterior defenses	Skin, mucus, cilia, normal flora, saliva, low pH of the stomach, skin, genitourinary tract	None
Specificity	Limited and fixed	Extensive
Memory	None	Yes
Time to response	Hours	Days
Soluble factors	Lysozymes, complement, C-reactive protein, interferons, mannose-binding lectin, antimicrobial peptides[a]	Antibodies, cytokines
Cells	Neutrophils, monocytes, macrophages, natural killer cells, eosinophils	B lymphocytes, T lymphocytes

[a]Cathelicidins α-defensins, β-defensins.

METHODS TO DISTINGUISH SELF FROM NONSELF

The immune system is designed to attack and destroy a broad spectrum of foreign antigens/pathogens. However, the immune system must be able to distinguish self from nonself, through a process now known as *self-tolerance*. If this did not occur, then it would be easy to see how the immune system could direct immune cells against self-tissues.[13] The body employs many tactics to avoid attacking itself, but when self-tolerance fails this may lead to the development of an autoimmune disease.

Innate Immune System

Physical Defense

Physical and chemical defenses are the most rudimentary form of innate immunity and the first line of defense against invading pathogens. The skin, the largest organ of the body, has the primary role of providing a physical defense. Alterations in the skin, such as burns or abrasions, allow an easy portal of entry for pathogens. The rapid turnover of intestinal cells also limits systemic infection as cells including infected cells are sloughed frequently. Drugs, such as cell-cycle, phase-specific antineoplastic agents, that disrupt the sloughing process, leave the patient at an increased risk for infections. Likewise, the respiratory tract has its forms of physical defense. The mucus coating the epithelial cells serves in part to prevent microorganisms from adhering to cell surfaces, and the cilia lining the epithelium of the lungs help to repel inhaled organisms. The combination of cilia, mucus, and reactive coughing provides a natural barrier to invasion via the respiratory tract. The low pH of the stomach (pH 1-2) is inhospitable to most organisms and is a chemical defense resulting in the death of the microorganism. Other examples of mechanical or chemical defenses include; normal urine flow, lysozymes in tears and saliva, and the normal flora in the throat, the lower GI tract, and the genitourinary tract. Disruption of the normal physical and chemical defense systems through mechanical ventilation, for example, places the host at substantial risk for penetration by a pathogenic organism.[14]

Phagocytosis and Opsonization

If an infectious pathogen invades and is able to infiltrate through a host's physical and chemical defense systems, the cells of the innate immune system are activated to halt progression of the infection. These cells are present from birth and use a preexisting, but limited, repertoire of unique receptors to recognize and destroy pathogens. Innate immune cells include subgroups of leukocytes: monocytes/macrophages, neutrophils, basophils, mast cells, and eosinophils. When stimulated by a foreign pathogen, mast cells, and basophils secrete inflammatory mediators. Monocytes/macrophages, neutrophils, mast cells, and eosinophils act as phagocytes. Phagocytes are cells, which recognize, internalize, and degrade the invading pathogens. This process may occur in two ways: opsonin-dependent or opsonin-independent phagocytosis. For opsonin-dependent phagocytosis, opsonins like antibody (eg, IgG), complement (eg, C3b), or lectin (eg, C-reactive protein) coat the infectious pathogen by sticking to conserved structures on the infectious pathogens. Once the pathogen is opsonized, the opsonin (antibody, complement, or lectin) binds to specific the receptors on the phagocyte (**Figure e86-2**) and activates the phagocytic process. For opsonin-independent phagocytosis, innate leukocytes use pattern recognition receptors (PRRs), which bind to highly conserved structures present on a large number of different microorganisms. PRRs on the phagocytes directly recognize the conserved ligands, also known as Pathogen Associated Molecular Patterns (PAMPs), on the surfaces of infectious pathogens (**Table e86-3**), leading to the immediate phagocytosis of the pathogen (see Figure e86-2). The PRRs include the macrophage mannose receptor, macrophage scavenger receptor, and members of the toll-like receptor family. Toll-like receptors are a family of PRRs on the cell-surface of innate leukocytes. To date, at least 10 toll-like receptors have been identified in humans. They recognize a broad spectrum

of conserved structures ranging from lipopolysaccharide and flagellin on bacteria, to zymosan on yeast, to double-stranded RNA from RNA viruses (see Table e86-3). Binding of the PAMPs to the toll-like receptors (a PRR) allows the phagocyte to recognize and engulf the pathogen. This binding of toll-like receptors (PRRs) to its PAMPs also results in secretion of chemokines, inflammatory cytokines, and antimicrobial peptides and increased expression of costimulatory proteins (eg, B7) and major histocompatibility complex (MHC) molecules by the phagocyte. This leads to the recruitment and activation of antigen-specific lymphocytes.[12,15,16]

FIGURE e86-2

Phagocytosis of bacteria by macrophages, dendritic cells (DCs), and neutrophils. Macrophages, DCs, and neutrophils recognize bacteria opsonized (coated) with antibody or complement (C3b). On the surface of macrophages, DCs, and neutrophils reside receptors for antibody (Fc receptors) and complement (CR1, CR3, and CR4). In addition, these cells may recognize the bacteria by pattern recognition receptors on the surface of macrophages, DCs, and neutrophils. Pattern recognition receptors include toll-like receptors, scavenger receptors, and mannose receptors.

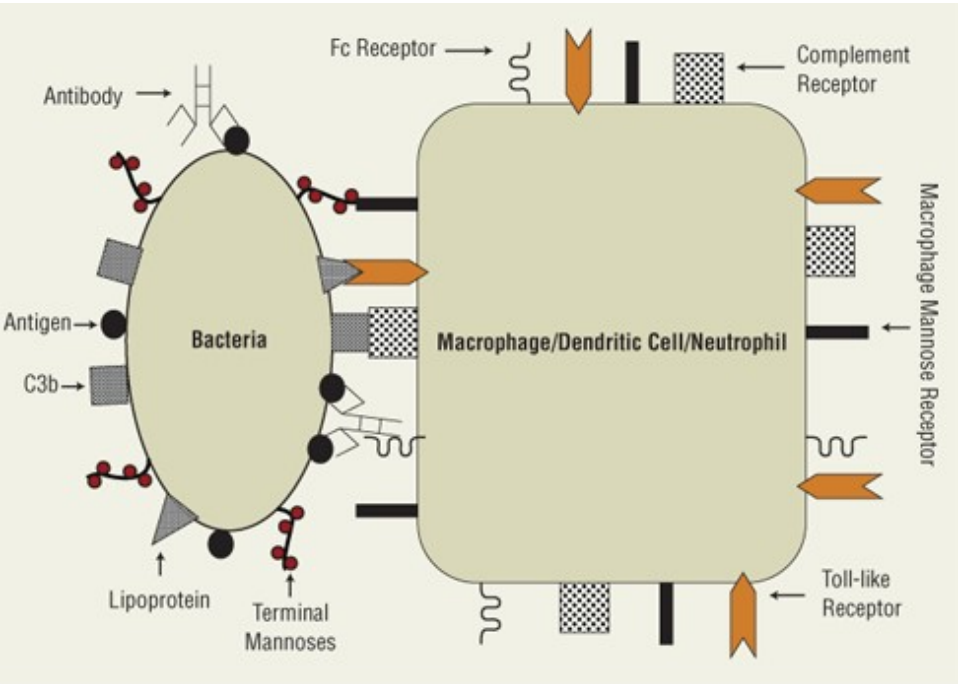

TABLE e86-3 Ligands for Pattern Recognition Receptors

Pathogen Ligand	Type of Organism
Lipoteichoic acid	Gram-positive organisms
Lipopolysaccharide	Gram-negative organisms
Mannose	Fungi, gram-positive, gram-negative
Double-stranded RNA	RNA viruses
Triacyl lipopeptides	Gram-positive, gram-negative

Pathogen Ligand	Type of Organism
Peptidoglycans	Gram-positive
Bacterial flagella	Various

Cells of the Innate Immune System

Neutrophils, eosinophils, and basophils are considered granulocytes because of the presence of numerous cytoplasmic granules in these cells that contain inflammatory mediators or digestive enzymes. Their names are derived from their staining characteristics. For example, neutrophils are named because they stain a neutral pink. Neutrophils comprise most of the total leukocytes in the bloodstream. They are polymorphonuclear cells, which serve as the primary human defense against invasive bacteria. Neutrophils migrate from the bloodstream into infected or inflamed tissue in response to chemotactic factors, such as IL-8 and breakdown products of complement (C3a and C5a). In this migration, a process termed *chemotaxis*, neutrophils reach the site of inflammation and then recognize (through the PRRs and PAMPs), adhere to, and phagocytose pathogens. Additionally, complement and antibody can bind to specific epitopes on a pathogen (opsonize), and then bind to their corresponding receptors on neutrophils to phagocytize the pathogen. During phagocytosis, the engulfed pathogen is internalized within the phagocyte into a cytoplasmic lysosome. The neutrophil then releases its granular contents into lysosomes to form phagolysosomal granules, which generates the release of oxidative metabolites that destroy the engulfed pathogens.[17]

Eosinophils are also granulocytic cells involved in innate immunity, and can migrate from the blood into the tissues. They play a less significant role in combating bacterial infections, but eosinophils play a major role against nonphagocytable multicellular pathogens, such as parasites. After activation via high-affinity receptor for IgE (ie, Fcε), eosinophils exocytose their granules causing the release of basic proteins or reactive oxygen species into the microenvironment, causing lysis of the parasite. In addition to Fcε receptors, eosinophils express lower levels of complement receptor 3 and Fcγ for IgG than neutrophils. The high affinity of eosinophils for IgE contributes to their role in the pathogenesis of allergies.[18]

Macrophages and monocytes are mononuclear cells capable of phagocytosis. Tissue macrophages arise from the migration of monocytes from the bloodstream into the tissues. Macrophages differ from monocytes by possessing an increased number of Fc and complement receptors. Macrophages are found within specific tissues and are often called histiocytes. However, they are most often referred to by specialized names depending on the site where they are found (eg, Kupffer cells in the liver, osteoclasts in the bone, and microglial cells in the CNS).[19] The term reticuloendothelial system was commonly used to refer to phagocytic cells of the reticular connective tissue, but the preferred nomenclature is now the mononuclear phagocyte system.

Despite the first description in 1868 of Langerhans cells, a type of dendritic cell (DC) found in the skin, our current understanding of the biologic function of DCs did not develop until the past decade. Before pathogen recognition, most DCs are in an immature/resting state with limited ability to activate T lymphocytes, but they express numerous receptors (eg, Fc receptors of IgG and IgE, macrophage mannose receptor, and toll-like receptors) enabling rapid recognition and phagocytosis

of multiple antigens. Following antigen recognition and particle engulfment, DCs become activated and greatly increase their expression of the MHC class II, B7-1/B7-2 (CD80/CD86), CD40, and adhesion molecules. In addition to phagocytosing pathogens in the innate immune system, macrophages, and DCs act as APCs to stimulate the adaptive immune system. Macrophages and DCs perform this function by internalizing the pathogens, digesting them into small peptide fragments, and then combining these antigenic fragments with MHC molecules, which move to the cells surface and present peptides to the T-cell receptor (TCR) on the surface of a T lymphocyte. The recognition of the antigen/MHC complex by the TCR is the first step in the activation of the T lymphocyte (**Figure e86-3**). B lymphocytes can also act as APCs, which is important to the development of specific antibodies (**Figure e86-4**).[19,20,21]

FIGURE e86-3

Induction of T-helper type 1 (TH_1) response. (1) The APC, in this case a DC, engulfs the pathogen by any of numerous cell surface receptors (Figure e86-2). After phagocytosis of the bacteria by the DC (A), the pathogen is digested into small peptides and become associated with major histocompatibility (MHC) class II within the endosome (B). Finally, the MHC class II plus peptide is expressed on the surface of the DC (C). The activated DC also secretes interleukin (IL)-12. (2) Naïve $CD4^+$ T-lymphocyte activation requires the T-cell receptor (TCR) to recognize the antigenic peptide in association with MHC class II as well as the B7-1 (CD80) binding to CD28. The binding of CD2-CD58 and LFA-1 (CD11a/CD18) allows adherence between the T lymphocyte and DC. Upon activation, the TH_1 $CD4^+$ T lymphocyte secretes IL-2 and interferon (IFN)-γ and increases the production and expression of the IL-2 receptor (ICAM, intercellular adhesion molecule).

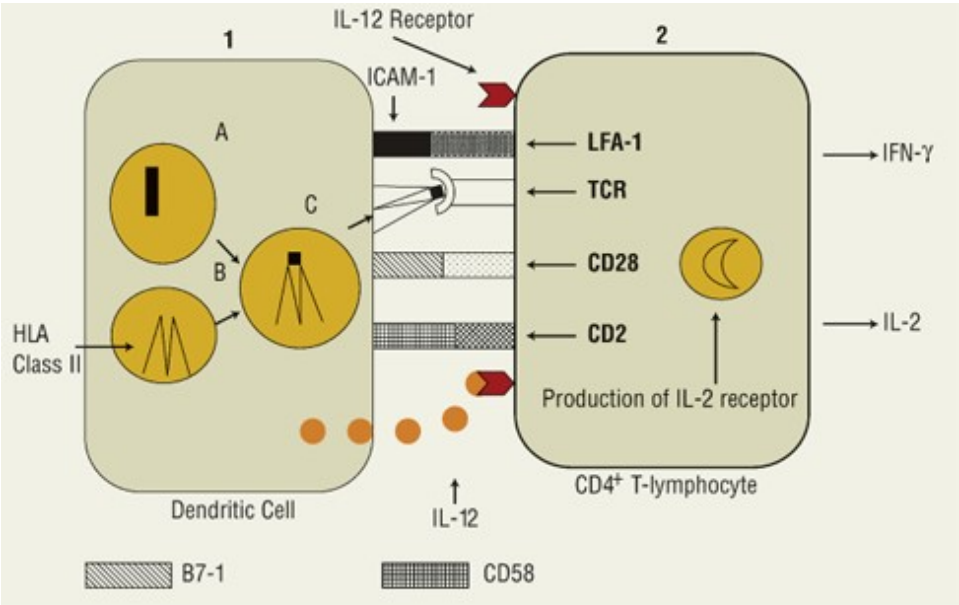

FIGURE e86-4

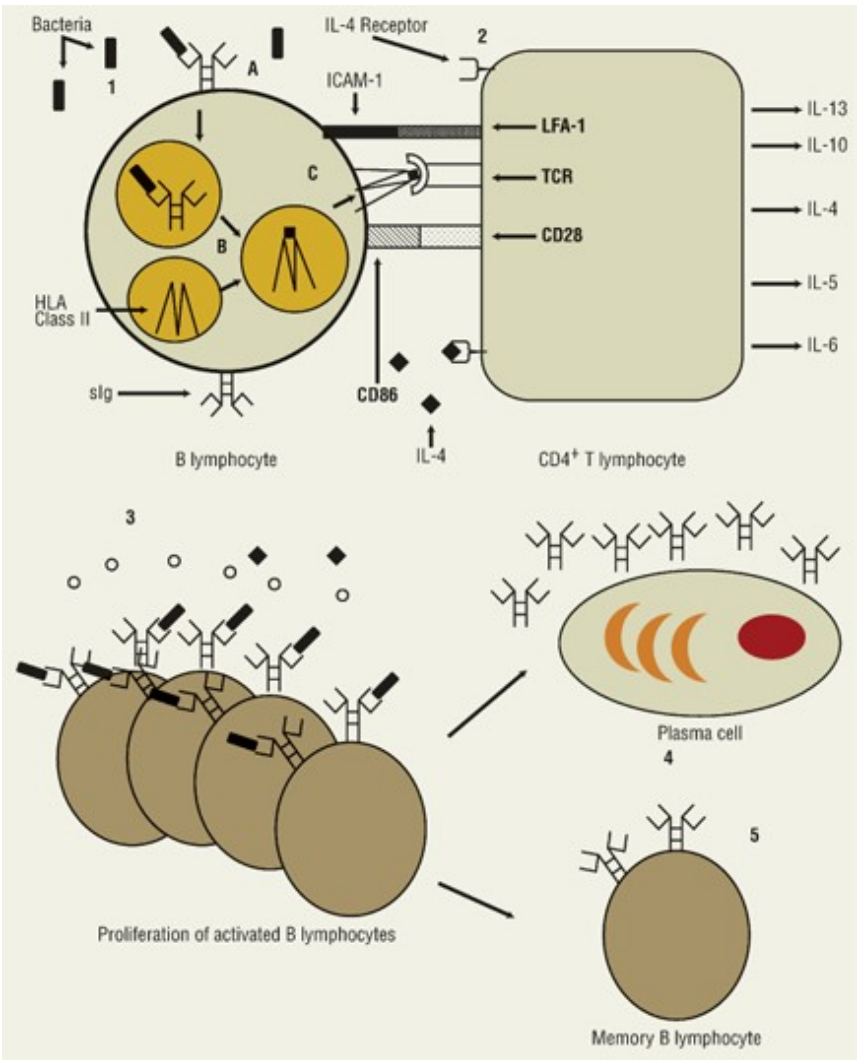
Induction of T-helper type 2 (TH_2) response. (1A) A B lymphocyte recognizes invading bacteria via its surface immunoglobulin (sIg). (1B) The bound bacteria are phagocytosed into an endosome, where the bacteria are broken down into small peptide fragments. (1C) The small peptide fragments are placed within MHC class II molecules and transported to the surface of the B lymphocyte for antigen presentation to a $CD4^+$ T lymphocyte. (2) $CD4^+$ T-lymphocyte recognition requires antigen recognition within the MHC class II peptide groove by the T-cell receptor (TCR) and a secondary signal from B7-2 from the antigen-presenting cell, in this case a B lymphocyte, binding to CD28 on the T lymphocyte. When both signals are delivered, the $CD4^+$ T lymphocyte becomes activated. In the TH_2 environment (see the text), the naive CD4+ T lymphocyte develops into a TH_2 subtype and secretes interleukin (IL)-4, IL-5, IL-6, IL-10, and IL-13, which promote a TH_2 response. (3) In the presence of these cytokines plus antigen binding to the sIg, the B lymphocyte becomes activated. The activated B lymphocyte becomes a plasma cell (4), which produces and secretes immunoglobulin or becomes a memory B lymphocyte (5). A minority of B lymphocytes become memory B lymphocytes.



Mast cells and basophils act primarily by releasing inflammatory mediators. Mast cells are tissue cells

predominately associated with IgE-mediated inflammation. They are especially abundant in the skin, lungs, nasal mucosa, and connective tissue. Granules within the mast cells contain large amounts of preformed mediators that include histamine, heparin, and serotonin. Mast cells can also phagocytize, destroy, and present bacterial antigens to T lymphocytes.[20] Basophils are similar to mast cells because they contain granules filled with histamine, but they are typically found circulating in the blood and are not found in connective tissue. Like mast cells, basophils also express high-affinity IgE Fc receptors (Fcε). IgE-mediated anaphylaxis (type I hypersensitivity; Chapter e88) is caused by the degranulation and the release of preformed mediators upon stimulation of mast cell and/or basophil by an allergen binding to IgE bound to the Fcε receptor on their cell surface.[21]

Soluble Mediators of the Innate Immune System

Soluble mediators of innate immunity involve proteins which include the complement system, mannose-binding lectin, antimicrobial peptides, and C-reactive protein (CRP).[11] The complement system consists of more than 30 proteins in the plasma and on cell surfaces that play a key role in immune defense. The four major functions of the complement system include: (a) lysis of certain microorganisms and cells; (b) Stimulation of chemotaxis of phagocytic cells; (c) coating or opsonization of foreign pathogens, which allows phagocytosis of the pathogen by leukocytes expressing complement receptors; and (d) clearance of immune complexes. Complement factors (C3a, C5a) also act as chemotactic factors for phagocytic cells.[22] Two different pathways stimulate the complement cascade. In the *classical pathway*, antibody binds to its target antigen and activates the first component of complement (C1), thereby initiating the complement cascade. The *alternative complement pathway* relies on the inability of microorganisms to clear spontaneously produced C3b, the active form of third complement protein, from their surface. Patients with hereditary deficiencies of complement have recurrent bacterial infections or immune complex disease because C3b plays a central role in opsonizing bacteria and clearing immune complexes.

Both mannan-binding lectin and CRP are acute-phase reactants produced by the liver during the early stages of an infection. They act as opsonins by binding to infectious pathogens that and serve as an intermediate by binding to their respective receptor on phagocytes. Mannan-binding lectin binds to mannose-rich glycoconjugates on microorganisms, while CRP binds to phosphorylcholine on bacterial surfaces.[11,22]

The chemokine system consists of a group of small polypeptides and their receptors. *Chemokines* play an essential role in linking the innate and adaptive immune response by orchestrating leukocyte trafficking. Chemokines possess four conserved cysteines. Based on the positions of the cysteines, almost all chemokines fall into one of two categories: (a) CC group in which the conserved cysteines are contiguous or (b) CXC subgroup in which the cysteines are separated by some other amino acid (X). As with all ligand–receptor interactions, a cell can only respond to a chemokine if the cell possesses a receptor that recognizes the chemokine. Chemokine receptors are unique in that they traverse the membrane seven times. CC receptors (CCR) and CXC receptors (CXCR) bind CC ligands (CCL) and CXC ligands (CXCL), respectively (**Table e86-4**).

TABLE e86-4 Common Chemokines

Receptor	Cell Expression	Ligand
CCR1	Immature DC	MIP-1α, MIP-1β, MCP-2, RANTES
CCR3	Eosinophils, basophils	Eotaxin-1, eotaxin-2, eotaxin-3, MCP-4
CCR6	Immature DC	Exodus-1
CCR7	Activated DC	CCL21 (SLC), CCL19 (ELC)
CXCR1/2	Neutrophils	IL-8
CXCR3	Natural killer cells, activated T lymphocytes	IP-10

DC, dendritic cell; ELC, EBI1 ligand chemokine; MCP, monocyte chemoattractant protein; RANTES, regulated upon activation normal T lymphocyte expressed and secreted; SLC, secondary lymphoid tissue chemokine.

Binding of infectious pathogens to PRRs stimulates the release of chemokines such as macrophage inflammatory protein (MIP)-1α, MIP-1β, MIP-3α, and IP-10 from macrophages and DCs embedded in the tissues. These chemokines attract more immature DCs to the site of inflammation/infection. Immature DCs constitutively express CCR1, CCR5, and CCR6. The interaction between PRRs on the DC to the infectious pathogen causes the activation and maturation of the DC. After activation, DCs downregulate the expression of CCR1, CCR5, and CCR6 and upregulate the expression of CCR7. This switch in chemokine-receptor expression results in the antigen-loaded DC leaving the tissue and migrating toward the lymph nodes.[23]

Naturally occurring antimicrobial peptides include α-defensins, β-defensins, and cathelicidins. These peptides exhibit antibacterial, antifungal, and antiviral activity. Human antimicrobial peptides range in size from 29 to 37 amino acid residues in length. Neutrophils are rich sources of both α- and β-defensins as well as cathelicidins. Other sources of the human antimicrobial peptides include keratinocytes, Paneth cells of the intestinal and genital tracts, and epithelial cells of the pancreas and the kidney. These peptides can be induced at sites of inflammation or can be constitutively produced. The clinical interest in human antimicrobial peptides centers on their broad-spectrum activity and their rapid onset of killing. They are believed to work by disrupting microbial membranes. An active area of research is how these peptides discriminate between microbial and host membranes.[24]

Adaptive Immune System

The body will generally employ both the innate and adaptive immune responses to rapidly kill foreign pathogens.[11] The greatest difference between the innate and adaptive immune responses is in specificity and memory, characterized by antigen-specific receptors located on the surface of B- (sIg) and T lymphocytes (TCR).[13] The adaptive immune response also secretes cytokines to further amplify the innate immune response. The adaptive immune response can evolve with each subsequent infection whereas the innate response stays the same with each infection. During B- and T-lymphocyte development, an individual B or T lymphocyte rearranges its immunoglobulin and TCR genes, respectively, to produce a unique immunoglobulin or TCR. This DNA rearrangement generates enough B or T lymphocytes to recognize an estimated 10^{12} and 10^{10} antigens, respectively.

The adaptive immune response can be divided into two major arms: humoral and cellular responses. The humoral response is so denoted because it was discovered that the factors that provided the immune protection could be found in the "humor" or fluids (eg, serum, plasma, lymph) and generally refers to antibody responses. To generate a good antibody response, T lymphocytes of the T helper cell phenotype are necessary. B lymphocytes activated in this way can differentiate into plasma cells and secrete antibody or they differentiate into memory B cells that are specific for the pathogen that reacted with its sIg.

Cells of the Adaptive Immune System

T lymphocytes constitute the cell-mediated arm of the adaptive system. The immune protection provided by T lymphocytes cannot be transferred by fluids alone. Rather, it is essential to actually have T lymphocytes present, thus the term cell-mediated immunity. T lymphocytes are specially tailored to defend against infections that are intracellular, such as viral infections, whereas B lymphocytes secrete antibodies that can neutralize pathogens prior to their entry into host cells.

The role of the T lymphocyte is to search respond to various pathogens extracellularly ($CD4^+$ T helper cells and MHC Class II), or intracellularly ($CD8^+$ T cytotoxic cells and MHC Class I). T lymphocytes use a specific antigen receptor, TCR, to propagate the immune response. The TCR is comprised of two chains with each chain having a variable and a constant region. The variation of the amino acid sequence within the variable domain of TCR gives the cell its unique antigen specificity. Linked to the TCR is a complex of single chains known as the CD3 complex.[11,21]

The MHC is a cluster of genes found on chromosome 6 in humans, also known as the human leukocyte antigen (HLA) complex, that are converted to proteins used by the immune system to distinguish self from non-self and provides a so-called immunologic "fingerprint." The MHC complex is divided into three different classes: I, II, and III. There are 6 MHC Class I genes (A, B, C, E, F, and G) of which only A, B, and C are considered major. These molecules can be found on all nucleated cells within the body as well as on platelets. As such, MHC Class I antigens are not found on mature red blood cells. Molecules encoded by class II MHC genes include DP, DQ, and DR. The expression of these molecules is more restricted and can be found primarily on APCs, such as macrophages, DCs, and B lymphocytes. The class III HLA antigens encode for soluble factors, complement, and tumor necrosis factors (TNFs).[25] In order for a $CD4^+$ T lymphocyte to become activated, it must recognize the antigenic peptide in association with MHC class II (see Figures e86-3 and e86-4).

$CD8^+$ T lymphocytes recognize antigenic peptide in association with class I molecules. Class I molecules generally contain endogenous peptides from within the cell, such as those derived from viruses. In contrast, Class II molecules contain exogenous peptides from antigen that has been phagocytosis and digested, such as bacterial peptides (see Figure e86-3). Thus, the MHC Class I and $CD8^+$ T cell interaction is a sensing system by which the immune system is constantly checking the nucleated cells of the body for what is happening inside the cells of your body.[25,26] DCs and to a lesser extent macrophages demonstrate the unique capacity to direct exogenous antigens toward MHC class I molecules, a process termed cross-presentation.[27] In contrast, the MHC Class II and $CD4^+$ T cell interaction is a sensing system by which the immune system is constantly checking out

what is happening outside of our cells.

Naïve T lymphocytes are cells that have not been previously exposed to an antigen specific for their TCR. These cells require 2 signals for activation. The first signal for activation involves the T lymphocyte recognizing both the processed antigen and the MHC molecule complex. The second signal involves the interaction of the B7-1 (CD80) or B7-2 (CD86) molecule on the APC with the CD28 molecule on the surface of the T lymphocyte (see Figure e86-3 and e86-4). Without the second signal, the naïve T lymphocyte becomes anergic or inactive. Memory T lymphocytes are less dependent on the second signal than are naïve T lymphocytes. CD28 is expressed on both resting and activated T lymphocytes. After the two activation signals, a message is sent through the TCR to the CD3 complex into the cell. Then calcium influx occurs, resulting in activation of the T lymphocyte. Activated $CD4^+$ T lymphocytes begin to express the high-affinity interleukin 2 (IL-2) receptor and release multiple soluble factors (eg, IL-2) to stimulate T lymphocytes and other cells of the immune system (see Figure e86-3). Autocrine stimulation by IL-2 leads to the proliferation of the activated T lymphocyte.

In addition to activation pathways, T lymphocytes can also express inhibitory receptors on their cell surface. One example is cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), which also binds B7, and is only expressed on activated T lymphocytes. When B7 binds to CTLA-4 on an activated T lymphocyte, an inhibitory signal is sent to the T lymphocyte, thereby modulating the T-lymphocyte response.[28] The exact mechanism by which CTLA-4 binding inhibits T-lymphocyte activity is not fully understood.

Cell surface markers delineate the functional activity of T-lymphocyte populations. All T lymphocytes express the CD3 protein. Typically, T lymphocytes are further divided into helper cells ($CD4^+$), suppressor cells ($CD8^+$), and cytotoxic cells ($CD8^+$). Each of the subclasses appears to play a distinct role in the cell-mediated immune response. Naïve T lymphocytes express CD45RA, a high-molecular-weight isoform of CD45, while memory T lymphocytes express CD45RO, a lower-molecular-weight isoform of CD45.[29] The primary role of $CD4^+$ cells is to stimulate other cells in the immune response. Functionally, $CD4^+$ cells can be divided into T-helper type 1 (TH_1), T-helper type 2 (TH_2), TH_{17}, T follicular helper (TH_{FH}), and T-regulatory (Tregs). This functional system was first described in mice. TH_1 cells secrete IL-2 and γ-interferon and stimulate $CD8^+$ cytotoxic cells, while TH_2 cells secrete IL-4, IL-5, and IL-10 and stimulate B-lymphocyte production of antibody toward extracellular pathogens.[30] Multiple factors determine whether a naïve $CD4^+$ T lymphocyte develops into a TH_1 or a TH_2 cell. The cytokine microenvironment plays an important role in this development. IL-12 secreted by the APCs promotes TH_1, whereas IL-4 promotes TH_2 development. Other factors that promote TH_1 development include B7-1 (CD80), high affinity of the TCR for the antigen, γ-interferon, and α-interferon. Factors that promote TH_2 development include B7-2 (CD86), low affinity of the TCR for the antigen, IL-10, and IL-1.[31] TH_{FH} also promote B-lymphocyte activation and play a crucial role in generation of memory B-lymphocytes which leads to long-lived antibody responses.[32] The TH_{17} subset was discovered because of selective production of IL-17 and plays an important role in immunity in mucosal tissues and in the pathogenesis of multiple inflammatory and autoimmune

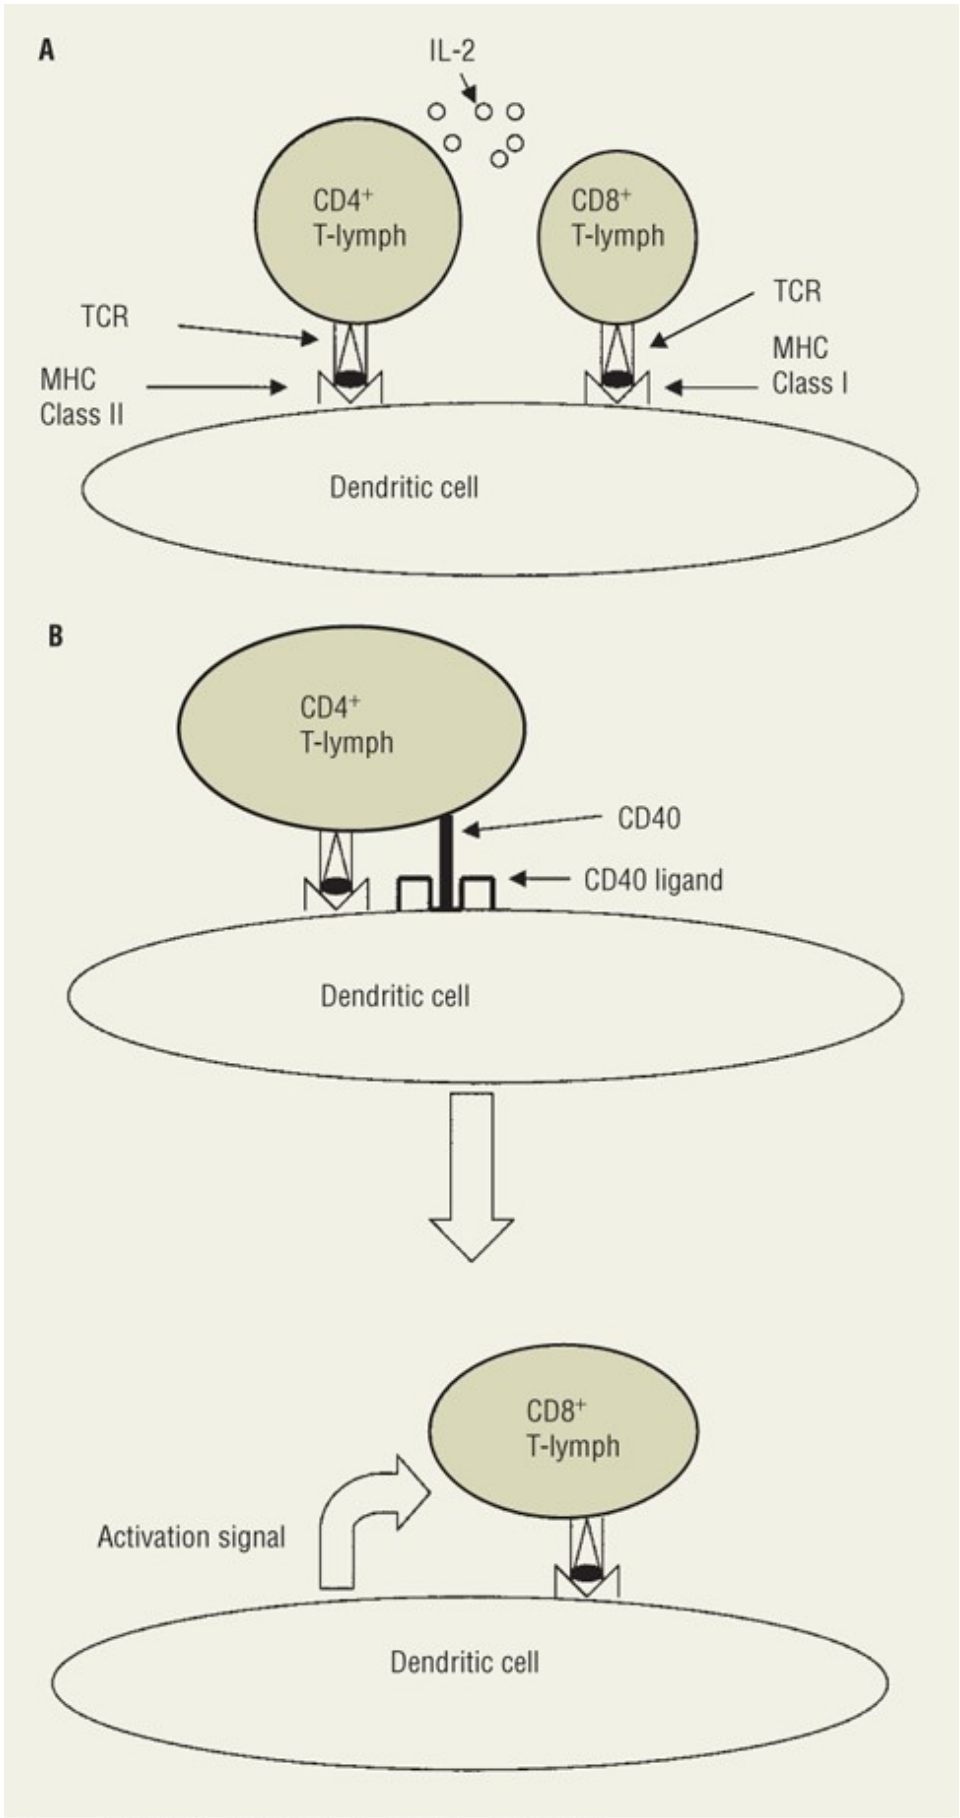
disorders.[33]

$CD8^+$ T lymphocytes recognize antigen in association with MHC class I. $CD8^+$ cytotoxic cells are instrumental in killing cells recognized as foreign, such as those that have become infected by a virus. $CD8^+$ cytotoxic T lymphocytes also play an important beneficial role in the eradication of tumor cells, but moreover are responsible for rejection of transplanted organs.[21] Classically, a second type of $CD8^+$ T lymphocytes was a suppressor cell. It is clear that some T lymphocytes help suppress the immune responses, but whether this subset is $CD8^+$ is debatable. Emerging evidence is leading away from $CD8^+$ T lymphocytes toward $CD4^+$, $CD25^+$ T lymphocytes in maintaining self-tolerance. The preferred term for these suppressive T lymphocytes is regulatory T lymphocytes.[34]

Our understanding of how $CD8^+$ T lymphocytes are activated is constantly evolving. The traditional model involves the interaction of a $CD8^+$ T lymphocyte with an APC, typically a DC. A more potent activation of $CD8^+$ T lymphocyte may result from the interaction of an APC, typically a DC, a $CD4^+$ helper lymphocyte (Th_1) and a $CD8^+$ T lymphocyte (**Figure e86-5A**). This model of $CD8^+$ cytotoxic T lymphocyte activation requires the close proximity of two antigen specific T lymphocytes (the $CD4^+$ and the $CD8^+$ T lymphocytes). In addition, $CD8^+$ cytotoxic T-lymphocyte activation can occur in the absence of direct interaction with $CD4^+$ T lymphocytes. Moreover, $CD4^+$ T-lymphocytes can activate (ie, prime) APCs through CD40. This interaction primes the APC to fully activate $CD8^+$ cytotoxic T lymphocytes (**Figure e86-5B**).[35] It is important to remember that the classification of $CD4^+$ lymphocytes as T-helper lymphocytes and $CD8^+$ lymphocytes as T-cytotoxic lymphocytes is not an absolute. Some $CD8^+$ T lymphocytes secrete cytokines similar to a T-helper lymphocyte, and some $CD4^+$ T lymphocytes can act as cytotoxic cells.

FIGURE e86-5

In the classic model of $CD8^+$ T-lymphocyte activation (A), $CD4^+$ and $CD8^+$ T lymphocytes recognize antigen on the same DC. In the presence of interleukin (IL)-2 from the activated $CD4^+$ T lymphocyte and the recognition of antigen in association with major histocompatibility complex (MHC) class I, the $CD8^+$ T lymphocyte becomes activated. In the new model (B), activated $CD4^+$ T lymphocytes activate DCs via CD40 ligand binding to CD40. The activated DC then migrates through the tissues to present antigen to $CD8^+$ T lymphocytes. If recognition via the T-cell receptor (TCR) on the $CD8^+$ T lymphocyte occurs, the DC can fully activate the $CD8^+$ T lymphocyte without the presence of $CD4^+$ T lymphocytes.



Unlike neutrophils and macrophages, cytotoxic T lymphocytes are unable to ingest their targets. They destroy target cells by two different mechanisms; the *perforin system*, and the *Fas ligand pathway*. After recognition by the cytotoxic T lymphocyte, cytoplasmic granules containing perforins and granzymes are rapidly oriented toward the target cell, and the contents of the granules are released into the intracellular space. Like the membrane attack complex formed after complement activation, perforins form a pore in the target cell membrane. Besides a direct cytotoxic effect on the target cell, the pores produced by perforins allow the granzymes to penetrate into the target cell to induce apoptosis. The second mechanism of cytotoxicity involves the binding of Fas ligand (FasL) on the cytotoxic T lymphocyte to the Fas receptor on the target cell. The FasL is predominately expressed on $CD8^+$ cytotoxic T lymphocytes and natural killer (NK) cells, and its expression increases after activation. When the Fas receptor on the target cell is bound by FasL expressed by the $CD8^+$ cytotoxic T lymphocyte, the target cell receives a very strong signal inducing it to undergo apoptosis (ie, commit suicide).[36] After destroying the target cell by either mechanism, the cytotoxic T lymphocyte detaches from the target cell and attacks other targets.[37]

A B lymphocyte recognizes antigen via its antibody or immunoglobulin (sIg) located on its cell surface (see Figure e86-4). The sIg can recognize an intact pathogen, such as bacteria, and present antigen to T lymphocytes (ie, acting as APC). However, another major function of B lymphocytes is to differentiate into a plasma cell to produce antibody specific for the invading pathogen, a process that first entails activation of the B lymphocyte. The activation of B lymphocytes also requires two steps: (a) recognition of antigen via the sIg; and (b) the presence of B-lymphocyte growth factors (IL-4, 5, and 6) secreted by activated $CD4^+$ T lymphocytes. Once activated, the B lymphocyte becomes a plasma cell, a differentiated cell capable of producing and secreting antibody and then dying. Some activated B lymphocytes do not differentiate into plasma cells, but rather form a pool of memory B cells. The memory B cells will respond to subsequent encounters with the pathogen, generating a quicker and more vigorous response to the pathogen. Some B lymphocytes can become activated without help from T lymphocytes, but these responses are generally weak and do not invoke memory.[11,21]

NK cells, often referred to as large granular lymphocytes, are defined functionally by their ability to lyse target cells without prior sensitization and without restriction by MHC. NK cells recognize target cells by two mechanisms. First, NK cells express an IgG Fc receptor, CD16, that allows recognition of IgG-coated cells. Second, NK cells express killer-activating and killer-inhibiting receptors. The killer-activating receptors recognize multiple targets on normal cells, but the binding of MHC class I to the killer-inhibitor receptor blocks the release of perforins and granzymes. Therefore, cells (eg, tumor cells, virally infected cells) that downregulate MHC class I expression are susceptible to NK cell cytolysis. NK cells play important roles in the surveillance and the destruction of tumors and virally infected host cells, and in the regulation of hematopoiesis.[11,38]

The immune system employs several mechanisms to downregulate responses to prevent autoimmune diseases. Many of these mechanisms are directed at T lymphocyte activation. After activation (about 2 days), T-lymphocytes express CTLA-4 (a second ligand for B7 [CD152]). As previously discussed, when CTLA-4 binds B7, T lymphocyte activity is inhibited. Another mechanism of T lymphocyte inhibition is the programmed cell death 1 (PD-1) system. Once a T lymphocyte is

activated, it begins to express the PD-1 receptor. The PD-1 receptor is capable of binding two separate ligands, known as PD-L1 and PD-L2. When bound to its ligand, PD-1 inhibits antigen receptor signaling in T lymphocytes, resulting in decreased production of proinflammatory cytokines by the T lymphocyte.[39] Interestingly, the same Fas/FasL system used by $CD8^+$ cytotoxic T lymphocytes to destroy their targets is also a mechanism that can be used to inhibit T lymphocytes. Once T lymphocytes become activated, they begin to express Fas receptors on their cell surfaces. If the Fas receptor on a T lymphocyte is bound by FasL, the T lymphocyte receives a signal inducing it to undergo apoptosis. Certain tissues, such as the testis, retina, and some types of cancer cells use the Fas system to protect themselves from harmful immune responses. These tissues constitutively express the FasL, which protects them from activated T-lymphocytes.[40] Another means of modulating T lymphocyte responses is through a functional subset of $CD4^+$ lymphocytes: Tregs. Tregs are antigen specific and require contact between the Tregs and the target lymphocyte in order to exert their inhibitory effect. Tregs can downregulate T-lymphocyte responses by secreting transforming growth factor-β and IL-10.[34]

Soluble Mediators of the Adaptive Immune Response

Antibodies

4 When binding of a specific antigen to the surface immunoglobulin receptor of B lymphocytes occurs, the B lymphocyte matures into a plasma cell and produces large quantities of antibody that have the ability to bind to the inciting antigen. The secreted antibodies may be of 5 different isotypes: IgA, IgD, IgE, IgG, and IgM. On primary exposure to a given pathogen, the plasma cell will secrete IgM, followed by an eventual switch to predominately IgG. Upon a second exposure to the same antigen, the memory B lymphocytes will predominately produce IgG. Isotype switching from IgM to IgG, IgA, or IgE is controlled by T lymphocytes.

An antibody or immunoglobulin is a glycoprotein comprised of two different chains, heavy and light (**Figure e86-6**). The basic structure of every immunoglobulin consists of four peptide chains: two identical heavy chains and two identical light chains held together by disulfide bonds. The basic structure of the antibody is a Y-shaped figure. Each arm of the Y is formed by the linkage of the end of the light chain to its heavy chain partner. These arms contain the portions described as the *fragments of antigen binding (Fab fragments)*. The stem of the Y contains the heavy chains, which comprise the *fragment crystallizable (Fc fragment)* portion of the antibody. It is within the Fc portion that complement is activated once the antibody has bound its target. Likewise, it is the Fc portion of the antibody that is recognized by Fc receptors on the surface of phagocytes (see Figure e86-2). The amino acid composition of the same isotype is homogenous except in the variable regions of the light (V_L) and heavy chains (V_H). The variation in amino acid composition of the variable region gives the antibody its unique specificity (see Figure e86-6).

FIGURE e86-6

Schematic diagram of the structure of the IgG molecule. IgG molecule consists of 2 heavy (H) and 2

light (L) chains covalently linked by disulfide bonds. Each chain is composed of variable (*V*) and constant (*C*) regions. A light chain consists of 1 variable (V_L) and 1 constant (C_L) region. Heavy chains consist of 1 variable (V_H) and 3 or 4 constant (C_H) regions, depending on the isotype. The variable regions (V_L and V_H) compose the antigen-binding region of the IgG molecule, or fragment antigen binding (Fab). The constant regions provide the structure to the IgG molecule as well as binding the first component of complement (C_H2) and binding to Fc receptors via the Fc portion of the molecule (C_H3).

IgG, the most prevalent of the antibody classes, comprises about 80% of serum immunoglobulins. IgG is usually the second isotype of antibody to be produced in an initial humoral immune response. IgG is the only isotype of antibody that can cross the placenta. Therefore, early maternal humoral protection of neonates is primarily due to maternal IgG that has crossed the placenta in utero.

Four different subclasses of IgG have been described: IgG1, IgG2, IgG3, and IgG4. These subclasses differ slightly in their constant amino acid sequences. IgG1 constitutes the majority (60%) of the subclasses. It appears that different subclasses recognize different types of antigen. IgG1 and IgG3 are principally responsible for recognition of protein antigens, while IgG2 and IgG4 commonly bind to carbohydrate antigens. Another difference in the subclasses is the ability to activate complement with IgG3 and IgG1 being the most efficient, while IgG4 is unable to activate the complement system.

IgM can be found on the surface of B-lymphocytes (sIg) as a monomeric Y-shaped structure. In contrast, secreted IgM is a pentamer in which five of the monomers are joined together by a joining chain (J-chain). IgM is the first class of antibody to be produced on initial exposure to an antigen.

Because the pentameric form of IgM has no Fc portions exposed, phagocytic cells cannot bind pathogens opsonized by IgM. However, IgM is an excellent activator of the complement cascade by the classic pathway.

IgA is found primarily in the fluid secretions of the body: tears, saliva, nasal fluids; and also in the GI, genitourinary, and respiratory tracts. IgA functions by preventing pathogens from adhering to and infecting the epithelial cells at these sites. IgA is also secreted in a nursing mother's breast milk as well as are IgG and IgM but in lower concentrations. In bodily secretions, IgA is in a dimeric form in which a J-chain and a secretory chain hold two monomers together. The dimeric form is resistant to proteolysis in mucosal secretions.

IgD is the least understood isotype. IgD is found on the surface of B-lymphocytes at different stages of maturation and may be involved in the differentiation of these cells. The main function of circulating IgD has not yet been determined. However, mice treated with exogenous anti-IgD antibody display a marked increase in immunoreactivity and secretion of all types of immunoglobulins and several T-cell specific cytokines. High levels of anti-IgD autoantibodies of various subtypes have also been observed in most autoimmune diseases with frequencies of more than 50%, suggesting that IgD may play an important role in the etiology of these diseases.[41]

IgE is the least common of the serum antibody isotypes. Most of the IgE in the body is bound to the IgE Fc receptors on mast cells. When the IgE on the surface of mast cells binds antigen, it causes the release of various inflammatory substances (eg, histamine) from the mast cell. The overall effect is the stimulation of inflammation. The major function of IgE antibody is to eliminate parasites, but because developed countries of the world have few if any parasites, the response has appeared to shift and it now plays an important role in allergies. Hay fever is an example of allergic reactions primarily due to antigen binding to IgE.

Cytokines

Cytokines are soluble factors released or secreted by cells. These proteins affect the activity of other cells (paracrine) or the secreting cell itself (autocrine). For example, activated $CD4^+$ T lymphocytes secrete IL-2, which further activates the secreting cells, $CD8^+$ T lymphocytes and NK cells. Research has shown that many cytokines have a broad spectrum of effects dependent on their concentration, the presence of other factors, and the target cell (**Table e86-5**). New cytokine families and their roles in disease processes are being discovered daily. Cytokines provide communication between the divisions of the immune system. Cytokines produced from APCs generally promote chemotaxis of other cells and induce a state of inflammation.[38] Cytokines can also prevent activation or response of immunologic cells. For example, IL-10 is an anti-inflammatory cytokine that is produced in the respiratory tract to prevent IgE synthesis and activation of eosinophils when exposed to benign inhaled particles.[38] Cytokines do not act alone in vivo, but in combination with other cytokines. For example, activated $CD4^+$ T lymphocytes secrete both IL-2 and interferon-γ, which are synergistic in activating NK cells. As shown in Tables e86-1 and e86-5, cytokines are broadly classified as regulatory or hematopoietic growth factors.[21,42,43,44,45,46] This classification does not describe all their activities. For example, GM-CSF released by activated T lymphocytes not only acts as a hematopoietic growth

factor, but it also activates circulating granulocytes and APCs to phagocytize foreign pathogens.

TABLE e86-5 Regulatory Cytokines

Cytokines	Sources	Principal Effects
IL-1	Macrophages, fibroblasts, endothelial cells	Activation of T- and B-lymphocytes, hematopoietic growth factor, and induction of inflammatory events
IL-2	$CD4^+$ T-lymphocytes (TH_1 subset)	Activation of T-lymphocytes, B-lymphocytes, and NK cells
IL-4	$CD4^+$ T-lymphocytes (TH_2 subset), mast cells, basophils, eosinophils	B- and T-lymphocytes growth factor, activation of macrophages, promotes IgE production, proliferation of bone marrow precursors
IL-5	$CD4^+$ T-lymphocytes (TH_2 subset), mast cells	Activation of B-lymphocytes and eosinophils, promotes IgE production
IL-6	$CD4^+$ T-lymphocytes (TH_2 subset), macrophages, mast cells, fibroblasts	T- and B-lymphocytes growth factor, hematopoietic growth factor, augments inflammation
IL-8	T-lymphocytes, monocytes, endothelial cells, fibroblasts	Neutrophil, basophil, and T-lymphocytes chemotaxis
IL-10	T- and B-lymphocytes, macrophages	Cytokine synthesis inhibitory factor, growth of mast cells
IL-12	Macrophages, neutrophils, dendritic cells	Induce TH_1 cells, ↑ NK cell activity, ↑ generation of cytotoxic T-lymphocytes
IL-13	Activated T-lymphocytes	Proliferation of B-lymphocytes, suppression of proinflammatory cytokines, directs IgE isotype switching
IL-14	T-lymphocytes	Induces B-lymphocytes proliferation, inhibits secretion of Igs
IL-15	Macrophages, fibroblasts, dendritic cells, epithelial cells	T-lymphocytes proliferation and activation of NK cells
IL-16	$CD8^+$ T-lymphocytes, epithelial cells	Chemoattractant for $CD4^+$ T-lymphocytes and eosinophils; stimulation of secondary cytokine secretion from and proliferation of $CD4^+$ T-lymphocytes
IL-17	$CD4^+$ T-lymphocytes (TH17 subset)	Proinflammatory cytokine that promotes the neutrophil expansion and accumulation in the tissues
IL-18	Macrophages	Induces γ-interferon production
IL-28 and 29[a]	Antigen presenting cells, but proposed that all nucleated cells may produce	Alternative to α/β interferons to provide immunity against viral infections by inhibiting viral replication

Cytokines	Sources	Principal Effects
IL-31	Activated T-lymphocytes	Involved in the recruitment of PMNs, monocytes, and T-cells to the site of inflammation
IL-32	NK-cells, T-lymphocytes, epithelial cells	Induces proinflammatory cytokines including TNF-α and IL-8
IL-35	$CD4^+$ T-lymphocytes (Treg subset)	T-cell suppression
TNF-α	Macrophages, NK cells, T-lymphocytes, B-lymphocytes, mast cells	Activation of neutrophils, endothelial cells, lymphocytes and liver cells to produce acute phase proteins
TNF-β	T-lymphocytes	Tumoricidal
IFN-α	Monocytes, other cells	Antiviral, activation of NK cells and macrophages, upregulation MHC class I
IFN-γ	T-lymphocytes, NK cells	Activation of macrophages, NK cells, upregulation of MHC class I and II

[a]Also known as the new type III IFN-λ family.

The division of the immune system into the two functional groups does not imply that the divisions do not interact. In order to generate a vigorous immune response, both soluble mediators (eg, complement, antibody, and cytokines) and cells (eg, neutrophils, macrophages, DCs, T lymphocytes, and B lymphocytes) are needed. The innate system will usually respond first. DCs, macrophages, and neutrophils in the tissues will recognize pathogen via surface receptors (see Figure e86-2). In order to amplify the immune response, the APCs will present antigen to $CD4^+$ T lymphocytes (see Figures e86-3 and e86-4). The activated $CD4^+$ T lymphocytes will then secrete cytokines to activate B lymphocytes, $CD8^+$ T lymphocytes, NK cells, macrophages, and neutrophils. The next section of the chapter discusses the evaluation of the immune system.

DISEASES OF THE IMMUNE SYSTEM

Although this chapter is not intended to detail the diseases of the immune system, it is necessary to review the terminology and provide specific examples of diseases of the immune system to understand the role of monitoring and possible intervention with pharmacotherapy. Diseases of the physical defense immune system are often not thought of as diseases of the immune system, but the loss of normal physical defenses is the most common cause of impaired immunity resulting in infectious sequelae. For example, thick respiratory secretions secondary to altered chloride transport in cystic fibrosis lead to pathogen airway colonization. Primary immunodeficiency diseases are those characterized by either a genetic inability to produce components of the immune system (ie, severe combined immunodeficiency or hypogammaglobulinemia) or acquired, as seen with HIV infection. Autoimmune diseases result from a dysregulation of a component or a combination of components of the immune system (eg, rheumatoid arthritis, systemic lupus erythematosus [SLE]).[47] Autoimmune diseases are often characterized by production of autoantibodies against a particular host structure

that is critical for normal function, or loss of tolerance or anergy to a ubiquitous antigen (ie, gluten in celiac sprue).[44] Often medications that suppress the immune system are necessary to control symptoms and halt autoimmune disease progression. Exposure to immunosuppressive medications in the setting of autoimmune diseases or organ transplantation may reduce disease symptoms but at the cost of the host's ability to fight off infection or cancer. Exogenous regulation of the immune system must be done judiciously, and we must continue to discover new methods for the appropriate evaluation of immune responses.

EVALUATION OF IMMUNE FUNCTION

Assessment of a patient's immune function requires knowledge and understanding of multiple components including mechanical defenses, cell phenotypes and cell numbers, and soluble components. Recent developments in biotechnology have allowed for progress in further characterization of immune system components and their functions. This is important because the upregulation and downregulation of immune responses is necessary to treat various disease states. Therefore, pharmacotherapeutic considerations must balance the risk of disrupting normal immunologic homeostasis. Improvements in immune monitoring are necessary for the goal of patient-specific immunologic pharmacotherapy. Despite the technological advances, careful patient evaluations are required to accurately assess the structure and function of the immune system. Specific methods for assessment of patient immune status are discussed later.

Innate Immunity: Evaluation of Mechanical Immunodefenses

As discussed earlier, the mechanical aspects of host defense are extremely important in protection from infection; therefore, assessment of mechanical defenses is critical. Much of the assessment of mechanical immunodefense is accomplished by recognition of situations where it may be compromised. Careful patient examination usually reveals the extent of compromise, and laboratory tests are generally not necessary for evaluation of this component. To assess the extent of compromise in mechanical immunodefenses, the clinician should carefully examine the patient and identify the specific types of risks present. Specific examples of altered mechanical defenses are listed in **Table e86-6**.

TABLE e86-6 Examples of Alteration in Mechanical Immunodefenses that Result in Impaired Immune Status

Reduced gastric pH	
	Achlorhydria
	Use of histamine-2 blockers and proton pump inhibitors
	Patients with acquired immunodeficiency syndrome
Break in skin barrier	
	Burns

Surgical incision

Penetrating trauma

Vascular access devices

Impaired mucociliary function of the lungs

Smoking

Impaired esophageal or epiglottal function

Endotracheal intubation

Stroke

Recumbent position

Altered urine flow

Urinary stones

Anatomic deformities obstructing flow

Bladder catheter

Anatomic alterations of the heart resulting in turbulent blood flow and endocarditis

Innate and Adaptive Immunity: Gross Evaluation of Cellular Components

A major aspect of the assessment of immune function relates to the cells of the immune system. Assessment of cells in the clinical setting includes determination of cell type, cell number, and/or function. Generally, determination of the cell types and quantification of the cell numbers are performed first because of the ease of obtaining these results and the common correlation with the clinical situation.

To quickly screen cell numbers, a *white blood cell* (*WBC*) *count* with differential is performed. Normal cell counts are shown in **Table e86-7**.[48] This simple test often steers the differential diagnosis. In interpreting a WBC with differential, the clinician must consider several factors. A normal cell count does not mean that a leukocyte disorder does not exist. For example, in chronic granulomatous disease, a child may have a normal neutrophil count, but the neutrophils are unable to destroy bacteria. Second, a differential is reported as percentage of the WBCs. Therefore, one must also assess both the absolute number and the percentage of white cell subtypes. For example, a patient admitted to the hospital with pneumonia has an elevated WBC (15,000 cells/mm^3 [15×10^9/L]) with a manual differential of 70% segs, 10% bands, 15% lymphocytes, and 5% monocytes. The WBC is predominately neutrophils; segs or mature neutrophils (70%) and bands or immature neutrophils (10%). The percentage of lymphocytes appears low at 15% (see Table e86-7), but the absolute

number of lymphocytes is actually normal, 2,250 cells/mm^3 (15,000 cells/mm^3 × 0.15) (2.25 × 10^9/L [or 15 × 10^9/L × 0.15]). A third factor to consider is that most lymphocytes are in secondary lymphoid organs (eg, lymph nodes and spleen), and changes in peripheral blood lymphocytes do not always mirror changes in the secondary lymphoid organs. Additionally, most granulocytes, macrophages, and mast cells are also in the tissues, not the bloodstream.

TABLE e86-7 Leukocyte Counts in Adults

Cell	Absolute Count (Range)[a]	Percentage (Range)[b]
White blood cells	7,500 (4,500-11,000)	100
Neutrophils	4,500 (2,300-7,700)	60 (50-70)
Eosinophils	20 (0-45)	3 (0-5)
Basophils	4 (0-20)	1 (0-2)
Monocytes	30 (0-80)	4 (0-10)
Lymphocytes	210 (160-240)	32 (28-39)
T lymphocytes	140 (110-170)	72 (67-76)[b]
$CD4^+$	80 (70-110)	42 (38-46)[b]
$CD8^+$	70 (50-90)	35 (31-40)[b]
B lymphocytes	30 (20-40)	13 (11-16)[b]
Natural killer cells	30 (20-40)	14 (10-19)[b]
CD4/CD8 ratio	1.2 (1-1.5)	

[a]Cell counts are expressed as cells/mm^3 or × 10^6/L.

[b]Percentage of lymphocyte subpopulations expressed as percentage of total lymphocyte population. For expression in SI units multiply each number by 0.01 to give the corresponding fraction.

To assess the numbers of granulocytes (neutrophils, basophils, and eosinophils) and monocytes, one uses a WBC with differential. An increased WBC count with immature neutrophils (eg, bands, metamyelocytes, myelocytes, and promyelocytes) in the peripheral blood is called a "shift to the left," and is abnormal. It most often indicates a bacterial infection, but also can indicate trauma or leukemia. It has long been recognized that the lower the absolute neutrophil count, the greater the risk of infection. Drugs (eg, chemotherapy) and diseases (eg, collagen vascular disorders) may lower the neutrophil count and make the patient more susceptible to infections. Patients with a neutrophil count less than 1,500 cells/mm^3 (1.5 × 10^9/L) are considered to have neutropenia. Functional analysis of these cell types is rarely done in routine clinical practice. Patients with suspected functional deficits in these cell types are generally referred to tertiary medical centers for evaluation and treatment.

A routine WBC with differential can determine the total lymphocyte count. Lymphocyte populations with different functions or in various stages of activation can be enumerated based on their cell surface markers. These cell surface markers are known as clusters of differentiation (CD). The CD is usually a protein or glycoprotein on the surface of the cell. CD followed by a number designates the

marker. Hundreds of monoclonal antibodies have been designed to recognize these cell surface markers. Monoclonal antibodies can be labeled with a fluorescent marker. The labeled monoclonal antibodies are then incubated with the patient's cells. The antibodies will recognize and bind to the cells expressing the CD of interest, and the cells are then counted using flow cytometry. For flow cytometry, the cell suspension is put under pressure such that the cells flow past a laser in a stream of single cells. The laser will excite the fluorescently labeled antibodies bound to the lymphocytes. A light detector is able to count the labeled cell as the fluorescent tag emits light and determines the size of the cell based on its light scatter characteristics. These evaluations are valuable for assessment of patients with immune deficiency states such as AIDS or leukemias, and for patients who have received organ transplants. For example, the number of $CD4^+$ cells in HIV-positive patients correlates with the risk of opportunistic infection and delineates the time to initiate antiviral therapy. Some of the more common CD antigens and their respective cellular distribution are listed in **Table e86-8**.[49] Flow cytometry can be used for leukocyte phenotyping, tumor cell phenotyping, and some types of DNA analysis.

TABLE e86-8 Cluster of Differentiation (CD) Guide: Characterization of Human Leukocyte Antigens

CD	Predominant Cellular Distribution
CD3	All T lymphocytes
CD4	Helper T lymphocytes, either TH_1 or TH_2
CD5	T lymphocytes, B-lymphocyte subset
CD8	Cytotoxic/suppressor T lymphocytes
CD14	Monocytes, neutrophils
CD20	B lymphocytes
CD25	Activated T lymphocytes, B lymphocytes, interleukin-2 receptor α-chain (Tac)
CD33	Committed myeloid progenitor cells
CD34	Hematopoietic progenitor cells that include the stem cell
CD56	Natural killer cells
CD83	Dendritic cells

Innate and Adaptive Immunity: Functional Evaluation

Several disease states are characterized by an adequate number of cells but the cells are nonfunctional or they do not produce cytokines to communicate effectively. Although no single test can predict the function of the immune system, available tests can measure the viability of certain cell lines and communication between cells. Historically, the most common in vivo assay of lymphocyte function is the delayed hypersensitivity skin test. This test specifically evaluates the presence of delayed-type hypersensitivity or the presence of memory T lymphocytes. Specifically, a small amount of antigen, of which the patient is known to have been previously exposed, is administered. Under normal immunologic host conditions, exposure to this amount of antigen in the skin should produce lymphocytic infiltrate into the area within a few hours; followed by additional lymphocyte recruitment and phagocytes (eg, macrophages and neutrophils) translocation. The maximal intensity of the inflammatory reaction occurs by 24 to 72 hours. This reaction is often referred to as type IV

hypersensitivity (ie, cell mediated; Chapter e88). A delayed-type hypersensitivity reaction is a test of cell-mediated immunity used to assess immunocompetency. The most common method to assess delayed-type hypersensitivity is to administer intradermally a panel of recall antigens. Commonly used antigens include *Candida albicans*, mumps, Trichophyton, tetanus toxoid, and purified protein derivative of tuberculin.[50] Measurements in millimeters of induration at the site of injection should be taken 48 to 72 hours after placement of the antigens. A reaction is considered positive if the diameter of induration is 2 mm or greater. The degree of sensitivity correlates with the area of induration.[49] Reaction to even a single antigen indicates a functioning cell-mediated immunity. Most immunocompetent individuals will show a positive reaction to at least one of these antigens. Possible reasons for not mounting a response to these antigens include congenital T-lymphocyte deficiency, cancer, HIV, or immunosuppressive drug therapy.[50] No response is sometimes mounted because the individual being tested has not been previously exposed to a particular test antigen, although this is rare.

Global assessment of the in vivo immunologic response is also used commonly in solid organ transplantation during the diagnosis and assessment of acute rejection. For example, pathologists can detect cellular rejection on gross tissue biopsy by counting the number of lymphocytes present in the tissue and correlating their presence with other clinical findings, such as increasing serum creatinine in kidney transplant.

In vivo assessment of B-lymphocyte function involves immunizing the patient with a protein (eg, tetanus toxoid) and a polysaccharide (eg, pneumococcal polysaccharide vaccine) antigen to elicit and measure antibody responses after immunization. Two to 3 weeks after immunization, the patient's serum is tested for antibodies specific for the immunized antigen. This test measures B-lymphocyte responsiveness to the inoculated antigens but is reserved for patients who are suspected to have impaired B-lymphocyte function.[48]

A number of specific in vitro lymphocyte functional assays are used in the research setting and a few assays are performed at specialized clinical laboratories. One of these tests is the lymphocyte proliferation assay. In this assay, lymphocytes are obtained from a patient's peripheral blood and cultured in vitro. The cells are exposed to nonspecific mitogens, such as pokeweed mitogen, phytohemagglutinin, or concanavalin A. Then the cells are incubated in growth media containing tritium-labeled (^{3}H) thymidine, a nucleotide used in the synthesis of DNA. Normally in the presence of the mitogens, lymphocytes will be stimulated to proliferate. Proliferating lymphocytes will incorporate ^{3}H thymidine as they replicate DNA. The level of radioactivity of the cells can be measured on a β-scintillation counter and is proportional to the degree of proliferation. The patient sample needs to be compared to normal, healthy controls' lymphocytes. Patients with immune deficiencies (eg, AIDS and cancer) have fewer active or less active lymphocytes, as detected by this test.

A modification of the lymphocyte proliferation assay can be used in allogeneic bone marrow transplantation to evaluate how closely a donor and host are "matched" in order to predict a patient's risk for developing graft-versus-host disease. A mixed lymphocyte culture (MLC) can be used to assess the potential of the donor cells to attack the host cells, graft-versus-host disease (Chapter

140). In this test, donor cells and host cells are incubated in vitro. The host lymphocytes are irradiated prior to the incubation so that they cannot proliferate. In vitro, ^{3}H thymidine is provided to the cells and uptake is measured. The degree of uptake correlates to the level of proliferation of donor lymphocytes. If the cells are well matched, proliferation is minimal. If the cells are mismatched, proliferation will be noted with the level of proliferation predictive of the potential extent of graft-versus-host disease. With the introduction of DNA-based, "high resolution" molecular typing of HLA antigens, the MLC is rarely used today.[50]

The Cylex Immune Cell Function Assay is an FDA approved test used to determine the magnitude of suppression of $CD4^+$ cells.[51] Briefly, activity of $CD4^+$ cells is measured by quantification of the amount of ATP produced and characterized as high, medium, or low.[52] Initial, retrospective experience has been reported in the solid organ transplant population. This assay is one of the first functional assays aimed at assessing individual patient response to immunosuppressive therapy and may allow for tailoring of immunosuppression.

More recently, evaluation of immune cell activity such as factor forkhead box P3 (FOXP3) Treg cell activity has been used to evaluate the incidence and severity of acute rejection based on elevated FOXP3 mRNA expression in urine and tissue cell samples. Since Tregs control autoimmune reactions, the presence of these cells in an allograft may indicate a level of "tolerance" to the donor tissue. Tolerance, basically, is a state in which the body knows that foreign tissue (eg, kidney transplant) exists but does not attack it. Initial studies have evaluated biopsy samples from organ transplant recipient and correlated them with levels of FOXP3. Early evidence suggests that FOXP3 is present only during periods of inflammation, such as rejection, and potentially projects the allograft tissue.[53] In addition to the tests described earlier, a number of other tests and assays have been devised to evaluate the function of $CD8^+$ T lymphocytes, NK cells, and monocytes/macrophages. Although these evaluations are not commonly performed, they may be helpful in some specific diseases and will likely be the way in which we monitor and detect immunologic events in the future. A thorough discussion of these tests is available.[54]

Immunoglobulins

Measurement of immunoglobulins is a direct measure of B-cell function. The most common evaluation of immunoglobulins is measurement of individual isotypes by immunoturbidity or immunonephelometry techniques. Although serum protein electrophoresis (SPEP) provides an estimate of the total immunoglobulin concentration, this technique is primarily used to investigate plasma cell dyscrasias and quantitate specific monoclonal protein peaks (eg, multiple myeloma and Waldenstrom macroglobulinemia). Depending on the specific SPEP technique, five or six separate zones are detected by this method: albumin, α_1-globulin, α_2-globulin, β-globulin (or β1 and β2 by some techniques), and γ-globulin.

5 The γ-globulin fraction contains the five isotypes of immunoglobulin (IgG, IgA, IgM, IgE, and IgD). A normal total immunoglobulin or γ-globulin concentration ranges from 0.8 to 1.6 g/dL (8-16 g/L). Total immunoglobulin or γ-globulin concentrations cannot be used to measure antigen-specific antibodies or specific isotypes, although they can be measured with other laboratory tests. In a

patient suspected of having humoral immune deficiency or B-lymphocyte failure (primary and secondary hypogammaglobulinemia), specific immunoglobulin isotypes in the plasma should be measured.

There are many indications for the measurement of antigen-specific antibody. Some common indications are listed in **Table e86-9**. More contemporary methods to perform these measurements include enzyme-linked immunosorbent assay (ELISA) and a variety of other immunoassay techniques. The most common reason to measure antigen-specific antibody is to determine whether or not a patient has been exposed to an infectious agent. Generally, IgM antibodies directed against the pathogen indicate an active or recent infection while IgG antibodies directed against the pathogen indicate prior exposure. This observation correlates with our understanding of B-lymphocyte responses in which plasma cells produce IgM initially in response to an infection, but later switches to IgG. Therefore, IgM antibodies will be present during an active infection and shortly after recovery from the infection. IgG concentrations will increase at the end of the primary exposure, but predominate after a second exposure. IgG predominates after a second exposure because memory B lymphocytes predominately secrete IgG in the serum. Other uses of antigen-specific antibody include determining if a patient has had exposure and is likely to be protected from infection (eg, hepatitis A virus) or to determine adequate response to vaccination (eg, hepatitis B vaccine). Measurement of antihuman IgG antibodies is used pre- and postsolid organ transplant to detect and potentially predict allograft compatibility and treat antibody-mediated rejection.

TABLE e86-9 Potential Indications for Measurement of Antigen-Specific Antibody

Environmental or drug allergy
Exposure to or infection with bacteria
Streptococci (ASO titer)
Staphylococcus aureus (teichoic acid antibody)
Neisseria gonorrhoeae
Legionella pneumophila
Exposure to or infection with viruses
Human immunodeficiency virus
Cytomegalovirus
Epstein–Barr virus
Hepatitis A, B, or C
Rubella
Exposure to or infection with other pathogens

- Syphilis
- Lyme disease
- Typhoid
- *Chlamydia*

Immune disorders

- Rheumatoid factor antibody, rheumatoid arthritis
- Antinuclear antibodies, systemic lupus erythematosus
- Platelet-associated immunoglobulin G, idiopathic thrombocytopenic purpura

Blood typing and crossmatching

Transplantation

- Human leukocyte antigen (HLA) antibodies

Antigen-specific IgE is not commonly measured in patients with allergies. Because the presence of antigen-specific IgE is related to clinical allergy, measurement of these antibodies can be helpful in diagnosing allergies and determining offending substances, but the circulating levels are so low they do not normally lead to interpretable results. Traditionally allergen-specific IgE was measured by radio-allergosorbent methodology. Contemporary laboratories have largely abandoned the use of radioisotope labels in immunoassays, and instead make use of enzymes labeled Anti IgE antibody as conjugate, with use of appropriate substrate for chemiluminescent, fluorescent, or colorimetric detection. The basic technique involves adding the antigen of interest, which is typically bound to beads or disks, to the patient's serum. After incubation and several washings, an enzyme-labeled antibody to IgE is added to bind to any IgE antibody bound to the antigen. After further washings, the enzyme-antibody conjugate bound to IgE, which is bound to the antigen on the bead or disk, is measured by an appropriate substrate, which generates the measurement signal, which is quantified.

Antigen skin testing is the preferred method to determine the presence of allergen-specific IgE. When it is produced, IgE binds to high-affinity IgE Fc receptors on basophils or mast cells. Contact of an allergen with the specific IgE on the basophil or mast cell surface causes activation of these cells and the release of inflammatory mediators (eg, histamine). When this occurs systemically, it can cause anaphylaxis. When it occurs in a confined area, such as the skin, erythema, and induration are observed within a few minutes of allergen injection. This is the principle used for detection of penicillin allergy and environmental or food allergies. A positive skin reaction (≥5 mm of induration) within 15 to 20 minutes indicates the presence of allergen-specific IgE.

The four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4 make up 65%, 20%, 10%, and 5% of total plasma IgG, respectively. Concentrations of the subclasses are often measured in patients with suspected primary and secondary hypogammaglobulinemia. IgG2 and IgG4 deficiencies are

associated with chronic infections. IgG4 deficiencies are also associated with autoimmune disorders.

Complement System

The complement system consists of a group of over 30 different proteins involved in lysing and opsonizing invading pathogens as well as serving as chemotactic factors. Numbers following the letter C (eg, C1 and C2) name the various proteins of the complement system. Assessment of the complement system is important in patients suspected of having humoral immune deficiencies (ie, recurrent infections).[49] A test for the global assessment of the complement system is the CH_{50}, the total hemolytic complement test. This test is based on the premise that complement is needed for a rabbit anti-sheep antibody to lyse sheep red blood cells. The source of the complement is the patient's serum. Each laboratory standardizes the test so normal ranges vary, but a standard curve is developed by adding titrated amounts of sera and measuring the amount of hemolysis. The hemolysis is determined with a spectrophotometer to measure the amount of hemoglobin released. The patient's serum is then tested, and the amount of serum that is needed to lyse 50% of the red blood cells is reported as the CH_{50}. Many laboratories assess total complement activity with semiquantitative enzyme immunoassay methods based on enzyme-conjugated monoclonal antibodies that bind to newly expressed antigens of the terminal complement proteins or methodology based on lysis of antibody sensitized dinitrophenyl-labeled liposomes with trapped glucose-6-dehydrogenase. These tests do not provide an indication of the function of any specific complement component but is used as a screening test for any complement system defects. If a defect is found, individual complement proteins can then be evaluated by either functional or immunochemical methods.

Several disease states can alter complement concentrations. Low complement concentrations are frequently found during states of acute inflammation (eg, SLE, rheumatoid arthritis, collagen vascular disorders, poststreptococcal glomerulonephritis, and subacute bacterial endocarditis). These states of apparent low complement concentrations are generally due to high rates of complement utilization or consumption that cannot be compensated for by increased complement synthesis.[22]

Since the liver is the primary source of several components of the complement system (ie, C2, C3, C4, factors B and D), a global decrease in complement factors occurs in severe liver failure. Inherited complement deficiencies have been described in patients with SLE, autoimmune diseases, recurrent gonococcal and meningococcal infections, membranoproliferative glomerulonephritis, and hereditary angioedema.[22]

The complement system has been used to diagnose and treat solid organ rejection. Antibody-mediated or humoral rejection is evaluated by quantifying the amount of donor MHC-specific antibody present in the recipient's serum. The presence of donor-specific antibodies is correlated with evidence of antibody-mediated rejection on tissue samples. This is characterized by the presence of complement split products, namely C4d, which is present after complement-dependent antibody-mediated rejection. C4d covalently binds to the allograft tissue and can be stained for biopsy samples. Unfortunately, unless biopsy findings can be correlated with a clinical finding consistent with rejection, the presence of C4d and its prognosis on long-term allograft function are

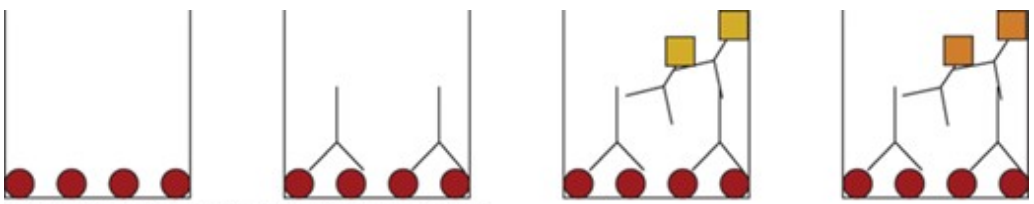
unknown.

Cytokines

Disease states involving the loss or upregulation of cytokines are sometimes overlooked as diseases of the immune system. However, as we have just reviewed, cytokines are essential components of both the innate and adaptive immune systems and provide the communication linking them together. Multiple cytokines with overlapping and redundant functions have been identified. Methods to detect and measure cytokines in biological samples have been developed. For nearly all the currently identified cytokines, commercial kits are available to measure endogenous and exogenously administered cytokines. The most common and preferable methods to measure cytokines are ELISAs (enzyme-linked immunosorbent assay) and RIAs (radioimmunoassay). ELISAs, RIAs or enzyme immunoassays are easy to run, and can identify and quantify the presence of cytokines, but they do not intrinsically measure biologic activity (**Figure e86-7**). Bioassays measure biologic activity, but are cumbersome and extremely variable. Using ELISA, we are able to measure only how much cytokine was produced by the cells in the culture. An ELISPOT is an enzyme-linked assay for detecting and enumerating cytokine-producing leukocytes.[55] In contrast to conventional ELISA, ELISPOT allows the user to detect absolute numbers and frequencies of cytokine-secreting leukocytes.

FIGURE e86-7

Enzyme-linked immunosorbent assay (ELISA). ELISA is a commonly used method for measuring concentrations of a wide variety of substances. To measure the concentration of antibodies to a particular antigen, the antigen is coated onto a solid phase, such as a microtiter plate or beads. If the purpose of the assay is to measure the concentration of antigen in solution, an antibody to the antigen is coated on the solid phase. The biologic fluid, often sera, is added to the wells. An enzyme-labeled antihuman antibody is added next. Finally, the chromogenic substrate for the enzyme is added. The intensity of the color as measured spectrophotometrically is proportional to the concentration of the antibody in the biologic fluid.



We are still at the very early stages of interpreting the clinical relevance of endogenous cytokine concentrations. Not only is the immune system affected by cytokines, such as IL-1, IL-6, TNF-α, but other systems (skeletal, endocrine, and CNS) are also affected. Therefore, measurement of cytokine concentrations may be important in the evaluation of other systems as well as the immune system.

Administration of cytokines in clinical practice may change not only the concentration of that

particular cytokine, but also the resultant concentration of other cytokines. For example, systemic administration of GM-CSF to patients not only increases concentrations of GM-CSF but also of TNF-α, IL-6, IL-8, macrophage CSF, and EPO.[56,57] Secondary endogenous cytokine release should be taken into account when considering the therapeutic effects of these agents and when monitoring cytokine concentrations.

In the future, tissue concentrations as well as blood concentrations may be measured. For example, while many centers currently measure blood cyclosporine concentrations to ensure adequate immunosuppression, it may be advantageous to monitor IL-2 concentrations because one of the primary actions of cyclosporine is the inhibition of IL-2 production. Furthermore, perhaps it would be beneficial to measure tissue concentrations of IL-2 in the transplanted organ to get a better estimate of the extent of immunologic suppression.

Soluble Receptors and Receptor Antagonists

The inflammatory response is highly regulated. The activity of cytokines, their receptors, and their antagonists are in a delicate balance. Although cytokine receptors are typically thought of as being found on the target cell, soluble cytokine receptors can modulate the activity of cytokines in at least two ways: (a) acting as antiinflammatory agents by binding cytokines with high affinity, but without biological activity[58]; and (b) augmenting cytokine activity by prolonging the cytokines plasma half-life and even maintaining agonist activity on cells that do not inherently respond to the cytokine.[59] Finally, antagonists to cytokine receptors have been identified.

TNF-α plays a central role in the inflammatory response by both increasing the expression of adhesion molecules in the tissues and by stimulating production of proinflammatory cytokines (eg, IL-2 and IL-8), prostaglandins, and nitric oxide. Soluble tumor necrosis factor receptors (sTNFRs) act primarily as inhibitors of TNF by preventing TNF from binding to the membrane-bound TNFRs, or by causing the cells to shed the receptor from the surface of the cell so that it can no longer serve as a signaling molecule.[60] Both monoclonal antibodies against TNF (eg, infliximab and adalimumab) and sTNFRs (eg, etanercept) have been shown to modulate the activity of TNF and are used clinically for the treatment of autoimmune diseases.

The best-characterized receptor-binding antagonist is the interleukin-1 receptor antagonist (IL-1RA). IL-1RA blocks the binding of IL-1 to its receptor by competing for the same binding site, but IL-1RA does not possess agonist activity.[61] A recombinant IL-1RA, anakinra, is used clinically for the treatment of severe rheumatoid arthritis.[62]

Our developing understanding of soluble receptors and receptor antagonists allows us to better mimic natural mechanisms for minimizing the toxicity of exogenously administered cytokines (eg, IL-1, IL-2, and TNF-α) and to immunomodulate various diseases (eg, solid organ transplant rejection, collagen vascular disorders, and sepsis).

MODULATION OF THE IMMUNE RESPONSE

6 Modulation of the immune response through administration of pharmacological agents or with blood product components comes with both risks and benefits. One example is the administration of recombinant activated protein C (drotrecogin alfa) to patients in septic shock. It was demonstrated that the administration of recombinant activated protein C reduced levels of IL-6, a potent proinflammatory cytokine that is thought to contribute to many of the clinical manifestations of septic shock. Unfortunately, protein C also possesses anticoagulant and fibrinolytic properties, leading to a significantly increased risk of bleeding. As a result, no survival benefit was observed when drotrecogin alfa was given to patients in septic shock. This ultimately led to the withdrawal of drotrecogin alfa from the market.[63] While TNF inhibitors suppress the immune system to halt the damage of autoimmune disorders and alleviate symptoms, they also place patients at increased risk of opportunistic viral infections. Many of our newer biological agents directed at immune pathways are derived from animals, and are subsequently humanized via various genetic engineering techniques to increase their biological effectiveness and decrease their antigenicity. Despite these efforts, these agents can serve as antigens and elicit an immune response, which may have a variety of consequences. One potential consequence is decreased efficacy over time. For example, an agent commonly used in solid organ transplantation is rabbit antithymocyte globulin (rATG), which is a polyclonal antibody derived from rabbits that have been immunized against human lymphocytes. rATG is given at the time of transplant to prevent graft rejection or given after transplant to treat graft rejection. Patients with previous exposure to rATG can develop antibodies against the drug because the rabbit antibodies can be antigenic in humans. This can result in decreased effectiveness of rATG, because the rabbit antibodies are neutralized by human antirabbit antibodies (HARAs). Once rATG is bound by HARAs, rATG is no longer able to bind to its target: human lymphocytes. Another potential consequence of HARAs is the deposition of the HARA/rATG complex in the kidneys and joints, producing high fevers and renal failure. Based on the few examples presented here, one can understand why manipulation of the immune system must be carefully assessed and appropriate patient instruction given.

Immunosuppression

Immunosuppression was first developed and used to allow transplantation of foreign tissues or to treat malignancies of the immune system. These medications are usually very expensive and associated with potentially serious adverse effects. Immunosuppressants block critical steps of the immune response, and patients must be counseled on their risk of infection and the plan to monitor effectiveness of the immunosuppressant. Several key concepts and questions can be used to help clinicians discern the potential benefits and harms of administering any immunosuppressant. These include: (a) what is its mechanism of action, (b) what arm of the immune system does it effect, (c) when is its onset of action, (d) how was this compound derived and does it have the potential to stimulate antibody production if the patient is reexposed, (e) is this compound's effect dose or duration related, (f) what type of infection is my patient at risk for and is infection prophylaxis required, and (g) how do I monitor the biological effect of this compound?

Immunopotentiation

In an attempt to restore normal immune system function or to activate the immune system,

immunopotentiators are often used. The best example of immunopotentiation of the immune system is the practice of immunizations. Active immunization with a vaccine or toxoid induces the host's immune system to confer protection against a pathogen (eg, hepatitis A, hepatitis B, and diphtheria toxoid). This process requires the uptake of the immunogenic epitope by APCs followed by presentation to $CD4^+$ T lymphocytes and the subsequent development of either a cellular or humoral immune response. Another example of immunopotentiation is the administration of IL-2 to patients with metastatic melanoma. As previously discussed, IL-2 is a potent activator of T lymphocyte and NK cell activity, which can be sufficient to break immune tolerance and result in immune-mediated tumor destruction.[64]

In contrast to active immunization, passive immunity entails the administration of human immunoglobulin to provide short-term protection to individuals who will be or have been exposed to a pathogen. IV immunoglobulin (IVIG) consists of more than 90% polyclonal IgG that is prepared from donated plasma. In patients with primary or secondary hypogammaglobulinemia, IVIG restores circulating IgG concentrations thus decreasing the risk of infections in these patients. In addition to restoring IgG concentrations, IVIG can potentially immunomodulate the immune response. For example, in immune thrombocytopenic purpura, an autoantibody directed against the platelets leads to the destruction of the platelets by antibody-dependent cellular cytotoxicity. IVIG saturates the Fc receptors on phagocytic cells, thereby preventing the engulfment of autoantibody-opsonized platelets. IVIG can also contain anti-idiotype antibodies to immunomodulate an immune response. Anti-idiotype antibodies are directed against the idiotype or hypervariable region of a native antibody. After administration of IVIG, the anti-idiotypes bind to the hypervariable region of the autoantibody and prevent the autoantibody from opsonizing circulating platelets. In addition, the anti-idiotypes directed against the autoantibody can bind to the surface immunoglobulin on the B lymphocyte producing the autoantibody that leads to the destruction of the B lymphocyte.[65]

Through our increased understanding of critical steps in T-lymphocytes responses, several monoclonal antibodies that enhance T-lymphocyte activity have been developed for the treatment of cancer. These new drugs are classified as immune checkpoint inhibitors. The first checkpoint inhibitor to be approved was ipilimumab, a humanized monoclonal antibody that binds to CTLA-4 on activated T-lymphocytes. Blockade of CTLA-4 prevents the inhibition of T-lymphocytes mediated by CTLA-4 signaling, and thus releases them to attack their target. Single agent ipilimumab improves overall survival in patients with unresectable or metastatic melanoma.[66] Two additional agents, pembrolizumab and nivolumab, bind to PD-1 on activated T-lymphocytes, blocking PD-L1 or PD-L2 expressed on tumor cells from inhibiting activated T-lymphocytes. By targeting two of the checkpoint pathways, the combination of nivolumab and ipilimumab has been shown to have even greater activity than either agent alone in patients with advanced melanoma.[67,68,69] The immune checkpoint inhibitors can also cause immune-mediated adverse events such as colitis, hepatitis, dermatitis, pneumonitis, and endocrinopathies. The combination of ipilimumab and nivolumab resulted in a higher incidence and severity of immune-mediated adverse events.[66,67,68,69]

Sipuleucel-T immunotherapy shows significant activity in castration-resistant prostate cancer. Sipuleucel-T takes advantage of our increased knowledge of APCs. Sipuleucel-T involves isolation of APCs from a patient by leukapheresis followed by in vitro activation of the APCs with a recombinant

fusion protein, PA2024, which contains GM-CSF to activate the APCs and a tumor antigen, prostatic acid phosphatase (PAP), common to prostate cancer. Finally, the activated APCs are reinfused into the patient every 2 weeks. The activated APCs then present PAP to the patient's T lymphocytes, which then leads to increased numbers of T lymphocytes attacking the prostate cancer.[70]

Adoptive cell transfer (ACT) is an active area of cancer research that shows great promise. ACT uses a patient's own T lymphocytes, derived either from a surgically resected tumor specimen or from peripheral blood and genetically engineered to express antitumor TCRs, to treat cancer.[71] In one study of patients with advanced melanoma, 40% of patients achieved a complete response that lasted at least 2.5 years.[72] As our understanding of the immune system has expanded, more advanced genetic engineering techniques have allowed a wider variety of cancers to be targeted through ACT. In patients with chemotherapy-refractory B-cell malignancies, ACT resulted in a 53% complete response rate, with some responses lasting almost two years.[73] As we continue to expand our knowledge of the immune system and its complex interactions, we will develop new therapeutic approaches to modulate immune responses in the treatment of human diseases.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

APC	antigen-presenting cell
CD	clusters of differentiation
CD4	T helper cells
CD8	T cytotoxic cells
CRP	C-reactive protein
CSF	colony-stimulating factor
DC	dendritic cell
ELISA	enzyme-linked immunosorbent assay
EPO	erythropoietin
FasL	Fas ligand
Fc	fragment crystallizable
FOXP3	factor forkhead box P3
GM-CSF	granulocyte-macrophage colony-stimulating factor
HLA	human leukocyte antigen
IgG	immunoglobulin G
IL-1RA	interleukin-1 receptor antagonist
IVIG	intravenous immunoglobulin
MALT	mucosa-associated lymphoid tissue
MHC	major histocompatibility complex
MIP	macrophage inflammatory protein

NK	natural killer
PAMPs	pathogen-associated molecular patterns
PD1	programmed cell death 1
PRRs	pattern recognition receptors
RIA	radioimmunoassay
sIg	surface immunoglobulin
SLE	systemic lupus erythematosus
SPEP	serum protein electrophoresis
TCR	T-cell receptor
TH_1	T-helper type 1
TH_2	T-helper type 2
Th17	T-helper 17 cells
Tregs	T regulatory cells
TNF-α	tumor necrosis factor-α
WBC	white blood cell

Chapter 87: Systemic Lupus Erythematosus

Beth H. Resman-Targoff

INTRODUCTION

KEY CONCEPTS

- 1 Systemic lupus erythematosus (SLE) is considered a disease primarily of young women, but can occur in anyone. The prevalence and severity vary with sex, race, ethnicity, and socioeconomic factors.
- 2 Understanding the etiology of SLE and environmental factors that can initiate or exacerbate the disease may make it possible to avoid those triggers.
- 3 SLE is an autoimmune disease characterized by the presence of autoantibodies, some of which may play a role in the pathogenesis of the disease. An understanding of disease mechanisms can lead to targeted drug therapy.
- 4 SLE is a multisystem disease that can involve almost any organ and may present in many different ways. Therapy is determined by the manifestations in each patient. These may change and fluctuate in severity over time.
- 5 Lifestyle changes can modify risk factors for SLE flares and complications.
- 6 The overall goals of therapy are to prevent disease flares and involvement of other organs, decrease disease activity and prevent damage, maintain remission, reduce use of corticosteroids, and improve quality of life, while minimizing adverse effects and costs. Most patients with SLE should receive hydroxychloroquine alone or in combination with other therapy appropriate for the disease manifestations.
- 7 Pregnancy planning is essential for good outcomes. Pregnancy outcomes are best when the disease is controlled before conception. Drugs used to treat SLE may adversely affect fertility and the fetus.
- 8 Antiphospholipid antibodies are associated with arterial and venous thrombosis and obstetric complications.

- 9 Many drugs can induce a lupus-like syndrome. The manifestations and laboratory findings may be different between the traditional drug-induced lupus and that seen with use of tumor necrosis factor-alpha inhibitors.

- 10 Since SLE can present in many different ways, it is difficult to design standard response criteria. Development of appropriate criteria is essential for getting new drugs approved.

Systemic lupus erythematosus (SLE) is an autoimmune disease associated with autoantibody production. The term "lupus" was first used to describe a skin disease in medieval times. The name may have been selected since the lesions looked like skin that had been gnawed by a wolf. In the mid-1800s, it was recognized that other organs may be affected and we now know that SLE is a multisystem disease. The common finding in SLE is production of antibodies to self-constituents.[1] This is an exciting time in the management of SLE because better understanding of disease mechanisms has led to the development of new drugs. In addition, new response criteria are being developed to show efficacy of drugs, even with the background of standard therapy. This has led to the first approval of a drug for treatment of SLE in over 50 years. Despite these advances, management of this disease remains a challenge. It has a myriad of manifestations and many of the drugs used to treat it are not approved for this indication. As a result, dosing of many of the drugs considered to be standard-of-care therapy must be personalized.

EPIDEMIOLOGY

1 Systemic lupus erythematosus is generally considered to occur most frequently in women of reproductive age (15-50 years old).[2] This is especially characteristic of the disease in nonwhite women. Statistics regarding SLE depend on the population studied and sampling and recruitment criteria. These have profound effects on estimates of incidence and prevalence, disease activity and severity, and mortality. The incidence is 1 to 10 per 100,000 person-years and the prevalence is 20 to more than 200 per 100,000 persons.[2,3] Rates are 9 times higher in women than in men so overall population statistics can be rather misleading.[2] It is affected by ethnicity, which includes genetic, geographic, cultural, social, and other aspects within a group. Rates are two to four times higher in nonwhites than in the white population.[3] It is most common in those of African origin, but is also more common in people of Asian, Arab, and Chaldean background, Hispanics, and Native Americans (called First Nations in Canada) than in whites.[3,4] Most people are of mixed race, so race by itself can be difficult to analyze. Nonwhites tend to have an earlier onset, more severe disease, and a higher mortality rate, but it can be difficult to separate out the influence of socioeconomic factors and access to medical care.[5] The disease tends to be more severe in men, children, and those with onset at a later age (over 50 years).[3]

Survival rates have improved recently with better therapy and earlier diagnosis and initiation of treatment. Overall SLE survival is 95% at 5 years and 92% at 10 years after diagnosis. This is reduced to about 88% at 10 years with lupus nephritis and even less than that in African Americans with lupus nephritis.[6] The survival rate may be lower in men, but the small number of males in most studies makes this difficult to determine.[3]

ETIOLOGY

The exact etiology for SLE is unknown but many abnormal factors have been identified that appear to play a role in the disease. Some are predisposing factors and others are involved in the disease mechanisms. Categories of these elements include genetic influences, epigenetic regulation of gene expression, environmental factors, hormones, and abnormalities in immune cells and cytokines.[4]

The incidence of SLE is increased in affected families. First-degree relatives of patients with SLE are 20 times more likely to develop the disease than those in a general population.[7] Ten percent of patients with SLE have relatives with the disease.[8] The concordance rate is 25% for identical twins and 2% for fraternal twins.[2] The genetic predisposition to SLE is a result of the interplay of a combination of genes. In rare cases, it is thought to result primarily from a single abnormal gene.[4] The major histocompatibility complex (MHC) class II alleles HLA-DR2 and HLA-DR3 are known to be linked to SLE. An increasing number of other gene loci are being identified as having associations with the disease.[2] Gene expression is regulated by deoxyribonucleic acid (DNA) methylation and histone modifications. These epigenetic changes can cause alterations that may influence SLE. Interestingly, hydralazine and procainamide, two drugs that may induce lupus, inhibit DNA methylation.[9]

In a genetically susceptible individual, environmental triggers can initiate the disease. It is possible that the type of trigger may influence the specific organ involvement. Cigarette smoke has many components, such as hydrazine, that may affect the immune system. Chronic smokers and former smokers are more likely to have elevated titers of anti-double-stranded DNA (anti-dsDNA) antibodies. Cigarette smoking is phototoxic and associated with cutaneous lupus.[10] Ultraviolet light can cause keratinocytes in the skin to release nuclear material that can further stimulate the immune system and autoantibody production by B cells.[9,10] Viruses may trigger SLE. Several studies have suggested a potential role for the Epstein–Barr virus.[11] Other implicated triggers include infections, medications (including vaccines and biologics), psychological stress, silica dust, hydrazines, petroleum, solvents (such as nail polish and metal cleaners), dyes, and pesticides.[10]

The higher prevalence in women suggests that hormones such as estrogens and progesterones may play a role in SLE, but the presence of the X chromosome may also contribute. The incidence of SLE is increased tenfold in men with Klinefelter (XXY) syndrome and decreased in women with Turner (XO) syndrome.[2]

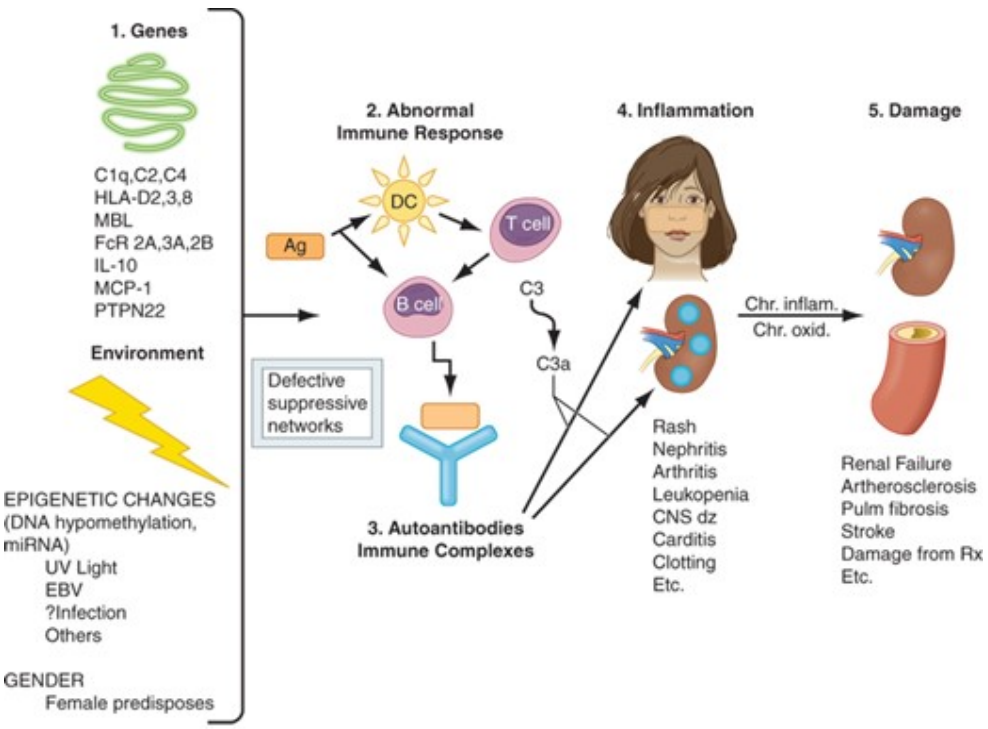
PATHOPHYSIOLOGY

Systemic lupus erythematosus is a multisystem disease characterized by disorders of the immune system (**Fig. 87-1**). T and B lymphocyte activation and signaling are altered in SLE and there is abnormal clearance of apoptotic debris.[2] The number of plasma cells is increased in active SLE and these cells produce autoantibodies, which can cause tissue damage.[9] Antibodies directed at dsDNA are seen in about 60% to 70% of patients with SLE and less than 0.5% of patients without the disease.[2] The titers of anti-dsDNA may fluctuate with disease activity and may predict disease flare. Some autoantibodies may play a role in the pathogenesis of clinical features of SLE; these autoantibodies may target Ro/SSA (antigen Ro/Sjögren syndrome A, ribonucleoprotein complex), La/SSB (antigen La/Sjögren syndrome antigen B, RNA-binding protein), C1q (subunit of the C1 complement component), Sm (nuclear particles), *N*-methyl-d-aspartate (NMDA) receptor (amino acid released by neurons), phospholipids, nucleosomes

(from apoptotic cellular debris), and histones (protein core of nucleosome). The autoantibodies can be present for many years before SLE is clinically apparent and they may be associated with specific organ involvement, such as anti-dsDNA with lupus nephritis.[2]

FIGURE 87-1

Pathogenesis of systemic lupus erythematosus (SLE). Genes confirmed in more than one genome-wide association analysis in northern European whites (several confirmed in Asians as well) as increasing susceptibility to SLE or lupus nephritis are listed (reviewed in SG Guerra et al. *Arthritis Res Ther* 2012;14:211). Gene-environment interactions (reviewed in KH Costenbader et al. *Autoimmune Rev* 2012;11:604) result in abnormal immune responses that generate pathogenic autoantibodies and immune complexes that deposit in tissue, activate complement, cause inflammation, and over time lead to irreversible organ damage (reviewed in GC Tsokos. *N Engl J Med* 2011;365:2110 and BH Hahn, in DJ Wallace, BH Hahn, eds. Dubois' Lupus Erythematosus and Related Syndromes, 8th ed. New York, Elsevier, 2013). Ag, antigen; C1q, complement system; C3, complement component; CNS, central nervous system; DC, dendritic cell; EBV, Epstein-Barr virus; HLA, human leukocyte antigen; FcR, immunoglobulin Fc-binding receptor; IL, interleukin; MCP, monocyte chemotactic protein; PTPN, phosphotyrosine phosphatase; UV, ultraviolet. *(Reproduced with permission from Hahn BH. Systemic lupus erythematosus. In: Kasper DL, Fauci AS, Hauser SL, et al., eds. Harrison's Principles of Internal Medicine. 19th ed. 2015.)*



Immune complexes form when antinuclear antibodies (ANA) bind to nuclear material in blood and tissues, and they can accumulate in the kidneys, skin, CNS, and other sites. They activate the complement cascade, leading to an influx of inflammatory cells and tissue injury. Antibodies to blood cells can cause cytopenias. Antibodies against phospholipids can lead to thrombosis and fetal loss. These antiphospholipid antibodies interfere with protein C and endothelial cell function, inducing tissue factor that leads to thrombus formation. They also cause platelet aggregation. The antiphospholipid antibodies bind to

placental trophoblast cells and activate complement, which can lead to fetal loss.[9]

T cell abnormalities contribute to the immune disorders observed in SLE. There are increased T helper cells type 2 and 17 and diminished number and function of T regulatory cells. Cytokines, such as tumor necrosis factor-alpha (TNF-α), interferon-gamma, and interleukin-10, produced by activated T cells can stimulate B cells.[2]

Cytokines play multiple roles in SLE. Anti-T-cell antibodies decrease interleukin-2 production, which can increase the risk for infections by decreasing the activity of cytotoxic T cells and increasing the lifespan of autoreactive T cells. Increased T cell production of interkeukin-17 and expression of adhesion molecule CD44 may contribute to kidney and other organ damage. Plasmacytoid dendritic cells accumulate in skin and kidneys and secrete interferon-α. B-lymphocyte stimulator (BLyS), also known as B cell activating factor of the TNF family (BAFF), increases survival of B cells. Interleukin-6 promotes production of antibodies.[9] The role of TNF-α in SLE is unclear. In some patients it appears to be harmful, and in others, protective.[2]

CLINICAL PRESENTATION

4 Systemic lupus erythematosus is an autoimmune disease that can involve almost any organ and may present in many different ways. This can make it difficult to establish a diagnosis and an extensive work-up may be needed to determine the full extent of involvement and to exclude other possible etiologies for the manifestations. More common features include involvement of the skin and mucus membranes, joints, kidneys, CNS, serous membranes, cardiovascular system, and hematologic cell lines. Fatigue and depression are frequent symptoms and can adversely affect quality of life.[12] Arthritis or arthralgias are experienced by 83% to 95% of patients with SLE.[8] SLE may present differently in men and women. For example, men tend to get SLE at an older age and are more likely to have renal and hematologic involvement, but have fewer dermatologic features. Race and ethnicity may also affect the specific manifestations.[13]

Disease manifestations fluctuate with periods of remission, flares, and progression.[14] The presence of ANA may be used as a screening test for SLE. Most patients with SLE have these antibodies, but they are not specific for the disease.[15]

An international group of SLE researchers developed and validated new criteria for classification of SLE in 2012. These are referred to as the Systemic Lupus International Collaborating Clinics (SLICC) classification criteria and were developed to identify patients with the disease for clinical studies. They are not intended for establishing a diagnosis in an individual patient, but may be helpful in assessing the likelihood that a patient has SLE. The widely used American College of Rheumatology (ACR) criteria were developed in 1982 and revised in 1997. The 1997 version was not validated. The SLICC criteria are more clinically relevant and sensitive than the ACR criteria. When validated, the SLICC criteria had a sensitivity of 97% and specificity of 84% compared to 83% and 96% for the ACR criteria. The number of criteria was expanded from 11 to 17 and, unlike the ACR criteria, they are divided into clinical and immunologic parameters. The ACR criteria required 4 of the 11 elements to be present, serially or simultaneously. To satisfy the SLICC criteria, a patient must still meet at least four of the elements, but now these must include at least one clinical and one immunologic criterion or the patient must have biopsy-proven lupus nephritis with

positive ANA or anti-dsDNA antibodies. An abbreviated version of the SLICC criteria, with comparison to the ACR criteria, is shown in **Table 87-1**.[16,17,18] It may be possible to classify patients earlier in their disease course as having SLE with the SLICC criteria.[19]

TABLE 87-1 2012 Systemic Lupus International Collaborating Clinics Classification Criteria for Systemic Lupus Erythematosus (SLICC)

Clinical Criteria

1. Acute/subacute cutaneous lupus/malar rash[a]/photosensitive rash[a]
2. Chronic cutaneous lupus/discoid rash
3. Oral OR nasal ulcers
4. Nonscarring alopecia
5. Arthritis/synovitis or tenderness
6. Serositis (pleuritis, pericarditis)
7. Renal (urine protein-to-creatinine ratio [or 24-hour urine protein] representing 500 mg protein/24 h OR red blood cell casts)
8. Neurologic (seizure, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, acute confusional state)
9. Hemolytic anemia[b]
10. Leukopenia (<4,000/mm^3 [<4 × 10^9/L]) OR lymphopenia (<1,000/mm^3 [<1 × 10^9/L])[b]
11. Thrombocytopenia (<100,000/mm^3 [<100 × 10^9/L])[b]

Immunologic Criteria

1. Antinuclear antibody (ANA)
2. Anti-double-stranded DNA (dsDNA)[c]
3. Anti-Sm[c]
4. Antiphospholipid antibody (lupus anticoagulant, anticardiolipin, anti-β_2-glycoprotein I, false positive rapid plasma reagin test for syphilis)[c]
5. Low complement (C3, C4, CH50)
6. Direct Coomb's test (without hemolytic anemia)

At least four criteria, including at least one clinical and one immunologic criterion OR biopsy-proven lupus nephritis with positive ANA or anti-dsDNA required for diagnosis.

[a]In the ACR Criteria, malar rash, and photosensitivity are two separate criteria.

[b] In the ACR Criteria, hemolytic anemia, leukopenia, lymphopenia, and thrombocytopenia count as one criterion.

[c]In the ACR Criteria, anti-dsDNA, anti-Sm, and antiphospholipid antibody count as one criterion.

Data from Petri M, Orbai AM, Alarcón GS, et al. Derivation and validation of the Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus. *Arthritis Rheum* 2012;64:2677-2686; Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982;25:1271-1277; and Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1997;40:1725.

An international working group of SLE experts devised a consensus definition of SLE flare: "A flare is a measurable increase in disease activity in one or more organ systems involving new or worse clinical signs and symptoms and/or laboratory measurements. It must be considered clinically significant by the assessor and usually there would be at least consideration of a change or an increase in treatment."[20]

Some skin involvement is seen in about 75% of patients with SLE.[21] This can be disfiguring and affect a patient's feelings of self-esteem.[22] Three main types of cutaneous lupus erythematosus have been observed. They may occur with or without SLE. Acute cutaneous lupus erythematosus is typically seen in patients with SLE and is characterized by a photosensitive malar rash over the cheeks and nose with sparing of the nasolabial folds. The malar rash is present in 52% of patients with SLE at the time of diagnosis. The arms and trunk may be involved. The manifestations usually wax and wane without scarring.[23] Severe SLE is less common with the other forms of cutaneous lupus. Subacute cutaneous lupus erythematosus is highly photosensitive and is manifested by annular or psoriasiform plaques that usually heal without scarring. It can be accompanied by musculoskeletal complaints and patients usually have anti-Ro/SSA autoantibodies.[24] It is more common than other types of cutaneous lupus erythematosus in patients with drug-induced lupus. About half of patients with subacute cutaneous lupus erythematosus meet criteria for SLE.[23] Many subtypes of chronic cutaneous lupus erythematosus have been identified. The most common is discoid lupus, which is confined to the head and neck in about two-thirds of patients, but it can be generalized.[25] Chronic discoid lupus is the first manifestation of SLE in up to 10% of cases. Discoid lupus progresses to SLE in about 5% to 10% of patients. It is more common in smokers and African Americans. It may be associated with scarring, scarring alopecia, malar rash, photosensitivity, oral ulcers, leukopenia, vasculitis, and chronic seizures. Chronic discoid lupus is associated with a lower incidence of arthritis, end-stage renal disease, and immunologic markers such as ANA, anti-dsDNA, and antiphospholipid antibodies.[26]

CLINICAL PRESENTATION Symptoms

- Fatigue, depression, photosensitivity, joint pain, headache, weight loss, nausea/abdominal pain

Signs

- Rash, alopecia, fever, oral and nasal ulcers, arthritis, renal dysfunction, seizure, psychosis, pleuritis, pleural effusion, cardiovascular disease, pericarditis/myocarditis, heart murmur, hypertension,

anemia, leukopenia, thrombocytopenia, lymphadenopathy, Raynaud's phenomenon, vasculitis

Diagnostic Tests

- Serology: autoantibodies, antiphospholipid antibodies, complement; inflammatory markers: C-reactive protein, erythrocyte sedimentation rate; blood chemistries; complete blood count; urinalysis; lumbar puncture; renal biopsy

Lupus nephritis is present at the time of SLE diagnosis in about 35% of adult patients and 50% to 60% of patients develop it by 10 years. It is more common in African American and Hispanic patients than in whites and more prevalent in men than in women. The International Society of Nephrology/Renal Pathology Society devised a classification system for lupus nephritis based on histologic findings: Class I: minimal mesangial, Class II: mesangial proliferative; Class III: focal (less than 50% of glomeruli involved); Class IV: diffuse (50% or more of glomeruli involved); Class V: membranous; and Class VI: advanced sclerosing (at least 90% globally sclerosed glomeruli without residual activity). Patients with nephritis may also have hypertension and atherosclerosis.[6]

The central and peripheral nervous systems can be involved in SLE. The frequency of this involvement is around 30% to 40%, but can range from 12% to 95% depending on the population studied and methods for detecting the occurrence.[27,28] About 50% to 60% of neuropsychiatric events appear within the first year after the diagnosis of SLE, usually during times of generalized disease activity. Mild nonspecific neuropsychiatric findings such as headache, mood disorders, anxiety, and mild cognitive dysfunction are common in SLE but may not reflect overt CNS disease activity. Findings more indicative of neuropsychiatric lupus include cerebrovascular disease (ischemic stroke and/or transient ischemic attack) and seizures in 5% to 15% of patients; severe cognitive dysfunction, major depression, acute confusional state, and peripheral nervous disorders (eg, polyneuropathy and mononeuropathy) in 1% to 5%; and psychosis, myelitis, chorea, cranial neuropathies, and aseptic meningitis in less than 1% of patients. Risk factors include general SLE disease activity, prior neuropsychiatric events, and presence of moderate-to-high titers of antiphospholipid antibodies.[27] It is important to assess contributing factors and to rule out other possible etiologies of these manifestations such as corticosteroid use.[29] The diagnostic approach will vary depending on the clinical presentation and preliminary findings, but can include a thorough history and physical, lumbar puncture with cerebrospinal fluid analysis (mostly to exclude infection), electroencephalogram, serology, complete blood count, blood chemistries, neuropsychological assessment of cognitive function, nerve conduction studies, and magnetic resonance imaging.[27]

Cardiovascular disease is a leading cause of death in patients with SLE. Not only are there cardiac manifestations of SLE, such as pericarditis and myocarditis, but patients with SLE are also at increased risk for accelerated atherosclerosis. This is probably related to the chronic inflammation associated with the disease and adverse effects of the drugs (eg, high-dose corticosteroids) used to treat it. Antiphospholipid antibodies and type I interferons may play a role in the pathogenesis. Drugs such as hydroxychloroquine and mycophenolate mofetil may have a cardioprotective effect.[30]

TREATMENT

Systemic Lupus Erythematosus

Treatment of SLE is determined by the patient's symptoms and organ involvement.

Desired Outcomes

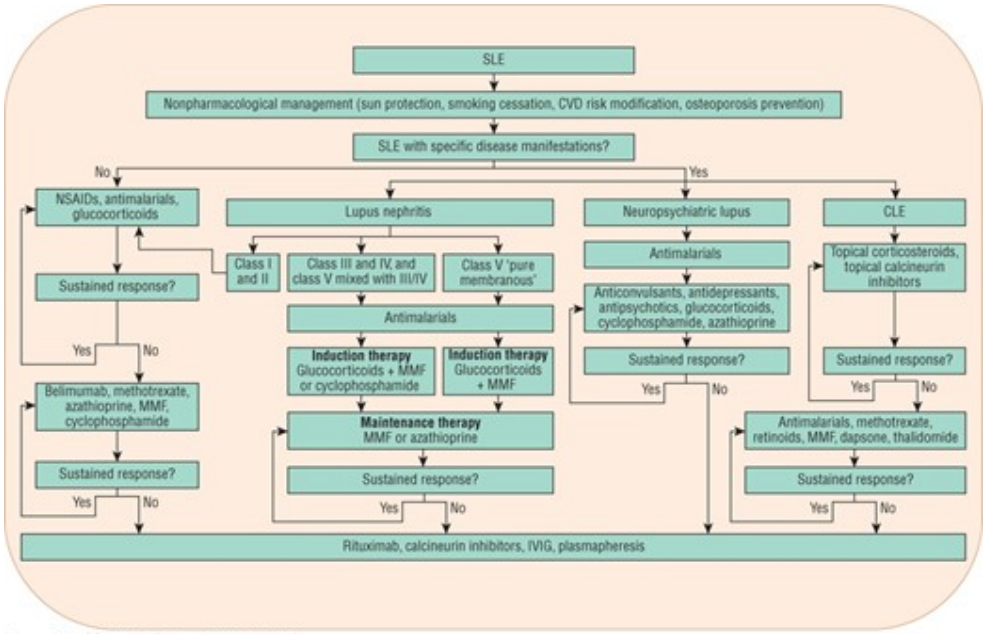
The overall goals of therapy are to prevent disease flares and involvement of other organs, decrease disease activity and prevent damage, maintain remission, reduce use of corticosteroids, and improve quality of life, while minimizing adverse effects and costs. Success in achieving these outcomes depends on disease severity and the type and extent of organ impairment. In general, the prognosis is better if lupus is limited to skin and musculoskeletal findings. The worst prognosis is seen with renal or CNS involvement.[8] Many of the desired outcomes have been observed with antimalarials, although most patients require additional therapy.[31] Survival and quality of life have improved with better understanding of disease mechanisms and new therapeutic options. Mortality is affected by SLE disease activity, cardiovascular risks, and infections.

General Approach

Patients with SLE should be counseled about the importance of lifestyle modifications such as protection from the sun, smoking cessation, exercise, and weight control. The need for immunizations should be assessed with consideration of appropriate timing with respect to immunosuppressive drug use. The effects of disease activity and treatment on pregnancy outcomes should be discussed. Patients should be evaluated and treated for any comorbidities such as hypertension, hyperlipidemia, and depression. Mild symptoms can be managed with nonsteroidal antiinflammatory drugs (NSAIDs) with or without other analgesics.[32] Antimalarial drugs have numerous beneficial effects in SLE and many experts feel that most patients with the disease should always receive one of these drugs.[31] Corticosteroids are used to treat most forms of SLE and up to 80% of patients receive low doses indefinitely as maintenance therapy. The need for osteoporosis prevention should be assessed.[33] If the above therapy is ineffective or major organs are involved, immunosuppressive or immunomodulatory drugs are added.[32] The specific treatment is determined by the organs involved and severity of the disease. It is summarized in **Fig. 87-2**.[14]

FIGURE 87-2

Algorithm for the treatment of SLE. Abbreviations: CLE, cutaneous lupus erythematosus; CVD, cardiovascular disease; IVIG, intravenous immunoglobulin; MMF, mycophenolate mofetil; SLE, systemic lupus erythematosus. *(Used with permission from Xiong W, Lahita RG. Pragmatic approaches to therapy for systemic lupus erythematosus. Nat Rev Rheumatol 2014;10:97-107.)*



Nonpharmacologic Therapy

5 Patient perceptions of well-being and quality of life are affected not only by disease activity, but also by social support, coping mechanisms, feelings of helplessness, and abnormal illness-related behaviors.[32] Good social support can improve outcomes, in part by making it easier for patients and their families to navigate the healthcare system and utilize resources. Counseling and support groups may help patients' mental well-being and coping mechanisms, but do not affect SLE disease activity. Aerobic cardiovascular exercise may help decrease patients' risk for cardiovascular events and osteoporosis and may also improve fatigue and sleep disturbances, which are frequently experienced in SLE.[34]

Since photosensitivity is common in SLE, patients should wear protective clothing and hats and use sunscreens to protect themselves from the sun. They should avoid tanning salons.[25] The FDA issued regulations for testing and labeling of sunscreens that took effect in 2012. Sunscreens labeled as broad spectrum protect against ultraviolet A and B radiation. They have sun protection factors (SPFs) of 15 to 50+.[35] Patients with SLE should use sunscreens with high SPF values and apply them every 2 hours while in the sun.[25]

Patients should be counseled to stop smoking. Smoking cessation is important, not only because it decreases cardiovascular risk, but because smoking can exacerbate SLE and diminish the effectiveness of antimalarials.[36] Smokers also have a higher incidence of active rashes with skin damage and scarring.[37]

Pharmacotherapy

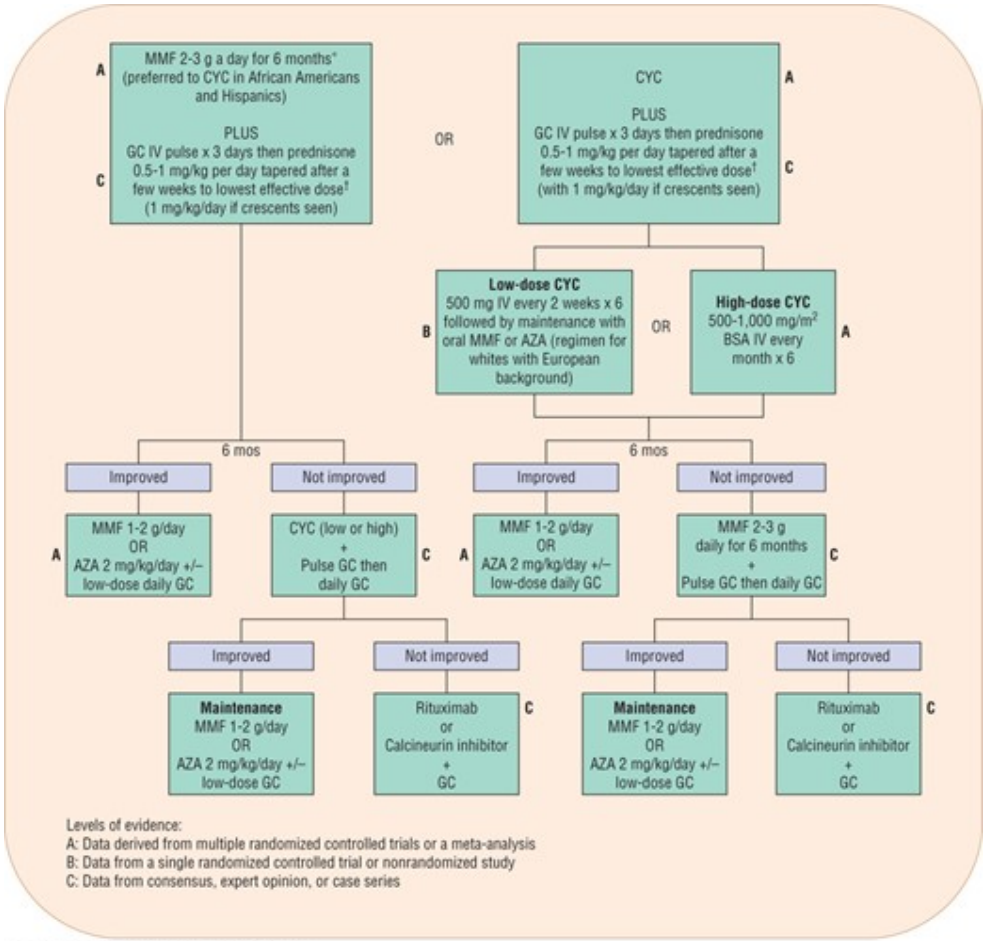
6 Treatment is personalized based on the manifestations of SLE in the patient. It consists of a combination of immunosuppression and symptomatic and supportive therapies. The only drugs approved by the FDA for treatment of SLE are aspirin, prednisone, hydroxychloroquine, and belimumab. The use of other drugs for SLE, even those considered "standard of care," is considered to be "off-label" use. For many of these drugs, the optimal doses and duration of therapy for induction and maintenance of

response in SLE have not been determined.

Organization or expert task force treatment recommendations have been published for lupus nephritis, neuropsychiatric lupus, and antiphospholipid antibody carriers.[6,27,38] A committee of the ACR developed guidelines for screening, treatment, and management of lupus nephritis. All patients with nephritis should receive hydroxychloroquine to reduce damage and flares. An angiotensin-converting enzyme inhibitor or angiotensin receptor blocker can reduce proteinuria by about 30% in those with proteinuria of 0.5 g/day or more, and delay progression of renal disease. Blood pressure should be maintained at no more than 130/80 mm Hg. Patients with a low-density lipoprotein cholesterol greater than 100 mg/dL (2.59 mmol/L) should receive a statin to prevent accelerated atherosclerosis. More specific treatment is based on the type of nephritis. The first two classes, minimal mesangial and mesangial proliferative lupus nephritis do not usually need immunosuppressive therapy. Focal and diffuse lupus nephritis (Classes III and IV) are treated similarly with aggressive use of glucocorticoids and immunosuppressive therapy. **Figure 87-3** shows the induction regimens for these patients and the levels of evidence to support the recommendations. Patients with a combination of Class V with III or IV would be treated similarly to those with only III or IV. The initial cyclophosphamide or mycophenolate mofetil therapy should be continued for 6 months unless proteinuria or serum creatinine worsens by 50% or more at 3 months (Level A evidence). After 6 months of induction therapy, patients who have improved can be maintained on mycophenolate mofetil or azathioprine, with low doses of corticosteroids if needed. Patients with pure Class V, membranous lupus nephritis, and nephrotic range proteinuria of more than 3 g/day should receive induction therapy with mycophenolate mofetil 2 to 3 g/day with prednisone 0.5 mg/kg/day for 6 months (Level A evidence). Those who improve can be maintained on mycophenolate mofetil 1 to 2 g/day or azathioprine 2 mg/kg/day. Patients who do not respond should be treated with cyclophosphamide 500 to 1,000 mg/m^2/mo for 6 months with IV pulse glucocorticoids, followed by prednisone 0.5 to 1 mg/kg/day.[6] Maintenance therapy should be continued for at least 3 years.[39] Patients with advanced sclerosing lupus nephritis (Class VI) should be considered for renal replacement therapy.[6]

FIGURE 87-3

American College of Rheumatology guidelines for therapy for Class III/IV lupus nephritis. (AZA, azathioprine; BSA, body surface area; GC, glucocorticoids; MMF, mycophenolate mofetil; *, preference of MMF over cyclophosphamide (CYC) in patients who desire to preserve fertility; †, recommended background therapies discussed in text.) *(Used with permission from Hahn BH, McMahon MA, Wilkinson A, et al. American College of Rheumatology guidelines for screening, treatment, and management of lupus nephritis. Arthritis Care Res 2012; 64:797 -808. Copyright © 2012 from John Wiley & Sons, Inc.)*



A task force of the European League Against Rheumatism (EULAR) developed recommendations for the management of neuropsychiatric lupus. Treatment depends on the manifestations. Symptomatic therapy (eg, anticonvulsants and antidepressants) should be given as needed. More specific treatment depends on whether the problem is determined to be inflammatory or thrombotic or both. If there is inflammation or neurotoxic damage in the presence of generalized SLE activity, glucocorticoids alone or in conjunction with immunosuppressive drugs such as azathioprine or cyclophosphamide should be given (Strong evidence). If the condition does not respond, other treatments such as plasma exchange, IV immunoglobulin, or rituximab can be tried. If the problem is related to moderate-to-high titers of antiphospholipid antibodies and/or thrombosis, anticoagulants and/or inhibitors of platelet aggregation should be used (Sufficient evidence).[27]

For patients with intermittent joint pain associated with SLE, NSAIDs are good initial therapy. If the pain is more severe or persistent, prednisone in a dose of 10 mg/day or less in combination with hydroxychloroquine should be instituted. Intra-articular corticosteroid injections can be used for localized joint pain. If this therapy is inadequate, methotrexate can be added to hydroxychloroquine therapy. For patients who fail or are intolerant of these therapies, mycophenolate mofetil or azathioprine can be tried. If alternative treatment is needed, leflunomide, belimumab, rituximab, abatacept, or TNF-α inhibitors may be considered.[40]

The first step in management of cutaneous lupus erythematosus is counseling patients to protect themselves from ultraviolet light as described above.[25] Drug treatment is personalized based on the

extent and severity of involvement. Topical corticosteroids are commonly used and may relieve symptoms such as itching or burning, but may not provide adequate clearing of lesions when used alone.[25] The choice of corticosteroid depends on the location of application. Low potency corticosteroids (eg, fluocinolone acetonide 0.01% and hydrocortisone 1%) should be used on areas with thin skin such as the face and groin, mid-potency (eg, triamcinolone acetonide) for trunk and extremities, and high potency (eg, clobetasol propionate) for thick-skin areas such as scalp, soles, and palms. Creams or, for more severe disease, ointments are used on the body, and foams or solutions on the scalp.[23] Intralesional corticosteroids may be used in discoid lupus, but should not be repeated more often than every 4 to 6 weeks.[25] To avoid the adverse effects of topical corticosteroids, such as skin atrophy, telangiectasias, and steroid-induced dermatitis, the lowest effective potency and duration of therapy should be used.[23] Alternatively, topical calcineurin inhibitors may be given instead. Pimecrolimus is more lipophilic than tacrolimus and has greater affinity for the skin. Antimalarials have photoprotective effects and are commonly used as first line systemic therapy in the management of cutaneous lupus. If hydroxychloroquine alone is ineffective, quinacrine, available from compounding pharmacies, may be added.[25] For refractory disease, systemic immunosuppressive drugs (eg, corticosteroids, methotrexate, mycophenolate mofetil, or azathioprine), immunomodulatory drugs (eg, dapsone, thalidomide, or lenalidomide), biologics (eg, rituximab or belimumab), or oral retinoids may be added. The evidence to support their use in management of cutaneous lupus is mainly from case reports rather than controlled studies. The choice of agents may be guided by other organ involvement.[23]

Dosing information for selected drugs is shown in **Table 87-2**. Since most of the drugs used to treat SLE are not FDA-approved for that indication, the doses given are based on other uses for those drugs. **Table 87-3** lists adverse effects and drug monitoring parameters. Selected issues concerning the drugs are discussed below.

TABLE 87-2 Dosing of Drugs Used to Treat Systemic Lupus Erythematosus

Drug	Brand Name	Initial or Starting Dose	Usual Range or Maintenance Dose	Special Population Doses	Comments (adverse drug reactions, special populations)
NSAIDs/salicylates	Various drugs				Caution in patients with renal insufficiency, cardiovascular disease, gastrointestinal problems
Glucocorticoids	Deltasone (prednisone), Medrol (prednisolone)	0.1-1.5 mg/kg/day PO	Prefer <10 mg/day PO		Dose depends on organ involvement and severity; initial dose may be given for 4-6

Drug	Brand Name	Initial or Starting Dose	Usual Range or Maintenance Dose	Special Population Doses	Comments (adverse drug reactions, special populations)
					weeks, then tapered down for maintenance; no standard dose
	Solu-Medrol (methylprednisolone)	100-1,000 mg IV daily × 3			Severe disease; later, dose tapered and changed to PO
Hydroxychloroquine	Plaquenil	400 mg PO daily or twice daily	200-400 mg PO daily	Dosing adjustment may be needed with renal or hepatic dysfunction	Dose should not exceed 6.5 mg/kg/day to minimize retinopathy risk
Belimumab	Benlysta	10 mg/kg IV every 2 weeks × 3	10 mg/kg IV every 4 weeks	Use with caution in African Americans; no data on use in hepatic impairment; no adjustment for renal impairment if CrCl ≥15 mL/min (≥0.25 mL/s); pregnancy category C; no studies in pregnant or breastfeeding women	IV infusion over 1 h; consider premedication to prevent infusion and hypersensitivity reactions; hypersensitivity reactions up to 4 hours after administration; most common with first two infusions
Cyclophosphamide	Cytoxan	500-1,000 mg/m^2 BSA IV every month × 6 or 500 mg IV every 2 weeks × 6		Dosing adjustment might be needed with renal dysfunction; low and high doses may have equivalent efficacy in white patients with European background	Infertility in women and men, teratogenicity of concern

Drug	Brand Name	Initial or Starting Dose	Usual Range or Maintenance Dose	Special Population Doses	Comments (adverse drug reactions, special populations)
Mycophenolate mofetil	Cellcept Myfortic (enteric coated mycophenolate sodium)	2-3 g/day PO	0.5-3 g/day PO	Lower doses may be needed in Asians than non-Asians; may be more effective than cyclophosphamide in African Americans and Hispanics	Contraindicated in pregnancy
Azathioprine	Imuran	2 mg/kg/day PO	1.5-2 mg/kg/day PO		Lower dose if thiopurine methyltransferase (TPMT) deficient
Methotrexate	Rheumatrex, Trexall, Otrexup, Rasuvo		15-25 mg PO or SC weekly		Decrease toxicity by giving with folic acid
Rituximab	Rituxan	375 mg/m^2 BSA IV weekly × 4 or 500-1,000 mg IV on days 1 and 15		Variable doses have been used	Alternative for patients refractory to other treatments; may be more effective in African Americans

BSA, body surface area; CrCl, creatinine clearance; IV, intravenously; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, orally.

TABLE 87-3 Monitoring of Drugs Used to Treat Systemic Lupus Erythematosus

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
NSAIDs/salicylates	Gastrointestinal bleeding, hepatic toxicity, renal toxicity, hypertension, cardiovascular events, aseptic meningitis	CBC[a], platelets[a], creatinine[a], urinalysis, AST/ALT[a], blood pressure[a]	Antihypertensive effects of calcium channel blockers affected less than other classes
Glucocorticoids, systemic	Osteoporosis, cataracts, glaucoma, hyperglycemia/diabetes,	Blood pressure[a], serum glucose[a], lipid panel[a], bone	Patients should receive osteoporosis preventive therapy; high doses of

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
	hypertension, dyslipidemia, thinning of the skin, weight gain, fat redistribution	densitometry, ophthalmic examinations	systemic corticosteroids are associated with infections, myopathy, psychological disturbances, osteonecrosis, and stroke
Glucocorticoids, topical	Skin atrophy, telangiectasias	Skin appearance	Avoid prolonged use, especially of high-potency steroids
Hydroxychloroquine	Retinal toxicity	Funduscopic and visual field examinations, consider electroretinogram, spectral domain optical coherence tomography, or fundus autofluorescence (frequency depends on level of risk), CBC, AST/ALT, albumin, chemistry panel, creatinine	Risk for retinal toxicity increased with doses >6.5 mg/kg/day ideal body weight, more than 5 years therapy, or age over 60 years
Belimumab	Infusion reactions, hypersensitivity, nausea, diarrhea, fever, nasopharyngitis, bronchitis, insomnia, pain in extremity, depression, migraine	Monitor for serious infections, hypersensitivity/infusion reactions, worsening depression, mood changes, or suicidal thoughts	No live vaccines 30 days before or during belimumab therapy; not recommended with other biologics or IV cyclophosphamide; consider premedication with acetaminophen and diphenhydramine
Cyclophosphamide	Myelosuppression, opportunistic infections, hemorrhagic cystitis, bladder malignancy, infertility	CBC[b], platelets[b], creatinine, AST/ALT, urinalysis[b], urine cytology[a], PAP test[a]	Greater risk for cystitis with oral form than IV; decrease with hydration and mesna
Mycophenolate mofetil	Myelosuppression, nausea, vomiting, diarrhea	CBC[c], platelets[c], creatinine, chemistry panel, AST/ALT, chest x-ray	Gastrointestinal side effects may limit use and compliance; these symptoms may be less with use of an enteric-coated form
Azathioprine	Myelosuppression, hepatotoxicity	CBC[c,d], platelets[c,d], creatinine[e], AST/ALT[c,f], chemistry panel[e], albumin, TPMT assay, PAP test	Test thiopurine methyltransferase (TPMT) before starting; toxicity greatly

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
			increased if deficient
Methotrexate	Hepatic, hematologic, pulmonary toxicity; stomatitis	CBC[c,g], platelets[c,g], creatinine[c,g], AST/ALT[c,g], albumin[c,g], bilirubin, chemistry panel[h], alkaline phosphatase[c], chest x-ray	Check hepatitis B and C serologies before starting if at risk
Rituximab	Infusion reactions, infections, neutropenia, mucocutaneous reactions, fever, fatigue, progressive multifocal leukoencephalopathy	CBC[i], platelets[i], creatinine, vital signs, human antichimeric antibody (HACA) titers	Consider pretreatment with acetaminophen, diphenhydramine, corticosteroid to decrease infusion reactions

Monitoring parameters should be checked at baseline and at interval noted: [a]52 weeks, [b]4 weeks, [c]12 weeks, [d]every 1-2 weeks after dose change, [e]26 weeks, [f]every 2 weeks after dose change, [g]2-4 weeks during 3 months after dose change, [h]8 weeks, [i]8-16 weeks.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs are used as first-line treatment for arthritis, musculoskeletal complaints, fever, and serositis.[14] Low-dose aspirin is used in patients with antiphospholipid antibodies.[41] One concern with use of NSAIDs is that they can decrease renal function, which can complicate evaluation of lupus nephritis. They have the potential to increase cardiac events in patients who already are at elevated risk. Other adverse effects include hepatotoxicity, GI bleeding, and aseptic meningitis.[14]

Corticosteroids

Corticosteroids as monotherapy or as adjuncts to other treatment can control flares and maintain low disease activity in SLE. Their effects have a rapid onset, whereas other therapies may take months or over a year to achieve their maximum benefits. The corticosteroids can be used topically or systemically.

Clinical Controversy…

Corticosteroids are commonly used to treat SLE and their adverse effects are well known, but optimal dosing is still unclear. What constitutes an appropriate dose in different situations? How long should therapy be continued? How should it be tapered?

Although corticosteroids have been used in the management of SLE since the 1950s, optimal doses have

not been determined. High doses given in a pulse IV administration regimen are used to treat flares and quickly reduce inflammation. Doses should slowly be tapered down to the lowest effective dose. Corticosteroids are the foundation for treatment of most forms of SLE.[33]

High doses of systemic corticosteroids are associated with infections, myopathy, psychological disturbances, osteonecrosis, and stroke.[33] Psychiatric disease, mostly mood disorder, occurs in 10% of patients receiving prednisone doses of 1 mg/kg or higher.[27] Common side effects of low (less than 7.5 mg prednisone/day) to moderate (7.5-30 mg/day) doses are shown in Table 87-3. Although higher doses may be divided, single morning doses may be associated with fewer adverse effects and less adrenal suppression. Chronic use of any dose is associated with coronary artery disease, cataracts, diabetes mellitus, and osteoporosis.[33] Corticosteroids increase catabolism of 25(OH) vitamin D and $1,25(OH)_2$ vitamin D. Osteoporosis prophylaxis is often found to be inadequate.[42] To avoid adrenal insufficiency, patients on chronic corticosteroid therapy should not have treatment stopped abruptly and they may need increased doses at times of stress such as surgery.[43] Prolonged use of topical corticosteroids can lead to atrophy of the skin and telangiectasias (small dilated blood vessels).[23]

Antimalarials

The antimalarials chloroquine and hydroxychloroquine have long been used in rheumatology practice. Hydroxychloroquine is thought to have fewer adverse reactions and is the preferred drug. In the past, hydroxychloroquine was primarily used for skin and joint manifestations of SLE, but many experts believe that all patients with SLE should receive hydroxychloroquine. There is high quality evidence that it decreases disease activity and improves survival; moderate quality evidence that it increases bone mineral density and has protective effects against thrombosis and irreversible organ damage; and low quality evidence that it reduces severe flares, enhances the response to other drugs in patients with nephritis, has a beneficial effect on lipids, and protects against cancer. It can allow corticosteroid doses to be decreased. When given to patients with some findings consistent with SLE, it can delay the time for them to fully meet criteria for the disease.[44] Patients receiving hydroxychloroquine often have disease flares when the drug is discontinued.[31]

Hydroxychloroquine has antiinflammatory, immunomodulatory, and antithrombotic effects. It reduces concentrations of inflammatory cytokines such as interleukins 1, 2, 6, 17, and 22, interferon alpha and gamma, and TNF-α. It alters antigen presentation and T cell proliferative responses. Its key activity may be decreasing activation of toll-like receptors, which are important in innate immunity and autoimmune diseases. It reduces platelet aggregation and thrombosis.[31] It also delays ultraviolet light absorption and may decrease the number of skin antigen-presenting cells.[22] Finally, it may reduce cardiovascular risk factors such as hyperlipidemia and diabetes mellitus and improve survival.[31] The LUMINA (LUpus in MInorities, NAture vs nurture) database was initiated in 1994 to look at differences in SLE outcomes based on ethnic backgrounds. It included African Americans, Hispanics, and Caucasians. Some findings based on study of this cohort are that hydroxychloroquine may delay the occurrence of integument damage (severe skin damage including scarring, ulcers, and scarring alopecia) and decrease accrual of damage.[22]

Clinical Controversy…

Should whole blood hydroxychloroquine concentrations be monitored? Some studies show a correlation

between concentration and SLE disease control while others do not. Should blood hydroxychloroquine concentrations be used to monitor adherence but not for dosage adjustment?

Although some studies showed reduced disease activity and flares with hydroxychloroquine whole blood concentrations over 1,000 ng/mL (mcg/L; 2,977 nmol/L), other studies where doses were adjusted to achieve that concentration did not shown better disease control. It has been suggested that hydroxychloroquine concentration monitoring be used as a measure of adherence to therapy. The drug has a long elimination half-life of at least 5 days with a terminal half-life of about 40 days. Low concentrations may therefore be an indicator of consistent nonadherence or abnormal metabolism.[45] It may take 2 to 8 weeks to see the therapeutic effects of hydroxychloroquine.[31]

Adverse effects with hydroxychloroquine are usually mild. Most common are GI and skin reactions and they usually improve with dose reduction. The main concern is retinal toxicity, but the incidence is low and less than that seen with chloroquine.[31] The incidence increases to 1% in patients receiving the drug for more than 5 years or who have received a cumulative dose of 1,000 g. Other risk factors are daily doses more than 400 mg or 6.5 mg/kg ideal body weight, advanced age, or patients with kidney or liver dysfunction or preexisting retinal or macular disease. The retinal damage has a characteristic bull's-eye appearance on funduscopic examination and is irreversible. Early recognition of damage may minimize vision loss. The current American Academy of Ophthalmology monitoring recommendations are to have several baseline screening tests including visual acuity, dilated examination of the cornea and retina, visual fields, and at least one newer, more sensitive test such as electroretinogram, spectral domain optical coherence tomography, or fundus autofluorescence. After 5 years, patients should begin annual examinations unless the patient is considered to be at high risk, in which case yearly testing would begin earlier. If there are changes suspicious for toxicity, the drug should be stopped, or, after consultation with the patient about risks of blindness, examinations should be repeated every 3 to 6 months until the diagnosis is confirmed.[46]

Biologic Agents

Since autoantibody formation is an important feature of SLE, B cells make a logical target for SLE therapy. B-lymphocyte stimulator (BLyS) is a cytokine that is important for B cell survival, maturation, and differentiation. Belimumab is a fully human IgG1-λ monoclonal antibody that binds to soluble BLyS, which prevents BLyS from binding to receptors on B cells and promotes apoptosis of B lymphocytes. Belimumab is FDA-approved for treatment of autoantibody-positive active SLE in addition to standard therapy. It is the first drug approved by the FDA in over 50 years for management of SLE.[47] Approval of belimumab was based on two international phase III trials: BLISS-76, conducted primarily in Western Europe and North America, and BLISS-52, which was carried out in Eastern Europe, Latin America, and the Asia-Pacific region. These trials had strict entry criteria and used the new SLE Responder Index (SRI) assessment criteria. For both studies, the primary efficacy endpoint was the SRI at 52 weeks. Entry requirements included age of at least 18 years old, positive ANA or anti-dsDNA, and active SLE (SELENA-SLEDAI [measure of disease activity] score of 6 or greater) while receiving standard treatment (prednisone, NSAIDs, antimalarials, and/or immunosuppressive drugs [but not cyclophosphamide or other biologics]). Patients had to be on stable therapy for at least 30 days. The most common organ systems involved were musculoskeletal and mucocutaneous. Patients with severe active lupus nephritis or CNS lupus were excluded. Patients received belimumab 1 mg/kg, 10 mg/kg, or placebo by IV infusion every 2 weeks for two doses, then every 4 weeks, in addition to their standard therapy. There were restrictions on

concomitant medications, and those became stricter as the studies progressed. The response rate was significantly higher in the group receiving belimumab 10 mg/kg as compared to placebo in both studies.[48] Patients receiving belimumab also had greater improvement in health-related quality of life.[49] A posthoc analysis of SRI response in patients of African descent showed that they did not benefit from belimumab and actually had lower SRI scores than those receiving placebo.[50] Subsequent experience from academic clinical practice found favorable responses to belimumab in all racial and ethnic groups.[51]

Rituximab is a chimeric monoclonal antibody directed at the CD20 antigen on B cells.[14] Although many case reports and open-label trials have reported beneficial effects of rituximab in SLE, randomized, placebo-controlled trials of rituximab have not demonstrated efficacy in SLE. The largest of these were the EXPLORER (Efficacy and Safety of Rituximab in Moderately-to-Severely Active Systemic Lupus Erythematosus) trial which evaluated patients with extrarenal involvement treated with rituximab and immunosuppressive drugs and the LUNAR (LUpus Nephritis Assessment with Rituximab) trial that examined use of rituximab with mycophenolate mofetil and corticosteroids in patients with lupus nephritis. Failure to show significant benefit could be due to the short duration of the trials or the choice of endpoints. Further improvement has been observed in the second year of therapy. Exploratory analyses of specific patient subgroups or use of different response criteria suggested some benefit. Rituximab may be more effective in patients of African descent with lupus nephritis than those of other races, or in combination with cyclophosphamide instead of mycophenolate mofetil.[52,53] It may serve as an alternative therapy in treatment of refractory lupus nephritis, severe hematological lupus, and some CNS manifestations of the disease. It may also prove useful for maintenance therapy, as a steroid-sparing agent, or when preservation of fertility is desired.[53]

Other drugs targeting B cells are being investigated in SLE. Examples of these are blisibimod, which inhibits BLyS, and atacicept which blocks both BLyS- and APRIL (a proliferation-inducing ligand)-mediated B cell stimulation. Sifalimumab blocks interferon alpha. Other biologic agents have been tried in SLE with varying degrees of success, such as tocilizumab, which inhibits interleukin-6, and abatacept, which inhibits T cell costimulation.[54] The observed efficacy of drugs may depend on the definition of response used. Interestingly, a study of abatacept for lupus nephritis failed to show efficacy, but when other investigators applied endpoint criteria used in different studies of the disease to that data, very different results were observed.[55]

As discussed later, there is concern about TNF-α inhibitors inducing lupus. However, short term induction therapy with infliximab may confer long-lasting benefits in patients with lupus nephritis. When TNF-α inhibitors are used to treat lupus arthritis, patients respond but relapse within a few months after the drug is stopped.[56] Good results have been observed with etanercept as long term treatment of refractory lupus arthritis.[57] Biologic drugs should not be combined.

Immunosuppressive Drugs

Cyclophosphamide has long been used to treat severe organ involvement in SLE such as lupus nephritis, neuropsychiatric lupus, and severe systemic vasculitis.[14] Its role in therapy is being redefined because of the availability of newer drugs, as discussed elsewhere in this chapter. Response rate and dosing requirements may vary with patient race. Cyclophosphamide is an alkylating agent that causes cross-linkage of DNA leading to cell death. It may also suppress B cells and IgG production, and decrease

production of adhesion molecules and cytokines. Cyclophosphamide has an oral bioavailability of 75% to 100%. It is a prodrug that is metabolized to active and inactive metabolites via the cytochrome P450 enzyme system. Cyclophosphamide is primarily cleared by the liver, but its active metabolites may persist in renal failure.[58]

Cyclophosphamide can potentially cause hemorrhagic cystitis and bladder cancer due to acrolein, a metabolite of the drug that concentrates in the bladder. The risk appears to be greater with oral administration, higher cumulative doses, and in smokers. The association with intermittent pulse IV doses in SLE patients is less clear. Hydration and frequent voiding may decrease the risk of these adverse effects. With oral administration, patients are advised to take the drug in the morning and to drink fluids for several hours. Adherence is not good with this regimen. With IV administration, IV fluids are begun before administration of the cyclophosphamide and continued for several hours after. Patients are encouraged to maintain oral hydration for 72 hours. Another method to decrease bladder toxicity is to use sodium-2-mercaptoethane sulfonate (Mesna), which binds acrolein and prevents its harmful effects on the bladder. Although mesna is sometimes used with high-dose cyclophosphamide, it is only FDA-approved for use with ifosfamide. Use of mesna with daily oral cyclophosphamide is expensive and inconvenient based on available dosage forms. The recommended mesna regimen with IV pulse doses of cyclophosphamide is to give IV doses, each equivalent to 20% of the cyclophosphamide dose, 15 to 30 minutes before the cyclophosphamide, then 4 and 8 hours after. Since oral mesna is about 50% bioavailable, the 4- and 8-hour mesna doses after cyclophosphamide may be given orally, each in doses equivalent to 40% of the administered dose of cyclophosphamide.[58] In practice, a variety of mesna regimens are used.

Mycophenolic acid (MPA) reversibly inhibits the enzyme inosine 5-monophosphate dehydrogenase (IMPDH), which is important for de novo synthesis of purine (guanosine) nucleotides. This inhibits proliferation and differentiation of lymphocytes. The drug also has other immunomodulating effects such as induction of activated T cell apoptosis, inhibition of adhesion molecule expression, and antifibrotic and antiproliferative effects on cells such as fibroblasts, dendritic cells, and vascular smooth muscle cells.[59]

Mycophenolate mofetil is hydrolyzed to MPA, its active form. The mofetil salt has greater bioavailability. MPA is bound to albumin, so unbound drug concentrations can be affected by changes in albumin. MPA is glucuronidated in the liver to an inactive metabolite, mycophenolic glucuronide. The metabolite undergoes enterohepatic recycling, with conversion back to the active form.[59]

Mycophenolate mofetil has been most studied in treatment of lupus nephritis. It has been shown to be at least as effective as cyclophosphamide for induction therapy and as azathioprine for maintenance treatment.[60,61] The Aspreva Lupus Management Study (ALMS) was a multinational study of lupus nephritis in 370 patients. The 6-month induction phase showed mycophenolate mofetil to be equivalent in efficacy to monthly IV pulse doses of cyclophosphamide, including in a small group of patients with an estimated glomerular filtration rate (eGFR) less than 30 mL/min (0.5 mL/s).[59] The response to therapy at 6 months correlated with the baseline complement C4 concentration, time since diagnosis of lupus nephritis, and eGFR. Normalization of complement C3 and/or C4 and reduction in proteinuria of at least 25% at 8 weeks also predicted renal improvement at 6 months.[62] In the 36-month maintenance phase, mycophenolate mofetil was superior to azathioprine in maintaining renal response to treatment and preventing disease relapse. Although adverse events occurred in more than 97% of patients in both groups, more patients receiving azathioprine withdrew from the study due to toxicity than those receiving mycophenolate

mofetil.[63] The MAINTAIN trial did not find a difference in the rate of renal flare with mycophenolate mofetil compared to azathioprine 5 years after induction with IV cyclophosphamide. The difference in these results compared to the ALMS trial may be due to the difference in populations studied. The MAINTAIN trial studied 105 predominantly white European patients, whereas the larger ALMS trial included a more racially diverse population.[59]

Mycophenolate mofetil may also be useful for other manifestations of SLE such as arthritis, cutaneous lupus, and hematologic involvement, including hemolytic anemia and thrombocytopenia.[59]

The most common adverse effects observed with mycophenolate mofetil are GI, including nausea, vomiting, and diarrhea. These may be severe enough to require discontinuation of therapy. Hematologic effects such as red cell aplasia may also be seen. The side effects may be diminished with a reduction in dose. Use of an enteric-coated form may decrease GI symptoms. Numerous congenital malformations have been reported with mycophenolate mofetil and it is contraindicated in pregnancy.[59]

Azathioprine is a purine analog that is metabolized to mercaptopurine. It inhibits DNA synthesis and prevents immune cell proliferation.[64] Mercaptopurine is inactivated by thiopurine methyltransferase (TPMT). If activity of that enzyme is low, patients may experience more severe toxicity. Myelosuppression and gastrointestinal adverse effects correlate with TPMT polymorphism, but hepatotoxicity may not. Other metabolic pathways are also involved in the elimination of azathioprine.[65] The metabolism of azathioprine and mercaptopurine is inhibited by allopurinol and febuxostat. If the combination of these drugs is to be used, a reduction in dose is required.[64] Azathioprine is less effective than cyclophosphamide for induction therapy in lupus nephritis, but it can be useful as an alternative to mycophenolate mofetil for maintenance treatment.[6] Azathioprine may also be used for SLE-related arthritis, serositis, and mucocutaneous manifestations. It has steroid-sparing effects, allowing use of lower doses of corticosteroids.[14]

Methotrexate is an inhibitor of dihydrofolate reductase, which is needed for DNA synthesis and cell proliferation.[32] Its toxicities are reduced by administration of folic acid. It is important to note that it is dosed once weekly in the management of SLE. It is used for arthritis and skin disease and as a steroid-sparing drug.[14]

Numerous other immunosuppressive drugs have been used in SLE, especially in patients who have contraindications to use of the agents already discussed or who cannot tolerate them, or those whose disease is refractory to conventional treatment.

Alternative Treatments

Studies have shown that SLE patients receiving conventional treatment frequently feel they have unmet needs. Often these are psychosocial and may include anxiety or depression. These needs can lead patients to try alternative therapies. It is important for healthcare providers to have an open dialogue with patients about these therapies so that patients will report them. This allows practitioners to monitor for interactions with other treatments and to guide patients to therapies with greater potential for benefit and less for harm.[66]

Complementary and alternative medicine includes health systems, products, and practices that are outside the realm of conventional medicine. In general, these have not been evaluated in randomized controlled

trials involving SLE patients.[66]

Concentrations of dehydroepiandrosterone (DHEA), a weak adrenal androgen, are typically decreased in SLE. Some small studies have suggested that DHEA supplementation may offer some limited benefit for patients' assessment of disease activity, steroid effects on bone mineral density, and time to flares in SLE.[66]

Vitamin D concentrations are decreased in SLE, especially in patients with high disease activity and those with darker skin pigmentation (eg, African Americans). A contributing factor to the deficiency is that patients are told to protect themselves from sunlight because of the photosensitivity that accompanies SLE.[42] This can not only affect bone health, but some studies show that low concentrations of vitamin D may also be associated with greater SLE disease activity, flares, and fatigue.[67] Low concentrations also correlate with increased cardiovascular risk factors such as hypertension and hyperlipidemia.[68] B and T lymphocytes, dendritic cells, macrophages, and neutrophils have vitamin D receptors, which suggests a role for vitamin D in both innate and adaptive immune processes.[67] Some experts suggest that most patients with SLE should receive vitamin D supplements of at least 400 IU/day of vitamin D3.[25] One recommendation is to check a baseline 25(OH) vitamin D concentration with a current goal of 30 ng/mL (75 nmol/L). An optimal goal has not yet been determined. The concentration should be rechecked 3 months after a change in vitamin D dosing since that is the time required to reach steady state.[42]

Special Populations

Pregnancy and Contraception

7 Pregnancy planning with assessment of risk factors is key for achieving good outcomes for women with SLE and healthy babies. Timing of pregnancies with respect to disease activity and use of teratogenic medications make contraception counseling very important.[69] Cyclophosphamide therapy is associated with ovarian failure and infertility. This is especially of concern in older women who wish to conceive.[6] Estrogen-containing oral contraceptives are associated with thrombosis, especially in women with antiphospholipid antibodies.[70] Estrogen replacement may increase the risk of thrombosis in postmenopausal women.[10] Although SLE flares have been a concern with use of hormonal contraceptives, recent studies in mild-to-moderate disease did not show such an association, but the results may be influenced by study inclusion and exclusion criteria.[70] Progesterone-only contraceptives may be used but the adverse effects of acne and hirsutism may make them less desirable and the risk of osteoporosis increases after 2 years of use. Intrauterine devices may be better choices for contraception.[71,72]

Pregnancy during SLE is considered to be high risk. The risk of maternal mortality, cesarean delivery, preterm labor, and preeclampsia and the risk of thrombotic, infectious, and hematologic complications are increased.[73,74] Fetal loss, intrauterine growth restriction, and early preeclampsia may relate to uterine-placental insufficiency with poor placental blood flow.[75] Preeclampsia occurs in 10% to 30% of women with SLE and is defined as hypertension (BP greater than 140/90) and proteinuria (greater than 300 mg/24 h) that develop for the first time after 20 weeks of gestation.[73,76] This can be difficult to distinguish from lupus nephritis. The risk for preterm preeclampsia may be decreased by 90% with daily use of low-dose aspirin begun before 16 weeks' gestation.[75] Flares during pregnancy may be difficult to identify since they

may share characteristics of a normal pregnancy.[72] The complications are more likely in patients with active disease, especially lupus nephritis. If the mother has anti-Ro/SSA or anti-La/SSB antibodies, the fetus is at risk for neonatal lupus with rash and cardiac abnormalities including heart block. These risks are significantly decreased with continued use of hydroxychloroquine.[73] Treatment of pregnant women with antiphospholipid antibodies is discussed below. Pregnancy should be discouraged in patients with severe pulmonary hypertension, advanced renal insufficiency, severe restrictive lung disease, heart failure, or a history of severe preeclampsia. It also is not advised within 6 months of a severe SLE flare, active lupus nephritis, or a stroke. The best pregnancy outcomes are observed in patients who have had inactive disease for at least 6 months prior to the pregnancy. Drugs used to control the SLE should be those such as hydroxychloroquine, which can be continued throughout the pregnancy and may decrease the incidence of flares.[73] Any potentially teratogenic drugs (eg, methotrexate, leflunomide, mycophenolate, cyclophosphamide, and thalidomide) should be stopped at least 3 months before attempting pregnancy. Leflunomide should be removed through the oral cholestyramine elimination procedure (8 g three times a day for 11 days with confirmation of undetectable serum concentrations) prior to conception. Close monitoring and disease management of the mothers and fetuses are essential during pregnancy. The risks of drug use and harmful effects of disease flare both need to be considered.[72] If a flare occurs and an immunosuppressive drug is required during the pregnancy, azathioprine may be considered, since the fetal liver is unable to metabolize it to its active form. The dose should not exceed 2 mg/kg/day.[77] If corticosteroids are needed, maintenance doses should be kept at the equivalent of prednisone 10 mg daily or less to decrease the risk of gestational diabetes mellitus, infections, and premature rupture of membranes.[33,72] Patients on long-term steroid therapy may need stress doses at the time of delivery. Fluorinated corticosteroids (such as dexamethasone or betamethasone) should be avoided unless they are being used to treat the fetus, since they cross the placenta.[73] Cyclophosphamide should only be used during pregnancy if alternatives failed and the mother's life is in danger.[72] If treatment of hypertension is needed, methyldopa and labetalol are preferred, with nifedipine or hydralazine considered as alternatives.[72,73] Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may cause fetal malformations and neonatal renal failure and death.[73] Diuretics are generally avoided but if one is needed, furosemide is preferred.[72] NSAIDs should be used with caution during early pregnancy. Congenital malformations have been reported with use in the first trimester and impaired fetal renal function after 20 weeks. They should not be used after 32 weeks of gestation because they increase the risk of premature closure of the ductus arteriosus by almost 15-fold.[73]

SLE–Antiphospholipid Syndrome Overlap

8 The antiphospholipid antibodies consist of anticardiolipin, anti-β-2-glycoprotein I, and lupus anticoagulant and they can promote clotting and inflammation.[78] Complement also plays a key role in antiphospholipid syndrome (APS) pathogenesis.[41] The diagnosis of APS requires at least one clinical and one laboratory feature. The clinical aspects are vascular events such as venous or arterial thrombi and/or obstetric complications. The obstetric complications meeting the criteria are three or more unexplained consecutive miscarriages before the 10th week of gestation, one or more unexplained deaths of fetuses at or beyond the 10th week of gestation, and one or more births of infants before the 34th week of gestation associated with eclampsia or severe preeclampsia or features of placental insufficiency.[79] Adverse pregnancy outcomes after 12 weeks of gestation are especially associated with the presence of lupus anticoagulant.[80] Laboratory criteria are the presence of antiphospholipid antibodies on two

separate occasions, 12 weeks apart.[79] Antiphospholipid antibodies are found in about 40% of patients with SLE, but less than 40% of those experience thrombotic events.[81] Patients with lupus anticoagulant or persistently positive anticardiolipin at medium-high titers are at high risk for thrombosis, and those with all three antibodies (triple positivity) are at highest risk. Patients with isolated, intermittently positive anticardiolipin or anti-β_2-glycoprotein I at low-medium titers are considered to be at low risk. Patients with thrombosis often have other cardiovascular risk factors (such as hypertension, hyperlipidemia, smoking, or use of estrogen-containing medications) or an underlying autoimmune disease such as SLE. It is recommended that any modifiable factors be controlled. In deciding choice, intensity, and duration of treatment, the clinician should balance benefits with the patient's risk of bleeding. Consideration should also be given to whether thrombotic events are associated with identified transient precipitating factors. An international group of physicians who had clinical and research experience with APS reviewed the literature and developed consensus guidelines for management of thrombosis in patients with antiphospholipid antibodies (**Table 87-4**).[38]

TABLE 87-4 Recommendations for Thromboprophylaxis in Patients with Systemic Lupus Erythematosus and Antiphospholipid Antibodies

Recommendation	Grade of Recommendation
1. General measures for aPL carriers	
Control cardiovascular risk factors if high-risk aPL profile	Nongraded
Thromboprophylaxis with low molecular weight heparin in high risk situations such as surgery, prolonged immobilization, and after childbirth	1C
2. Primary thromboprophylaxis	
Regularly assess patients for presence of aPL	Nongraded
Thromboprophylaxis with hydroxychloroquine (1) and low-dose aspirin (2) for patients with positive LA or persistent aCL at medium-high titers	1B (1) 2B (2)
3. Secondary thromboprophylaxis	
Treat patients with arterial or venous thrombosis and aPL who do not meet APS criteria with standard thrombosis treatment	1C
Treat patients with definite APS and first venous event with warfarin to target INR 2-3	1B
Treat patients with definite APS and arterial thrombosis with warfarin at INR greater than 3 or combined antiaggregant-warfarin (INR 2-3) therapy	Nongraded
Assess bleeding risk before high-intensity warfarin or combined antiaggregant-warfarin therapy	Nongraded
4. Duration of treatment	
Indefinite antithrombotic therapy in patients with definite APS and thrombosis	1C
For first venous event, low-risk APS profile and known transient precipitating factor, anticoagulate for 3-6 months	Nongraded
5. Refractory and difficult cases	
If recurrent thrombosis, fluctuating INR, major bleeding or high risk for major bleeding, consider alternative such as low molecular weight heparin,	Nongraded

	Recommendation	Grade of Recommendation
	hydroxychloroquine, or statins	

aPL, antiphospholipid antibodies; LA, lupus anticoagulant; aCL, anticardiolipin; APS, antiphospholipid syndrome; INR, international normalized ratio.

Grades of recommendation: 1B: Strong recommendation, moderate quality evidence, 1C: Strong recommendation, low or very low-quality evidence; 2B: Weak recommendation, moderate quality evidence; 2C: Weak recommendation, low or very low-quality evidence

Used with permission from Ruiz-Irastorza G, Cuadrado MJ, Ruiz-Arruza I, et al. Evidence-based recommendations for the prevention and long-term management of thrombosis in antiphospholipid antibody-positive patients: Report of a Task Force at the 13th International Congress on Antiphospholipid Antibodies. Lupus. 2011;20:206-218.

Patients with antiphospholipid antibodies may also have a false-positive test for syphilis (rapid plasma reagin).[15] Other common manifestations of APS are cognitive impairment, thrombocytopenia, stroke or transient ischemic attack, chorea, migraine, heart valve lesions, and livedo reticularis.[78,79]

It is not clear how to treat pregnant women with antiphospholipid antibodies. Those with no history of thrombosis who have experienced early fetal loss may be treated with low-dose aspirin (81 mg) alone or in combination with prophylactic doses of heparin or low-molecular-weight heparin.[78] Not only does heparin have anticoagulant effects, but it also has anti-inflammatory and immunomodulating properties and can inhibit complement activation.[81] Those without thrombosis who have had later miscarriages or premature births associated with preeclampsia or placental insufficiency may receive low dose aspirin plus prophylactic or intermediate doses of heparin or prophylactic doses of low-molecular-weight heparin. Pregnant patients with APS and a history of thrombosis should receive low-dose aspirin with therapeutic doses of heparin or low-molecular-weight heparin. Warfarin should be avoided during pregnancy; it is teratogenic between 6 and 12 weeks gestation and increases the risk of fetal bleeding after 12 weeks.[78] If low-molecular-weight heparin is used, it should be switched to unfractionated heparin 4 weeks before the anticipated delivery date. The heparin should be stopped at the start of labor or 8 hours before a planned cesarean delivery.[72] All women with APS should receive anticoagulation with prophylactic doses of heparin, low-molecular-weight heparin, or warfarin for 4 to 6 weeks postpartum. Both heparin and warfarin are safe during breastfeeding.[78]

Better control of APS can be achieved by adding hydroxychloroquine, statins, and vitamin D to standard therapy. For patients who do not respond to conventional APS treatment or for whom it is contraindicated, alternative therapies include other platelet inhibitors, new oral anticoagulants, rituximab, and the complement inhibitor, eculizumab.[41,78]

Clinical Controversy…

Can new oral anticoagulants be used to treat APS? Some evidence suggests that they are effective, but thrombotic events have been reported when patients are switched to them from warfarin. Large ongoing controlled studies may provide answers.

The most severe form of APS is called catastrophic and is associated with widespread thrombosis, multiorgan failure, and 50% mortality.[78,79]

Drug-Induced Lupus

9 About 10% to 15% of cases of SLE can be attributed to drugs.[82] These are idiosyncratic reactions precipitated by the interplay of genetic predisposition, concurrent illnesses, environmental factors, and other drugs or foods. Various pathophysiologic mechanisms have been proposed for different drugs in inducing lupus. Most drugs are small molecules that can induce an immune response by binding to larger molecules such as proteins, a process called haptenization. Another proposed mechanism is interfering with macrophage uptake of apoptotic or necrotic cells, leading to accumulation of nucleosomes that can be targets for anti-DNA antibodies.[83] Other proposed mechanisms are altered T cell function due to DNA hypomethylation and interference with T cell maturation.[82]

Because the manifestations of drug-induced lupus are so diverse, there are no standard diagnostic criteria. The diagnosis is based on lupus-like findings in a patient with no history of the disease and the temporal relationship with the drug, including onset at least 1 month after initiation and improvement in symptoms within days to months after the drug is discontinued. The time-frame, however, can be variable. The patient will often have laboratory findings such as a positive ANA or anti-histone antibodies, but usually not anti-dsDNA or anti-Sm antibodies.[82]

Many drugs of varied classes have been implicated. The drugs considered to have the highest risk for inducing traditional symptomatic drug-induced lupus are procainamide (20%) and hydralazine (5%-8%), especially with hydralazine doses over 200 mg per day or a cumulative dose of more than 100 g. The incidence of positive ANAs with these drugs is 80% to 90% and 50% respectively.[82] Common manifestations include arthralgias, arthritis, and myalgias. Constitutional symptoms such as fever, fatigue, and weight loss are common, but the incidence is about one-half that seen with idiopathic SLE. Other clinical features include rash, serositis (pleuritis, pericarditis), hematologic abnormalities, and hepatosplenomegaly. Glomerulonephritis and neuropsychiatric symptoms are rare in drug-induced lupus. The incidence and types of reactions vary depending on the offending drug. Laboratory abnormalities associated with drug-induced lupus include positive ANA (99%) and antibodies to histones (96%). Other antibodies such as anticardiolipin (5%-20%), anti-dsDNA (less than 5%), and antineutrophil cytoplasmic antibodies (ANCA) may be seen with some drugs. A drug with moderate risk for lupus is quinidine. The incidence of quinidine- and procainamide-induced lupus is declining because of decreased prescribing of the drugs and use of lower doses. The other almost 100 drugs of many different classes that have been implicated are considered to be of low risk. One that affects younger patients, including children, is minocycline.[83] Other drugs with well-established links to lupus are isoniazid, methyldopa, and chlorpromazine.[82] A variant of the syndrome is drug-induced subacute cutaneous lupus, which has been associated with calcium channel antagonists, thiazide diuretics, angiotensin-converting enzyme inhibitors, interferon, ticlopidine, leflunomide, and terbinafine. The mean age for this syndrome is 59 years; most patients are women, and positive ANA, anti-Ro/SSA, and anti-La/SSB are common. It may occur after weeks to years of therapy.[82,83] Chronic cutaneous lupus has been reported with fluorouracil and NSAIDs.[83] It can take months for skin lesions to resolve after the offending drug has been stopped.[10]

A separate category of drug-induced lupus is that involving TNF-α inhibitors, such as infliximab,

etanercept, adalimumab, and certolizumab pegol. This is called TAILS or TNF-α inhibitor-induced lupus syndrome. These drugs, especially chimeric infliximab, are known to induce autoantibodies. Other theories explaining the mechanism for TNF-α inhibitor-induced lupus are that they cause a shift into other pathways of cytokine production, induce cell apoptosis, increase the risk for bacterial infection, or suppress T-helper 1 immune response and favor T-helper 2 response. It is common for patients receiving these drugs to develop positive ANAs and anti-dsDNA of the IgM subtype. Antihistone antibodies are less commonly seen than with other drug-induced lupus (17%-57%). As with traditional drug-induced lupus, the incidence of clinical lupus is low compared to the numbers that develop autoantibodies.[82,83] Rashes, hypocomplementemia, leukopenia, and thrombocytopenia are more common features with TNF-α inhibitors than traditional drug-induced lupus, and arthralgias, arthritis, and myalgias are less common. Renal and neurological disorders are rare. The underlying diseases being treated with these drugs may be a factor in development of the observed reactions. Autoimmune diseases have also been reported following use of interferon therapy.[83]

The primary treatment for drug-induced lupus is stopping the implicated drug. Some patients require treatment with corticosteroids. If patients do not improve, a diagnosis of idiopathic SLE should be considered.[83]

Immunizations

Patients with SLE are at increased risk for infections because of immune dysfunction caused by the disease itself and the immunosuppressive therapy the patients receive. It is important to try to protect patients against these infections, but there are areas of concern regarding the safety and efficacy of vaccines in patients with SLE. SLE cases developing or flaring after vaccine administration have been reported, but the actual risk appears low when considering how many people receive immunizations.[84] These reactions may be a response to adjuvants added to increase the immunogenicity of vaccines and could be part of the syndrome called "ASIA—Autoimmune/inflammatory Syndrome Induced by Adjuvants."[85] Another concern is that immunosuppressed patients may have an impaired response to vaccines as compared with healthy individuals. This can be assessed by checking titers after immunization. In some cases revaccination may be needed. Whenever possible, to achieve the best response, vaccines should be administered when SLE is stable and prior to initiating immunosuppressive medications. Killed vaccines are considered safe in immunosuppressed patients. It is recommended that SLE patients receive pneumococcal vaccine, since they are particularly susceptible to *Streptococcus pneumoniae* infections. They should also receive annual influenza vaccines. Hydroxychloroquine may improve the response to vaccines and decrease the risk of infections. Patients with splenectomy should receive Haemophilus influenzae and meningococcal vaccines. Those considered to be at risk should be immunized against hepatitis B.[84] Live-attenuated virus vaccines, such as measles–mumps–rubella, varicella, zoster, intranasal influenza, and yellow fever, are contraindicated in patients receiving biologic agents. They should be avoided with consideration of risks versus benefits in patients taking high doses of other immunosuppressive drugs.[86] Doses of corticosteroids equivalent to prednisone 20 mg/day or more given for at least 2 weeks are considered immunosuppressive.[87] Live vaccines should be given at least 4 weeks before starting immunosuppressive drugs or 1 month after stopping them, depending on the duration of drug effects.[86,87]

PERSONALIZED PHARMACOTHERAPY

Pharmacotherapy is determined by disease manifestations and patient-specific factors. Primary goals should be remission of symptoms and organ manifestations or low disease activity and prevention of flares. Hydroxychloroquine should be considered for all patients with SLE. Corticosteroids should be used in the lowest effective dose or discontinued. Symptoms affecting quality of life such as fatigue, pain, and depression should be managed.[39] Organ function should be considered in selection of therapy. Leading causes of mortality in SLE are infections, cardiovascular disease, malignancy, and renal complications related to the disease and treatment. Therapy to prevent and manage these conditions should be individualized based on comorbidities present.[88]

Race appears to influence response to treatment, but many people are of mixed race. Genetic testing may provide a better guide in the future. In studies of lupus nephritis, whites with Western or Southern European backgrounds respond as well to low-dose IV cyclophosphamide ("Euro-Lupus" regimen of 500 mg every 2 weeks for six doses) as to high-dose regimens (500-1,000 mg/m^2 body surface area once a month for six doses) (Level B evidence). African Americans and Hispanics respond less well to IV cyclophosphamide than do whites or Asians. Patients of African or Hispanic origin may respond better to mycophenolate mofetil than to cyclophosphamide. Asians require lower doses of mycophenolate mofetil (Level C evidence).[6] African Americans and Hispanics may respond to rituximab better than whites.[54] Patients of African descent did not respond to belimumab in the BLISS studies, but favorable results were seen in later studies.[50,51]

Blood concentrations of drugs are not usually measured in SLE management, even for drugs that are monitored that way when used for other diseases. Hydroxychloroquine blood concentrations may correlate with efficacy or adherence, but they are not routinely monitored.[45] Although therapeutic mycophenolate drug concentration monitoring is used in transplant patients, it is not yet standard practice in SLE patients. Preliminary studies have shown that MPA area under the plasma concentration–time curve and trough concentrations correlate with SLE disease activity but only weakly with adverse effects or daily doses.[89] Patients should have TPMT testing before receiving azathioprine[89] and be screened for glucose-6-phosphate dehydrogenase (G6PD) deficiency before getting dapsone.[24]

Pregnancy plans should be considered in choosing therapy. Attention must be given to the effects of drugs on fertility and on the fetus, as well as the adverse effects of active disease on pregnancy outcomes.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients must be assessed for the activity and extent of lupus and monitored for adverse drug effects. Monitoring for specific drugs is listed in Table 87-3. Many instruments have been developed and modified over the years to assess SLE therapy in trials. It is difficult to assess SLE therapy because milder forms of the disease may fluctuate, regardless of therapy. Examples of measures of disease activity include the Safety of Estrogens in Lupus Erythematosus National Assessment-Systemic Lupus Erythematosus Disease Activity Index (SELENA-SLEDAI), and British Isles Lupus Assessment Group (BILAG). The SELENA-SLEDAI is a measure of disease activity that scores severity of 24 manifestations. BILAG measures clinical disease activity in eight organ systems compared to the prior month. The organ domains are given scores based on severity: A (severe disease activity flare that requires additional treatment), B (moderate disease activity), C (mild, stable disease), D (previously affected but no current disease activity), and E (never been involved). Updates of these instruments are the SLEDAI-2K and the BILAG-2004. Individually, these indices

were inadequate for showing superiority of new drugs over standard therapy. To overcome this problem, belimumab investigators developed the SRI assessment criteria. The SRI has three components: (a) Reduction in disease activity by SELENA-SLEDAI by at least 4 points; (b) No worsening of disease activity (BILAG A) and no more than one new BILAG B score; and (c) less than 0.3 point increase (worsening) in physician global assessment (PGA). The PGA assesses patients' general health status. Another important assessment of therapy is health-related quality of life (HRQoL), which may use a tool such as the generic Medical Outcomes Survey Short Form-36 (SF-36).[90]

A EULAR panel developed recommendations for the monitoring of patients with SLE in clinical practice and observational studies. Patients should be evaluated for SLE disease activity and organ involvement, cardiovascular risk factors, comorbidities, and risk for infection. Clinical and laboratory assessments should be performed every 6 to 12 months in patients with inactive disease and no organ damage, and more frequently if abnormalities are found.[91]

The Cutaneous Lupus Erythematosus Disease Area and Severity Index (CLASI) may be used to assess disease activity and damage in cutaneous lupus erythematosus and response to therapy.[92]

Chapter e88: Drug Allergy

FIGURE e88-1

Lynne M. Sylvia

INTRODUCTION

KEY CONCEPTS

- 1 Drug allergy is responsible for 6% to 10% of adverse reactions to medications. Most of these immune events are mediated by IgE or activated T cells.
- 2 Two theories—the prohapten/hapten concept and the p-i concept—have been proposed to explain how drugs stimulate the immune response.
- 3 Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that generally begins within 1 hour but almost always within 2 hours after exposure to the inciting allergen. Anaphylaxis requires prompt treatment to restore respiratory and cardiovascular functions. Epinephrine is the drug of first choice and should be administered to counteract bronchoconstriction and peripheral vasodilation. IV fluids should be administered aggressively to restore intravascular volume.
- 4 Factors that influence the likelihood of drug allergy are the chemical composition of the drug, whether the drug contains proteins of nonhuman origin, the route of drug administration, and the sensitivity of the individual as determined by genetics or environmental factors. For some drugs, genetic predisposition to specific human leukocyte antigen alleles has been identified as a risk factor for allergic-mediated skin reactions.
- 5 Ideally, cephalosporins should be avoided in patients with history of an immediate penicillin allergy but, most studies suggest there is little risk of an allergic response to a cephalosporin even in a person with a positive penicillin skin test result. Similarities in the R1 side chain of the agents should be considered when assessing the risk of cross-reactivity.

- 6 Fewer than 1% of patients receiving nonionic radiocontrast agents experience some type of adverse reaction. Of the variety of reactions reported, about 90% are nonimmediate and mostly urticarial, with severe immediate reactions occurring as infrequently as 0.02%.

- 7 Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can produce two general types of reactions, urticaria/angioedema and rhinosinusitis/asthma, in susceptible patients. Most patients with aspirin sensitivity requiring aspirin for prevention of cardiovascular disease can safely undergo and complete a graded challenge or desensitization.

- 8 Cross-reactivity between sulfonamide antibiotics and nonantibiotics is low. The low cross-reactive rate may be explained by differences in the chemical structures and reactive metabolites of the sulfonamide antibiotics and nonantibiotics.

- 9 The basic principles of management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible; (b) treatment of the adverse clinical signs and symptoms; and (c) substitution, if necessary, of another agent.

- 10 The gold standard for evaluating the risk of an immediate allergy to penicillin is the skin test. Skin testing can demonstrate the presence of penicillin-specific immunoglobulin E and predict a relatively high risk of immediate reactions. Skin testing does not predict the risk of delayed reactions or most dermatologic reactions.

- 11 When an allergenic drug is considered medically necessary, no adequate therapeutic alternative exists, and there is no reliable skin testing method, two options are available to the clinician: induction of drug tolerance (previously known as desensitization) and graded challenge.

1 *Drug allergy*, as defined by the World Health Organization, is an immunologically mediated drug hypersensitivity reaction.[1] The hyper-response of the immune system to the antigenic drug leads to host tissue damage manifesting as an organ-specific or generalized systemic reaction. The International CONsensus (ICON) on Drug Allergy has recently proposed that the term *drug allergy* should be used for drug reactions in which a definite immune mechanism (either antibody- or T cell-mediated) has been proven.[2] *Drug hypersensitivity reaction (DHR)* is the term that should be used for more heterogenous reactions that clinically resemble allergy but may or may not be mediated via an immune response.[2] The expert panel has recommended that the term *pseudoallergy* be abandoned. Examples of drug allergies are anaphylaxis from β-lactam antibiotics, halothane hepatitis, Stevens–Johnson's syndrome (SJS) from carbamazepine, heparin-induced thrombocytopenia, allopurinol hypersensitivity syndrome, and serum sickness from phenytoin. Examples of drug hypersensitivity reactions are isolated urticaria after radiocontrast media, aspirin-induced asthma, opiate-related urticaria, and flushing after vancomycin infusion.

Immunologically mediated adverse drug reactions account for 6% to 10% of all adverse drug reactions and even up to 15% when the more heterogenous DHRs are included.[3,4] The true frequency of drug allergies is difficult to determine because many reactions may not be reported, and others

may be difficult to distinguish from nonimmune DHRs. Dermatologic reactions represent the most frequently recognized and reported form of drug allergy.

MECHANISMS OF ALLERGIC DRUG REACTIONS

Drugs can cause allergic reactions by a variety of immunologic mechanisms. Although some reactions are relatively well defined, most are due to mechanisms that are either unknown or poorly understood.[4] At least two theories or concepts have been proposed to describe the initiation of an immune response to a drug.

The first is the *prohapten/hapten* concept. This concept is predicated on the assumption that small-molecular-weight molecules (less than 10 kDa) do not have the ability to serve as antigens on their own. With the exception of polypeptide compounds, most drugs are smaller than 1,000 Da. To become immunogenic, these small compounds must first covalently bind to carrier proteins in plasma or tissue. The combination of the drug bound to a carrier protein is recognized as foreign by antigen processing cells (APCs) such as macrophages and dendritic cells. The drug's *antigenic determinant*, the drug portion that is immunogenic, is subsequently processed by APCs and presented on MHC molecules for recognition by T cells, thereby initiating the immune response. Drugs of low molecular weight that combine with a carrier macromolecule for processing by APCs are referred to as *haptens* or *incomplete antigens*.[2,5,6] Penicillin G (356 Da) is an example of a drug that binds covalently to serum proteins through amide or disulfide linkages thereby forming a complete antigen. For some drugs, such as the sulfonamides, the parent compound must be converted to a metabolite before it can combine with the macromolecule. Drugs that are chemically inert and rely on conversion to a metabolite with an antigenic determinant are referred to as *prohaptens*.[2,5,6] Some macromolecular drugs such as insulin are *complete antigens* because they are large enough to initiate an immune response without binding to another protein.

The second is the *p-i* concept. Some small-molecular-weight drugs may cause an immune response through a nonhapten pathway.[5,6,7] Known as the p-i concept, this pathway involves a 'pharmacologic interaction of drugs with immune receptors that does not require the initial binding of the drug to a carrier protein or processing by APCs.[5,6,7] Based on this theory, drugs are able to bind to T cell receptors in a reversible manner, similar to the binding of a ligand to a receptor.[5] It is currently unknown if the drug binds initially to the T cell receptor or whether the drug binds first to the MHC molecule on the APC, thereby signaling T cell activation. The p-i concept appears most applicable to the initiation of delayed T-cell mediated reactions as opposed to hapten-initiated immediate IgE reactions.[5,6,7]

EFFECTORS OF ALLERGIC DRUG REACTIONS

Allergic drug reactions can involve most of the major components of the innate and adaptive immune systems, including the cellular elements, immunoglobulins, complement, and cytokines. Although most immunoglobulin isotypes have been implicated in drug allergy, reactions are usually mediated by IgE and activated T cells. Immunoglobulin E (IgE) bound to basophils or mast cells

mediates immediate reactions. IgG or IgM antibodies also may be involved in drug allergy, resulting in destruction of cells and tissues. T lymphocytes have a major role in hypersensitivity reactions and are involved in all four types (I–IV) of the drug hypersensitivity reactions described by Coombs and Gell (**Table e88-1**).[2,4,8]

TABLE e88-1 Classification of Allergic Drug Reactions

Type	Descriptor	Characteristics	Typical Onset	Drug Causes
				Penicillin anaphylaxis, angioedema
I	Immediate (IgE mediated)	Allergen binds to IgE on basophils or mast cells, resulting in release of inflammatory mediators	Within 1 hour (may be within 1-6 hours)	Blood products Polypeptide hormones Vaccines Dextran
II	Delayed; Cytotoxic	Cell destruction occurs because of cell-associated antigen that initiates cytolysis by antigen-specific antibody (IgG) and complement. Most often involves blood elements.	Typically >72 hours to weeks	Penicillin, quinidine, quinine, heparin, thiouracils, sulfonamides, methyldopa
III	Delayed; Immune complex	Antigen–antibody (IgG or IgM) complexes form and deposit on blood vessel walls and activate complement. Result is a serum sickness-like syndrome or vasculitis.	>72 hours to weeks	May be caused by penicillins, sulfonamides, minocycline, hydantoins
IV	Delayed; T Cell-mediated	Antigens cause activation of T lymphocytes, which release cytokines and recruit effector cells	>72 hours	
	IVa	Th1 cells and interferon-γ, monocytes and eosinophils respond to the antigen	1-21 days	Tuberculin reaction, contact dermatitis
	IVb	Th2 cells, interleukin-4 and interleukin-5 respond to the antigen	1-6 weeks	Maculopapular rashes with eosinophilia
	IVc	Cytotoxic T cells, perforin, granzyme B, FasL respond to the antigen	4 to 28 days	Bullous exanthems; fixed drug eruptions
	IVd	T cells and interleukin-8 respond to the antigen	>72 hours	Acute generalized exanthematous pustulosis

Cellular Elements

A variety of cells are involved in drug allergy. The APCs, which include macrophages, dendritic cells, and cutaneous Langerhans cells, process the antigenic drug for subsequent recognition by T and B lymphocytes. Basophils and mast cells are instrumental in the development of immediate reactions, whereas eosinophils are recruited in both immediate and nonimmediate reactions. Platelets and vascular endothelial cells are important because they also can release a number of inflammatory mediators.[9] Most cells of the body, including nerve cells, can become involved directly or indirectly in drug allergy.

Mediators of Allergic Reactions

The release of a number of preformed, pharmacologically active chemical mediators (eg, histamine, heparin, proteases such as tryptase and chymase, and a variety of other enzymes) is triggered when antigens cross-link IgE molecules on the surface of circulating basophils and tissue mast cells. Newly formed mediators include platelet-activating factor (PAF) and arachidonic acid metabolites (eg, prostaglandins [PGs], thromboxanes, and leukotrienes [LTs]).

Histamine is a low-molecular-weight amine compound formed by decarboxylation of histidine and is stored in basophil and mast cell granules.[10] Release of histamine from these cells is triggered by antigen cross-linking IgE bound to specific receptors on the surface membranes of mast cells and basophils. The tissue effects of histamine are evident within 1 to 2 minutes, but it is rapidly metabolized within 10 to 15 minutes. The major effects of histamine on target tissues include increased capillary permeability, contraction of bronchial and vascular smooth muscle, and hypersecretion of mucous glands. Four classes of histamine receptors (H_1-H_4) are present in varying degrees in organs and tissues. H_1 receptors are most prominent in blood vessels and bronchial and intestinal smooth muscle.

Platelet-activating factor is a glyceride-derived substance that is released by mast cells, alveolar macrophages, neutrophils, platelets, and other cells but not by basophils. It has potent bronchoconstrictor effects and causes platelet aggregation and lysis. It attracts neutrophils and causes their activation. PAF enhances vascular permeability and can cause pain, pruritus, and erythema.

The LTs are metabolites of arachidonic acid produced through the 5-lipoxygenase pathway that have potent effects on bronchial and vascular smooth muscle. Three important LTs, LTC_4, LTD_4, and LTE_4, are produced by basophils or mast cells. These three substances are also referred to as *cysteinyl LTs* and were previously referred to as *slow-reacting substances of anaphylaxis*. The LTs have more potent and longer-lasting bronchoconstrictor effects than histamine and can increase vascular permeability and cause arteriolar vasoconstriction followed by vasodilation. Their effects are slower in onset but longer lasting than those of histamine. Another product, LTB_4, is a potent chemoattractant, particularly for neutrophils. It is also produced by neutrophils, macrophages, and monocytes.

PGs and thromboxanes are metabolites of arachidonic acid produced through the cyclooxygenase (COX) pathway. Some PGs have vasoconstrictive or bronchodilatory properties, whereas others are vasodilatory or bronchoconstrictive. PGD_2 is the major PG product of mast cells. It is a potent

inhibitor of platelet aggregation and is a bronchoconstrictor. Thromboxanes cause platelet aggregation and are important regulators of coagulation.

The complement system consists of about 30 plasma proteins and is involved in allergy through a variety of immunologic responses, including enhancement of phagocytosis (opsonization of target cells), cell lysis, and generation of anaphylatoxins C3a, C4a, and C5a, which can cause non-IgE-mediated activation of mast cells and release of inflammatory mediators.

CLASSIFICATION OF ALLERGIC DRUG REACTIONS

Immunologic drug reactions are most commonly classified by the system described by Coombs and Gell in 1968.[2,4,8] This system classifies the varied reactions based on the effector cells involved, the timing and clinical presentation of the immune event. The Coombs and Gell classification was developed before our understanding of the varied roles of T cells in the immune response. As such, the original classification system has been adapted to better represent our current understanding of drug allergy (see Table e88-1).[2,4,8]

The ICON expert panel on drug allergy has recommended that drug allergies be classified as *immediate* or *nonimmediate* based on the onset of the reaction.[2] Immediate reactions are those culminating in the production of an IgE-mediated response. Immediate reactions typically occur within 1 hour of first re-exposure to an immunogenic drug and manifest as angioedema, bronchospasm, anaphylaxis or anaphylactic shock.[2] Nonimmediate or delayed drug allergies constitute a broader category of events; they may occur at least 1 hour after initial drug exposure and up to weeks or months after initial exposure.[2] Nonimmediate reactions are typically mediated by activated T cells and manifest as maculopapular exanthems or delayed urticaria. As noted by the expert panel, this classification system has limitations because route of drug administration and the presence of immune co-factors (eg, viruses, drug interactions affecting drug metabolism) can influence the onset or progression of the immune reaction.[2]

Immediate (Type I) Reaction

Type I immediate reactions require the presence of IgE specific for the drug's or drug metabolite's antigenic determinant. After recognition by T cells and presentation on MHC molecules, the drug immunogen stimulates plasma cells to produce IgE on initial exposure. IgE then binds to basophils and mast cells through high-affinity receptors. On repeat exposure to the drug, B memory cells allow for early recognition of the immunogen. Two or more IgE molecules on the basophil or mast cell surface bind to one multivalent antigen molecule (referred to as *cross-linking*), initiating cellular activation. Activation causes the extracellular release of granules with preformed inflammatory mediators, including histamine, heparin, and proteases (tryptase in the mast cell), as well as generation of newly formed mediators, as previously discussed, such as LTs, PGs, thromboxanes, and PAF, among others.

Generation of a type I reaction results in an immediate reaction that may be limited to single organs, typically in the nasal mucosa (rhinitis), respiratory tract (acute asthma), skin (urticaria), or

gastrointestinal tract, or they can involve multiple organs simultaneously, termed *anaphylaxis*.

Delayed Type II Reaction

Type II allergic reactions are relatively uncommon and involve destruction of host cells (usually blood cells) through cytotoxic antibodies by one of two mechanisms. First, the drug binds to the cell as a hapten (eg, the platelet or red blood cell). Antibodies (IgG or IgM) are produced that are specific for the bound drug or for a component of the cell surface altered by the drug. The antigen-antibody binding initiates a cytolytic reaction. Cell destruction may be mediated by complement or by phagocytic cells that have antibody Fc receptors on their surfaces. Activation of complement near the cell surface can result in loss of cell membrane integrity and cell death. Alternatively, neutrophils, monocytes, or macrophages may bind to an antibody-coated cell through IgG Fc receptors on their cell surfaces, resulting in phagocytosis of the target cell. The process of enhancement of phagocytosis by antibody binding to cell surfaces or other particles is referred to as *opsonization*. In addition, cell-bound IgG may direct the nonphagocytic action of T cells or natural killer cells, which results in cell destruction by a process called *antibody-dependent cellular cytotoxicity*. This process can proceed in a nonspecific fashion as T cells bind to the target cell through IgG Fc receptors on the T-cell surface. Contact between the target and effector cells is necessary.

Cells commonly affected by these type II reactions include erythrocytes, leukocytes, and platelets, resulting in hemolytic anemia, agranulocytosis, and thrombocytopenia, respectively. This process may be initiated by drugs such as penicillin, quinidine, quinine, phenacetin, cephalosporins, and sulfonamides.

Delayed Type III Reactions

Type III allergic reactions occur uncommonly and are caused by antigen–antibody complexes that are formed in blood. The complexes form with drug immunogen and antibody in varying ratios and may deposit in tissues, resulting in local or disseminated inflammatory reactions. Antigen–antibody complex formation can result in platelet aggregation, complement activation, or macrophage activation. Chemotactic substances such as C4a may be produced. These substances cause the influx of neutrophils and result in the release of a number of toxic substances from the neutrophil (eg, proteinases, collagenases, kinin-generating enzymes, and reactive oxygen and nitrogen substances), which can cause local tissue destruction.

Platelet aggregation may occur as a result of immune-complex formation, resulting in the formation of microthrombi and the release of vasoactive mediators. Also, insoluble complexes may be phagocytized by macrophages and activate these cells.

The formation of antigen–antibody complexes can lead to clinical syndromes such as the Arthus reaction. In this model, a high level of preformed specific IgG antibody combines with antigen to produce a localized edematous, erythematous reaction within 5 to 8 hours. The reaction involves local formation of insoluble antigen–antibody complexes, complement activation with release of C3a and C5a collectively referred to as *anaphylatoxins,* mast cell degranulation, and influx of polymorphonuclear cells. Both vasculitis and serum sickness are often the result of Type III reactions.

Delayed Type IV Reactions

Type IV reactions typically manifest as dermatologic events mediated by activated T cells ($CD4^+$ or $CD8^+$).[5,7] Four subclasses of type IV reactions (IVa-IVd) have been described based on the responding T cell (eg, T helper type 1 cell, T helper type 2 cell, cytotoxic T cell), effector mechanism (eg, recruitment of macrophages, eosinophils, or neutrophils), and clinical manifestations (eg, contact dermatitis, bullous exanthems, maculopapular eruptions, pustular exanthems) (see Table e88-1).[2,5,7] Type IV reactions require memory T cells specific for the antigen in question. On exposure to the antigen, the immune response is mediated by a specific subtype of T cell that orchestrates an inflammatory response through the secretion of cytokines and the recruitment of effector cells. These reactions are associated with a wide variety of adverse effects and they also may be useful for diagnostic purposes. Examples of the latter include the purified protein derivative (PPD) antigen from *Mycobacterium tuberculosis* used in the tuberculin skin test and other recall skin test antigens, such as mumps. After intradermal injection, these antigens produce a local reaction (erythema and induration) within 48 to 72 hours. Delayed contact hypersensitivity and maculopapular rashes frequently result from a Type IV reaction.

Other Allergic Reactions

Not all drug allergies can be classified with the system described by Coombs and Gell because the precise immune drug mechanism may not be known. In some cases, hepatic drug reactions (cholestatic or hepatocellular) and pulmonary reactions (eg, nitrofurantoin-associated interstitial pneumonitis) have been described as immune events. Perhaps most common are the delayed dermatologic reactions that occur with a variety of drugs (especially penicillins and sulfonamides). These reactions may be evident as fixed drug eruptions; macropapular, morbilliform, or erythematous rashes; exfoliative dermatitis; photosensitivity reactions; or eczema. These reactions also may manifest as late onset pruritus, urticaria, and angioedema.

A number of serious cutaneous adverse reactions (SCARs) may be the result of immunologic reactions. SCARs include drug rash with eosinophilia and systemic symptoms (DRESS) and the mucocutaneous disorders, SJS and toxic epidermal necrolysis (TEN). Both SJS and TEN are purported to result from a T-cell response leading to keratinocyte apoptosis. Cytotoxic T cells stimulated in response to the drug immunogen activate caspases, intracellular proteases that can cleave a key intracellular protein in the keratinocyte resulting in apoptosis.[11] The caspase cascade may be activated by two T-cell mediated pathways, the Fas-FasL pathway and the perforin-granzyme pathway.[12] The blister fluid of patients with SJS/TEN has contained concentrations of FasL, perforin and granzyme B that correlated with the severity of the events. Overexpression of tumor necrosis factor-β, IL-2 and Il-5 has also been seen in skin lesions of patients with SJS and TEN.

Drug Hypersensitivity Reactions

Based on the new terminology, DHRs include adverse events that clinically resemble drug allergy but have not yet been proven to be associated with an immune response. Various drugs can produce reactions that are clinically similar to drug allergy, both immediate and delayed in onset, but are not

mediated by immune mechanisms. Drugs can cause release of mast cell- and basophil-derived mediators by a pharmacologic or physical effect rather than through cell-bound IgE. Nonimmune DHR refers to a wide array of reactions ranging from localized hives to life-threatening angioedema, hypotension, and anaphylaxis, all of which are explained by the nonimmunologic release or activation of inflammatory mediators.[2] Drugs that can produce nonimmune DHR include vancomycin, opiates, iodinated radiocontrast agents, angiotensin-converting enzyme (ACE) inhibitors, amphotericin B, and D-tubocurarine. The "red man syndrome" is a common example of a DHR from vancomycin. If vancomycin is infused too rapidly, it can cause the direct release of histamine and other mediators from cutaneous mast cells, producing a clinical picture of itching, flushing, and hives, first around the neck and face and then progressing to the chest and other parts of the body usually beginning shortly after the infusion has begun. In some cases, the cutaneous manifestations of "red man syndrome" may be accompanied by hypotension, thereby constituting an immediate DHR. Most patients who have had "red man syndrome" will tolerate vancomycin if the rate of infusion is slowed. In rare cases, the severity of the reaction may preclude continued therapy with vancomycin. A number of other agents (including aspirin) may produce nonimmune DHRs by altering the metabolism of inflammatory mediators such as PGs or kinins. Angioedema from ACE inhibitors or sacubitril, a neprilysin inhibitor, are classic examples of nonimmune DHRs. With these agents, angioedema results from pharmacologic inhibition of the breakdown of bradykinin, leading to inflammation, increased vascular permeability, and vasodilation.

CLINICAL MANIFESTATIONS OF DRUG ALLERGIES and DRUG HYPERSENSITIVITY REACTIONS

Anaphylaxis

3 Anaphylaxis is an acute, life-threatening reaction, usually mediated by an immune mechanism, that involves multiple organ systems and occurs in 10 to 20 per 100,000 population per year.[13] About 1,500 deaths from anaphylaxis occur annually in the United States.[14] From 1.2% to 15% of the United States population may be at risk for anaphylactic reactions.[15] The prevalence is rising, most notably in association with the increased use of biologic agents and in the younger age group due to food allergies. Although many drugs may cause anaphylaxis, the most commonly reported are penicillins, aspirin and other NSAIDs, and insulins.[16,17] In most patients, the initial signs and symptoms occur in the skin (flushing, pruritus, urticaria, and angioedema). The second most common symptoms are respiratory (tightness of the throat and chest, dysphagia, dysphonia and hoarseness, cough, stridor, shortness of breath, dyspnea, congestion, rhinorrhea, and sneezing) followed by dizziness, hypotension, and gastrointestinal tract symptoms (nausea, crampy abdominal pain, vomiting, and diarrhea).[17] About 10% to 30% of patients develop hypotension. Additional cardiovascular effects include syncope, altered mental status, chest pain, and dysrhythmia.[13]

A consensus panel on allergy has defined anaphylaxis as highly likely when one of the following three scenarios is present:[17]

1. Acute onset of a reaction (minutes to several hours) that involves the skin (mucosal tissue) and the respiratory tract and/or a decrease in blood pressure.

2. The rapid onset of a reaction after exposure to a likely allergen that involves two organ systems (respiratory tract, skin, decrease in blood pressure and/or persistent gastrointestinal symptoms).

3. A decrease in blood pressure alone after exposure to a known allergen.

The panel indicated that other presentations may indicate anaphylaxis, such as acute chest pain or arrhythmia without dermatologic manifestations, and that the potential exists for false-positive results.

Anaphylaxis generally begins within 1 hour but almost always within 2 hours of exposure to the inciting allergen. The risk of fatal anaphylaxis is greatest within the first few hours. Late phase or "biphasic reactions" can occur 1 hour to 72 hours after the initial presentation with most occurring within 6 hours. Because of the possibility of a biphasic reaction, patients should be observed for at least 8 hours after an anaphylactic reaction.[17] Fatal anaphylaxis most often results from asphyxia caused by airway obstruction either at the larynx or within the lungs. Cardiovascular collapse may occur as a result of asphyxia in some cases; in other cases, cardiovascular collapse may be the dominant manifestation from the release of mediators within the heart muscles and coronary blood vessels.

Clinical markers may aid in the diagnosis of anaphylaxis. Serum levels of tryptase or mature tryptase (also known as β-tryptase) peak in the serum within 0.5 to 2 hours after the onset of anaphylaxis.[17] Tryptase levels are most helpful in making the diagnosis if they are drawn no more than 6 hours after the onset of symptoms. Since plasma histamine levels remain elevated for only 30 to 60 minutes, they are not clinically useful in patients who present 1 hour or later after the onset of anaphylaxis.[17]

Serum Sickness and Serum Sickness–Like Disease

Serum sickness is a clinical syndrome resulting from the effects of soluble circulating immune complexes that form under conditions of antigen excess. The reaction commonly results from the use of antisera containing foreign (donor) antigens such as equine serum in the form of antitoxins or antivenoms. The onset of serum sickness is usually 7 to 14 days after antigen administration. The onset may be more rapid with reexposure to the same agent in an individual with prior serum sickness. Fever, malaise, and lymphadenopathy are the most common clinical manifestations. Arthralgias, urticaria, and morbilliform skin eruption also may be present. A milder and more transient form of serum sickness is serum sickness–like disease (SSLD). The predominant feature of SSLD is a cutaneous eruption, either urticarial or maculopapular, that occurs within 5 to 21 days of drug administration.[18] As with serum sickness, the rash is usually preceded by a prodromal phase consisting of fever, malaise, lymphadenopathy, and arthralgias. SSLD has been associated with the administration of ciprofloxacin, bupropion, hydantoins, minocycline, sulfonamides, penicillins, and cephalosporins (especially cefaclor). SSLD is usually self-limiting after discontinuation of the causative agent, but it can sometimes progress to include vasculitis.

Drug Rash with Eosinophilia and Systemic Symptoms

Previously known by the term *drug hypersensitivity syndrome*, the triad of rash, eosinophilia, and internal organ involvement is currently referred to as drug rash with eosinophilia and systemic symptoms (DRESS). Bocquet et al.[19] described the following criteria for a diagnosis of DRESS: (a) cutaneous drug eruption (usually a diffuse maculopapular rash accompanied by facial and neck edema); (b) hematologic abnormalities including eosinophilia greater than 1,500 cells/mm^3 (1.5×10^9/L) or the presence of atypical lymphocytes; and (c) systemic involvement including adenopathies greater than 2 cm in diameter, hepatitis, interstitial nephritis, interstitial pneumonia, or carditis.[19] Both the allopurinol hypersensitivity syndrome and anticonvulsant hypersensitivity syndrome are examples of DRESS.[20] Other drugs associated with DRESS include minocycline, dapsone, lamotrigine, and the sulfonamides.[21] The onset of DRESS is typically delayed ranging from 3 to 8 weeks after drug initiation and the clinical manifestations (targeted organs and the severity of organ involvement) can vary between patients.[19,20] The mortality rate associated with DRESS is 10%, and it is largely attributed to systemic involvement of the liver, kidneys, or lungs.[20] After discontinuation of the causative drug, the skin rash resolves and laboratory abnormalities normalize over a period of 4 to 8 weeks. Systemic corticosteroids (0.5-1 mg/kg/day prednisone or steroid equivalent) have been used in the treatment of DRESS based on the severity of organ involvement.

Drug Fever

Fever may occur in response to an inflammatory process or develop as a manifestation of a drug reaction. Drug fever has been estimated to occur in as many as 10% of hospital inpatients.[22] Many drugs have been reported to cause fever with the most frequently implicated classes being the antimicrobials (eg, acyclovir, amphotericin B, β-lactams, minocycline, rifampin, sulfonamides, and tetracycline), anticonvulsants (eg, carbamazepine and phenytoin), antiarrhythmics (eg, procainamide and quinidine), and other cardiac medications (eg, clofibrate, diltiazem, dobutamine, furosemide, heparin, methyldopa, and procainamide).[22] These drugs may affect the central nervous system (CNS) directly to alter temperature regulation or stimulate the release of endogenous pyrogens (eg, interleukin-1 and tumor necrosis factor), PGs, or nervous system monamines that alter the thermoregulatory set point.[22] Drugs also may cause fever as a result of their pharmacologic effects on tissues (eg, fever resulting from massive tumor cell destruction caused by chemotherapy).

The temperature pattern of drug-induced fever is quite variable and therefore of little help in the diagnosis. Four patterns of drug fever have been described: continuous, remittent, intermittent, and hectic. A combination of intermittent and remittent, hectic fever is the most common pattern with temperatures of 102°F to 104°F (38.9°C-40.0°C) interrupting normal temperatures throughout the day.[22] Drug fever may occur at any time during the course of therapy with a median reported time of 7 to 10 days after drug initiation. Antimicrobials and antineoplastic drugs have been associated with the shortest time to onset (median, 6 and 0.5 days, respectively), whereas CNS agents and cardiovascular drugs have longer times to onset (median, 10 and 16 days, respectively).[22] Laboratory findings such as leukocytosis, eosinophilia, elevated lactic dehydrogenase, and elevated erythrocyte sedimentation rate may aid in the diagnosis. Generally, withdrawal of the causative agent results in

prompt defervescence as soon as the drug is eliminated completely. Fever usually recurs on readministration of the causative agent.

Drug-Induced Autoimmunity

Autoimmune diseases have been associated with drugs and may involve a variety of tissues and organs. A commonly recognized drug-related autoimmune disorder is systemic lupus erythematosus (SLE) induced by infliximab, etanercept, procainamide, hydralazine, quinidine, or isoniazid (Chapter e88).[23] Exposure of susceptible persons to these agents appears to alter normal body proteins, RNA, or DNA in such a way as to make these components antigenic, leading to the formation of autoreactive antibodies and cells. Most patients treated with infliximab develop antinuclear antibodies, but only 2% of patients present with SLE symptoms. The most common clinical manifestations include arthralgias, myalgias, and polyarthritis. Facial rash, ulcers, and alopecia occur less frequently. Renal or pulmonary involvement also may occur. These reactions typically develop several months after beginning the drug and generally resolve soon after the drug is discontinued.

Other syndromes believed to involve autoimmune mechanisms include drug-induced hemolytic anemia attributed to methyldopa, interstitial nephritis produced by methicillin, and hepatitis caused by phenytoin and halothane. Interstitial nephritis is characterized by fever, rash, and eosinophilia associated with proteinuria and hematuria. Hepatic damage due to drugs generally is manifested as either hepatocellular necrosis or cholestatic hepatitis. Drug-induced hepatitis has been associated with phenothiazines, sulfonamides, halothane, phenytoin, and isoniazid (Chapter e38). Hepatocellular destruction is evidenced by elevations in serum transaminases. Hepatomegaly and jaundice sometimes may be evident. Cholestasis may be manifested by jaundice and elevations in serum alkaline phosphatase and sometimes by rash, fever, and eosinophilia.

Vasculitis

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessel walls. The vasculitic process may be limited to the skin, or it may involve multiple organs, including the liver or kidney, joints, or CNS. Characteristically, cutaneous vasculitis is manifested by purpuric lesions that vary in size and number. Vasculitis also may be manifested as papules, nodules, ulcerations, or vesiculobullous lesions, generally occurring on the lower extremities but sometimes involving the upper extremities, including the hands. Drugs associated with vasculitis include allopurinol, β-lactam antibiotics, sulfonamides, thiazide diuretics, phenytoin, and vancomycin.

Serious Cutaneous Adverse Reactions

Although most dermatologic reactions are mild and resolve promptly after discontinuing the drug, SJS and TEN are serious or even life-threatening reactions. Both SJS and TEN are classified as progressive bullous or “blistering” disorders that constitute dermatologic emergencies.[24] They are considered severe variants of erythema multiforme. Similar to erythema multiforme, SJS and TEN are associated with the widespread development of a variety of skin lesions, including macules, purpuric lesions, and the target iris lesion. The target lesion is discrete and round and identified by an area of

central clearing surrounded by two concentric rings of edema and erythema. Unlike erythema multiforme, SJS and TEN are most commonly drug induced rather than associated with recurrent herpes simplex viral infection, and they progress to include mucous membrane erosion and epidermal detachment.[24] Mucosal membranes in the mouth, lips, nasal cavity, and conjunctivae are usually involved. As these syndromes progress, the erythematous lesions become more widespread on the face, trunk, and extremities, and many evolve into blisters. Within days after the onset of the lesions, full-thickness epidermal detachment occurs. SJS and TEN are often considered as a continuous spectrum of a disease, with TEN being the most severe form. The extent of epidermal detachment is used to distinguish between SJS and TEN (ie, less than 10% detachment of body surface area with SJS; greater than 30% detachment of body surface area with TEN). The term *SJS-TEN overlap* is used to describe cases in which epidermal detachment occurs on 10% to 30% of the body surface area.[24,25] Both SJS and TEN are associated with a number of long-term sequelae, including permanent visual impairment, temporary nail loss, cutaneous scarring, and irregular pigmentation. Being the more severe form, TEN is also more likely to be complicated by systemic organ involvement, including acute kidney failure, neutropenia, and respiratory failure. A severity-of-illness scoring system known as SCORTEN has been developed to predict prognosis in patients with TEN.[26] SCORTEN uses seven independent risk factors based on an assessment within 24 hours of clinical presentation.

TEN is estimated to occur in 0.4 to 1.3 cases per 1 million people per year, and SJS has been reported in 1 to 6 cases per 1 million people per year.[27,28] The mortality rates associated with SJS and TEN range from 1% to 5% and 10% to 70%, respectively.[28] **Table e88-2** lists drugs and agents associated most commonly with cutaneous reactions.[29] Antimicrobials are implicated most frequently as the cause of cutaneous events with reaction rates ranging from 1% to 8%. The most likely offenders of SJS and TEN, determined in case–control studies, are the sulfonamides, particularly trimethoprim–sulfamethoxazole.[30] Other major offenders of SJS and TEN identified in these studies are allopurinol, the aminopenicillins, carbamazepine, chlormezanone, cephalosporins, the imidazole antifungals, lamotrigine, nevirapine, the oxicam NSAIDs, phenytoin, quinolones, and the tetracyclines.[30]

TABLE e88-2 Top 10 Drugs and agents Reported to Cause Skin Reactions

	Reactions per 1,000 Recipients
Amoxicillin	51.4
Trimethoprim–sulfamethoxazole	33.8
Ampicillin	33.2
Iopodate	27.8
Blood	21.6
Cephalosporins	21.1
Erythromycin	20.4

	Reactions per 1,000 Recipients
Dihydralazine hydrochloride	19.1
Penicillin G	18.5
Cyanocobalamin	17.9

Data from Roujeau JC, Stern RS. Severe adverse cutaneous reactions to drugs. N Engl J Med 1994;331:1272-1285.

Respiratory Reactions

Drugs may produce upper or lower respiratory tract reactions, including rhinitis and asthma. Respiratory tract manifestations may result from direct injury to the airways or may occur as a component of a systemic reaction (eg, anaphylaxis). Asthma may be induced by aspirin and other NSAIDs or by sulfites used as preservatives in foods and medications. Other pulmonary drug reactions believed to be immunologic include acute infiltrative and chronic fibrotic pulmonary reactions. The latter is often caused by antineoplastic agents such as bleomycin. For a more detailed discussion of drug-induced pulmonary disease, see Chapter e30.

Hematologic Reactions

Most formed elements and soluble components of the hematopoietic system may be affected by immunologic drug reactions. Eosinophilia is a common manifestation of drug hypersensitivity and may be the only presenting sign. Hemolytic anemia may result from hypersensitivity to drugs. Other hematologic reactions include thrombocytopenia, granulocytopenia, and agranulocytosis. For a detailed discussion of hematologic drug reactions, see Chapter e103.

FACTORS RELATED TO THE RISK OR SEVERITY OF ALLERGIC DRUG REACTIONS

4 Among the factors that influence the likelihood of drug allergy are the degree to which the drug and its metabolites bind covalently to human proteins, how the drug is metabolized, whether the drug contains proteins of nonhuman origin (eg, chimeric monoclonal antibodies, and streptokinase) or antigenic excipients (eg, peanut oil, FD&C dyes, sulfites, and soybean emulsion), the route of exposure, and the sensitivity of the individual as determined by genetics and environmental factors. Hypersensitivity can occur with any dose of a drug, but sensitization is more likely to occur with continuous dosing rather than single dosing. After a patient has become sensitized, the severity of a reaction is often determined by the dose and the duration of exposure. The route of administration may also influence drug sensitivity. The topical route of drug administration appears to be the most likely to sensitize and predispose to drug reactions. The oral route is the safest, and the parenteral route is the most hazardous for administration of drugs in sensitive individuals. Relatively few cases of immediate hypersensitivity-associated deaths with oral β-lactam antimicrobials have been

reported.

The presence of genetically determined human leukocyte antigen (HLA) alleles increases susceptibility to a number of drug hypersensitivity syndromes. In patients infected with the human immunodeficiency virus (HIV), hypersensitivity to abacavir has been associated with the presence of *HLA-B*5701*.[31] Severe immune-mediated cutaneous reactions to allopurinol, including SJS and TEN, have been associated with the presence of *HLA-B*5801* in Han Chinese.[32] In this same patient population, the presence of *HLA-B*1502* increases the risk of SJS and TEN with carbamazepine, phenytoin, and fosphenytion.[33] Most recently, HLA-A*3101 has been related to the development of nonblistering DHRs such as DRESS to carbamazepine in European and North Asian populations.[34] Associations between HLA alleles and drug reactivity have been described for aminopenicillins, aspirin, iodinated contrast media, gold, lamotrigine, and trimethoprim–sulfamethoxazole.[35] In patients with history of immediate reactions to β-lactam antibiotics, single nucleotide polymorphisms of HLA-*DRA*, a MHC Class II gene, was a predictor of skin test positivity to amoxicillin and other penicillins but not cephalosporins.[36] Genetic factors can also influence the metabolic deactivation of drugs via phase 1 and 2 metabolism. For example, slow acetylators of procainamide and hydralazine are at increased risk for SLE. A genetic variant in CYP2C, notably CYP2C9*3, was recently found to be associated with phenytoin-induced SCARs.[37] Genes also encode for the type of T-cell receptor and the specific cytokines involved in the signaling of allergic drug reactions.

Drug allergies appear to develop with equal frequency in atopic and nonatopic individuals. In addition, patients with a history of drug allergy appear to be at increased risk for adverse reactions to other pharmacologic agents. Age seems to be related to the risk of allergic reactions because they occur less frequently in children. This may be related to immaturity of the immune system or decreased exposure. The presence of some concurrent diseases, particularly viral infections, predisposes to drug reactions. Examples include the higher rate of morbilliform rash when ampicillin is administered to patients with infectious mononucleosis, the higher rate of reactions to trimethoprim–sulfamethoxazole in HIV-infected patients, and the relationship between infection with human herpes virus 6 (HHV-6) and the development of DRESS.

DRUGS COMMONLY ASSOCIATED WITH ALLERGIC OR ALLERGIC-LIKE DRUG REACTIONS

β-Lactam Antimicrobials

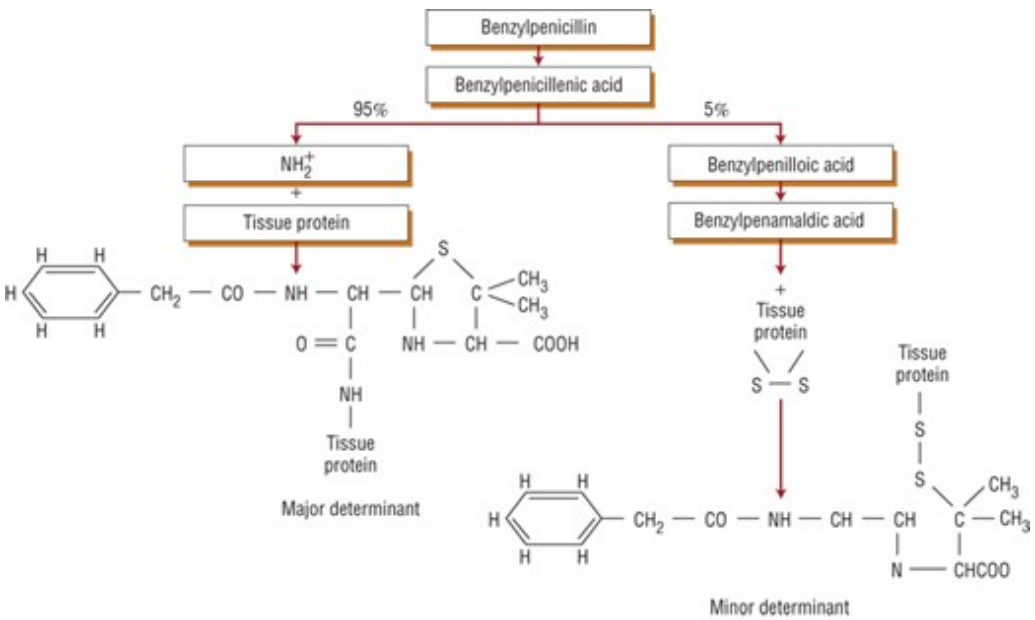
About 8% of individuals in the United States healthcare system report an allergy to penicillin and 1% have a noted cephalosporin allergy.[38] Avoidance of penicillins in patients with self-reported allergy is a growing health concern. Use of alternative antibiotics in these patients is associated with increased medical costs and an increased frequency of infection with methicillin-resistant *Staphylococcus aureas* (MRSA) and *Clostridium difficile*.[39] Only 10% to 20% of patients reporting penicillin allergy are found to be allergic by skin testing.[16, 40] Patients with a history of immediate penicillin allergy who have a negative penicillin skin test result are unlikely to react on subsequent courses of penicillins.[16,40]

The most common reactions to penicillin include urticaria, pruritus, and angioedema. All four of the major types of allergic reactions have been reported with penicillin, as well as some reactions that do not fit into these categories. A wide variety of idiopathic reactions occur, such as maculopapular eruptions, eosinophilia, SJS, and exfoliative dermatitis. Cutaneous reactions can occur in up to 4.4% of treatment courses of penicillin[41] and in up to 8% of those of aminopenicillins.[42] The incidence of ampicillin rash is close to 100% in patients with viral infections such as infectious mononucleosis.[43]

Some aspects of the mechanism of penicillin immunogenicity have been determined. As a relatively small molecule (356 Da), benzylpenicillin must combine with macromolecules (presumably proteins) to elicit an immune response. Penicillin is rapidly hydrolyzed to a number of reactive metabolites that have the ability to covalently link to proteins. Of these metabolites, 95% is in the form of benzylpenicilloyl that binds covalently to the lysine residues of proteins such as albumin through an amide linkage involving the *β*-lactam ring (**Fig. e88-1**). This penicilloyl–protein conjugate is referred to as the *major antigenic determinant*. The other penicillin metabolites such as penilloate and penicilloate bind in lesser quantities to proteins. These are referred to as *minor antigenic determinants*. The terms *major* and *minor* refer to the relative proportions of these conjugates that are formed and not to the clinical severity of the reactions generated. Immediate hypersensitivity reactions may be mediated by IgE for both minor and major determinants. In fact, the minor antigenic determinants are more likely to cause life-threatening anaphylactic reactions.

FIGURE e88-1

Formation of a benzylpenicilloyl hapten–protein complex.



In addition to the major and minor determinants, unique side-chain determinants may mediate allergy to some penicillins. Based on recent studies, the frequency of reactions to the *β* lactam core of penicillin as determined via skin testing is decreasing while reactions to the R-group side chains of the penicillins are increasing in occurrence.[44] Both the aminopenicillins and piperacillin may cause

hypersensitivity reactions via unique side-chains on their structures.[45,46] Therefore, a patient may exhibit hypersensitivity to amoxicillin or piperacillin via a side chain determinant while exhibiting no reactivity to other penicillins. Reports of selective allergy to amoxicillin have become relatively common. The R-group side chain of amoxicillin is believed to be the primary epitope, but selective reactivity to clavulanic acid has been postulated and explored in those experiencing a reaction to amoxicillin clavulanate.[47,48,49] Careful history taking is needed to identify patients with high likelihood of side-chain–specific reactions. Skin testing with dilute concentrations of amoxicillin, ampicillin, and piperacillin has been used to aid in the determination of side-chain–specific reactions.[50,51,52]

Patients who are allergic to penicillins also may be sensitive to other β-lactams. The exact incidence of cross-reactivity between cephalosporins and penicillins is not known but is believed to be low.[16,38,53] The risk was originally reported as 10% to 15% in the 1970s when cephalosporins were contaminated with trace amounts of penicillin. Current estimates of the cross-reactive risk between penicillin and the first- and second-generation cephalosporins are 5% to 7.5% and as low as 1% between penicillin and the third- and fourth-generation cephalosporins.[16] One percent to 8% of patients with penicillin-specific IgE may develop an immediate-type hypersensitivity reaction to cephalosporins.[54] In contrast, patients with reported penicillin allergy and negative skin test results are at no greater risk.[16]

5 Ideally, cephalosporins should be avoided in patients with history of an immediate hypersensitivity reaction to penicillin, although most studies report low risk of an allergic response to a cephalosporin even in a person with a positive skin test result to penicillin. Based on the results of one meta-analysis, patients with penicillin allergy have the highest risk of cross-reactivity with the first-generation cephalosporins (odds ratio [OR] 4.79; 95% confidence interval [CI] 3.71-6.17).[55] The odds of reacting to a second- and third-generation cephalosporin were 1.13 (95% CI 0.61-2.12) and 0.45 (95% CI 0.18-1.13), respectively.[55] The higher rate of cross-reactivity between penicillin and the first-generation cephalosporins has been attributed to similarities in the R1 side chains of these agents.[16,52] The R1 side chain is connected to the opened β-lactam ring, thereby influencing the antigenicity of these agents. When assessing the potential for cross-reactivity between penicillins and cephalosporins, clinicians should evaluate the similarities in the R1 side chains of the agents.[52,55,56] β-lactam antibiotics with an R1 substitution chemically similar to that of penicillin G are cephaloridine, cephalothin, and cefoxitin. In the R1 position, amoxicillin is chemically similar to ampicillin, cefaclor, cephalexin, and cefadroxil. Cefotaxime, ceftizoxime, ceftriaxone, cefpodoxime, and cefepime have chemically similar substitutions in the R1 position that may influence the risk of cross-reactivity.[56]

Cephalosporins rarely induce immune responses mediated by the core β-lactam structure, but they are more likely to do so via unique R-group side-chain determinants.[55] In a patient with a cephalosporin allergy, skin testing with the major and minor determinants of penicillin can be used to identify the likelihood of reactivity to the core β-lactam ring. The risk of cross-reactivity between cephalosporins is considered to be higher than that between the penicillins and cephalosporins. Cross-reactions may occur through identical R1 side chains. Of note, ceftazidime shares a common

side chain with aztreonam.

The actual risk of a cross-reaction between the penicillins and the carbapenems appears to be much lower than originally described. The initial estimate of the cross-reactive risk was 47.4%, but current estimates range from 0.9% to 11%.[53] The initial estimate was based on the results of skin testing with penicillin and nonstandardized carbapenem reagents. A number of retrospective studies reporting variable rates of cross-reactivity relied on self-reported histories as confirmation of penicillin allergy. In four recently published prospective studies, both skin testing methods and carbapenem challenge dosing were used to assess cross-reactive risk. In one of these studies, only one of 112 patients with skin test–confirmed penicillin allergy had a positive skin test result for imipenem.[57] Challenge dosing with imipenem to a final dose of 500 mg was subsequently performed in 110 patients with negative imipenem skin test results; none of the 110 patients had a reaction. Results of two additional prospective studies, one of which was performed in children ages 3 to 14 years, suggest a low risk of cross-reactivity between penicillin and meropenem.[58,59] In both studies, only one patient with skintest positivity to penicillin had a positive skin test result for meropenem. Graded challenge dosing with meropenem was tolerated in 100% of the skin test–negative patients in both studies. Most recently, 212 patients with skin test positively to a penicillin underwent skin testing with ertapenem, meropenem, and imipenem.[60] None of the 212 patients had skin test positivity to a carbapenem. Graded challenge to a full therapeutic dose of each carbapenem was subsequently performed in 211 subjects.[60] No patient exhibited a reaction during challenge dosing. Based on these results, the routine practice of avoiding carbapenem use in patients with history of penicillin allergy should be reconsidered.

Of the monobactams, aztreonam only weakly cross-reacts with penicillin and can be administered safely to most patients who are penicillin allergic.[16,53] In 211 patients with skin test positivity to a penicillin, graded challenge dosing to a full therapeutic dose of aztreonam was uneventful in all patients.[60]

Radiocontrast Media

6 Radiocontrast agents frequently cause reactions categorized as immediate (in 1 hour) or nonimmediate (less than or equal to 1-10 days) via both IgE-mediated and non-IgE-mediated mechanisms.[61] The frequency and severity of these reactions are influenced by the type of radiocontrast agent (ionic vs nonionic), and patient-specific factors such as history of atopy, asthma, or prior reaction to a radiocontrast agent. Current reported estimates of the frequency of immediate reactions with ionic and nonionic agents are 1% to 3% and less than 0.5%, respectively.[16,17] Delayed skin reactions, usually presenting as maculopapular exanthems, occur in 1% to 3% of patients over 5 to 7 days.[61] Severe, immediate anaphylactic reactions occur in 0.01% to 0.04% of patients.[61] In addition, radiocontrast agents may cause dose-dependent toxic reactions that can produce renal impairment, cardiovascular effects, and arrhythmias.[62] The mechanism of reactions to radiocontrast agents is not clearly understood. Histamine release and mast cell triggering have been documented in severe immediate reactions, suggesting an IgE-mediated mechanism. The older, high-osmolar radiocontrast agents can activate mast cells, basophils, and the complement system directly

(IgE-independent mechanism), resulting in the release of inflammatory mediators. The delayed-onset maculopapular rash appears to be T-cell mediated. The low-osmolar nonionic contrast agents appear to cause fewer acute reactions.

The risk of immediate reactions to radiocontrast media is greater in women and in patients with a history of atopy or asthma.[61] Other recognized risk factors include a history of previous reaction, severe drug allergies, cardiac disease, and treatment with β-blockers.[16,17] Despite a common misconception, seafood allergy or iodine allergy does not predispose to radiocontrast media reactions. Although not recommended in current guidelines, there is a trend toward skin testing of patients with prior immediate reactivity to a radiocontrast agent. Skin testing with a panel of different radiocontrast agents may aid in the identification of a product with low reactive risk.[61] Although some regimens have been recommended to prevent the recurrence of immediate events in patients who have experienced reactions previously, the value of these preventive regimens has not been proven, and their use remains controversial.[61,63] A commonly recommended regimen in high-risk patients is oral prednisone (50 mg) 13, 7, and 1 hours before exposure with 50 mg of diphenhydramine given orally or intramuscularly 1 hour before exposure to prevent immediate reactions.[17] Ephedrine 25 mg orally has also been recommended 1 hour before the radiocontrast study as a component of the pretreatment regimen, but ephedrine should not be used if the patient has history of unstable angina, hypertension, or arrhythmia.[16,17] Other studies have examined the use of H_1- and H_2-antihistamines, clemastine, or cimetidine, respectively.[16,17]

Immediate reactions to gadolinium, a noniodinated contrast agent, have been reported at frequencies of 0.07% in adults and 0.04% in children.[64] Most reactions have been mild, requiring either no medical management or treatment with antihistamines. Moderate and severe reactions have also been rarely reported. Pretreatment regimens similar to those used with iodinated contrast studies are usually effective, but they have been associated with breakthrough reactions, particularly in patients with a history of reactions to gadolinium or iodinated contrast agents.[65]

Insulin

Insulin can produce an IgE mediated reaction, an immune complex reaction and delayed T cell mediated allergy. The reported prevalence of insulin allergy is 0.1% to 3% and the most common manifestation is an IgE-mediated local reaction at the injection site.[66] Allergic reactions have been reported with beef and pork insulin and more rarely with the recombinant human insulin. Insulin's antigenicity may be explained by alterations in protein unfolding during the manufacturing process.[66] Reactions may also occur to additives in insulin such as zinc or protamine. Development of anti-insulin IgG antibodies occurs commonly after a few months of therapy, but these antibodies remain inactive in most patients.

Local reactions present most often as a wheal and flare at the injection site and may occur immediately after injection or up to 8 to 12 hours later. These reactions are generally mild, do not require treatment, and resolve with continued insulin administration. Before labeling the patient as allergic to insulin, consideration should be given to the patient's insulin administration technique.

Systemic antihistamines may be administered in patients who continue to have local reactions, and a different insulin source may be substituted. Systemic reactions to insulin (eg, urticaria or anaphylaxis) rarely occur. Skin testing with various products is recommended to identify the type of insulin least likely to cause a systemic reaction.[66] In some patients, insulin desensitization may be indicated.[66]

Aspirin and Nonsteroidal Anti-inflammatory Drugs

7 Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can produce eight general types of DHRs, four of which are related to COX inhibition.[67,68] These DHRs can involve asthma and rhinitis, urticarial/angioedema, anaphylaxis, aseptic meningitis, or pneumonitis. The two most prevalent aspirin sensitivity reactions are respiratory (asthma and rhinorrhea) and urticarial/angioedema in patients without chronic urticaria. About 9% to 20% of people with asthma are sensitive to aspirin and other NSAIDs.[67,69]

The rhinosinusitis/asthma syndrome typically develops in middle-aged patients who are nonatopic and have no history of aspirin intolerance. Women are 2.5 times more likely to develop aspirin-induced asthma than men.[70] It usually progresses from rhinitis to sinusitis with nasal polyps and steroid-dependent asthma. It is uncommon in children and young adults. However, children with asthma may be aspirin sensitive. Aspirin-sensitive asthma appears to be an inherited disorder characterized by overexpression of LTC_4 synthase in airways.[71] In aspirin-sensitive people with asthma, administration of aspirin and NSAIDs may provoke severe and sometimes fatal asthmatic attacks. The mechanism of aspirin sensitivity is not completely understood.

One suspected mechanism of aspirin and NSAID sensitivity is COX-1 blockade, which may facilitate depletion of prostaglandin E_2 (PGE_2) and production of alternative arachidonic acid metabolites (eg, LTs).[67] PGE_2 prevents mast cell degranulation, while LTs cause bronchoconstriction and increased mucus production. Increased LT production may also explain the development of angioedema and urticaria, based on the observed correlation between the degree of COX-1 blockade and the risk of a sensitivity reaction. Therefore, agents such as acetaminophen, which minimally block COX-1, rarely cause reactions. This mechanism is also supported by the clinical observation that LT-modifying drugs can reduce the severity of aspirin-induced asthma and urticaria.[67] It is also possible that aspirin and NSAIDs stimulate mast cells directly to release inflammatory mediators. Subjects with aspirin-induced asthma also have a marked increase in airway responsiveness to LTs. Aspirin and the COX-2–selective inhibitors celecoxib and rofecoxib do not appear to be cross-reactive.[72,73]

In patients with aspirin sensitivity (asthma or urticaria) in which aspirin is indicated for cardiovascular disease, oral graded challenge dosing and/or desensitization is recommended.[74] A number of different protocols have been described, and the risk for anaphylaxis cannot be reliably predicted.[67,70,74] Both graded challenge and desensitization should be performed with caution in a hospital setting with resuscitation equipment at hand. For patients with history of cutaneous reactions to aspirin, a two-dose challenge of 40.5 mg (one-half of an 81 mg tablet) given 90 minutes apart with no pretreatment has shown promising results.[74] If no reaction occurs after administration of the second dose, the patient may receive 81 mg of aspirin per day for cardioprotective therapy.[74]

For patients with aspirin-induced asthma, induction of drug tolerance (desensitization) is recommended. A number of aspirin desensitization protocols have been described, ranging from 2- to 4-day protocols for patients with history of asthma to rapid (2- to 5-hour) protocols.[16,74,75] If oral challenge is not successful and desensitization is not performed, patients with aspirin sensitivity must avoid aspirin and the nonselective NSAIDs as the major preventive measure.

Individual NSAIDs (eg, ibuprofen, sulindac), and rarely aspirin, can cause IgE-mediated allergy. These reactions occur on reexposure to the drug and may present as urticaria, bronchospasm, or anaphylaxis with or without hypotension. A careful and complete allergy history may suggest true allergy to an isolated NSAID. Such patients should be advised to avoid the specific NSAID and any structurally similar NSAIDs (eg, all propionic acid derivatives, all indole acetic acid derivatives) because of the risk of cross-reactivity. Patients with a history of reacting to a specific NSAID other than aspirin can safely receive aspirin.[74]

NSAIDs have been associated with pulmonary infiltrates and eosinophilia syndrome. Pulmonary infiltrates and eosinophilia syndrome are associated with fever, cough, dyspnea, infiltrates on chest radiography, and a peripheral eosinophilia that develops 2 to 6 weeks after initiating treatment. Pulmonary infiltrates and eosinophilia syndrome occurs more frequently for naproxen compared with other NSAIDs and is noted to resolve rapidly after discontinuation of the offending agent.[76]

Sulfonamides

Sulfonamide drugs containing the sulfa (SO_2NH_2) moiety include antibiotics, thiazide and loop diuretics, oral hypoglycemics, COX-2 inhibitors and carbonic anhydrase inhibitors. Other less commonly recognized sulfonamides include antivirals (amprenavir, fosamprenavir, and darunavir), probenecid, tamsulosin, triptans, and zonisamide. Allergic reactions have been reported in 4.8% of 20,226 patients who received a sulfonamide antibiotic and in 2% of patients who received a nonantibiotic sulfonamide.[77] Although immediate IgE-mediated reactions such as anaphylaxis can occur, sulfonamides typically cause delayed cutaneous reactions, often beginning with fever and then followed by a rash (eg, maculopapular or morbilliform eruptions). Infrequently, a seemingly benign maculopapular rash may progress to a mucocutaneous syndrome (eg, SJS or TEN).[3] Other reactions to sulfonamides may include hepatic, renal, or hematologic complications, which may be fatal.

Immune-mediated sulfonamide reactions depend on the production of reactive metabolites in the liver.[78] Trimethoprim–sulfamethoxazole, considered the most highly reactive sulfonamide, contains an arylamine in the N4 position of its chemical structure, allowing for the drug's metabolism to two highly reactive metabolites, a hydroxylamine and a nitroso-sulfonamide.[78,79] Structural differences between the sulfonamides antibiotics and nonantibiotics may influence the metabolic conversion and resultant reactivity of these compounds. Slow acetylator phenotype may also increase the risk for these reactions. When assessing the potential for allergy to a sulfonamide, the clinician should consider the chemical structure of the agent. Attention should be given to the presence of an arylamine group in the N4 position and/or an N-containing ring attached to the N1 nitrogen of the sulfonamide group.[79]

8 Cross-reactivity between sulfonamide antibiotics and nonantibiotics appears to be minimal, with cross-reactivity characterized as "highly unlikely."[80] In one study, about 10% of patients with a history of allergy to an antibiotic sulfonamide subsequently reacted to a nonantibiotic sulfonamide (eg, acetazolamide, loop diuretic, sulfonylurea, and thiazide).[77] This low rate of cross-reactivity has been attributed in part to differences in the chemical structures of the antibiotic and nonantibiotic sulfonamides. The occurrence of allergic reactions after receipt of nonantibiotic sulfonamides has also been attributed to a predisposition to allergic reactions in the affected individuals rather than cross-reactivity with sulfonamide antibiotics.[77] In fact, in one study, cross-reactivity between sulfonamide antibiotics and penicillin was higher than that between the antibiotic and nonantibiotic sulfonamides.[77]

Trimethoprim–sulfamethoxazole is used frequently for preventive or active treatment of *Pneumocystis jiroveci* pneumonia in patients with AIDS. Adverse reactions to trimethoprim–sulfamethoxazole occur much more frequently in HIV-positive patients.[81,82] Adverse effects to trimethoprim–sulfamethoxazole occur in 50% to 80% of AIDS patients compared with 10% of other immunocompromised patients.[82] Trimethoprim–sulfamethoxazole was associated with an adverse event rate of 26.3 per 100 person-years and hypersensitivity events at 22 per 100 person-years. Although reactions may include angioedema, SJS, and thrombocytopenia, most reactions to trimethoprim–sulfamethoxazole in HIV-infected patients are delayed and present as diffuse maculopapular rash with or without fever. The mechanism by which these allergic or allergic-like reactions occur in HIV-infected patients is unclear. It is unlikely that these reactions are IgG or IgE mediated.[83] Proposed mechanisms include alterations in drug metabolism caused by glutathione deficiency, a direct toxic or immunologic effect of the sulfonamide metabolites on body tissues, and increased expression of major histocompatibility complex proteins with increased recognition of the drug antigen by CD4 and CD8 cells.[83] The adverse event rate has been related to higher $CD4^+$ T-cell count greater than 20 cells/mm^3 (20×10^6/L), CD4-to-CD8 ratio less than 0.10, and treatment for fewer than 14 days.[82]

Pharmaceutical Excipients and Additives

Pharmaceutical products contain a number of "inert" additives (eg, dyes, fillers, buffers, and stabilizers) in addition to the therapeutic ingredients. These additives are not always inert and may cause adverse effects, including allergic reactions. Excipients that may cause allergic reactions include benzyl alcohol, carboxymethylcellulose, povidone, dyes, sodium benzoate, sulfites, and polyethoxylated surfactants.[84]

The azo dye tartrazine (FD&C Yellow No. 5) has been associated with acute bronchospasm, urticaria, rhinitis, and contact dermatitis.[85,86] Although the immunologic mechanisms are unclear, about 10% of aspirin-sensitive people with asthma have shown intolerance to tartrazine.[87] Doses as low as 0.85 mcg or as much as 25 mg tartrazine have provoked positive responses.[87] Most recently, challenge dosing with 35 mg of tartrazine was not shown to provoke either respiratory or cutaneous reactions in a double-blind, placebo cross-over study of 26 atopic individuals.[88]

Sulfites (including sulfur dioxide, sodium sulfite, sodium and potassium bisulfite, and sodium and potassium metabisulfite) are used commonly as antioxidants in pharmaceutical products and some foods. Many cases of adverse reactions associated with ingestion of sulfites (usually in foods) have been reported to the US Food and Drug Administration (FDA),[89] including wheezing, dyspnea, chest tightness, urticaria, angioedema, flushing, weakness, nausea, anaphylaxis, and death. IgE-mediated and nonimmunologic sulfite hypersensitivity has been demonstrated in children with a history of chronic asthma. Adverse reactions to sulfite-preserved injectables, such as gentamicin, metoclopramide, lidocaine, and doxycycline, have been reported. In contrast to reactions caused by foods, these reactions do not occur more frequently in steroid-dependent people with asthma and do not always coincide with a positive oral sulfite challenge.[90] Blunted bronchodilation may be observed in individuals with asthma after inhalation of sulfite-containing nebulizer solutions. Although many nebulizer solutions contain sulfites, metered-dose inhalers do not. Many aqueous epinephrine products also contain sulfites. The FDA labeling states that in emergency situations when sulfite-free preparations are not available, sulfite-containing epinephrine should not be withheld from a sulfite-intolerant individual because small subcutaneous doses of sulfites usually are well tolerated. However, an increased risk of anaphylaxis exists after subcutaneous injection in rare patients with a positive oral challenge to 5 to 10 mg of sulfite.

Parabens (including methyl-, ethyl-, propyl-, and butylparaben) are used widely in pharmaceutical products as a biocidal agent. Most allergic reactions to parabens are observed after topical exposure.[91] Delayed hypersensitivity contact dermatitis occurs more often in individuals with preexisting dermatitis.[87] Immediate hypersensitivity after parenteral administration is rare. Although these agents are chemically related to benzoic acid and *p*-aminobenzoic acid, the evidence for cross-sensitivity is lacking.[87]

Cancer Chemotherapy Agents

Chemotherapy agents are implicated in hypersensitivity reactions in 5% to 15% of patients who receive them.[92] Up to 65% of patients receiving L-asparaginase experience immediate hypersensitivity reactions such as urticaria and anaphylaxis.[93]

The combination regimen of paclitaxel (or docetaxel) and carboplatin is frequently responsible for producing hypersensitivity reactions. Each agent precipitates a distinct reaction, allowing for differentiation between causative factors. Hypersensitivity or allergy-like reactions have been observed with paclitaxel and docetaxel in as many as 34% of patients.[3,94,95] The reaction typically occurs within minutes after initiation of the first or second dose, suggesting a non-IgE-mediated mechanism. Both the vehicles of the taxanes (polyoxyethylated castor oil for paclitaxel; polysorbate 80 for docetaxel) and the taxanes themselves have been implicated as the cause of the reactions. A cross-reactive risk of 90% (nine of 10 patients) between paclitaxel and docetaxel provides further evidence that the reaction is most likely attributed to the taxane moiety.[96] Severe reactions are characterized by dyspnea, bronchospasm, urticaria, and hypo- or hypertension. Minor reactions include flushing and rashes. In patients receiving a 3-hour infusion, the incidence of severe reactions is reduced to 1.3%, and the incidence of minor reactions is 42%.[97] To reduce the risk of

hypersensitivity reaction, patients are routinely premedicated with corticosteroids and H_1- and H_2-receptor antagonists. A protein-bound formulation of paclitaxel (Abraxane®) devoid of the castor oil vehicle is available, avoiding some but not all reactions.

Hypersensitivity to platinum-containing agents is delayed, developing after six or more courses of carboplatin, cisplatin, or oxaliplatin.[98,99,100,101] The reaction rates differ depending on the platinum agent with reported frequencies of 5% to 20% with cisplatin, 9% to 27% with carboplatin, and 10% to 19% with oxaliplatin.[102] Reactions typically develop shortly after completing the infusion or up to 3 days after therapy.[98] Symptoms of severe reaction include tachycardia, dyspnea, facial swelling, rigors, and hypotension. Mild reactions include itching, erythema, and facial flushing. An association between reactivity and the duration of the platinum-free interval has been described for carboplatin.[103] The risk of a severe reaction was 47% if the platinum-free interval was greater than 24 months versus only 6.5% within intervals less than 12 months.[103] Management strategies include decreasing the rate of infusion and administration of corticosteroids and H_1 and H_2 receptor antagonists.[101] Skin testing with carboplatin has been described.[99,102] Desensitization to carboplatin[99,100] and oxaliplatin[104,105] has been shown to be well tolerated.

Anticonvulsants

Many anticonvulsant drugs produce a variety of DHRs. Drugs such as phenytoin, phenobarbital, carbamazepine, and lamotrigine can cause an "anticonvulsant hypersensitivity syndrome" characterized by fever, rash, lymphadenopathy, and internal organ involvement. Eosinophilia is frequently present and many reactions meet the definition of DRESS. The onset usually occurs several weeks into therapy.[34] In some cases, morbilliform rash develops into exfoliative dermatitis. The risk of cross-reactivity between the aromatic anticonvulsants (eg, carbamazepine, phenobarbital, and phenytoin) ranges from 40% to 80%.[34] Oxcarbazepine, the 10-keto derivative of carbamazepine, has exhibited both in vitro and in vivo cross-reactivity with carbamazepine. A genetic marker for severe reactions to carbamazepine, phenytoin, and fosphenytoin is the presence of the *HLA-B*1502* allele.[33] This allele is found in 10% to 15% of patients from China, Thailand, Malaysia, Indonesia, the Philippines, and Taiwan. In a population of patients from Taiwan, Japan and Malaysia, genetic variation in the CYP2C gene, notably CYP2C9*3, was associated with phenytoin-induced SCARs (OR 11, 95% CI 6.2-11.8, $P<0.0001$).[37] Concomitant use of valproate with lamotrigine significantly increases the risk of DHRs as a result of reduced lamotrigine metabolism, leading to a prolonged elimination half-life.[106]

ACE inhibitors and Angiotensin Receptor Blockers

ACE inhibitor-associated angioedema occurs in 0.2% to 1% of treated patients.[107] It usually involves the face, tongue, lips, and pharynx but may also extent to the gastrointestinal tract. ACE is a nonspecific dipeptidase that not only inhibits the conversion of angiotensin I to angiotensin II but is involved in the inactivation of bradykinin, substance P and neurokinin A. High levels of bradykinin and substance P have been associated with vasodilation, increased vascular permeability and

inflammation resulting in angioedema in susceptible patients. The prevalence of ACE inhibitor-induced angioedema is highest in women and African Americans.[107] An added risk factor is the concomitant use of medications that inhibit bradykinin metabolism, such as the neprilysin inhibitor, sacubitril. Current labeling for the sacubitril/valsartan combination product provides a cautionary recommendation for a 36 hour washout period when converting from an ACE inhibitor.[108]

Reports of angioedema secondary to angiotensin-receptor blockers (ARBs) exist; the weighted incidence was 0.11% in a meta-analysis of 35,000 patients treated with an ARB.[109] The mechanism by which ARBs cause angioedema is poorly understood. As such, the risk of a 'cross reaction' between ACE inhibitors and ARBs is not clear. ARBs may cause repeat events through an independent mechanism or through a common pathway not yet determined. Based on a systematic review of 71 patients, the risk of subsequent angioedema after switching to an ARB was 9.4% for possible cases and 3.5% for confirmed cases.[110] None of the events were fatal. Before switching to an ARB in a patient with history of ACE inhibitor-related angioedema, consideration must be given to the severity of the initial event (ie, isolated nondiffuse facial swelling vs diffuse angioedema with laryngeal inflammation, esophageal or intestinal involvement), the prior responsiveness to treatment for angioedema and the benefit:risk ratio of using the ARB in the patient.

Chlorhexidine

The prevalence of allergy or DHRs to chlorhexidine is not known, but cases ranging from anaphylaxis to contact dermatitis have been increasingly reported over the past 10 years.[111] Chlorhexidine is one of the most frequently used antiseptics. Having both bacteriostatic and bactericidal activity, chlorhexidine is used as a skin antiseptic prior to surgery, for urethral catheterization as a lubricant gel, and as a coating in central venous catheters.[112] It can also be found as an ingredient in toothpastes, mouthwashes and mouth rinses. Sensitization is most commonly associated with the application to mucous membranes.[112] When applied to the skin as a hand-washing solution, low sensitization rates are attributed to poor transdermal absorption of chlorhexidine. Most allergic reactions are confined to the skin and manifest as urticaria with itching or contact dermatitis; however, anaphylaxis has been reported perioperatively after skin antisepsis, following insertion of a chlorhexidine-coated central venous catheter, and during toothbrushing. Both skin prick and intradermal testing have been used to identify high risk patients prior to surgery. In a case series of 6 severe, immediate reactions to chlorhexidine that occurred during surgery, the onset of reactivity was within 10 to 20 minutes of chlorhexidine exposure.[111] When assessed 6 weeks after surgery, 5 of the 6 patients had self-reported prior histories of reactivity to chlorhexidine and 4 of the 6 demonstrated reactivity to skin prick testing.[111] The results of skin testing, the rapid onset and the increased intensity of reactivity observed on re-exposure to chlorhexidine support an IgE-mediated mechanism. Based on the widespread use of this antiseptic, chlorhexidine should be considered as a potential cause of any unexplained allergy. Once recognized as reactive, patients must be educated to avoid subsequent exposures in both healthcare settings (eg, handwashing solutions and skin antiseptics) and in the private home (eg, personal hygiene products containing chlorhexidine).

Biologics

Biologic agents (eg, monoclonal antibodies, fusion proteins, and recombinant proteins) are derived from living sources such as yeast, bacteria, animal cells, or mammalian cells.[113] Unlike nonbiologic agents, these large proteins can serve as complete antigens. Examples include recombinant insulin, erythropoietin, interferon-β, human growth hormone, infliximab, cetuximab, rituximab, and omalizumab. Immunologic reactions to these agents range from minor infusion or injection-site reactions to anaphylaxis. Depending on the agent, reactions can occur on first or subsequent exposure, and the timing may be within 4 hours of drug administration or up to 14 days after an infusion.[113]

Factors influencing the antigenicity of biologic agents are patient specific (eg, atopy, congenital protein deficiency), production related (eg, presence of contaminants or stabilizing agents, degree of protein glycosylation, presence of nonhuman protein sequences, and storage temperature), and administration related (eg, route of administration, frequency of use, concurrent immunosuppressant use).[113] Of the monoclonal antibodies, reactions are most frequently observed with the murine-derived agents (0% human) and chimeric agents (75% human) as opposed to the humanized (greater than 90% human) and human (100% human) agents. Some immune reactions to biologic agents result from the development of neutralizing antibodies that can prevent the protein from exerting its intended effect. Neutralizing antibodies have been shown to mediate reactions to interferon-β_{1b} and β_{1a}, infliximab, natalizumab, recombinant factor VIII, and recombinant factor IX.[113] Anti-infliximab antibodies, which occur in up to 60% of treated patients, are associated with higher frequency of infusion reactions and decreased therapeutic effect.[114] Concomitant administration of immunosuppressive agents such as prednisone or low-dose methotrexate has been shown to decrease the incidence of antibody formation to infliximab.[113,114]

Cetuximab, a human-murine IgG1 monoclonal antibody used in the treatment of metastatic colon cancer and locally or advanced head and neck cancer, presents a unique situation as an allergen.[115] Cetuximab carries a black box warning regarding serious infusion reactions that occurred largely on first dose administration in 3% of patients in pre-marketing studies. Following release of the drug, reactive rates as high as 20% were noted in specific regions of southern United States.[116] These reactions also occurred on first infusion, but many were severe enough to warrant total discontinuation of therapy. Further investigation of these regional cases revealed a common link: the presence of pre-existing IgE antibodies against the oligosaccharide, galactose-α-1,3- galactose secondary to lone star tick bites.[117] This oligosaccharide present in the tick is also found on the Fab portion of the heavy chain of cetuximab, resulting in IgE cross-reactions on first drug exposure. Galactose-α-1,3-galactose is also present in the serum of nonprimate mammals and may be responsible for delayed hypersensitivity reactions secondary to ingestion of certain meats.[117] Experience with cetuximab as an immunogen has raised awareness of potential drug-food-environmental cross-reactions.

Delayed onset anaphylaxis, ranging from minutes to days postinjection, has been reported with omalizumab, a humanized monoclonal antibody targeted against IgE.[118,119] Omalizumab-treated patients require observation for 2 hours after the first three injections and for 30 minutes after subsequent injections.[119] Patients are advised to carry an epinephrine autoinjector during and for 24

hours after drug administration.[118,119] Risk factors for this adverse event have not been identified. Inclusion of polysorbate 80 as a stabilizing agent in the formulation, and an alteration in the protein sequence via glycosylation, may influence the immunogenicity of omalizumab.[119]

Management of allergic or DHRs to biologic agents varies based on the culprit agent and the severity and nature of the reaction. Immediate management with epinephrine and permanent discontinuation of the drug may be warranted (eg, omalizumab-induced anaphylaxis). Depending on the biologic agent, reactions may be managed by decreasing the infusion rate or lessened by pretreating with antihistamines or corticosteroids or administering concomitant steroid therapy. Desensitization protocols for infliximab,[102,120] cetuximab,[121] rituximab,[102,120] and trastuzumab[102,120] have also been described.

TREATMENT

9 The basic principles for management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible; (b) treatment of the adverse clinical signs and symptoms; and (c) substitution, if necessary, of another agent.

Anaphylaxis

Anaphylaxis requires prompt treatment to minimize the risk of serious morbidity or death. On presentation, attention should be given first to stopping the likely offending agent, if possible, and restoring respiratory and cardiovascular function. In 2015, the Joint Task Force on Practice Parameters for Allergy and Immunology updated the treatment guidelines for anaphylaxis (**Table e88-3**).[17] Epinephrine remains the drug of first choice, although it is underused and often dosed suboptimally for this indication.[122] Underuse and delays in its administration have been associated with poor outcomes. Epinephrine should be administered as primary treatment to counteract bronchoconstriction and peripheral vasodilation leading to hypotension.[17,122] At recommended doses, epinephrine also enhances coronary blood flow. The recommended administration technique is intramuscularly in the lateral aspect of the thigh.[17,123] If blood pressure is not restored by epinephrine, crystalloid IV fluids should be administered to restore intravascular volume. Typically, 1 L of 0.9% sodium chloride is administered over 5 to 10 minutes. This can be repeated if the patient is still believed to be volume depleted. A maintenance IV fluid then is initiated. IV fluids should be given early in the course of treatment in an attempt to prevent shock. An immediate priority is to establish and maintain an airway by the use of endotracheal intubation if necessary. When a patient with anaphylaxis is hypotensive, vasopressors may be needed in addition to crystalloids. Norepinephrine is the vasoconstrictor agent of choice for treatment of anaphylactic shock, and use of a continuous IV infusion of epinephrine has also been described.[17,124] Patients in shock should remain supine.[17]

TABLE e88-3 Treatment of anaphylaxis

1. Remove the inciting allergen, if possible.

2. Assess airway, breathing, circulation and orientation. Support the airway.

3. Cardiopulmonary resuscitation: Start chest compressions (100/min) if cardiovascular arrest occurs at any time.

4. Administer epinephrine 1:1,000 (adults: 0.3-0.5 mg; children: 0.01 mg/kg) IM in the lateral aspect of the thigh.

5. Place patient in recumbent position.

6. Administer oxygen 8-10 L/min through facemask or up to 100% oxygen as needed; monitor by pulse oximetry, if available.

7. Repeat IM epinephrine every 5-15 minutes for up to 3 injections if the patient is not responding.

8. Establish IV line for venous access. Keep line open with 0.9% saline solution. For hypotension or failure to respond to epinephrine, administer 1-2 L at a rate of 5-10 mL/kg in the first 5-10 minutes. Children should receive up to 30 mL/kg in the first hour.

9. Consider nebulized albuterol 2.5-5 mg in 3 mL of saline for lower airway obstruction; repeat as necessary.

10. In cases of refractory bronchospasm or hypotension not responding to epinephrine because a β-adrenergic blocker is complicating management, glucagon 1-5 mg IV (20-30 mcg/kg; maximum, 1 mg in children) given IV over 5 minutes.

11. Give epinephrine by continuous IV infusion for patients with inadequate response to IM epinephrine and IV saline. Add 1 mg (1 mL of 1:1,000) of epinephrine to 1,000 mL of 0.9% saline solution; Start infusion at 2 mcg/min and increase up to 10 mcg/min based on blood pressure, heart rate and cardiac function.

12. Consider intraosseous access for either adults or children if attempts at IV access are unsuccessful.

13. Consider the antihistamine diphenhydramine (adults 25-50 mg; children 1 mg/kg, up to 50 mg) IM or by slow IV infusion.

14. Consider ranitidine 50 mg in adults and 12.5-50 mg (1 mg/kg) in children. The dose may be diluted in 5% dextrose in water to a volume of 20 mL and injected over 5 minutes.

15. Consider methylprednisolone 1-2 mg/kg/dose up to 125 mg (or an equivalent steroid) to reduce the risk of recurring or protracted anaphylaxis. Prednisone 20 mg orally can be given in mild cases. These doses can be repeated every 6 hours as required.

IM, intramuscular.

Elsevier.

Other agents may be required for treatment of anaphylactic reactions. Corticosteroids (hydrocortisone sodium succinate IV) should never be given in place of or before epinephrine.[17] Their onset of action is delayed, and their role is to reduce the risk of late-phase "biphasic" reactions. In patients treated chronically with β-blockers, glucagon should be considered because its inotropic and chronotropic effects do not rely on β-receptor responsiveness.[17] Histamine (H_1) receptor blockers (eg, diphenhydramine) can be administered to reduce some of the symptoms associated with anaphylaxis, but these agents are not effective as primary therapy. The combination of diphenhydramine and an H_2 receptor blocker (eg, ranitidine) has been shown to be superior to diphenhydramine alone in the treatment of cutaneous manifestations of anaphylaxis.[17] Intraosseous access should be considered for adult and pediatric patients in whom attempts at IV access are unsuccessful.[17,124]

Following treatment of anaphylaxis, patients should be assessed for possible recurrence. Patients who may re-encounter the allergic trigger (eg, peanuts, shellfish, and medication) should be prescribed auto-injectable epinephrine.[125] Adults should receive the 0.3 mg dose and children should receive the auto-injector that delivers 0.15 mg per dose.[125] Patients should be instructed to carry 2 auto-injectors at all times.[17] Optimal dosing has not been described for obese patients. Both adequate needle length for intramuscular delivery of the drug and weight-based dosing are concerns in the obese population.[125] Patient education is crucial to prevent fatalities due to underuse and incorrect administration of epinephrine.

Delayed Allergic Reactions

With the exception of anaphylaxis, the treatment of other drug allergies or DHRs is less defined and standardized. Questions most often arise regarding the preferred treatment of SCARs. After the offending agent is discontinued, treatment of SJS/TEN is directed at supportive care including wound care, nutritional support, fluid and electrolyte balance, temperature regulation, pain management and the prevention of infectious complications.[11] Affected patients, particularly those with extensive epidermal involvement, should be managed in a burn center or ICU. Wounds should be treated similar to that of burn injuries, but topical use of silver sulfadiazine is typically avoided because of a high risk of cross-reactivity with sulfamethoxazole, a major offender in SJS/TEN. To prevent blindness or conjunctival scarring, ocular therapy involves the use of antiseptics, lubricants, antibiotics and steroid eye drops or ointments. The use of systemic steroids remains controversial. In a systematic review of published studies, only 1 of 6 retrospective cohort studies demonstrated a significant impact of steroids on mortality (OR 0.4, 95% CI 0.2-0.9).[126] Lack of controlled prospective studies makes it difficult to determine the appropriate dose, time of initiation of therapy and duration of steroid therapy. Additional therapies used in the treatment of SJS/TEN include intravenous immunoglobulin (IVIG) and cyclosporine. A proposed mechanism of IVIG is inhibition of dermal cell apoptosis triggered by the Fas-FasL pathway. Both low dose (0.2-0.5 g/kg) and high dose (2-3 g/kg) IVIG regimens have been described with most studies supporting the use of mean total IVIG doses not less than 2 g/kg.[127] In a recent single-center retrospective study of 64 patients, cyclosporine (3-5

mg/kg/day for 7 days) was associated with a greater mortality benefit as compared to IVIG (total of 1 g/kg for 3 days).[128] Similar to corticosteroids, treatment protocols of these agents substantially differ, and the optimal doses, time of initiation and durations of therapy are yet to be determined.

Skin Testing

10 Identification of patients at high risk for drug allergy requires careful history taking with attention to the specific agent to which the patient reacted, a complete description of the reaction, and the time since last exposure to the culprit drug. The importance of accurate and complete history taking cannot be overstated. Skin testing and oral challenges (eg, test dosing) are used to assess reactive risk to some drugs, but many of the testing procedures have not been validated. Reliable skin test reagents are not available for most culprit drugs. When available, skin testing should be performed before a drug challenge because of the lesser risks incurred to the patient. Skin testing should not be performed in patients with history of severe mucocutaneous reactions (eg, SJS, TEN) or other nonimmediate reactions (eg, serum sickness, vasculitis, and hepatitis).

10 Skin testing can reduce the uncertainty of penicillin sensitivity and should be performed in all patients who have a history of an immediate allergy and require treatment with a β-lactam antibiotic. Penicillin skin testing in advance of need for penicillin treatment in patients with a history of penicillin allergy does not appear to induce sensitization.[129] Testing for the major penicillin determinant is accomplished with penicilloyl-polylysine (PPL; Pre-Pen), a product recently reintroduced in the United States. Ideally, skin testing should be performed with both the major and minor determinants. Of the minor determinants, only penicillin G is commercially available in the United States, and it should be used at a concentration of 10,000 units/mL with PPL in skin testing.[38,130] If left in solution to "age," penicillin G will not spontaneously degrade to form the other minor determinants, penilloate and penicilloate.[16] Similar reaction rates to oral penicillin challenges have been shown in patients with skin test negativity to PPL plus penicillin G compared with those with skin test negativity to the full set of major and minor determinants.[16,38,40] Skin testing with the major and minor determinants has been shown to facilitate the safe use of penicillin in up to 90% of patients with a history of immediate penicillin allergy.[38] In patients who report a history of penicillin allergy but are skin test negative, the risk of resensitization (ie, conversion to a positive skin test result) after a course of penicillin ranges from 1% to 28%.[131] The procedure for performing penicillin skin testing is given in **Table e88-4**. In Europe, skin testing can be accomplished with a kit containing both the major and minor determinant mixture (Diater Labs, Madrid, Spain).[102]

TABLE e88-4 Procedure for Performing Penicillin Skin Testing

A. Percutaneous (Prick) Skin Testing (Using a 22- to 28-Gauge Needle)

Materials	Volume
Pre-Pen 6×10^6 M	1 drop
Penicillin G 10,000 units/mL	1 drop
β-Lactam drug (amoxicillin) 2 mg/mL	1 drop

A. Percutaneous (Prick) Skin Testing (Using a 22- to 28-Gauge Needle)

Materials	Volume
Saline control	1 drop
Histamine control (1 mg/mL)	1 drop

1. Place a drop of each test material on the volar surface of the forearm.
2. Prick the skin with the needle to make a single shallow puncture of the epidermis through the drop.
3. Interpret skin responses during the next 15 minutes. Observe for a wheal or erythema and the occurrence of itching.
4. A wheal in diameter of 5 mm or greater surrounding the puncture site is considered a positive test result.
5. Wipe off the solution near the puncture site.
6. If the prick test result is negative or equivocal (wheal <5 mm in diameter with no itching or erythema), proceed to the intradermal test.
7. If the histamine control is nonreactive, the test is considered uninterpretable. Ensure no interference by antihistamines.

B. Intradermal Skin Testing[a]

Materials	Volume
Pre-Pen 6×10^6 M	0.02 mL
Penicillin G 10,000 units/mL	0.02 mL
β-Lactam drug (amoxicillin) 2 mg/mL	0.02 mL
Saline control	0.02 mL
Histamine control (0.1 mg/mL)	0.02 mL

1. Inject 0.02—0.03 mL of Pre-Pen intradermally (amount sufficient to produce a small bleb of about 3 mm in diameter) in duplicate at least 2 cm apart.
2. Inject 0.02—0.03 mL of the other materials at least 5 cm from the Pre-Pen sites.
3. Interpret skin responses after 20 minutes.
4. Itching or a significant increase in the size of the original bleb to at least 5 cm is considered a positive result. An ambiguous response is a wheal only slightly larger than the original bleb or discordance between the duplicates. The control site should show no increase in the original

A. Percutaneous (Prick) Skin Testing (Using a 22- to 28-Gauge Needle)

Materials	Volume

bleb.

5. If the histamine control is nonreactive, the test is considered uninterpretable. Antihistamines may blunt the response and cause false-negative results.

[a]Using a 0.5- to 1-cc syringe with a 3/8- to 5/8-inch long (1-1.6 cm), 26- to 30-gauge short-bevel needle.

Pre-Pen (benzylpenicilloyl polylysine injection, solution) Product Information, AllerQuest LLC and ALK-Abello, Inc., Round Rock TX, 2009.

A negative penicillin skin test result indicates that the risk of life-threatening immediate reactions is extremely low with administration of penicillin or other β-lactams. Such patients are candidates for treatment with full therapeutic doses of a penicillin or a related β-lactam. Certain types of patients (eg, those with dermatographism, taking antihistamines) may be unsuitable for skin testing because a false-positive or false-negative test may result. To prevent interference with skin testing, antihistamines should be discontinued at least 1 week before skin testing. Penicillin is the only drug for which the predictive value of skin testing has been well established. Although the negative predictive value is high, penicillin skin testing with the major and minor determinants does not identify patients who are at risk for unique side chain–mediated reactions to β-lactams (eg, third-generation cephalosporins, piperacillin). Dilute concentrations of amoxicillin and piperacillin have been used to skin test for side chain–mediated reactions.[50,51,52] The value of skin testing to predict the risk of allergic reactions to other antibiotics (eg, sulfonamides, tetracyclines, and fluoroquinolones) is largely unknown.[130]

Skin testing is used to identify patients at risk for hypersensitivity reactions to carboplatin. The negative predictive value of intradermal skin testing with carboplatin has been shown to be 98% to 99% in patients who have received a number of treatment courses.[99]

Induction of Drug Tolerance and Desensitization

11 For some patients with history of an immediate reaction to a drug, no reasonable alternatives exist, and the inciting drug or a related compound may be necessary for treatment of an underlying condition (eg, infection). In this situation, the temporary induction of drug tolerance is indicated. In the past, the term "desensitization" was used to describe the procedure of temporarily acquiring drug tolerance, whether the underlying mechanism of intolerance was immunologically mediated or not. Experts in drug allergy currently recommend that the phrase "induction of drug tolerance" be used in place of "desensitization" to globally describe procedures used to modify a patient's response to a drug and temporarily allow safe drug therapy.[10] Induction of drug tolerance can involve a variety of drug mechanisms, including IgE-mediated immune mechanisms, non-IgE mechanisms, pharmacologic mechanisms, and undefined mechanisms (**Table e88-5**).[16] Regardless of the

underlying mechanism, all procedures used to induce drug tolerance involve a stepwise process of incremental dosing of the inciting drug or a related compound. Desensitization, a form of inducing drug tolerance, specifically refers to the process in which the mast cells are rendered less responsive to degranulation. This term should be used when the underlying mechanism of drug intolerance is believed to be IgE mediated (ie, anaphylaxis to penicillin).[16] Immediate reactions most amenable to desensitization include dermatologic (eg, flushing, pruritus, urticaria, and angioedema), upper and lower respiratory tract (eg, sneezing, dyspnea, and wheezing), gastrointestinal (eg, abdominal pain, nausea and vomiting), and cardiovascular (eg, hypotension).[102] Procedures to induce drug tolerance should not be used in patients with history of severe non-IgE reactions to a drug such as DRESS, SJS, TEN, exfoliative dermatitis, hemolytic anemia, or hepatitis.

TABLE e88-5 Characteristics of Drug Intolerance Protocols

Underlying Mechanism	Initial Dose	Duration of Protocol	Potential Outcome of Process	Duration of Induced Tolerance	Example
Immunologic IgE (desensitization)	Micrograms	Hours	Desensitization; render mast cells less responsive to degranulation	Temporary	β-Lactam antibiotics; taxanes
Immunologic non-IgE	Milligrams	Hours to days (eg, 6 hours to 10 days)	Not known	Temporary	Delayed cutaneous reactions to trimethoprim–sulfamethoxazole in HIV-infected individuals
Pharmacologic	Milligrams	Hours to days (eg, 2 hours to 5 days)	Cautious induction of a reaction followed by a shift in a metabolic process	Temporary	Aspirin
Undefined	Micrograms to milligrams	Prolonged; days to weeks	Not known	Temporary	Isolated cutaneous reactions to allopurinol

All procedures to induce drug tolerance should be performed by a physician experienced in the risks and management of severe allergic reactions in a hospital setting with resuscitation equipment available. The potential risks and benefits should be discussed with the patient. The procedures differ in starting dose, number of steps in the dosing process, and frequency of drug dosing. The specific procedure should be chosen based on an analysis of the patient's history of the reaction and with consideration to the specific inciting drug and the suspected underlying mechanism of drug

intolerance (ie, IgE mechanism vs non-IgE mechanism vs pharmacologic mechanism). The starting dose for a desensitization procedure is typically 1/1000th of the final therapeutic dose and the procedure can be completed within 4 to 12 hours.[16,40] A rapid 12-step desensitization protocol has been described and tested in patients with both IgE- and non-IgE-mediated reactions to antibiotics, platinum-containing chemotherapeutic agents, taxane chemotherapy agents, and monoclonal antibodies.[100,102] The 12-step method starts with a 1:1,000 dilution of the final dose of the inciting drug. Incrementally increased doses are administered every 15 minutes with three-10-fold diluted solutions. This method has been tested in nearly 800 patients, including patients with cystic fibrosis and allergy to antibiotics.[102] In high-risk patients, desensitization is achieved with either a 16- or a 20-step protocol.[100,102]

In the case of penicillin or β-lactam allergy, desensitization should be performed with the specific β-lactam antibiotic that will be administered for treatment of the patient's infection. Before initiating the protocol, the patient should be stabilized and fluid, pulmonary, and cardiovascular function optimized. Premedications (antihistamines or corticosteroids) have not been routinely advised because these agents may mask the early signs of acute reactions and do not reliably reduce the severity of acute reactions. About one-third of patients who have undergone desensitization to a penicillin will experience mild, transient allergic reactions either during the desensitization procedure or during penicillin therapy. Patients who can take oral medication should undergo desensitization with oral drug. After the desensitization protocol is begun, it should not be interrupted except for severe reactions. Antihistamines or epinephrine can be administered to treat reactions. In addition, if the patient completes the desensitization regimen and then undergoes full-dose treatment, a lapse between doses of as few as 24 hours can allow for reemergence of sensitivity. A protocol for IV cephalosporin desensitization is listed in **Table e88-6**. Protocols for desensitization with other β-lactam antibiotics are also available.[132,133] The use of standardized antibiotic desensitization protocols are recommended to reduce the potential for medication error and better achieve the goals of antimicrobial stewardship.[134]

TABLE e88-6 Induction of Drug Tolerance Protocol for IV Cephalosporin[a]

Preparation of Solutions

	Volume of Diluents (eg, 0.9% NSS)	Total to be Injected in Each Bottle	Final Concentration (mg/mL)
Solution 1	250 mL	10 mg	0.04
Solution 2	250 mL	100 mg	0.4
Solution 3	250 mL	1,000 mg	4

Induction of Drug Tolerance Protocol

Step	Solution	Rate (mL/h)	Time (min)	Administered Dose (mg)	Cumulative Dose (mg)
1	1	2	15	0.02	0.02
2	1	5	15	0.05	0.07
3	1	10	15	0.1	0.17
4	1	20	15	0.2	0.37

Preparation of Solutions

			Volume of Diluents (eg, 0.9% NSS)	Total to be Injected in Each Bottle	Final Concentration (mg/mL)
5	2	5	15	0.5	0.87
6	2	10	15	1	1.87
7	2	20	15	2	3.87
8	2	40	15	4	7.87
9	3	10	15	10	17.87
10	3	20	15	20	37.87
11	3	40	15	40	77.87
12	3	75	184.4	922.13	1,000

NSS, normal saline solution.

[a]Full dose equals 1,000 mg. Total time was 349.4 minutes.

Most reactions to trimethoprim–sulfamethoxazole in HIV-infected patients are considered to be non-IgE-mediated, and a number of protocols to induce tolerance to trimethoprim–sulfamethoxazole have been described. The preferred regimen is not known because the regimens have not been compared in controlled clinical trials. Tolerance to trimethoprim–sulfamethoxazole can be achieved within 2 days in most HIV-infected patients.[3,135] This can be accomplished with the following schedule of oral doses (milligrams of sulfamethoxazole–trimethoprim): day 1: 9 am, 4 and 0.8 mg; 11 am, 8 and 1.6 mg; 1 pm, 20 and 4 mg; 5 pm, 40 and 8 mg; day 2: 9 am, 80 and 16 mg; 3 pm, 160 and 32 mg; 9 pm, 200 and 40 mg; day 3: 9 am, 400 and 80 mg, and 400 and 80 mg daily thereafter. With this regimen, the failure rate was associated with higher relative and absolute CD4 cell counts. Other investigators have described a 6-hour oral regimen in HIV-infected patients[136] and a more gradual 9-day oral regimen.[137] Induction of drug tolerance should not be attempted in any patient with history of an exfoliative reaction to trimethoprim–sulfamethoxazole.

Both rapid (over less than 4 hours) and traditional desensitization protocols are available for aspirin and clopidogrel.[75,138] With few exceptions, patients with aspirin-induced asthma and urticaria/angioedema can be effectively desensitized to subsequently receive aspirin for treatment of cardiovascular disease.[74]

Graded Challenge

Also known as test dosing, a graded drug challenge involves the cautious introduction of a drug when the risk of a reaction is deemed to be low. A graded drug challenge is an alternative to the induction of drug tolerance, and it does not modify the immune or nonimmune response to the

drug.[16,132] Instead, graded challenge is used when the risk of a severe reaction to a drug on reexposure is low, no alternative drug is equally effective, and a reliable skin testing method is not available. A classic example is the slow introduction of a cephalosporin in a patient with a history of reacting to another cephalosporin with a dissimilar R1 side chain.[132] Graded challenge protocols have been described for the slow introduction of furosemide in a patient with heart failure and history of sulfonamide allergy.[139,140] Challenge dosing is not recommended in patients with a history of a severe drug allergy (eg, anaphylaxis, SJS, and TEN). Premedications should not be used because they may mask signs of an early breakthrough allergic reaction. Compared with drug tolerance procedures, graded challenges involve higher starting doses and fewer steps in the dosing process. The starting dose is typically 1/10th to 1/100th of the final treatment dose, and the oral route of drug administration is preferred to limit the risk of a severe reaction.[132] If no reaction occurs to the initial dose, the dose may be increased in twofold to fivefold increments and administered every 30 to 60 minutes until the full therapeutic dose is achieved.[52,132] There is no standard protocol for graded challenge dosing; a therapeutic dose may be achieved over a matter of hours or days. Because of the risk of breakthrough allergic reactions, graded challenges should be performed in monitored settings.

Chapter 89: Solid-Organ Transplantation

Heather J. Johnson; Kristine S. Schonder

INTRODUCTION

KEY CONCEPTS

- 1 Generally patients receive a combination of two to four immunosuppressive drugs in order to minimize individual drug toxicities as well as block different aspects of the immune response.
- 2 While the calcineurin inhibitors (CI) tacrolimus and cyclosporine, inhibitors of interleukin (IL)-2 and thus T-cell activation, are the backbone of immunosuppressive regimens, they are associated with serious adverse effects, primarily, nephrotoxicity, and neurotoxicity.
- 3 Calcineurin inhibitor-induced nephrotoxicity is one of the most common adverse effects observed in renal and nonrenal transplant recipients. Therapeutic drug monitoring is used in an attempt to optimize the use of calcineurin inhibitors and prevent toxicity.
- 4 Corticosteroids are a key component of most immunosuppressive strategies because they block the initial steps in allograft rejection. Their significant adverse effects have led to steroid-minimizing and steroid-free imunosuppressive protocols. Corticosteroids, however, remain first-line treatment for allograft rejection.
- 5 Azathioprine and mycophenolic acid derivatives inhibit T-cell proliferation by altering purine synthesis. Bone marrow suppression is the most significant adverse effect associated with these agents.
- 6 Sirolimus and everolimus inhibit the mTOR (mammalian target of rapamycin) receptor, which alters T-cell response to IL-2. The adverse effects associated with these agents include leukopenia, thrombocytopenia, anemia, and hyperlipidemia.
- 7 Antibody preparations that target specific receptors on T cells are classified based on their ability to deplete lymphocyte counts. Most lymphocyte-depleting antibodies are associated with significant infusion-related reactions, where as nondepleting agents are generally better tolerated.

- 8 Long-term allograft and patient survival is limited by chronic rejection, cardiovascular disease, infection, and long-term immunosuppressive complications such as malignancy.

Solid-organ transplantation provides a lifesaving treatment for patients with end-stage cardiac, kidney, liver, lung, and intestinal disease. Over 300 U.S. hospitals offer transplant services, and pharmacists are often an integral part of the transplant team.[1] In 2009, over 250 pharmacists were members of the American College of Clinical Pharmacy's Transplant Interest Group and more that 65% of responding centers reported a pharmacist on their transplant teams.[2] The Centers for Medicare and Medicaid Services regulations require that transplant programs have a multidisciplinary team including individuals with experience in pharmacology. While the regulations do not specifically state that each center must have a pharmacist, a pharmacist could provide the desired expertise in transplant pharmacotherapy that the regulations mandate.[1]

Since 1980 over 630,000 transplants have been performed, with over half being kidney transplants. A recent analysis estimated that since 1987 over 2.27 million life years have been saved by transplantation, with an average of 4.3 years per patient.[3] In 2014, 29,532 solid-organ transplants were performed and over half of these in were for patients over 50 years of age. Kidneys remain the most commonly transplanted organs; 11,570 from cadaveric donors and 5,536 from living donors in 2014. The next most frequently transplanted organ was the liver, with 6,449 from cadaveric donors and 280 from living donors. Heart and pancreas (or combined kidney–pancreas) transplants account for over 2,600 and 700 transplants, respectively while 1,900 lung transplants were performed during 2014.[1] While the demand for transplantation continues to grow, the number of cadaveric donors has remained relatively stable during the past decade. In 2014, more than 122,000 persons in the United States were waiting for a transplant (over 101,000 people were awaiting a kidney, 15,000 a liver, 4,100 and 1,500 respectively were on the list for a heart or lung). Median waiting time for a cadaveric kidney is more than 4 years. The median waiting time for a liver or heart transplant is about 1 year and approximately 6 months, respectively. For heart, liver, and lung transplantation clinical status is an important factor affecting waiting times, with the sickest patients receiving priority for available organs.[1]

To increase the number of organs available for transplantation, several strategies have been employed in the past several years. Living donors account for one third of all renal transplants, more than any other organ. Living-donor transplantation is also becoming increasingly important for those with end-stage liver and lung disease. Efforts to expand the cadaveric donor pool have included relaxation of age restrictions, development of better preservation solutions, use of "extended-criteria" and nonheart-beating donors, and, in the case of liver transplants, the transplantation of one liver to more than one recipient or implantation of only a segment of a liver. Although very controversial, some have advocated the creation of a regulated system for compensating individuals (paying them) for the "donation" of a kidney.[4]

Clinical Controversy…

Given the availability of non-interferon-based highly effective oral therapies for hepatitis c virus infection, some clinicians believe the donor pool could be expanded to include previously excluded

donors with evidence of HCV infection.

Despite these efforts, more than 8,000 people who were on transplantation waiting lists died in 2012. Efforts to improve organ allocation have included allocation primarily on “medical necessity” versus time on the waiting list. Although dialysis can be used for an extended period of time to partially replace the function of the kidneys, such options are not readily available for most liver and heart transplantation candidates. Left ventricular assist devices are now used commonly as a bridge to transplantation for many heart transplantation candidates however, hepatocyte transplantation and artificial liver support remain investigational alternatives or bridges to liver transplantation.[5]

Patient and graft survival rates following transplantation have improved significantly over the past 30 years as a result of advances in pharmacotherapy, surgical techniques, organ preservation, and the postoperative management of patients (**Table 89-1**). The half-life of transplanted kidneys has continued to improve, but is lower for kidneys from deceased donors compared to living donors, 14.7 versus 26.6 years, respectively. Similarly, the half-life of transplanted livers and hearts from deceased donors has improved to10 years for livers and 14.9 years for hearts.[1] In this chapter the epidemiology of end-stage kidney, liver, lung, and heart disease is briefly reviewed, the pathophysiology of organ rejection is presented, the pharmacotherapeutic options for individualized immunosuppressive regimens are critiqued, and the unique complications of these regimens along with the therapeutic challenges they present are discussed.

TABLE 89-1 Organ-Specific Patient and Graft Survival Rates[1]

	Patient Survival (%)		**Graft Survival (%)**	
Organ	1 year	5 years	1 year	5 years
Kidney				
Living donor	97.9	89.4	95.1	79.8
Deceased donor	94.3	80.4	89.0	66.6
Liver				
Living donor	90.1	77.6	82.5	65.9
Deceased donor	86.2	71.9	82.0	95.1
Heart	88.0	75.0	88.3	73.9
Lung				
Living donor	85.8	35.8	83.7	34.0
Deceased donor	83.3	47.3	82.5	46.0

EPIDEMIOLOGY AND ETIOLOGY

The epidemiology and etiology associated with solid organ transplant is specific to the type of organ transplant.

Kidney

Kidney transplantation is the preferred long-term therapeutic option for most patients with end-stage renal disease because it provides the greatest potential improvement in quality of life. Dialysis catheter-related infections, peritoneal dialysis-associated peritonitis, and scheduled dialysis treatments are avoided, and dietary restrictions are fewer. Patients who receive a kidney transplant before the initiation of dialysis have markedly improved quality of life and prolonged life expectancy compared to those who were sustained on dialysis prior to their transplant.[6] The expanded use of living-donor transplantation has made this increasingly possible. Although the analysis of quality of life is complex, patients generally report improved quality of life following transplantation as compared with patients on maintenance dialysis.[7]

Diabetes mellitus, hypertension, and glomerulonephritis are the three leading causes of end-stage renal disease and account for more than 70% of patients (see Chapter 44).[1] Patients with medical conditions such as unstable cardiac disease or recently diagnosed malignancy, for whom the risk of surgery or chronic immunosuppression would be greater than the risks associated with chronic dialysis, are generally excluded from consideration for transplantation.

Liver

Noncholestatic cirrhosis (hepatitis C, alcoholic cirrhosis, hepatitis B, nonalcoholic steatohepatitis, and autoimmune hepatitis) is the primary cause of end-stage liver disease and more than 70% of liver transplant recipients have been diagnosed with one of these conditions.[1] Other indications for transplantation include acute liver failure, primary biliary cirrhosis, primary sclerosing cholangitis, as well as hepatocellular carcinoma. Livers are allocated based on a United Network for Organ Sharing-adapted, Model for End-stage Liver Disease (MELD) score.[8] This score, calculated from the patient's serum creatinine concentration, total serum bilirubin concentration, international normalized ratio, and etiology of cirrhosis, has been demonstrated to be a useful tool to predict impending mortality.

In general, active substance abuse is a contraindication to liver transplantation, but given the high mortality for acute alcoholic hepatitis and the current lack of viable treatments, some non-US centers have explored transplantation in this patient population.[9] Although hepatitis B and C can recur in the transplanted liver, these are not absolute contraindications to liver transplantation.[5,10]

Clinical Controversy…

While liver transplant recipients with alcoholic hepatitis must generally be substance abuse free, some clinicians believe the 6-month waiting period before transplant eligibility should be waived given the high mortality without transplantation.

Heart

Cardiac transplant candidates are typically patients with New York Heart Association class III or IV signs and symptoms despite maximal medical management and have an expected 1-year mortality risk of 50% or greater without a transplant.[11] Idiopathic cardiomyopathy and ischemic heart disease account for heart failure in more than 90% of heart transplantation recipients.[1] Other etiologies

include valvular disease, retransplantation for graft atherosclerosis or dysfunction, and congenital heart disease. The role of heart transplantation as a therapeutic option for patients with heart failure is discussed in Chapter 14.

Absolute contraindications to orthotopic cardiac transplantation include the presence of an active infection (except in the case of an infected ventricular assist device, which is an indication for urgent transplantation) or the presence of other diseases (eg, malignancy) that may limit survival and/or rehabilitation and severe, irreversible pulmonary hypertension.

Lung

Lung transplantation is becoming an increasing viable life-saving option for patients with end-stage pulmonary failure not amenable to other treatment. The primary indications for lung transplantation are chronic obstructive lung disease/emphysema, idiopathic pulmonary arterial hypertension, cystic fibrosis, and idiopathic pulmonary fibrosis. The vast majority of lung transplants are cadaveric (greater than 99%) and bilateral lung transplants accounted for 67% of lung transplants in 2012. Lungs are allocated on the basis of the complex lung allocation score (LAS) which is used to prioritize candidates based on medical need and expected posttransplant survival given patient specific characteristics such as antecedent disease, age, body mass index, renal function, diabetes as well as measures of current functional status.[1,12]

PHYSIOLOGIC CONSEQUENCES OF TRANSPLANTATION

Transplantation is truly lifesaving for heart, liver, and lung transplantation recipients, whereas kidney transplantation is associated with improved quality of life and survival when compared with dialysis.[13] Although not all heart transplant recipients return to work, 89.9% of patients consider themselves to have no activity limitations at 1-year follow-up.[14] The specific physiologic consequences of kidney, liver, and heart transplantation are discussed below.

Kidney Transplantation

The glomerular filtration rate of a successfully transplanted kidney may be near normal almost immediately after transplantation. In some patients, however, the concentration of standard biochemical indicators of renal function, such as serum creatinine and blood urea nitrogen, may remain elevated for several days. Standard formulas used to predict drug dosing rely on a stable serum creatinine and may be inaccurate immediately following transplantation (see Chapter e42).

Although the allograft is able to remove uremic toxins from the body, it may take several weeks for other physiologic complications of ESRD, such as anemia, calcium and phosphate imbalance, and altered lipid profiles, to resolve. The renal production of erythropoietin and 1-hydroxylation of vitamin D may return toward normal early in the postoperative period. Because the onset of physiologic effects may be delayed, continuation of the patient's pretransplantation vitamin D, calcium supplementation, and/or phosphate binders may be warranted. Patients should be monitored for hypophosphatemia and hypercalcemia for the first few days to weeks after kidney

transplantation.

Primary nonfunction of a renal allograft or delayed graft function (DGF) is characterized by the need for dialysis in the first postop week or the failure of the serum creatinine to fall by 30% of the pretransplantation value. The incidence of DGF in cadaveric kidney transplantation ranges from 8% to 50% and results in a slower return of the kidney's excretory, metabolic, and synthetic functions. DGF is associated with prolonged hospital stays, higher costs, difficult management of immunosuppressive therapy, slower patient rehabilitation, and poor graft survival.[15] Other early causes of renal dysfunction such as urethral obstruction or arterial or venous stenosis or thrombosis should be distinguished from DGF.

The primary cause of DGF is acute tubular necrosis (ATN). The incidence of ATN is higher when kidneys are harvested from donors who recently experienced a cardiac arrest, those who were hypotensive or on vasopressors, or older donors (age greater than 55 years). While cyclosporine and tacrolimus have been implicated in the prolongation of ATN, a clear cause-and-effect relationship has not been established. Nonetheless, most clinicians will decrease calcineurin inhibitor doses in patients with ATN. DGF predisposes patients to acute rejection, possibly as a consequence of decreased calcineurin inhibitor concentrations and a resultant reduction in the level of immunosuppression.[16]

Liver Transplantation

The physiologic consequences of liver transplantation are complex, involving changes in both its metabolic and synthetic function. Postoperatively, the liver transplant recipient will likely have many fluid, electrolyte, and nutritional abnormalities. Biliary tract dysfunction may alter the absorption of fats and fat-soluble drugs.[17] Poor absorption of the lipid-soluble drug cyclosporine improves after successful liver transplantation and reestablishment of bile flow. Vitamin E deficiency and its neurologic complications are usually reversed after successful liver transplantation. In stable adult liver transplant patients, the concentrations of retinol and tocopherol are similar to those seen in normal healthy subjects, indicating recovery of liver production and excretion of bile salts needed for fat-soluble vitamin absorption. **Table 89-2** summarizes the effects of liver transplantation on metabolism and renal elimination that are seen in the immediate postoperative period. Most of these changes resolve as liver function normalizes.

TABLE 89-2 Perioperative Changes in Drug Disposition and Elimination Following Liver Transplantation

	Result	Comment
Serum proteins		
↓ Albumin	↑ Free fraction of drugs usually bound to albumin	Diazepam, salicylic acid binding greater in liver transplant than chronic liver disease because of endogenous binding inhibitors (up to 45 days post-transplant)
↑ Alpha-1-acid glycoprotein	Lower unbound fraction of drugs	Lidocaine

	Result	Comment
Metabolism/elimination		
Microsomal enzymes	↑ CYP2E1 activity	Increased drug metabolism (induction)
	↔ CYP2D6	Unaffected
	↓ CYP activity	Decreased drug elimination (inhibition)
Oxidation	Stable	
Conjugation	Normalizes after transplant	
Biliary function	↓ Absorption of lipophilic compounds	
	↑ Cyclosporine metabolites in blood	
Renal elimination	Elimination of gentamicin, vancomycin, cephalosporins less than predicted by serum creatinine	Renal elimination of metabolites limited

Data from reference 12.

Failure of the newly transplanted liver to function occurs in 10% to 15% of recipients. Early graft failure can result from preexisting disease in the donor, and even coagulation defects have been acquired through donor organs. The technical complexity of the operation can produce flaws in revascularization that also lead to graft nonfunction. Surgical complications include portal vein or hepatic artery thrombosis and bile duct leaks. Ischemic injury can also result in early graft dysfunction. While hyperacute rejection in liver transplantation rarely occurs, graft failure in the first 2 postoperative weeks may indicate antibody-mediated graft destruction.

Heart Transplantation

The orthotopically transplanted heart is denervated and no longer responds to physiologic stimuli and pharmacologic agents in a normal manner (**Table 89-3**).[13] In situations requiring an increased heart rate such as exercise or hypotension, the denervated heart is unable to increase heart rate but instead relies on increasing the stroke volume. Later in the course of exercise or hypotension, heart rate increases in response to circulating catecholamines. While the maximum exercise capacity of heart transplant recipients is below normal, most patients are able to resume normal lifestyles and participate in reasonably vigorous activities.[14] Partial reinnervation may occur over time, thereby facilitating more normal physiologic and pharmacologic responses and better exercise capacity.[14]

TABLE 89-3 Altered Responses to Cardiac Drugs in the Denervated Transplanted Heart

Drug	Effect	Mechanism	Comment
Digitalis	Normal inotropic effect; minimal	Direct myocardial effect; denervation	

Drug	Effect	Mechanism	Comment
	effect on AV node		
Atropine	No effect on AV node	Denervation	
Adrenaline/noradrenaline	Increased contractility; increased chronotropy	Denervation; hypersensitivity	Increased cardiac output mediated by increased heart rate
Isoproterenol	Normal increase in contractility; normal increase in chronotropy	No neuronal uptake	
Quinidine	No vagolytic effect	Denervation	
Verapamil	AV block	Direct effect	
Nifedipine	No reflex tachycardia	Denervation	
Hydralazine	No reflex tachycardia	Denervation	
β-Blocker	Increased antagonist effect	Denervation	Impaired heart rate response, use sparingly
Adenosine	Negative chronotropic effect	Hypersensitivity; effect on sinus node of denervated heart	Life-threatening asystole (>0.5 minute) may occur if used to treat supraventricular arrhythmia or stress testing
Acetylcholine	Negative chronotropic effect	Hypersensitivity; effect on sinus node of denervated heart	

AV, atrioventricular.

A number of autoregulatory and physiologic responses present in the normal heart are interrupted or blunted for the first6 weeks after transplantation. The donor sinus node function may be impaired as the result of the preservation regimen, direct surgical trauma at excision, the presence of long-acting antiarrhythmics (eg, amiodarone) taken prior to transplant by the recipient, and a lack of "conditioning" responsiveness to catecholamines.[14] Consequently, the transplanted heart generally requires chronotropic support with either milrinone or pacing in the perioperative period to maintain a heart rate greater than 90 beats minute and satisfactory hemodynamics (ie, blood pressure, urine output, and tissue perfusion).[18] Approximately 10% to 20% of transplant patients will have persistent chronotropic incompetence requiring either short courses of medications, such as terbutaline or

theophylline, or permanent cardiac pacing.

Right ventricular function is frequently impaired, presumably as a result of preservation regimen injury and elevated pulmonary vascular resistance. A “restrictive” hemodynamic pattern may be present initially but usually improves in 6 weeks following transplantation. Donor–recipient size mismatch may contribute to early posttransplantation hemodynamic abnormalities characterized by higher right and left ventricular end-diastolic pressures. Supraventricular arrhythmias are usually transient and may result from over vigorous use of catecholamines or milrinone.

Myocardial depression frequently occurs and generally requires inotropic support with agents such as dobutamine, milrinone, and epinephrine. On occasion, intra- or postoperative administration of vasodilators, including nitric oxide, and inotropic agents may be necessary to treat right-sided failure in the transplant patient; milrinone and isoproterenol are preferred in this setting.[18]

Persistent abnormalities of diastolic function are often noted in the transplanted heart such that intracardiac pressures increase in an exaggerated fashion in response to exercise and/or volume infusion.[14] These abnormalities are due in part to denervation, but also to acute rejection or to the scarring secondary to previously treated rejection episodes, hypertension, or cardiac allograft vasculopathy.

Hypertension may occur following surgery secondary to the effect of elevated catecholamine levels and systemic vascular resistance as the residual effects of end-stage heart failure on the healthy heart. Systolic blood pressure should be maintained at 110 to 120 mm Hg to enhance cardiac function. In the acute post-transplantation period, intravenous nitroprusside or nitroglycerin may be needed, whereas oral angiotensin-converting enzyme inhibitors (ACEIs) and/or amlodipine are commonly used once the patient can ingest oral medications.

Lung Transplantation

Lung transplant recipients experience more complications than other solid organ transplant recipients as evidenced by a higher rate of posttransplant re-hospitalization. Primary graft dysfunction with a mortality of 30% to 40% occurs within 72 hours of transplant in up to 20% of recipients. It presents as noncardiogenic pulmonary edema and is thought to be a manifestation of ischemia-reperfusion injury and may be associated with prolonged cold ischemia (greater than 6 hours) as well as a number of other factors including female gender. Airway complications include ischemia and associated anastomotic dehiscence, bronchial stenosis and bronchiolitis obliterans. Dehiscence may result in mediastinitis, pneumothorax or hemorrhage. Bronchial stenosis which may occur in up to 24% of patients results in a narrowing the bronchus that is usually managed by bronchoscopy and balloon dilation. Respiratory infections are especially problematic in lung transplant recipients as their newly transplanted organ is in direct contact with the outside environment. Additionally, the absence of a cough reflex as well as a reduction in mucociliary clearance as the result of denervation and lymphatic interruption also contribute to the risk of pulmonary infections. Patients with cystic fibrosis are susceptible to the pathogens with which they were colonized before transplant.[1,12,19]

PATHOPHYSIOLOGY OF REJECTION

Rejection of a transplanted organ can take place at any time following surgery and is classified clinically as hyperacute, acute cellular, and/or humoral or chronic rejection.

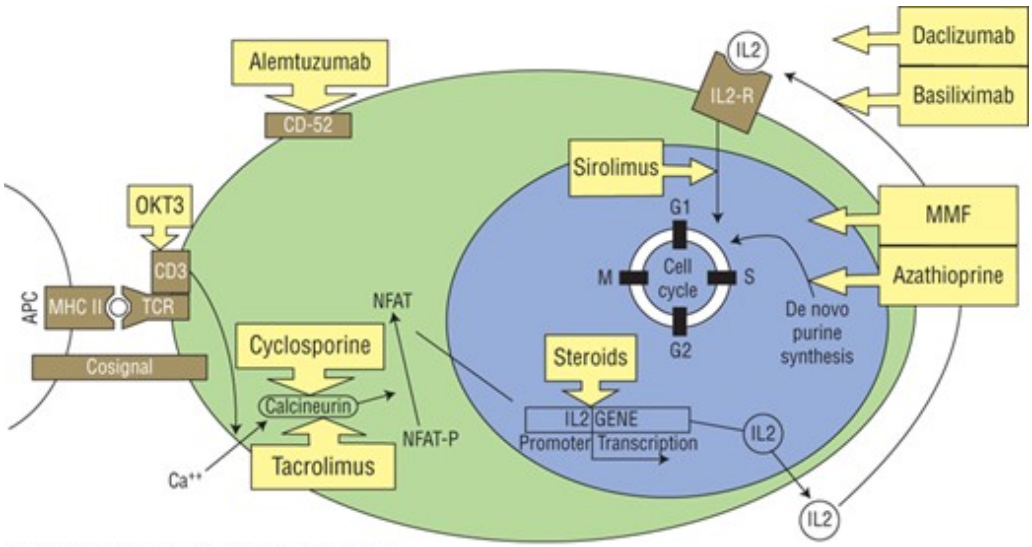
General Concepts

Rejection is primarily mediated by activation of alloreactive T cells and antigen-presenting cells such as B lymphocytes, macrophages, and dendritic cells. Acute allograft rejection is caused primarily by the infiltration of T cells into the allograft, which triggers inflammatory and cytotoxic effects on the graft. Complex interactions between the allograft and cellular cytokines, cell-to-cell interactions, CD4+ and CD8+ T cells, and B cells ultimately lead to chronic rejection and graft loss if adequate immunosuppression is not maintained.[20]

The sequence of events that underlies graft rejection is recognition, via MHC class I and II antigens, of the donor's histocompatibility differences by the recipient's immune system, recruitment of activated lymphocytes, initiation of immune effector mechanisms, and finally graft destruction. The specifics of this immune cascade of organ rejection are discussed in Chapter e86. The complex nature of cytokine interactions makes it very difficult to design drugs with exclusive actions (**Fig. 89-1**).

FIGURE 89-1

Stages of CD4 T-cell activation and cytokine production with identification of the sites of action of different immunosuppressive agents. Antigen major histocompatibility complex (MHC) II molecule complexes are responsible for initiating the activation of CD4 T cells. These MHC-peptide complexes are recognized by the T-cell recognition complex (TCR). A costimulatory signal initiates signal transduction with activation of second messengers, one of which is calcineurin. Calcineurin removes phosphates from the nuclear factors (NFAT-P) allowing them to enter the nucleus. These nuclear factors specifically bind to an interleukin (IL)-2 promoter gene facilitating IL-2 gene transcription. Interaction of IL-2 with the IL-2 receptor (IL-2R) on the cell membrane surface induces cell proliferation and production of cytokines specific to the T cell. (APC, antigen-presenting cells; MMF, mycophenolate mofetil.) (*Reprinted from Ann Thorac Surg, Vol. 77, Mueller XM, Drug immunosuppressive therapy for adult heart transplantation. Part I. Immune response to allograft and mechanism of action of immunosuppressants, pages 354–362, Copyright © 2004, with permission from Elsevier.*)



Efforts to allocate well-matched kidneys, according to human leukocyte antigens (HLA)-A, -B, and -DR, are foundational to minimize rejection and enhance survival. However, the benefit of having no recipient donor mismatches may be negated by excessive cold ischemia time (greater than 36 hours) and donor age older than60 years. HLA tissue matching is not performed routinely before transplantation for livers and hearts because organ availability is more limited and the optimal cold ischemia time is shorter.[21] However, if the potential recipient's blood is reactive against a panel of random donor blood samples (ie, panel reactive antibody [PRA] greater than 10% to 20%), a negative T-cell crossmatch is required prior to transplantation. Transplanted organs must be matched for ABO blood group compatibility with the recipient. Liver transplantation may be carried out in emergency situations across ABO blood groups, but survival is lower.

Hyperacute Rejection

Hyperacute rejection may be evident within minutes of the transplantation procedure when preformed donor-specific antibodies are present in the recipient at the time of the transplant. It can also be induced by immunoglobulin G antibodies that bind to antigens on the vascular endothelium, such as class I MHC, ABO, and vascular endothelial cell antigens. Tissue damage can be mediated through antibody-dependent, cell-mediated cytotoxicity or through activation of the complement cascade. If present the ischemic damage to the microvasculature rapidly results in tissue necrosis.

Hyperacute rejection has become uncommon in kidney and heart transplants. A positive crossmatch presents a serious risk for graft failure even if hyperacute rejection does not occur. A negative lymphocytotoxicity crossmatch does not entirely rule out the possibility of hyperacute rejection because non-MHC antigens on the vascular endothelium can serve as targets of donor-specific antibodies. Early graft dysfunction is treated with supportive care and retransplantation if possible. The reason for the rarity of hyperacute rejection in liver transplantation is not fully understood, but the local release of cytokines may alter the immunologic reaction inthe liver.[22]

Acute Cellular Rejection

Acute rejection is most common in the first few months following transplantation but can occur at any time during the life of the allograft. It is mediated by alloreactive T-lymphocytes that appear in the circulation and infiltrate the allograft through the vascular endothelium. After the graft is infiltrated by lymphocytes, the cytotoxic cells specifically target and kill the functioning cells in the allograft. At the same time, local release of lymphokines attracts and stimulates macrophages to produce tissue damage through a delayed hypersensitivity-like mechanism. These immunologic and inflammatory events lead to nonspecific signs and symptoms including pain and tenderness over the graft site, fever, and lethargy.

Kidney

Acute rejection, which may affect up to 20% of patients during the first 6 months following transplantation, is evidenced by an abrupt rise in serum creatinine concentration of greater than or equal to 30% over baseline. A specific histologic diagnosis can be obtained via biopsy of the allograft and is often used to guide rejection therapy. A biopsy specimen with a diffuse lymphocytic infiltrate is consistent with acute cellular rejection (ACR). After the diagnosis of rejection has been confirmed, the potential risks and benefits of specific antirejection therapies must be evaluated. Hypertension often worsens during an episode of rejection, and edema and weight gain are common as a result of sodium and fluid retention. Symptomatic azotemia may also develop in severe cases.

Liver

Approximately 18% of liver transplantation recipients will experience a rejection episode in the first post-transplant year. The clinical signs of ACR include leukocytosis and a change in the color or quantity of bile for those who still have an external drainage tube in place. A serum bilirubin 50% over baseline or increases in hepatic transaminases to values more than three times the upper limit of normal, are sensitive markers of rejection. Although a liver biopsy provides definitive evidence of the diagnosis of rejection, a prompt response to antirejection medication has also proven useful as a means to differentiate rejection from other causes of hepatic dysfunction.

Heart

Approximately 16% of heart transplantation recipients will experience at least one episode of acute rejection during the first year.[23] Because rejection of the cardiac allograft is not necessarily accompanied by overt clinical signs or symptoms and because the incidence of acute rejection is highest during the first year post-transplant, endomyocardial biopsies are often performed at regularly scheduled intervals following transplantation.[18] A typical biopsy schedule would be weekly for the first postoperative month, biweekly for the next 2 months, and monthly to bimonthly through the remainder of the first post-transplant year. Nonspecific symptoms, including low-grade fever, malaise, mild reduction in exercise capacity, heart failure, or atrial arrhythmias may also be evident and if present are reflective of a more severe rejection episode.

Lung

Up to 36% of lung transplant recipients will experience acute rejection in the first year.[19] Patients with acute rejection often present with nonspecific symptoms including fatigue, fever, cough, dyspnea, hypoxemia, mucus as well as a diminished FEV_1 Because spirometry and radiography cannot delineate the cause of these nonspecific symptoms, bronchoscopy and transbronchial biopsy are the standard for establishing a diagnosis of rejection. Eosinophilia, lymphocyte proliferation, and infiltration are hallmark signs of rejections. Routine assessment after transplantation includes pulmonary functions tests as well as clinical and radiologic evaluations.[12,19]

Antibody-Mediated Rejection

Antibody-mediated rejection (AMR), sometimes referred to as vascular or humoral rejection, is characterized by the presence of antibodies directed against HLA antigens present on the donor vascular endothelium. The antibodies activate complement, which creates a membrane attack complex that directly damages the organ and further attracts inflammatory cells to the allograft. The resultant damage is histologically distinct from cellular rejection and involves microvascular injury, often to the peritubular capillaries.[24] Definitive diagnosis of AMR is based on the presence of three criteria: presence of donor-specific antibodies, immunofluorescence staining of C4d deposits in the peritubular capillaries, and evidence of allograft dysfunction.[25] Circulating immune complexes often precede humoral rejection. This form of rejection is less common than cellular rejection and generally occurs in the first 3 months after transplantation. It is associated with an increased fatality rate and appears to be more common when antilymphocyte antibodies are used for rejection prophylaxis. An increased risk of humoral rejection is associated with female gender, elevated PRA, cytomegalovirus seropositivity, a positive crossmatch, and prior sensitization to OKT3 (muromonab CD3).[26] Strategies to reverse humoral rejection include plasmapheresis, often in combination with intravenous immunoglobulin, high-dose intravenous corticosteroids, antithymocyte globulin (ATG), bortezomib, rituximab, and mycophenolate mofetil.

Chronic Rejection

Chronic rejection is a major cause of graft loss. It presents as a slow and indolent form of ACR, in which the involvement of the humoral immune system and antibodies against the vascular endothelium appear to play a role. Persistent perivascular and interstitial inflammation is a common finding in kidney, liver, and heart transplantation. As a result of the complex interaction of multiple drugs and diseases over time, it is difficult to delineate the true nature of chronic rejection. Unlike acute rejection, chronic rejection is not reversible with any immunosuppressive agents currently available.

Kidney

While advances in immunosuppression have reduced the rates of acute rejection in the first year post-transplant from over 50% to about 10%, chronic allograft nephropathy remains the most common cause of graft loss in the late post-transplantation period (greater than 1 year).[25] The syndrome is characterized in histological terms as interstitial fibrosis and tubular atrophy (IFTA) of

unknown etiology. As many as two-thirds of allografts will be affected 5 years after transplantation.[27] Hypertension, proteinuria, and a progressive decline in kidney function represent the classic clinical triad of chronic allograft nephropathy. Factors that contribute to the development of chronic allograft nephropathy include calcineurin inhibitor nephrotoxicity, polyomavirus infection, hypertension, donor-related factors including ischemia time and undetected kidney disease in the donor kidney, and recurrence of the primary kidney disease in the recipient.

Liver

Approximately 3% to 5% of transplant livers are affected by chronic rejection, which is characterized by an obliterative arteriopathy and the gradual loss of bile ducts, often referred to as the vanishing bile duct syndrome. Initially patients experience an asymptomatic rise in the alkaline phosphatase and γ-glutamyl transpeptidase. As levels of bilirubin increase, patients become jaundiced and may experience itching.

Heart

Cardiac allograft vasculopathy, characterized by accelerated intimal thickening or development of atherosclerotic plaques, is the leading cause of graft failure and death in heart transplant recipients.[28] Endothelial injury, caused by both cell-mediated and humoral responses, is the first step in the process. Vasculopathy is restricted to the transplanted allograft. Routine surveillance with coronary angiography, intravascular ultrasound, or other procedures can aid in the diagnosis of vasculopathy. Evidence of cardiac allograft vasculopathy can be seen in as many as 14% of patients within 1 year of transplantation and up to 50% of patients within 5 years.[28] While chronic rejection of the kidney or liver allograft is generally not amenable to treatment, 3-hydroxy-3-methylglutaryl-coenzyme A (HMGCoA) reductase inhibitors and ACEIs have been used to decrease the incidence of vasculopathy in the heart allograft recepient.[28] Recently, sirolimus and everolimus have been shown to reduce the incidence and slow progression of cardiac allograft vasculopathy.[28] Percutaneous transluminal coronary angioplasty and coronary artery bypass grafting have been used in severe cases of vasculopathy; these procedures, however, are of limited value because of their association with increased mortality compared with the general population.[28]

Lung

Chronic rejection in the lung is known as bronchiolitis obliterans syndrome, a fibroproliferative disease which impacts the small airways. It is characterized by a reduction of FEV1 greater than 20% and occurs in up to 50% of patients in the first 5 years post-transplant. The long term prognosis is poor and survival is limited. Treatments are lacking, but chronic use of the azithromycin has shown some promise.[12,19]

TREATMENT OF REJECTION

Immunosuppression achieved with a variety of agents is the cornerstone to rejection management and the accepted regimens for most solid organs are usually comprised of two or more agents.

Desired Outcomes

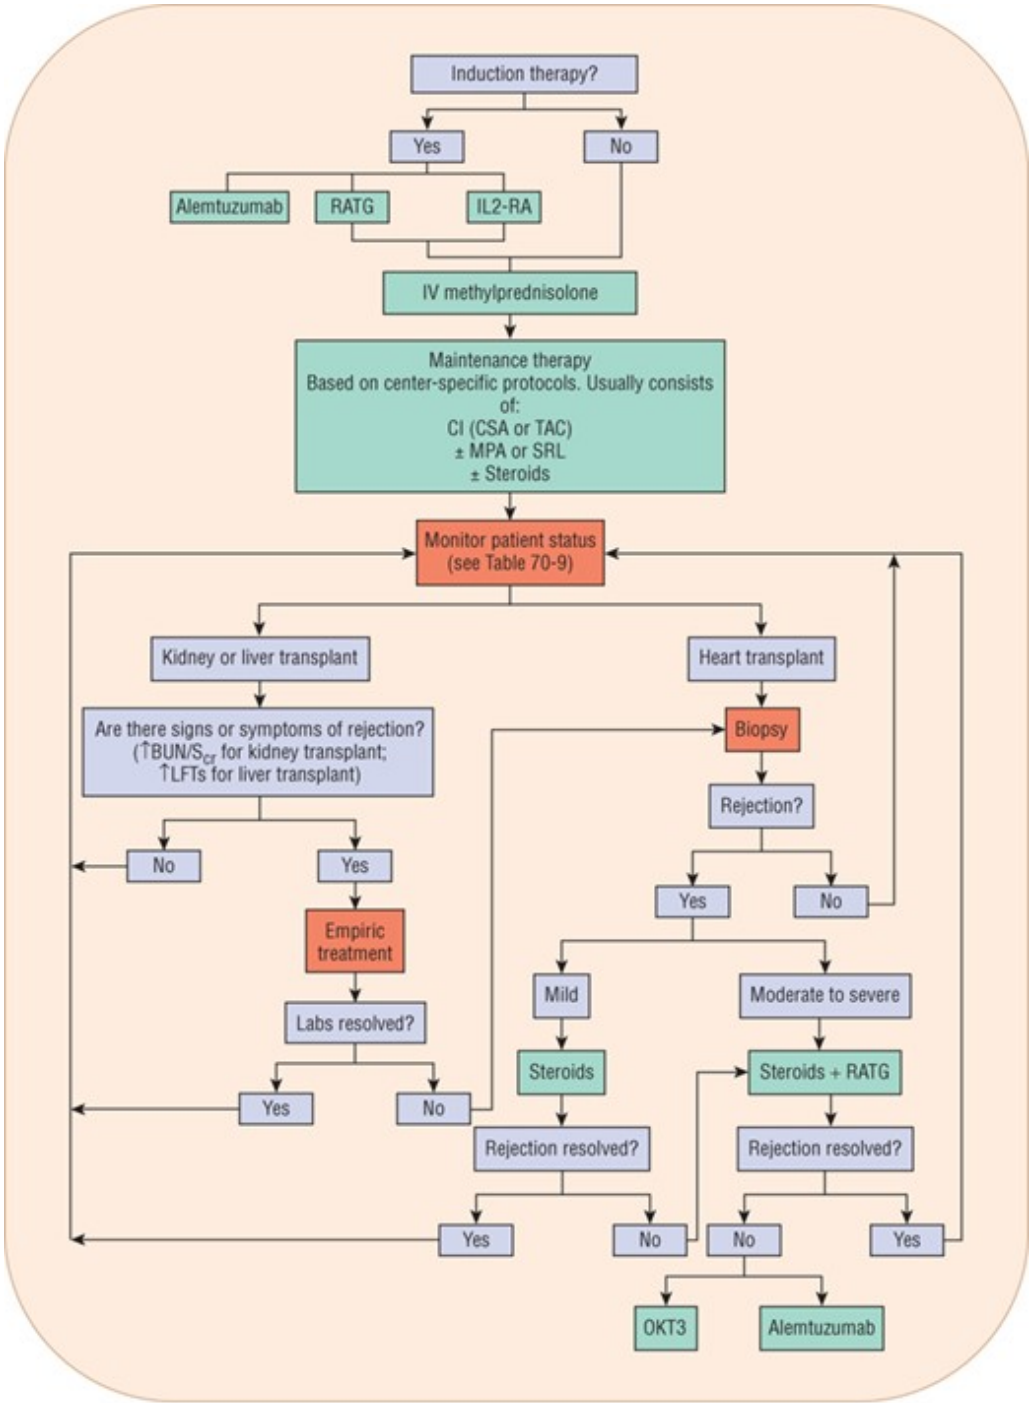
Immediately following surgery, the primary goal of therapy is to prevent hyperacute and acute rejection. The high doses of immunosuppressants required to achieve this goal, if maintained long term, may result in serious complications such as nephrotoxicity, infection, thrombocytopenia, and drug-induced diabetes. Therefore rapid dosage reductions are frequently used to minimize these effects. Transplant immunosuppression must be balanced to optimize both graft and patient survival.

General Approach to Treatment

1 A multidrug approach is rational from an immunomechanistic viewpoint because the many agents have overlapping and potentially synergistic mechanisms of action. Furthermore, the use of a multidrug immunosuppression regimen may allow the use of lower doses of individual agents, thus reducing the severity of dose-related adverse effects (**Fig. 89-2**). The protocols and individual drug regimens tend to be medical center specific.[18,22,29] Although induction therapy may not be uniformly used, in almost every setting, patients receive IV methylprednisolone intraoperatively. Patients may also receive a descending dose of methylprednisolone over the first 5 to 7 postoperative days before beginning oral prednisone. Protocols generally combine a drug from two or three of the following classes: calcineurin inhibitors, antimetabolites or proliferation signal inhibitors, and corticosteroids.

FIGURE 89-2

(BUN, blood urea nitrogen; CI, calcineurin inhibitor; CSA, cyclosporine; IL2RA, interleukin-2 receptor antagonist; LFTs, liver function tests; MPA, mycophenolic acid; OKT3, muromonab CD3; RATG, rabbit antithymocyte immunoglobulin; S_{cr}, serum creatinine; SRL, sirolimus; TAC, tacrolimus.)



If rejection is suspected, a biopsy can be done to ascertain the definitive diagnosis or the patient may be empirically treated for rejection. Empiric treatment generally involves administration of high-dose corticosteroids, usually 500 to 1,000 mg of methylprednisolone intravenously for one to three doses.[12,18,22,29] If signs and symptoms of rejection are resolved with empiric therapy, the maintenance immunosuppressive regimen is generally modified to provide a greater level of overall immunosuppression. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection with polyclonal and monoclonal antibodies being reserved for moderate to severe rejections for those patients that have not responded to a course of corticosteroids.

Induction Therapy

Induction therapy provides a high level of immunosuppression, at the time of transplantation, with or without the immediate introduction of cyclosporine or tacrolimus (see Fig. 89-2). Two perioperative immunosuppressive strategies have been predominantly utilized to achieve this goal: (a) the provision of a highly intense immunosuppression, often on the basis of patient-specific risk factors such as age and race, or (b) the use of antibody therapy to provide enough immunosuppression to delay the initiation of therapy with the potentially nephrotoxic calcineurin inhibitors. The rationale for delayed calcineurin inhibitor administration varies slightly depending on the type of transplant. In renal transplantation, the newly transplanted kidney is very susceptible to nephrotoxic injury, whereas in liver and heart transplantation, the idea is to protect patients with preexisting renal insufficiency from further insults during the perioperative period. Additionally, calcineurin inhibitor dosage adjustment to maintain target concentrations may be difficult in the perioperative period secondary to fluctuations in gastrointestinal (GI) absorption and enteral intake.[22,29,30]

Acute Rejection

The primary goal of acute rejection therapy is to minimize the intensity of the immune response and prevent irreversible injury to the allograft. The available options include (a) increasing the doses of current immunosuppressive drugs, (b) starting "pulse" corticosteroids with subsequent dosage taper, (c) addition of another immunosuppressant indefinitely, or (d) short-term treatment with a polyclonal or monoclonal antibody. The treatment of acute rejection almost always begins with "pulse" corticosteroid therapy for several days (oral or intravenously). However, African American kidney transplant recipients may not respond as well to corticosteroids; thus ATG may be preferable for this patient population.[31]

Cytolytic agents are often reserved for those with corticosteroid-resistant rejection, signs of hemodynamic compromise (heart), or more severe rejections. Other innovative forms of therapy for persistent or intractable rejection have been investigated, including mycophenolate mofetil, tacrolimus, low-dose methotrexate, sirolimus, total lymphoid irradiation, and plasmapheresis and intravenous immunoglobulin. Prophylactic agents such as valganciclovir, nystatin, trimethoprim-sulfamethoxazole, H_2-receptor antagonists or proton-pump inhibitors, and/or antacids may be added to minimize adverse effects associated with these intensive immunosuppression regimens.[32]

Maintenance Therapy

The goal of maintenance immunosuppression is to prevent acute and chronic rejection while minimizing drug-related toxicity. As patients progress through the post-transplant course, the risk of acute rejection decreases, thus allowing the clinician to gradually reduce the doses of immunosuppressants or in some cases totally withdraw them over a period of 6 to 12 months. Transplant organ and type (cadaveric vs living-donor), the degree of HLA mismatch, time after transplantation, post-transplantation complications (including the number of acute rejections), previous immunosuppressive adverse reactions, compliance, and financial considerations are among the patient-specific factors considered in individualizing maintenance immunosuppression.

Calcineurin inhibitors are generally a central component in most maintenance regimens, although calcineurin inhibitor-free immunosuppression remains a future goal because of the significant nephrotoxicity associated with these agents. Ideally, immunosuppression should be optimized to prevent acute rejection episodes, minimize the occurrence of chronic rejection, and prevent long-term toxicities.

Calcineurin Inhibitors

Cyclosporine and tacrolimus are the two calcineurin inhibitors (CIs) currently used for most solid-organ transplant recipients. More than 80% of transplant recipients receive tacrolimus as part of their immunosuppressive regimen.[1]

Pharmacology/Mechanism of Action

Calcineurin inhibitors block T-cell proliferation by inhibiting the production of IL-2 and other cytokines by T cells (see Fig. 89-1). Cyclosporine and tacrolimus bind to unique cytoplasmic immunophilins: cyclophilin and FK-binding protein-12 (FKBP12), respectively. The drug–immunophilin complex inhibits the action of calcineurin, an enzyme that activates the nuclear factor of activated T cells, which is, in turn, responsible for the transcription of several key cytokines necessary for T-cell activity, including IL-2. IL-2 is a potent T-cell growth factor and ultimately is responsible for activation and clonal expansion.

Pharmacokinetics

The calcineurin inhibitors are highly lipophilic compounds, with variable but generally low bioavailability of approximately 30% (range: 5%-60%). Unlike tacrolimus, cyclosporine depends on bile for intestinal absorption, which lends to more interpatient and intrapatient variability. Liver recipients with a T-tube for diversion of bile may thus experience incomplete and erratic absorption of cyclosporine.[30]

Because of the significant variability in absorption of cyclosporine, and its associated pharmacokinetic problems, a microemulsion formulation was developed. Both forms are available commercially in the United States and are referred to as "cyclosporine, USP" and "cyclosporine, USP [MODIFIED]." The two formulations are not bioequivalent and should not be used interchangeably. The microemulsion formulation is self-emulsifying and forms a microemulsion spontaneously with aqueous fluids in the gastrointestinal tract, making it less dependent on bile for absorption. The result is a significantly greater rate and extent of absorption and decreased intraindividual variability in pharmacokinetic parameters. The relative bioavailability of the microemulsion formulation is 60% and peak concentrations are generally reached within 1.5 to 2 hours after oral administration. Tacrolimus, on the other hand, has a more predictable absorption pattern, reaching peak concentrations within 1 to 3 hours but still with a variable bioavailability ranging from 4% to 93% (average 20%).[30]

Following oral absorption, both cyclosporine and tacrolimus are highly protein bound. Ninety percent of cyclosporine is bound to lipoproteins in the blood while 99% of tacrolimus is bound primarily to

albumin and α_1-acid glycoprotein. Cyclosporine is distributed widely into tissue and body fluids, resulting in a large and variable volume of distribution, ranging from 3 to 5 L/kg. Because of the high concentration of FKBP12 that is found in red blood cells, tacrolimus is distributed primarily in the vasculature, with a volume of distribution of 0.8 to 1.9 L/kg. Both drugs are extensively metabolized by the cytochrome P450 3A4 (CYP3A4) in both the gut and the liver, which accounts for both the poor bioavailability and numerous drug interactions which are highlighted in this is the first mention of this table so it should be highlighted in blue. Also it should be changed to be **Table 89-4**.[30,33,34,35]

Efficacy

Both cyclosporine and tacrolimus are currently approved for prophylaxis of organ rejection in kidney, liver, and heart transplantation. The microemulsion formulation of cyclosporine has demonstrated equivalent or superior efficacy in kidney, liver, and heart transplantation recipients. Studies comparing tacrolimus with either formulation of cyclosporine as primary immunosuppression demonstrate equivalent efficacy between the two agents in all transplantation situations.

Adverse Effects

Table 89-5 summarizes the adverse effects of calcineurin inhibitors, cyclosporine and tacrolimus, and other immunosuppressants. The nephrotoxic potential of both drugs is equal and is often related to the dose and duration of exposure. Neurotoxicity typically manifests as tremors, headache, and peripheral neuropathy; occasionally, however, seizures have been observed. Tacrolimus may be associated with an increased occurrence of neurologic complications compared with cyclosporine.

Cyclosporine appears to have a greater propensity to cause or worsen hypertension and hyperlipidemia compared with tacrolimus.[36,37] On the other hand, hyperglycemia is more common with tacrolimus than with cyclosporine but is often reversible when doses of tacrolimus and/or corticosteroids are reduced.[37] Cyclosporine is associated with cosmetic effects, such as hirsutism and gingival hyperplasia, which may be managed by converting from cyclosporine to tacrolimus or by improving hygiene in patients who cannot be switched to tacrolimus. Tacrolimus, in contrast, has been reported to cause alopecia, which is usually self-limiting and reversible.

Calcineurin Inhibitor Nephrotoxicity

3 Two types of nephrotoxicity can occur with calcineurin inhibitors. Acute nephrotoxicity is frequently seen early and is dose dependent and reversible, but chronic nephropathy is more common. Clinical manifestations of calcineurin inhibitor nephrotoxicity include elevated serum creatinine and blood urea nitrogen concentrations, hyperkalemia, hyperuricemia, mild proteinuria, and a decreased fractional excretion of sodium. Calcineurin inhibitor nephrotoxicity is the leading cause of renal dysfunction following nonrenal solid-organ transplant.

The predominant mechanism for calcineurin inhibitor nephrotoxicity is renal vasoconstriction, primarily of the afferent arteriole, resulting in increased renal vascular resistance, decreased renal blood flow by up to 40%, reduced glomerular filtration rate by up to 30%, and increased proximal tubular sodium reabsorption with a reduction in urinary sodium and potassium excretion. A number of other mechanisms have been implicated, including changes in the renin–angiotensin–aldosterone system, prostaglandin synthesis, nitrous oxide production, sympathetic nervous system activation, and calcium handling.[38]

Several approaches have been proposed to reduce calcineurin inhibitor nephrotoxicity including delaying administration immediately postoperatively in patients at high risk for nephrotoxicity (using alternative induction protocols including an IL-2 receptor antagonist or antilymphocyte globulin), monitoring calcineurin inhibitor trough blood concentrations, reducing the calcineurin inhibitor dosage if the vasoconstrictive effects are problematic, and avoiding other nephrotoxins (eg, aminoglycosides, amphotericin B, and nonsteroidal antiinflammatory agents) when possible[15,38] Currently, no proven therapies consistently prevent or reverse the nephrotoxic effects of calcineurin inhibitors.

In patients who have received a kidney transplant, it is often difficult to differentiate calcineurin inhibitor nephrotoxicity from renal allograft rejection. Because the clinical features of acute renal allograft rejection and calcineurin inhibitor nephrotoxicity overlap considerably, a renal biopsy is often necessary to differentiate the two (**Table 89-6**). However, differentiating between chronic renal allograft rejection and calcineurin inhibitor nephrotoxicity may be more difficult because, in addition to clinical signs and symptoms, biopsy findings may also be similar.

TABLE 89-6 Differential Diagnosis of Acute Rejection and Cyclosporine or Tacrolimus Nephrotoxicity

	Nephrotoxicity in Renal Transplant Recipients	
	Acute Rejection	**CSA or TAC Nephrotoxicity**
History	Often <4 weeks postoperatively	Often >6 weeks postoperatively
Clinical presentation	Fever	Afebrile
	Hypertension	Hypertension
	Weight gain	Graft nontender
	Graft swelling/tenderness	Good urine output
	Decreased daily urine volume	

Nephrotoxicity in Renal Transplant Recipients		
	Acute Rejection	**CSA or TAC Nephrotoxicity**
Laboratory biopsy	Rapid rise in serum Cr (0.3 mg/dL/day [27 µmol/L/day])	Gradual rise in serum Cr (>0.15 mg/dL/day [>13 µmol/L/day])
	Normal CSA or TAC concentration	Elevated CSA or TAC concentration
	Interstitial lymphocytic infiltrates	Interstitial fibrosis, tubular atrophy, glomerular thrombosis, arterial inflammation

Cr, creatinine; CSA, cyclosporine; TAC, tacrolimus.

Drug–Drug and Drug–Food Interactions

Drug interactions occur frequently with the calcineurin inhibitors because they are substrates for CYP3A4 and P-glycoprotein.[33,34,35] The most commonly administered drugs that are known to significantly alter cyclosporine and tacrolimus levels are highlighted in Table 89-4. Inhibitors of CYP3A4, such as diltiazem or erythromycin, can increase drug concentrations up to 82%, whereas drugs that induce CYP3A4 activity, such as phenytoin or rifampin, can decrease drug concentrations by 50%.[35] While in vitro data suggest that drugs that increase the pH of the GI tract, such as magnesium-, aluminum-, or calcium-containing antacids, sodium bicarbonate, and magnesium oxide, can cause a pH-mediated degradation of tacrolimus by physically adsorbing tacrolimus in the GI tract, this has not been borne out in clinical studies.[39] Some clinicians suggest separating such compounds from tacrolimus administration by at least 2 hours to avoid any potential interaction.

Cyclosporine, and to a lesser extent, tacrolimus, are inhibitors of CYP3A4 and P-glycoprotein.[30,40] The inhibitory effects of cyclosporine and tacrolimus on CYP3A4 can be seen with weaker substrates, such as the HMG-CoA reductase inhibitors (“statins”). Concomitant administration of a calcineurin inhibitor with an HMG-CoA reductase inhibitor results in an increase in the HMG-CoA reductase inhibitor levels, which increases the risk of HMG-CoA reductase inhibitor adverse effects, most notably myopathy.[41] Patients should be monitored for clinical signs of myopathy when receiving HMG-CoA reductase inhibitors in combination with cyclosporine and tacrolimus. The interaction appears to be more pronounced between cyclosporine and HMG-CoA reductase inhibitors due to inhibition of organic anion-transporter proteins (OATP) by cyclosporine.[42]

Consistency in administration of the calcineurin inhibitors with regard to meals and food intake is important to sustain an effective concentration time profile. High-fat meals can enhance both plasma clearance and the volume of distribution of cyclosporine by more than 60%.[43] Food reduces the rate and extent of tacrolimus absorption, and a high-fat meal may further delay gastric emptying and reduce the maximum achieved serum concentration (C_{max}), and the area under the concentration–time curve (AUC).[30] Furocoumarins, such as quercetin, naringin, and bergamottin, found in grapefruit juice, are potent inhibitors of CYP3A4 and have been reported to increase both cyclosporine and tacrolimus concentrations significantly. The AUC and C_{max} of cyclosporine have been reported to be increased by more than 55% and 35%, respectively. In addition the components

of green tea as well as tumeric and ginger have been noted to increase calcineurin exposure.[30]

Dosing and Administration

Initial oral cyclosporine doses range from 8 to 18 mg/kg per day administered every 12 hours. Higher doses of cyclosporine are used more commonly in two-drug regimens, whereas lower doses are part of triple-drug regimens. Oral tacrolimus doses usually are in the range of 0.1 to 0.3 mg/kg per day given every 12 hours. A recently-approved tacrolimus extended-release tablet (Envarsus®) has greater bioavailability than the immediate release formulation and thus a lower recommended daily starting dose range of (0.11-0.17 mg/kg/day).[44] Children require higher doses to maintain therapeutic drug concentrations, up to 14 to 18 mg/kg per day for cyclosporine and 0.3 mg/kg per day for tacrolimus. The two once-daily formulations of tacrolimus are not interchangeable. Astagraf XL® or Advagraf® (tacrolimus extended-release capsule) is generally converted from standard tacrolimus formulations on a mg:mg basis whereas the more recently developed extended release form of tacrolimus, Envarsus® XR (tacrolimus prolonged release tablets) has greater bioavailability than the immediate release tacrolimus and the recommended conversion factor is 1 mg immediate release to 0.8 mg prolonged release, that is, a 20% reduction in total daily dose.[30,44,45] When patients were converted from immediate release tacrolimus to extended AstagrafXL® on a mg:mg conversion based on total daily dose, about one third of patients required downward dose adjustments to maintain the same 24-trough serum concentrations.[45] If oral administration is not possible, both CSA and TAC can be administered intravenously at approximately one third the oral dosage, since administration by this route avoids first-pass metabolism. The usual intravenous dose of cyclosporine is 2 to 5 mg/kg per day, given as a continuous infusion or as single or twice-daily injection. Intravenous tacrolimus doses range from 0.05 to 0.1 mg/kg per day and must be administered by continuous infusion.

Therapeutic Drug Monitoring

Calcineurin inhibitor trough blood concentrations should be measured routinely to optimize therapy (**Table 89-7**). Radioimmunoassay (RIA) and fluorescence polarization immunoassay are among the methods to measure cyclosporine concentrations. Tacrolimus concentrations are most commonly measured by microparticle enzyme immunoassays or enzyme-linked immunoassays. Both drugs can be measured by high-performance liquid chromatography (HPLC), which is recognized as the reference procedure.[43] Therapeutic target ranges are assay specific because some quantitate parent plus metabolite concentration, while others only measure the parent compound. Thus, the target concentrations will be lower for the specific assays (LC-MS/MS) compared with nonspecific assays (RIA and microparticle enzyme immunoassays) by approximately 20% to 25%. The specific goal level for both drugs is dependent on transplant type, time after transplantation, concomitant immunosuppression, and transplantation center. One review of the role of tacrolimus in renal transplantation suggests that target 12-hour whole blood concentrations for tacrolimus should be 15 to 20 ng/mL (mcg/L; 18.6 to 24.8 nmol/L) 0 to 1 month after transplantation, 10 to 15 ng/mL (mcg/L; 12.4 to 18.6 nmol/L) 1 to 3 months after transplantation, and 5 to 12 ng/mL (mcg/L; 6.2 to 14.9 nmol/L) greater than 3 months after transplantation.[36] Blood drug concentrations should be

measured frequently (daily or three times per week) following initiation of the drug and during the stabilization period after transplantation. With time, blood concentrations can be measured less frequently.

TABLE 89-7 Therapeutic Concentrations of Immunosuppressants

		Concentrations (ng/mL or mcg/L)	
Drug	Sampling medium	HPLC	RIA
Cyclosporine	Whole blood	100-300	375-400
	Plasma	75-100	150-250
Tacrolimus	Whole blood	8-13	5-20
	Plasma		0.2-0.8
Sirolimus (with CIs)	Whole blood	10-15	15-20
Sirolimus (without CIs)	Whole blood	15-25	20-30
Everolimus (with CIs)	Whole blood	3-8	

CIs, calcineurin inhibitors; HPLC, high performance liquid chromatography; RIA, radioimmunoassay. For expression of immunosuppressant drugs in SI units of nmol/L multiply levels in ng/mL(or mcg/L) by 0.832 for cyclosporine, 1.24 for tacrolimus, 1.094 for sirolimus, and 1.044 for everolimus.

Studies have revealed lack of predictive value of trough cyclosporine concentrations and rejection.[46] Alternative strategies, including AUC and peak concentration determination, have been suggested to better correlate with rejection.[43,46] Limited sampling techniques using two to five blood samples within the first 4 hours after an oral dose have been used to determine AUC and it was observed that AUC levels greater than 4,400 ng/mL (mcg/L; greater than 3,361 nmol/L) per hour correlated with a reduction in rejection.[43,46] Cyclosporine peak concentration (C_{peak}) has also been found to correlate with rejection and toxicity. Some transplantation centers have adopted this strategy to manage cyclosporine concentrations because of the convenience and reduced cost associated with the measurement of a single blood concentration. The suggested therapeutic range for C_{peak} cyclosporine levels is 1,500 to 2,000 ng/mL (mcg/L; 1,248-1,664 nmol/L) for the first few months after transplant and 700 to 900 ng/mL (mcg/L; 582-749 nmol/L) after 6 to 12 months.[46]

Corticosteroids

Corticosteroids have been used since the beginning of the modern transplantation era. Despite their many adverse events, they continue to be a cornerstone of immunosuppression regimens in many transplant centers, with 30% and 60% of liver and kidney transplant patients, respectively, receiving corticosteroids for at least the first year after transplantation.[1] The most commonly used corticosteroids are methylprednisolone and prednisone.

Pharmacology/Mechanism of Action

Corticosteroids block cytokine activation by binding to corticosteroid response elements, thereby

inhibiting IL-1, IL-2, IL-3, IL-6, γ-interferon, and tumor necrosis factor-α synthesis (see Fig. 89-1). Additionally, corticosteroids interfere with cell migration, recognition, and cytotoxic effector mechanisms.[47]

Pharmacokinetics

Prednisone is converted to prednisolone, its active moiety, in the liver and has multiple effects on the immune system. Prednisone is rapidly absorbed from the GI tract, achieving peak concentrations in 1 to 3 hours in transplant recipients. Bioavailability is greater than 90%. In kidney transplant recipients the pharmacokinetic half-life is short, 2 to 4 hours, but the pharmacodynamic effects extend beyond the time that concentrations are measurable, permitting daily administration.[47]

Efficacy

Their efficacy is irrefutable based on the decades of clinical experience. Systematic studies comparing corticosteroid-free immunosuppressive agent combinations with conventional therapy are difficult to perform because of the hundreds of potential combinations that now exist. However, recent studies of corticosteroid-free immunosuppressive agent combinations with newer, more specific immunosuppressants suggest that corticosteroids may in the future have less of a role in maintenance immunosuppression.[48]

Adverse Effects

Adverse effects of prednisone that occur in more than 10% of patients include increased appetite, insomnia, indigestion (bitter taste), and mood changes. Side effects that occur less often but which are seen with high doses or prolonged therapy include cataracts, hyperglycemia, hirsutism, bruising, acne, sodium and water retention, hypertension, bone growth suppression, and ulcerative esophagitis. The adverse effects of corticosteroids are summarized in Table 89-5.

Drug–Drug and Drug–Food Interactions

Barbiturates, phenytoin, and rifampin induce hepatic metabolism of prednisolone and thus may decrease the effectiveness of prednisone. Prednisone decreases the effectiveness of vaccines and toxoids.[47]

Dosing and Administration

An intravenous corticosteroid, commonly high-dose methylprednisolone (250-1,000 mg), is given at the time of transplantation. The dose of methylprednisolone is tapered rapidly and usually discontinued within 3 to 5 days when oral prednisone is initiated. Prednisone doses are tapered progressively over several weeks to months, depending on the type of additional immunosuppression and organ function. It is preferable to administer corticosteroids between 7 AM and 8 AM to mimic the body's diurnal release of cortisol. While conversion to alternate-day regimens or complete withdrawal of prednisone in patients with stable post-transplantation courses has been

used with success in some transplantation centers, corticosteroids are often continued for the entire life of the functional graft.[47]

The first-line therapy for the treatment of acute graft rejection is high-dose intravenous methylprednisolone (250-1,000 mg) daily for 3 days or oral prednisone (200 mg) daily for 3 days. Doses of oral prednisone are then tapered over 5 days to 20 mg/day. Prednisone should be taken with food to minimize GI upset. Corticosteroids should never be discontinued abruptly; tapering should be gradual because of suppression of the hypothalamic–pituitary–adrenal axis. Corticosteroids slow the growth rate of children, prompting clinicians to use alternate-day dosing or to withhold corticosteroids until rejection occurs.

Antimetabolites

5 Antimetabolites have been used since the early days of transplantation because they prevent proliferation of lymphocytes. Azathioprine, long considered a part of the "gold standard" regimen with cyclosporine and corticosteroids, has largely been supplanted by mycophenolic acid derivatives which are more specific in their effects on lymphocytes and have fewer side effects.

Mycophenolatic Acid Derivatives

Two formulations of mycophenolic acid (MPA) are currently available in the United States: mycophenolate mofetil, the morpholinoethyl ester of MPA, and mycophenolate sodium, which is available as an enteric-coated formulation of the sodium salt of MPA.

Pharmacology/Mechanism of Action

The immunosuppressive effect of MPA is exerted through noncompetitive binding to inosine monophosphate dehydrogenase (IMPDH), the key enzyme responsible for guanosine nucleotide synthesis via the de novo pathway. Inhibition of IMPDH results in decreased nucleotide synthesis and diminished DNA polymerase activity, ultimately reducing lymphocyte proliferation.[49] Although MPA inhibits both types of IMPDH: IMPDH I, expressed by all cells in the body, and IMPDH II, which is expressed only in T and B lymphocytes, it is more specific for IMPDH II.[49] In addition to this, T and B lymphocytes only use the de novo pathway for nucleotide synthesis (see Fig. 89-1), making MPA very specific for these cells. Other cells within the body have a salvage pathway by which they can synthesize nucleotides, making them less susceptible to the actions of MPA and thereby reducing, but not eliminating, the potential for the hematologic adverse effects seen with azathioprine. In addition to decreasing lymphocyte proliferation, MPA may also downregulate activation of lymphocytes.[50]

Pharmacokinetics

Because MPA is unstable in an acidic environment, mycophenolate mofetil acts as a prodrug that is readily absorbed from the GI tract, after which it is rapidly and completely converted to MPA in the liver. The enteric coating of mycophenolate sodium protects MPA from the acidic gastric pH and

allows MPA to be released directly into the small intestine for absorption. The absolute bioavailability of mycophenolate mofetil and mycophenolate sodium is 94% and 72% of the active moiety, respectively. Peak concentrations of mycophenolate mofetil are reached within 1 to 2 hours following oral administration, while the enteric coating of mycophenolate sodium delays absorption and peak concentrations are not reached until 4 hours after administration.[50]

MPA is extensively bound (97%) to albumin and is eliminated by the kidney and also undergoes glucuronidation in the liver to an inactive glucuronide metabolite (MPAG) that is subsequently excreted in the bile and urine. Enterohepatic cycling of MPAG can lead to deconjugation, thereby recirculating MPA into the bloodstream. This can account for 10% to 60% of total MPA exposure and results in a second peak 6 to 12 hours after oral administration.[50] The half-life of MPA is 18 hours.

Efficacy

Currently, mycophenolate mofetil is approved for use in kidney, liver, and heart transplantation and is recommended as a component of maintenance immunosuppression regimens for most kidney and heart transplant recipients.[18,29] Early studies comparing mycophenolate to azathioprine in patients receiving cyclosporine and corticosteroids demonstrated a statistically significant improvement with MPA in patient and graft survival at 1 and 3 years.[50] Subsequent studies have confirmed the efficacy of mycophenolate combined with tacrolimus. Mycophenolate has also demonstrated efficacy in the treatment of acute rejection.[50]

Mycophenolic acid derivatives are a key component of calcineurin inhibitor–sparing protocols. MPA monotherapy has been associated with an unacceptable rejection rate. Combination of MPA with sirolimus, on the other hand, resulted in improved renal function with no change in acute rejection incidence or and patient and graft survival.[50]

Adverse Effects

Unlike cyclosporine and tacrolimus, MPA is not associated with nephrotoxicity, neurotoxicity, or hypertension. The most common side effects are related to the GI tract, including nausea, vomiting, diarrhea, and abdominal pain (see Table 89-5), which occur with similar frequency during intravenous and oral therapy. Strategies to reduce GI symptoms are not well studied. Changing formulation may or may not improve symptoms and it is clear that dose reduction and discontinuation increase the risk of rejections.[50] Mycophenolic acid also has hematologic effects, such as leukopenia and anemia, particularly with higher doses. Recently, the rare but serious adverse event of progressive multifocal leukoencephalopathy (PML) has been reported, but could not substantiated in further analyses.[50] Because peripheral intravenous mycophenolate administration is associated with local edema and inflammation, central venous administration may be the preferred route.

Drug–Drug and Drug–Food Interactions

Food has no effect on MPA AUC, but it delays the absorption and decreases MPA C_{max} by 40% and 33% when mycophenolate mofetil and mycophenolate sodium, respectively, are administered. Concomitant administration with aluminum- and magnesium-containing antacids or cholestyramine

significantly decreases the AUC of MPA and should be avoided.[50] It has been suggested that administration of iron may produce similar results, but this has not been tested. Concomitant administration of mycophenolate mofetil with pantoprazole has been reported to decrease MPA levels by 57% and AUC by 12% in healthy volunteers. The same effect was not observed with mycophenolate sodium.[51]

Acyclovir, commonly used in renal transplant recipients for the treatment and prevention of viral infections, competes with MPAG for renal tubular secretion. AUCs of both entities are increased during concomitant acyclovir and MPA administration. No pharmacokinetic interaction with other antiviral agents has been demonstrated, but, there is potential for additive pharmacodynamic effects such as bone marrow suppression.

Decreased MPA trough concentrations have been reported when MPA is administered with cyclosporine compared with those achieved when MPA is given with tacrolimus or sirolimus.[50] This interaction is most likely a result of cyclosporine inhibition of multidrug-resistance-associated protein 2 (MRP2), which inhibits the enterohepatic recycling of MPAG, resulting in decreased MPA concentrations.[50] Cyclosporine decreases MPA levels by approximately 40% to 50% compared to tacrolimus.[34] To achieve equivalent MPA and MPAG serum concentrations, it may be necessary to administer higher doses of MPA with cyclosporine compared to tacrolimus. Antibiotics may also interfere with enterohepatic recycling of MPAG by decreasing bacterial-mediated deglucuronidation in the colon.[50]

Dosing and Administration

Mycophenolate mofetil is currently available in both oral and intravenous formulations. Although intravenous administration of equal doses closely mimics oral administration, the two cannot be considered bioequivalent. Mycophenolate sodium is only available as an oral formulation. To optimize immunosuppression and minimize adverse effects, MPA is administered in two divided doses given every 12 hours. The total daily dose for kidney and liver transplants is typically 2 g/day for mycophenolate mofetil and1.44 g/day for mycophenolate sodium. Higher doses may be required in heart transplant recipients if targeting a trough concentration of greater than 1.5 mcg/mL (mg/L; greater than 4.7 µmol/L) in select patients.[18] The recommended pediatric dose is 600 mg/m^2 for mycophenolate mofetil and 400 mg/m^2 for mycophenolate sodium, in two divided doses.

While an increasing body of literature suggests that therapeutic drug monitoring of MPA is of value it remains controversial.[51,52,53] Plasma appears to be the most appropriate medium in which to measure MPA for therapeutic drug monitoring. Numerous studies have demonstrated a relationship between plasma MPA concentrations and improved clinical outcomes in patients receiving concomitant CIs and corticosteroids. Patients with trough MPA levels between 1.0 and 3.5 mcg/mL (mg/L; 3.1-10.9 µmol/L) experienced fewer significant complications. Unbound concentrations as opposed to total MPA concentrations have been suggested as the most relevant to measure, especially in patients with liver disease, hypoalbuminemia, and severe infection.[50] Trough concentrations may not be accurate in predicting total drug exposure during a 12-hour interval and thus AUC monitoring has been proposed as the most appropriate measure of MPA drug exposure to

guide therapy.[50] Better outcomes are associated with MPA AUC concentrations of greater than 42.8 mcg/mL (mg/L; 134 µmol/L) per hour (by HPLC),[52] although a reference range of 30 to 60 mcg/mL (mg/L; 94 to 188 µmol/L) has been proposed. The correlation between MPA AUC levels and adverse effects is low. Further studies are required to determine the best means to evaluate MPA concentrations, the acceptable targets for each, and the appropriate strategy to monitor MPA concentrations.[52]

Clinical Controversy...

Therapeutic drug monitoring of mycophenolic acid is controversial. Its ability to diminish adverse effects or predict long-term survival remains unknown.

Azathioprine

Azathioprine, a prodrug for 6-mercaptopurine (6-MP), has been used as an immunosuppressant in combination with corticosteroids since the earliest days of the modern transplantation era. Its use has dramatically declined with the availability of newer immunosuppressants, but it remains an option for patients intolerant of other medications.[18,29]

Pharmacology/Mechanism of Action

Azathioprine is an inactive compound that is converted rapidly to 6-MP in the blood and is subsequently metabolized by three different enzymes. Xanthine oxidase, found in the liver and GI tract, converts 6-MP to the inactive final end product, 6-thiouric acid. Thiopurine *S*-methyltransferase (TPMT), found in hematopoietic tissues and red blood cells, methylates 6-MP to an inactive metabolite, 6-methylmercaptopurine. Finally, hypoxanthine-guanine phosphoribosyltransferase is the first step responsible for converting 6-MP to 6-thioguanine nucleotides (6-TGNs), the active metabolites, which are incorporated into nucleic acids, ultimately disrupting both the salvage and de novo pathways of DNA, RNA, and protein synthesis. This process is toxic to the cell and renders the cell unable to proliferate (see Fig. 89-1). Eventually, 6-TGNs are catabolized by xanthine oxidase and thiopurine *S*-methyltransferase to inactive products.[53]

Pharmacokinetics

Oral bioavailability of azathioprine is approximately 40%. Metabolism of 6-MP is primarily by xanthine oxidase to inactive metabolites, which are excreted by the kidneys. The half-life of azathioprine, the parent compound, is very short, approximately 12 minutes. The half-life of 6-MP is longer, ranging from 0.7 to 3 hours. However, it is the activity of the 6-TGNs that determines the pharmacodynamic half-life of the drug which has been estimated to be 9 days.[54]

Adverse Effects

Dose-limiting adverse effects of azathioprine are often hematologic (see Table 89-5). Leukopenia, anemia, and thrombocytopenia can occur within the first few weeks of therapy and can be managed by dose reduction or discontinuation of azathioprine. Other common adverse effects include nausea

and vomiting, which can be minimized by taking azathioprine with food. Alopecia, hepatotoxicity, and pancreatitis are less common adverse effects of azathioprine and are reversible on dose reduction or discontinuation. Activity of TPMT can affect the occurrence of adverse effects with azathioprine. Approximately 10% of the population has intermediate TPMT activity and 0.3% has low activity of the enzyme. In both scenarios, the incidence of leukopenia and hepatotoxicity is increased. As a result, TPMT genotyping may be useful to guide dosing of azathioprine to minimize adverse effects.[53]

Drug–Drug and Drug–Food Interactions

The xanthine oxidase inhibitors allopurinol and febuxostat can increase azathioprine and 6-MP concentrations by as much as fourfold.[54] The metabolic pathways shift to favor production of 6-TGNs, which ultimately results in increased bone marrow suppression and pancytopenia. Doses of azathioprine should be reduced by 50% to 75% when allopurinol is added to a patient's drug regimen.

Dosing and Administration

Usual initial doses of azathioprine range from 3 to 5 mg/kg per day intravenously or orally. Individualization to maintain the white blood cell count between 3,500 and 6,000 cells/mm^3 (3.5 and 6.0 × 10^9/L) may be accomplished in some patients with doses as low as 0.25 mg/kg per day. Patients are often instructed to take azathioprine in the evening when initiating or titrating therapy to allow for dose adjustments based on morning determinations of their white blood cell count.

Proliferation Signal Inhibitors

6 Two proliferation signal inhibitors (PSI) have been approved in the United States for use in transplantation. Sirolimus, also known as rapamycin, is an immunosuppressive macrolide antibiotic that is structurally similar to tacrolimus, and is effective in reducing the risk of acute rejection. Everolimus, a synthetic derivative of sirolimus, was developed to improve upon the pharmacokinetics of sirolimus. Everolimus was approved in the United States in 2009 and has a significantly shorter half-life than sirolimus.

Pharmacology/Mechanism of Action

Sirolimus and everolimus both bind to FKBP12, forming a complex that binds to the mammalian target of rapamycin (mTOR), which inhibits the body's response to cytokines (see Fig. 89-1). As such, the drugs are commonly referred to as mTOR inhibitors. IL-2 stimulates mTOR to activate kinases that ultimately advance the cell cycle from G1 to the S phase. Thus these drugs reduce T-cell proliferation by inhibiting the cellular response to IL-2 and progression of the cell cycle.[55,56]

Pharmacokinetics

Bioavailability after oral administration is low for both, only 14% to 20%, with peak concentrations being reached within 1 to 2 hours.[55,56] Both have large volumes of distribution, 5.6 to 16.7 L/kg for

sirolimus and approximately 110 L (about 1.5 L/kg for a 70 kg individual) for everolimus. Both are metabolized primarily by CYP3A4 in the gut and the liver. Likewise, both are also substrates for P-glycoprotein. The half-life for sirolimus is reported to be 60 hours but can be as long as 110 hours in patients with liver dysfunction, while that of everolimus is much shorter, 18 to 35 hours.[55,56]

Efficacy

Sirolimus is only approved for the prevention of rejection in kidney transplant recipients when given in combination with corticosteroids and cyclosporine or after withdrawal of cyclosporine in patients with low to moderate immunologic risk. Because of the risks of delayed wound healing sirolimus is usually not started until 3 months after transplantation or once the surgical wound has healed. Sirolimus has also been demonstrated to be effective in combination with tacrolimus or mycophenolate in kidney transplants, with patient survival rates greater than 99% and graft survival rates greater than 96%.[47] Combination therapy with sirolimus and mycophenolate can be used to avoid the use of calcineurin inhibitors and decrease the risk of nephrotoxicity. Everolimus is approved for use in both kidney and liver transplantation. In kidney transplant recipients it was studied in combination with basiliximab, cyclosporine, and corticosteroids, whereas in liver transplant recipients it was initiated at least 30 days after transplantation in combination with reduced-dose tacrolimus and corticosteroids. Everolimus has also been used with tacrolimus with similar results as sirolimus.[57] Everolimus appears to have less of an effect on wound healing and thus may potentially be used earlier after transplantation.

Early cyclosporine withdrawal has been studied in patients receiving sirolimus-based immunosuppressive protocols. Ideal candidates are patients who have not had a recent or severe rejection episode and have adequate renal function 3 months after transplant. Rejection occurred in 5.6% of patients after discontinuation of cyclosporine and no difference in graft survival was noted. Long-term follow-up (2 years) showed improved renal function and blood pressure without an increase in acute rejection or graft loss in patients who discontinued cyclosporine.[47] Similar results have been demonstrated with everolimus.[57]

PSIs have demonstrated efficacy to reduce CI use and nephrotoxicity in liver,[58] heart,[55] and lung transplant patients.[56] PSIs are also being investigated in liver transplant patients as a means to reduce the recurrence of hepatitis C and hepatocellular carcinoma.[58] They may also reduce the incidence of chronic rejection and prolong long-term patient survival after heart transplantation.[28]

Clinical Controversy…

The benefits of PSIs after liver and lung transplant include decreased CI-induced nephrotoxicity, anti-cancer properties, and anti-CMV and anti-HCV activity. Early introduction in these patients has demonstrated increased hepatic artery thrombosis and bronchial anastamotic dehiscence. The optimal timing of initiation of PSIs in these populations is controversial to minimize potential benefits while minimizing serious complications.

Adverse Effects

Both everolimus and sirolimus are associated with dose-related myelosuppression. Thrombocytopenia is usually seen within the first 2 weeks of sirolimus therapy but generally improves with continued treatment; leukopenia and anemia are also typically transient.[55,56] Sirolimus trough serum concentrations greater than 15 ng/mL (mcg/L; 16 nmol/L) have been correlated with thrombocytopenia and leukopenia.[55] Hypercholesterolemia and hypertriglyceridemia are also common in patients receiving everolimus or sirolimus. It is postulated that the mechanism of this adverse effect is related to an overproduction of lipoproteins or inhibition of lipoprotein lipase. Peak cholesterol and triglyceride levels are often seen within 3 months of sirolimus initiation but usually decrease after 1 year of therapy and can be managed by reducing the dose, discontinuing sirolimus, or initiating therapy with an HMG-CoA reductase inhibitor or fibric acid derivative. One study suggested that the dyslipidemia associated with sirolimus is not a major risk factor for early cardiovascular complications following kidney transplantation.[55] Delayed wound healing and dehiscence could be a result of inhibition of smooth muscle proliferation and intimal thickening.[55] Mouth ulcers are reported in as many as 60% of patients treated with sirolimus and appear to be dose-related.[55] Reversible interstitial pneumonitis has been described in kidney, liver, and heart–lung transplantation recipients.[47] Other adverse effects reported with sirolimus include increased liver enzymes, hypertension, rash, acne, diarrhea, and arthralgia (see Table 89-4).

Drug–Drug and Drug–Food Interactions

The major metabolic pathway for everolimus and sirolimus is CYP3A4; thus, the drug interactions mediated by induction or inhibition of the CYP3A4 enzyme system are similar to those seen with cyclosporine and tacrolimus (see Table 89-4). Administration of the microemulsion formulation of cyclosporine with sirolimus significantly increases the AUC and trough sirolimus serum concentrations: this has not been observed with the standard formulation of cyclosporine. Conversely, cyclosporine concentrations and AUC are increased when it is given concomitantly with sirolimus. The mechanism is proposed to be competitive binding to CYP3A4 and P-glycoprotein.[55,56] It is recommended that patients separate the dose of sirolimus and cyclosporine by 4 hours to minimize the interaction.[55] Concomitant administration of tacrolimus does not affect sirolimus levels.[55] Although everolimus AUC was increased by the administration of a single dose of the microemulsion cyclosporine formulation, no specific recommendations for dose timing are given. It should be expected, however, that any changes in CSA dose may also necessitate a modification of everolimus dose and increased attention to therapeutic drug monitoring.[56]

As with cyclosporine and tacrolimus, grapefruit juice increases sirolimus levels. Administration of sirolimus with a high-fat meal is associated with a delayed rate of absorption, decreased C_{max}, and increased AUC, indicating an increased drug exposure, whereas the half-life remains unchanged.[55] Conversely, administration of everolimus with a high-fat meal was associated with decreases in both C_{max} and AUC.[56]

Dosing and Administration

The fixed sirolimus dosing regimen, approved for concomitant use with cyclosporine includes a

loading dose of 6 to 15 mg followed by 2 or 5 mg daily, respectively. Therapeutic monitoring of sirolimus is advocated using whole-blood concentrations measured by HPLC, which is specific for the parent compound (see Table 89-7). For everolimus a starting dose of0.75 mg twice daily is indicated in regimens that contain cyclosporine, corticosteroids, and basiliximab. Target serum concentrations are 3 to 8 ng/mL (mcg/L; 3-8 nmol/L).

Co-Stimulatory Signal Inhibitor

Belatacept, derived from abatacept, is the only drug currently approved in this class of immunosuppressive agents. Belatacept may ultimately replace calcineurin inhibitors in the majority of immunosuppressive regimens, since its use has not been associated with toxicities seen with CIs, namely nephrotoxicity.[59] As of the fall of 2016, belatacept is only approved for kidney transplantation.

Pharmacology/Mechanism of Action

Belatacept is a selective costimulation blocker that binds costimulatory ligands (CD80 and CD86) on antigen presenting cells, preventing interaction with CD28 on T cells. The interaction of CD80 and CD86 with CD28 is required for the initiation of "signal 2," the co-stimulatory signal that produces calcineurin, protein kinases, and nuclear factor-κ β that lead to activation and proliferation of T-cells. Thus, blockade of CD80 and CD86 prevents T-cell activation.[60]

Pharmacokinetics

Belatacept which is only available as an intravenous formulation has a volume of distribution of 0.11 L/kg, half-life of approximately 11 days and is not effected by reduced kidney or liver function.[59]

Efficacy

A phase III clinical trial comparing belatacept to cyclosporine in first time kidney transplant patients demonstrated similar efficacy in terms of both patient and graft survival. In the trial, the cyclosporine group experienced more chronic allograft nephropathy at month 12. However, the belatacept group experienced more frequent and more severe ACR. Despite this, the measured GFR was 13 to 15mL/min (0.22-0.25 mL/s) higher in the belatacept group compared to the cyclosporine group, a trend that persisted for 7 years.[59]

Additionally, belatacept-treated patients had better blood pressure control and lower lipid levels as well as less diabetes than CI-treated patients. Whether this translates long term to less cardiovascular mortality remains to be demonstrated.[60]

Studies have also evaluated conversion from CI-based regimens to belatacept in kidney transplant recipients with stable kidney function. The results show improved GFR from baseline in those converted to belatacept compared to patients who remained on CIs. However, the difference was not statistically significant as the study was not adequately powered.[61] Acute rejection occurred more

frequently in patients who switched to belatacept, compared with no acute rejection in the patients who remained on CIs.[59]

Early studies with belatacept in liver transplant patients were associated with increased graft loss and death which lead to the subsequent termination of ongoing studies.[62] There is limited postmarketing experience with belatacept in liver transplant recipients with poor kidney function as a bridge to future calcineurin therapy.[63]

Adverse Effects

The most common adverse effects of belatacept include anemia, neutropenia, diarrhea, urinary tract infections, headache, and peripheral edema.[59] In the clinical trials, patients who were Epstein Barr virus (EBV) naïve experienced a significantly higher incidence of post-transplant lymphoproliferative disease (PTLD). Most of the cases of PTLD occurred within the first 18 months of treatment and the majority occurred in the central nervous system. There was no increase in incidence of PTLD in patients who were EBV-seropositive. As a result, belatacept carries a black box warning for PTLD and is contraindicated in patients who are EBV-seronegative. Progressive multifocal leukoencephalopathy (PML) was also reported with belatacept.[59]

Drug-Drug and Drug-Food Interactions

No drug or food interactions have been reported with belatacept.

Dosing and Administration

Patients for whom belatacept is being considered must be screened for EBV-serostatus prior to initiation of therapy. Only patients who are EBV-seropositive should receive belatacept due to the increased risk of PTLD in EBV-seronegative patients. The risk evaluation and mitigation strategy (REMS) for belatacept involves screening for symptoms of PTLD and PML with counseling and education. As a primary immunosuppressant for first time kidney transplants, belatacept is administered as 10 mg/kg intravenously over 30 minutes on days 0, 4, 14, 28, and at the end of weeks 8 and 12. Thereafter, the dose is reduced to the maintenance dose of 5 mg/kg administered IV over 30 minutes every 4 weeks beginning at week 16.

When converting to belatacept from a CI-based regimen, the proposed dosing schedule is 5 mg/kg IV administered every 2 weeks for 5 doses on days 0, 14, 28, 42, and 56, then every 4 weeks thereafter. The CI dose should be decreased by 50% after the second dose of belatacept and then discontinued after the fourth dose.[59]

Antibody Agents

7 Both polyclonal and monoclonal antibody preparations are used in transplantation. These agents can be differentiated by their level of specificity, that is, particular receptor(s) they effect, or their downstream effects.

Antithymocyte Globulin

Two ATG formulations are available in the United States: ATG (Atgam, Pfizer, New York, NY), an equine polyclonal antibody, and RATG (Thymoglobulin, Genzyme, Cambridge, MA), a rabbit polyclonal antibody. The rabbit preparation is less immunogenic and may have other advantages over the equine preparation. Both ATG and RATG are often used as induction therapy to prevent acute rejection. In 2012, over 60% of kidney transplant recipients received RATG induction whereas fewer than 20% of liver transplant recipients did.[1]

Pharmacology/Mechanism of Action Because of their polyclonal antibody nature, both ATG and RATG exert their immunosuppressive effect by binding to a wide array of lymphocyte receptors such as CD2, CD3, CD4, CD8, CD25, and CD45. Binding of ATG or RATG to the various receptors results in complement-mediated lysis and subsequent lymphocyte depletion. While T cells are the major lymphocytic target for the compounds, other blood cell components such as B cells and other leukocytes are also affected (see Fig. 89-1). Damaged T cells are subsequently removed by the spleen, liver, and lungs.

Pharmacokinetics ATG is poorly distributed into lymphoid tissue and binds primarily to circulating lymphocytes, granulocytes, and platelets. The terminal half-life of ATG is 5.7 days. RATG has a volume of distribution of 0.12 L/kg, and its terminal half-life in renal transplant recipients is significantly longer than ATG at 30 days.[32] Peak plasma concentrations are reached after 5 to 7 days of ATG or RATG infusions. Antiequine antibodies have been noted in up to 78% of patients who are receiving ATG therapy. Similarly, antirabbit antibodies have been reported in up to 68% of patients who are receiving RATG therapy. The effects of preformed antibodies on the efficacy and safety of these preparations have not been well studied.

Efficacy ATG and RATG are used most commonly for the treatment of acute allograft rejection or as induction therapy to prevent acute rejection. ATG is currently approved for both indications in kidney transplants. RATG is approved only for the treatment of acute allograft rejection in kidney transplantations. Both drugs have been studied extensively for both indications.[26,32]

Use of RATG as part of quadruple therapy in liver transplantation is associated with similar rates of patient and graft survival and acute rejection compared with dual therapy. In kidney transplant RATG was associated with improved graft survival at 5 years as compared with equine ATG. Quadruple-drug therapy results in similar rates of patient and graft survival and malignancy in heart transplantations, but a significantly lower rate of acute rejection and infection episodes is seen at 1 year compared with triple-drug therapy. Cytomegalovirus (CMV) is an adverse effect of this strategy, but recent data indicate that routine prophylaxis is successful in preventing its development.[56]

Adverse Effects Most adverse effects reported with ATG and RATG are related to the lack of specificity for T cells. Dose-limiting myelosuppression (leukopenia, anemia, and thrombocytopenia) occurs frequently. Other adverse effects include anaphylaxis, hypotension, hypertension, tachycardia, dyspnea, urticaria, and rash. Serum sickness is seen more frequently with ATG than with RATG.

Nephrotoxicity has been reported but is rare in the absence of serum sickness. Infusion-related febrile reactions are common with the first few doses and can be managed by premedicating the patient with acetaminophen, diphenhydramine, and corticosteroids. Finally, as with any immunosuppressive agent, ATG and RATG are associated with an increased risk of infections, particularly viral infections, and malignancy.

Drug–Drug and Drug–Food Interactions No drug or food interactions have been reported with ATG or RATG.

Dosing and Administration ATG doses range from 10 to 30 mg/kg per day as a single dose for 7 to 14 days. RATG is a more potent compound and is administered at doses of 1 to 1.5 mg/kg per day as a single daily dose for 7 to 14 days for acute rejection or for 5 to 10 days for induction of immunosuppression. It is recommended that both ATG and RATG be administered through a central line or through a high-flow vein with an in-line 0.22-micron filter over at least 4 hours to minimize phlebitis and thrombosis.[32] Heparin and hydrocortisone are commonly added to the infusion to minimize phlebitis and thrombosis.[32]

Alemtuzumab

Alemtuzumab is approved for use in B-cell chronic lymphocytic leukemia.[64] However, its effects on depleting both T and B lymphocytes make it useful in solid-organ transplants. While alemtuzumab is not FDA approved for solid organ transplantation, it is increasingly recognized as a viable therapeutic option for induction or treatment of acute rejection. In 2012, commercial distribution of alemtuzumab ceased for transplantation and leukemia, requiring centers to enroll in the manufacturer's distribution program for these indications.[65]

Pharmacology/Mechanism of Action Alemtuzumab is a humanized monoclonal antibody against the CD52 surface antigen found on both T and B lymphocytes, as well as macrophages, monocytes, eosinophils, and natural killer cells. When alemtuzumab binds to the CD52 surface antigen, antibody-dependent lysis occurs, which removes both T and B lymphocytes from the blood, bone marrow, and organs, resulting in complete lymphocyte depletion.[64]

Pharmacokinetics The pharmacokinetics of alemtuzumab in solid-organ transplantation patients have not been investigated. Data from patients with B-cell chronic lymphocytic leukemia indicate that the volume of distribution of alemtuzumab after repeated dosing is 0.18 L/kg. The mean half-life after the first 30 mg dose was 11 hours, but increased to 6 days after 12 weeks of therapy. The extrapolation of these data to solid-organ transplantation is difficult because of the differences in dosing strategies (single or multiple 30-mg doses in solid-organ transplantation vs weekly to thrice weekly dosing in B-cell chronic lymphocytic leukemia). One or two doses of alemtuzumab result in complete and prolonged lymphocyte depletion. Following administration, B lymphocyte counts return to normal within 3 to 12 months. T lymphocytes, however, remain depressed for as long as 3 years following administration.[34,64]

Efficacy Alemtuzumab is effective as induction therapy for the prevention of acute rejection in kidney, liver, pancreas, intestinal, and lung transplants.[56] Additionally, alemtuzumab has been used to

successfully treat acute rejection following transplantation and is effective for corticosteroid- and antibody-resistant rejection.[26]

Adverse Effects Adverse effects of alemtuzumab are primarily infusion related, hematologic, and infectious. Because alemtuzumab causes complete lymphocyte depletion and associated cytokine release, infusion-related reactions include rigors, hypotension, fever, shortness of breath, bronchospasms, and chills. The potential for developing these reactions can be reduced by administering premedications such as acetaminophen, corticosteroids and diphenhydramine or by administering smaller doses and escalating the dose gradually. Hematologic effects include pancytopenia, neutropenia, thrombocytopenia, and lymphopenia.

Drug–Drug and Drug–Food Interactions No drug or food interactions have been reported with alemtuzumab.

Dosing and Administration Several dosing regimens have been proposed for alemtuzumab in solid-organ transplantation. The most common dosing strategy is 30 mg as a single dose; some centers administer a second dose 1 to 5 days after transplantation.[64] Other studied dosing strategies include 0.3 mg/kg per dose, as a single- or multiple-dose regimen, and, finally, two 20-mg doses given on the day of transplantation and the first postoperative day.[64]

Nondepleting Antibodies

Interleukin-2 Receptor Antagonists

Basiliximab, a chimeric monoclonal antibody (25% murine) is the only available IL-2 receptor antagonist currently marketed in the United States. It is approved for use in kidney transplantation, but is also extensively used in other organ transplants as well.[66]

Pharmacology/Mechanism of Action Basiliximab exerts its immunosuppressive effect by specifically binding with high affinity to the α-chain (CD25) on the surface of activated T lymphocytes (see Fig. 89-1). Binding of basiliximab to the IL-2 receptor prevents IL-2-mediated activation and proliferation of T cells, a critical step in clonal expansion of T cells and the development of allograft rejection. Saturation of the IL-2 receptor occurs rapidly and confers an immunosuppressive effect that lasts for 4 to 6 weeks after administration.[66]

Pharmacokinetics Most of the pharmacokinetic data available for basiliximab was derived following administration to renal transplantation patients. Caution must be used when extrapolating these data to nonrenal transplantation recipients. The volume of distribution is approximately 8 L and it has a half-life of approximately 7 days. Clearance is increased in patients who have received a liver transplant, and therefore it is recommended that patients with greater than 10 L of ascites receive an additional dose of basiliximab on postoperative day 8.[67]

Efficacy Basiliximab is approved for use in kidney transplantation in combination with cyclosporine and corticosteroids, although induction therapy has also been studied extensively in liver and heart transplantation recipients. In 2012, over 20% of kidney, liver and heart transplant recipients received

an IL-2 receptor antagonist at the time of transplant.[1] Use of basiliximab in liver transplant recipients has been increasing as a means of delaying CI initiation in the setting of acute kidney injury. A meta-analysis of basiliximab efficacy in renal transplantation concluded that IL-2 receptor antagonists reduced the risk of rejection significantly with no increases in graft loss, infectious complications, malignancy, or death.[66] Similar results were seen in liver and heart transplantation patients.[67]

IL-2 receptor antagonists offer a reasonable addition to calcineurin inhibitor—or corticosteroid-sparing protocols. While CI therapy cannot be completely avoided in most cases, IL-2 receptor antagonists allow for delayed use or reduced doses of CIs, thus minimizing the risk of nephrotoxicity in the early post-transplantation period. Similar rates of rejection and corticosteroid-resistant rejection were seen in patients with DGF who received an IL-2 receptor antagonist in conjunction with lower tacrolimus doses compared with patients without DGF who received standard tacrolimus doses and no IL-2 receptor inhibitor induction.[67]

Adverse Effects

Few adverse effects have been reported with basiliximab. In contrast to lymphocyte-depleting agents, basiliximab has not been associated with infusion-related reactions. However, since the marketing of basiliximab, an increased number of hypersensitivity reactions have been reported. Of note, only one patient developed anti-idiotypic antibodies to the murine portion during clinical trials.[67] No increased risk of malignancy has been reported.

Drug–Drug and Drug–Food Interactions Reports of increased cyclosporine and tacrolimus levels in patients receiving concomitant basiliximab were recently published.[66]

Dosing and Administration Basiliximab is usually administered as two 20-mg intravenous doses, intraoperatively and again on postoperative day 4. Basiliximab is compatible with both 0.9% sodium chloride and 5% dextrose and can be administered either centrally or peripherally over 20 to 30 minutes in a volume of 50 mL. This regimen results in saturation of the IL-2 receptor for 30 to 45 days.

Investigational Agents

Rituximab

Rituximab is a chimeric monoclonal antibody against the CD20 receptor found on B cells. While it is FDA approved for non-Hodgkin lymphoma and rheumatoid arthritis, it has also been used for the treatment of antibody mediated rejection and post-transplant lymphoproliferative disorder as well as suppression of alloantibodies prior to transplantation.[68] Rituximab has been shown to improve graft survival when given in combination with plasmapheresis and IVIG in patients with AMR.[26] In highly sensitized patients, rituximab administration prior to transplantation has been shown to suppress alloantibodies and even allow transplantation across ABO-incompatibility.[68] In PTLD, rituximab is most effective in patients with CD20 positive malignancies.[68] The optimal dose of rituximab in transplantation has not been defined.

Bortezomib

Bortezomib, a proteosomal inhibitor that is FDA approved for the treatment of multiple myeloma, has been used in the treatment of AMR. In one series, 20 patients with AMR received 4 doses of bortezomib 1.3 mg/m^2 on days 1, 4, 7, and 11 with plasmapheresis. Bortezomib was effective in lowering donor specific antibodies by 50%.[26] Another series showed benefit of bortezomib over rituximab.[26] However, bortezomib is associated with a high incidence of side effects (up to 33% required hospitalization)that primarily effect the GI tract; diarrhea that leads to dehydration, nausea, edema, vomiting, and infections.[26]

Janus Kinase Inhibitors

Janus kinases are important for transduction of intracellular signals in lymphocytes to stimulate proliferation and lymphocyte activity. Tofacitinib is a Janus Kinase 3 (JAK3) inhibitor that has been compared to cyclosporine in combination with mycophenolate mofetil and steroids. Tofacitinib showed similar efficacy to cyclosporine, but was associated with an increased incidence of cytomegalovirus and BK virus infections.[69] Clinical trials continue to evaluate long-term efficacy and safety of JAK3 inhibitors.

EVALUATION OF THERAPEUTIC OUTCOMES

8 The success of transplantation can be measured in terms of length of graft and patient survival as well as improvements in quality of life. Several donor and recipient factors that have an impact on graft and patient survival have been identified (**Table 89-8**). The greatest risk to short-term graft survival is acute rejection. Routine surveillance of appropriate biochemical markers and serum drug concentrations are essential to minimize the potential for acute rejection. These parameters should be assessed daily to weekly for the first 1 to 3 months after transplantation. Monitoring should include complete blood counts, serum electrolyte concentrations, serum creatinine and blood urea nitrogen concentrations, and the appropriate serum drug concentrations. Liver function tests should also be evaluated using the same schedule in liver transplantation recipients. Routine biopsies are necessary to monitor for acute rejection in heart transplantation recipients. As the time after transplantation increases, the frequency of monitoring decreases. Once 3 months have elapsed after transplantation, monitoring of these parameters can be reduced to biweekly or monthly for most patients. **Table 89-9** depicts a typical post-transplantation laboratory monitoring plan.

TABLE 89-8 Factors Negatively Effecting Allograft and Patient Survival

	Kidney	Liver	Heart
Donor factors	Decreased HLA matching	Size mismatch	Size mismatch
		Age (youngest, oldest)	Increased age
	Increased age		Prolonged ischemia time
	Increased serum creatinine		
	Cardiac instability		

	Kidney	Liver	Heart
	Prolonged ischemia time		
	History of hypertension		
Recipient factors	Age <15, >50 years	Increased age	Age <5, >60 years
	Retransplantation	Retransplantation	ICU pretransplant
	African race	African race	Mechanical ventilation
	Elevated PRA	ICU pretransplant	
	Multiparous women	ABO blood type	LVAD
	Poor drug compliance	Poor drug compliance	IABP
			Poor drug compliance

HLA, human leukocyte antigens; IABP, intraaortic balloon pump; LVAD, left ventricular assist device; PRA, panel of reactive antibodies.

TABLE 89-9 Laboratory Monitoring after Transplantation

	1-2 Weeks	1 Month	2-4 Months	4-12 Months	>12 Months
SCr/BUN	Daily	1-2 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Chemistries[a]	Daily	1-2 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Liver function tests[b]					
Kidney or heart recipient	Once	Once	Monthly	Every 1-3 months	Every 1-3 months
Liver recipient	Daily	1-3 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Immunosuppressant level	Daily	1-2 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Complete blood count[c]	Daily	1-2 times per week	Every 1–2 weeks	Monthly	Every 1-2 months
Lipid panel[d]	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months
HbA_{1c}	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months

BUN, blood urea nitrogen; HbA_{1c}, hemoglobin A1c; SCr infusion, serum creatinine.

[a]Chemistries include sodium, potassium, chloride, CO_2 content, magnesium, calcium, phosphorus, and blood glucose.

[b]Liver function tests include total bilirubin, aspartate transaminase (AST), alanine transaminase (ALT),

gamma glutamyl transpeptidase (GGTP), alkaline phosphatase.

[c]Complete blood count includes white blood cells (WBC), red blood cells (RBC), platelets, and/or differential.

[d]Lipid panel includes total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglyceride, and/or very low-density lipoprotein (VLDL).

Long-term graft survival is limited by chronic rejection. Overall survival rates for solid-organ transplantations are described in terms of half-life, or the time after transplantation at which only 50% of transplanted organs are still functioning. Estimated half-lives for kidneys are 26.9 years for HLA-identical grafts and 12.2 and 10.8 years, respectively, for grafts from a sibling or parent who are 1-haplotype matches. The estimated half-life for HLA-matched grafts was 17.3 years while a markedly lower value of 7.8 years has been noted with mismatched kidneys.[1] The overall median patient survival time for heart transplantation recipients is 9.8 years, but in these patients surviving the first year after transplantation, the median survival increases to 12 years.[1] The highest rate of mortality occurs within the first year after liver transplantation due to the risks of surgery and early postoperative complications.

PERSONALIZED PHARMACOTHERAPY

Individualization of immunosuppression therapy starts with identifying the patient's risk of rejection prior to transplantation. Most clinicians will use induction therapy with a lymphocyte depleting agent for patients at high risk of rejection, including those patients who are sensitized to more HLA antigens due to previous exposure to blood products or previous transplant, younger patients and African Americans. Similarly, organs associated with a higher risk of rejection, including heart and lung transplants, require higher doses of immunosuppressants as maintenance therapy.

Therapeutic drug monitoring is a key component of individualizing the immunosuppressant regimen to ensure adequate immunosuppression is achieved while minimizing drug-related toxicities. Blood concentrations are routinely monitored for CIs and PSIs throughout the duration of therapy. Studies are ongoing to determine the correlation between blood concentrations and MPA. Consensus guidelines suggest that MPA monitoring may be warranted when MPA is used as the primary immunosuppressant, CI doses are reduced or discontinued, the patient has altered liver or kidney function, or medications that interact with MPA are administered concomitantly.[52]

Other patient-specific factors can influence CI pharmacokinetics and thus dosing requirements. Children require significantly higher CI doses on a mg/kg basis than do their adult counterparts, up to 3-fold higher in the youngest of patients. Advancing age appears to decrease CI requirements, presumably through increased absorption and decreased metabolic activity. Patients greater than64 years required lower doses than younger recipients.[30] Beyond these factors, some transplant dependent factors can also impact immunosuppressant exposure. Ischemic reperfusion injury in the setting of liver transplantation has been shown to increase p-gP expression and thus decrease CI absorption whereas uremia seen in the setting of delayed graft function in renal transplantation is

associated with decreased p-gP and thus higher CI levels.[30]

Pharmacogenetic assessment to optimize immunosuppressive therapy regimens is slowly emerging. Cytochrome P450 genetic polymorphisms are important for CI metabolism. Both cyclosporine and tacrolimus are metabolized by CYP3A5, which contributes to the interpatient variability associated with CIs. It is estimated that 30% of Caucasians and 50% of African Americans express high levels of CYP3A5 enzymes. Patients who express CYP3A5 require significantly higher doses of CIs to achieve therapeutic levels.[70] There are ethnic differences in CYP3A5 expressions that impact tacrolimus exposure as well as ultimate graft outcome. Up to 73% of patients of African descent express CYP3A5*1 which is associated with a 2-fold reduction in dose normalized tacrolimus levels, that is, patients require higher doses to achieve the same target as nonexpressers.[30] In African Americans who do not achieve target tacrolimus trough concentrations, the risks of antibody mediated rejection and ACR are significantly elevated.[71] Furthermore, one study suggests that African Americans may require monitoring of MPA levels due to more rapid clearance of MPA compared to Caucasians.[72] CYP3A5 genotyping may help to identify patients who require higher doses of CIs to optimize immunosuppressive therapy earlier after transplantation and potentially decrease the risk of rejection. However, larger studies are needed to determine the effectiveness of this strategy.

Pharmacodynamic monitoring of immunosuppressants of the specific targets of immunosuppressants rather than blood concentrations is in its infancy. Research is ongoing to determine the value of monitoring calcineurin activity for CIs[73] and IMPDH activity for MPA.[50]

Generic Substitution

In recent years a number of generic versions of immunosuppressants have entered the market. While generic versions of corticosteroids and azathioprine have long been available, there are now generic versions of cyclosporine, USP [MODIFIED], tacrolimus, and mycophenolate mofetil. While these formulations have demonstrated bioequivalence to the innovator product in healthy individuals, bioequivalence testing in transplant patients is not required for approval.[74]

Several potential factors including the complexity of the regimens and the impact of end organ disease could alter absorption and result in PK variability not seen in healthy volunteers. The presence of diabetes may delay gastric emptying, whereas cystic fibrosis may lead to differences in tacrolimus or cyclosporine secondary to fat malabsorption. Finally, none of the available generic formulations have been studied in pediatric patients.[75]

As generic medications may offer a significant cost advantage compared with the innovator product, their use will increase over time. Much of the concern with generic substitution for immunosuppressant and other narrow therapeutic index medications relates to the potential for increased or decreased systemic exposure that although within the “acceptable” regulatory range may put patients at risk because of inadequate maintenance of the desired serum concentrations. Systems that alert patients and prescribers to changes in formulation (eg, labels on medications, direct notification to physicians) could trigger clinicians to more closely monitor patients for efficacy and toxicity as well as heighten therapeutic drug monitoring during a switch. However, the extent to

which increased monitoring could offset cost savings associated with generic substitution has not been fully delineated.

IMMUNOSUPPRESSION-RELATED COMPLICATIONS

Comorbidities such as cardiovascular disease and malignancy, recurrent disease, drug toxicities (namely nephrotoxicity), and chronic rejection are the primary causes of mortality in patients who have a functioning graft for 5 or more years after transplantation.[1]

Cardiovascular Disease

Cardiovascular disease is a leading cause of morbidity and mortality in transplant patients.[76] Hypertension, hyperlipidemia, and diabetes are common complications in transplantation recipients and are independent risk factors for cardiovascular disease. Chronic rejection has been linked to hypertension and hyperlipidemia.[37,76]

Hypertension

Corticosteroids, cyclosporine, tacrolimus, and impaired kidney graft function may cause post-transplantation hypertension. Calcineurin inhibitor-associated hypertension may be due to increased endothelin production as well as stimulation of the sympathetic and renin angiotensin systems.[77] In addition to the propensity to cause peripheral vasoconstriction, CIs promote sodium retention, resulting in extracellular fluid volume expansion. Tacrolimus appears to have less potential to induce hypertension following transplantation than cyclosporine.[36,78]

Calcium channel blockers have traditionally been the first-line agents to treat hypertension after transplantation.[29,79] They may ameliorate the nephrotoxic effects of cyclosporine, improve renal hemodynamics, decrease the incidence of DGF and the development of allograft atherosclerosis, and enhance the degree of immunosuppression.

ACEIs and angiotensin II receptor blockers have traditionally been avoided in kidney transplantation recipients, especially in the perioperative period, because of the potential for hyperkalemia and negative influence on glomerular filtration rate. They are now however, considered to be an equivalent alternative to calcium channel blockers for the treatment of hypertension in all transplant recipients, and are preferred in patients with proteinuria.[29] When ACEIs or angiotensin II receptor blockers are used in patients after transplantation, serum creatinine and potassium levels should be monitored closely. If the increase in serum creatinine is greater than 30% within 1 to 2 weeks after initiating ACEIs or angiotensin II receptor blockers, other alternatives must be considered (see Chapter 46).

Multiple antihypertensive agents are usually necessary to achieve the goal blood pressure in transplant recipients; consequently, the addition of a β-blocker, diuretic, or centrally acting antihypertensive may also be necessary. Beta-blockers are generally considered to be second-line therapy in solid-organ transplantation recipients because of the potential to worsen metabolic

disturbances caused by immunosuppressants, such as hyperkalemia and dyslipidemia. Calcineurin inhibitor-induced hypertension is often salt-sensitive, making it very responsive to diuretics. Central-acting agents (eg, clonidine) are used often as adjunctive therapy in transplantation recipients who are unable to achieve blood pressure control with calcium channel blockers or ACEIs.

Hyperlipidemia

Hyperlipidemia may be exacerbated by corticosteroids, calcineurin inhibitors, sirolimus, diuretics, and β-blockers.[22,29] Corticosteroids promote insulin resistance and a decrease in lipoprotein lipase activity, as well as excessive triglyceride production. The mechanism of CIs may decrease the activity of the low-density lipoprotein (LDL) receptor or lipoprotein lipase, altering LDL catabolism.[22] Tacrolimus appears to have less potential than cyclosporine to induce hyperlipidemia.[36] It is controversial whether the management of hyperlipidemia in transplant recipients should be more aggressive than current guidelines for the general population.[29,79] (see Chapter 21) Aggressive lipid lowering may not only arrest the progress or prevent the complications of atherosclerosis but may also promote graft survival in kidney and heart transplant recipients. Current recommendations suggest monitoring lipid panels 2 to 3 months after transplantation and annually thereafter.[18,29]

HMG-CoA reductase inhibitors should be used with caution in transplantation recipients because of several reports of rhabdomyolysis when these agents are combined with calcineurin inhibitors.[41] However, beyond their impact on hyperlipidemia, HMG-CoA reductase inhibitors also have immunomodulatory effects on MHC expression and T-cell activation and reduce cardiac allograft rejection.[41]

Concurrent use of simvastatin and cyclosporine is contraindicated, due to the increased risk of rhabdomyolysis.[80] The concurrent use of medications known to increase the risk of myopathy (such as gemfibrozil) should be avoided.[41] Baseline and follow-up creatinine phosphokinase measurements (every 6 months) have proven useful to identify patients with subclinical rhabdomyolysis. Pravastatin may be preferred as a result of its lower interactive potential with CIs because it is not metabolized by CYP3A4. The potential for hepatotoxicity from HMG-CoA reductase inhibitors warrants close monitoring of liver function in all transplant recipients.[29,79]

Bile acid-binding resins may be used to lower cholesterol in transplant patients, but adequate doses are difficult to achieve without the development of GI adverse effects. Because the absorption of cyclosporine is dependent on the presence of bile in the GI tract, patients should be instructed to separate dosing of bile acid-binding resins and cyclosporine and most other immunosuppressants by at least 2 hours. For transplant patients who have hypertriglyceridemia refractory to dietary intervention, fish oil and fibric acid derivatives are well-tolerated, effective alternatives (see Chapter 21). Fibric acid derivatives are most effective in lowering serum triglyceride concentrations.

New-Onset Diabetes after Transplantation

Corticosteroids and CIs can impair glucose control in previously diabetic patients, as well as cause

new-onset diabetes after transplantation (NODAT) in 5% to 30% of patients.[24,29] Corticosteroids induce insulin resistance and impair peripheral glucose uptake, whereas CIs appear to inhibit insulin production.[22] Tacrolimus seems to be more diabetogenic than cyclosporine, although recent studies have failed to show a statistical difference.[36] Other possible risk factors that have been identified for NODAT include African American or Hispanic ethnicity, age greater than 40 years at time of transplant, family history, and weight, as well as CMV and Hepatitis C virus infection.[22]

Up to 40% of patients with NODAT will require insulin therapy.[22] In diabetic patients who can be managed with an oral hypoglycemic agent, glipizide, which is metabolized extensively by the liver, may be preferred over renally eliminated agents such as glyburide. Metformin should be used with extreme caution because of the risk of lactic acidosis in those with moderate renal impairment. Frequent blood glucose monitoring is imperative in the early postoperative phase to improve glucose control and to identify those with NODAT. Changes in renal function secondary to CI nephrotoxicity or DGF or acute rejection in kidney transplant recipients affects the elimination of many hypoglycemic agents, including insulin, and may result in hyper- or hypoglycemia. Dose changes of immunosuppressant drugs also affect glycemic control. Tapering of immunosuppressive medications may result in reduced insulin requirements, whereas corticosteroid pulses for the treatment of rejection may result in increased insulin requirements.

Infection

Increased risk of infection is a natural consequence of therapeutic immunosuppression. Many infections, including cytomegalovirus and fungal infections, in solid organ transplant recipients are reviewed in Chapter 122.[81]

Polyomavirus-associated nephropathy (PVAN) is an important cause of renal dysfunction in kidney transplant recipients. Primary infection with BK virus occurs in childhood as an asymptomatic infection in 50% to 90% of the general population. The precise mechanism of transmission is not clear but is suspected to be via the oral or respiratory routes. The virus may remain latent primarily in the genitourinary tract until reactivation as the result of compromised immune function and is common in kidney transplant recipients. Reactivation can be detected by measuring the presence of BK virus in the urine, a finding that is seen in approximately 30% to 40% of kidney transplant recipients, although it does not progress to nephropathy in the majority of patients. However, BK viremia if it develops has been noted to progress to allograft nephropathy in 50% of patients.[80] The development of BK virus nephropathy results in graft loss in about 46% of effected patients.[81]

It has been recommended that all kidney transplant recipients be screened for urinary BK virus replication monthly for the first 3 to 6 months after transplant and every 3 months thereafter for the first year.[29,81] Screening for BK virus presence in serum should also occur any time the serum creatinine is elevated without known cause and after treatment of acute rejection.[29] Treatment of BK virus should be initiated when plasma concentrations persist above 10,000 copies/mL(10×10^6/L).[29,81,82] The first line of treatment is to reduce immunosuppressive medications. Other treatment strategies include the addition of cidofovir, leflunomide, or fluoroquinolones, although

studies with these agents are limited.[82]

Hepatitis C virus (HCV) recurs almost universally following liver transplantation and the course of the disease is accelerated. Within 5 years, 10% to 20% of liver transplant recipients with HCV recurrence will progress to cirrhosis requiring retransplantation, compared to the general population where 20% to 30% will develop cirrhosis over 20 to 30 years. Recipient risk factors for recurrence include HCV viremia either before or in the first 3 month post-transplant, interleukin-28B TT genotype, and female sex. Advanced donor age and the presence of graft steatosis have also been associated with HCV progression.[10,84] Recommendations for the treatment of HCV were developed in 2014 by the American Association for the Study of Liver Diseases and the Infectious Disease Society of America and continue to rapidly evolve. [85] Additionally pretransplant antiviral therapy may reduce the risk of recurrent HCV post-liver transplant.[83] First generation direct acting antivirals (DAA) boceprevir and telaprevir have significant drug interactions with both CIs and PSIs, and have largely been replaced by the latter generation DAAs. Management of drug–drug interactions with immunosuppressants and the DAAs is an important consideration for clinicians. The ritonavir-boosted combination of ombitasvir/paritaprevir and dasabuvir (Viekira Pak) resulted in a 57-fold increase is tacrolimus AUC, whereas the same combination caused a 5.8-fold increase in cyclosporine AUC. Simeprevir, an intestinal CYP3A4 and p-glycoprotein inhibitor, is contraindicated with cyclosporine-based regimens due to a 6-fold increase in simeprevir exposure when co-administered with cyclosporine. Conversely, ledipasvir, sofosbuvir and daclatasvir do not appear to significantly impact immunosuppressant concentrations. Ribavirin does not have any direct pharmacokinetic interactions with immunosuppressants, however, clinicians should note the overlapping toxicities, especially anemia as well as the need to adjust doses of ribavirin in patients with reduced kidney function. The DAAs have been generally well-tolerated, but simeprevir and ombitasvir/paritaprevir/ritonavir should be used in patients with Child-Pugh class B or C liver disease.[85]

In the absence of preventative therapy, hepatitis B recurs in approximately 80% of patients after transplantation. Initial studies with short-term intravenous administration of hepatitis B immunoglobulin (HBIg) showed equally high rates of recurrence upon discontinuation of therapy. However, strategies that employ the long-term administration of HBIg with or without antiviral therapy report much lower recurrence rates, 15% to 30% and 20% to 40%, for nonreplicative and replicative hepatitis B virus, respectively.[87] Common strategies include intravenous HBIg 10,000 units during the anhepatic phase followed by 10,000 units daily for 6 days. Antihepatitis B surface titer should be monitored weekly to ensure adequate levels for protection as well as to optimize HBIg use. HBIg has been typically dosed to maintain titers greater than 100 to 500 international units/L. Long-term HBIg therapy is extremely costly, estimated at $100,000 for the first postoperative year and $50,000 for each subsequent year. Combination therapy with antiviral agents appears to be synergistic and is the current standard. Lamivudine resistance is a concern with long-term utilization both pre- and post-transplant. The role of newer antiviral agents, including adefovir, entecavir, and tenofovir, remains to be defined. Treatment for active hepatitis B virus graft infection should include HBIg, antiviral therapy, and concomitant reduction in immunosuppression.[87]

Malignancy

Although advances in immunosuppression have decreased the incidence of acute rejection and increased patient survival, they have also increased the patient's lifetime exposure to immunosuppression. While the precise mechanism is unclear, post-transplantation malignancy seems to be related to the overall level of immunosuppression, as evidenced by a difference in the rates of malignancy associated with quadruple versus triple versus dual immunosuppressant regimens. The risk of de novo malignancy in transplantation recipients is increased threefold to fivefold over the general population.[50] The risk of lung and colon cancers may be as much as doubled in renal transplant recipients.[88] A number of cancers that are uncommon in the general population occur with much higher prevalence in transplantation recipients: post-transplantation lymphomas and lymphoproliferative disorders (PTLDs), Kaposi sarcoma, renal carcinoma, in situ carcinomas of the uterine cervix, hepatobiliary tumors, and anogenital carcinoma are a few examples.[88] Skin cancers are the most common tumors. Factors that may predispose transplant recipients to skin cancers include copious sun exposure and therapy with azathioprine.[50] While too early to definitively assess the impact of MPA derivatives on malignancy, one analysis showed a lower risk of PTLD with MMF compared with AZA.[50] Proliferation signal inhibitors have a theoretical benefit in terms of the development of malignancy. In addition to immunosuppressive properties, PSIs also have antiproliferative effects. In fact, a decreased incidence of malignancy was reported in patients receiving PSIs versus CIs, and conversion to PSIs from CIs can result in regression of Kaposi sarcoma.[88]

PTLD encompasses a broad spectrum of disorders, ranging from benign polyclonal hyperplasia to malignant monoclonal lymphomas. Factors that predispose patients to PTLD include Epstein-Barr virus seronegativity at transplantation and intense immunosuppression, particularly with lymphocyte depleting agents. Nonrenal transplantation recipients are more likely to develop PTLD secondary to the intensive immunosuppression used to reverse rejection. Administration of ganciclovir or acyclovir preemptively during antilymphocyte therapy may decrease the risk of EBV seroconversion and infection, reducing the eventual risk of PTLD. Treatment of life-threatening PTLD generally includes severe reduction or cessation of immunosuppression. Other options include systemic chemotherapy or rituximab.[88]

Post-transplantation malignancies appear an average of 5 years after transplantation and increase with the length of follow-up. As many as 72% of patients surviving greater than 20 years may be effected. Malignancy accounts for 11.8% of deaths after cardiac transplantation and is the single most common cause of death in the 6th to the 10th post-transplant years.[88]

CLINICAL BOTTOM LINE

Transplantation is a lifesaving therapy for several types of end-organ failure. Advances in the understanding of transplant immunology have produced an unprecedented number of choices in terms of immunosuppression. The increasing number of effective immunosuppressive therapies offers clinicians diverse ways to prevent allograft rejection.

However, the vast array of currently available immunosuppressive agents make it increasingly difficult

to evaluate their long-term efficacy. Clinicians must be keenly aware of the adverse effects of immunosuppressive medications and their management in order to optimize the care of the transplanted patient.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACEI	angiotensin-converting enzyme inhibitor
ACR	acute cellular rejection
AMR	antibody-mediated rejection
ATG	antithymocyte globulin
ATN	acute tubular necrosis
AUC	area under the concentration curve
C_2	concentration 2 hours after dose
C_{peak}	peak concentration
CI	calcineurin inhibitors
CMV	cytomegalovirus
CYP	cytochrome P450 liver enzyme system
DAA	direct acting antivirals
DGF	delayed graft function
EBV	Epstein Barr virus
FKBP	FK-binding protein
GI	gastrointestinal
HBIg	hepatitis B immunoglobulin
HLA	human leukocyte antigen
HMGCoA	hydroxy-3-methylglutaryl-coenzyme A
HPLC	high-performance liquid chromatography
IFTA	interstitial fibrosis and tubular atrophy
IL	interleukin
IMPDH	inosine monophosphate dehydrogenase
LAS	lung allocation score
LDL	low-density lipoprotein
MELD	model for end-stage liver disease
MHC	major histocompatibility complex
6-MP	6-mercaptopurine
MPA	mycophenolic acid
MPAG	mycophenolic acid glucuronide
MRP2	multidrug-resistance-associated protein 2

mTOR	mammalian target of rapamycin
NODAT	new-onset diabetes after transplantation
OATP	organic anion-transporter proteins
OKT3	muromonab-CD3
PML	progressive multifocal leukoencephalopathy
PRA	panel of reactive antibodies
PSI	proliferation signal inhibitor
PTLD	post-transplantation lymphoproliferative disorder
PVAN	polyomavirus associated nephropathy
RIA	radioimmunoassay
REMS	risk evaluation and mitigation strategy
TPMT	thiopurine *S*-methyltransferase

Chapter 90: Osteoarthritis

Lucinda M. Buys; Sara A. Wiedenfeld

INTRODUCTION

KEY CONCEPTS

- 1 Millions of Americans have osteoarthritis (OA). OA prevalence increases with age and number of other chronic conditions, with women more commonly affected than men.
- 2 Contributors to OA are systemic (age, genetics, hormonal status, obesity, occupational, or recreational activity) and/or local (injury, overloading of joints, muscle weakness, or joint deformity).
- 3 OA is primarily a disease of cartilage that reflects a failure of the chondrocyte to maintain proper balance between cartilage formation and destruction. This leads to loss of cartilage in the joint, local inflammation, pathologic changes in underlying bone, and further damage to cartilage triggered by the affected bone.
- 4 The most common symptom associated with OA is pain, which leads to decreased function and motion. Pain relief is the primary objective of medication therapy.
- 5 Manifestations of OA are local, affecting one or a few joints; the knees are most commonly affected, as well as the hips and hands. Osteophytes (bony proliferation of affected joints) are often found, in contrast to the soft tissue swelling of rheumatoid arthritis.
- 6 Nonpharmacologic therapy is the foundation of the treatment plan for all patients with OA. Nonpharmacologic therapy should be initiated before or concurrently with pharmacologic therapy.
- 7 Based upon efficacy, safety, and cost considerations, scheduled acetaminophen, up to 4 g/day, should be tried initially for pain relief in knee and hip OA. If this fails, topical or oral nonsteroidal anti-inflammatory drugs (NSAIDs) are recommended, if there are no contraindications.

- 8 To decrease the risks of systemic toxicity, topical NSAIDs are recommended for patients older than 75 years.
- 9 Strategies to reduce NSAID-induced gastrointestinal (GI) toxicity include the use of nonacetylated salicylates, cyclooxygenase-2 (COX-2) selective inhibitors, or the addition of misoprostol or a proton pump inhibitor (PPI).
- 10 Other agents useful in treating knee OA include tramadol, intra-articular injections of corticosteroids, or duloxetine.

Osteoarthritis (OA) is the most common joint disease and is one of the leading causes of disability in the United States.[1,2] Knee OA alone is as important a contributor to disability as cardiovascular disease and more important than other comorbidities. OA is a common co-occurrence with other chronic health conditions that adversely affect quality of life.[1]

The progressive destruction of articular cartilage has long been appreciated in OA, but OA involves the entire diarthrodial joint, including articular cartilage, synovium, capsule, and subchondral bone, with surrounding ligaments and muscles also playing important roles. Changes in structure and function of these tissues produce clinical OA, characterized by joint pain and tenderness, with decreased range of motion, weakness, joint instability, and disability.

This chapter will review the epidemiology, etiology, pathogenesis, and diagnosis of OA. It will then focus on nonpharmacologic and pharmacologic treatments for OA. As millions of persons take medications for OA, the overall risks posed by these medications require careful consideration, particularly by clinicians who treat or advise patients on drug therapy for OA. This chapter examines the risks and benefits of OA treatments, with emphasis on those individuals who have the highest risk for adverse events, to help clinicians maximize benefit and minimize risks to their patients with OA.

EPIDEMIOLOGY

1 In 2010-2012, an estimated 52.5 million adults in the United States reported physician-diagnosed arthritis (OA, rheumatoid arthritis, gout, lupus or fibromyalgia) with 22.7 million reporting arthritis-attributable activity limitation (AAAL).[3] This represents an increase from 49.9 million adults in 2007-2009.[3] These rates are more than doubled from 21 million adults in 1995.[4] Prevalence of AAAL is expected to increase to 22 million in the United States by 2020, and an estimated 67 million persons will have OA by 2030.[2,3] OA imposes a tremendous cost burden, with total hospital costs in 2011 for care associated with a diagnosis of OA reaching approximately $15 billion and nearly 1 million OA-related hospital discharges.[5] The vast majority of these costs are related to knee- and hip-replacement surgery.[5] In 2012, medical expenses for treatment of OA and other nontraumatic joint disorders totaled $73.8 billion.[6] It is estimated that each individual with knee OA will use nearly $130,000 on total direct medical costs with 10% of the total attributable to OA over their lifetime.[7]

Prevalence By Age, Gender, and Race

Prevalence estimates for OA vary depending on the age group of interest, gender, ethnic group, and the specific joint involved. Estimates also depend on the specific means by which OA is assessed and documented. Clinical OA is based on physical examination and patient history, whereas radiographic OA is determined by x-ray or other imaging, and symptomatic OA is based on history and physical examination plus x-ray OA is more prevalent with increasing age.[2] In the United States, prevalence of self-reported doctor-diagnosed arthritis in the 2012 National Health Interview Survey (NHIS) is 22.7% for all persons over age 18, but 49.7% for persons age 65 and older.[3] Prevalence for AAAL among persons with doctor-diagnosed arthritis is 43.2% for all persons over age 18, and 44.4% for persons age 65 and older.[3] Radiologically confirmed hip OA shows clear trends through all age groups, affecting 1.6% of those between ages 30 to 39, up to a prevalence of 14% in those older than 85 years.[8] Radiographic hand OA is found in 5% of those aged 40, but in 65% of those older than 80 years.[9]

Prevalence of doctor-diagnosed arthritis is 25.9% in white populations, and ranges from 4.9% for Asian populations to 21.3% for black populations.[3] African-American men are approximately 35% more likely to have radiographic knee OA and twice as likely to have more severe knee OA than Caucasian men.[10] No significant differences were found between the prevalence of knee OA in African-American women and Caucasian women, but African-American women were 50% more likely than Caucasian women to have more severe involvement.[10] Before age 50, men are more likely to have OA than women, attributed to higher rates of sports and other injuries. Women exhibit a higher prevalence of hip and knee OA than men, and are at especially greater risk for hand OA, with 26% of women and 12% of men over age 70 affected.[9] Women are also more likely to have inflammatory OA of the proximal and distal interphalangeal joints of the hands, giving rise to the formation of Bouchard and Heberden nodes, respectively (**Fig. 90–1**).

FIGURE 90-1

Heberden nodes (distal interphalangeal joint) noted on all fingers and Bouchard nodes (proximal interphalangeal joint) noted on most fingers. *(Used with permission from Johnson BE. Chapter 23. Arthritis: Osteoarthritis, Gout, & Rheumatoid Arthritis. In: South-Paul JE, Matheny SC, Lewis EL. eds. Current Diagnosis & Treatment in Family Medicine, 3e. New York, NY: McGraw-Hill; 2011.)*

Incidence

The incidence of symptomatic OA determined in a large HMO was 100 per 100,000 patient years for hand OA, 88 per 100,000 patient years for hip OA, and 240 per 100,000 patient years for knee OA.[8] As the incidence of a disease describes the number of newly diagnosed cases each year, OA poses a challenging situation for determining disease incidence. These reasons include: (1) not all patients with OA seek medical treatment, (2) OA is very common within the population, (3) not all radiographically diagnosed OA is symptomatic, and (4) many patients have multiple affected joints.

ETIOLOGY

2 The etiology of OA is multifactorial and complex, with development of OA depending on interplay between factors such as genetic predisposition and joint injury.[11,12] Many patients have more than one risk factor for the development of OA. The most common risk factors for the development of OA include age, obesity, sex, occupation, participation in certain sports, history of joint injury or surgery, and genetic predisposition.

Obesity

Obesity is the most important preventable risk factor for OA. This linkage is strongest for knee OA, although hip OA and even hand and wrist OA may be linked with obesity. As the epidemic of obesity spreads in the United States and in other developed countries, so will the burdens imposed by OA will continue to increase. Obesity often precedes OA and contributes to its development, rather than occurring as a result of inactivity from joint pain.[13] In an 11-year study of approximately 30,000 Norwegian men and women, obesity significantly increased the risk of developing OA.[14] Men who

were obese at baseline had a 2.8-fold increase in developing knee OA compared with the non-obese men, whereas women who were obese at baseline had a 4.4-fold increased risk in developing knee OA compared with non-obese women. Also, there was an increased risk for severe knee OA in obese subjects. In addition to being a risk factor for OA, obesity is also a predictor for eventual prosthetic joint replacement. In a US study, women who were obese at age 18 were at increased risk of undergoing hip replacement surgery in later life.[2] The risk of developing OA increases by approximately 10% with each additional kilogram of weight, and in obese persons without OA, weight loss of even 5 kg (11 lbs) decreases the risk of future knee OA by half.[13]

Occupation, Sports, and Trauma

OA risk is increased for people in occupations involving excessive mechanical stress. Work that involves prolonged standing, kneeling, squatting, lifting, or moving of heavy objects increases risk of OA. Such occupations include construction, mining, healthcare assistance, factory work, carpentry, and farming.[2,11] Repetitive motion also contributes to hand OA, with the dominant hand usually affected.[9] Risk for OA depends on the type and intensity of physical activity and whether injury is incurred in the activity. Increased risk of OA is associated with participation in activities such as wrestling, boxing, baseball pitching, cycling, and football, although recreational participants do not have the increased risk seen in the professional athlete.[2,11] In a study of 30,000 Norwegians, exercise intensity was not associated with any increased risk in the obese subjects compared with those of normal weight.[14]

Traumatic injury to articular cartilage during sports and other activities or in accidents greatly increases OA risk.[2,15] Meniscal damage increases the risk of knee OA because of the loss of proper load bearing and shock absorption, increased focal load on cartilage and on subchondral bone. Knee injury in young persons is also an important risk factor for knee OA in old age.[11] Quadriceps muscle weakness is also recognized to increase the risk for knee OA, as these muscles are important in maintaining joint stability.[13] Whether knee malalignment increases risk of developing OA remains unsettled.[11] In the person who already has OA, knee malalignment is strongly associated with faster progression of OA.[11]

Genetic Factors

OA is a complex, polygenic disease. Identification of the genes involved may promote development of agents to prevent OA or to slow or halt its progression. Genetic influences on OA have been appreciated for many years. Heberden nodes are 10 times more prevalent in women than in men, for example, with a twofold higher risk if the woman's mother had them. Genetic links have been shown with OA of the first metatarsophalangeal joint and with generalized OA. Twin studies indicate that OA can be attributed substantially to genetic factors.[16] In other twin studies of OA progression, radiographic measurements over 2 years showed that the increased risk for a sibling having radiographic progression if the proband had progression was threefold for joint space narrowing and 1.5-fold for osteophyte progression.[17]

One approach OA researchers have used is the candidate gene approach which is hypothesis-based and focuses on genes with known function that could be plausibly linked with the disease. Genome-wide association studies (GWAS) associating OA with a specific region out of the total human genome, using cases versus controls, offers a powerful approach in seeking the genetic basis for OA.[18] Using GWA studies and candidate gene approaches, possible genetic associations to OA have been found, and some of these appear to code for known proteins which have intriguing connections.[18,19,20] These genes include *Col11A1* (extracellular matrix), *Chrom 19* (cartilage morphogenesis), *MCFL* (pain perception), *CHST11* (cartilage morphogenesis), *GDF5* (TGF-beta signaling), and *Chrom7Q22*. A meta-analysis of GWA studies with 6,709 knee OA cases and 44,439 controls revealed that the *Chrom7Q22* locus was very highly significantly associated with knee OA. The locus also included six genes that code for proteins known to be expressed in joint tissues.[19]

For most genes that appear to be linked to OA, the associations have been weak or modest, even if replicable.[21] It is quite likely that the genetic risk of developing OA, like many other diseases, may be substantially determined by a combination of modest genetic differences, and this underscores the point that understanding of the genetics and pathology of OA is in its infancy.

PATHOPHYSIOLOGY

OA falls into two major etiologic classes. *Primary* (*idiopathic*) *OA*, the more common type, has no identifiable cause. *Secondary OA* is associated with a known cause such as rheumatoid or another inflammatory arthritis, trauma, metabolic or endocrine disorders, and congenital factors.[22]

The old view of OA as a "wear-and-tear" or degenerative disease, largely focused on joint cartilage, has long been superseded by an appreciation of the dynamic nature of OA and that it represents a failure of the joint and surrounding tissues.[23] Some changes in the OA joint may reflect compensatory processes to maintain function in the face of ongoing joint destruction. Not only biomechanical forces but also inflammatory, biochemical, and immunologic factors are involved. An appreciation of the biology and function of normal cartilage can aid in understanding osteoarthritic cartilage and is summarized below.

Normal Cartilage

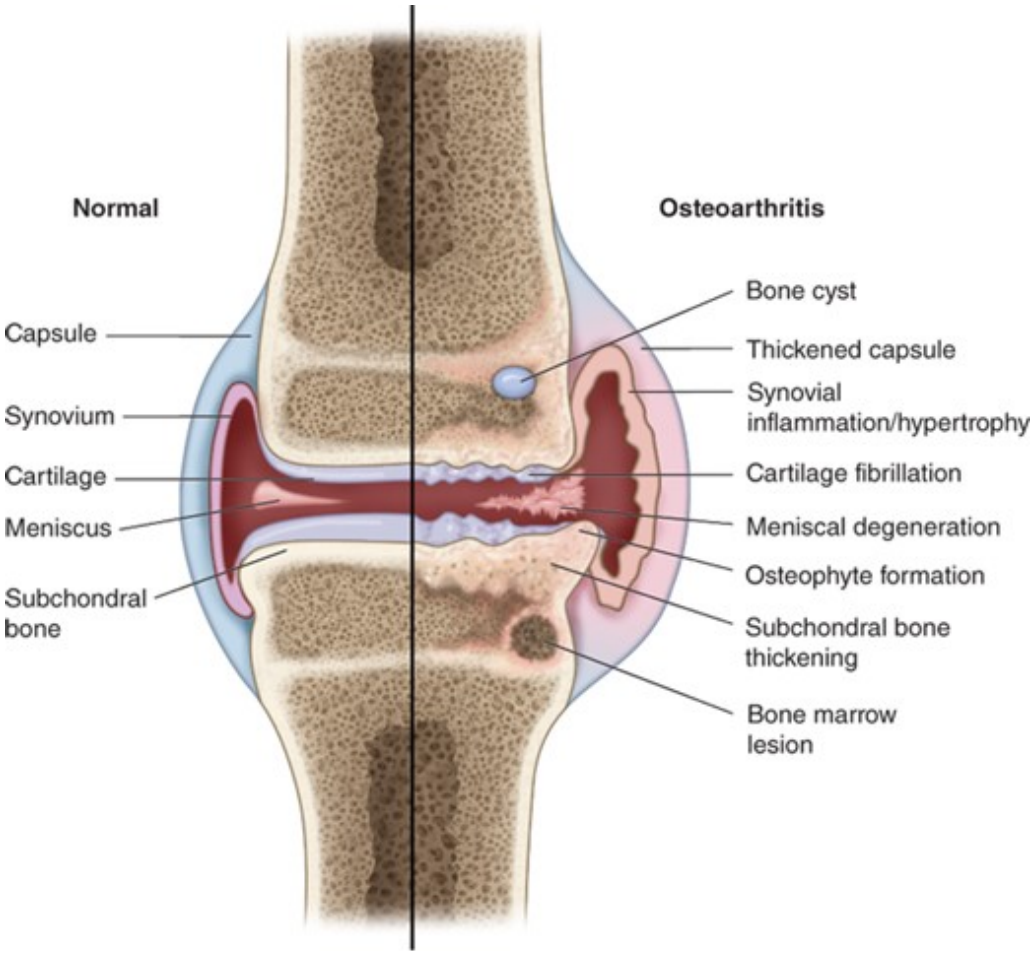
Function, Structure, and Composition of Cartilage

Articular cartilage possesses viscoelastic properties that provide lubrication with motion, shock absorbency during rapid movements, and load support. In synovial joints, articular cartilage is found between the synovial cavity on one side and a narrow layer of calcified tissue overlying subchondral bone on the other side (**Fig. 90-2**).[24] The layer of cartilage is narrow, with human medial femoral articular cartilage being approximately 2 to 3 mm thick. Despite this, healthy articular cartilage in weight-bearing joints withstands millions of cycles of loading and unloading each year. Cartilage is easily compressed, losing up to 40% of its original height when a load is applied. Compression increases the area of contact and disperses force more evenly to underlying bone, tendons,

ligaments, and muscles. In addition, cartilage is almost frictionless, and together with its compressibility, this enables smooth movement in the joint, distributes load across joint tissues to prevent damage, and stabilizes the joint.

FIGURE 90-2

Characteristics of osteoarthritis in the diarthrodial joint. *(Courtesy of Dr. D. Gotlieb.)*



Strength, a low coefficient of friction, and compressibility of cartilage derive from its unique structure. Cartilage is a complex, hydrophilic, extracellular matrix (ECM). It is approximately 75% to 85% water and contains 2% to 5% chondrocytes collagen and other proteins, proteoglycans, and long hyaluronic acid (HA) molecules.[24] The two major structural components in articular cartilage are type II collagen and aggrecans.[25] Type II collagen has a tightly woven triple helical structure, which provides the tensile strength of cartilage. Aggrecan is a proteoglycan linked with HA, providing the long aggrecan molecules a high negative charge. These are squeezed together by surrounding fibrils of type II collagen. The strong electrostatic repulsion of proteoglycans held in close proximity gives cartilage the ability to withstand further compression. Within the cartilage ECM are the chondrocytes, the only cells in cartilage, responsible for laying down all the components of cartilage.

Normal cartilage turnover helps repair and restore cartilage in response to demands of joint loading and during physical activity. In adults, cartilage chondrocyte metabolism is slow and is regulated by growth factors, including bone morphogenetic protein 2, insulin-like growth factor-1, and transforming growth factor, and by catabolism and proteolysis stimulated by matrix metalloproteinases (MMPs), tumor necrosis factor-α (TNF-α), interleukin-1, and other cytokines. Tissue inhibitors of metalloproteinase (TIMP) also contribute to the balance by restraining the catabolic actions of MMPs. If cartilage is injured, chondrocytes react by removing the damaged areas and increasing synthesis of matrix constituents to repair and restore cartilage.[25,26]

Another component supporting healthy joints are the joint protective mechanisms, such as muscles bridging the joint, sensory receptors in feedback loops to regulate muscle and tendon function, supporting ligaments, and subchondral bone that has shock-absorbent properties.

Finally, it is important to note that adult articular cartilage is avascular, with chondrocytes nourished by synovial fluid. With movement and cyclic loading and unloading of joints, nutrients flow into the cartilage, whereas immobilization reduces nutrient supply. This is one of the reasons that normal physical activity is beneficial for joint health.

Osteoarthritic Cartilage

3 Important contributors to the development of OA are local mechanical influences, genetic factors, inflammation, and aberrant chondrocyte function leading to loss of articular cartilage.[25,26] At a molecular level, OA pathophysiology involves the interplay of dozens, if not hundreds, of extracellular and intracellular molecules with roles including chondrocyte regulation, phenotypic changes, proteolytic degradation of cartilage components, and interactions between articular cartilage, underlying subchondral bone, and the joint synovium.[25,26,27,28]

OA most commonly begins with damage to articular cartilage, through trauma or other injury, excess joint loading from obesity or other reasons, or instability or injury of the joint that causes abnormal loading. In response to cartilage damage, chondrocyte activity increases in an attempt to remove and repair the damage. Depending on the degree of damage, the balance between breakdown and resynthesis of cartilage can be lost, and a vicious cycle of increasing breakdown can lead to further cartilage loss and apoptosis of chondrocytes.[25,26,27,29] Recent studies have revealed several aspects of the very complex nature of OA. For example, expression of hundreds of specific genes are affected by acute experimental injury of human cartilage tissue, that is, injury alters the chondrocyte phenotype.[30] Researchers have also shown that within different regions of human OA cartilage obtained at surgery, chondrocyte gene expression from the most damaged areas of cartilage is different from that of less damaged or normal areas.[31] Another exciting discovery is that comparative proteomics of articular cartilage from normal persons compared with cartilage from those with OA showed different expression.[32]

There is an increased appreciation of the role of tissues beyond cartilage, within the joint and surrounding it, subchondral bone.[26] Subchondral bone undergoes pathologic changes that may precede, coincide with, or follow damage to the articular cartilage. In OA, subchondral bone releases

vasoactive peptides and MMPs, and damage to subchondral bone may trigger further damage to articular cartilage.[33] Neovascularization and subsequent increased permeability of the adjacent cartilage occur and contributes further to cartilage loss.

Joint space narrowing resulting from loss of cartilage can lead to a painful and deformed joint (**Fig. 90-3**). Remaining cartilage softens and develops fibrillations (vertical clefts into the cartilage), followed by splitting off more cartilage and exposure of underlying bone.[34] During this time, adjacent subchondral bone undergoes further pathologic changes, cartilage is eroded completely, leaving denuded subchondral bone, which becomes dense, smooth, and glistening (eburnation). A more brittle, stiffer bone results, with decreased weight-bearing ability and development of sclerosis and microfractures. New bone formations, or osteophytes, also appear at joint margins, distant from cartilage destruction and are thought to arise from local and humoral factors. There is direct evidence that osteophytes can help stabilize osteoarthritic joints.[35]

FIGURE 90-3

Plain x-ray films of the knee demonstrating joint space narrowing. *(Used with permission from Johnson BE. Chapter 23. Arthritis: Osteoarthritis, Gout, & Rheumatoid Arthritis. In: South-Paul JE, Matheny SC, Lewis EL. eds. Current Diagnosis & Treatment in Family Medicine, 3e. New York, NY: McGraw-Hill; 2011.)*

In the joint capsule and synovium, inflammatory changes and pathologic changes can occur.[24,26,27,28] Contributors to inflammation may include crystals or cartilage shards in synovial fluid. Other possible players are interleukin-1, prostaglandin E_2, TNF-α, and nitric oxide which are found in synovial fluid. With inflammatory changes in the synovium, effusions and synovial thickening occur.

4 The pain of OA is not related to the destruction of cartilage but arises from the activation of nociceptive nerve endings within the joint by mechanical and chemical irritants.[29] OA pain may result from distension of the synovial capsule by increased joint fluid, microfracture, periosteal irritation, or damage to ligaments, synovium, or the meniscus.

CLINICAL PRESENTATION

Diagnosis

5 The diagnosis of OA is made through history, physical examination, characteristic radiographic findings, and laboratory testing.[36] The major diagnostic goals are (1) to discriminate between primary and secondary OA and (2) to clarify the joints involved, severity of joint involvement, and response to prior therapies, providing a basis for a treatment plan. The American College of Rheumatology has published traditional diagnostic criteria and "decision trees" for OA diagnosis.[36] As with all guidelines, the authors stress these are for assisting the clinician rather than replacing clinical judgment. For example, traditional criteria are as follows: (1) For hip OA, a patient must have pain in the hip and at least two of the following three: an erythrocyte sedimentation rate less than 20 mm/h (<5.6 μm/s), femoral or acetabular osteophytes on radiography, or joint space narrowing on radiography. This provides a sensitivity of 89% and a specificity of 91%.[2] For a clinical diagnosis of knee OA, a patient must have pain at the knee and osteophytes on radiography plus one of the following: age older than 50 years, morning stiffness not more than 30 minutes, crepitus on motion, bony enlargement, bony tenderness, or palpable warmth. This provides a sensitivity of 95% and a specificity of 69%. The addition of laboratory or radiographic data further improves accuracy of diagnosis. Criteria for hand OA have also been published.[37]

Clinical Presentation Osteoarthritis Age

- Usually older

Gender

- Age < 45 more common in men
- Age > 45 more common in women

Symptoms

- Pain
- Deep, aching character
- Pain on motion
- Stiffness in affected joints

- Resolves with motion, recurs with rest (“gelling phenomenon”)
- Usually duration <30 minutes
- Often related to weather
- Limited joint motion
- May result in limitations of activities of daily living
- Instability of weight-bearing joints

Signs, history, and physical examination

- Monoarticular or oligoarticular, asymmetrical involvement
- Hands
    - Distal interphalangeal joints
        - Herberden nodes (osteophytes or bony enlargements) (Fig. 90-1)
    - Proximal interphalangeal joints
        - Bouchard’s nodes (osteophytes)
    - First metacarpal joint
        - Osteophytes give characteristic square appearance to hands
- Knee
    - Pain related to climbing stairs
    - Transient joint effusion
    - Genu varum (“bow-legged”)
- Hips
    - Groin pain during weight bearing exercises
    - Stiffness, especially after activity
    - Limited joint movement
- Spine
    - Lumbar involvement is most common at L3 and L4
    - Paresthesias

    - Loss of reflexes
- Feet
    - Typically involves the first metatarsalphalangeal joint
    - Shoulder, elbow, acromioclavicular, sternoclavicular, tempomandibular joints may also be affected
- Observation on joint examination
    - Bony proliferation or occasional synovitis
    - Local tenderness
    - Crepitus
    - Limited motion with passive/active movement
    - Deformity
- Radiologic Evaluation
    - Early Mild OA
        - Radiographic changes often absent
    - Progressive OA
    - Joint space narrowing (Fig. 90-3)
    - Subchondral bone sclerosis
    - Marginal osteophytes
- Late OA
    - Abnormal alignment of joints
    - Effusions

Prognosis

The prognosis for patients with primary OA is variable and depends on the joint involved. If a weight-bearing joint or the spine is involved, considerable morbidity and disability are possible. In the case of secondary OA, the prognosis depends on the underlying cause. Treatment of OA may relieve pain or improve function but does not reverse preexisting damage to the joint.

TREATMENT

Desired Outcome

Management of the patient with OA begins with a diagnosis based on a careful history, physical examination, radiographic findings, and an assessment of the extent of joint involvement. Treatment should be tailored to each individual. Goals are (1) to educate the patient, family members, and caregivers; (2) to relieve pain and stiffness; (3) to maintain or improve joint mobility; (4) to limit functional impairment; and (5) to maintain or improve quality of life.[38,39,40]

General Approach to Treatment

Treatment for each OA patient depends on the distribution and severity of joint involvement, comorbid disease states, concomitant medications, and allergies. Management for all individuals with OA should begin with both oral and written patient education, a customized activity and exercise program, and weight loss, if the patient is overweight or obese.[38,39,40]

The primary objective of medication is to alleviate pain.[38,39,40] Scheduled acetaminophen, up to 4 g/day, should be tried initially (knee, hip), if contraindications are not present. Application of topical NSAIDs over specific joints (knee, hands) and topical capsaicin (hands) is recommended as initial therapy. NSAIDs or possibly a cyclooxygenase-2 (COX-2)–selective inhibitor (celecoxib) can be prescribed after careful risk assessment if additional pain control is needed. Intra-articular corticosteroid injections (knee or hip) can relieve pain and are offered concomitantly with oral analgesics or after failed trials of first-line medications, depending on the practitioner's preference. With centrally acting serotonin reuptake inhibition and analgesic properties, tramadol can also be considered if acetaminophen or topical treatment is ineffective or not tolerated.

Opioid analgesics may be considered if first-line medications are ineffective or pose significant safety concerns in an individual patient. Consideration can also be given to duloxetine or less likely, HA injections when additional pain control is needed for knee OA. When symptoms are intractable or there is significant loss of function, joint replacement can be appropriate if the patient is a surgical candidate.

There is general agreement that glucosamine and/or chondroitin and topical rubefacients lack uniform efficacy in the treatment of hip and knee OA pain and are not preferred treatment options.

Nonpharmacologic Therapy

6 Nonpharmacologic therapy is an integral part of the treatment plan for all patients with OA.[38,40,41] Nonpharmacologic therapy is the only available treatment that has been shown to delay the progression of OA.[42] Delaying the progression of OA through active participation in nonpharmacologic therapy is critical to prevent future functional impairment. Patient-specific characteristics such as (1) number and location of affected joints, (2) degree of functional impairment, (3) body mass index (BMI), (4) motivation, and (5) overall health status determine which nonpharmacologic therapies should be offered. Nonpharmacologic therapy should be ongoing treatment for all patients, even those who require pharmacologic therapy for pain control **(Table**

90-1).

TABLE 90-1 Nonpharmacologic Interventions in the Treatment of OA[37,38,39]

Type of Nonpharmacologic Intervention	Strength of Recommendation
Exercise	Strong
Weight loss (if overweight)	Strong
Patient education	Strong
Use of assistive device (ie, cane)	Moderate
Use of shoe insoles	Moderate
Application of heat	Moderate
Use of fitted knee braces	Minimal
Lateral patellar taping	Minimal
Passive exercise alone	Minimal

Strength of recommendation: Strong—fully supported by evidence-based guidelines, moderate—supported by evidence-based guidelines, minimal—little support by evidence-based guidelines.

Patient Education

The first step in OA treatment is patient education about the disease process, the extent of OA, the prognosis, and treatment options. Education is paramount because OA is often seen as a wear-and-tear disease, an inevitable consequence of aging for which nothing helps. Even worse, patients may resort to the use of alternative but unproven medications or treatments. Organizations such as the Arthritis Foundation provide a wealth of educational information for patients regarding OA, OA medications, information about local clinics, and agencies offering physical and economic assistance. Exercise, weight loss, and nutritional information are also available. Most educational information is readily available online for patient use. Several mobile applications are available to provide education, track symptoms and exercise, and encourage better self-management of OA.

The benefits of patient education have been documented in a variety of programs.[43] These programs are provided across a wide spectrum of delivery methods: from trained volunteers using telephone calls to group sessions for patient support to one-on-one educational sessions with physical therapists or nurse educators. While nearly all of these delivery methods are effective, cost of delivery is highly variable. Long-term cost-effectiveness is very important for sustainability of these patient education programs.

Weight Loss

The association between OA and obesity has been well established. Studies also indicate a strong association between increasing BMI and surgical replacement of the hip and knee joints.[44] Weight loss of amounts as small as 4% body weight can lessen OA pain in the knee.[45] Greater amounts of weight loss, especially when associated with regular exercise improve joint function and substantially

lessen pain.[45] Modest weight loss (5%) has been shown to provide some relief in obese patients with OA, but the goal weight loss should be an initial decrease in body weight of at least 10% to provide significant reductions in pain.[44] Patients with appropriate indications for bariatric surgery have significant improvement in joint function and pain associated with the subsequent weight loss.[46] The Intensive Diet and Exercise for Arthritis (IDEA) trial found that after 18 months, overweight and obese adults with knee OA who participated in the diet and exercise treatment group had less inflammation, less pain, better function, and better quality of life.[47] Weight loss requires a motivated patient, but it should be encouraged and supported for all obese and overweight patients with OA. Effective behavior change strategies should be employed to promote weight loss in patients with OA.[42]

Exercise

Exercise programs can improve joint function and can decrease disability, pain, and analgesic use by OA patients.[48,49] Low-impact aerobic exercise including both land- and water-based methods are preferred.[50] Exercises can be taught and then observed before the patient exercises at home. The frequency, types of exercise and setting of exercise are still uncertain, but patients who exercise at least two to three times per week with a variety of exercises (>8 types) have improved outcomes.[51] The patient should be instructed to decrease the number of repetitions if severe pain develops with exercise.

Some regular exercise should be encouraged for all patients with OA.[40] With weak or deconditioned muscles, the load is transmitted excessively to the joints; so weight-bearing activities can exacerbate symptoms. Many patients fear that exercise will promote further joint damage and avoid exercise as a means to protect the joint. However, avoidance of regular exercise by those with hip or knee OA leads to further deconditioning and/or weight gain. Further weight gain and deconditioning leads to more pain and impaired joint function, promoting a downward spiral of disability. Exercise therapy in addition to patient education has been shown to decrease or postpone the need for hip replacement surgery in patients with hip OA.[52]

Referral to the physical and/or occupational therapist is especially helpful for developing a customized exercise plan for patients with functional disabilities. The therapist can assess muscle strength and joint stability and recommend exercises and assistive and orthotic devices, such as canes, walkers, braces, heel cups, splints, or insoles for use during exercise or daily activities. Heat or cold treatments help maintain and restore joint range of motion and to reduce pain and muscle spasms. Warm baths or warm water soaks may decrease pain and stiffness. Heating pads should be used with caution, especially in the elderly. Patients should be warned not to fall asleep on the heat source or to lie on it for more than brief periods to avoid burns.

Surgery

Surgery can be recommended for OA patients with functional disability and/or severe pain unresponsive to medical therapy. Criteria for total joint replacement (arthroplasty) of the knee and hip have been developed although there is substantial overlap in eligibility criteria.[53] Total joint

replacement surgeries are quite common and expected to increase. By 2030, projections estimate that 3.5 million total knee replacements will occur annually.[54] Although total knee arthroplasty can decrease pain and improve function for many patients, about 20% experience little or no improvement in pain, disability, and/or quality of life.[55]

Total joint arthroplasty is responsible for a large portion of the direct medical costs associated with OA in the United States. The cost-effectiveness of total knee arthroplasty has been evaluated for a Medicare-age population.[56] Calculations were based on Medicare claims data and costs and outcomes data. Cost projections were calculated for lifetime costs as well as quality-adjusted life expectancy (QALE) for different risk populations and across low-volume to high-volume hospitals. Although total knee arthroplasty was found to be cost-effective across hospital settings and patient risk categories, the procedure was found to be most cost-effective when performed in high-volume centers. Compared with nonsurgical management, knee arthroplasty is cost-effective at both low and high levels of improvement in pain and function in patients with severe knee OA.[54]

Other surgical options are also available. Arthrodesis (joint fusion) can reduce pain but will restrict motion and may be appropriate for smaller joints that are causing intractable pain. For patients with mild knee OA, an osteotomy (removal of bony tissue) may correct the misalignment of genu varum ("bowlegged" knees) or genu valgum ("knock-knees"). In addition, osteotomies of the pelvis or femur can ameliorate joint misalignment in hip OA, subsequently slowing progression of disease. Knee arthroscopy or lavage is not recommended.[38,50]

Pharmacologic Therapy

Drug therapy in OA is targeted at relief of pain. OA is commonly seen in older individuals who have other medical conditions, and OA treatment is often long-term. As such, a conservative and patient-centered approach to drug treatment is warranted.[38,39,40,41] (**Figs. 90-4** and **90-5**) Even when pharmacologic therapy is initiated, appropriate nondrug therapies should be continued and reinforced. Specific drug therapy recommendations depend on which joint(s) are affected, response to previous trials of medication, and patient comorbidities.

Knee and Hip OA

First-Line Treatments

Acetaminophen

7 The American College of Rheumatology, as well as others, recommend acetaminophen as a first-line treatment for knee and hip OA **(Fig. 90-4)**.[38,40,57] Acetaminophen has been extensively studied in the treatment of knee and hip OA and is more effective than placebo in controlling OA pain.[58] Compared with oral NSAIDs, acetaminophen may be modestly less effective, but it has a lower risk of serious GI and cardiovascular adverse events and as a consequence is preferred as first-line treatment.[57] The significantly lower risks of both minor and major adverse events associated with acetaminophen in the treatment of knee and hip OA favors a trial of acetaminophen in all patients without underlying hepatic disease.[57]

Oral NSAIDs

If the patient fails acetaminophen, the American College of Rheumatology and other key groups

recommend nonspecific or COX-2 selective NSAIDs, depending on patient risk factors, as a first-line option for knee and hip OA.[38,40,57] NSAIDs have a consistent record of providing superior pain relief in comparison to acetaminophen, but no NSAID has proven superior to another.[57] Nonselective and COX-2 selective NSAIDs pose higher risks for GI, renal, and cardiovascular adverse events compared with acetaminophen. COX-2 inhibitors carry less risk for both minor and serious GI adverse events in comparison to nonselective NSAIDs (with the exception of diclofenac). It is unclear whether the reduced GI risk seen with COX-2 selectivity persists past 3 to 6 months, and this advantage is substantially diminished for patients taking aspirin.[57] PPIs and misoprostol significantly reduce the occurrence of GI adverse events in those taking NSAIDs.[57]

Topical NSAIDs–Knee Only

8 The American College of Rheumatology and other authorities recommend topical NSAIDs as a first-line option for knee OA if the patient fails acetaminophen, and is preferred over oral NSAIDs for those older than 75.[38,40,57] Randomized trials have demonstrated that topical NSAIDs provide pain relief for OA similar to that obtained with oral NSAIDs but with fewer GI adverse events. Topical NSAIDs are associated with more frequent local (application site) adverse events compared with oral NSAIDs.[57]

Intra-Articular Corticosteroids

Intra-articular corticosteroid injections are recommended as alternative first-line treatment for both knee and hip OA when pain control with acetaminophen or NSAIDs is suboptimal.[38,40] Injections can also be administered with concomitant oral analgesic therapy as needed for additional pain control. Intra-articular corticosteroids are generally safe and well tolerated, but should not be administered more frequently than once every 3 months due to risks of systemic adverse effects.

Tramadol

Tramadol is recommended as an alternative first-line treatment of knee and hip pain due to OA in patients who have failed treatment with scheduled full-dose acetaminophen and topical NSAIDs, who are not appropriate candidates for oral NSAIDs and are not able to receive intra-articular corticosteroids.[40] Tramadol can also safely be added to partially effective acetaminophen or oral NSAID therapy. Fewer data support the use of tramadol as monotherapy for OA pain.

Second-Line Treatments

Opioid Analgesics

The American College of Rheumatology recommends opioid analgesics as the primary second-line medication for both knee and hip OA.[40] Opioids should be considered in patients who have not had an adequate response to both nonpharmacologic and first-line pharmacologic therapies. Patients who are at high surgical risk, precluding joint arthroplasty are also candidates for opioid therapy. Opioids provide effective short-term pain control in patients with OA, although data from long-term

use trials are less compelling.[59] Adverse effects, including serious events, limit the routine use of opioids in the treatment of OA pain. Common adverse events include nausea, vomiting, constipation, somnolence, and dry mouth. Serious events include falls, respiratory depression, and addiction.[59]

Duloxetine

Duloxetine can be used as adjunctive treatment in patients with a partial response to first-line analgesics.[38,40] It may be a preferred second-line medication in patients with both neuropathic and musculoskeletal OA pain. Duloxetine has demonstrated efficacy primarily as add-on therapy when there has been less than optimal response to acetaminophen or oral NSAIDs.[60,61] Reduction in pain occurs at about 4 weeks after initiation.[62] Adverse events associated with duloxetine in the treatment of knee and hip OA are most commonly GI with nausea, vomiting, and constipation being the most common. The recommended dose is 60 mg once daily. However, some patients may benefit from higher doses; up to a maximum dose of 120 mg daily.[62] Adverse events have not been reported in OA trials that most commonly used doses of 60 mg per day. A higher dose is associated with an increased risk of adverse reactions.

Intra-Articular Hyaluronic Acid

The American College of Rheumatology, NICE, and others do not routinely recommend the use of intra-articular HA injections for knee OA pain.[38,40,41] HA injections do not appear to provide clinically meaningful improvement in pain and/or function scores, although some studies may report statistical differences in scores. These agents may be associated with serious adverse events such as increased pain, joint swelling, and stiffness. Limited efficacy and risks of serious events limit the routine use of these agents.

Hand Osteoarthritis

First-Line Treatments

Nonsteroidal Anti-inflammatory Drugs

The American College of Rheumatology and NICE recommend topical NSAIDs as a first-line option for hand OA (Fig. 90-5).[41] Application of diclofenac gel compared with vehicle for hand OA provided significant relief, with mild application-site paresthesia as the only treatment-related adverse effect.[63] Topical diclofenac showed similar efficacy as oral ibuprofen and oral diclofenac, but with fewer GI adverse events.[64,65] Topical diclofenac was associated with more frequent local (application site) events compared with oral NSAIDs. In all of these studies, topical diclofenac had fewer GI adverse events.[57,64,65]

Oral NSAIDs are recommended as an alternative first-line treatment for hand OA by the American College of Rheumatology and as second-line therapy in the NICE guidelines.[40,41] For hand OA, there has long been a focus toward topical treatment, perhaps due to reluctance to undergo systemic exposure to strong treatment in patients without pain in a weight-bearing joint.[65] For the person

who cannot tolerate local skin reactions or who received inadequate relief from topical NSAIDs, oral NSAIDs can offer relief, but the patient then faces increased risk for GI, renal, and cardiovascular adverse events.

Topical Capsaicin

Capsaicin cream is recommended as an alternative first-line treatment for hand OA.[40] Clinical trial data supporting the use of capsaicin for the treatment of hand OA are limited to small studies, but the agent demonstrates modest benefits in improvement of pain scores.[64] Adverse effects associated with capsaicin are primarily skin irritation and burning, therefore it is a reasonable therapeutic alternative for patients not able to take oral NSAIDs.

Tramadol

Tramadol is recommended by the American College of Rheumatology as an alternative first-line treatment for OA of the hand.[40] In clinical practice, tramadol is a therapeutic option for patients who do not respond to topical therapy and are not candidates for oral NSAID treatment because of high GI, cardiovascular, or renal risks. Tramadol may also be used in combination with partially effective acetaminophen, topical therapy, or oral NSAIDs.

Drug Class Information

Highlighted drug information will be reviewed further. This section is not intended to be all inclusive, but aims to provide pertinent drug information to facilitate the safe and effective use of these medications in patients with OA (Table 90-2).

TABLE 90-2 Drug Dosing Table

Drug	Brand Name	Starting Dose	Usual Range	Special Population Dose	Other
Oral Analgesics					
Acetaminophen	Tylenol	325-500 mg three times a day	325-650 mg every 4-6 hours or 1 g three to four times a day	Chronic alcohol intake, hepatic disease	Contained in many combination analgesics
Tramadol	Ultram	25 mg in the morning	Titrate dose in 25 mg increments to reach a maintenance dose of 50-100 mg three times a	Creatinine clearance <30 mL/min (<0.5 mL/s)—maximum dose is 200 mg daily	May need to taper dose upon discontinuation to prevent withdrawal symptoms
Tramadol ER	Ultram ER	100 mg daily			

Drug	Brand Name	Starting Dose	Usual Range	Special Population Dose	Other
			day Titrate to 200-300 mg daily	Do not use if creatinine clearance <30 mL/min (<0.5 mL/s)	
Hydrocodone/acetaminophen	Lortab, Vicodin	5 mg/325 mg three times daily	2.5-10 mg/325-650 mg three to five times daily	Titrate dose slowly in older patients	Maximum dose limited by total daily dose of acetaminophen
Oxycodone/acetaminophen	Percocet	5 mg/325 mg three times daily	2.5-10 mg/325-650 mg three to five times daily	Titrate dose slowly in older patients	Maximum dose limited by total daily dose of acetaminophen
Topical Analgesics					
Capsaicin 0.025% or 0.075%	Capzasin-HP		Apply to affected joint three to four times per day		—
Diclofenac 1% gel	Voltaren		Apply 2 or 4 g per site as prescribed, four times daily		
Diclofenac 1.3% patch	Flector		Apply one patch twice daily to the site to be treated, as directed. Apply 40 drops to the affected knee, applying and rubbing in 10 drops		

Drug	Brand Name	Starting Dose	Usual Range	Special Population Dose	Other
Diclofenac 1.5% solution	Pennsaid		Apply 40 drops to the affected knee, applying and rubbing in 10 drops at a time. Repeat for a total of four times daily		
Diclofenac 2% solution	Pennsaid		Apply 40 mg (2 pump actuations) twice daily		
Intra-articular Corticosteroids					
Triamcinolone	Kenalog	5-15 mg per joint	10-40 mg per large joint (knee, hip, shoulder)	If multiple joints injected, maximum total dose is usually 80 mg	Often administered concomitantly with a local anesthetic
Methylprednisolone acetate	Depo-Medrol	10-20 mg per joint	20-80 mg per large joint (knee, hip, shoulder)	10-40 mg for medium joints (elbows, wrists)	
Nonsteroidal Antiinflammatory Drugs (NSAIDs)					
Aspirin, plain, buffered, or enteric-coated	Bayer, Ecotrin, Bufferin	325 mg three times a day	325-650 mg four times a day		Doses of 3,600 mg/day are needed for anti-inflammatory activity
Celecoxib	Celebrex	100 mg daily	100 mg twice daily or 200 mg daily		
Diclofenac XR	Voltaren-XR	100 mg daily	100-200 mg daily		
Diclofenac IR	Cataflam				

Drug	Brand Name	Starting Dose	Usual Range	Special Population Dose	Other
		50 mg twice a day	50-75 mg twice a day		
Diflunisal	Dolobid	250 mg twice a day	500-750 mg twice a day		
Etodolac	Lodine	300 mg twice a day	400-500 mg twice a day		
Fenoprofen	Nalfon	400 mg three times a day	400-600 mg three to four times a day		
Flurbiprofen	Ansaid	100 mg twice a day	200-300 mg/day in two to four divided doses		
Ibuprofen	Motrin, Advil	200 mg three times a day	1,200-3,200 mg/day in three to four divided doses		Available OTC and Rx
Indomethacin	Indocin	25 mg twice a day	Titrate dose by 25-50 mg/day until pain controlled or maximum dose of 50 mg three times a day		
Indomethacin SR	Indocin SR	75 mg SR once daily	Can titrate to 75 mg SR twice daily if needed		
Ketoprofen	Orudis	50 mg three times a day	50-75 mg three to four times a day		

Drug	Brand Name	Starting Dose	Usual Range	Special Population Dose	Other
Meclofenamate	Meclomen	50 mg three times a day	50-100 mg three to four times a day		
Mefenamic acid	Ponstel	250 mg three times a day	250 mg four times a day		FDA approval for 1 week of therapy
Meloxicam	Mobic	7.5 mg daily	15 mg daily		
Nabumetone	Relafen	500 mg daily	500-1,000 mg one to two times a day		
Naproxen	Naprosyn	250 mg twice a day	500 mg twice a day		Available OTC and Rx
Naproxen sodium	Anaprox, Aleve	220 mg twice a day	220-550 mg twice a day		
Naproxen sodium controlled-release tablets	Naprelan		375-750 mg twice a day		
Oxaprozin	Daypro	600 mg daily	600-1,200 mg daily		
Piroxicam	Feldene	10 mg daily	20 mg daily		
Salsalate	Disalcid	500 mg twice a day	500-1,000 mg two to three times a day		

First-Line Treatments

Acetaminophen

Pharmacology and Mechanism of Action

Acetaminophen is understood to act within the central nervous system (CNS) by inhibiting synthesis of prostaglandins—agents that enhance pain sensations. Acetaminophen prevents prostaglandin synthesis by blocking the action of central cyclooxygenase (COX). Acetaminophen is well absorbed after oral administration, with a bioavailability of 60% to 98%. It achieves peak concentrations within

1 to 2 hours, it is inactivated in the liver by conjugation with sulfate or glucuronide, and its metabolites are renally excreted.

Adverse Effects

Although acetaminophen is one of the safest analgesics, its use carries some risks, primarily hepatotoxicity.[66] Serious hepatotoxicity, including fatalities, have been well documented with acetaminophen overdose (see Chapter 9, for information on treatment of acetaminophen overdose). Continued reports of serious hepatotoxicity, including fatalities from unintentional overdose, have led to labeling revisions of all nonprescription acetaminophen containing analgesics.[67] Unintentional overdoses of acetaminophen are due to a variety of circumstances including narrow therapeutic window at the maximum dose (4 g/day), interpatient differences in sensitivity to liver injury from acetaminophen, a wide array of nonprescription and prescription products that contain acetaminophen, which may be hard for patients to identify on the label, and consumers' lack knowledge about the association of acetaminophen and serious liver injury.

Acetaminophen-related hepatotoxicity is dose-dependent. Even at therapeutic doses, acetaminophen may cause transient liver enzyme elevations and is potentially hepatotoxic.[68] Acetaminophen should be used cautiously for patients with liver disease or for those who abuse alcohol.[69] The most common risk factor for liver failure for these patients was chronic alcohol intake.[70] The FDA has recommended that chronic alcohol users (three or more drinks daily) avoid acetaminophen intake as it increases the risk of liver damage or GI bleeding. Other individuals do not appear to be at increased risk of GI bleeding.

Drug–Drug Interactions and Drug–Food Interactions

Drug interactions with acetaminophen can occur; for example, isoniazid can increase the risk of hepatotoxicity. Chronic ingestion of maximal doses of acetaminophen may intensify the anticoagulant effect for patients taking warfarin; such individuals may need closer monitoring. Although food decreases the maximum serum concentration of acetaminophen by approximately half, the overall efficacy is unchanged.

Dosing and Administration

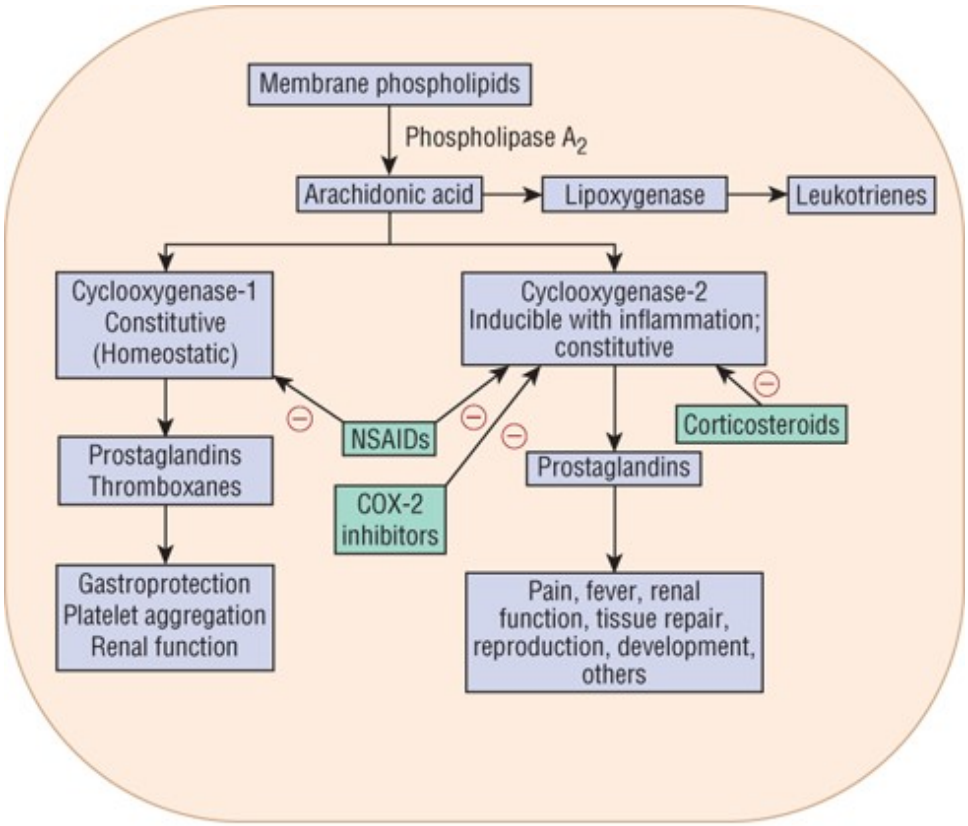
When used for chronic OA, acetaminophen should be administered in a scheduled manner. It may be taken with or without food. Acetaminophen can be taken at 325 to 650 mg every 4 to 6 hours, but the total dose must not exceed 4 g daily (see "Adverse Effects" under "Acetaminophen"). FDA labeling requirements warn patients about potential liver toxicity if they inadvertently ingest more than the recommended dose when using multiple products containing acetaminophen. Additionally, prescription analgesics containing acetaminophen are limited to 325 mg per tablet to further decrease the opportunity for inadvertent overdose. Acetaminophen should be avoided in the setting of chronic alcohol intake or in those with underlying liver disease.

Oral Nonsteroidal Anti-inflammatory Drugs

NSAIDs reduce pain, inflammation, and fever by preventing synthesis of tissue prostaglandins and related prostanoids, which play a role in triggering these symptoms. All NSAIDs bind (reversibly) to the COX-2 enzyme, blocking its action and thus prostanoid production. Blockade of prostaglandin synthesis by inhibiting COX enzymes (mainly COX-2) is thought to account for NSAIDs' ability to relieve pain and inflammation (**Fig. 90-6**).[71] Nonselective NSAIDs were developed prior to extensive knowledge of COX enzymes, but in fact they block both COX-2 and COX-1. COX-1 has required "housekeeping" functions such as gastroprotection. COX-2 inhibitors selectively block COX-2 but not COX-1 activity.

FIGURE 90-6

Pathway of synthesis for prostaglandins and leukotrienes. COX-1 and COX-2 are cyclooxygenase-1 and cyclooxygenase-2 enzymes, respectively. The minus (–) sign indicates inhibitory influence. Prostaglandins include PGE_2 and PGI_2; the latter is also known as prostacyclin.



The various NSAIDs exhibit several pharmacokinetic similarities, including high oral availability, high protein binding, and absorption as active drugs (except for sulindac and nabumetone, which require hepatic conversion for activity). There is a broad range of serum half-lives for different NSAIDs, which influence dosing frequency, and potentially, compliance with therapy.[72] Elimination of NSAIDs largely depends on hepatic inactivation, with a small fraction of active drug being renally excreted. NSAIDs

penetrate joint fluid, reaching approximately 60% of blood levels.

Adverse Effects

GI Effects of Nonselective NSAIDs

The most common adverse effects of NSAIDs involve the GI tract, contributing to many treatment failures.[73,74] Minor complaints such as nausea, dyspepsia, anorexia, abdominal pain, heartburn, and diarrhea affect 10% to 60% of patients. All NSAIDs increase ulcer risk, but the serious GI complications associated with NSAIDs include perforations, gastric outlet obstruction, and bleeding. These important GI complications occur in 1.5% to 4% of patients per year. NSAIDs are so widely used that these small percentages translate into substantial morbidity and mortality. Moreover, the risk increases substantially for patients with risk factors including a longer duration of NSAID usage, higher dosage, age older than 60, history of peptic ulcer disease of any cause, history of alcohol use, and concomitant use of glucocorticoids and/or anticoagulants.[71] A patient treated with NSAIDs has a three- to five-time higher risk of developing GI complications than a patient not treated with these medications.[75]

9 Options are available to reduce the GI risk of traditional NSAIDs. (1) Take the lowest dose possible, and take only when needed. (2) Take with the prostaglandin analog misoprostol four times daily to reduce the rate of ulcers and serious GI complications. However, many patients cannot tolerate the GI adverse events of misoprostol, especially diarrhea. (3) Take with a PPI daily.[75] Take with a full-dose H2 blocker daily. The PPI and the H2 blocker reduce minor GI complaints and the risk of ulcers, but they are not rigorously proven to decrease the serious complications, possibly because of lack of power to detect rare events in clinical trials.

Another choice that is available to reduce risk of GI events with an NSAID is to take a COX-2 selective inhibitor ("coxib").[72,73,74] Celecoxib is the only coxib available in the United States. Because this drug does not block the "housekeeping" gene, it may not have the same GI risks, but it is important to note it is not without GI risk.[70] A meta-analysis showed that COX-2 selective inhibitors were associated with significantly fewer gastroduodenal ulcers and clinically important ulcer complications. Celecoxib has been shown to be as safe to the upper GI tract as a nonselective NSAID plus a PPI.[76] Another concern is the risk associated with NSAID use in patients taking aspirin for cardioprotection. It appears that the GI risk is lower in patients taking a coxib medication and low-dose aspirin than a nonselective NSAID. However, in patients with high GI risk the combination may still be harmful and gastroprotection is appropriate.[76]

Cardiovascular Risk of COX-2 Inhibitors and Traditional NSAIDs

Both nonselective and selective NSAIDs are associated with an increased risk for hypertension, stroke, myocardial infarction (MI), and death. NSAIDs should be avoided in patients with known active ischemic heart disease, cerebrovascular disease, and moderate-to-severe heart failure.[71] It is not entirely clear the mechanism for the cardiovascular effects of NSAIDs.[75] NSAIDs are associated with hypertension, increased preload, volume expansion, and reduced sodium excretion.[77] A large

meta-analysis showed some differences among NSAIDs in terms of vascular risk. The risks with diclofenac and ibuprofen were similar to that of coxibs, but naproxen was not associated with an increased risk of major vascular events. Overall, coxibs were found to increase vascular risk by approximately one-third.[78]

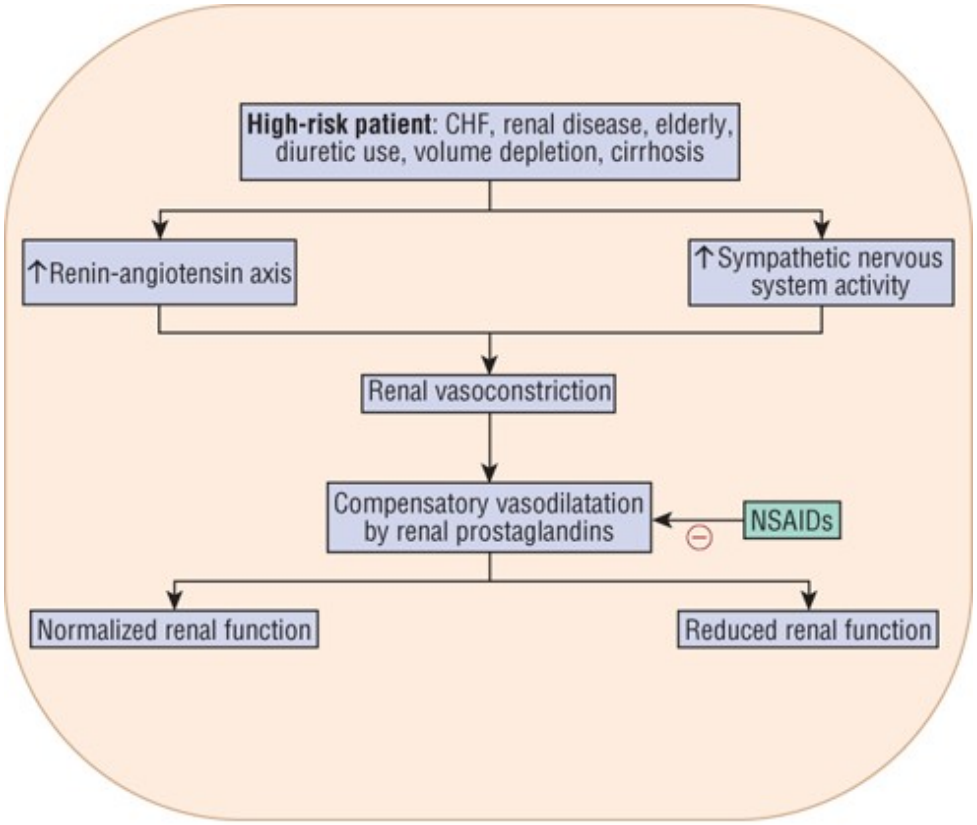
In February 2014, an advisory committee to the FDA met to discuss the data relating the cardiovascular risk and NSAIDs. After their review, FDA decided to strengthen the warning label for non-aspirin NSAIDs, warning patients on the risk of heart attack and stroke. The updated labeling warns that cardiovascular events can happen at any point during NSAID therapy, and the risk may increase with longer treatment and higher doses. The FDA concluded that there was insufficient evidence that the risk of any NSAID was higher or lower than another. An increased risk for cardiovascular events is present even in patients with no underlying cardiovascular disease. The data reviewed also showed patients taking an NSAID following a first MI were more likely to die in the first year following the MI.[79,80] Strategies to reduce cardiovascular risk with NSAIDs are not well documented. Naproxen may present less cardiovascular risk than coxibs and diclofenac at higher doses; its use therefore seems prudent to consider when choosing a specific NSAID.[75,76,79]

Other Toxicities Associated with NSAIDs

NSAIDs may cause kidney diseases, including acute renal insufficiency, sodium retention, acute interstitial nephritis, renal papillary necrosis, and accelerated chronic kidney disease. Sodium retention has been reported to occur in up to 25% of NSAID-treated patients and can be a cause of exacerbations of congestive heart failure.[77] Clinical features of these NSAID-induced renal syndromes include increased serum creatinine and blood urea nitrogen, hyperkalemia, elevated blood pressure, peripheral edema, and weight gain. Patients at high risk are those with conditions associated with decreased renal blood flow or taking certain medications. Examples are those with chronic renal insufficiency, congestive heart failure, severe hepatic disease, and nephrotic syndrome, those of advanced age, or those taking diuretics, angiotensin-converting enzyme inhibitors, cyclosporine, or aminoglycosides (**Fig. 90-7**).

FIGURE 90-7

Mechanisms implicated in NSAID-induced renal injury. The minus (–) sign indicates inhibitory influence (CHF, congestive heart failure; NSAIDs, nonsteroidal anti-inflammatory drugs).



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Close monitoring is advisable for high-risk patients taking an NSAID, with monitoring of serum creatinine at baseline and within 3 to 7 days of drug initiation. For those with impaired renal function, the National Kidney Foundation recommends acetaminophen over NSAIDs, although acetaminophen may pose risks, as discussed earlier.

Coxibs and NSAIDs uncommonly cause drug-induced hepatitis; the two NSAIDs most frequently implicated are diclofenac and sulindac. Patient monitoring should include periodic liver enzymes (aspartate aminotransferase and alanine aminotransferase), with cessation of therapy if these values exceed two to three times the upper limit of normal. In a pooled analysis of 41 studies including celecoxib, there was a low rate of serious, hepatic-related adverse events with celecoxib (1.11%), with no significant difference from naproxen or ibuprofen, but a significantly higher incidence with diclofenac (4.24%).[81]

Other toxic effects of NSAIDs include hypersensitivity reactions, rash, and CNS complaints of drowsiness, dizziness, headaches, depression, confusion, and tinnitus.[72] It is also recommended that NSAIDs be avoided for patients with asthma who are aspirin-intolerant.

All nonspecific NSAIDs inhibit COX-1–dependent thromboxane production in platelets and thus increase bleeding risk. Unlike aspirin, celecoxib and nonspecific NSAIDs inhibit thromboxane formation reversibly, with normalization of platelet function 1 to 3 days after the drug is stopped. Warfarin and celecoxib are metabolized by the cytochrome P450 isoenzyme CYP2C9; patients receiving warfarin and COX-2 inhibitors should be followed closely.

Finally, if misoprostol is taken for GI protection, great care is indicated. Because of its abortifacient properties, misoprostol is contraindicated in pregnancy and in women of childbearing age who are not maintaining adequate contraception. It must be dispensed in its original container, which carries a warning for these individuals. Misoprostol is also available in a combination product with diclofenac, which bears the same restrictions as misoprostol alone.

Drug–Drug Interactions

Avoidance of concomitant use, or anticipation and careful monitoring, can often prevent serious events with potentially interacting drugs. The most potentially serious interactions include the use of NSAIDs with lithium, warfarin, other agents that increase bleeding risk, oral hypoglycemics, methotrexate, antihypertensives, angiotensin-converting enzyme inhibitors, β-blockers, and diuretics.[72] In addition, there are probable drug interactions with tacrolimus for ibuprofen, naproxen, diclofenac, and possibly other NSAIDs.

Specific drug interactions are also seen with celecoxib.[82] Celecoxib metabolism is primarily via CYP2C9.[82] Cytochrome P450 inducers such as rifampin, carbamazepine, and phenytoin have the potential to reduce celecoxib levels. Concomitant administration of celecoxib with fluconazole can increase plasma concentrations of celecoxib, due to fluconazole inhibition of the CYP2C9 isoenzyme. Because warfarin and celecoxib are both metabolized by CYP2C9, patients receiving warfarin and COX-2 inhibitors should be followed closely. Because celecoxib inhibits CYP2D6, it has the potential to increase concentrations of a variety of agents, including antidepressants. Celecoxib is a sulfonamide and is thus noted to be contraindicated for those with sulfa allergies.[82]

Another drug interaction has been noted for those taking some NSAIDs and cardioprotective doses of aspirin. Ibuprofen, used at doses of 400 mg or more, may block aspirin's antiplatelet effect if it is taken before aspirin. Patients taking ibuprofen have been advised to take a single dose of ibuprofen at least 30 minutes after taking aspirin, or to take their aspirin at least 8 hours after taking ibuprofen. Other nonselective NSAIDs, such as naproxen, also may cause such interactions. Currently, the ACR recommends that patients who need an oral NSAID for OA choose an NSAID other than ibuprofen or COX-2 selective inhibitors.[40] Acetaminophen does not appear to interfere with the antiplatelet effect of aspirin.

Dosing and Administration

Administration of NSAIDs must be tailored to the individual patient with OA. Selection of an NSAID depends on the prescriber's experience, medication cost, patient preference, allergies, toxicities, and adherence issues. Individual patient response differs among NSAIDs, so if an inadequate response is obtained with one NSAID, another NSAID may yet provide benefit.[40,41]

Topical Nonsteroidal Anti-inflammatory Drugs

Pharmacology and Mechanism of Action

The mechanism of action of topical NSAIDs is considered to be through inhibition of the COX-2 enzyme in tissues near the site of application. Studies show significant placebo effects that could result from rubbing the product into the skin, which may have a counterirritant effect. Topical NSAIDs are significantly more efficacious compared with placebo vehicle in reducing pain due to musculoskeletal conditions, including OA. Most trials have shown topical diclofenac to be as effective as oral NSAIDs, including both oral diclofenac and other comparators.[57,65,83] Diclofenac 1% gel as well as the newer diclofenac solution, and diclofenac patches are currently approved in the United States for OA.

Adverse Effects

Compared with oral NSAIDs, topical NSAIDs are associated with many fewer GI adverse events and fewer adverse events overall, except for local application site reactions. In comparison with placebo or oral NSAIDs, topical NSAID use is associated with more local adverse events, most often mild skin reactions such as itching or rash, but with very few serious adverse effects. In a comparison of oral (n=311) and topical diclofenac (n=311), significantly more persons receiving topical diclofenac developed dry skin, rash, and itching, but none was considered serious. However, significantly more persons receiving oral diclofenac had severe GI effects, asthma, dizziness, dyspnea, change from normal to abnormal hemoglobin, alanine aminotransferase increase to more than three times upper the limit of normal, and creatinine clearance changing from normal to abnormal.[57]

A nested case–control study from the United Kingdom revealed no significant association between topical NSAID use and renal failure, whereas oral NSAID use was significantly associated with a doubling of risk.[57] An estimated 1% to 15% of topical NSAID enters the systemic circulation; this is usually less than 5%, which contributes to its greater safety profile.[39,83]

Drug–Drug Interactions

Interactions listed for topical diclofenac are the same as for oral NSAIDs, which are listed for oral NSAIDs. The most potentially serious interactions include the use of NSAIDs with lithium, warfarin, and other agents that increase bleeding risk, oral hypoglycemics, methotrexate, antihypertensives, angiotensin-converting enzyme inhibitors, β-blockers, and diuretics. Other topical agents have not been studied with topical diclofenac and changes in tolerability and absorption are possible. For all of these interactions, as there is only a small percentage of diclofenac absorbed, the risks are likely significantly less than with oral drug, but the patient and provider would have to be wise to monitor appropriately for these interactions with any of these drugs the patient is taking. Patients should avoid oral NSAIDs while using topical products to minimize potential for additive adverse effects. Care should be taken to avoid contact with the eyes or open wounds and to wash hands after application (except when treating hand OA).

Dosing and Administration

Diclofenac 1% gel (Voltaren) can be used for hand or knee OA or other joints amenable to topical application (eg, not the hip). It is applied four times daily using the dose measuring cards provided by

the manufacturer. The gel (4 g) is recommended for application to the affected area in the lower limb four times daily, and for upper extremities, the dose is 2 g four times daily. Diclofenac solution (Pennsaid®), only approved for knee OA, is available in 1.5% and 2% solution. Forty drops of the 1.5% solution are to be applied four times a day to each affected knee. The solution should be applied to the back, front, and sides of the knee. For each dose, the patient is advised to place 10 drops at a time directly onto the painful knee (or first into the hands and then immediately spread onto the knee) and rub the solution in. The patient is advised to repeats this process three more times until 40 drops have been applied to the painful knee for that particular dose. The 2% diclofenac solution is available in a meter-dose pump. Two actuations or 40 mg are applied twice daily to the affected knee(s). The entire dose should be pumped into the palm of the hand then applied evenly to the knee. The diclofenac patch (diclofenac epolamine 180 mg) is applied twice daily. If the patch does not stick well, the patient can secure the edges using first-aid tape. Patient counseling is important to carefully explain how to apply the topical products and how long to wait before dressing, putting on gloves, showering, and so forth.

Intra-Articular Corticosteroids

Pharmacology and Mechanism of Action

The anti-inflammatory properties of corticosteroids as a class are the primary mechanism of pain relief in the treatment of OA. These properties decrease the formation and release of prostaglandins, kinins, liposomal enzymes, and histamine. These actions decrease erythema, swelling, heat, and tenderness of the inflamed joints.[40,84] Aspiration of the effusion and injection of glucocorticoid are carried out aseptically, with examination of the aspirate recommended to exclude crystalline arthritis or infection. Several randomized, placebo-controlled, double-blind studies have shown that intra-articular corticosteroids are superior to placebo in alleviating knee pain and stiffness caused by OA but with a relatively short duration.[84] The most commonly used corticosteroids for intra-articular use are triamcinolone acetonide and methylprednisolone acetate. The branched esters of triamcinolone and methylprednisolone are preferred by practitioners because of the reduced solubility that allows the agents to remain in the joint space longer.[85,86]

Adverse Events

Adverse events associated with intra-articular injection of corticosteroids can be local or systemic in nature. Systemic adverse events are the same as with any other systemic corticosteroid and can include hyperglycemia, edema, elevated blood pressure, flushing, dyspepsia, and hypercortisolism. Evidence shows an acute (2- to 3-day) rise in blood glucose in patients with diabetes following a single corticosteroid injection. The risk of systemic adverse effects can be lessened by limiting the dose of the corticosteroid since doses greater than 40 mg for triamcinolone or methylprednisolone have not been shown to provide any additional benefit.[86] Local adverse effects can include infection in the affected joint, osteonecrosis, tendon rupture, and skin atrophy at the injection site. Systemic corticosteroid therapy is not recommended in OA, given the lack of proven benefit and the well-known adverse effects with long-term use.

Dosing and Administration

Doses for injection of triamcinolone and methylprednisolone acetate into large joints in adults are shown in **Table 90-2**. Local anesthetics such as lidocaine or bupivacaine are commonly combined with corticosteroids to provide rapid pain relief.[86] This therapy is generally limited to three or four injections per year due to the potential systemic effects of corticosteroids and because the need for more frequent injections indicates little response to the therapy.

After injection, the patient should minimize activity and stress on the joint for several days. Initial pain relief may be seen within 24 to 72 hours after injection, with peak pain relief about 7 to 10 days after injection and lasting up to 4 to 8 weeks.

Capsaicin

Pharmacology and Mechanism of Action

Capsaicin, isolated from hot peppers, releases and ultimately depletes substance P from afferent nociceptive nerve fibers. Substance P has been implicated in the transmission of pain in arthritis, and capsaicin cream has been shown in four placebo-controlled studies to provide pain relief in knee and hand OA when applied over affected joints.[65] Due to the larger surface area and distance from the site of application to the joint, it is not expected that application of capsaicin would provide efficacy in the treatment of hip OA.

Adverse Effects

Adverse events associated with capsaicin are primarily local, with one in three patients experiencing burning, stinging, and/or erythema that usually subsides with repeated application. The FDA has issued a public drug safety communication notifying consumers that rare cases of severe burns have been reported.[87] Some patients may experience coughing associated with application.

Dosing and Administration

To be effective, capsaicin must be used regularly, and it may take up to 2 weeks to take effect. Although use is recommended four times a day, a twice-daily application may enhance long-term adherence and still provide adequate pain relief.[65] Patients should be counseled not to get the cream in their eyes or mouth. Patients should also notify their healthcare provider immediately if they experience pain, swelling, or blistering skin at the site of application.

Capsaicin is a nonprescription product available as a cream, gel, solution, lotion, or patch in concentrations ranging from 0.025% to 0.15%.

Tramadol

Pharmacology and Mechanism of Action

10 Tramadol, an analgesic with affinity for the μ-opioid receptor, as well as weak inhibition of the reuptake of norepinephrine and serotonin neurotransmitter, has shown moderate pain improvement for patients with OA when compared with placebo.[88,89] Tramadol is also modestly effective as add-on therapy for patients taking concomitant acetaminophen, NSAIDs, or COX-2–selective inhibitors. Tramadol may be helpful for patients who cannot take NSAIDs or COX-2–selective inhibitors.

Adverse Events

Opioid-like adverse effects such as nausea, vomiting, dizziness, constipation, headache, and somnolence are common with tramadol. These occur in 45% to 84% of treated patients.[90] Although the frequency of adverse effects is high, the severity of adverse effects is less than with NSAIDs, as tramadol use is not associated with life-threatening GI bleeding, cardiovascular events, or renal failure. The most notable serious adverse event associated with tramadol use is seizures. Withdrawal symptoms can occur if tramadol is stopped abruptly. Patients older than 65 are significantly more likely to experience adverse events.[90] Tramadol was initially not classified as a controlled substance but has been rescheduled as a class IV controlled substance due to its potential for dependence, addiction, and diversion.[91]

Drug–Drug Interaction

Medications that lower the seizure threshold should be used with caution in patients taking tramadol. These include tricyclic antidepressants, first-generation antipsychotic medications, and cyclobenzaprine, as well as others. There is also an increased risk of serotonin syndrome (see Chapter 9, for information on this condition) when tramadol is used concomitantly with other serotonergic medications, including duloxetine.

Dosing and Administration

Tramadol should be initiated at a lower dose (100 mg per day) and may be titrated as needed for pain control to a dose of 200 mg per day, with a maximum dose of 400 mg per day. Tramadol is available in a combination tablet with acetaminophen and as an extended-release tablet or capsule.

Second-Line Treatments

Opioid Analgesics

Opioid analgesics may be useful for patients who experience limited pain relief with acetaminophen, oral NSAIDs, intra-articular injections, or topical therapy or who cannot tolerate the adverse effects of these agents.[70] For patients with underlying conditions that limit the use of first-line analgesics, opioid analgesics can effectively relieve acute OA pain. A common clinical scenario may include the patient who cannot take oral NSAIDs because of renal failure or cardiovascular disease. Patients in whom all other treatment options have failed and who are at high surgical risk, precluding joint arthroplasty are also candidates for opioid therapy. It is important to carefully use opioids to promote

safety. The CDC recommends the best practice for prescribing opioid include using the lowest effective dose and the smallest quantity needed, providing patients with information on how to use, store, and dispose of opioid medications, and avoiding combinations of opioids and sedating medications unless there is a specific indication to do so.[92]

Sustained-release (SR) compounds usually offer better pain control throughout the day, and are used when immediate-release (IR) opioids do not provide a sufficient duration of pain control. A variety of immediate and sustained-release opioid compounds have been studied including oxycodone IR and SR, morphine IR and SR, hydromorphone, and fentanyl transdermal patch.[59]

Adverse effects are common in opioid-treated OA patients. More than 75% of patients in clinical trials experience at least one typical opioid-related (ie, nausea, somnolence, constipation, dry mouth, and dizziness) adverse effect. Although this is not an unexpected finding, it serves as a reminder to use opioids cautiously in elderly patients who may be more susceptible to adverse effects.

Opioid dependence, addiction, tolerance, hyperalgesia, and issues surrounding drug diversion are more serious adverse effects associated with long-term treatment. Prescription opioid misuse/abuse /addiction is a major public health concern with the CDC reporting more than 16,000 deaths in 2013. In 2011, there were 420,000 emergency department visits attributed to the misuse and abuse of prescription opioids.[93] Patients should be educated on the risks of taking opioids including addiction, overdose, and death.[93,94]

If pain is intolerable and limits activities of daily living, and the patient has sufficiently good cardiopulmonary health to undergo major surgery, joint replacement may be preferable to continued reliance on opioids.

Duloxetine

Duloxetine is a centrally acting dual-reuptake inhibitor of both serotonin and norepinephrine, although norepinephrine reuptake inhibition does not occur until doses reach 60 mg per day. While the most common pain target in OA is peripheral nociceptive pain, there is some evidence that chronic nociceptive pain leads to central pain sensitization thereby lowering the pain threshold.[61] Duloxetine provides pain relief through the blocking of central pain transmitters, including serotonin and norepinephrine.

Adverse effects commonly associated with duloxetine therapy include nausea, dry mouth, constipation, and anorexia. Expected neurologic adverse effects include fatigue, somnolence, and dizziness. Rare, but serious adverse events associated with duloxetine include Stevens-Johnson syndrome and liver failure. Patients should be notified to contact their healthcare provider immediately if they develop a rash while taking duloxetine.

Particular care should be taken to avoid the use of duloxetine with other serotonergic medications including tramadol. As tramadol is a first-line treatment recommendation for OA, the likelihood of encountering this combination is high. Concomitant use of duloxetine with other medications that increase serotonin concentrations increases the risk of serotonin-syndrome.

Hyaluronic Acid Injections

Hyaluronate is a naturally occurring component of cartilage and synovial fluid. Exogenous intra-articular hyaluronate is available as a treatment for the symptoms of knee OA. The goal of intra-articular HA is to provide and maintain intra-articular lubrication. HA may also have anti-inflammatory, analgesic, and chondroprotective effects on the articular cartilage and joint synovium.[95] The efficacy of HA injections remains debated and uncertain after many trials and meta-analyses.[95] Many trials show a large placebo effect. Most HA products are injected once weekly for either 3 or 5 weeks, depending on the specific agent administered. Patients are generally advised to repeat the injection schedule by 6 months if they are satisfied with the previous course.[84] Strenuous or prolonged weight-bearing activities should be avoided for 48 hours after treatment. Routinely, the most improvement is expected from 5 to 13 weeks after injection with some effect still occurring at 24 weeks.[95] Injections are generally well tolerated, although acute joint swelling, effusion, and stiffness can occur as well as local skin reactions, including rash, ecchymosis, and pruritus have been reported. Local adverse effects are more frequent in products from animal origin.[96] Rarely, systemic adverse events including hypersensitivity reactions have occurred. Joint infections are rare but have been reported.

The effect of HA injections on knee OA appears to be modest at best.[95] HA products have not been shown to benefit patients with hip OA.[97] These agents are expensive because the treatment includes both drug costs and administration costs. Patient expectations and cost-effectiveness must be considered before choosing HA injection.[84]

Glucosamine and Chondroitin

Interest in chondroitin and glucosamine was spurred initially by anecdotal reports of benefit in animals and humans and by the ability of these substances to stimulate proteoglycan synthesis from articular cartilage in vitro. Enthusiasm for these agents has waned recently as additional efficacy data have become available to the point that the American College of Rheumatology conditionally recommends against the use of glucosamine and chondroitin.[40] Glucosamine, alone or in combination, has not been shown to provide uniform improvements in pain control or functional status in patients with OA of the knee or hip.[98]

Numerous trials have examined the safety and efficacy of glucosamine and chondroitin, but the duration of these studies has been relatively short. The efficacy of glucosamine and chondroitin was evaluated after 2 years and found not to be statistically superior than placebo.[99] The combination of glucosamine and chondroitin was well tolerated. There has previously been some concern that glucosamine may worsen diabetes or asthma; however, a 2-year follow-up trial did not substantiate this.[99] When the combination of glucosamine and chondroitin was compared with celecoxib in patients with knee OA, it was found to be noninferior in the reduction of pain at 6 months. The combination was well tolerated and the authors suggest glucosamine and chondroitin as a potential safe alternative for patients with cardiovascular or GI conditions.[100]

Because glucosamine and chondroitin are marketed in the United States as dietary supplements, neither the products nor their purity is adequately regulated by the FDA. The potential consequences related to the lack of regulatory oversight for these products can affect both efficacy and safety. Products containing less than labeled doses can compromise efficacy, while those containing ingredients not included on the labeling can compromise safety. A variety of brand name and generic products are available in various doses and formulations.

Clinical Controversy…

Vitamin D is hypothesized to play a role in many diseases including OA. Vitamin D is known to play a role in bone health and frequently vitamin D deficiency is found to coexist in older patients with OA. Studies have found conflicting evidence on whether vitamin D deficiency leads to an increased risk of development or progression of OA.

Considerations for Future Therapeutic Options

Strategies aimed at expanding therapeutic options for OA include an array of disease-modifying drugs, new drug classes to provide symptomatic relief of OA pain, and behavior modification strategies to improve patient participation in nonpharmacologic therapies.[101] Disease-modifying drugs are targeted at preventing, retarding, or reversing damage to articular cartilage. Currently, OA is a progressive disease. Current approaches to slow progression of OA are directed at three different tissue specific targets: (1) cartilage, (2) synovial membrane and associated inflammation, and (3) subchondral bone. Therapies directed at preserving cartilage include enzyme inhibitors of MMPs, inhibitors of inducible nitric oxide synthase, cathepsin K inhibitors, and nerve growth factor inhibitors.[101] Several of these investigational agents are in Phase I and Phase II clinical trials in humans.[102]

Several anti-inflammatory agents targeting symptom improvement as well as structure-modifying properties at the synovial membrane are in clinical trials. The agents include interleukin-1 inhibitors, the antitumor necrosis factor inhibitor, adalimumab, and adenosine A2 and A3 receptor agonists.[101] Current animal research supports these receptor targets to prevent ongoing joint destruction and early results for some of these agents, particularly adalimumab are encouraging.

Slowing the progression of OA may also be achieved by attempts to modify or repair bony changes associated with OA. Current strategies being evaluated in humans include the use of bisphosphonates, calcitonin, cholecalciferol, selective estrogen receptor modulators, parathyroid hormone, strontium, and MMP-13 inhibitors. The definitive role of these agents in modifying bone resorption as a strategy to delay the progression of bone damage associated with OA is yet to be determined.

Additionally, attempts to find new agents or methods to treat symptoms of OA are being made. Current research is exploring the utility of nerve growth factor inhibitors, cannabinoid receptor agonists, bradykinin receptor antagonists, kainate receptor antagonists, transient receptor potential ion channel agonists (TRVP-1).[101] Although many of these compounds are years away from potential market approval, the extensive nature of the work is encouraging.

In addition to pharmacologic agents, acupuncture has been examined in OA. In a systematic analysis of 18 randomized, controlled trials of manual or electroacupuncture, 10 showed positive effects for acupuncture.[103] However, in a recent, large, randomized, and well-controlled study, acupuncture was not seen to be any more effective than sham controls.[104]

Clinical Controversy…

The use of stem-cell therapy for the treatment of OA lacks efficacy and safety data from large, randomized, placebo controlled trials. Additionally, stem clinics in the United States are unlicensed and as such, their services are not covered by health insurance. The regulatory language authorizing stem cell clinics is ambiguous, allowing the proliferation of these entities, potentially exposing patients to risks without any known benefits.

PERSONALIZED PHARMACOTHERAPY

There is substantial negative impact on the quality of life for individual patients with OA. It is also clear that OA is associated with a negative impact on society as the disease is extremely common, and OA ranks second in causes of disability in the United States.[3,40] Most OA patients use a multidisciplinary approach to their treatment.[40] Treatments include nonpharmacologic and pharmacologic therapy, in addition to surgical options in some patients. Unfortunately, many patients have less than optimal response to treatment and commonly require a change in therapy or augmentation of partially effective therapy. Achieving adequate pain control and minimizing functional impairment in OA patients requires careful assessment of comorbid conditions in each patient to safely provide effective pharmacotherapy treatments. Nonpharmacologic interventions may also require regular reinforcement and modifications.

It is becoming more important to consider OA as significant contributor to quality-of-life measures in the patients with multiple chronic conditions. About one-half of the US population has 1 chronic health condition, and 25% have 2 or more conditions.[1] Of those with at least 1 chronic health condition, 6.1% had arthritis only and 16.6% had arthritis with at least one other condition.[1] With nearly 25% of US adults with a least one chronic health condition having arthritis, comprehensive patient-centered medication management must be provided to these patients to maximize treatment goals for OA and other chronic conditions, while minimizing medication-related adverse outcomes.

A multidisciplinary intervention for knee OA initiated by pharmacists has been shown to improve adherence to OA guideline recommendations, decrease pain scores, and improve functional assessment scores.[105] These types of multidisciplinary disease state management programs that implement strategies to provide comprehensive care should be offered to all OA patients to maximize outcomes.

Total indirect and direct medical costs for OA patients are high. Direct medical costs associated with joint replacement continue to increase at higher than predicted rates due to increasing willingness of patients to undergo joint replacement surgery.[6] The highest costs associated with the pharmacotherapy of OA are hospitalization for treatment of NSAID-related complications, particularly

serious GI adverse events. Historically, gastroprotective therapy or the use of COX-2–selective inhibitors for low-risk patients has not been cost-effective because of the large number needed to treat to prevent serious events, but most currently available PPIs are generic, multisource products, making concomitant treatment with PPIs cost-effective.[106] Pharmacoeconomic considerations for OA involve the selection of therapy for the initial treatment of patients with OA. Use of the nonprescription analgesic acetaminophen as initial therapy has greatly reduced medication costs in comparison with the use of NSAIDs, many of which are by prescription only. Oral NSAID costs vary considerably, depending on the medication, daily dose, and regimen selected. As oral NSAIDs as a class are therapeutically similar, the use of a less-expensive agent such as nonprescription ibuprofen or naproxen or a multisource generic product, may minimize the cost. More-expensive NSAIDs can be prescribed if neither of these offers benefit after a 2-week trial at sufficient doses. Topical NSAIDs are significantly more costly than oral agents, although may still be cost-effective in patients at high-risk for costly complications associated with oral NSAID therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

For the person with OA, treatment decisions and pharmacotherapy monitoring (**Table 90-3**) is patient-specific. The patient's situation and individual needs should be considered when devising a treatment plan. Is the patient bothered primarily by pain, by limitations in activity, or with concerns about side effects from medications? Does the patient understand what OA is and why certain treatments are useful?

TABLE 90-3 Drug Monitoring Table

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Oral Analgesics			
Acetaminophen	Hepatotoxicity	Total daily dose limits	Use caution with multiple acetaminophen-containing products—total 4 g limit
Tramadol	Nausea, vomiting, somnolence	No routine laboratory tests recommended	Drug–drug interaction with other serotonergic medications
Opioids	Sedation, constipation, nausea, dry mouth, hormonal changes	No routine laboratory tests recommended	Risks of addiction, dependence, and drug diversion
NSAIDs	Dyspepsia, cardiovascular events, GI bleeding, renal impairment	BUN/creatinine, hemoglobin/hematocrit, blood pressure	Risks higher in those older than 75 years of age
Topical Analgesics			

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Capsaicin	Skin irritation and burning	Inspection of areas of application	Wash hands thoroughly after application
NSAIDs	Skin itching, rash, irritation, dyspepsia, cardiovascular events, GI bleeding, renal impairment	Inspection of areas of application As needed: blood urea nitrogen/creatinine, hemoglobin/hematocrit, blood pressure	Wash hands thoroughly after application. Avoid oral NSAID or aspirin other than cardioprotective dose. Ensure patient applying gel, solution, or patch correctly
Injectable Drugs			
Intraarticular corticosteroids	Hypertension, hyperglycemia	Glucose, blood pressure	Hypothalamic–pituitary–adrenal axis suppression if used too frequently
Intraarticular hyaluronates	Local joint swelling, stiffness, pain	No routine laboratory tests recommended	Less effective than intraarticular corticosteroids; expensive

When the patient is first being assessed for the possibility of OA, the diagnosis is often straightforward, including history and physical examination, plain films of the affected joint(s), and laboratory tests. The older patient with unilateral knee pain, limited range of motion, no palpable warmth, crepitus, without prolonged morning stiffness, and without other suspicious findings, is highly likely to have knee OA. It is still reasonable to obtain x-ray films, which may help follow disease over time (although joint space narrowing often does not correlate with the extent of pain or difficulty walking). Basic laboratory tests can help decide what pharmacologic therapy is possible (eg, NSAIDs should not be used in patients with poor renal function), assessment of pain using a visual analog scale, range of motion for affected joints. Additional tests of OA severity may include measurement of grip strength, 50 ft walking time, patient and physician global assessment of OA severity, and assessment of ability to perform activities of daily living. Once the patient is assessed and diagnosed, patient and family education is essential. Nondrug therapy may include a referral for physical and/or occupational therapy services, where the therapists can help maintain and improve range of motion. Referral for nutritional counseling and weight loss may also be necessary if the patient is overweight or obese. These interventions may decrease pain and facilitate improved activity for OA patients.

Although all patients must be provided with nonpharmacologic therapies, these interventions usually require weeks to months to assess for efficacy. In the meantime, the patient needs pain relief. First-line therapy continues to be acetaminophen. Adverse events with acetaminophen are uncommon, although it is important that the patient understands the maximum daily dose limits and all possible sources of acetaminophen containing products. Although some do well on acetaminophen, many do not achieve sufficient pain relief. A step up to oral NSAIDs or opioid

therapy might be necessary but poses significant risks beyond acetaminophen. A switch to NSAIDs requires careful consideration of the patient's age and comorbidities, renal function, history of GI problems, hypertension, and cardiovascular health. Periodic monitoring would include open-ended questions followed by direct questions relating to the commonest adverse effects associated with the respective medication. For an oral NSAID, symptoms of abdominal pain, heartburn, nausea, or change in stool color provide valuable clues to the presence of GI complications, although serious GI complications can occur without warning. Patients should be monitored for the development of hypertension, weight gain, edema, skin rash, and CNS adverse effects such as headaches and drowsiness. Baseline serum creatinine, complete blood count, and serum transaminases are repeated at 6- to 12-month intervals to identify GI, renal, and hepatic toxicities.

Topical NSAIDs have demonstrated efficacy in OA of the hand and knee and are as effective as oral NSAIDs. Although they carry the same cardiovascular, renal, and GI warnings, their AUC for a typical dose is only a few percent of the AUC from an equivalent dose of oral NSAID. Topical NSAIDs' most common side effects are local, with irritated skin, rash, or itching, usually mild, and with many fewer adverse effects of cardiovascular, GI, or renal nature. These agents are a welcome addition to the limited treatment modalities for the very common, costly, painful, and often disabling disease of OA. It is important that the patient apply the topical products appropriately to achieve maximum benefit and avoiding adverse events.

For patients receiving intra-articular corticosteroids, pain relief should begin with 2 to 3 days and last 4 to 8 weeks. Patients should be advised about possible injection site reactions, as well as possible systemic effects, especially for those with hypertension or diabetes, as there is a potential for increased blood pressure or blood glucose. For patients receiving opioids or tramadol, relief from pain should occur rapidly. Frail or elderly patients should be monitored carefully and cautioned about sedation, dysphoria, nausea, risk of falls, and constipation. Additional monitoring should include strategies to assess development of opioid tolerance and addiction.

CONCLUSION

OA is a very common, slowly progressive disorder that affects diarthrodial joints and is characterized by progressive deterioration of articular cartilage, subchondral sclerosis, and osteophyte production. Clinical manifestations include gradual onset of joint pain, stiffness, and limitation of motion. The primary treatment goals are to reduce pain, maintain function, and prevent further destruction. An individualized approach based on education, rest, exercise, weight loss as needed, and analgesic medication can succeed in meeting these goals. Recommended drug treatment starts with acetaminophen less than or equal to 4 g/day and topical analgesics as needed. If acetaminophen is ineffective, oral NSAIDs may be used in appropriately selected patients, often providing satisfactory relief of pain and stiffness. Individuals at increased risk for toxicity from NSAIDs, especially for GI, cardiovascular, or renal events, deserve special attention. Celecoxib may have safety advantages in some OA patients, but its safety relative to other NSAIDs and its role in OA remains poorly defined. Adjunctive therapy with tramadol, intra-articular corticosteroids and opioid analgesics may be helpful in patients with poorly controlled pain. Experimental therapy aimed at preventing the progression of OA requires further clinical investigation before entering widespread clinical use.

Chapter 91: Rheumatoid Arthritis

Kimberly Wahl; Arthur A. Schuna

INTRODUCTION

KEY CONCEPTS

- 1 Rheumatoid arthritis (RA) is a systemic disease characterized by symmetrical inflammation of joints, yet may involve other organ systems.
- 2 Control of inflammation is the key to slowing or preventing disease progression as well as managing symptoms.
- 3 Drug therapy should be only part of a comprehensive program for patient management, which would also include physical therapy, exercise, and rest. Assistive devices and orthopedic surgery may be necessary in some patients.
- 4 Patients should be treated to target of low disease activity or remission.
- 5 Traditional or conventional synthetic disease-modifying antirheumatic drugs (referred to as DMARDs) should be started as soon as possible after diagnosis of RA.
- 6 Nonsteroidal anti-inflammatory drugs (NSAIDs) and/or corticosteroids should be considered adjunctive therapy early in the course of treatment and as needed if symptoms are not adequately controlled with DMARDs or biologic DMARDs (referred to as biologics).
- 7 When DMARDs used alone are ineffective or not adequately effective, other monotherapies or combination therapy with two or more DMARDs or a DMARD plus biologic agent may be used to induce a response.
- 8 Patients require careful monitoring for toxicity and therapeutic benefit for the duration of treatment.

Rheumatoid arthritis (RA) is the most common systemic inflammatory disease characterized by symmetrical joint involvement. Extra-articular involvement, including rheumatoid nodules, vasculitis, eye inflammation, neurologic dysfunction, cardiopulmonary disease, lymphadenopathy, and

splenomegaly, can be manifestations of the disease. Although the usual disease course is chronic, some patients will enter a remission spontaneously.

EPIDEMIOLOGY

RA is estimated to have a prevalence of 1% and does not have any racial predilections. It can occur at any age, with increasing prevalence up to the seventh decade of life. The disease is three times more common in women. In people aged 15 to 45 years, women predominate by a ratio of 6:1; the sex ratio is approximately equal among patients in the first decade of life and in those older than 60 years.

Epidemiologic data suggest that a genetic predisposition and exposure to unknown environmental factors may be necessary for expression of the disease. The major histocompatibility complex molecules, located on T lymphocytes, appear to have an important role in most patients with RA. These molecules can be characterized using human lymphocyte antigen (HLA) typing. A majority of patients with RA have HLA-DR4, HLA-DR1, or both antigens in the major histocompatibility complex region. Patients with HLA-DR4 antigen are 3.5 times more likely to develop RA than those patients who have other HLA-DR antigens.[1] Although the major histocompatibility complex region is important, it is not the sole determinant as patients can have the disease without these HLA types. RA is six times more common among dizygotic twins and nontwin children of parents with rheumatoid factor-positive, erosive RA when compared with children whose parents do not have the disease. If one of a pair of monozygotic twins is affected, the other twin has a 30 times greater risk of developing the disease.[2,3]

PATHOPHYSIOLOGY

1 Chronic inflammation of the synovial tissue lining the joint capsule results in the proliferation of this tissue. The inflamed, proliferating synovium characteristic of RA is called *pannus*. This pannus invades the cartilage and eventually the bone surface, producing erosions of bone and cartilage and leading to destruction of the joint. The factors that initiate the inflammatory process are unknown.

The immune system is a complex network of checks and balances designed to discriminate self from nonself (foreign) tissues. It helps rid the body of infectious agents, tumor cells, and products associated with the breakdown of cells. In RA, this system is no longer able to differentiate self from nonself tissues and attacks the synovial and other connective tissues.

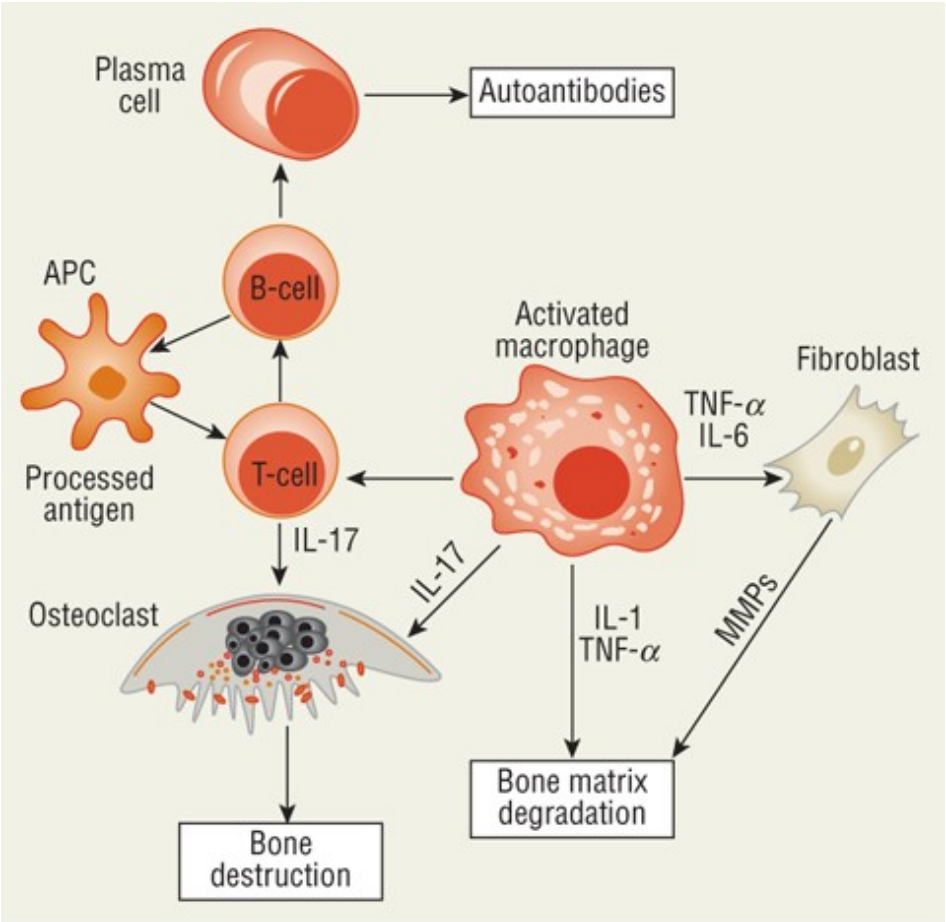
In addition to the genetic factors mentioned above, environmental factors play a role. It is known that smoking and pulmonary disease may increase risk. Infectious agents (eg, Epstein-Barr virus, *Escherichia coli*) and periodontal disease (*Porphyromonas gingivalis*) have been associated with RA.

The immune system has both humoral and cell-mediated functions (**Fig. 91-1**). The humoral component is necessary for the formation of antibodies. These antibodies are produced by plasma cells, which are derived from B lymphocytes. Most patients with RA form antibodies called *rheumatoid factors*. Rheumatoid factors have not been identified as pathogenic, nor does the

quantity of these circulating antibodies always correlate with disease activity. Seropositive patients tend to have a more aggressive course of their illness than do seronegative patients. Anticitrullinated protein antibody (ACPA) is another antibody identified, which is produced in most patients with RA and has become an important diagnostic tool. Patients may develop ACPA long before they develop symptoms of RA, and those with positive antibodies have a poorer prognosis than those without.

FIGURE 91-1

Pathogenesis of the inflammatory response. Antigen-presenting cells process and present antigens to T cells, which may stimulate B cells to produce antibodies and osteoclasts to destroy and remove bone. Macrophages stimulated by the immune response can stimulate T cells and osteoclasts to promote inflammation. They also can stimulate fibroblasts, which produce matrix metalloproteinases to degrade the bone matrix and produce proinflammatory cytokines. Activated T cells and macrophages release factors that promote tissue destruction, increase blood flow, and result in cellular invasion of synovial tissue and joint fluid. (APC, antigen-presenting cell; IL, interleukin; MMP, matrix metalloproteinase; TNF-α, tumor necrosis factor α.)



The invasion of the synovium and joint by leukocytes results in synovitis. These leukocytes migrate to the region directed by chemokines and adhesion molecules. Early in the inflammatory process,

increased vascularity aids in cell trafficking. The synovium proliferates and fibroblasts are activated, and this promotes bone and connective tissue destruction.

Immunoglobulins can activate the complement system. The complement system amplifies the immune response by encouraging chemotaxis, phagocytosis, and the release of lymphokines by mononuclear cells, which are then presented to T lymphocytes. The processed antigen is recognized by major histocompatibility complex proteins on the lymphocyte, which activates it to stimulate the production of T and B cells. The proinflammatory cytokines tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6 are key substances in the initiation and continuance of rheumatoid inflammation. IL-17 can induce proinflammatory cytokines in fibroblasts and synoviocytes and stimulate the release of matrix metalloproteinases and other cytotoxic substances, which leads to cartilage destruction. Activated T cells produce cytotoxins, which are directly toxic to tissues, and cytokines, which stimulate further activation of inflammatory processes and attract cells to areas of inflammation. Macrophages are stimulated to release prostaglandins and cytotoxins.[4,5,6] T-cell activation requires both stimulation by proinflammatory cytokines as well as interaction between cell surface receptors, called *costimulation*. One of these costimulation interactions is between CD28 and CD80/86. The binding of the CD80/86 receptor by the drug abatacept has proved to be an effective treatment for RA by preventing costimulation interactions between T cells.[7]

Although it has been suggested that T cells play a key role in the pathogenesis of RA, B cells clearly have an equally important role. Evidence for this importance may be found in the effectiveness of B-cell depletion using the drug rituximab in controlling rheumatoid inflammation. Activated B cells produce plasma cells, which form antibodies. These antibodies in combination with the complement system result in the accumulation of polymorphonuclear leukocytes, which release cytotoxins, oxygen-free radicals, and hydroxyl radicals that promote cellular damage to synovium and bone. The benefits of B-cell depletion occur even though antibody formation is not suppressed with rituximab therapy; this suggests that other mechanisms play a role in reducing RA activity. B cells produce cytokines that may alter the function of other immune cells, and they also have the ability to process antigens and act as antigen-presenting cells, which interact with T cells to activate the immune process.[8,9,10,11]

In the synovial membrane, $CD4^+$ T cells are abundant and communicate with macrophages, osteoclasts, fibroblasts, and chondrocytes either through direct cell–cell interactions using cell surface receptors or through proinflammatory cytokines such as TNF-α, IL-1, and IL-6. These cells produce metalloproteinases and other cytotoxic substances, which lead to the erosion of bone and cartilage. They also release substances promoting growth of blood vessels and adhesion molecules, which assists in proinflammatory cell trafficking and attachment of fibroblasts to cartilage and eventual synovial invasion and destruction.[12,13,14,15] TNF inhibitors are widely used to treat RA. Although anakinra inhibits IL-1 by attaching to receptors on cell surface, the benefits of this approach have not been as great as expected. Tocilizumab has proven effective as an inhibitor of IL-6 activity.

CLINICAL PRESENTATION Arthiritis Symptoms

- Joint pain and stiffness of more than 6 weeks' duration. May also experience fatigue, weakness, low-grade fever, loss of appetite. Muscle pain and afternoon fatigue may also be present. Joint

deformity is generally seen late in the disease.

Signs

- Tenderness with warmth and swelling over affected joints usually involving hands and feet. Distribution of joint involvement is frequently symmetrical. Rheumatoid nodules may also be present.

Laboratory Tests

- Rheumatoid factor (RF) detectable in 60% to 70%.
- Anticyclic citrullinated peptide (anti-CCP) antibodies have similar sensitivity to RF (50%-85%) but are more specific (90%-95%) and are present earlier in the disease.
- Elevated ESR and CRP are markers for inflammation.
- Normocytic normochromic anemia is common as is thrombocytosis.

Other Diagnostic Tests

- Joint fluid aspiration may show increased white blood cell counts without infection, crystals.
- Joint radiographs may show periarticular osteoporosis, joint space narrowing, or erosions.

There are also a number of signaling molecules that are important for activating and maintaining inflammation. One of these is Janus kinase (JAK), which is a tyrosine kinase responsible for regulating leukocyte maturation and activation. JAK also has effects on the production of cytokines and immunoglobulins. Tofacitinib, an oral JAK inhibiting drug, has proven to be very effective in RA and appears to inhibit IL-6 activity as the major mechanism of action.

Vasoactive substances also play a role in the inflammatory process. Histamine, kinins, and prostaglandins are released at the site of inflammation. These substances increase both blood flow to the site of inflammation and the permeability of blood vessels. These substances cause the edema, warmth, erythema, and pain associated with joint inflammation and make it easier for granulocytes to pass from blood vessels to the site of inflammation.

The end results of the chronic inflammatory changes are variable. Loss of cartilage may result in a loss of the joint space. The formation of chronic granulation or scar tissue can lead to loss of joint motion or bony fusion (called *ankylosis*). Laxity of tendon structures can result in a loss of support to the affected joint, leading to instability or subluxation. Tendon contractures also may occur, leading to chronic deformity.[12,16]

The symptoms of RA usually develop insidiously over the course of several weeks to months. Prodromal symptoms include fatigue, weakness, low-grade fever, loss of appetite, and joint pain. Stiffness and muscle aches (myalgias) may precede the development of joint swelling (synovitis). Fatigue may be more of a problem in the afternoon. During disease flares, the onset of fatigue begins earlier in the day and subsides as disease activity lessens. Most commonly, joint involvement tends to

be symmetrical; however, early in the disease some patients present with an asymmetrical pattern involving one or a few joints that eventually develops into the more classic presentation. Approximately 20% of patients develop an abrupt onset of their illness with fevers, polyarthritis, and constitutional symptoms (eg, depression, anxiety, fatigue, anorexia, and weight loss).[2,3]

No single test or physical finding can be used to make the diagnosis of RA. In early disease, the diagnosis can be particularly challenging given that radiographic findings are usually absent and rheumatoid factor (RF) test can be undetectable. Duration of joint pain and swelling, morning stiffness lasting more than 1 hour, and involvement of three or more joints are important early predictors of the development of persistent erosive RA.[17]

JOINT INVOLVEMENT

The joints affected most frequently by RA are the small joints of the hands, wrists, and feet (**Fig. 91-2**). In addition, elbows, shoulders, hips, knees, and ankles may be involved. Patients usually experience joint stiffness that typically is worse in the morning. The duration of stiffness tends to be correlated directly with disease activity, usually exceeds 30 minutes, and may persist all day. Chronic inflammation with lack of an adequate exercise program results in loss of range of motion, atrophy of muscles, weakness, and deformity (**Figs. 91-3** and **91-4**).

FIGURE 91-2

Patterns of joint involvement in rheumatoid arthritis and osteoarthritis.

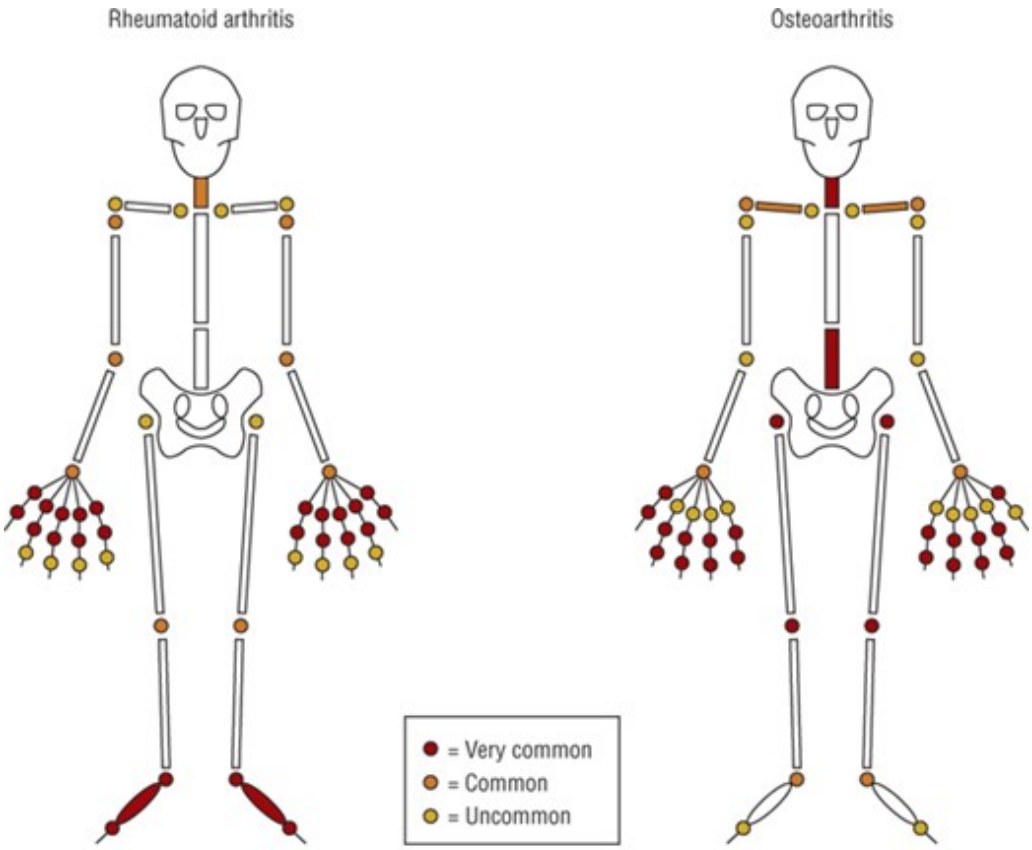


FIGURE 91-3

Deformities of rheumatoid arthritis, with marked ulnar deviation, swan-neck deformity, active synovitis, and nodules. *(Reproduced with permission from Brunicardi FC, Anderson DK, Billiar TR, et al.* Schwartz's Principles of Surgery, *8th ed. New York, NY: McGraw-Hill, 2005.)*

On examination, the swelling of the joints may be visible or may be apparent only by palpation. The swelling feels soft and spongy because it is caused by proliferation of soft tissues or fluid accumulation within the joint capsule. The swollen joint may appear erythematous and feel warmer than nearby skin surfaces, especially early in the course of the disease. In contrast, the swelling associated with osteoarthritis usually is bony (caused by osteophytes) and infrequently is associated with signs of inflammation.

Involvement of the hands and wrists is common in RA. Hand involvement is manifested by pain, swelling, tenderness, and grip weakness during the acute phase and by subluxation, instability, deformity, and muscle atrophy in the chronic phase of the disease. Functional difficulties with clasp, grasp, and pinch alter both strength and fine motor movement.

Deformity of the hand may be seen with chronic inflammation. These changes may alter the mechanics of hand function, reducing grip strength and making it difficult to perform usual daily activity.

Pain in the elbow and shoulder may be the result of true joint inflammation or inflammation of soft-tissue structures such as tendons (tendonitis) or the bursa (bursitis). The knee also can be involved, with loss of cartilage, instability, and joint pain. Synovitis of the knee may cause the formation of a cyst behind the knee called a *popliteal* or *Baker's cyst*. These cysts may become painful as they get tense, or they may rupture, producing a clinical picture similar to thrombophlebitis secondary to the release of inflammatory components into the area of the calf muscle (pseudothrombophlebitis syndrome). Chronic joint pain leads to muscle atrophy, which can result in a laxity of the ligamentous structures that support the knee, causing instability. Maintenance of an adequate range of motion of the knee is essential to normal gait.

Foot and ankle involvement in RA is common. The metatarsophalangeal joints are involved frequently

in RA, making walking difficult. Subluxation of the metatarsal heads leads to “cock-up” or hammer toe deformities. Subluxation also may cause a flexion deformity at the proximal interphalangeal joint of the toe, leading to pressure necrosis of the skin over the joint secondary to irritation caused by shoes. Hallux valgus (lateral deviation of the digit) and bunion or callus formation may occur at the great toe. A widening of the foot occurs commonly with long-standing disease.

Involvement of the spine usually occurs in the cervical vertebrae; lumbar vertebral involvement is rare. Involvement of the first and second cervical vertebrae (C1 to C2) can lead to instability of this joint. Patients with this problem are at a greater risk for spinal cord compression, although this complication is rare.

The temporomandibular joint (jaw) can be affected, resulting in malocclusion and difficulty in chewing food. Inflammation of cartilage in the chest can lead to chest wall pain. Hip pain may occur as a result of destructive changes in the hip joint, soft-tissue inflammation (eg, bursitis), or referred pain from nerve entrapment at the lumbar vertebrae.

EXTRA-ARTICULAR INVOLVEMENT

Although joint involvement in RA is a hallmark finding in RA, it is important to recognize that, as a systemic disease, other organ systems are often involved.

Rheumatoid Nodules

Rheumatoid nodules occur in 20% of patients with RA. These nodules are seen most commonly on the extensor surfaces of the elbows, forearms, and hands but also may be seen on the feet and at other pressure points. They also may develop in the lung or pleural lining of the lung and, rarely, in the meninges. Rheumatoid nodules usually are asymptomatic and do not require any special intervention. Nodules are observed more commonly in patients with erosive disease.[18]

Vasculitis

Vasculitis usually is seen in patients with long-standing RA. Vasculitis may result in a wide variety of clinical presentations. Invasion of blood vessel walls by inflammatory cells results in an obliteration of the vessel, producing infarction of tissue distal to the area of involvement. Most commonly, small-vessel vasculitis produces infarcts near the ends of the fingers or toes, especially around the nail beds. These infarcts are usually of little consequence.

Vasculitis also may cause the breakdown of skin, especially in the lower extremities, producing ulcers that may be indistinguishable in appearance from stasis ulcers. However, these ulcers do not heal with the usual modes of treatment used for stasis ulcers. Involvement of larger vessels with vasculitis can result in life-threatening complications. Infarction of vessels supplying blood to nerves can cause irreversible motor deficits. Involvement of vessels supplying other organ systems can lead to visceral involvement and a polyarteritis nodosa-like illness. Aggressive treatment of the inflammatory process is necessary in these patients. Fortunately, vasculitis has become much less frequently seen since the

advent of methotrexate and biologic therapy.

Pulmonary Complications

RA may involve the pleura of the lung, which is often asymptomatic, although pleural effusions may result. Pulmonary fibrosis also may develop as a result of rheumatoid involvement; smoking appears to increase the risk of this complication. Rheumatoid nodules may develop in lung tissue and appear similar to neoplasms on chest radiographs. Interstitial pneumonitis and arteritis are rare, potentially life-threatening complications of RA.

Ocular Manifestations

Ocular manifestations include keratoconjunctivitis sicca and inflammation of the sclera, episclera, and cornea. Atrophy of the lacrimal duct may result in a decrease in tear formation, causing dry and itchy eyes, termed *keratoconjunctivitis sicca*. When this is observed in association with RA, it is referred to as *Sjögren syndrome*. Artificial tears may be used to relieve symptoms. The salivary glands may also be involved in Sjögren syndrome, resulting in dry mouth (xerostomia). Inflammation of the superficial layers of the sclera (episcleritis) is generally self-limiting. Involvement of deeper tissues (scleritis) usually results in a more serious, painful, and chronic inflammation. Rheumatoid nodules may develop on the sclera.

Cardiac Involvement

The heart is sometimes affected by RA. RA is associated with an increased risk of cardiovascular mortality. This risk appears to be higher in those with more active inflammation and is reduced with treatment, particularly with methotrexate.[19,20] Pericarditis may occur, resulting in the accumulation of fluid. Although many patients show evidence of previous pericarditis at autopsy, the development of clinically evident pericarditis with tamponade is a rare complication. Cardiac conduction abnormalities and aortic valve incompetence, caused by aortic root dilation, may occur. Myocarditis is a rare complication of RA.

Felty Syndrome

RA in association with splenomegaly and neutropenia is known as *Felty syndrome*. Thrombocytopenia also may be a manifestation of the syndrome. Patients with Felty syndrome and severe leukopenia are more susceptible to infection. The decrease in granulocytes appears to be mediated by the immune system because splenectomy does not result in improvement of the patient.[18]

Other Complications

Lymphadenopathy may occur in patients with RA, particularly in nodes proximal to more actively involved joints. Renal involvement is rare but can be associated with treatment, including nonsteroidal anti-inflammatory drugs (NSAIDs). Amyloidosis is a rare complication of longstanding RA. It appears to be more common in Europe than in the United States.

LABORATORY FINDINGS

Hematologic tests often reveal a mild-to-moderate anemia with normocytic, normochromic indices. The hematocrit may fall as low as 30% [0.30]. The anemia is usually inversely related to inflammatory disease activity and is referred to as an *anemia of chronic disease*. This type of anemia does not respond to iron therapy and can present a diagnostic dilemma because NSAIDs may induce gastritis and chronic blood loss, leading to iron-deficiency anemia. Laboratory tests useful in differentiating these anemias include stool guaiac (or other stool tests for occult blood), serum iron-to-iron-binding capacity ratio (decreased in iron deficiency), ferritin (decreased in iron deficiency), and mean corpuscular volume (more likely to be decreased in iron deficiency). Other causes of anemia also must be considered in the differential diagnosis (see Chapters 100 and 102).

Thrombocytosis is another common hematologic finding with active RA. Platelet counts rise and fall in direct correlation with disease activity in many patients. Thrombocytopenia may result from toxicity of immunosuppressive therapy. Thrombocytopenia also may be observed in Felty syndrome or vasculitis.

Although leukopenia is associated with Felty syndrome, it also may result from toxicity of methotrexate, gold, sulfasalazine, penicillamine, and immunosuppressive drugs. Leukocytosis is seen commonly as a result of corticosteroid treatment.

The erythrocyte sedimentation rate (ESR) is usually elevated in patients with RA and other inflammatory diseases. This test is very nonspecific, and although the ESR usually falls as patients respond to therapy, there is a large variability among patients in response to treatment. C-reactive protein (CRP) is another nonspecific marker for inflammatory arthritis when it is elevated. This protein is produced by the liver in response to certain cytokines.

RF is present in 60% to 70% of patients with RA. The usual laboratory test for RF is an antibody specific for immunoglobulin (Ig)M RF. Patients with RA and a negative test for RF may have IgG or IgA RFs, but tests for these are not routinely available. RF tests may be reported positive at a specific serum dilution. Serum is diluted to a standard series of dilutions; the greatest dilution that yields a positive test result will be reported (eg, RF positive at 1:640). Some laboratories quantify RF rather than using titers. Higher dilutional titers or serum concentrations of RFs usually indicate a more severe disease, but like the ESR, the large interpatient variability makes this test unreliable as a means of assessing patient progress. RF may be positive in patients without RA (**Table 91-1**).

TABLE 91-1 Diseases Associated with a Positive Rheumatoid Factor

Rheumatic diseases

- Rheumatoid arthritis
- Sjögren syndrome (with or without arthritis)
- Systemic lupus erythematosus
- Progressive systemic sclerosis

- Polymyositis/dermatomyositis

Infectious diseases

- Bacterial endocarditis
- Tuberculosis
- Syphilis
- Infectious mononucleosis
- Infectious hepatitis
- Leprosy

Other causes

- Aging
- Interstitial pulmonary fibrosis
- Cirrhosis of the liver
- Chronic active hepatitis
- Sarcoidosis

ACPA has similar sensitivity for RA, being found in 50% to 85% of patients with the disease, but is more specific (90%-95%) and is detectable very early in the disease. Many rheumatologists will do both tests in evaluating new patients.

Antinuclear antibodies (ANAs) are detected in 25% of patients with RA. These antibodies usually have a diffuse pattern of immunofluorescence. Tests for antibodies to double-stranded DNA (usually positive in systemic lupus erythematosus) are negative. Serum complement is usually normal, although complement concentrations of joint fluid often are depressed from consumption secondary to the inflammatory process. In patients with vasculitis, serum complement concentrations may be low.[21,22]

Synovial fluid usually is turbid because of the large number of leukocytes in inflammatory fluid. White cell counts of 5,000 to 50,000/mm^3 (5×10^9 to 50×10^9/L) are not uncommon in inflamed joints. The fluid is usually less viscous than that in normal joints or fluid associated with osteoarthritis. Glucose concentrations of joint fluid are normal or low compared with those in serum drawn at the same time as synovial aspirates. The decrease is not as profound as the decrease associated with joint infection or systemic lupus erythematosus.

Early radiographic manifestations of RA include soft-tissue swelling and osteoporosis near the joint

(periarticular osteoporosis). Joint space narrowing occurs as a result of cartilage degradation. Erosions tend to occur later in the course of the disease and usually are seen first in the metacarpophalangeal and proximal interphalangeal joints of the hands and the metatarsophalangeal joints of the feet. Periodic joint radiographs are a useful way of evaluating disease progression.

Diagnostic Criteria

The American College of Rheumatology and European League Against Rheumatism (ACR/EULAR) revised criteria for the diagnosis of RA.[23] These criteria were developed to be used for patients early in their disease; they, therefore, emphasize early manifestations of the disease. Late manifestations of RA such as erosive disease or nodules are no longer in the diagnostic criteria, but these patients would have previously met these criteria based on retrospective data.

Patients with synovitis of at least one joint and no other explanation for the finding are candidates for these criteria. The criteria use a scoring system with a score of more than 6 out of a possible total score of 10 as being diagnostic for RA. More points are given for patients presenting with more actively involved joints. Positive laboratory tests including RF, ACPA, CRP, and ESR result in additional points.

Duration of symptoms more than or equal to 6 weeks results in an additional point. It is important to note that not all patients with RA may have a score more than 6 initially, particularly if seen very early in their disease but may evolve to higher scores over time. Reassessment should be considered for those with ongoing symptoms.

Seronegative Inflammatory Arthritis

Although RA may have a negative RF titer, a number of other systemic inflammatory arthritic conditions exist including psoriatic arthritis, reactive arthritis, ankylosing spondylitis, and arthritis associated with inflammatory bowel disease. These conditions often tend to be less aggressive than what is typically seen with RA. Detailed discussion about these conditions is beyond the scope of this chapter, but further information may be found elsewhere.[2] Management principles are similar to those for RA.

TREATMENT

Desired Outcomes

2 The primary objective in the treatment of RA is to achieve remission or low disease activity which is referred to as "Treat to Target."[24] This goal is largely achieved by reducing inflammation using drugs known to alter disease progression. See Table 91-2 for a list of commonly used tools to assess RA disease activity with definitions for remission and low disease activity. While achieving complete clinical remission is the ideal target, it may not be possible to achieve in some patients; in this subset of patients, especially those with long-standing disease, achieving low-disease activity may be an appropriate alternative. It is important to recognize that no therapy will reverse joint damage which

has already occurred.

General Approach to Treatment

The multifaceted treatment approach includes pharmacologic and nonpharmacologic therapies with recent emphasis being placed on aggressive treatment early in the disease course. Early aggressive treatment may prevent irreversible joint damage and disability. The current guideline recommends intial treatment with a conventional synthetic disease-modifying antirheumatic drug, preferably methotrexate, for most patients regardless of clinical disease activity.[25,26,27] Those who continue to have moderate-to-severe disease activity despite initial treatment should be switched to alternative therapies (another disease-modifying antirheumatic drug [DMARD] or biologic agent) or combination DMARD therapy. Patients who achieve remission can be considered for tapering, though not discontinuance of all RA therapies. Though remission is the target for treatment, patients who achieve low disease activity should continue RA treatment.

Clinical Controversy...

Currently there are no known predictors of which therapies are likely to be effective in a given patient. Once therapy is begun, some patients who achieve excellent response may taper and in some cases discontinue some drugs if they are on combination therapy. It is not clear which patients would benefit from this approach.

Nonpharmacologic Therapy

3 Rest, occupational therapy, physical therapy, use of assistive devices, weight reduction, and surgery are the most useful types of nonpharmacologic therapy used in patients with RA. Rest is an essential component of a nonpharmacologic treatment plan.[27,28] It relieves stress on inflamed joints and prevents further joint destruction. Rest also aids in alleviation of pain. Too much rest and immobility, however, may lead to decreased range of motion and, ultimately, muscle atrophy, and contractures.

Occupational and physical therapy can provide the patient with skills and exercises necessary to increase or maintain mobility. These disciplines may also supply patients with supportive and adaptive devices such as canes, walkers, and splints.

Other nonpharmacologic therapeutic options include weight loss and surgery. Weight reduction helps alleviate stress on inflamed joints. Tenosynovectomy, tendon repair, and joint replacements are surgical options for patients with RA. Such management is reserved for patients with severe disease.

Pharmacologic Therapy

4 5 Pharmacologic agents that reduce RA symptoms and impede radiographic joint damage can be categorized as either conventional synthetic DMARDs, biologic DMARDs (referred to as *biologics*) which include TNF-α inhibitor (TNFi) biologics or non-TNF biologics, and tofacitinib, which is

considered different from DMARDs in the ACR 2015 RA treatment guidelines. DMARDs are a treatment cornerstone; they should be started as soon as possible after disease onset as early introduction results in more favorable outcomes,[29] including reducing mortality rates comparable to patients without the disease.[19] Nonsteroidal anti-inflammatory drugs (NSAIDs) and/or corticosteroids may be used for symptomatic relief if needed.[28] They provide relatively rapid improvement in symptoms compared with DMARDs, which may take weeks to months to take effect; however, NSAIDs have no impact on disease progression and the long-term complication risks of corticosteroids make them less desirable. NSAIDs and DMARDs have steroid-sparing properties that permit corticosteroid dose reductions.

DMARDs, biologics, and tofacitinib slow RA disease progression. DMARDs commonly used include methotrexate, hydroxychloroquine, sulfasalazine, and leflunomide. The biologic agents with disease-modifying activity include the TNFi drugs (adalimumab, certolizaumab, etanercept, golimumab, infliximab), the costimulation modulator abatacept, the IL-6 receptor antagonist tocilizumab, and rituximab, which depletes peripheral B cells. Tofacitinib, a newer agent, is a synthetic small molecule similar to DMARDs but with a very specific mechanism of action. Agents less frequently used because of reduced efficacy and/or greater toxicity include the IL-1 receptor antagonist anakinra, azathioprine, D-penicillamine, gold (including auranofin), minocycline, cyclosporine, and cyclophosphamide.

Clinical Controversy…

Though the current guideline recommends methotrexate as initial therapy for most patients with RA, the order in which DMARDs or biologic agents are choosen or the choice of monotherapy with an alternative agent versus combination therapy is not clearly defined. No direct comparative studies exist for biologics to guide in the determination of optimal treatment order.

DMARD monotherapy, preferably with methotrexate, is first-line therapy for patients with early (<6 months duration of disease symptoms) or established (≥6 months duration of disease symptoms) RA.[27] Methotrexate is recommended initially because long-term data suggest superior outcomes with methotrexate than with other DMARDs. There is also good documentation for better outcomes with methotrexate in combination therapy if methotrexate monotherapy does not achieve an adequate response. Leflunomide appears to have similar long-term efficacy as that of methotrexate.[30]

6 Monotherapy with nonmethotrexate DMARDs or combination therapy with two or more DMARDs may be effective when the initial DMARD treatment is unsuccessful.[27] For patients with moderate-to-high disease activity, dual DMARD combinations (methotrexate plus hydroxychloroquine, methotrexate plus leflunomide, or methotrexate plus sulfasalazine) or triple DMARDs (sulfasalazine, hydroxychloroquine, and methotrexate) are recommended as initial therapy.[25,27] Initial combination therapy with either methotrexate plus etanercept or methotrexate plus sulfasalazine plus hydroxychloroquine has been found to be more effective at 24 weeks of therapy than methotrexate monotherapy for most patients; however, stepwise therapy to dual or triple therapy may have similar efficacy later in the course of treatment.[31]

The biologic agents have proven effective for patients who fail treatment with DMARDs. However, the ACR now endorses use of anti-TNF biologics as monotherapy or as combination with DMARDs in patients who have moderate-to-high disease activity after treatment with previous DMARD.[25,27] Furthermore, use of biologics in combination with methotrexate is more effective than biologic monotherapy.[25] Infliximab, specifically, should be given in combination with methotrexate to prevent development of antibodies that may reduce infliximab drug efficacy or induce allergic reactions.

The ACR published recommendations for use of DMARDs, biologics, and tofacitinib in 2008 and updated them in 2012 and 2015. These recommendations are not intended to be prescriptive but provide guidance for treatment choice. Recommendations are given based on disease duration and degree of disease activity. The recommendations take into account barriers to treatment, including cost and insurance restrictions, by suggesting treatment options with and without expensive biologic agents. Simplified algorithms summarizing these treatment recommendations are provided in **Fig. 91-5**. For more details, see the published recommendations.[25,26,27]

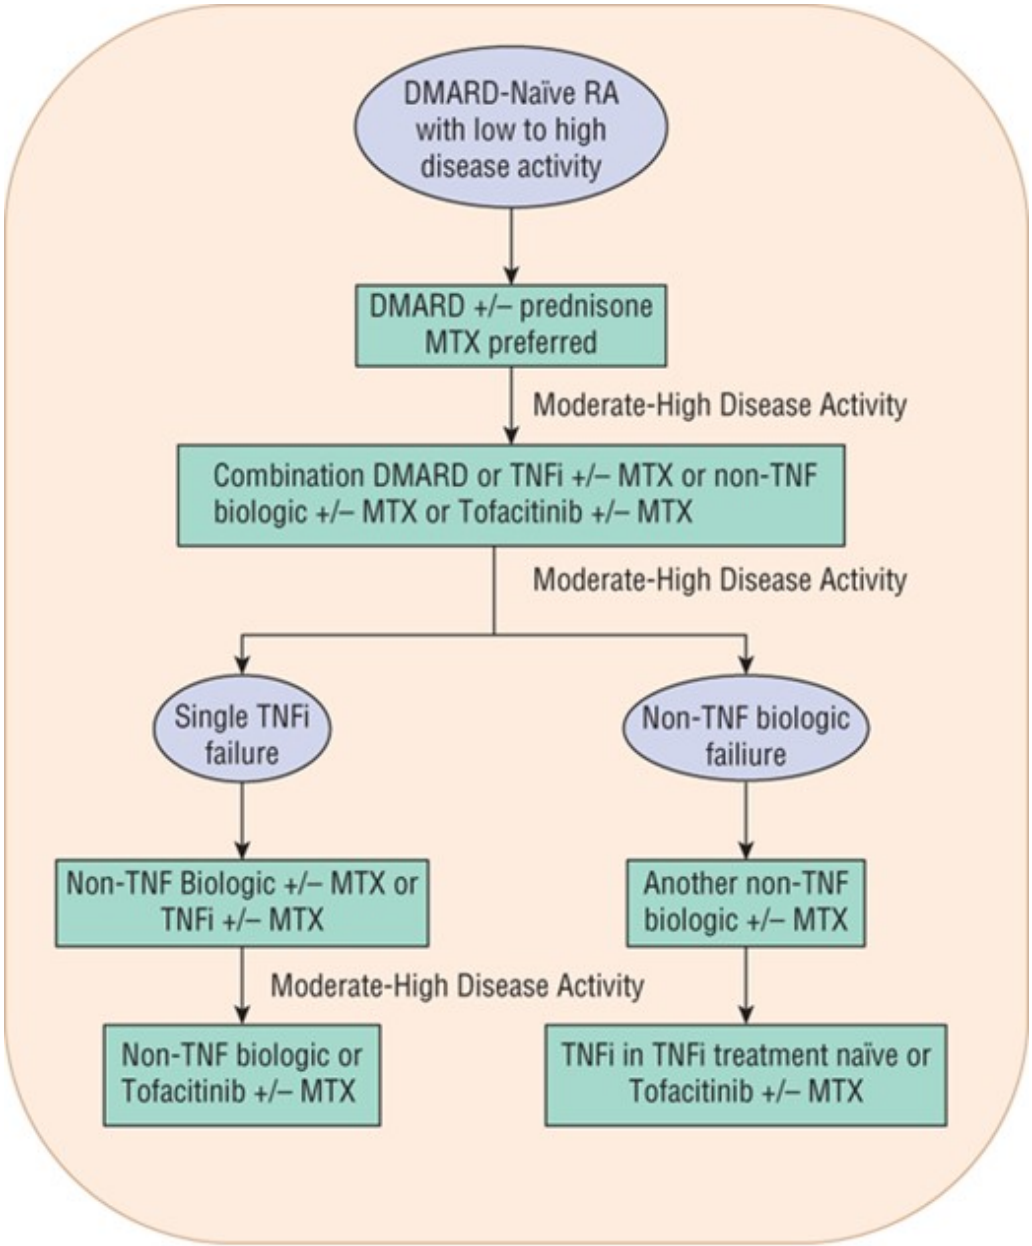
Algorithm for treatment of rheumatoid arthritis (RA) in early (<6 months) or established (≥6 months) RA with low to high disease activity. (DMARD, disease-modifying antirheumatic drug; MTX,

methotrexate.)



Therapy with DMARDs and biologics result in immunosuppression. Additionally, prednisolone doses of 20 mg/day or more for 2 weeks is also generally accepted to produce a state of immunosupression. Therefore, vaccination status should be assessed and updated before therapy is initiated to protect against vaccine-preventable infections. Corticosteroids significantly increase the risk for mild (relative risk 1.15) and serious infections (relative risk 1.9).[33] The use of corticosteroids in addition to DMARDs has been shown to produce a similar elevated risk of infection as corticosteroid monotherapy. Biologic agents are associated with an increased risk of serious infections as compared with DMARD therapy, increasing by 6 per 1000 patient–years for standard dosing and 17 per 1000 patient–years for high dosing.[34] When using a DMARD and biologic as combination therapy, the risk of serious infection increased by 55 per 1000 patient–years. Dual biologic use is not recommended

due to the risk of infection.

While the ACR recommends vaccination before start of DMARD or biologic therapy when possible, killed (pneumococcal, intramuscular influenza, hepatitis B) and recombinant (human papillomavirus) vaccines can be given during therapy.[27] Live vaccines can be administered to patients already on DMARD therapy; however, they are not recommended for patients already taking biologics. For those patients who will be starting a biologic or tofacitinib, the ACR recommends administering the herpes zoster vaccine to patients who have reached 50 years of age instead of waiting until after the general-population recommended age of 60 years.

Some biologic agents are contraindicated in the setting of hepatitis C or malignancies because of immunosuppression. Conventional synthetic DMARDs are preferred for treatment of RA in patients with hepatitis C virus who have not been treated or are requiring treatment.[27] However, the 2015 ACR notes that for patients with hepatitis C virus who have completed or are currently undergoing treatment for hepatitis be treated no differently than other patients with RA. No restrictions are needed for patients with hepatitis B virus.

Patients with history of skin cancer should be preferentially treated with DMARDs. For those requiring biologic therapy, regular surveillance for new skin cancer is important. Rituximab is preferred in patients with previous lymphoproliferative malignancies. No restrictions are recommended for patients with solid tumors. Patients with a history of previous severe infections should use combination DMARD or abatacept over TNF inhibitors.[27]

Tables 91-2, 91-3, 91-4 provide monitoring parameters and dosing guidelines for DMARDs and NSAIDs used in RA.

TABLE 91-2 Assessment Tools Used to Measure Rheumatoid Arthritis Disease Activity and Definitions for Low Disease Activity and Remission

Assessment Tool	Low Disease Activity	Remission
Clinical Disease Activity Index (CDAI) (range 0-76)	>2.8-10	<2.8
Disease Activity Score (DAS28) (range 0-9.4)	>2.6-3.2	<2.6
Patient Activity Scale (PAS) or PASII (range 0-10)	>2.5-3.7	0-2.5
Routine Assessment of Patient Index Data 3 (RAPID-3) (range 0-10)	>1.0-2.0	0-1.0
Simplified Disease Activity Index (SDAI) (range 0-86)	>3.3-<11.0	<3.3

TABLE 91-3 Usual Doses for Antirheumatic Drugs

Drug	Brand Name	Starting Dose	Usual Range or Maintenance Dose	Comments
Nonsteroidal anti-inflammatory drugs			See Table 90-2 in Chapter 90	
Methotrexate	Rasuvo Trexall	Oral: 7.5 mg once weekly or 2.5 mg q	Oral SC or IM: 7.5-15 mg q wk	May be given with folic acid 1-5 mg/day

Drug	Brand Name	Starting Dose	Usual Range or Maintenance Dose	Comments
	Otrexup (SC)	12 h for 3 days/wk or 10-15 mg once weekly SC or IM		to reduce adverse reactions
Leflunomide	Arava	Oral: loading dose: 100 mg daily for 3 days, then 20 mg/day or 10-20 mg daily without loading dose	Oral: 10-20 mg daily	Not recommended in liver disease (ALT >2 times ULN)
Hydroxychloroquine	Plaquenil	Oral: 200-300 mg BID	Oral: After 1-2 mo may decrease to 200 mg daily or 200 mg BID	Take with food or milk; use with caution in renal or hepatic impairment
Sulfasalazine	Azulfidine	Oral: 0.5-1 g/day	Oral: Increase weekly to 1 g BID (max. dose is 3 g/day if inadequate response after 12 weeks of 2 g/day)	Not recommended in renal or hepatic impairment
Etanercept	Enbrel		50 mg SubQ once weekly or 25 mg twice weekly	
Infliximab	Remicade	3 mg/kg IV at 0, 2, 6 weeks then 3 q 8 weeks	3-10 mg/kg IV q 4-8 weeks	Given in combination with methotrexate therapy
Adalimumab	Humira		40 mg SubQ q 2 weeks (may increase to 40 mg once weekly if not taking methotrexate)	
Certolizumab	Cimzia	400 mg SubQ at 0, 2, 4 weeks	200 mg SubQ every other week	
Golimumab	Simponi		50 mg SubQ once monthly	
Rituximab	Rituxan	1,000 mg IV twice, 2 weeks apart	Initial dose may be repeated every 16-24 weeks based on response	

Drug	Brand Name	Starting Dose	Usual Range or Maintenance Dose	Comments
Abatacept	Orencia	IV: <60 kg: 500 mg 60-100 kg: 750 mg >100 kg: 1,000 mg at 0, 2, and 4 weeks or initial IV dose followed by 125 mg SubQ within 24 hours	IV: dose based on weight q 4 weeks SubQ: 125 mg once weekly	
Tocilizumab	Actemra	4 mg/kg IV q 4 weeks	4-8 mg/kg q 4 weeks (max 800 mg/infusion)	
Tofacitinib	Xeljanz		5 mg BID	5 mg once daily in moderate-to-severe renal insufficiency, moderate hepatic impairment, or concomitant CYP3A4 or CYP2C19 inhibitors
Minocycline	Dynacin Minocin		Oral: 100-200 mg daily	Use with caution in renal impairment
Anakinra	Kineret		100 mg SC once daily	
Auranofin	Ridaura		Oral: 3 mg daily to BID	
Gold thiomalate	Myochrysine	IM: 10 mg test dose first week, then 25 mg second week; then 25-50 mg/wk until toxicity or cumulative 1 g dose given	IM: 25-50 mg every other week for 2-20 weeks then every 3-4 weeks	CL_{cr} 50-80 mL/min (0.83-1.33 mL/s): give 50% recommended dose; CL_{cr} <50 mL/min (<0.83 mL/s) avoid use
Azathioprine	Imuran Azasan	Oral: 1 mg/kg/day (50-100 mg) for 6-8 weeks. May increase by 0.5 mg/kg q 4 weeks to 2.5 mg/kg/day	Oral: 50-150 mg daily	
D–Penicillamine	Cuprimine Depen	Oral: 125-250 mg daily	Oral: may ↑ by 125-250 mg q 1-2	Caution with renal impairment

Drug	Brand Name	Starting Dose	Usual Range or Maintenance Dose	Comments
			months, max. 750 mg daily	
Cyclophosphamide			Oral: 1-2 mg/kg/day	
Cyclosporine	Gengraf Neoral Sandimmune	Oral: 2.5 mg/kg/day divided twice daily	Oral: may ↑ by 0.5-0.75 mg/kg/day at 8 and 12 weeks to max dose 4 mg/kg/day	
Corticosteroids			Oral, IV, IM, IA, and soft-tissue injections: variable	

ALT, alanine aminotransferase; BID, twice daily; CL_{cr}, creatinine clearance; CYP, cytochrome P450; IA, intra-articular; IM, intramuscular; IV, intravenous; q, every; SC, subcutaneous; ULN, upper limits of normal.

TABLE 91-4 Clinical Monitoring of Drug Therapy in Rheumatoid Arthritis

Drug	Adverse Drug Reaction	Initial Monitoring	Maintenance Monitoring	Symptoms to Inquire About[a]
NSAIDs and salicylates	GI ulceration and bleeding, renal damage	sCr or BUN, CBC q 2-4 wk p starting therapy × 1-2 mo salicylates: serum salicylate levels if therapeutic dose and no response	Same as initial plus stool guaiac q 6-12 mo	Blood in stool, black stool, dyspepsia, nausea/vomiting, weakness, dizziness, abdominal pain, edema, weight gain, SOB
Corticosteroids	Hypertension, hyperglycemia, osteoporosis[b]	Glucose, blood pressure q 3-6 mo	Same as initial	Blood pressure if available, polyuria, polydipsia, edema, SOB, visual changes, weight gain, headaches, broken bones or bone pain
Gold (intramuscular or oral)	Myelosuppression, proteinuria, rash, stomatitis	Baseline & until stable: UA, CBC w/plt	Same as initial —every other dose	Symptoms of myelosuppression, edema, rash, oral

Drug	Adverse Drug Reaction	Initial Monitoring	Maintenance Monitoring	Symptoms to Inquire About[a]
		preinjection		ulcers, diarrhea
Hydroxychloroquine	Macular damage, rash, diarrhea	Baseline: color fundus photography and automated central perimetric analysis	Ophthalmoscopy q 9-12 mo and Amsler grid at home q 2 wk	Visual changes including a decrease in night or peripheral vision, rash, diarrhea
Methotrexate	Myelosuppression, hepatic fibrosis, cirrhosis, pulmonary infiltrates or fibrosis, stomatitis, rash	Baseline: AST, ALT, alk phos, alb, t. bili, hep B and C studies, CBC w/plt, S_{cr}	CBC w/plt, AST, alb q 1-2 mo	Symptoms of myelosuppression, SOB, nausea/vomiting, lymph node swelling, coughing, mouth sores, diarrhea, jaundice
Leflunomide	Hepatitis, GI distress, alopecia	Baseline: ALT, CBC with platelets	CBC with platelets and ALT monthly initially and then every 6-8 wk	Nausea/vomiting, gastritis, diarrhea, hair loss, jaundice
Penicillamine	Myelosuppression, proteinuria, stomatitis, rash, dysgeusia	Baseline: UA, CBC w/plt, then q week × 1 month	Same as initial—q 1-2 mo, but q 2 wk if dose change	Symptoms of myelosuppression, edema, rash, diarrhea, altered taste perception, oral ulcers
Cyclophosphamide	Alopecia, infertility, GI distress, hemorrhagic cystitis, myelosuppression, nephrotoxicity, cardiotoxicity	UA, CBC w/plt q week × 1 month	Same as initial—q 2-4 wk	Nausea/vomiting, gastritis, diarrhea, hair loss, urination difficulties, chest pain, rash, respiratory difficulties
Cyclosporine	Hepatotoxicity, nephrotoxicity, hypertension, headache, malignancy, infections, GI distress	S_{cr}, blood pressure q month	Same as initial	Nausea/vomiting, diarrhea, symptoms of infection, symptoms of elevated blood pressure

Drug	Adverse Drug Reaction	Initial Monitoring	Maintenance Monitoring	Symptoms to Inquire About[a]
Sulfasalazine	Myelosuppression, rash	Baseline: CBC w/plt, then q week × 1 month	Same as initial—q 1-2 mo	Symptoms of myelosuppression, photosensitivity, rash, nausea/vomiting
Tocilizumab	Local injection-site reactions, infection	AST/ALT, CBC w/plt, lipids	AST/ALT, CBC w/plt, lipids q 4-8 weeks	Symptoms of infection
Anakinra	Local injection-site reactions, infection	Neutrophil count	Neutrophil count monthly for 3 months then quarterly up to 1 year	Symptoms of infection
Etanercept, adalimumab, golimumab, certolizumab	Local injection-site reactions, infection	Tuberculin skin test hepatitis C screening	None	Symptoms of infection
Infliximab, rituximab, abatacept	Immune reactions, infection	Tuberculin skin test hepatitis C screening	None	Postinfusion reactions, symptoms of infection
Tofacitinib	Infection, malignancy, GI perforations, upper respiratory tract infections, headache, diarrhea, nasopharyngitis	Tuberculin skin test, hepatitis C screening, neutrophil count, lymphocytes, Hgb, AST/ALT	Neutrophils, Hgb, FLP at 4-8 weeks after treatment start, then lymphocytes, neutrophils, and Hgb q 3 months	Symptoms of infection or myelosuppression, SOB, blood in stool, black stool, dyspepsia

alb, albumin; alk phos, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count; FLP, fasting lipid panel; GI, gastrointestinal; hep, hepatitis; Hgb, hemoglobin; p, after; plt, platelet; q, every; S_{cr}, serum creatinine; t. bili, total bilirubin; UA, urinalysis; NSAIDs, nonsteroidal anti-inflammatory drugs; SOB, shortness of breath.

[a]Altered immune function increases infection; this should be considered particularly in those patients taking azathioprine, methotrexate, and corticosteroids or other drugs as a symptom of myelosuppression.

[b]Osteoporosis is unlikely to manifest itself early in treatment, but all patients should be taking appropriate steps to prevent bone loss.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs should seldom be used as monotherapy for RA because they do not alter the course of the disease; instead, they should be viewed as adjuncts to DMARD treatment. NSAIDs possess both analgesic and antiinflammatory properties and reduce stiffness associated with RA. These agents mainly inhibit prostaglandin synthesis, which is only a small portion of the inflammatory cascade. For details on these agents see Chap. 90, Osteoarthritis.

Corticosteroids

Corticosteroids are used in RA for their anti-inflammatory and immunosuppressive properties but should not be used as monotherapy.[35] They interfere with antigen presentation to T lymphocytes, inhibit prostaglandin and leukotriene synthesis, and inhibit neutrophil and monocyte superoxide radical generation. Corticosteroids also impair cell migration and cause redistribution of monocytes, lymphocytes, and neutrophils, thus blunting the inflammatory and autoimmune responses.

Corticosteroids may be injected into joints and soft tissues to control local inflammation or taken orally for a more systemic effect. Oral corticosteroids are absorbed rapidly and completely from the gastrointestinal tract. They are metabolized and inactivated primarily by the liver and excreted in the urine. The elimination half-life of most corticosteroids is sufficiently long that once-daily dosing is possible.

Oral corticosteroids can be used in several ways. They can be used in bridging therapy, continuous low-dose therapy, and short-term, high-dose bursts to control flares. Oral steroids (eg, prednisone, methylprednisolone) can be used to control pain and synovitis while DMARDs are taking effect. This is termed *bridging therapy* and is often used in patients with debilitating symptoms when DMARD therapy is initiated. Patients with difficult-to-control disease may be placed on low-dose, long-term corticosteroid therapy to control their symptoms. Prednisone doses below 7.5 mg daily are well tolerated but are not devoid of the long-term adverse effects associated with corticosteroids. The lowest dose of corticosteroid that controls symptoms should be used to reduce adverse effects. Alternate-day dosing of low-dose oral corticosteroids usually is ineffective in RA; symptoms usually flare on days without medication. High-dose corticosteroid bursts often are used to suppress disease flares. High doses are sustained for several days until symptoms are controlled, followed by a taper to the lowest effective dose.

Corticosteroids also may be delivered by injection. The intramuscular route may be preferable in patients with adherence problems for short-term therapy. Long-acting depot forms of corticosteroids include triamcinolone acetonide, triamcinolone hexacetonide, and methylprednisolone acetate. This provides the patient with 2 to 6 weeks of symptomatic control. The depot effect provides a physiologic taper, avoiding withdrawal reaction associated with hypothalamic–pituitary axis suppression. IV corticosteroids may be used to provide the patient with large amounts of drug during a steroid burst to control severe symptoms. Intra-articular injections of depot forms of corticosteroids can be useful in treating synovitis and pain when a small number of joints are affected. The onset and duration of symptomatic relief are similar to those of intramuscular injection. The intra-articular route often is preferred because it is associated with the fewest number of systemic adverse effects. If

efficacious, intraarticular injections may be repeated every 3 months. No one joint should be injected more than two to three times per year because of the risk of accelerated joint destruction and atrophy of tendons. Soft tissues such as tendons and bursae also may be injected. This may help control the pain and inflammation associated with these structures. The onset and duration of symptomatic relief are similar to those of intramuscular and intra-articular injections.

The major limitation to the long-term use of corticosteroids is adverse effects. They include hypothalamic-pituitary–adrenal suppression, Cushing syndrome, osteoporosis, myopathies, glaucoma, cataracts, gastritis, hypertension, hirsutism, electrolyte imbalances, glucose intolerance, skin atrophy, and increased susceptibility to infections. To minimize these effects, use the lowest effective corticosteroid dose and limit the duration of use. Prednisolone 7.5 mg daily results in an average of 9.5% loss of bone density from the spine. Corticosteroids double the risk for osteoporosis in patients.[36] Patients on long-term therapy should be given calcium and vitamin D to minimize bone loss. Alendronate is effective in preventing bone loss in corticosteroid-treated patients and should be considered prophylactically for patients when long-term corticosteroid therapy is anticipated, particularly for patients who are at high risk of bone loss (eg, postmenopausal women, patients >65 years).[37,38,39,40] There is no evidence that corticosteroids alone increase the risk of gastrointestinal ulcerations, although they often have been implicated. Consequently, gastrointestinal protective measures usually are not indicated.[41,42]

Methotrexate

Methotrexate is now considered the DMARD of choice for initial therapy of most patients with RA. It inhibits cytokine production, inhibits purine biosynthesis, and may stimulate release of adenosine, all of which may lead to its anti-inflammatory properties. The drug has a fairly rapid onset of action; results may be seen as early as 2 to 3 weeks after starting therapy. Some 45% to 67% of patients remain on methotrexate therapy in studies ranging from 5 to 7 years.[43]

Absorption of methotrexate is variable and averages approximately 70% of an oral dose. Methotrexate is 35% to 50% bound to albumin; it may be displaced by highly protein-bound drugs such as NSAIDs, but the clinical importance of this interaction in the relatively low doses of methotrexate used in RA is unknown. Methotrexate is extensively metabolized intracellularly to polyglutamated derivatives. It is excreted by the kidney, 80% unchanged, by glomerular filtration and active transport. Some methotrexate may be reabsorbed, but this transport process may be saturated even with low doses, resulting in increased renal clearance.

Methotrexate is contraindicated in pregnant and nursing women as it is teratogenic. Patients should use contraception to avoid pregnancy and discontinue the drug if conception is planned. It is also contraindicated in patients with chronic liver disease, immunodeficiency, pleural or peritoneal effusions, leukopenia, thrombocytopenia, preexisting blood disorders, and a creatinine clearance of less than 40 mL/min (0.67 mL/s).

The toxicities of methotrexate therapy are mainly gastrointestinal, hematologic, pulmonary, and hepatic. Stomatitis occurs in 3% to 10% of patients and may be painful or painless. Diarrhea, nausea, and vomiting may occur in up to 10% of patients. The most common hematologic toxicity is

thrombocytopenia in 1% to 3% of patients. Leukopenia also may occur, but in a smaller number of patients. Although pulmonary fibrosis and pneumonitis can be severe adverse effects, they are rare.

Elevated liver enzymes may occur in up to 15% of patients; cirrhosis is rare. Liver function tests, aspartate aminotransferase or alanine aminotransferase, should be performed periodically. Methotrexate should be discontinued if these test values show sustained results greater than twice the upper limits of normal. Albumin should also be checked periodically as a sign of liver toxicity because some patients may not have liver inflammation manifested by aspartate aminotransferase or alanine aminotransferase elevation. Liver biopsy is now recommended before beginning methotrexate therapy only for patients with a history of excessive alcohol use, ongoing hepatitis B or C infections, or recurring elevation of aspartate aminotransferase. Biopsies during methotrexate therapy are recommended only for patients who develop consistently abnormal liver function tests.[27]

Because it is a folic acid antagonist, methotrexate can induce a folic acid deficiency. This deficiency is thought to be partly responsible for methotrexate toxicity, and supplementation with folic acid does alleviate some adverse effects. Addition of folic acid to a methotrexate regimen for RA does not compromise drug efficacy.[25,27,44]

Methotrexate may be given intramuscularly, subcutaneously, or orally. Doses greater than 15 mg per week generally are given parenterally because of decreased oral bioavailability of larger doses.

Leflunomide

Leflunomide is a DMARD that inhibits pyrimidine synthesis, leading to a decrease in lymphocyte proliferation and modulation of inflammation. It has efficacy similar to methotrexate for treating RA. The drug may cause liver toxicity and is contraindicated in patients with preexisting liver disease. Patients taking the drug should have alanine aminotransferase monitored monthly initially and periodically thereafter as long as they continue treatment. Leflunomide may cause bone marrow toxicity and complete blood count with platelets is recommended monthly for 6 months and then every 6 to 8 weeks thereafter.

The drug is teratogenic, and appropriate contraceptive measures are recommended to avoid pregnancy for all sexually active male and female patients who are taking leflunomide. If conception is desired, leflunomide must be discontinued. Because leflunomide undergoes enterohepatic circulation, the drug takes many months to drop to a plasma concentration considered safe during pregnancy (<0.02 µg/mL [mg/L; <74 nmol/L]). Cholestyramine may be used to rapidly clear the drug from plasma. In addition to pregnancy, cholestyramine use may be warranted to rapidly clear the drug in the event of severe toxicity.

Leflunomide may be given as a loading dose of 100 mg daily for 3 days, followed by a maintenance dose of 20 mg daily. Lower doses may be used if patients have gastrointestinal intolerance, complain of hair loss, or have other signs of dose-related toxicity. The loading dose allows the patient to achieve a more rapid therapeutic response, usually within the first month. The long elimination half-life of the drug (14-16 days) would require the patient to take the drug for several months to achieve steady state without a loading dose. Some rheumatologists prefer to begin with maintenance

dosing as the loading dose may put the patient at increased risk for toxicity.[30,45,46]

Hydroxychloroquine

Hydroxychloroquine is often used in mild RA or as an adjuvant in combination DMARD therapy in more progressive disease. The pharmacokinetics and mechanism of action of this drug are poorly understood, but it is thought to dampen antigen–antibody reactions at sites of inflammation.[28] It is well absorbed orally and widely distributed to body tissues. Hydroxychloroquine is partially metabolized in the liver and is excreted by the kidney. The onset of action of hydroxychloroquine may be delayed up to 6 weeks, but the drug is considered a therapeutic failure only when 6 months of therapy without a response has elapsed.

The main advantage of hydroxychloroquine is the lack of myelosuppressive, hepatic, and renal toxicities that may be seen with other DMARDs, which simplifies monitoring. Short-term toxicities of hydroxychloroquine include gastrointestinal effects such as nausea, vomiting, and diarrhea, which can be managed by taking doses with food. Ocular toxicity includes accommodation defects, benign corneal deposits, blurred vision, scotomas (small areas of decreased or absent vision in the visual field), and night blindness. Although the risk of true retinopathy with hydroxychloroquine approaches zero, preretinopathy may occur in 2.7% of patients. All patients must understand the importance of adhering to hydroxychloroquine monitoring guidelines, as delineated in Table 91-2. Any visual change must be reported immediately. Dermatologic toxicities include rash, alopecia, and increased skin pigmentation; neurologic adverse effects such as headache, vertigo, and insomnia usually are mild.[47,48]

Sulfasalazine

Sulfasalazine, a prodrug, is cleaved by bacteria in the colon into sulfapyridine and 5-aminosalicylic acid.[49] It is believed that the sulfapyridine moiety is responsible for the agent's antirheumatic properties, although the exact mechanism of action is unknown. Once the colonic bacteria have cleaved sulfasalazine, sulfapyridine and 5-aminosalicylic acid are absorbed rapidly from the gastrointestinal tract. Sulfapyridine distributes rapidly throughout the body, but higher concentrations are found in certain tissues such as serous fluid, liver, and intestines. Both sulfasalazine and its metabolites are excreted in the urine. Antirheumatic effects should be seen in 2 months.

Use of sulfasalazine is often limited by its adverse effects. Gastrointestinal adverse effects such as nausea, vomiting, diarrhea, and anorexia are the most common. These can be minimized by initiating therapy with low doses and titrating gradually to higher doses, dividing the dose more evenly throughout the day, or using enteric-coated preparations. Rash, urticaria, and serum sickness-like reactions can be managed with antihistamines and, if indicated, corticosteroids. If a hypersensitivity reaction occurs, therapy should be stopped immediately and another DMARD substituted. Sulfasalazine is associated with leukopenia, alopecia, stomatitis, and elevated hepatic enzymes. It also may cause the patient's urine and skin to turn a yellow-orange color, which is of no clinical consequence however; patients should be educated about this to avoid premature discontinuance.

Sulfasalazine's absorption can be decreased when antibiotics are used that destroy the colonic bacteria. Sulfasalazine also binds iron supplements in the gastrointestinal tract that can lead to a decreased absorption of sulfasalazine. The administration of these two agents should be separated temporally to avoid this interaction. Sulfasalazine can potentiate warfarin's effects by displacing it from protein-binding sites. Close monitoring of the patient's international normalized ratio is indicated.

In a meta-analysis of 15 randomized controlled trials, sulfasalazine was found to be superior in various rating scales compared with placebo, hydroxychloroquine, D-penicillamine, and gold.[50]

Other Disease-Modifying Antirheumatic Drugs

Gold salts, azathioprine, D-penicillamine, cyclosporine, minocycline, anakinra, and cyclophosphamide have all been used to treat RA. Although these drugs can be effective and they may be of value in certain clinical settings, they are used less frequently today because of toxicity, lack of long-term benefit, or both. Tables 91-2 and 91-3 provide dosing information and toxicity information.

Tofacitinib

Tofacitinib (Xeljanz) is a JAK inhibitor for use in patients with moderate to severe RA who have failed, or have intolerance to methotrexate.[51] JAK is a tyrosine kinase protein that facilitates the phosphorylation of the signal transducers and activators of transcription (STATs) proteins. These proteins in turn regulate inflammatory gene transcription. Thus, inhibition of JAK by tofacitinib results in modulation and suppression of the immune system through preventing activation of STATs.

In clinical trials, oral doses of tofacitinib 5 mg twice daily resulted in a statistically higher percentage of patients achieving at least a 20% improvement in RA symptoms at 3 months compared with placebo. An improvement in symptoms of 50% occurred in approximately 30% of patients.[52] In a comparison trial including adalimumab 40 mg every other week, tofacitinib showed similar ACR20 responses and both treatment arms achieved a greater ACR20 response compared with placebo.[53]

The FDA-approved dosing of tofacitinib is 5 mg twice daily as monotherapy or in combination with other nonbiologic DMARDs; tofacitinib should not be given with biologics. A dose reduction of 5 mg once daily should be used in patients with moderate or severe renal dysfunction, moderate hepatic dysfunction, concurrent therapy with potent CYP3A4 inhibitors such as rifampin or moderate CYP3A4 inhibitors, and potent CYP2C19 inhibitors such as fluconazole.[51]

Initiation of tofacitinib should be avoided in patients with severe hepatic impairment, lymphocyte count less than 500 cells/mm^3 (<0.5 × 10^9/L), ANC less than 1000 cells/mm^3 (<1 × 10^9/L), or hemoglobin less than 9 g/dL (<90 g/L; 5.59 mmol/L). Concurrent use of a potent CYP3A4 inducer may lead to a reduced effect from tofacitinib.

Risks, for which black box warnings exist, include serious infections, lymphomas, and other malignancies. Patients should be tested and treated for latent tuberculosis before therapy with tofacitinib. Monitoring for reductions in lymphocytes, neutrophils, and hemoglobin should be

completed at baseline and periodically throughout therapy at 4 to 8 weeks postinitiation and every 3 months thereafter.

Tofacitinib therapy has been associated with elevated plasma liver enzymes and lipids. Gastrointestinal perforations have also been reported. Live vaccinations should not be given during treatment. Though tofacitinib is similar to DMARDs in that it is a synthetic, small molecule that is orally absorbed, it is considered to be in a different category than other synthetic DMARDs in the ACR 2015 RA treatment guidelines.[27] It is recommended for use after DMARDs and biologics due to lack of long-term efficacy and safety data. It may be a convenient oral alternative to other biologic agents; however, this must be considered along with the monitoring schedule required due to safety concerns.

Biologic Agents

Biologic agents are genetically engineered protein molecules that block the proinflammatory cytokines TNF-α (infliximab, etanercept, adalimumab, golimumab, and certolizumab), IL-1 (anakinra), and IL-6 (tocilizumab), deplete peripheral B cells (rituximab), or bind to CD80/86 on T cells to prevent the costimulation needed to fully activate T cells (abatacept). These drugs may be effective when DMARDs fail to achieve adequate responses but are considerably more expensive to use. These agents have no toxicities requiring laboratory monitoring, but they do carry a small increased risk for infection. There is an increased incidence of tuberculosis in patients treated with these agents. Tuberculin skin testing or interferon gamma release assay (IGRA) blood test is recommended prior to treatment with biologic agents so that latent tuberculosis can be detected.[26] Patients with a history of significant tuberculosis exposure or recurrent infection may not be good candidates for these drugs. Those who develop infections while on biologic agents should at least temporarily discontinue them until the infection is cured. Live vaccines should not be given to patients taking biologic agents.

TNF-α Inhibitors

While the TNFi biologics have differing structures, pharmacokinetics, and dosing, their side effects and contraindications are similar in that they all block TNF. Chronic heart failure (CHF) is a relative contraindication for all TNFi agents. Increased cardiac mortality has been seen in patients treated with infliximab and etanercept-associated heart failure exacerbations have been documented.[46,54] Patients with New York Heart Association class III or IV and an ejection fraction of 50% or less should not use TNFi therapy. Additionally, patients whose CHF worsens while taking TNFi therapy should discontinue the drug.[25] In the subset of patients with CHF or whose CHF worsens on TNFi therapy, combination DMARDs, non-TNF biologics, or tofacitinib are recommended.[27]

TNFi therapy has also been reported to induce a multiple sclerosis-like illness or exacerbate multiple sclerosis in patients with the disease. Patients with neurologic symptoms suggestive of multiple sclerosis should discontinue therapy. TNFi may predispose patients to increased cancer risk, especially lymphoproliferative cancer, as TNF plays a role in ridding the body of cancer cells. The US Food and Drug Administration (FDA) added a black box warning to product labeling for TNFi drugs alerting prescribers of increased lymphoproliferative and other cancers in children and adolescents

treated with these drugs.[55]

Etanercept

Etanercept is a fusion protein consisting of two p75-soluble TNF receptors linked to an Fc fragment of human IgG_1. The drug binds to TNF, making it biologically inactive and preventing it from interacting with the cell-surface TNF receptors that would lead to cell activation.

The drug is given by subcutaneous injection, 50 mg once weekly or 25 mg twice weekly, usually through self-injections or administration by a caregiver. Aside from local injection-site reactions, adverse effects are rare. There are case reports of pancytopenia and neurologic demyelinating syndromes such as multiple sclerosis associated with use of etanercept, but these are rare. No laboratory monitoring is required. Clinical trials have used etanercept in patients who failed DMARDs. Response was seen in 60% to 75% of patients. The drug has also been FDA approved for the treatment of juvenile RA, ankylosing spondylitis, psoriatic arthritis, and moderate-to-severe psoriasis. Clinical trials have shown that it slows erosive disease progression to a greater degree than oral methotrexate therapy.[56,57,58]

Infliximab

Infliximab is a chimeric antibody combining portions of mouse and human IgG_1. Approximately 25% of the antibody is derived from mouse amino acids. This antibody, when injected in humans, binds to TNF and prevents its interaction with TNF receptors on inflammatory cells.

Infliximab is given by IV infusion at a dose of 3 mg/kg at 0, 2, and 6 weeks and then every 8 weeks. To prevent the formation of an antibody response to this foreign protein, oral methotrexate should be given concurrently in doses typically used to treat RA for as long as the patient continues on infliximab. Antibodies develop in 14% to 40% of patients, which results in a greater risk of infusion reactions and also may reduce the efficacy of the drug. Loss of response may be seen in patients with RA who have good initial response requiring increased doses or shorter intervals between doses to maintain response. Infusion reactions may occur in any patient treated with the drug. Both acute (within 24 hours of infusion) and delayed (24 hours to 14 days) reactions following infusion have been identified. An acute infusion reaction with symptoms including fever, chills, pruritus, and rash may occur during infusion or within 1 to 2 hours after giving the drug. Treatment includes slowing infusion rates and administering acetaminophen, diphenhydramine, or corticosteroids, depending on the severity of symptoms. Fortunately these reactions are rarely severe or anaphylactic in nature.[59] The drug may increase the risk of infection. Autoantibodies and lupus-like syndrome also have been reported. In addition to RA, infliximab is indicated for the treatment of psoriatic arthritis and ankylosing spondylitis.[60,61]

Adalimumab

Adalimumab is a human IgG_1 antibody to TNF. Because it has no foreign protein components, it is less antigenic than infliximab. The drug is provided as either premixed syringes or injection pens

containing 40 mg, which is administered by subcutaneous injection every 14 days. It has similar response rates to those seen with the other TNFi. Local injection-site reactions were the most common adverse reactions noted in clinical trials. It has the same precautions regarding tuberculosis and other infections as the other biologics.[62,63,64]

Golimumab

Golimumab is a human antibody to TNF-α. In addition to RA, this agent is also indicated for treatment of psoriatic arthritis and ankylosing spondylitis. The drug is available as an injection pen, through which a dose of 50 mg is given monthly by subcutaneous injection. Precautions are similar to other TNFi.[65]

Certolizumab

Certolizumab is a humanized antibody specific for human TNF-α. For RA, dosing recommendations are for 400 mg (2 doses of 200 mg) given by subcutaneous injection at weeks 0, 2, and 4 followed by 200 mg every 2 weeks. Precautions and side effects are similar to other TNFi.[66]

Clinical Controversy…

After failure of an initial anti-tumor necrosis factor (TNF) agent, subsequent treatment may include trials of an alternative anti-TNF agent or a change to a non-TNF biologic. It is not clear which of these strategies is more likely to be effective as randomized trials in anti-TNF treatment failures are lacking.

Non-TNF Biologics

Abatacept

Abatacept is a costimulation modulator approved for the treatment of RA in patients with moderate to severe disease who fail to achieve an adequate response from one or more DMARDs. In patients who failed to achieve adequate responses with TNFi, one-half had a clinical response to abatacept.[67] Additionally, in the first head-to-head trial with biologic agents, the addition of abatacept to a stable methotrexate dose showed similar efficacy and adverse effects to adalimumab plus methotrexate in biologic-naive patients with an inadequate response to methotrexate monotherapy.[68]

By binding to CD80/CD86 receptors on antigen-presenting cells, abatacept inhibits interactions between the antigen-presenting cells and T cells. This prevents T-cell activation to promote the inflammatory process, thus resulting in reductions in cytokines, T-cell proliferation, and other consequences of T-cell activation.

Abatacept is a fusion protein made using the extracellular domain of human cytotoxic T lymphocyte antigen 4 (the binding portion of the drug) and a fragment of the Fc domain of human IgG modified to prevent complement fixation. The drug is given by IV infusion based on patient weight (<60 kg [<132 lb]: 500 mg; 60 to 100 kg [132-220 lb]: 750 mg; >100 kg [>220 lb]: 1,000 mg) every 2 weeks for two doses after the initial dose and then every 4 weeks. Alternatively, the drug may be given by

subcutaneous injection with the first dose of 125 mg given within 24 hours of a single IV infusion and every 7 days after that. Abatacept may be used as monotherapy or in combination with DMARDs.

The adverse effects include headache, nasopharyngitis, dizziness, cough, back pain, hypertension, dyspepsia, urinary tract infection, rash, and extremity pain reported more frequently than placebo in clinical trials. Infusion reactions were 50% more likely with abatacept than with placebo and there was a slightly higher rate of serious infections with active treatment.[67,69,70] Live vaccines should not be given to patients during and for 3 months after the completion of abatacept therapy.[71]

Rituximab

Rituximab is a monoclonal chimeric antibody consisting of mostly human protein with the antigen-binding region derived from a mouse antibody to CD20 protein found on the cell surface of mature B lymphocytes. The binding of rituximab to B cells results in nearly complete depletion of peripheral B cells. Although its mechanism of action in RA is not completely known, it is thought that this depletion in B cells decreases antigen presentation to T cells, thus decreasing symptoms and delaying structural damage. After administration of rituximab, it takes several months for B-cell recovery. This prolonged effect on B cells results in a variable duration of action that allows for intermittent therapy based on reactivation of arthritis symptoms.

Rituximab is useful in patients who failed methotrexate or TNFi.[72,73,74,75,76] Two infusions of 1,000 mg are given 2 weeks apart. Methylprednisolone 100 mg should be given 30 minutes prior to rituximab to reduce the incidence and severity of infusion reactions. Acetaminophen and antihistamines may also be of benefit in patients who have a history of reactions. Methotrexate should be given concurrently in the usual doses used for RA, as the combination has proved to provide the best therapeutic outcomes. Duration of benefit is variable after a course of rituximab and patients will need retreatment with reactivation of their disease. Live vaccines should not be given to patients given rituximab.

Tocilizumab

IL-6 is a major cytokine believed to have a role in promoting inflammation in RA. Tocilizumab is a humanized monoclonal antibody that attaches to IL-6 receptors, preventing the cytokine from interacting with the IL-6 receptor.[77] It is FDA approved for use in adults with moderately to severely active RA who have failed to respond to one or more DMARDs. It is used as either monotherapy or in combination with methotrexate or another DMARD. A recent study completed in patients with severe RA unable to use methotrexate found tocilizumab monotherapy more efficacious in symptom improvement than adalimumab monotherapy.[78]

The initial starting dose is 4 mg/kg given IV every 4 weeks with dose escalation to 8 mg/kg IV every 4 weeks based on clinical response and tolerance.[77] The rates of adverse events are generally low but higher with combination therapy as compared to monotherapy. The most serious adverse effects reported include infusion reactions, increased infection risk, elevated plasma lipids, elevated liver enzymes, and gastrointestinal perforation. Tocilizumab use may also lead to increased metabolism of

concomitant cytochrome P450 (CYP)3A4 substrate medications. It is recommended to monitor agents with narrow therapeutic window such as warfarin. Oral contraceptives and CYP3A4 statins may also be affected.

Anakinra

Anakinra is a naturally occurring IL-1 receptor antagonist. Results of clinical trials suggest it to be less effective than other biologics.[79] The ACR did not include anakinra in their RA treatment recommendations because of limited use of this drug, but select patients with refractory disease could benefit from treatment with this drug.[25]

Treatment Strategies for Patients with Suboptimal Response to Biologics

TNFi are generally the first biologic agents chosen for most patients with RA. Approximately 30% of patients discontinue treatment with these drugs because of lack of efficacy or adverse effects. Lack of efficacy can further be defined as a primary failure (failure to see a treatment response 3 to 6 months after therapy initiation) or secondary failure (loss of response after an initial improvement is observed).

In such situations, addition of a DMARD may be beneficial if the patient is not already taking one. Dose escalation or decreased interval between infusions may be useful for those patients taking infliximab; higher doses of other TNFi have not been demonstrated to be effective. Choosing an alternative TNFi after failure of the initial TNFi agent may be beneficial for some patients[80]; however, no randomized controlled trials have compared the effectiveness of cycling among agents in this class. Treatment with rituximab, abatacept, tocilizumab or tofacitinib may also prove to be effective in TNFi treatment failures.[63,72,80]

Clinical Controversy…

As biologics lose patent protection, generic formulations of these products, called biosimilars, will be marketed. It remains to be seen whether these biosimilars will be as safe and effective as currently used biologics that they may replace.

PERSONALIZED PHARMACOTHERAPY

With various pathways involved leading to inflammation in RA and an increasing number of agents available, it is important to consider patient-specific factors when making therapeutic decisions. Disease activity and the presence of poor prognostic guide treatment and lead to early aggressive therapy in patients with more severe disease.

Therapy must be tailored for various comorbidities the patient may have (**Table 91-6**). Hepatitis and other liver diseases, heart failure, renal failure, and history of cancer are among the comorbidities that influence treatment choice. Individual patients may also significantly differ in their response to a specific agent; currently, there are no clear predictors of response to therapeutic interventions.

TABLE 91-5 Dosage Regimens for NSAIDs

	Recommended Anti-inflammatory Total Daily Dosage		
Drug	***Adult***	***Children***	**Dosing Schedule**
Aspirin	2.6-5.2 g	60-100 mg/kg	Four times daily
Celecoxib	200-400 mg	—	Daily to twice daily
Diclofenac	150-200 mg		Three times per day to four times daily
			Extended release twice daily
Diflunisal	0.5-1.5 g	—	Twice daily
Etodolac	0.2-1.2 g (max. 20 mg/kg)	—	Twice daily to four times daily
Fenoprofen	0.9-3.0 g	—	Four times daily
Flurbiprofen	200-300 mg	—	Twice daily to four times daily
Ibuprofen	1.2-3.2 g	20-40 mg/kg	Three times per day to four times daily
Indomethacin	50-200 mg	2-4 mg/kg (max. 200 mg)	Twice daily to four times daily
			Extended release daily
Meclofenamate	200-400 mg	—	Three times per day to four times per day
Meloxicam	7.5-15 mg	—	Daily
Nabumetone	1-2 g	—	Daily to twice daily
Naproxen	0.5-1.0 g	10 mg/kg	Twice daily
			Extended release–daily
Naproxen sodium	0.55-1.1 g	—	Twice daily
Nonacetylated salicylates	1.2-4.8 g	—	Twice daily to six times per day
Oxaprozin	0.6-1.8 g (max. 26 mg/kg)	—	Daily to three times a day
Piroxicam	10-20 mg	—	Daily
Sulindac	300-400 mg	—	Twice daily
Tolmetin	0.6-1.8 g	15-30 mg/kg	Twice daily to four times daily

NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 91-6 Treatment of Rheumatoid Arthritis in Patients with High-Risk Conditions

Comorbidity	**Recommendation**
Latent TB	Use biologic, tofacitinib after 1 month treatment for

Comorbidity	Recommendation
	latent TB
Active TB	Use biologic, tofacitinib only after completion of treatment for active TB
Pregnant/breastfeeding	Avoid methotrexate, leflunomide, minocycline
CHF	Prefer non-TNF inhibitor therapy
Skin cancer (melanoma or nonmelanoma	Use DMARDs preferably over biologics or tofacitinib
Previously treated lymphoproliferative disorder	Use rituximab, combination DMARD, abatacept or tocilizumab over TNF inhibitor
• Hepatitis B	No restrictions
• Hepatitis C infection not receiving or requiring treatment	Use DMARD over TNF inhibitor
• Hepatitis C infection treated or receiving treatment	No restrictions
• Previous serious infections	Use combination DMARD or abatacept over TNF inhibitor

CHF, chronic heart failure; DMARD, disease-modifying antirheumatic drug; TB, tuberculosis; TNF, tumor necrosis factor.

Pharmacokinetic parameters should be taken into consideration when determining therapeutic options for specific patients. NSAIDs should be avoided in patients with renal impairment or in patients at high risk for NSAID-induced renal injury including the elderly, those with congestive heart failure or cirrhosis, or patients at risk for volume depletion such as those using diuretics.[81] Dose adjustments are recommended in patients with renal dysfunction for methotrexate and anakinra. Dose reductions are also recommended with tofacitinib in patients with moderate or severe renal impairment, moderate hepatic dysfunction, or patients treated concomitantly with CYP3A4 inhibitors.

While azathioprine is now used less frequently for RA, genetic testing for null or decreased thiopurine *S*-methyltransferase (TPMT) activity is available to help predict those patients with a higher risk of myelosuppression due to reduced metabolism of the drug, and dosage reductions may be made in those patients.[82]

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of therapeutic outcomes is based primarily on improvements of clinical signs and symptoms of RA. Clinical signs of improvement include a reduction in joint swelling, decreased warmth over actively involved joints, and decreased tenderness to joint palpation. Improvement in RA symptoms includes reduction in perceived joint pain and morning stiffness, longer time to onset of afternoon fatigue, and improvement in ability to perform activities of daily living. Improvement of activities of daily living may be assessed objectively using a health assessment questionnaire score. Joint radiographs may be of some benefit in assessing the progression of the disease and should

show little or no evidence of disease progression if treatment is effective.

Laboratory monitoring is of little value in monitoring individual patient response to therapy. Tables 91-2 and 91-3 provide monitoring of drug toxicity information. Routine monitoring of patients is essential to the safe use of these drugs. In addition, patients should be questioned about symptoms of the adverse effects outlined in the drug section of this chapter.

CONCLUSIONS

RA is the most common inflammatory arthritis, affecting approximately 1% of the population. The disease is characterized by symmetrical swelling and stiffness of the involved joints. The stiffness is usually more prominent in the morning. Extraarticular features of RA include rheumatoid nodules, vasculitis, and ocular, cardiac, and pulmonary complications. The course of the disease is highly variable. Treatment is aimed at reaching remission or low disease activity, which will result in relief of pain and inflammation and maintain and preserve joint function. Nondrug therapy, including exercise and adequate rest periods, should also be used early in the course of treatment. Early use of a DMARD or biologic agent results in better patient outcomes. Methotrexate should be considered for initial therapy in most patients. Patients who fail to achieve at least low disease activity with initial therapy could be considered for other DMARDs, combination DMARDs or biologics agent. These approaches have been shown to be effective in patients who fail to achieve adequate response from initial DMARD monotherapy. Corticosteroids and NSAIDs may be useful adjuncts for treatment, but because of adverse effects and limited impact on long-term outcomes, they should not be considered as sole treatment for most patients.

Chapter 92: Osteoporosis and Osteomalacia

Mary Beth O'Connell; Jill S. Borchert

INTRODUCTION

KEY CONCEPTS

- 1 Osteoporosis is a public health epidemic that affects all ages, genders, races, and ethnicities. Lifestyle behaviors, diseases, and medications should be reviewed to identify risk factors for developing osteoporosis and osteoporotic fractures. Healthcare providers should identify and resolve reversible risks. Patients with early onset or severe osteoporosis should be evaluated for secondary causes of bone loss.

- 2 Bone physiology and pathophysiology are complex, involving many different cell lines, pathways, and biofeedback systems. As these processes become more delineated, additional drug targets exist creating new investigational agents.

- 3 Ten-year probabilities for a major osteoporotic and hip fracture can be estimated for women (postmenopausal to age 90 years old) and men (50-90 years old) with the FRAX tool. This tool is a questionnaire that can be used in any setting, including a pharmacy, health fair, or clinic. Central bone densitometry can determine bone mass, predict fracture risk, and influence patient and provider treatment decisions.

- 4 Throughout life, everyone should practice a bone healthy lifestyle, which emphasizes regular exercise, nutritious diet, tobacco avoidance, minimal alcohol use, and fall prevention to prevent and treat osteoporosis.

- 5 Treatment should be considered for postmenopausal women and men older than 50 years who have a low-trauma hip or vertebral fracture, T-score of –2.5 or less at the femoral neck, total hip, or spine or low bone mass (T-score between –1.0 and –2.5) and a FRAX 10-year probability of major osteoporotic fracture of 20% or more or hip fracture of 3% or more.

- 6 The recommended dietary intake for calcium for American adults is 1,000 to 1,200 mg of elemental calcium daily with diet as the preferred source. Supplements are added only when diet is insufficient.

- 7 The recommended daily dietary intake for vitamin D for American adults is 600 units and for older adults 800 units, with some organizations and guidelines recommending higher doses of at least 800 to 1,000 units daily. The daily target is achieved through sun exposure, fortified foods, and supplements. Vitamin D insufficiency and deficiency, defined as 25(OH) vitamin D concentrations of less than 30 ng/mL [mcg/L; less than 75 nmol/L]) and less than 20 ng/mL [mcg/L; less than 50 nmol/L] respectively, are common in Americans.

- 8 Alendronate, risedronate, zoledronic acid, and denosumab decrease vertebral, hip, and nonvertebral fractures and are considered first-line osteoporosis treatments. Ibandronate, raloxifene, and teriparatide are alternatives and calcitonin is an agent of last resort.

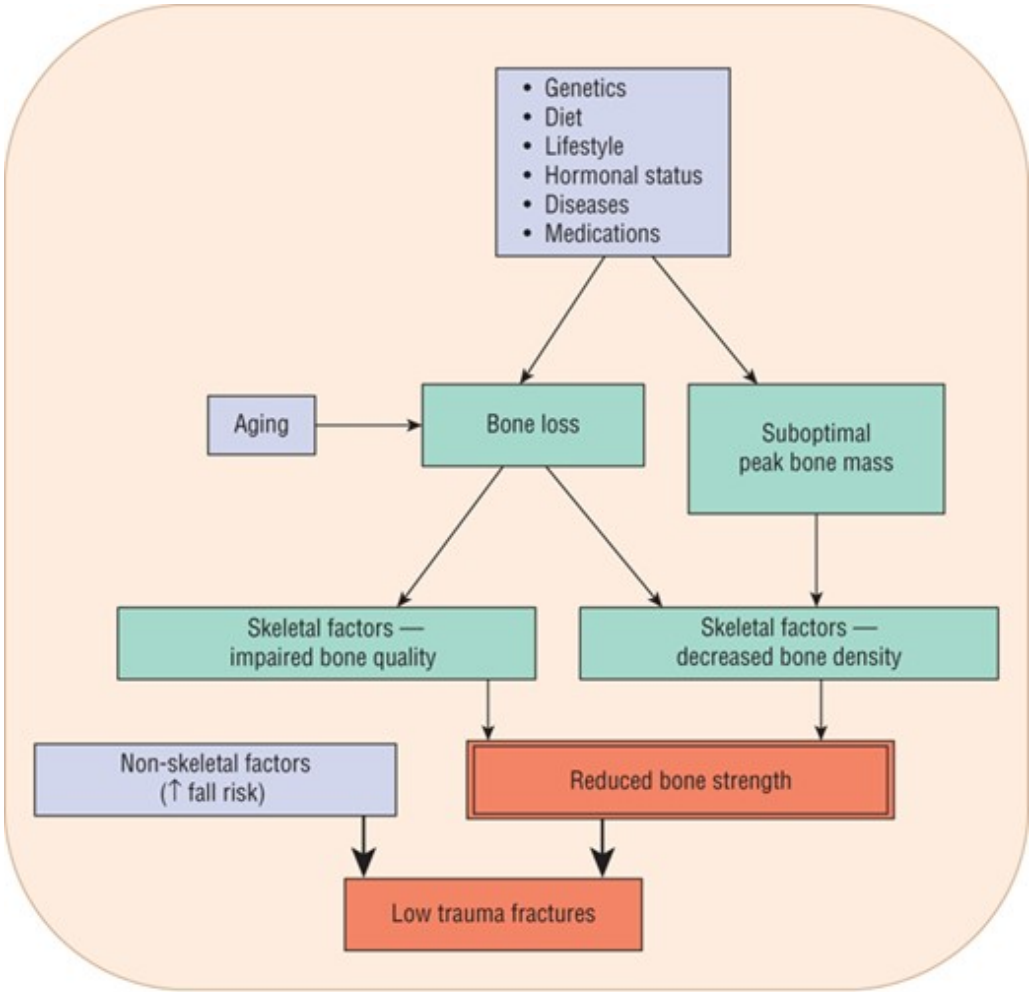
- 9 Adherence to osteoporosis medications is frequently suboptimal, and poor adherence is associated with less fracture prevention. Healthcare providers should assess medication administration technique and adherence at each visit and provide needed education and medication problem solving.

- 10 The most common causes of medication-induced osteoporosis are long-term oral glucocorticoids and certain chemotherapeutic agents. All patients taking medications known to increase bone loss should practice a bone healthy lifestyle, be evaluated for a switch to a safer alternative medication, and be considered for osteoporosis therapy.

1 Osteoporosis is a bone disorder characterized by low bone density, impaired bone architecture, and compromised bone strength that predisposes a person to increased fracture risk.[1] Osteoporosis is a major public health threat, especially with 55% of the people 50 years of age and older expected to have this disease. In the United States, 10.2 million Americans are estimated to have osteoporosis.[2] An additional 43.4 million Americans are estimated to have low bone density (sometimes referred to as osteopenia) and are at risk for osteoporosis. Attention to bone health is a requirement for all ages. Osteoporosis and osteoporotic fractures are multifactorial conditions, beginning at birth with genetics and then throughout life related to health behaviors that influence bone growth and maintenance, skeletal factors that lead to compromised bone strength, and nonskeletal factors that lead to falls (**Fig. 92–1**). Healthcare providers should educate patients about bone healthy lifestyles and encourage them to practice these health behaviors. Monitoring bone health in patients at risk and providing optimal treatment for patients with osteoporosis are also important.

FIGURE 92–1

Etiology of osteoporosis and osteoporotic fractures.



EPIDEMIOLOGY

1 Low bone density, osteoporosis, and osteoporotic fractures are very common and affect all races and ethnic groups. Low bone density is estimated to occur in 53% of non-Hispanic white, 48% of Mexican American, and 36% of non-Hispanic Black women age 50 and older.[2] Osteoporosis affects 16% of non-Hispanic White, 20% of Mexican American, and 8% of non-Hispanic Black women age 50 and older. Disease prevalence greatly increases with age; from 7% in women 50 to 59 years of age to 35% in women 80 years of age and older. White and Hispanic women have the highest fragility fracture rate followed by Native American, African American, and Asian women when the data are adjusted for weight, bone mineral density (BMD), and other factors.[3] Approximately 35% of men aged 50 years and older have low bone density rising to 53% in men 80 years and older. Osteoporosis prevalence in non-Hispanic White men is 4%, Mexican American men is 6%, non-Hispanic Black men is 1%. Osteoporosis prevalence rises to 11% in men 80 years and older. Although osteoporosis is a common finding in older adults with fractures, in one study up to 50% of fragility fractures occurred in patients with normal or low bone mass.[3]

Fragility wrist and vertebral fractures are common throughout adulthood, and hip fractures are more common in older adults. While women experience the majority of fractures, approximately 30% to

40% of fractures due to osteoporosis occur in men.[4] Forecasting predicts osteoporosis care to cost $25 billion by 2025.[1] Because of associated morbidity, hip fractures are the most costly accounting for almost 75% of fracture costs.[1,5] In a woman's lifetime, she has a 17% likelihood of a hip fracture, 15.6% likelihood of a vertebral fracture and 16% likelihood of a forearm fracture. In a man's lifetime, osteoporotic fracture risk is 13% to 30%.[4] The incidences of hip fracture and associated mortality are decreasing for both sexes,[5] possibly due to better efforts at osteoporosis prevention (eg, bone-healthy lifestyle) and use of bisphosphonates. However, rates in the United States remain higher than those in other countries and comorbidities are increasing[1] suggesting a need for continued focus on bone health.

ETIOLOGY

Figure 92–1 depicts a model describing the etiology of osteoporosis and fractures. The major risk factors (see **Tables 92–1**, **92–2**, **92–3**) influencing bone loss are hormonal status, genetics, exercise, aging, nutrition, lifestyle, concomitant diseases, and medications. [1,3,4,6,7,8,9,10,11,12,13,14] Nonhormonal risk factors are similar between women and men.

TABLE 92-1 Risk Factors for Osteoporosis and Osteoporotic Fractures

Low bone mineral density[a]
Female sex[a]
Advanced age[a]
Race/ethnicity[a]
History of a previous fragility (low-trauma) fracture as an adult[a] (especially clinical vertebral fracture or hip fracture)
Osteoporotic fracture in a first-degree relative (especially parental hip fracture[a])
Low body weight or body mass index[a]
Premature menopause (before 45 years old)
Secondary osteoporosis (especially rheumatoid arthritis[a,b])
Past or present systemic oral glucocorticoid therapy[a,c]
Current cigarette smoking[a,c]
Alcohol intake of 3 or more drinks/day[a,c]
Low calcium intake
Low physical activity or immobilization
Vitamin D insufficiency and deficiency
Recent falls
Cognitive impairment
Impaired vision

[a]Factors included in World Health Organization fracture risk assessment tool (FRAX).

[b]Secondary causes included in the FRAX tool are type 1 diabetes, osteogenesis imperfecta as an adult, long-standing untreated hyperthyroidism, hypogonadism, premature menopause (<45 years old), chronic malnutrition, malabsorption, and chronic liver disease.

[c]Risk is larger with greater exposure.

Data from references 1, 3, 4, and 6, 7, 8, 9, 10, 11, 12, 13.

TABLE 92-2 Select Medical Conditions Associated with Osteoporosis in Children and Adults

Endocrine/Hormonal
Primary or secondary ovarian failure
Testosterone deficiency
Hyperthyroidism
Cushing's syndrome
Growth hormone deficiency (in children)
Primary hyperparathyroidism
Diabetes, type 1 and type 2
Gastrointestinal
Nutritional disorders (eg, anorexia nervosa)
Malabsorptive states (eg, Crohn disease, celiac disease, gastrectomy, and bariatric surgery)
Chronic liver disease (eg, primary biliary cirrhosis)
Disorders of Calcium Balance
Hypercalciuria
Vitamin D deficiency
Inflammatory Disorders
Rheumatoid arthritis
Chronic Illness
Chronic kidney disease
Malignancies (eg, multiple myeloma, lymphoma, and leukemia)
Human immunodeficiency virus infection/acquired immunodeficiency syndrome
Organ transplant
Disuse/Immobility
Muscular dystrophy
Multiple sclerosis
Stroke/cerebrovascular accident
Genetic
Osteogenesis imperfecta

Cystic fibrosis

Hemochromatosis

Hypophosphatasia

Data from references 3, 4, 6, 7, 8, 9, 12, and 32.

TABLE 92-3 Select Medications Associated with Increased Bone Loss and/or Fracture Risk

Medications	Comments
Anticonvulsant therapy (phenytoin, carbamazepine, phenobarbital, and valproic acid)	↓ BMD and ↑ fracture risk; increased vitamin D metabolism leading to low 25(OH) vitamin D concentrations
Antiretroviral therapy (ART)	
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) (zidovudine, didanosine, lamivudine, and tenofovir)	↓ BMD (NRTIs > PI), no fracture data; increased osteoclast activity and decreased osteoblast activity
Protease inhibitors (PI) (nelfinavir, indinivir, saquinavir, ritonavir, and lopinavir)	
Aromatase inhibitors (eg, letrozole and anastrozole)	↓ BMD and ↑ fracture risk; reduced estrogen concentrations
Canagliflozin	↓ BMD and ↑ fracture risk (FDA reviewing SLGT2 inhibitor class of medications)
Furosemide	↑ fracture risk; increased calcium renal elimination
Glucocorticoids (long-term oral therapy)	↓ BMD and ↑ fracture risk; increased bone resorption and decreased bone formation; dose and duration dependent; see special populations section
Gonadotropin-releasing hormone agonists or analogs (eg, leuprolide and goserelin)	↓ BMD and ↑ fracture risk; decreased sex hormone production
Heparin (unfractionated, UFH) or low molecular weight heparin (LMWH)	↓ BMD and ↑ fracture risk (UFH >>> LMWH) with long-term use (eg > 6 months); decreased osteoblast replication and increased osteoclast function
Medroxyprogesterone acetate depot administration	↓ BMD, no fracture data; possible BMD recovery with discontinuation; decreased estrogen concentrations
Proton pump inhibitor therapy (long-term therapy)	↓ BMD and ↑ fracture risk; possible calcium malabsorption secondary to acid suppression for carbonate salts
Selective serotonin reuptake inhibitors	↓ BMD and ↑ fracture risk; decreased osteoblast activity

Medications	Comments
Thiazolidinediones (pioglitazone and rosiglitazone)	↓ BMD and ↑ fracture risk; decreased osteoblast function
Thyroid—excessive supplementation	↓ BMD and ↑ fracture risk; risk increases with TSH concentration < 0.1 mIU/L; possible increase in bone resorption
Vitamin A—excessive intake (> 1.5 mg of retinol form)	↓ BMD and ↑fracture risk; decreased osteoblast activity and increased osteoclast activity

BMD, bone mineral density; TSH, thyroid-stimulating hormone; DXA, dual-energy X-ray absorptiometry.

Data from references 7, 8, and 10, 11, 12, 13, 14.

Low Bone Density

BMD is a major predictor of fracture risk. Every standard deviation decrease in BMD in women represents a 10% to 12% decrease in bone mass and a 1.5- to 2.6-fold increase in fracture risk.[3] Low BMD can occur as a result of failure to reach a normal peak bone mass, bone loss or both. Genetics accounts for 60% to 80% of peak bone mass variability.[3,12] Bone loss occurs when bone resorption exceeds bone formation, which also can result from high bone turnover when the number or depth of bone resorption sites greatly exceeds the rate and ability of osteoblasts to form new bone. Women and men begin to lose a small amount of bone mass starting in the third to fourth decade of life.[3,15] During perimenopause and menopause, bone loss occurs predominantly due to increases in bone resorption. By age 70 to 80, 30% to 40% of bone mass is lost. Older adults steadily lose bone mass as a consequence of an accelerated rate of bone remodeling combined with reduced bone formation.

Impaired Bone Quality

Bone strength is highly affected by the quality of the bone's composition and its structure, and a better predictor of fracture than BMD. Changes in bone mass do not fully reflect changes in bone thinning and decreased connectivity, both related to strength. BMD explains only 70% of femur and 44% of spine bone strength. Accelerated bone turnover can increase the amount of immature bone that is not adequately mineralized. Sex differences exist with thinning of trabeculae with aging in men causing less bone quality damage and impaired bone strength than in women.[15] With aging, fracture risk increases for a given T-score, partly related to bone quality changes.

Falls

One third to one half of older adults fall each year.[16] In older adults, 87% of fractures resulted from a fall. In 2013, 2.5 million older adults were treated in the emergency department for falls resulting in 734,000 hospitalizations, incurring costs of about $30 billion. The risk factors for falls overlap with the risk factors for osteoporosis and osteoporotic fractures.[1]

PATHOPHYSIOLOGY

Bone Physiology

The skeleton has two types of bone. Cortical bone makes up the majority of the skeleton (80%) and is found mostly in the long bones (eg, forearm and hip).[17] Trabecular bone is found mostly in the vertebrae and ends of long bones. This bone type is metabolically more active compared with cortical bone due to a much higher bone turnover rate because of its large surface area and honeycomb-like shape.

Bone is made of collagen and mineral components.[17] The collagen component gives bone its flexibility and energy-absorbing capability. The mineral component gives bone its stiffness and strength. The correct balance of these substances is needed for bone to adequately accommodate stress and strain and resist fractures. Imbalances can impair bone quality and lead to reduced bone strength.[18]

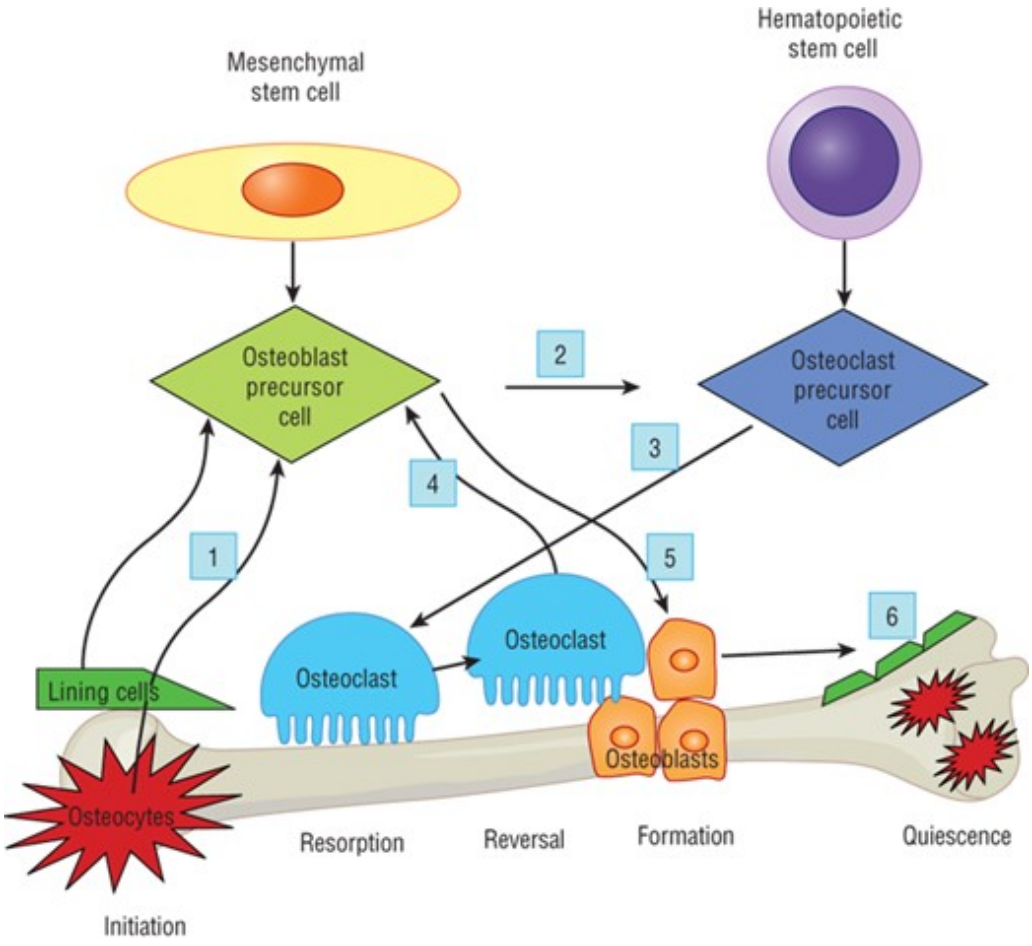
Bone strength reflects the integration of bone mass and bone quality (composition and microarchitecture). Bone mass increases rapidly throughout childhood and adolescence. Peak bone mass is attained by age 18 to 25 years.[1] Peak bone mass is highly dependent on genetic factors, which accounts for 60% to 80% of the variability.[6] The remaining 20% to 40% is influenced by modifiable factors such as nutritional intake (eg, calcium, vitamin D, and protein), exercise, adverse lifestyle practices (eg, smoking), hormonal status, and certain diseases and medications. Optimizing peak bone mass is important for preventing osteoporosis. The higher the peak bone mass, the more bone one can lose before being at an increased fracture risk. As the microarchitecture of bone deteriorates, the bone strength greatly decreases. Women lose more structure than men.[4]

2 Bone remodeling is a dynamic process that occurs continuously throughout life (see **Fig. 92–2A-C**).[19,20,21,22] One to two million tiny sections of bone are in the process of remodeling at any given time. Within these sections, the bone remodeling activities of bone resorption and bone formation are coupled and balanced. Bone remodeling is triggered to repair microdamage to the skeleton and serves to support calcium homeostasis through maintaining normal serum calcium by releasing calcium from the bone. Within an active bone remodeling unit, osteoclasts (bone resorbing cells) work to resorb bone during the resorptive phase then this process reverses and osteoblasts (bone-forming cells) work to form bone during the formation phase. Osteoblasts then become incorporated into the bone matrix as osteocytes (bone-communication cells). The unit then becomes inactive and enters a quiescent phase. If remodeling becomes unbalanced and bone resorption surpasses bone formation or if the phases become uncoupled and bone resorption occurs without adequate formation, a decrease in BMD is the result. Osteocytes play a key role in the process and can trigger a new remodeling cycle.

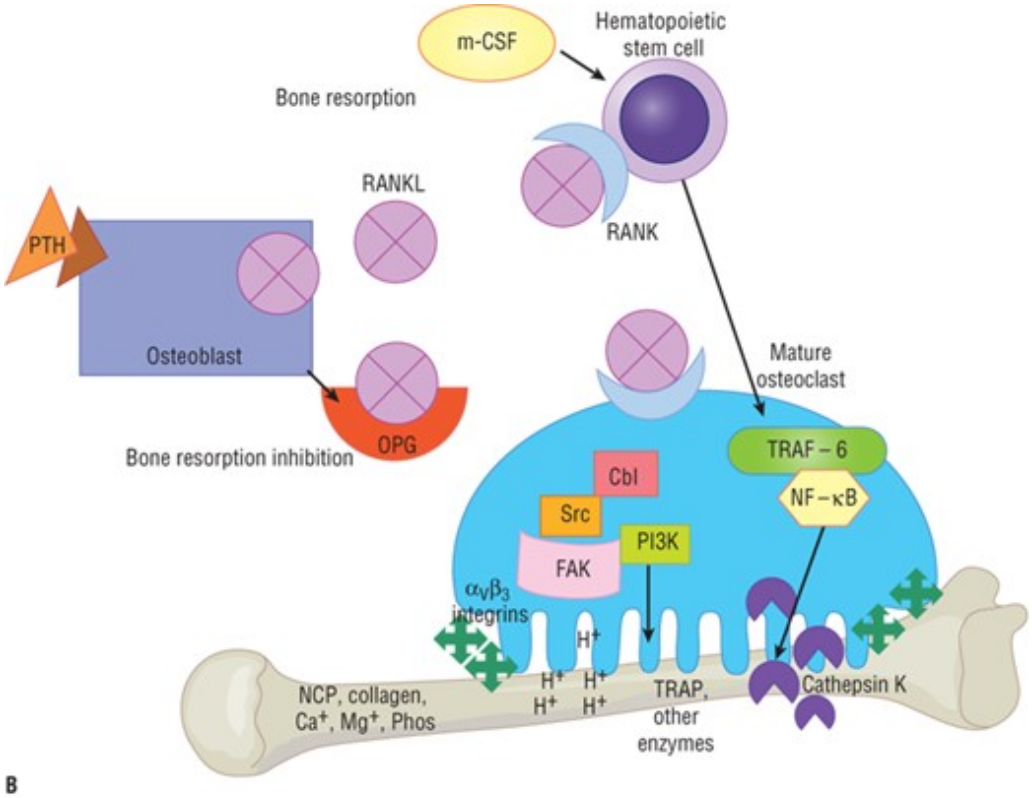
FIGURE 92–2

Bone remodeling cycle. (A) Overview of remodeling process, Step 1 = initiation, Step 2 and 3 =

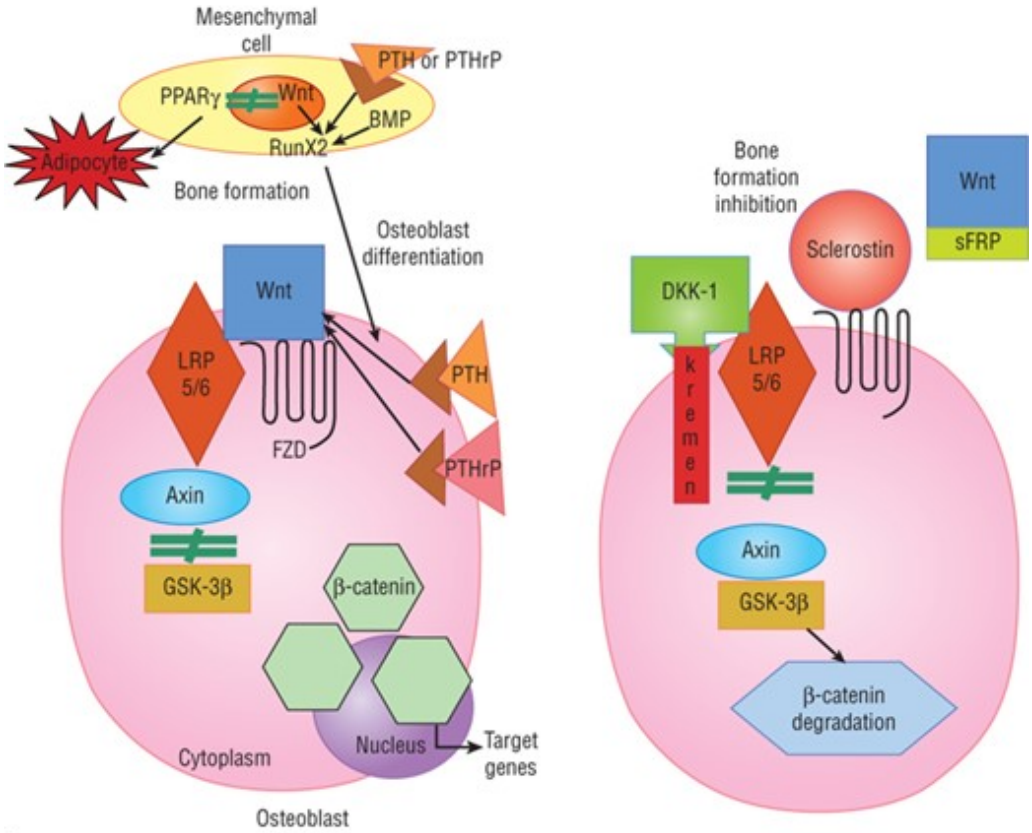
resorption, Step 4 = reversal, Step 5 = formation, and Step 6 = quiescence; (B) = molecular level detail of major pathways during bone resorption steps 2 and 3, which also showcase drug targets for approved and investigational agents; (C) = molecular level detail of major pathways during bone formation steps 4 and 5, which also showcase drug targets for approved and investigational agents; BMP, bone morphogenetic protein; Ca+, calcium; m-CSF, macrophage-colony-stimulating factors; DKK-1, Dickkoff1; FAK, focal adhesion kinase, GSK-3β, glycogen synthase kinase-3β; H+, hydrogen ion; LRP5/6, lipoprotein-receptor related protein; Mg, magnesium; NF-KB, nuclear factor kappa B; NCP, noncollagenous proteins; OPG, osteoprotegerin; Phos, phosphorous; PI3K, phosphatidylinositol 3-kinase; PPARγ, peroxisome proliferator-activated receptor; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related protein; RANK, receptor activator of nuclear factor-kb; RANKL, receptor activator of nuclear factor-kb; runX2, runtrelated transcription factor; Scr; tyrosine scr kinase; TRAF-6, tumor necrosis factor receptor associated factor 6; TRAP, tartrate-resistant acid phosphate; Wnt, wingless tail. *(Data from references 19, 20, 21.)*



A



B



C

The signaling of the bone remodeling cycle through the steps from resorption through quiescence is highly complex; many cytokines, growth factors, and hormones influence each step.[19,20,21] The

complete physiology of bone remodeling is not fully known, but appears to begin with signals from lining cells or osteocytes that are triggered by stress, microfractures, biofeedback systems responsive to cytokines and growth factors, and potentially certain diseases and medications (see **Fig. 92–2B**, step 1). A major stimulus for hematopoietic stem cell differentiation to become mature osteoclasts is the receptor activator of nuclear factor kappa β ligand (RANKL), which is a cytokine emitted from osteoblasts or osteocytes in step 2. Interleukin 1 and 6, macrophage colony stimulating factor (m-CSF), parathyroid hormone (PTH), parathyroid-releasing protein (PTHrP), 1,25(OH) vitamin D, tissue growth factor-β (TGF-β), prostaglandin E_2, and tumor necrosis factor-α (TNF-α) stimulate RANKL release whereas estrogen and calcitonin inhibit RANKL release. The RANKL then binds to its receptor RANK on the surface of osteoclast precursors initiating differentiation. The RANKL also stimulates mature osteoclast activation and bone adherence via $\alpha_v\beta_3$ integrins to resorb bone (step 3). This step is influenced by TGF-β, insulin-like growth factor-1 and 2 (IGF), platelet derived growth factor, bone morphometric protein, and fibroblast growth factor (FGF). After bone attachment, the osteoclasts secrete proteinases, such as cathepsin K, collagenase, gelatinase, tartrate-resistant acid phosphate, and matrix metalloproteases, and hydrogen ions to dissolve the mineralized bone. The hydrogen ion production is under src kinase control, which needs to be bound to other compounds such as Cbl, Fak, and phosphatidylinositol 3-kinase (PI3K).

After bone is resorbed and a cavity is created, osteoclasts produce cytokines and growth factors to elicit osteoblast differentiation from mesenchymal stem cells, maturation and activity (step 4).[19,20] PTH and PTHrP also directly increase osteoblast differentiation and activity. Osteoblast differentiation can be inhibited by leptin and PPARγ, which direct mesenchymal cell maturation to adipocytes instead of osteoblasts. Mature osteoblasts and osteocytes produce osteoprotegerin (OPG) that binds to RANKL, thereby stopping bone resorption.

Bone formation occurs over two phases—formation then mineralization of bone (see **Fig. 92–2C**).[19,20,21,23] First wingless tail ligands (Wnt) bind to low-density lipoprotein receptor related protein 5 or 6 (LRP5/6) and a frizzled coreceptor. Wnt function is also influenced by PTH and PTHrP, which fit into the same receptor. Next LRP5/6 binds to axin, which then cannot bind to glycogen synthase kinase-3β (GSK-3β), thus preventing degradation of β-catenin (step 5). Accumulated β-catenin then enters the nucleus and signals target genes to create proteins to fill the resorption cavity with osteoid. Growth hormone and IGF-1 also increase bone collagen production. Next mineralization of bone with calcium, magnesium, and phosphorus follows to give the new matrix strength.

Once the cavity is mineralized, bone formation can be stopped through multiple signaling processes.[19,20,21] Both sclerostin and Dickkopf-1 (Dkk-1) are secreted from osteocytes and bind to LRP5/6 or secreted frizzled–related proteins, which can bind to Wnt to prevent Wnt signaling. Axin can then bind to GSK-3β, which then can cause β-catenin degradation, osteoblast apoptosis, and the end of osteoblastic activity (step 6). The mature osteoblasts can become lining cells or osteocytes. Quiescence is the phase when bone is at rest until another remodeling cycle is initiated. Later, osteocytes may trigger initiation of a new remodeling cycle through secretion of sclerostin or RANKL to stimulate osteoclasts and bone resorption.

Hormones can influence the remodeling steps. Estrogen has many positive effects in both sexes on the bone remodeling process, with most of its actions helping to maintain a normal bone resorption rate.[15,24] Estrogen suppresses the proliferation and differentiation of osteoclasts and increases osteoclast apoptosis. Estrogen decreases the production of several cytokines that are potent stimulators of osteoclasts, including interleukins 1 and 6, TNF-α, and m-CSF, and increases TGF-α, which increases osteoclast apoptosis. Estrogen also decreases the production of RANKL to reduce osteoclastogenesis.

Testosterone's role in bone health is becoming more apparent with recent identification of some direct effects on bone resorption and osteoblasts.[24] Most of testosterone's bone effects relate to its metabolism to estradiol and the above estrogen bone effects. Testosterone can also increase OPG production, which will inhibit bone resorption. Increased osteoblast proliferation and differentiation are direct effects. These effects might be from increasing TGF- β, TGF mRNA, FGF, and IGF-2, and decreasing IL-6.

CALCIUM HOMEOSTASIS, VITAMIN D, AND PARATHYROID HORMONE

Calcium homeostasis is maintained by vitamin D and PTH, which influence calcium gastrointestinal (GI) absorption and renal reabsorption.[18] Calcium absorption under normal conditions is approximately 30% to 35%, decreasing to 10% to 15% with low vitamin D concentrations.[22] Calcium absorption is thus lower in the winter due to decreased exposure to required ultraviolet light converting less vitamin D in the skin. It is reported to be higher in obesity, which is associated with greater vitamin D storage. Calcium absorption is predominantly an active rate-limited process in the duodenum and jejunum, which is controlled by many hormones, such as 1,25-dihydroxyvitamin D [1,25(OH) vitamin D], estrogen, and TRPV6, which is under genomic control and responsive to dietary calcium intake. A calcium transporter (calmodulin or calbindin) is required to bring calcium from the gut into the tissue wall and then across the enterocyte. Calcium is extruded into the circulation via Ca^{2+} adenosine triphosphatase (ATPase) and the sodium/calcium exchanger, high-energy steps. Throughout the intestine, paracellular passive calcium diffusion occurs. This diffusion accounts for less than 15% of absorbed calcium, is not rate limited, and possibility is sensitive to 1,25(OH) vitamin D. Solvent drag plays a minor role in calcium absorption.

When the calcium-sensing receptor on parathyroid cells detects low serum calcium, PTH production increases.[18,22] PTH then directly (minimal effect) and indirectly (predominant effect via increasing calcitriol production) cause calcium reabsorption by the kidney. Calcium reabsorption increases as 25(OH) vitamin D concentrations increases, plateauing around 10 to 15 ng/mL (mcg/L; 25-37 nmol/L).[25] Furosemide decreases and thiazide diuretics increase calcium resorption in the kidney.

Sometimes the increased fractional calcium absorption is insufficient to maintain normal serum calcium, requiring bone resorption for correction.[22] Consistent and high concentrations of PTH and calcitriol increase RANKL and decrease OPG resulting in increased osteoclast activity, which releases calcium from bone to restore calcium homeostasis. Of note, low PTH concentrations for a short time

(eg, teriparatide) increase bone formation.

Active 1,25(OH) vitamin D concentrations depend on skin conversion, dietary and supplemental intake, and PTH control.[18,22,26] The sun's ultraviolet B rays convert 7-dehydrocholesterol in the skin to cholecalciferol (vitamin D_3), which is the most abundant vitamin D source. Few foods contain ergocalciferol (vitamin D_2). Supplements and multivitamins include cholecalciferol or ergocalciferol. Subsequent conversion of cholecalciferol and ergocalciferol to 25-hydroxyvitamin D [25(OH) vitamin D; calcidiol] occurs in the liver, and then PTH stimulates conversion of 25(OH) vitamin D via 25(OH) vitamin D-1α-hydroxylase (CYP27B1) to its final active form, 1α,25-dihydroxyvitamin D (calcitriol), in the kidney. Calcitriol binds to the intestinal vitamin D receptor (VDR) and then increases calcium-binding proteins calmodulin and calbindin. As a result, calcium and phosphorous intestinal absorption are increased. The feedback system is completed with CYP27B1 activity inhibited by adequate calcium and phosphorus, and FGF23 inhibiting PTH synthesis. Vitamin D receptors and CYP27B1 are found in many other tissues, such as bone, muscle, brain, breast, colon, heart, stomach, pancreas, lymphocytes, skin, and gonads.[26,27,28] Vitamin D is increasingly recognized as contributing to many nonbone benefits.

POSTMENOPAUSAL OSTEOPOROSIS

Estrogen deficiency causes significant bone density loss and compromises bone architecture. Estrogen deficiency increases proliferation, differentiation, and activation of new osteoclasts and prolongs survival of mature osteoclasts.[3,15] Interleukins, prostaglandin E_2, TNF-α, and interferon γ also increase resulting in more RANKL and less OPG. Loss of estrogen also increases calcium excretion and decreases calcium gut absorption through decreases in TRPV6 activity and 1,25(OH) vitamin D binding proteins. Estrogen deficiency can also be seen in other settings such as anorexia nervosa and during lactation, and from medications, such as prolonged depot medroxyprogesterone acetate implants, aromatase inhibitors, and gonadotropin releasing hormone agonists.[10,12]

Accelerated bone loss begins during perimenopause and continues up to 8 years after menopause due to increased bone resorption that exceeds bone formation.[3,15] During this time bone loss can be as high as 2% per year, with total BMD loss due to menopause about 10%. The number of remodeling sites increases and resorption pits are deeper and inadequately filled by normal osteoblastic function. During menopause, trabecular bone is most susceptible, leading predominantly to vertebral and wrist fractures.[3,15,29] Initially, women with early menopause (ie, before age 40) due to natural or induced causes have lower BMD than matched premenopausal women but risk for fractures and low bone density become the same after age 70.[3]

MALE OSTEOPOROSIS

Men are at a lower risk for developing osteoporosis and osteoporotic fractures because of larger bone size, greater peak bone mass, increase in bone width with aging, fewer falls, and shorter life expectancy.[4,30] However, the mortality rate after a fracture is greater for men than women. Male osteoporosis results from aging or secondary causes (see Tables 92–2 and 92–3). With aging sex

hormone binding globulin increases, which results in less free testosterone and thereby less testosterone available for conversion to estrogen. Estrogen also inhibits bone resorption in men. The most common risk factors for men are smoking, alcohol abuse, low body weight, weight loss, age, long-term glucocorticoid use, androgen deprivation therapy, and low testosterone concentrations. Medical conditions and medications that cause hypogonadism increase bone loss.

AGE-RELATED OSTEOPOROSIS

Age-related bone loss begins after peak bone mass reached. About 0.5% BMD is loss each year after age 30 years, increasing to 1.6% after 80 years.[16,29] Age-related osteoporosis occurs in older adults because of accelerated bone turnover rate and reduced osteoblast bone formation, with a greater effect on cortical bone. These bone changes occur from hormone deficiencies; calcium and vitamin D deficiencies due to changes in intake, absorption, and metabolism; decreased production or function of cytokines or other bone biochemicals; increase in redox status and free radical formation, increase adipocytes, telomere shortening, and less exercise.[29,31] Fracture risk for a given BMD value increases with aging.[3,15] Hip-fracture risk rises dramatically in older adults as a consequence of the cumulative loss of cortical and trabecular bone and an increased risk for falls. Aging is associated with muscle changes as well, resulting in weakness, balance instability, and greater likelihood of falls.

SECONDARY CAUSES OF OSTEOPOROSIS

1 A secondary cause of osteoporosis is common (see Tables 92–2[3,4,6,7,8,9,12,32] and 92–3).[7,8,10,11,12] Symptoms, initial screening laboratory test results, medication profile review, and or a decreased Z-score from a dual-energy absorptiometry (DXA) test can suggest a secondary cause, warranting a more comprehensive work-up.

CLINICAL PRESENTATION

Table 92–4 outlines the clinical presentation of osteoporosis.[3,4,6,32,33,34,35] Osteoporosis is a silent disease, frequently not detected until a fracture is experienced or noticed on X-ray. Many vertebral fractures are asymptomatic, with patients sometimes attributing mild back pain to "old age." Some new vertebral fractures present with moderate to severe back pain that can radiate down the leg. The pain usually subsides after 2 to 4 weeks; however, residual chronic back pain can persist. Multiple vertebral fractures decrease height and sometimes curve the spine (kyphosis or lordosis). Patients with a nonvertebral fracture frequently present with severe pain, swelling, and reduced function and mobility at the fracture site.

TABLE 92-4 Clinical Presentation of Osteoporosis

General

- Many patients are unaware they have osteoporosis until testing or fracture
- Fractures can occur after bending, lifting, or falling, or independent of any activity

CTX, C-terminal crosslinking telopeptide of type 1 collagen; NTX, N-terminal crosslinking telopeptide of type 1 collagen; PINP, procollagen type 1 N-terminal propeptide.

CONSEQUENCES OF OSTEOPOROSIS

Osteoporosis can lead to fragility/low-trauma fractures, defined as fracture that occurs as a result of a fall from standing height or less or with minimal to no trauma.[1] Fractures of the vertebrae, hip, forearm, and humerus are considered major osteoporotic fractures whereas other fractures are generally not considered osteoporosis-related. Osteoporotic fractures can lead to increased morbidity and mortality and decreased quality of life. Pain and physical deformity are common, and these changes can lead to other health consequences, for example, severe kyphosis can lead to respiratory problems as a result of compression of the thoracic region and GI complications such as poor nutrition, from intra-abdominal compression. Depression is common because of fear, pain, loss of self-esteem from physical deformity, and loss of independence and mobility.

Hip fractures are associated with the greatest increase in morbidity and mortality. After a hip fracture, only 40% of patients regain their prefracture level of independence, while 20% require long-term care.[1] Following a hip fracture, almost one quarter of patients die within 1 year either from complications of the hip fracture or other comorbid disease processes.[1,3] Men have a higher 1-year mortality rate after hip fracture than women.

Wrist fractures occur more commonly in younger postmenopausal women and are frequently a result of a fall on an outstretched hand.[1] Though they cause less disability than other fracture sites, negative outcomes include prolonged pain and weakness, and decreased activities of daily living such as cooking and shopping.

Once a low-trauma fracture has occurred, the risk for subsequent fractures goes up exponentially.[1] Vertebral fractures, even if asymptomatic, are a major predictor of a future fracture with up to a 5-fold increase in future vertebral fractures and a doubling of the risk at other sites. Hip fractures are associated with a 2-fold or greater increase in risk for future fracture.

PATIENT ASSESSMENT

Bone pain, postural changes (ie, kyphosis or lordosis), and loss of height are simple useful physical examination findings. A measured height loss of greater than 0.8 inches (2 cm) or historic height loss (ie, from the tallest height recalled by the patient) of 1.5 inches (4 cm) warrants further investigation.[6,32] Height should be measured annually using a wall-mounted stadiometer.[32] A spine radiograph can be obtained to confirm the presence of vertebral fractures. Low bone density or osteopenia reported on routine radiographs is a sign of significant bone loss and requires further evaluation for osteoporosis. In addition to physical examination and laboratory studies (see Table 92–4), patients can be assessed with risk factor assessments tools, osteoporosis quality-of-life questionnaires, peripheral and central DXA, ultrasonography, and bone turnover biomarkers.

RISK FACTOR ASSESSMENT

The aim of an initial osteoporosis risk assessment screening (see Table 92–1) is to identify those patients who are at risk for osteoporosis and osteoporotic fractures, and or would benefit from further evaluation or pharmacologic intervention. The most commonly used questionnaire is the fracture risk assessment (FRAX) tool, with the Garvan tool as another option.[36]

3 The FRAX tool was created for the World Health Organization to be used with or without BMD data. This model uses 11 risk factors: age, race/ethnicity, sex, previous fragility fracture, parent history of hip fracture, body mass index, glucocorticoid use (current use or past use for 3 or more months of prednisolone 5 mg daily or equivalent doses of other glucocorticoids), current smoking, alcohol use of 3 or more drinks per day, rheumatoid arthritis, and select secondary causes; with femoral neck or total hip BMD data optional. The FRAX tool calculates an individual's percent probability of any major osteoporotic and hip fracture in the next 10 years. Each country establishes cut-off points for fracture risk treatment decisions. Some important risk factors for fracture, for example, falls, multiple fractures, or recent fracture, are not accommodated in the FRAX model.

The Garvan calculator uses 4 risk factors (age, sex, low-trauma fracture, and falls) with the option to also use BMD.[36,37] It calculates 5- and 10-year risk estimates of any major osteoporotic and hip fracture. This tool corrects some disadvantages of the FRAX tool since it includes falls and number of previous fractures, but it does not use as many other risk factors.

SCREENING USING PERIPHERAL BONE MINERAL DENSITY DEVICES

Peripheral bone density devices that use DXA (pDXA) or quantitative ultrasonography are helpful as screening tools to determine which patients require further evaluation with central DXA or for decision making if central DXA testing is not available.[1,34] Peripheral DXA of the forearm, heel, and finger uses a low amount of radiation and requires personnel with special training. Heel quantitative ultrasonography uses sound waves without radiation or need for specially trained personnel. Heel ultrasonography has better fracture predictive value than pDXA. The specific peripheral T-score threshold for referral is not universally defined and varies by device. These tests should not be used for diagnosis or for monitoring response to therapy.

Peripheral devices are considerably less expensive than central DXA, easy to use, portable, fast (less than 5 minutes), and can predict general fracture risk. They are popular for screening postmenopausal women at health fairs and community pharmacies. Because evidence is lacking to show fracture prediction in men, other assessments should be used for men.[1] Patients already identified as being at high risk for osteoporosis based on risk factors, fragility fracture, or secondary causes for osteoporosis should be referred for central DXA testing.

CENTRAL DUAL-ENERGY X-RAY ABSORPTIOMETRY

3 BMD measurements at the hip or spine can be used to assess fracture risk, establish the diagnosis and severity of osteoporosis, and sometimes confirm osteoporosis as causative for low-trauma fractures.[1,4,6,34] Central DXA is considered the gold standard for measuring BMD because of its high precision, short scan times, low radiation dose (comparable to the average daily dose from natural background), and stable calibration. Measurements of lumbar spine, femoral neck, and total hip BMD are recommended with the lowest BMD value used for diagnosis. The forearm (distal third of the radius) can be used as an alternative if these above areas cannot be scanned. Newer technologies available on some densitometers, such as the trabecular bone score, can provide measurements of bone quality and microarchitecture to better identify those at risk for fracture.[1]

Several consensus guidelines and position statements are consistent in recommending central BMD testing for all women aged 65 years or older, men aged 70 years or older, postmenopausal women younger than 65 years of age and men 50 to 69 years old with risk factors for fracture, and patients with an identified secondary cause for bone loss.[1,3,4,6,34] The United States Preventive Services Task Force (USPSTF) agrees with these recommendations for women 65 years and older, but for women between 50 to 65 years old, they recommend only ordering a DXA for those women with a FRAX score of 9.3% or more.[38] This group feels data are inadequate to make recommendations for men. Patients with a fragility fracture do not need a DXA for an osteoporosis diagnosis, but the results are helpful for determining the severity of osteoporosis and as a baseline for monitoring response to therapy. The DXA results can also help patients make decisions about the need for lifestyle changes and prescription osteoporosis medications. In the absence of a suspected or known secondary cause for osteoporosis or a history of a low-trauma fracture, central BMD testing is not recommended for children, premenopausal women, or men younger than 50 years of age.

A central DXA BMD report provides the actual bone density value, T-score, and Z-score.[33,34] The actual bone density value (g/cm^2) is most useful for serial monitoring of therapy response, which is typically performed 2 years after medication initiation. The T-score is used for diagnosis and is a comparison of the patient's BMD to the mean BMD of a healthy, young (20- to 29-year-old), sex-matched White reference population; no adjustments for race or ethnicity. The T-score is the number of standard deviations from the mean of the reference population. The Z-score is similar but compares the patient's BMD to the mean BMD for a healthy sex- and age-matched population. Patient-reported ethnicity should be used for the Z-score if available. The Z-score is sometimes helpful in determining whether a secondary cause for osteoporosis is present and is used for diagnosis (value ≤ –2.0) in children, premenopausal women, and men younger than 50 years of age. Follow-up monitoring for patients has not been clearly defined but in general recommendations are to repeat BMD testing every 2 years.[1] For patients with normal bone density or those in the upper range of low bone mass, time between screenings can be lengthened with some recommending repeat in 15 years.[1,6,15]

Using the spine DXA image, an assessment of morphometric vertebral fractures, the vertebral fracture assessment (VFA), can be calculated.[34] Each vertebra is assessed for compression (wedge, biconcave, and crush) and described as normal or mild (20%-25%), moderate (25%-40%), or severe (greater than 40%) compression.[3] This result becomes important for treatment decisions in patients with low bone

mass. Because many vertebral fractures are asymptomatic, VFA is recommended in those who most likely have an undiagnosed vertebral fracture. For example, women 70 years or older or men 80 years or older with a T-score of –1.0 or less, postmenopausal women or men age 50 and older who have lost more than 1.5 inches (4 cm) in height, and those on glucocorticoids (≥ 5 mg prednisone or equivalent daily for 3 months or more.[1,3,4,34]

LABORATORY TESTS

Routine laboratory testing (see Table 92–4) is used for initial bone health assessment. To evaluate secondary causes, additional testing is conducted, which will be specific to the suspected secondary cause.

BONE TURNOVER MARKERS

Bone turnover markers are commonly used in clinical trials and sometimes in clinical practice.[1,35] They can be used to assess bone pathophysiology, predict fracture risk, and monitor response to osteoporosis medications. Markers of bone formation are bone-specific alkaline phosphatase, osteocalcin, and procollagen type 1 propeptides. Markers of bone resorption are hydroxypyridinium crosslinks of collagen pyridinoline and deoxypyridinoline, C-terminal crosslinking telopeptide of type 1 collagen, and N-terminal crosslinking telopeptide of type 1 collagen. Response to osteoporosis therapy can be measured as early as 2 to 3 months. Circadian variability, seasonal variations, food intake, recent exercise, some diseases and conditions, and assay variability can affect results and decrease utility in clinical practice. For serum markers, fasting morning samples should be obtained with repeat tests done at the same facility with the same assay. Coverage for these tests varies by health insurance.

DIAGNOSIS OF OSTEOPOROSIS

The diagnosis of osteoporosis is based on a low-trauma fracture or femoral neck, total hip and/or spine DXA using WHO T-score thresholds. Low bone mass (preferred term) or osteopenia is a T-score between –1 and –2.5, and osteoporosis is a T-score at or below –2.5.[1,4,6,34] Although these definitions are based on data from postmenopausal white women, they are also applied to perimenopausal women, men age 50 years and older, and adults from different races and ethnicities. The diagnosis of osteoporosis in children, premenopausal women, and men under 50 years of age should be based on a Z-score at or less than –2.0 in combination with other risk factors or fracture.[4,33,34] Without a history of clinically significant fracture, children and premenopausal women are given a diagnosis of bone mass below the expected range for age.

PREVENTION AND TREATMENT

Osteoporosis

Osteoporosis prevention and treatment begins with a bone healthy lifestyle starting at birth and continuing throughout life. Supplements and medications are used when lifestyle habits are suboptimal, osteoporosis has developed, or after a low-trauma fracture.

DESIRED OUTCOMES

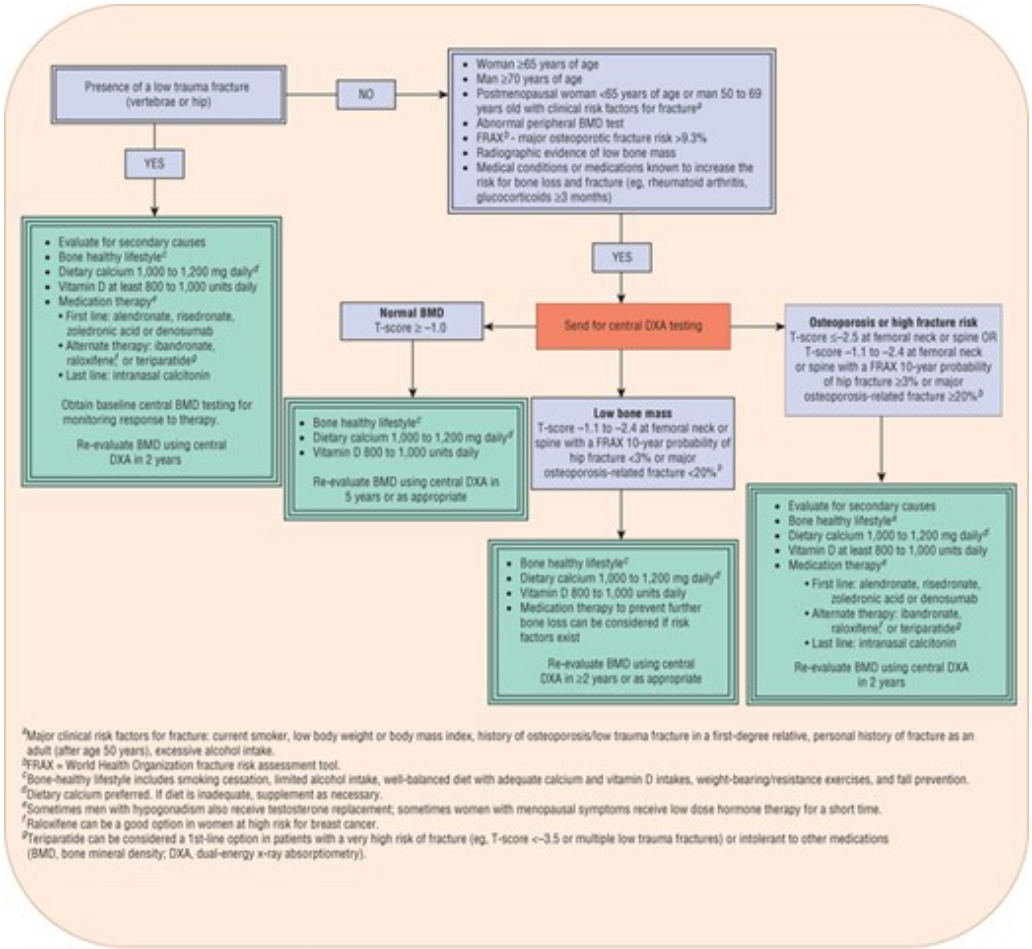
The primary goal of osteoporosis care should be prevention. Optimizing skeletal development and peak bone mass accrual in childhood, adolescence, and early adulthood will ultimately reduce the future incidence of osteoporosis. Once low bone mass or osteoporosis develops, the objective is to stabilize or improve bone mass and strength and prevent fractures. In patients who have already suffered osteoporotic fractures, reducing pain and deformity, improving functional capacity, improving quality of life, and reducing future falls and fractures are the main goals.

GENERAL APPROACH TO PREVENTION AND TREATMENT

4 5 A bone-healthy lifestyle should begin at birth and continue throughout life. Insuring adequate intake of calcium and vitamin D along with other bone-healthy lifestyle practices are the first steps in prevention and treatment. Guidelines and position statements recommend considering prescription therapy in any postmenopausal woman or man age 50 years and older presenting with one of the following scenarios: a hip or vertebral fracture; T-score of –2.5 or lower at the femoral neck, total hip, or spine; or low bone mass (T-score between –1.0 and –2.5 at the femoral neck, total hip, or spine) with a 10-year probability of hip fracture of 3% or more, or a 10-year probability of any major osteoporosis-related fracture of 20% or more.[1,3,4,6] **Figure 92–3** provides an osteoporosis management algorithm for postmenopausal women and men 50 years and older that incorporates both nonpharmacologic and pharmacologic approaches.

FIGURE 92–3

Algorithm for the management of osteoporosis in postmenopausal women and men aged 50 and older. *Data from references* 1, 3, 4, and 6.



NONPHARMACOLOGIC THERAPY

4 Nonpharmacologic therapy, referred to as a bone-healthy lifestyle, includes proper nutrition, moderation of alcohol intake, smoking cessation, exercise, and fall prevention. A bone healthy lifestyle that is employed early in life will help to optimize peak bone mass and if continued throughout life it will minimize bone loss over time. Not only does a bone healthy lifestyle target BMD, but it also contributes to decreasing the risk of falls and fragility fractures.

Diet

Overall, a diet well balanced in nutrients and minerals without excessive protein and limited use of salt, alcohol and caffeine are important for bone health.[1,3,4,39] Adequate amounts of calcium, vitamin D, and protein have documented impacts on bone health.[25,26,27,39,40,41,42,43,44] Magnesium, boron, and vitamin K have a physiologic role in bone development and maintenance but either no or insufficient data exist to establish them independently as supplemental agents for prevention and treatment of osteoporosis.[40] Some of these agents are included in calcium combination products and are found in multivitamins. Strontium ranelate has documented positive bone effects and is marketed in Europe for prevention of osteoporosis.

Eating disorders are associated with increased bone loss and fractures. Being thin or having anorexia nervosa are well known to decrease bone mass.[12,45] In the past, obesity was thought protective due to increased estrogen production and stimulation of bone remodeling due to weight bearing; however, emerging literature suggests leptin and adipose have negative impacts on bone health.

Calcium

6 Adequate calcium intake is necessary for calcium homeostasis throughout life, bone development during growth, and bone maintenance.[46] The Institute of Medicine (IOM) recommended calcium intakes are based on age and gender (**Table 92–5**).[47] This value represents the amount needed for 97.5% of the population. Higher intakes might be needed when concomitant diseases and medications known to negatively affect calcium and vitamin D homeostasis exist. Using calcium-containing or fortified foods and beverages, which also contain other essential nutrients, is the preferred method to achieve daily calcium requirements. Dairy products have the highest amount of calcium per serving and are available in low-fat options. Some food sources are absorbed well but have low elemental calcium content (eg, broccoli). Carbohydrates, fat, and lactose increase calcium absorption whereas fiber, wheat bran, phytates (eg, beans), oxylates (eg, spinach and rhubarb), high-protein diets, caffeine, and smoking decrease absorption.

TABLE 92-5 Calcium and Vitamin D Recommended Dietary Allowances and Upper Limits

Group and Ages	Elemental Calcium (mg)	Calcium Upper Limit (mg)	Vitamin D (Units)[a]	Vitamin D Upper Limit (Units)
Infants				
Birth to 6 months	200	1,000	400	1,000
6-12 months	260	1,500	400	1,500
Children				
1-3 years	700	2,500	600	2,500
4-8 years	1,000	2,500	600	3,000
9-18 years	1,300	3,000	600	4,000
Adults				
19–50 years	1,000	2,500	600[b]	4,000
51-70 years (men)	1,000	2,000	600[b]	4,000
51-70 years (women)	1,200	2,000	600[b]	4,000
>70 years	1,200	2,000	800[b]	4,000

[a]Other guidelines recommend intake to achieve a 25(OH) vitamin D concentration of more than 30 ng/mL (mcg/L; > 75 nmol/L),[1,4,6] which is higher than the Institute of Medicine goal of more than 20 ng/mL (mcg/L; > 50 nmol/L).[47]

[b]2014 National Osteoporosis Foundation Guidelines recommend 400 to 800 units for adults under 50 years old and 800 to 1,000 units for adults 50 years and older.[1]

Data from reference 47.

People should be encouraged to evaluate their food and beverage intake to determine if they are receiving adequate amounts of calcium. To calculate the amount of calcium in a serving of food, consumers can add a zero to the percentage of the daily value listed on food labels. For example, a serving of milk (8 oz. [~240 mL]) has 30% of the daily value of calcium. This translates to 300 mg calcium per serving. Websites can be used to calculate calcium content and identify foods and beverages high in calcium.[47,48]

Although many foods and beverages are high in calcium, the average calcium dietary intake is insufficient. Adult women consumed 590 to 730 mg and adult men consumed 725 to 970 mg calcium daily with amounts decreasing with advancing age for both sexes. Lactose intolerance limits dietary calcium intake. Approximately 25% of the US population has some level of lactose intolerance, with the incidence in Asian (85%) and African American (50%) populations higher than in whites (10%).[46,49] Lactose-intolerant patients have several options, including products containing lactase (Lactaid), lactose-reduced milk, lactose-free milk, calcium-fortified milk alternatives (eg, soy and almond), certain aged cheeses, or yogurt with active cultures along with other nondairy calcium-fortified products (eg, orange juice, breakfast cereals, and energy bars). Vegan diets sometimes have insufficient calcium intake, but products, such as tofu, calcium-fortified milk alternatives, and juices can be used. When diet cannot be enhanced to achieve adequate intakes, calcium supplements will be required.

Vitamin D

Table 92–5 lists the IOM recommended adequate intakes for Vitamin D.[47] The 3 main sources of vitamin D are sunlight (cholecalciferol and vitamin D3), diet, and supplements.[26] Vitamin D3 comes from oily fish, eggs, and fortified dairy products. Vitamin D2 comes from fungi and eggs (chickens given vitamin D2 in their diet). Websites can be used to identify the few foods high in vitamin D.[50] To calculate the amount of vitamin D in a serving of food, multiply the % daily value of vitamin D listed on the food label by 4 (eg, 20% vitamin D = 80 units).

Inadequate concentrations of 25(OH) vitamin D are common in all age groups, especially in older adults, minorities, malnutrition, obesity, institutional living (eg, nursing home), and northern latitude residences. Overall prevalence of hypovitaminosis D (≤ 20 ng/mL[mcg/L; ≤ 50 nmol/L]) was 42% in adults; similar between sexes but greater in minorities (ie, Blacks 82%, Hispanics 69%, and Whites 30%).[51] Low vitamin D concentrations result from insufficient intake, dietary fat malabsorption, decreased sun exposure, decreased skin production, or decreased liver and renal metabolism. Endogenous synthesis of vitamin D can be decreased by factors that affect exposure to or decrease skin penetration of ultraviolet B light rays. Sunscreen use, full body coverage with clothing (eg, women wearing veiled and full-length dresses), and darkly pigmented skin can all decrease vitamin D production. Seasonal variations in vitamin D concentrations are also seen with nadirs in late winter

and peaks in late summer. Because few foods are naturally high or fortified with vitamin D, most people, especially older adults, require supplementation. Based on the NHANES 2007-2010 data, only 1% to 4% of adults ingested recommended vitamin D daily allowances from diet alone.[52]

Isoflavones

Phytoestrogens (isoflavones, lignans, and coumestans) are plant-derived compounds that possess weak estrogenic agonist and antagonist effects throughout the body. Isoflavones are found in soy products, lignans in seeds, berries, and grains and coumestans in broccoli and sprouts. Genistein is the most abundant and biologically active isoflavone in soybeans. Isoflavones, genistein and daidzein are also available as single agent or combination supplements. The evidence supporting a positive bone benefit from phytoestrogen intake is conflicting with most studies showing no effects[1,3,53]; however, a meta-analysis of randomized placebo controlled studies have found foods and supplements with at least 75 mg isoflavones increased spine but not hip BMD when compared to placebo.[54] Isoflavones from soy foods appear safe; however, more information is needed, especially in women with breast cancer and for isoflavone supplements.

Alcohol

4 Excessive but not moderate alcohol consumption is associated with an increased risk for osteoporosis and fractures.[1,3,4,39,40,46] Alcohol increases bone resorption by increasing RANKL and decreases bone formation by inhibiting Wnt signaling pathway and increasing oxidative stress that results in osteoblast apoptosis. Patients with alcohol problems might also have poor nutrition, decreased calcium absorption, altered vitamin D metabolism, and have balance impairments resulting in more falls and fractures. Alcohol consumption should not exceed 1 to 2 drinks per day for women and 2 to 3 drinks per day for men.

Caffeine

4 Although results are conflicting, excessive caffeine consumption is associated with increased calcium excretion, increased rates of bone loss, and a modestly increased risk for fracture.[39,46] Ideally, caffeine consumption should be limited to two servings or less per day. For those with greater intakes, the increased calcium excretion might be compensated by additional calcium intake.

Smoking

4 Counseling patients of all ages on smoking cessation can help to optimize peak bone mass, minimize bone loss, and ultimately reduce fracture risk.[39,40,55] Cigarette smoking is an independent risk factor for osteoporosis and is associated with an increased relative risk for fracture at all sites. The effect is dose and duration dependent, but even passive smoking shows adverse effects on BMD. The negative bone effects are associated with reduced intestinal calcium absorption, lower 25(OH) vitamin D concentrations possibly due to increased hepatic metabolism, an increase in bone resorption from a decrease in production and increase in metabolism of estradiol, increase in RANKL

and decrease in OPG, decrease in osteoblasts and bone formation secondary to increase in cortisol and dehydroepiandrosterone sulfate, and impairment of osteoid production and mineralization. The detrimental effects of smoking on physical function and balance can contribute to an increased risk of falls.

Exercise

4 Physical activity or exercise is an important nonpharmacologic approach to preventing osteoporotic fractures. Exercise can decrease the risk of falls and fractures by stabilizing bone density and improving muscle strength, coordination, balance, and mobility.[1,39] Physical activity is especially important early in life as lack of exercise during growth can lead to suboptimal loading/straining, decreased stimulation of bone deposition, and a subsequently reduced peak bone mass. All patients who are medically fit should be encouraged to perform a moderate-intensity weight-bearing activity (eg, walking, jogging, golf, and stair climbing) daily and a resistance activity (eg, weight machines, free weights, or elastic bands) at all ages. For men, guidelines specifically suggest men at risk of osteoporosis participate in weight-bearing activities three to four times weekly for 30 to 40 minutes per session.[4]

Fall Prevention

4 Risk of falling increases with advanced age predominantly as a result of balance, gait, and mobility problems, poor vision, reduced muscle strength, impaired cognition, multiple medical conditions (eg, arrhythmias, postural hypotension, Alzheimer's disease, and Parkinson disease), and polypharmacy (especially psychoactive, cardiovascular, diabetes, seizure, and pain medications).[16,56,57] The ability to adapt to falls also decreases with aging. Older adults are more likely to sustain a hip or pelvic fracture because they tend to fall backward or sideways instead of forward.[16]

Because of the link between falls and fractures, all older adults should be asked at least annually if they have fallen.[16,56] The Centers for Disease Control and Prevention have created an assessment tool; if an older adult scores 4 or more, a comprehensive falls assessment should be conducted. Patients with low (no falls) or moderate fall risk (1 fall per year and no injury) should have adequate vitamin D and calcium intake and increase exercise to improve gait and balance. Patients at high fall risk (≥2 falls or 1 fall with injury) should do the above plus have blood pressure, vision, foot, and medication assessments to resolve any problems, and have home optimized to prevent falls.

Generally, intervention programs that are multifactorial have greater effects on decreasing falls, fractures, other injuries, and nursing home and hospital admissions than single interventions.[1,16,39,56,57] Medication profiles should also be reviewed for any unnecessary medications that can affect cognition and balance and potentially increase fall risk. Consideration should be given to replacing high-risk medications with safer alternatives. Vitamin D supplementation has been associated with reduced falls. Maintenance of a regular individualized exercise program, such as tai chi, should be recommended to improve body strength, balance, and

agility. Other recommendations include resolving vision, low blood pressure, heart rate/rhythm, and foot problems and using proper footwear. External hip protectors are specialized undergarments designed to pad the area surrounding the hip, decreasing the force of impact from a sideways fall. Conflicting results and poor adherence limit their use.

VERTEBROPLASTY AND KYPHOPLASTY

During a vertebroplasty and kyphoplasty cement is injected into fractured vertebra(e) for patients with debilitating pain from vertebral compression fractures.[58] In some studies the procedure stabilized the damaged vertebrae, reduced pain, and decreased opioid intake; however in other studies, the effects are similar to sham interventions, are short-term, and or are associated with vertebral fracturing around the cement, cement leakage into the spinal column, and rarely nerve damage.

PHARMACOLOGIC THERAPY

Because nonpharmacologic interventions alone are frequently insufficient to prevent or treat osteoporosis, medication therapy is often necessary. **Table 92–6**[1,3,15,59,60] describes fracture and BMD effects, **Table 92–7** describes dosing and **Table 92–8** outlines adverse effects and monitoring of osteoporosis medications. These medications should always be combined with a bone-healthy lifestyle.

TABLE 92-6 Fracture and Bone Mineral Density Effects of Osteoporosis Medications from Pivotal Fracture Trials[a] in Postmenopausal Women

Medication	Vertebral Fracture	Nonvertebral Fracture	Hip Fracture	% Change in Spine BMD[b]	% Change in Hip BMD[b,c]

%, percent; BMD, bone mineral density; ↓, decrease; ↑, increase; ↔, no significant change; ND = no data.

[a]Fracture reductions are relative risk reductions, no head to head fracture studies except for raloxifene and bazedoxifene, data should only be used for relative between class comparisons, clinical trials with different patient samples and study designs, most pivotal fracture trials 3 years duration except for teriparatide studies (18 months).

[b]Relative to placebo; may vary based on duration of therapy and timing relative to menopause.

[c]Total hip (alendronate, ibandronate, zoledronic acid, bazedoxifene, denosumab, estrogen, and teriparatide) or femoral neck (calcitonin, estrogen, risedronate, and raloxifene).

[d]50% decreases in nonvertebral fractures in subgroup of high-risk postmenopausal women (very low BMD and or previous fractures).

[e]Risedronate and zoledronic acid only; nonvertebral fracture reductions with ibandronate and alendronate were not significant.

[f]Alendronate, risedronate, and zoledronic acid only; hip fracture data not reported with ibandronate.

[g]Data obtained from nonpivotal fracture trials.

[h]Plus data from a pivotal bazedoxifene trial with raloxifene as one of the comparators.

Data from references 1, 3, 15, 59, and 60.

TABLE 92-7 Drug Dosing Table

Drug	Brand Name	Dose	Comments
Antiresorptive Medications—Nutritional Supplements			
Calcium	Various	*Adequate daily intake:* IOM: 200-1,200 mg/day, varies per age; see Table 93–5); Supplement dose is difference between required adequate intake and dietary intake. Immediate-release doses should be <500-600 mg.	Recommend food first to achieve goal intake. Available in different salts including carbonate and citrate, absorption of other salts not fully quantified. Different formulations including chewable, liquid, gummy, softgel, drink, and wafer; different combination products. Review package to determine number of units to create a serving size and desired amount of elemental calcium. Give calcium carbonate with meals to improve absorption.
Vitamin D D3 (cholecalciferol)	Over the counter, Tablets, 400, 1,000, and	Adequate daily intake: IOM: 400-800 units/day to achieve adequate intake (see Table 93-5); NOF:	Vegetarians and vegans need to read label to determine if a plant-based product. Slight advantage of D3 over D2 for

Drug	Brand Name	Dose	Comments
D_2 (ergocalciferol)	2,000 units Capsule, 400, 1,000, 2,000, 5,000, and 10,000 units Gummies, 300, 500, 1,000 units Drops 300, 400, 1,000 and 2,000 units/mL or drop Solution, 400 and 5,000 units/mL Spray 1,000 and 5,000 units/spray Creams and lotions 500 and 1,000 units per ¼ teaspoonful. Prescription, Capsule, 50,000 units Solution, 8,000 units/mL	800-1,000 units orally daily; If low 25(OH) vitamin D concentrations, malabsorption, or altered metabolism higher doses (>2,000 units daily) might be required. *Vitamin D deficiency*: 50,000 units orally once to twice weekly for 8-12 weeks; repeat as needed until therapeutic concentrations.	increasing serum 25(OH) vitamin D concentrations. For drops, make sure measurement is correct for desired dose. Ability of sprays, lotions, and creams to resolve deficiencies or maintain adequate intakes is unknown.
Antiresorptive Prescription Medications			
Bisphosphonates			
Alendronate	Fosamax Fosamax Plus D	Treatment: 10 mg orally daily or 70 mg orally weekly Prevention: 5 mg orally	Generic available for weekly tablet product. 70 mg dose is available as a tablet, effervescent tablet, oral liquid or

Drug	Brand Name	Dose	Comments
			combination tablet with 2,800 or 5,600 units of vitamin D3.
	Binosto (effervescent tab)	daily or 35 mg orally weekly	Administered in the morning on an empty stomach with 6 to 8 ounces of plain water. Do not eat and remain upright for at least 30 minutes following administration. Do not co-administer with any other medication or supplements, including calcium and vitamin D.
Ibandronate	Boniva	Treatment: 150 mg orally monthly, 3 mg intravenous quarterly Prevention: 150 mg orally monthly	Generic available for oral product. Administration instructions same as for alendronate, except must delay eating and remain upright for at least 60 minutes.
Risedronate	Actonel Atelvia (delayed-release)	Treatment and Prevention: 5 mg orally daily, 35 mg orally weekly, 150 mg orally monthly	Generic available for immediate-release product. 35 mg dose is also available as a delayed-release product. Administration instructions same as for alendronate, except delayed-release product is taken immediately following breakfast.
Zoledronic acid	Reclast	Treatment: 5 mg intravenous infusion yearly Prevention: 5 mg intravenous infusion every 2 years	Can premedicate with acetaminophen to decrease infusion reactions. Contraindicated if CrCl <35 mL/min Also marketed under the brand name Zometa (4 mg) for treatment of hypercalcemia and prevention of skeletal-related events from bone metastases from solid tumors with different dosing.
RANK Ligand Inhibitor			
Denosumab	Prolia	Treatment: 60 mg subcutaneously every 6 months	Administered by a healthcare practitioner. Correct hypocalcemia before

Drug	Brand Name	Dose	Comments
			administration. Also marketed under the brand name Xgeva (70 mg/mL) for treatment of hypercalcemia and prevention of skeletal-related events from bone metastases from solid tumors with different dosing.
Estrogen Agonist/Antagonist and Tissue Selective Estrogen Complex			
Raloxifene	Evista	60 mg daily	Generic available
Bazedoxifene with conjugated equine estrogens (CEE)	Duavee	20 mg plus 0.45 mg CEE daily	For postmenopausal women with an uterus; no progestogen needed. Bazedoxifene monotherapy available in some countries.
Calcitonin			
Calcitonin (salmon)	Fortical	200 units (1 spray) intranasally daily, alternating nares every other day.	Generic available. Refrigerate nasal spray until opened for daily use, then room temperature.
		100 units subcutaneously daily	Prime with first use.
Formation Medications			
Recombinant human parathyroid hormone (PTH 1-34 units)			
Teriparatide	Forteo	20 mcg subcutaneously daily for up to 2 years	First dose at night. Refrigerate before and after each use. Use new needle with each dose. Inject thigh or stomach. Discard after 28 days or if cloudy.

IOM, Institute of Medicine; NOF, National Osteoporosis Foundation; NSAID, nonsteroidal anti-inflammatory drug.

TABLE 92-8 Drug Monitoring Table

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Antiresorptive Medications—Nutritional Supplements			
Calcium	Constipation, gas, upset stomach, kidney stones	Dietary calcium intake, constipation	Education about a bowel healthy lifestyle (eg, adequate water, fiber, and exercise)

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Vitamin D	Hypercalcemia, hypercalciuria, weakness, headache, somnolence, nausea. Rare: cardiac rhythm disturbance	Serum 25(OH) vitamin D concentration, symptoms	Adverse effects usually not experienced until 25(OH) vitamin D concentrations more than 100-150 ng/mL (mcg/L; > 250-375 nmol/L), which are generally not achieved with recommended therapeutic doses
Antiresorptive Prescription Medications			
Bisphosphonates			
Bisphosphonates	Dyspepsia (oral), transient or chronic musculoskeletal pain, nausea, transient flu-like illness (injectable) Rare: GI perforation, ulceration, and/or bleeding (oral); osteonecrosis of the jaw; atypical femoral shaft fracture, severe musculoskeletal pain	Bone density, fractures, GI symptoms, muscle aches Serum calcium for zoledronic acid	Pregnancy category C for alendronate, risedronate, and ibandronate. Pregnancy category D for zoledronic acid. Adherence is suboptimal, thus should be frequently assessed Assess correct use of products with refills.
RANK Ligand Inhibitor			
Denosumab	Back pain, arthralgia, eczema, cellulitis, and infection; Rare: osteonecrosis of the jaw, atypical femoral shaft fracture	Serum calcium, bone density, fractures	Pregnancy category X. REMS: Medication guide and monitoring plan due to risks of serious infections, dermatologic adverse reactions, and suppression of bone turnover
Estrogen Agonist/Antagonist and Tissue Selective Estrogen Complex			
Raloxifene	Hot flushes, leg pain, spasms, or cramps, peripheral edema, venous thromboembolism (warm swollen leg, chest pain, shortness of breath, coughing up blood, and change in vision)	Bone density, fractures, hot flushes, leg cramps, and blood clots	Pregnancy category X. Warning for fatal stroke-rare events predominantly seen in women at high risk for stroke

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Bazedoxifene with conjugated equine estrogens	Similar to raloxifene and estrogens	Bone density, fractures, leg cramps, blood clots	Pregnancy category X.
Calcitonin			
Calcitonin (salmon)	Nasal: rhinitis, epistaxis Injection: nausea, flushing, local inflammation	Bone density, fractures, nasal symptoms	Pregnancy category C.
Formation Medications			
Recombinant human parathyroid hormone (PTH 1-34 units)			Pregnancy category C. If serum calcium is high (>10.6 mg/dL [>2.65 mmol/L]), calcium intake should be decreased.
Teriparatide	Orthostasis with first few injections, pain at injection site, nausea, headache, dizziness, leg cramps, rare increase in uric acid, slightly increased calcium stays with regular adverse effects	Bone density, fractures, trough serum calcium concentration 1 month after therapy initiation	Warning about osteosarcoma in rats and therefore contraindicated in patients at high risk for this adverse event. REMS: Medication guide and communication plan due to the increased risk of osteosarcoma and to inform healthcare providers of the 2 year maximum lifetime treatment

REMS, Risk Evaluation and Mitigation Strategies.

MEDICATION

Drug Treatments of First Choice

8 Combined with adequate calcium and vitamin D intake, alendronate, risedronate, zoledronic acid, or denosumab are the prescription medications of choice based on evidence to reduce the risk of hip and vertebral fractures.[6] Ibandronate, teriparatide or raloxifene are alternatives and calcitonin is last-line therapy. The algorithm (see Fig. 92–3)[1,3,4,6] helps determine for whom medication therapy

should be used. In general, prescription therapy should be considered in any postmenopausal woman or man age 50 years and older presenting with osteoporosis or low bone mass combined with a 10-year probability of hip fracture of 3% or more or a 10-year probability of any major osteoporosis-related fracture of 20% or more. The use of osteoporosis prescription medications in children, pre- and perimenopausal women, and men younger than 50 years old is undergoing further investigation. Universal use of calcium and vitamin D to achieve adequate intakes (see Table 92–5) is controversial; however, guidelines recommend adequate intake.

The National Osteoporosis Foundation's clinician's guide,[1] the North American Menopause Society's position statement,[3] the American Association of Clinical Endocrinologists' guidelines for women,[6] the Endocrine Society's guidelines for men,[4] and the Agency for Healthcare Research and Quality update[61] provide guidance on osteoporosis prevention and treatment strategies.

Drug Class Information

Antiresorptive Therapies

Antiresorptive therapies include calcium, vitamin D, bisphosphonates, estrogen agonists antagonists (known previously as selective estrogen receptor modulators or SERMs), tissue selective estrogen complexes, calcitonin, denosumab, estrogen, and testosterone.

Calcium Supplementation

6 Calcium imbalance can result from inadequate dietary intake, decreased fractional calcium absorption, enhanced calcium excretion, and diseases and medications altering these processes. Adequate calcium intake (see Table 92–5) is considered a foundation for osteoporosis prevention and treatment in the guidelines and should be combined with vitamin D, especially when osteoporosis medications are taken.[1,3,4,6,46,47] In contrast, the USPSTF states low doses of calcium (ie, ≤1000 mg) for adults are ineffective and insufficient data existed to recommend higher doses to prevent osteoporotic fractures.[62] If dietary intake cannot be increased to achieve adequate intake, calcium supplements can be used. Dietary calcium intake needs to be quantified via calculators, questionnaires, or estimates to determine supplement dose. The National Osteoporosis Foundation has a calcium calculator,[1] the CaQ questionnaire assesses 23 food and beverage groups,[63] and age and gender estimates exist from the NHANES study.[41,49]

Efficacy

Calcium generally maintains BMD although small BMD increases (0.6%-1.8%) have been documented. These BMD effects are less than other osteoporosis medications. Calcium alone does not prevent fractures, but when combined with vitamin D, it decreases fractures by 11% to 15%, vertebral fractures by 16%, and hip fractures by up to 30%.[42,43,44] Higher-than-recommended calcium intakes are not associated with any clinical advantages.

Adverse Events

Calcium's most common adverse reaction, constipation, can first be treated with increased water intake, dietary fiber, and exercise. If still unresolved, smaller and more frequent administration or a lower total daily dose can be tried. Calcium carbonate can create gas and cause stomach upset, which might resolve with calcium citrate, a product with fewer GI side effects.

Clinical trials of calcium show no effect to a 17% increase in kidney stones.[64] In some cases, calcium binds to oxalate in the gut, which decreases oxalate urinary excretion thereby decreasing kidney stones. Increased fluid intake and decreased salt intake might be warranted to prevent kidney stones.

In 2008, an analysis revealed that calcium was associated with a 30% in myocardial infarction.[65] Since then multiple meta-analyses, reanalysis of trial data, and secondary analyses of studies that had diet, calcium supplements, cardiovascular disease, and mortality data have been conducted showing outcomes from no effect to a small negative effect depending on the methodology, studies included, control of confounders, and various other study design issues.[64,66,67] Recent studies do not find calcium causing coronary artery calcifications. Furthermore, coronary artery calcifications can result from other causes such as coronary inflammation.

The most recent osteoporosis guideline and expert consensus indicate calcium intake to meet IOM requirements is safe, but intakes should remain less than 1500 mg daily (less than the IOM upper limit) and preferably achieved through diet.

Drug Interactions

Since calcium carbonate requires acid for disintegration, drugs such as the proton pump inhibitors can decrease absorption from the carbonate product. Fiber laxatives can decrease the absorption of calcium if given concomitantly. Calcium can decrease the oral absorption of some drugs including iron, tetracyclines, quinolones, bisphosphonates, and thyroid supplements.

Administration

Most children and adults of all race and ethnic backgrounds do not ingest sufficient dietary calcium and therefore require supplements. To ensure adequate calcium absorption, 25(OH) vitamin D concentrations should be at least 10 to 15 ng/mL (mcg/L; 25-37 nmol/L). Because fractional calcium absorption is dose limited, maximum single doses of 500 to 600 mg or less of elemental calcium are recommended.[25] Since peaks in serum calcium concentrations after supplementation are hypothesized as a reason for negative cardiovascular effects, using lower doses more frequently has been proposed.[66] Calcium carbonate is the salt of choice as it contains the highest amount of elemental calcium (40%) and is the least expensive. Calcium carbonate should be taken with meals, which increases gastric acidity resulting in product dissolution and disintegration. Calcium citrate (21% calcium) has acid-independent absorption and does not need to be administered with meals. A 24-hour sustained-release calcium citrate product was designed to deliver 1,200 mg throughout the day; however, concern with intakes more than IOM recommended intakes, which potentially increases cardiovascular disease, limits its use. Although tricalcium phosphate contains 38% calcium, calcium-phosphate complexes could limit overall calcium absorption. This product might be helpful in patients with hypophosphatemia that cannot be resolved with increased dietary intake.

Disintegration and dissolution rates vary significantly between products and lots. Products labeled "USP Verified" for United States Pharmacopeia, which guarantees the identity, strength, purity, and quality of the product, or products from a reputable company, should be recommended. Products from unrefined oyster shell or coral calcium should not be recommended because of concerns for high concentrations of lead and other heavy metals. Some calcium products come in alternative dosage forms (eg, chews, dissolvable tablet, and liquid), which can be beneficial for select patients (eg, swallowing problems). For all products, encourage patients to read the labeling carefully as multiple tablets per day can be needed to obtain adequate calcium intake.

Some commercial calcium supplements contain other nutrients associated with bone physiology such as magnesium, vitamin K, "natural estrogens," or isoflavones. Minimal BMD and no fracture data exist for these combination products. These products are also more expensive. Combining too many vitamins and supplements might exceed upper-tolerable nutrient limits and increase toxicities.

Vitamin D Supplementation

7 Vitamin D intake is critical for intestinal calcium absorption and when combined with calcium can prevent bone loss and decrease osteoporotic fractures.[25,26,27] The IOM recommends adequate intakes of vitamin D from diet and or supplementation for all ages (see Table 92–5).[47] Osteoporosis guidelines recommend higher vitamin D maintenances doses (800-2,000 units daily).[1,3,4] The USPSTF states low doses of vitamin D (ie, ≤ 400 units) are not effective, but in 2014 they stated insufficient data existed to recommend higher doses to prevent osteoporotic fractures.[62]

The desired therapeutic range for vitamin D is controversial. The IOM defines 20 ng/mL (50 nmol/L; 1 ng/mL = 2.5 nmol/L) as the cut point for normal 25(OH) vitamin D,[47] below which a patient would be considered deficient. However, some experts and guidelines state the goal 25(OH) vitamin D concentration should be 30 to 60 ng/mL (mcg/L; 75-150 nmol/L) or 30 to 100 ng/mL (mcg/L; 75-250 nmol/L) with concentrations between 20 and 29 ng/mL (mcg/L; 50-72 nmol/L) considered insufficient and those less than 20 ng/mL (mcg/L; 50 nmol/L) considered deficient.

Current evidence suggests that the major effects of vitamin D are achieved with 25(OH) vitamin D concentrations between 6 and 20 ng/mL (mcg/L; 15-50 nmol/L), including increasing calcium absorption (10-15 ng/mL [mcg/L; 25-37 nmol/L]) and decreasing BMD loss (up to 20 ng/mL [mcg/L; 50 nmol/L]).[25] Daily vitamin D doses of 500 to 700 units generally are sufficient to achieve vitamin D concentrations more than 20 ng/mL (mcg/L; greater than 50 nmol/L), leading some experts to suggest the higher daily doses recommended in guidelines are not warranted. Other experts point out that not everyone achieves a 25(OH) vitamin D greater than 30 ng/mL (mcg/L; 75 nmol/L), and because the product is inexpensive and safe, the higher recommended doses are appropriate.

Serum 25(OH) vitamin D is the best indicator of total body vitamin D status.[1] Interassay variability exists; thus, the same laboratory should be used for repeat testing. Measurement of 25(OH) vitamin D concentration could be considered in anyone with high risk for low vitamin D (eg, older, obese, minimal sun exposure, insufficient vitamin D intake, dark pigmented skin, certain medical conditions especially liver and kidney disease or medications known to affect vitamin D metabolism), low bone

density, history of a low-trauma fracture, frequent falls, unexplained muscle weakness, and/or bone pain.

Clinical Controversy…

A clinical question is should all older adults be supplemented with guideline recommended vitamin D doses or should a 25(OH) vitamin D level be drawn first to assess need and/or determine appropriate supplementation. Universal supplementation is supported by the fact vitamin D supplementation is safe and inexpensive. Treating 1,000 high-risk patients, defined as living in an institution, with vitamin D and calcium would prevent 9 hip fractures, which are associated with significant morbidity, mortality, and cost.[68] The vitamin D dose to prevent falls has been around 800 units; with studies based on dose and not on serum concentrations.[25,26,27]Adverse effects from vitamin D therapy are usually not seen until concentrations are greater than 100 ng/mL (mcg/L; 250 nmol/L); concentrations generally not achieved with guideline recommended vitamin D doses.[25,26] Because adequate intakes do not always result in vitamin D sufficiency, a vitamin D level could then be ordered after initiation to assess impact of vitamin D supplementation, saving the health system the cost of one vitamin D level. On the other hand, in 2014, the USPSTF stated insufficient evidence exists to support universal vitamin D screening in asymptomatic patients.[62] Results from a cost savings simulation showed population screening to determine need for vitamin D supplementation was significantly more cost beneficial than universal supplementation ($224 vs $189 savings, respectively), assuming the cost of a vitamin D level is $45.[69] In women and men around 65 years old, the difference is statistically significant but only a savings of $6 to $12. However, in 80-year-olds the cost savings from vitamin D screening is $132 to $135. Additional levels would be needed to assess impact of vitamin D replacement or maintenance doses. Vitamin D screening would identify vitamin D deficiency and insufficiency sooner allowing replacement therapy to begin sooner. Another vitamin D level would still be required for assessment of vitamin D doses but in this case, only for those that needed supplementation.

Efficacy

Data show that higher-dose vitamin D supplementation (≥800 units) combined with calcium can decrease hip (16%-21%), nonvertebral (12%), and overall (8%-13%) fracture rates and increase BMD. However, these effects are generally not seen with vitamin D alone.[25,26,27,28,70] Megadose studies (greater than 300,000 units/year) demonstrated an increased fracture rate, and thus should be avoided.

Most studies and meta-analyses support vitamin D increasing muscle strength and balance, increasing to no change in gait, decreasing numbers of people falling, and decreasing the rate of falls. These findings are consistent with the USPSTF recommendations advocating vitamin D to prevent falls in community-dwelling older adults. Low vitamin D concentrations are associated with many diseases, but data supporting supplementation to prevent or treat these conditions are minimal. At this time, vitamin D supplementation is advocated in older adults with falls or at high risk for falls, and combined with calcium and vitamin D to decrease bone loss and fractures.

Drug Interactions

Some medications can induce vitamin D metabolism including rifampin, phenytoin, barbiturates, valproic acid, and carbamazepine. Vitamin D absorption can be decreased by cholestyramine, colestipol, orlistat, and mineral oil. Vitamin D can enhance the absorption of aluminum; therefore aluminum-containing products should be avoided to prevent aluminum toxicity.

Administration

The vitamin D dose is based on IOM adequate intakes (see Table 92–5**)**, osteoporosis guideline recommendations or to achieve a 25(OH) vitamin D concentration ≥20-30 ng/mL (mcg/L; ≥50-75 nmol/L).[1,3,6,71] About 40% of older adults have hypovitaminosis D (≤ 20 ng/mL [mcg/L; ≤50 nmol/L]), which is higher in blacks (82%) and Hispanics (69%). Replacement doses will first be required in these patients before recommended maintenance doses.[51]

Vitamin D can be taken as a single agent or combination product. Supplements and multivitamins contain vitamin D3 or D2. Synthesized vitamin D3 can be made from irradiated sheep's wool and vitamin D2 from irradiated mushrooms. Although some data support slight differences between vitamin D3 and D2 absorption,[26] guidelines suggest either for prevention and treatment of vitamin D deficiency. Based on a meta-analysis, vitamin D3 was more efficient than vitamin D2 at raising 25(OH) vitamin D concentrations, and produced greater BMD changes with bolus dosing but not with maintenance doses.[72] The differences could be related to greater metabolism of vitamin D2 to inactive metabolites. The vitamin D3 dose to increase 25(OH) vitamin D concentration varies from 40 units to increase concentration by 0.8 ng/mL(mcg/L; 2 nmol/L) to 100 units to increase concentration by 1 ng/mL (mcg/L; 2.5 nmol/L),[71,73] with higher vitamin D doses needed to raise concentrations in obese patients. Higher-dose prescription vitamin D regimens administered weekly, monthly, or quarterly can be used for replacement therapy.[26] More than one multivitamin or large doses of cod liver oil daily are no longer advocated because of the risk of hypervitaminosis A, which can increase bone loss. Because the half-life of vitamin D is about 1 month, approximately 3 months of therapy are required before a new steady state is achieved and a repeat 25(OH) vitamin D concentration can be obtained.

Individuals with deficient concentrations of vitamin D are at risk for osteomalacia. Their management is discussed later in the chapter. In patients who are pregnant, obese, or with disorders (eg, celiac disease, cystic fibrosis, or Crohn's disease), or medications (eg, anticonvulsants, glucocorticoids, antifungals, and AIDS medications) affecting vitamin D absorption, higher doses and more frequent monitoring are required. In patients with severe hepatic or renal disease, the activated form of vitamin D (calcitriol) might be needed, however, newer research suggests adequate amounts of 25(OH)vitamin D are important for total body health creating a need for both cholecalciferol and calcitriol co-administration for these disease conditions.[74]

Bisphosphonates

8 9 Alendronate, risedronate, and intravenous zoledronic acid are FDA-indicated for postmenopausal, male, and glucocorticoid-induced osteoporosis. Intravenous and oral ibandronate and some specialized oral formulations of other bisphosphonates are indicated only for

postmenopausal osteoporosis.

Pharmacology

Bisphosphonates mimic pyrophosphate, an endogenous bone resorption inhibitor.[75,76] Bisphosphonate antiresorptive activity results from blocking prenylation and inhibiting guanosine triphosphatase-signaling proteins, which lead to decreased osteoclast maturation, number, recruitment, bone adhesion, and life span. Their various R2 side chains produce different bone binding, persistence, and affinities; however, the resulting clinical significances are not known.

Pharmacokinetics

Oral bisphosphonate bioavailability is less than 1%; and is greatly decreased with concomitant food and beverages.[75,76,77] Within 24 hours of administration, bisphosphonates undergo rapid skeletal uptake and any drug not incorporated into bone is renally excreted. Incorporation into bone gives bisphosphonates long biologic half-lives of up to 10 years. Absorbed bisphosphonates are renally eliminated and elimination decreases linearly with declining renal function. Bisphosphonates differ in the strength of binding to bone (zoledronic acid greater than alendronate greater than ibandronate greater than risedronate) with zoledronic acid having greater bone absorption, longer bone retention times (less desorption), and more reattachment after bone release.

Efficacy

Of the antiresorptive agents, bisphosphonates consistently provide some of the higher fracture risk reductions and BMD increases (see Table 92–6). Fracture clinical trial data are from daily oral bisphosphonate or annual intravenous therapy, not weekly, monthly, or quarterly regimens. Hip-fracture reduction has not been demonstrated with daily oral ibandronate; however, the study might have been underpowered. Because of the lack of hip-fracture reduction data, ibandronate is not a first-line therapy (see Fig. 92–3). Comparative fracture prevention trials do not exist. Annual intravenous zoledronic acid has documented secondary fracture prevention and a decrease in mortality in the treated group.[3,61]

BMD increases with bisphosphonates are dose dependent and greatest in the first 12 months of therapy.[44,78] Small increases in hip BMD continue for at least 3 years before plateauing, with the exact timing of the plateau varying by agent. For all bisphosphonates, increases in BMD are typically greater at the spine than at the hip. Weekly alendronate, weekly and monthly risedronate, and monthly oral and quarterly intravenous ibandronate therapy produce equivalent BMD changes to their respective daily regimens.[3,78] Alendronate and ibandronate therapy increases lumbar spine BMD more than risedronate therapy[78]; however, no evidence indicates that this difference would equate to greater fracture efficacy. After discontinuation, the increased BMD is sustained for a prolonged period of time that varies per bisphosphonate.[44]

The BMD increases with alendronate, risedronate, zoledronic acid, and oral ibandronate in men are similar to those in postmenopausal women.[4] Because of a lack of fracture data from pivotal trials in men, bisphosphonates are only FDA indicated to increase BMD, not to reduce fracture risk in men. A

meta-analysis combining data from published randomized controlled trials showed reductions in vertebral and nonvertebral fractures in men.[79]

Adverse Events

Oral bisphosphonates are well tolerated if patients are selected for therapy appropriately and the patient takes them correctly (see Table 92–8).[1,6] Patients with creatinine clearances less than 30 to 35 mL/min (0.50–0.58 mL/s), who have serious GI conditions (abnormalities of the esophagus that delay emptying, such as stricture or achalasia), or who are pregnant should not take bisphosphonates. Some experts suggest bisphosphonates can be used in select patients with decreased renal function.[80]

GI complaints, including heartburn and dyspepsia, are one of the most common reasons cited by patients for discontinuing therapy.[6,76] While these mild GI effects are common, bisphosphonates are also associated with rare severe GI events, such as esophageal erosion, ulcer, or GI bleeding. If GI adverse events occur, switching to a different bisphosphonate or less frequent administration schedule might resolve the problem. Patients should be encouraged to discuss GI complaints with a healthcare provider. Intravenous ibandronate and zoledronic acid can be used for patients with GI contraindications or intolerances to oral bisphosphonates. Other common bisphosphonate adverse effects include injection reactions and musculoskeletal pain. If severe musculoskeletal pain occurs, the medication can be discontinued temporarily or permanently. Acute phase reactions (eg, fever, flulike symptoms, myalgias, and arthralgias) are typically associated with intravenous administration, but rarely have been reported with daily, weekly or monthly oral bisphosphonates. This reaction usually diminishes with subsequent administration.

Rare adverse effects include osteonecrosis of the jaw (ONJ) and subtrochanteric femoral (atypical) fractures.[76,81] ONJ occurs more commonly in patients with cancer, receiving higher-dose intravenous bisphosphonate therapy and other risk factors including glucocorticoid therapy and diabetes mellitus. In osteoporosis, the incidence of ONJ is 0.001% to 0.01%, which is similar to the incidence in the general population. Maxillary or mandibular bone surgery and poor oral hygiene are dental-specific risk factors for development of ONJ. When possible, major dental work should be completed before bisphosphonate initiation. For patients already on therapy, some practitioners withhold bisphosphonate therapy during and after major dental procedures, but no data exist to support any benefit of such practice. Atypical femoral shaft fractures are rare; some evidence suggests the risk may increase with longer duration of bisphosphonate use.[76] Since some patients with atypical fracture experience prodromal thigh or hip pain, any such pain should be evaluated.

Drug Interactions

Because of poor bioavailability, oral bisphosphonates should not be administered at the same time as other medications. The administration instructions described below should be followed.

Dosing and Administration

Because bioavailability is very poor for bisphosphonates (less than 1%) and to minimize GI side

effects, each oral tablet should be taken with at least 6 ounces (~180 mL) of plain water (not coffee, juice, mineral water, or milk) at least 30 minutes (60 minutes for ibandronate) before consuming any food, supplements (including calcium and vitamin D), or medications (see Table 92–7). The patient should also remain upright (ie, either sitting or standing) for at least 30 minutes after alendronate and risedronate and 1 hour after ibandronate administration. For patients with swallowing difficulties (eg, stroke and tube feeding), a buffered, strawberry-flavored effervescent tablet form of alendronate, which is dissolved in 4 ounces (~120 mL) of room temperature water, could be used. This formulation has the same food restrictions as traditional oral tablets. In contrast, delayed-release risedronate is available and it is administered immediately following breakfast with at least 4 ounces (~120 mL) of plain water. A patient who misses a weekly dose can take it the next day. If more than 1 day has lapsed, that dose is skipped until the next scheduled ingestion. If a patient misses a monthly dose, it can be taken up to 7 days before the next administration.

Before intravenous bisphosphonates are used, the patient's serum calcium concentration must be normal. Creatinine clearance should be monitored before each dose of zoledronic acid. The intravenous products need to be administered by a healthcare provider. The quarterly ibandronate injection comes as a prefilled syringe (3 mg/mL) kit with a butterfly needle. The injection is given intravenously over 15 to 30 seconds. The injection can also be diluted with dextrose 5% in water or normal saline and used with a syringe pump. Once-yearly administration of zoledronic acid should be infused over at least 15 minutes with a pump. Acetaminophen can be given to decrease acute phase reactions.

Although these medications are effective, adherence is poor and results in decreased effectiveness.[82] Although adherence is improved with once-weekly bisphosphonate administration over daily therapy, it is unclear if once-monthly therapy improves adherence more. While dosing frequency is a common barrier to adherence, adverse effects (eg, GI complaints) and concerns about adverse effects remain important predictors of adherence and persistence. Even after a hip fracture, bisphosphonate persistence is suboptimal.[61,82] To help overcome the barrier associated with dosing frequency, intravenous ibandronate and zoledronic acid could be used as replacements if cost is not an issue. Weekly alendronate plus vitamin D can potentially help to ensure better adherence with vitamin D intake, but at an increased cost over generic alendronate.

Clinical Controversy…

The ideal duration of bisphosphonate therapy is not known. Bisphosphonates are deposited into the bone and continue to suppress bone turnover after discontinuation, and some adverse effects, such as atypical fracture, are associated with duration of therapy.[83] To balance risk and benefit, some clinicians recommend a 'drug holiday,' defined as disruption of therapy during which medication effects exist with a plan for reinstitution. Two randomized, double-blind studies with a drug holiday after therapy with alendronate for 5 years or zoledronic acid for 3 years show a continued fracture benefit with discontinuing therapy. Because a beneficial response was predicted by hip T-score, experts recommend that a drug holiday could be considered in postmenopausal women after 5 years of oral bisphosphonates or 3 years of intravenous bisphosphonates if no significant fracture history, hip BMD T-score is above –2.5, and fracture risk is not high. In women with a high fracture risk or lower hip BMD T-scores, continuing oral bisphosphonates for 10 years or intravenous

bisphosphonates for 6 years should be considered. These recommendations are based on limited data and questions remain regarding the applicability of this approach for patients with glucocorticoid-induced osteoporosis and men.

Denosumab

8 Denosumab is FDA approved for treatment of osteoporosis in women and men at high risk for fracture. It is also approved to increase bone mass in men receiving androgen deprivation therapy for nonmetastatic prostate cancer and in women receiving adjuvant aromatase inhibitor therapy for breast cancer who are at high risk for fracture.

Pharmacology

Denosumab is a fully human monoclonal antibody that binds to RANKL, blocking its ability to bind to its RANK receptor on the surface of osteoclast precursor cells and mature osteoclasts. Denosumab inhibits osteoclastogenesis and increases osteoclast apoptosis.

Pharmacokinetics

Following subcutaneous injection, rapid suppression of bone turnover occurs within 12 hours. Denosumab achieves peak concentration in approximately 10 days. The half-life is approximately 25 days and the concentration slowly declines over a period of 4 to 5 months.[84] The drug does not accumulate with repeated dosing at 6-month intervals. No dosage adjustment is necessary in renal impairment; however, hypocalcemia is more common in severe renal impairment. No studies have been conducted in hepatic impairment.

Efficacy

Over 3 years, denosumab significantly decreased vertebral fractures, nonvertebral fractures, and hip fractures in postmenopausal women with low bone density (see Table 92–6).[84] The BMD effects are at least similar to weekly alendronate and can increase BMD in patients with prior alendronate therapy. Activity appears to dissipate upon medication discontinuation.

Adverse Events

In trials up to 8 years in duration, denosumab was generally well tolerated (see Table 92–8).[84] Dermatologic reactions not specific to the injection site such as dermatitis, eczema, and rashes were more common than with placebo.

Rare, serious adverse effects of denosumab include bone turnover suppression and serious infections including skin infections. If any signs of skin infection such as cellulitis appear, patients should be advised to seek medical attention. Since ONJ has been reported, major dental work should be completed before use when possible. As with the bisphosphonates, muscle, bone, and joint pain and atypical fractures have been reported with this antiresorptive agent. Since hypocalcemia can occur, any existing hypocalcemia should be corrected prior to use and adequate calcium and vitamin D intakes ensured. Severe hypocalcemia is more common in patients with underlying kidney

dysfunction and the manufacturer recommends monitoring of serum calcium, magnesium, and phosphorus within 14 days of administration in those with a CrCl less than 30 mL/min (0.50 mL/s).

Drug Interactions

No drug–drug interactions have been identified with denosumab.

Dosing and Administration

Denosumab is administered subcutaneously by a healthcare professional in the upper arm, upper thigh, or abdomen (see Table 92–7). The product is available as a refrigerated prefilled syringe that can be at room temperature up to 14 days before administration.

Mixed Estrogen Agonists/Antagonists and Tissue Selective Estrogen Complexes

Raloxifene is a second-generation mixed estrogen agonist/antagonist (EAA) approved for prevention and treatment of postmenopausal osteoporosis and for reducing the risk of invasive breast cancer in postmenopausal women with and without osteoporosis. Bazedoxifene is a third-generation EAA combined with conjugated equine estrogens (CEE) making it a tissue selective estrogen complex approved for prevention of postmenopausal osteoporosis and vasomotor menopausal symptoms. Raloxifene's breast cancer–prevention benefits make this medication desirable for younger postmenopausal women at risk for or with osteoporosis and breast cancer. Bazedoxifene with CEE is a good choice for younger postmenopausal women at risk for osteoporosis with menopausal symptoms.

Pharmacology

EAAs bind with α- and β-estrogen receptors and various coactivators or corepressors to cause varying agonist or antagonist effects at different tissue sites.[59] Raloxifene is an agonist at bone receptors and antagonist at breast receptors; it has minimal effect on the uterus. Bazedoxifene is an agonist at bone, and antagonist at the uterus and breast, however it has no breast cancer prevention effects.

Pharmacokinetics

Food has a nonsignificant effect on absorption, which is about 2% for raloxifene and 6%[85] for bazedoxifene due to extensive presystemic glucuronidation.[86] Raloxifene is 95% protein bound. The half-life of raloxifene is 28 hours and of bazedoxifene is 30 hours. EAAs are predominantly metabolized via glucuronidation and eliminated in the feces.

Efficacy

Raloxifene and bazedoxifene decrease vertebral, but not hip fractures.[3,15,59,60] In a subgroup of high-risk postmenopausal women, bazedoxifene decreased nonvertebral fractures. The fracture prevention effects of bazedoxifene combined with CEE are unknown. EAAs increase spine and hip BMD, but to a lesser extent than bisphosphonates (see Table 92–6). Raloxifene's vertebral fracture

prevention is greater in women without previous fracture. Bazedoxifene's BMD increases are greater than raloxifene but vertebral fracture prevention rates are similar. Bazedoxifene with CEE produced significantly greater increases in spine and hip BMD than raloxifene and placebo.[60] Raloxifene 7- and 8-year data and bazedoxifene 5- and 7-year data support long-term effects.[6,59] After raloxifene discontinuation, the medication effect is lost, with bone loss returning to age- or disease-related rates. EAAs cause some positive lipid effects (decreased total and low-density lipoprotein cholesterol, neutral to increased high-density lipoprotein cholesterol); however, triglycerides can increase slightly.[59] No benefit of raloxifene on cardiovascular disease was demonstrated in the RUTH (Raloxifene Use for the Heart) or MORE-CORE (Multiple Outcomes with Raloxifene study and its continuation) trials.

Adverse Events

Hot flushes are common (less than 28%) with raloxifene but decreased with bazedoxifene with CEE (see Table 92–8).[59,60] Raloxifene rarely causes endometrial thickening and bleeding; bazedoxifene decreases these adverse events making progestogen therapy not needed when combined with CEE. Leg cramps and muscle spasms are also common. Thromboembolic events are uncommon (less than 1.5%), but can be fatal. In large trials, no change in overall death, cardiovascular death, or overall stroke incidence was seen with raloxifene; however, a slight increase in fatal stroke (0.7/1,000 women–year difference) was documented, resulting in a boxed warning for raloxifene.[3,59] Fatal stroke with raloxifene occurred most frequently in women with a Framingham stroke risk score of 13 or more. Bazedoxifene with CEE also has all the adverse effects listed for estrogens as a class including increased thromboembolic events.

Drug Interactions

Because of raloxifene's highly protein bound nature (95%), when given concomitantly with other highly protein bound medications, like warfarin, a potential for binding interactions exist therefore monitoring of both medications is suggested.[85] Cholestyramine can decrease raloxifene absorption. Rifampin, phenytoin, carbamazepine, and phenobarbital can decrease bazedoxifene intestinal and liver uridine diphosphate glucuronosyltransferase metabolism.[86] Estrogen metabolism is decreased with CYP3A4 inhibitors.

Dosing and Administration

Although once daily administration is easy, adherence and persistence problems exist (see Table 92–7). EAAs are contraindicated for women with an active or past history of venous thromboembolic disease, pregnancy, or childbearing potential.[85,86] Therapy should be stopped if a patient anticipates extended immobility. Women at high risk for a stroke (eg, Framingham stroke risk score ≥13) or coronary events and those with known coronary artery disease, peripheral vascular disease, atrial fibrillation, or a prior history of cerebrovascular events might not be good candidates for EAAs. These medications should be used with caution in patients with severe liver impairment or moderate to severe renal impairment, due to a lack of data. Bazedoxifene with CEE has all the contraindications and precautions for estrogens as a class.

Calcitonin

8 Calcitonin is FDA indicated for osteoporosis treatment for women who are at least 5 years past menopause. An FDA Advisory Committee Panel voted against calcitonin use for postmenopausal osteoporosis; however, it can be used if alternative therapies are not appropriate.[87] Other countries have discontinued the product.

Pharmacology

Calcitonin is an endogenous hormone released from the thyroid gland when serum calcium is elevated. The prescription product contains salmon calcitonin, which is more potent and longer lasting than the mammalian form.

Pharmacokinetics

Availability is 3% to 5%; and half-life is 18 minutes with nasal administration.[88]

Efficacy

Only vertebral fractures have been documented to decrease with intranasal calcitonin therapy (see Table 92–6).[1,3,4,6,15] Calcitonin does not consistently affect hip BMD. No data exist for men. Intranasal calcitonin might provide some short-term pain relief to some patients with acute vertebral fractures.[3]

Adverse Events

Recent meta-analyses have revealed a weak relationship between calcitonin and cancer with no consistency in dose–response relationship or cancer cell line (see Table 92–8).[87,88] Risk–benefit ratio needs to be assessed before use.

Drug Interactions

Lithium doses might need reduction.[88]

Dosing and Administration

Some patients do not like to administer medications intranasally (see Table 92–7). In clinical trials of calcitonin, a high dropout rate exists. Subcutaneous administration with 100 units daily is available, but rarely used because of more adverse effects and cost.[3] If the nasal product is used for vertebral fracture pain, calcitonin should be prescribed for short-term (4 weeks) treatment and should not be used in place of other more effective and less-expensive analgesics nor should it preclude the use of more appropriate osteoporosis therapy.

Hormone Therapies

Hormone therapies are not recommended solely for osteoporosis but have positive bone effects when used for other indications. Estrogens are FDA indicated for prevention of osteoporosis for

women at significant risk and for whom other osteoporosis medications cannot be used. Estrogens can be a good choice for women going through early menopause when positive bone effects are needs in addition to vasomotor symptom reduction.[89]

Testosterone is used to treat hypogonadism in men, but an osteoporosis medication should be added in men when risk for osteoporotic fracture is high.[4] A complete discussion of adverse events, drug interactions, dosing, and administration for estrogen and testosterone products for women can be found in Chapter 82, Hormone Therapy in Women, and for testosterone products for men in Chapter 84, Erectile Dysfunction.

Estrogen

In women estrogens with or without a progestogen significantly decrease fracture risk and bone loss (see Table 92–6).[3,6,15,89] Oral and transdermal estrogens at equivalent doses and continuous or cyclic HT regimens have similar BMD effects. Effect on BMD is dose dependent, with some benefit seen with lower estrogen doses; however, fracture risk reduction has not been demonstrated with the lower doses. When estrogen therapy is discontinued, bone loss accelerates and fracture protection is lost.

Testosterone

No fracture data are available, but some data support minor bone loss prevention for testosterone use in men and women.

Anabolic Therapies

Teriparatide

8 Teriparatide is FDA indicated for postmenopausal women who are at high risk for fracture, for men with idiopathic or hypogonadal osteoporosis who are at high risk for fracture, men or women intolerant to other osteoporosis medications, and patients with glucocorticoid-induced osteoporosis. Patients who have a history of osteoporotic fracture, multiple risk factors for fracture, very low bone density (eg, T-score less than –3.5), or have failed or are intolerant of previous bisphosphonate therapy could be candidates for teriparatide therapy.

Pharmacology

Teriparatide is a recombinant human product representing the first 34 amino acids in human PTH. Teriparatide increases bone formation, the bone remodeling rate, and osteoblast number and activity. Its actions result from activation of Wnt signaling, induction of runx2 (transcription factor), increased IGF-1 production, and inhibition of osteoblast apoptosis and sclerostin.[3,15,19,21] Both bone mass and architecture are improved. PTH (1-84) is marketed in Europe.

Pharmacokinetics

Bioavailability is 95%.[90] The peptide is cleared through hepatic and extrahepatic pathways, with a half-life of 60 minutes. No pharmacokinetic changes are noted with decreasing renal function. No studies have been performed in hepatic impairment. Alternative delivery formulations and once weekly administration are being investigated.[19]

Efficacy

Two years of teriparatide reduces vertebral and nonvertebral fracture risk in postmenopausal women (see Table 92–6)[3,6,15]; however, no fracture data are available in men or patients taking glucocorticoids. Lumbar spine BMD increases are greater than other osteoporosis medications. Although wrist BMD is decreased, wrist fractures are not increased. Discontinuation of teriparatide therapy results in a decrease in BMD, which can be alleviated with subsequent antiresorptive therapy.[1]

Adverse Events

Transient hypercalcemia rarely occurs with teriparatide (see Table 92–8). Because of an increased incidence of osteosarcoma in rats, teriparatide contains a box warning against use in patients at increased baseline risk for osteosarcoma (eg, Paget's bone disease, unexplained elevations of alkaline phosphatase, pediatric patients, young adults with open epiphyses, or patients with prior radiation therapy involving the skeleton). This adverse effect has not been seen in people.

Drug Interactions

An increased calcium concentration could be a concern if on digoxin therapy.

Dosing and Administration

Teriparatide is commercially available as a prefilled "pen" delivery device (see Table 92–7). The pen must be kept refrigerated and can be used immediately after removing from the refrigerator. The daily subcutaneous injection is delivered to the thigh or abdominal area with site rotation. The administration of the first dose should take place with the patient either sitting or lying down in case orthostatic hypotension occurs. The pen must be discarded 28 days after the initial injection. Duration of therapy is 18 to 24 months. The patient should receive patient education with each pen refill. Suboptimal adherence is documented to decrease efficacy. Besides the conditions listed above, teriparatide should not be used in patients with hypercalcemia, metabolic bone diseases other than osteoporosis, metastatic or skeletal cancers, or premenopausal women of child-bearing potential. Teriparatide should not be used in men with previous radiation therapy.[4]

Teriparatide is the most expensive osteoporosis therapy. Prior authorization might be required. Special arrangements need to be made when patients travel especially on airplanes.

Sequential and Combination Therapy

In the most recent guideline, sequential therapy is recommended but reserved for patients with severe osteoporosis because of cost.[1,91] In sequential therapy, the anabolic agent teriparatide is used

for up to 2 years and then followed by an antiresorptive agent (eg, alendronate or denosumab). Starting with an antiresorptive first and then switching to teriparatide results in lower BMD increases.

Clinical Controversy…

The most recent osteoporosis guidelines[1] and some experts[32] recommend considering combination anabolic (teriparatide continuous or 3 months on and 3 months off) and antiresorptive (bisphosphonate or denosumab) therapy for very severe osteoporosis, especially when additional increases in hip BMD are necessary. These combinations improved hip BMD more than teriparatide alone, but generally did not improve spine BMD over monotherapy.[6,321,92] Of note, these results are not seen if the combination includes alendronate. Combination therapy produces greater BMD effects within the first 2.5 to 3 years; however, after 4 years the BMD effects are similar to sequential therapy with teriparatide followed by denosumab.[91] Because of no documented fracture benefit, increased cost, concern for dual suppression of bone turnover and decreased bone strength, and potential for more adverse effects with combination therapy, others feel combination therapy should not be used. Some experts feel sequential therapy with teriparatide followed by an antiresorptive is preferred over concurrent combination therapy for severe osteoporosis.[32] This controversy does not refer to multiple antiresorptive agents used together for multiple uses, for example bisphosphonate for osteoporosis and estrogens for menopause or raloxifene for breast cancer prevention.

Investigational Therapies

2 Besides the aforementioned investigational products, additional new classes of medications are beginning to show promise in phase II and III studies.[15,19,93] Investigational antiresorptive agents inhibit bone matrix degradation (cathepsin K inhibitors, eg, odanacatib) or block osteoclast activation (c-src kinase inhibitor, eg, saracatinib). Anabolic therapies under investigation include subcutaneously administered neutralizing antibodies against sclerostin (eg, romosozumab and blosozumab) or Dickkopf-1. These potential agents would allow for stimulation of bone formation through the Wnt-β-catenin signaling pathway. Other potential anabolic agents include novel parathyroid hormone–based drugs including a synthetic parathyroid hormone–related protein (PTHrP) analog (abaloparatide). Clinical trials of these new antiresorptive and anabolic agents will be carefully reviewed for antifracture efficacy and safety to determine potential place in therapy.

SPECIAL POPULATIONS

Osteoporosis is a particular threat in some subgroups because of age, genetic abnormalities, diseases, and medications.

Children

Although rare, osteoporosis in children and adolescents can lead to significant pain, deformity, and chronic disability. Secondary causes are the main contributors to osteoporosis in children (see Tables 92–2 and 92–3),[1,3,4,6,7,8,9,10,11] but genetic disorders and idiopathic juvenile osteoporosis can be the

origin of bone disease.

The diagnosis and treatment of osteoporosis in children and adolescents are challenging.[9] No guidelines or consensus recommendations exist. The diagnosis of osteoporosis in children (less than 20 years of age) requires the presence of a clinically significant fracture history (vertebral compression fracture or two or more long bone fractures by age 10 or three or more long bone fractures by age 19) in combination with low bone mass.[33] Low bone mass is defined as a Z-score of –2.0 or less (adjusted for gender, age, and race/ethnicity) using central DXA of the spine or total body.

After correcting any underlying causes and instituting a bone-healthy lifestyle, pharmacologic treatment should be considered for children with low bone mass and fragility fractures.[9] Several small studies, mostly evaluating the intravenous bisphosphonate pamidronate or oral alendronate, have demonstrated increases in BMD. One study evaluating oral risedronate demonstrated increased spine BMD and a reduced risk of nonvertebral fracture. The optimal medication, dose, and duration of therapy are unknown, and more safety data are needed. A major concern with bisphosphonates is their effect on longitudinal bone growth and modeling; however, fracture healing, skeletal growth/maturation, or the appearance of growth plates does not appear to be impaired. Because bisphosphonates are released from bone for many years and cross the placenta, teratogenic effects are also a concern. Teriparatide cannot be used in children as it has a box warning indicating an increased risk for osteosarcoma. Pediatric experience with denosumab is limited.

Premenopausal Women

Clinically significant bone loss and fractures in healthy premenopausal women are rare. Risk factors are similar between premenopausal and postmenopausal osteoporosis.[12,94] Common risk factors in this group are anorexia nervosa, glucocorticoid use, and celiac disease. Bone loss during pregnancy is usually gained back after delivery and breastfeeding. Fifty percent to 90% of premenopausal women with osteoporosis have a secondary cause (see Tables 92–2 and 92–3) for the bone loss. Low-trauma fractures occurred in 28% of premenopausal women with normal BMD. Premenopausal fractures predict postmenopausal osteoporotic fractures.

Routine bone density screening and testing are not cost effective and should not be performed in healthy premenopausal women. Premenopausal women with known osteoporosis risk factors and low-trauma fractures can undergo central DXA examinations. In this case, the Z-score is used with Z-scores of –2.0 or less listed as bone mass below the expected range for age.[34]

Pharmacologic therapy for osteoporosis should be used with caution in premenopausal women as efficacy and safety have not been adequately demonstrated.[12,94] All premenopausal women should practice a bone healthy lifestyle. Secondary causes of bone loss should be resolved. For example, gaining weight and resumed menses are more effective in correcting bone loss secondary to anorexia nervosa than oral contraceptives. If the contributing factor cannot be eliminated, for example, chemotherapy or glucocorticoids, pharmacological therapy can be considered. Women with an unidentified cause for osteoporosis and no history of fracture should be treated with a bone-healthy

lifestyle and watchful waiting.

Osteoporosis medication safety during pregnancy (medication pregnancy categories in Table 92–8) and breastfeeding have not been determined. Because of this, osteoporosis medications are generally not used in childbearing women, although they sometimes are prescribed along with contraceptive agents. A theoretical concern is risk for fetal harm with pregnancies that occur during and after bisphosphonate therapy due to the long half-lives of these agents and the potential for fetal exposure after therapy discontinued.

The Older Adult

Although osteoporosis, osteoporotic fractures, and postfracture morbidity and mortality increase with age, osteoporosis is underdiagnosed and undertreated in older adults. In a multinational study, only 17% of older adults received osteoporosis medications after a fracture.[95] Only 33% of nursing home residents with an osteoporosis diagnosis or past fracture received an osteoporosis medication, even though 89% of them were considered at high risk for a fracture.[96] When diagnosed with osteoporosis or after a low-trauma fracture, many older adults do not receive osteoporosis medications.

Guidelines recommend DXA for people 65 and older, however all older adults are not evaluated for osteoporosis.[1,3,4,34] Universal screening of older women was found to be cost effective, with more cost savings generated with greater age.[97] Reference standards for osteoporosis assessment tools are generally not available for the oldest older adults (eg, maximum age for FRAX is 90 years). In clinical practice, estimates for a 90-year-old person are applied to those adults older than 90 years. FRAX slightly overestimated whereas ultrasound underestimated osteoporosis in nursing home residents.[98] In an older adult with falls, the Garvan calculator might be better as falls are not included in FRAX.[99] Sarcopenia and decreased muscle mass and function are prevalent in older adults and can increase falls. Sarcopenia increased from 9% in 45 to 54 year olds to 33% to 46% in those 85 years and older.[27] After a hip fracture, 22% of women and 87% of men were found to have sarcopenia. Vitamin D 800 to 1,000 units daily has been associated with increasing muscle strength and balance and decreasing falls.

Older adults should practice a bone-healthy lifestyle, ingest adequate calcium and vitamin D,[1,3,4,29] and implement measures to prevent falls.[1,3,16,39,56,57] Exercise might be difficult in older adults due to osteoarthritis, and or limited by underlying cardiac and respiratory diseases. However, walking and lifting light weights can still stimulate bone remodeling. Lactose intolerance and hypercholesterolemia increase with aging; and can lower calcium intake from dairy products, which can increase the need for calcium supplements. Limited sun exposure due to frailty and institutional residence can increase the need for vitamin D supplementation for bone and muscle health. Encouraging older adults to do a home safety evaluation for falls can assist with fracture prevention. Multidisciplinary fall prevention programs with multiple interventions generally have greater impact on fall prevention than single discipline or single intervention. Many fall prevention materials are free on the Internet.

Osteoporosis medication efficacy and safety data are limited in the oldest older adults.[29] When

deciding whether or not to use prescription medications in older adults, the following factors need to be taken into consideration: remaining life span, ability to take and afford medications, cognitive function, swallowing ability, GI disorders, polypharmacy, desire to avoid additional medications, and regimen complexity. Challenges with oral bisphosphonate administration requirements exist for older adults who are bed bound, have difficulties swallowing, have fluid restrictions for cardiovascular or kidney diseases, or forget to drink adequate amounts of fluid or stay upright for the given time. Sometimes not initiating or stopping osteoporosis medications might be warranted for older adults with conditions such as severe Alzheimer disease or during palliative or hospice care. Osteoporosis medications can put an older adult into the Medicare Part D medication insurance plan "donut hole," or timeframe older adult pays most of the medication expenses out of pocket, which might create adherence problems.

Chronic Kidney Disease

Fractures in patients with chronic kidney disease (CKD; glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2 [less than 1 mL/s/1.73 m^2] can stem from osteoporosis alone or in combination with chronic kidney disease-mineral and bone disorder (CKD-MBD) or renal osteodystrophy (see Chapters 50, Calcium and Phosphorus Homeostasis, and 44, Chronic Kidney Disease).[100] CKD, especially stages 4 and 5, is a risk factor for fracture, stemming from abnormalities in mineral and bone metabolism that result from progressive kidney disease. Bone turnover markers or sometimes bone biopsy might be necessary to differentiate the different types of bone diseases from osteoporosis in this population.

Vitamin D deficiency exists in 70% of patients with CKD stage 3 (GFR 30-59 mL/min [0.5-0.99 mL/s]) and 83% of patients with CKD stage 4 (GFR 15-29 mL/min [0.25-0.49 mL/s]) disease warranting 25(OH) vitamin D monitoring and replacement when needed. Adequate 25(OH) vitamin D concentrations should be achieved in end stage renal disease patients (CKD 5 – GFR less than 15 mL/min [less than 0.25 mL/s] and CKD5D – dialysis) as well; however, the strength of data are not yet strong.

Antiresorptive therapies would be appropriate for the management of osteoporosis; however, they are contraindicated in patients with osteomalacia or adynamic bone disease and might be ineffective for osteitis fibrosa cystica. In patients with osteoporosis and a CrCl more than 30 mL/min (>0.50 mL/s), routine management can be used (see Fig. 92–3**)**. For patients with osteoporosis and a CrCl less than 30 or 35 mL/min (0.50 or 0.58 mL/s), bisphosphonates are not FDA indicated because of potential drug accumulation. However, limited data suggest oral bisphosphonates appear safe and efficacious in the low numbers of patients studied with CrCl as low as 15 mL/min (0.25 mL/s).[100] Some experts recommend decreasing the bisphosphonate dose by 50% and using the agent for less than 3 years.[80] Bisphosphonates have been associated with nephrotoxicity. Oral bisphosphonates have not been shown to cause renal damage, while zoledronic acid has been associated with an acute tubular necrosis-like reduction in GFR.[100] For this reason, assessment of renal function prior to infusion and proper hydration are important. Denosumab is not renally eliminated and one post-hoc analysis demonstrated reductions in vertebral fractures in patients with a GFR as low as 15 mL/min (0.25 mL/s). Hypocalcemia including severe hypocalcemia is more common in CKD.[84] Kidney and or

bone specialists usually provide care to patients with significant kidney disease and osteoporosis.

Drug-Induced Disease

Glucocorticoid-Induced Osteoporosis

10 Current and prior glucocorticoid use is the most common cause of drug-induced osteoporosis.[101,102,103] Approximately 30% to 50% of adult patients taking chronic oral glucocorticoids will experience a fracture, with annual fracture rates of 5.1% for vertebral fractures and 2.5% for nonvertebral fractures within the first year of use, changing to 3% for both fracture types for long-term users.[104] All doses and formulations have been associated with increased bone loss and fractures; however, risk is much greater with prednisone doses of 5 mg or more daily or equivalent and oral therapy. Fracture risk is not increased for patients receiving glucocorticoids for adrenal insufficiency. Although a well-documented risk, many patients receiving glucocorticoids are not evaluated and or treated for glucocorticoid-induced osteoporosis (GIO).[105] Various strategies have been tried to increase GIO prevention, assessment and treatment, but suboptimal patient care still existed warranting greater vigilance by all healthcare providers.

Bone losses with glucocorticoids are rapid with up to 12% to 15% loss over the first year, with the greatest decrease occurring in the first 6 months of therapy. Afterward bone loss is about 2% to 3% per year. Trabecular bone is affected more than cortical bone. The pathophysiology of glucocorticoid bone loss is multifactorial. Glucocorticoids decrease bone formation through decreased proliferation and differentiation and enhanced apoptosis of osteoblasts. They can interfere with the bone's natural repair mechanism through increased apoptosis of osteocytes. Glucocorticoids increase bone resorption by increasing RANKL and decreasing OPG. They can reduce estrogen and testosterone concentrations. A negative calcium balance is created from decreased calcium absorption and increased urinary calcium excretion via alterations in calcium transporters. The underlying disease requiring this medication also can affect bone metabolism negatively.

FRAX and central DXA can be used for BMD evaluation.[101,102,103] Based on FRAX estimates of the 10 year risk of major osteoporotic fracture, the patients are risk stratified; low: less than 10%, medium: 10% to 20%, and high: more than 20%.[103] Since FRAX does not account for specific dose, duration or accumulation, FRAX major osteoporotic fracture risk predictions are decreased by 20% if dose is less than 2.5 mg and increased by 15% if dose is more than 7.5 mg. For hip fracture risk predictions, the adjustments are decreased by 35% and increased by 20%, respectively. Patients are also classified as high risk if DXA T-score of –2.5 or less or a history of fragility fracture. A baseline central DXA is recommended before glucocorticoid initiation. Because of the rapid loss of bone that can occur with oral glucocorticoid therapy, central DXA can be repeated yearly thereafter or more often if needed. A VFA is suggested for patients with significant height loss, pain consistent with a vertebral fracture or spine, or receiving 5 or more mg prednisone or equivalent daily.

All patients using glucocorticoids should practice a bone-healthy lifestyle (described above) and minimize glucocorticoid exposure when possible.[101,102,103] All patients starting or receiving glucocorticoid therapy (any dose or duration) should ingest 1,200 to 1,500 mg elemental calcium and

800 to 1,200 units of vitamin D daily or more to achieve therapeutic 25 (OH) vitamin D concentrations. Minimizing fall risk is important. Counseling should occur for all patients using this medication for 3 months or more regardless of dose. Glucocorticoids should be used at the lowest dose and for the shortest duration possible. After discontinuation, fracture risk is still higher than never users.[101]

Revisions of the 2010 American GIO guidelines are expected in 2017. The current guidelines divide recommendations for prescription osteoporosis medication use by fracture risk, age, menopause and childbearing status, glucocorticoid dose and duration, and fragility fracture (see **Tables 92–9** and **92–10**).[103] Alendronate, risedronate, zoledronic acid, and teriparatide have FDA indications for GIO.[101,103] They decrease bone loss with a few studies showing decreased fracture rate with some agents. Raloxifene and denosumab do not have FDA indications, but have some clinical data documenting decreasing bone loss from glucocorticoids. Based on a database analysis, osteoporosis medications have been documented to decrease fracture rates by 48% at 1 year and 32% at 3 years in patients taking glucocortiocoids.[105] Standard osteoporosis therapy doses are used. Patients receiving glucocorticoids are considered high risk, and therefore, a bisphosphonate drug holiday is generally not considered. Usually osteoporosis medications are not used in women with childbearing potential or pregnant. For premenopausal and younger men (less than 50 years old) who have already experienced a fragility fracture, osteoporosis medications could be used after explaining risks and paucity of data to drive decisions.

TABLE 92-9 Therapy to Prevent or Treat Glucocorticoid-Induced Osteoporosis in Postmenopausal Women and Men of More Than 50 Years Old

	Low Risk FRAX <10%	**Medium Risk FRAX 10% to 20%**	**High Risk FRAX >20%, DXA T-score < -2.5, or fragility fracture**

Patient	**Prednisone**	**Prednisone More**	**Prednisone Less**	**Prednisone More**

	5-7.4 mg Daily for 1-3 Months	Than 7.5 mg Daily for 1-3 Months	Than 7.5 mg Daily for More Than 3 Months	Than 7.5 mg Daily for More Than 3 Months
Nonchildbearing premenopausal women and men <50 years old	Alendronate and risedronate	Alendronate, risedronate, and zoledronic acid	Alendronate, risedronate, zoledronic acid, and teriparatide	Alendronate, risedronate, zoledronic acid, and teriparatide
Childbearing women	No consensus	No consensus	No consensus	Alendronate, risedronate, and teriparatide

Data from reference 103.

Since glucocorticoids can cause hypogonadism, sometimes hormone therapy will be prescribed. The hormonal therapy for correcting hypogonadism symptoms most likely will have some positive bone effects as well.

Cancer-Treatment–Related Bone Loss

10 Cancers, metastases, and chemotherapies, such as antiandrogen and antiestrogen agents, can cause bone loss and osteoporosis.[106] Chemotherapy-induced ovarian failure can enhance bone loss. Glucocorticoids used as chemotherapy, chemotherapy premedication, and/or treatment for chemotherapy-induced nausea and vomiting also increase bone loss in patients with cancer.

DXA screening is advocated for patients at high risk for osteoporosis, which would include certain chemotherapies and cancers. When using FRAX, secondary osteoporosis can be checked "yes" when premature menopause and hypogonadism caused by chemotherapy and cancer are present.

Certain osteoporosis medications are used to prevent bone loss or treat osteoporosis due to chemotherapy, cancer, and metastases.[106] Bisphosphonates and denosumab decrease chemotherapy-induced bone loss and in some trials fractures.[106,107,108,109,110,111] These agents might also decrease cancer progression. Most research has been conducted in women with breast cancer and men with prostate cancer. Raloxifene decreases the risk of invasive breast cancer in high-risk women. Teriparatide might be used sometimes but it is contraindicated in patients with prior radiation to the skeleton because of risk for osteosarcoma. Zoledronic acid and denosumab are used for cancer-related hypercalcemia and skeletal-related events and are marketed with different product names since dosages are much higher than for osteoporosis.

Personalized Pharmacotherapy

Bone physiology and pathophysiology are under many genomic and genetic influences, thus isolating one or a few genes for correction will unlikely resolve the osteoporosis public epidemic. Heredity is important since family history, especially of a hip fracture in a parent, is a strong risk factor for osteoporosis development.[3,12] So far, 56 loci have been identified that influence BMD and

14 loci for fracture risk, ranging from impacts on bone resorption (RANKL, OPG) to formation (Wnt, LRP5, and sclerostin).[112] Calcium, vitamin D, and estrogen receptors are also under genetic influence. Studies investigating whether there is an association between response to currently available antifracture drugs and genetic profile have been conflicting. Genetic modulation is in its infancy for osteoporosis prevention and treatment but might lead to new medications and/or the ability to tailor medication choices to an individual's genetic profile.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

Assessment of adherence and tolerability of medication should be performed at each visit. Having a patient repeat back instructions for medication administration will help identify administration problems and enable timely correction. Assessment of fracture, back pain, and height loss can help identify worsening osteoporosis.

To evaluate efficacy, a central DXA BMD measurement can be obtained after 2 years of initiating a medication to monitor response. To minimize test variability, BMD testing should be performed on the same DXA machine. A statistical change needs to be greater than the least significant change for that specific piece of equipment generally more than 2% to 3% for the lumbar spine and 5% to 6% for the femoral neck.[15] Since BMD continues to decrease with aging, no change from baseline can be an acceptable response. Because changes in BMD do not entirely explain changes in fracture risk, many experts believe that decisions on whether or not to continue a particular therapy should not be based solely on BMD response. Central DXAs are repeated every 2 years until BMD is stable, at which time the interval for reassessment could be lengthened. In patients with conditions associated with higher rates of bone loss (eg, glucocorticoid use and certain chemotherapy agents), more frequent monitoring might be warranted.

Bone turnover markers have been used to determine response to an osteoporosis prescription medication.[1,3,35] The patient either provides a first or second morning voiding sample or has blood drawn after an overnight fast to measure the markers 3 to 6 months after therapy initiation. The results are compared to baseline values. Significant changes need to be greater than the least significant change for that test, beyond that no specific guidelines for interpretation exist. Because no consensus on result interpretation and high-test variability exists, these tests are not routinely ordered.

Osteoporosis Services

9 Even with guidelines, many patients are not being evaluated or do not receive appropriate osteoporosis therapy.[1] Following a fracture less than one-quarter of women receive BMD testing or start osteoporosis therapy within 6 months of fracture.[113] Community pharmacies and health fairs can provide osteoporosis screenings using the FRAX tool to estimate fracture risk or ultrasonography to measure heel BMD. Osteoporosis prevention and treatment services have been clinically successful

and financially sustainable in the community pharmacy setting[114,115] and as part of pharmacy services in a patient-centered medical home.[116] All healthcare providers should identify and resolve barriers to optimal medication adherence. Some pharmacists are beginning to administer denosumab in community pharmacies to improve adherence and ease of administration. Databases can be used to identify patients after a low-trauma fracture who have not had a DXA exam or osteoporosis medication started. Many institutions are developing a fracture liaison service, which is generally a multidisciplinary, multifaceted program to increase treated patient numbers and improve osteoporosis treatment outcomes.[113]

To improve patient care, the Centers for Medicare and Medicaid Services have established quality measures centering on improving clinical processes related to screening for or treatment of osteoprososis.[117] Financial incentives tied to these measures could help bridge the gap in quality of care.

Osteomalacia

Osteomalacia is a condition of defective or delayed bone mineralization in adults, known as rickets in children.[118,119] The most common cause of osteomalacia is nutritional deficiency in vitamin D and or calcium intake. Other causes include chronic hypophosphatemia and diseases or medications that alter vitamin D metabolism (eg, long-term anticonvulsants) and certain rare diseases. Patients with osteomalacia present with pathologic fractures and/or deep bone pain, proximal muscle weakness, or no obvious symptoms besides low BMD. Children can present with additional symptoms. Patients with osteomalacia have a low 25(OH) vitamin D concentration (less than 12 ng/mL [mcg/L; less than 30 nmol/L]) and might have an elevated bone-specific alkaline phosphate, hypophosphatemia, and hypocalcemia.

Preventive vitamin D therapy can be considered for those with a history of symptomatic vitamin D deficiency, have conditions or take medications reducing metabolism or intake of vitamin D, and for pregnant women (600 units per day) and infants under 12 months (400 units per day).[119]

For patients with nutritional osteomalacia, high-dose vitamin D–replacement therapy was preferred therapy in the past but now high dose daily oral therapy is being used more frequently.[118,119] Prescription oral vitamin D3 50,000 units once to thrice weekly for at least 10 weeks is a commonly used high dose regimen for adults, which has a longer duration than vitamin D2. Depending on age, 2,000 to 6,000 units of vitamin D3 or D2 daily for 3 months is recommended for children with rickets. Other high-dose oral and intramuscular vitamin D regimens are less common. Adequate daily intake of calcium is also recommended. Once 25(OH) vitamin D concentrations are greater than 30 ng/mL (mcg/L; 75 nmol/L), chronic vitamin D maintenance therapy can be instituted. Oral ergocalciferol 50,000 units once or twice a month or nonprescription cholecalciferol 1,000 to 2,000 units once daily are reasonable maintenance options. For hypophosphatemic osteomalacia, phosphate therapy, and calcitriol are recommended. For secondary osteomalacia, the underlying condition should be treated.

CONCLUSION

Osteoporosis prevention begins at birth and continues throughout life by practicing a bone-healthy lifestyle (adequate calcium and vitamin D intake, exercise, no smoking, minimal alcohol use, and fall prevention). Generally, osteoporosis occurs in postmenopausal women and older men; however, the disease can occur in all ages as a result of secondary causes such as genetics, diseases, and medications. Central DXA can be used for screening, diagnosis, and monitoring and the FRAX tool can be used for screening and to assist in identifying patients at high risk for fracture requiring treatment.

Alendronate, risedronate, zoledronic acid, and denosumab are first-line therapies since these medications decrease hip, nonvertebral, and vertebral fractures. Teriparatide is the only medication that can build bone; however, cost and subcutaneous administration limit its use. Although medications decrease fracture risk, prescribing of osteoporosis medications and patient adherence to such therapy is suboptimal. All healthcare providers need to be actively involved in osteoporosis education, counseling, and prevention across the lifespan and attentive to treatment and medication adherence to prevent osteoporotic fractures in patients with osteoporosis.

DESIRED OUTCOMES

The primary goal of osteoporosis care should be prevention. Optimizing skeletal development and peak bone mass accrual in childhood, adolescence, and early adulthood will ultimately reduce the future incidence of osteoporosis. Once low bone mass or osteoporosis develops, the objective is to stabilize or improve bone mass and strength and prevent fractures. In patients who have already suffered osteoporotic fractures, reducing pain and deformity, improving functional capacity, improving quality of life, and reducing future falls and fractures are the main goals.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

25(OH) vitamin D	25-hydroxyvitamin D/calcidiol
BMD	bone mineral density
CEE	conjugated equine estrogens
CKD-MBD	chronic kidney disease-mineral and bone disorder
DKK-1	Dickkoff-1
DXA	dual-energy X-ray absorptiometry
EAA	estrogen agonist antagonist
FAK	focal adhesion kinase
FRAX	World Health Organization fracture risk assessment tool
GFR	glomerular filtration rate
GI	gastrointestinal
GIO	glucocorticoid-induced osteoporosis
GSK-3β	glycogen synthase kinase-3β

IOM	Institute of Medicine
LRP5/6	lipoprotein-receptor related protein
NF-kβ	nuclear factor kappa β
OPG	osteoprotegerin
PINP	procollagen type 1 N-terminal propeptide
PPARγ	peroxisome proliferator-activated receptor g
PTH	parathyroid hormone
PTHrP	parathyroid hormone-related protein
RANK	receptor activator of nuclear factor-kβ
RANKL	receptor activator of nuclear factor-kappa β ligand
runX2	runt-related transcription factor
Scr	tyrosine scr kinase
TRAF-6	tumor necrosis factor receptor associated factor 6
USPSTF	United States Preventive Services Task Force
WHO	World Health Organization
Wnt	wingless tail

Chapter 93: Gout and Hyperuricemia

Michelle A. Fravel; Michael E. Ernst

INTRODUCTION

KEY CONCEPTS

- 1 In the absence of a history of gout, asymptomatic hyperuricemia may not require treatment.
- 2 Acute gouty arthritis may be treated effectively with short courses of high-dose nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, or colchicine.
- 3 Low-dose colchicine is highly effective at relieving acute attacks of gout; dose titration leads to more adverse effects but does not improve efficacy.
- 4 Treatment with urate-lowering drugs to reduce risk of recurrent attacks of gouty arthritis is considered cost-effective for patients having two or more attacks of gout per year.
- 5 Xanthine oxidase inhibitors are efficacious for the prophylaxis of recurrent gout attacks in both underexcreters and overproducers of uric acid. Either allopurinol or febuxostat should be initiated in patients with one of the following indications for urate-lowering therapy (ULT): (a) two or more gout attacks per year, (b) the presence of one or more tophus, (c) chronic kidney disease (stage 2 or worse), or (d) a history of urolithiasis. The dose of the xanthine oxidase inhibitor should be titrated to a goal serum urate concentration of less than 6 mg/dL (less than 357 µmol/L) (or less than 5 mg/dL [less than 297 µmol/L] if signs of gout persist at a level of 6 mg/dL [357 µmol/L]).
- 6 Uricosuric agents should be avoided for patients with renal impairment (a creatinine clearance below 50 mL/min [0.83 mL/s]), a history of renal calculi, or overproduction of uric acid.
- 7 Low-dose colchicine, NSAID, or corticosteroid therapy should be administered during the first 3 to 6 months of urate-lowering therapy (ULT) to minimize the risk of acute gout attacks that may occur during this initiation period.
- 8 Uric acid nephrolithiasis should be treated with adequate hydration (2-3 L/day), a daytime urine-alkalinizing agent, and 60 to 80 mEq/day (mmol/day) of potassium bicarbonate or

potassium citrate.

- 9 Patients with hyperuricemia or gout should undergo comprehensive evaluation for signs and symptoms of cardiovascular disease, and aggressive management of cardiovascular risk factors (ie, weight loss, reduction of alcohol intake, control of blood pressure, glucose, and lipids) should be undertaken as indicated.

The term *gout* describes a heterogeneous clinical spectrum of diseases including elevated serum urate concentration (hyperuricemia), recurrent attacks of acute arthritis associated with monosodium urate (MSU) crystals in synovial fluid leukocytes, deposits of monosodium urate crystals (tophi) in tissues in and around joints, interstitial renal disease, and uric acid nephrolithiasis.[1]

The underlying metabolic disorder of gout is hyperuricemia, defined physiochemically as serum that is supersaturated with monosodium urate. At 37°C (98.6°F), serum urate concentrations above (or around) 7 mg/dL (416 µmol/L) begin to exceed the limit of solubility for monosodium urate.[1] For determination of the risk of gout, hyperuricemia is defined statistically as serum urate concentrations greater than two standard deviations above the population means for age- and sex-matched healthy populations, usually 7 mg/dL (416 µmol/L) for men and 6 mg/dL (357 µmol/L) for women.[1,2] Although hyperuricemia is fundamental to the development of gout, the mere presence of hyperuricemia itself is often an asymptomatic condition.

EPIDEMIOLOGY

Historically, gout has been referred to as the "disease of kings" since it was often associated with affluent societies and lifestyles of overindulgence, gluttony, and intemperance.[1] Gout continues to occur more commonly in developed countries (eg, United States, Japan, United Kingdom, and Australia) as compared to developing countries (eg, China).[3] In the United States, the prevalence of gout is increasing. According to data from the 2007 to 2008 National Health and Nutrition Examination Survey (NHANES), the prevalence of gout in US adults is 3.9%, which corresponds to an estimated 8.3 million people. This represents a 1.2% increase in prevalence compared with NHANES-III survey data from 1988 to 1994.[4]

Elevated serum urate levels are the single most important risk factor for the development of gout, and the relationship between the risk of an attack of acute gouty arthritis and serum urate levels is linearly correlated. The 5-year cumulative risk of gout for patients with serum urate concentrations less than 7 mg/dL (less than 416 µmol/L) is 0.6%, compared with a risk of 30.5% for those with urate levels more than 10 mg/dL (more than 595 µmol/L).[5] Sustained elevation of serum urate is virtually essential for the development of gout; however, hyperuricemia does not always lead to gout, and many patients with hyperuricemia remain asymptomatic.[2] Although unusual, acute gouty arthritis has been reported to occur in the presence of normal serum uric acid concentrations.[6] The prevalence of hyperuricemia in the United States mirrors the trend seen with gout, affecting 21.4% of adults (43.3 million people) in 2007 to 2008 compared to just 18.2% in 1998 to 1994.[4]

The increased prevalence of gout and hyperuricemia may be partly explained by the aging of the

population. Gout and hyperuricemia occur more commonly in the older adult with the highest prevalence, 12.6%, in those 80 years and older compared with just 0.4% in those between ages 20 and 29 years.[4] Another major contributor to the increased prevalence of gout in the United States is the obesity epidemic. Obese persons are twice as likely to have gout as nonobese counterparts.[7] Dietary and lifestyle factors linked to obesity have also been independently associated with gout. These include consumption of alcohol, sugary beverages, and red meat along with a sedentary lifestyle.[8]

Regarding sex distribution, gout affects men about three times more often than women.[4] The lowest rates of gout are observed in women younger than 45 years, approximately 0.6 cases per 1,000 person-years.[9] Serum uric acid levels in women approach those of men once menopause has occurred; thus, in older age groups the gender gap narrows, and approximately half of newly diagnosed cases of gout are found in women.[10,11] Gout in men younger than 30 years or in premenopausal women may indicate an inherited enzyme defect or the presence of renal disease. Although no genetic marker has been isolated for gout, the familial nature of gout strongly suggests an interaction between genetic and environmental factors.

ETIOLOGY AND PATHOPHYSIOLOGY

In humans, the production of uric acid is the terminal step in the degradation of purines. Uric acid serves no known physiologic purpose and is regarded as a waste product. Normal uric acid levels are near the limits of urate solubility, because of the delicate balance that exists between the amount of urate produced and excreted.[2] Humans have higher uric acid levels than other mammals because they do not express the enzyme uricase, which converts uric acid into the more soluble allantoin.[10]

Gout occurs exclusively in humans in whom a miscible pool of uric acid exists. Under normal conditions, the amount of accumulated uric acid is about 1,200 mg in men and about 600 mg in women. The size of the urate pool is increased several fold in individuals with gout. This excess accumulation may result from either overproduction or underexcretion of uric acid. Several conditions are associated with either decreased renal clearance or an overproduction of uric acid, leading to hyperuricemia. **Table 93-1** lists some of these conditions.

TABLE 93-1 Conditions Associated with Hyperuricemia

Primary gout	Obesity
Diabetic ketoacidosis	Sarcoidosis
Myeloproliferative disorders	Congestive heart failure
Lactic acidosis	Renal dysfunction
Lymphoproliferative disorders	Down syndrome
Starvation	Lead toxicity
Chronic hemolytic anemia	Hyperparathyroidism
Toxemia of pregnancy	Acute alcoholism
Pernicious anemia	Hypoparathyroidism
Glycogen storage disease type 1	Acromegaly

Psoriasis	Hypothyroidism
Hypoxanthine-guanine phosphoribosyltransferase deficiency	Phosphoribosylpyrophosphate synthetase overactivity
Polycythemia vera	Berylliosis
Renal transplantation	

Overproduction of Uric Acid

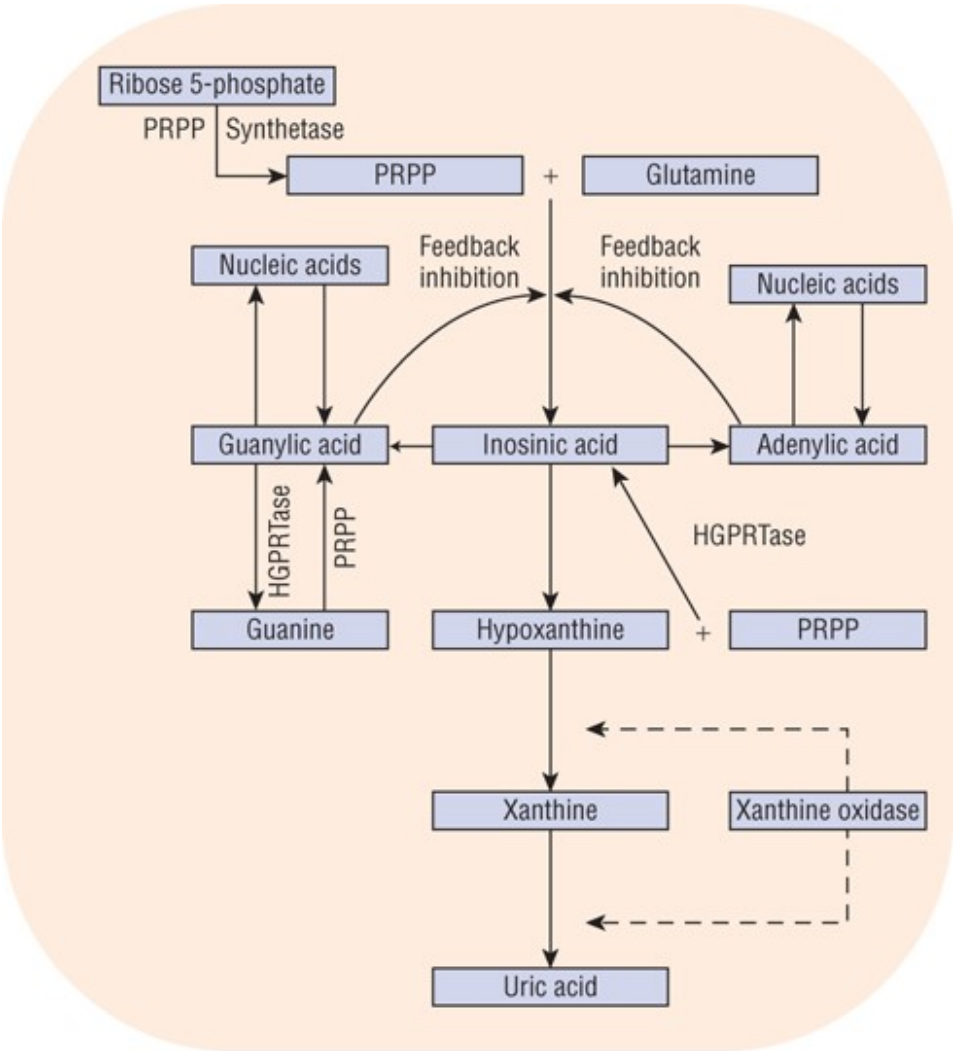
The purines from which uric acid is produced originate from three sources: dietary purine, conversion of tissue nucleic acid into purine nucleotides, and de novo synthesis of purine bases. The purines derived from these three sources enter a common metabolic pathway leading to the production of either nucleic acid or uric acid. Under normal circumstances, uric acid may accumulate excessively if production exceeds excretion. The average human produces about 600 to 800 mg of uric acid each day. Dietary purines play an unimportant role in the generation of hyperuricemia in the absence of some derangement in purine metabolism or elimination. However, diet modifications are important for patients with such problems who develop symptomatic hyperuricemia.

Several enzyme systems regulate purine metabolism. Abnormalities in these regulatory systems can result in overproduction of uric acid. Uric acid may also be overproduced as a consequence of increased breakdown of tissue nucleic acids and excessive rates of cell turnover, as observed with myeloproliferative and lymphoproliferative disorders, polycythemia vera, psoriasis, and some types of anemias. Cytotoxic medications used to treat these disorders can result in overproduction of uric acid secondary to lysis and breakdown of cellular matter.

Two enzyme abnormalities resulting in an overproduction of uric acid have been well described (**Fig. 93-1**). The first is an increase in the activity of phosphoribosyl pyrophosphate (PRPP) synthetase, which leads to an increased concentration of PRPP. PRPP is a key determinant of purine synthesis and uric acid production. The second is a deficiency of hypoxanthine-guanine phosphoribosyltransferase (HGPRT). HGPRT is responsible for the conversion of guanine to guanylic acid and hypoxanthine to inosinic acid. These two conversions require PRPP as the cosubstrate and are important reactions involved in the synthesis of nucleic acids. A deficiency in the HGPRT enzyme leads to increased metabolism of guanine and hypoxanthine to uric acid and to more PRPP to interact with glutamine in the first step of the purine pathway.[12] Complete absence of HGPRT results in the childhood Lesch–Nyhan syndrome, characterized by choreoathetosis, spasticity, intellectual disability, and markedly excessive production of uric acid. A partial deficiency of the enzyme may be responsible for marked hyperuricemia in otherwise normal, healthy individuals.

FIGURE 93-1

Purine metabolism. (HGPRT, hypoxanthine-guanine phosphoribosyltransferase; PRPP, phosphoribosyl pyrophosphate.)



Underexcretion of Uric Acid

Normally, uric acid does not accumulate as long as production is balanced with elimination. About two-thirds of the daily uric acid production is excreted in the urine and the remainder is eliminated through the gastrointestinal (GI) tract after enzymatic degradation by colonic bacteria. The vast majority of patients (90%) with gout have a relative decrease in the renal excretion of uric acid for an unknown reason (primary idiopathic hyperuricemia).[2]

CLINICAL PRESENTATION Acute Gouty Arthritis General

- Gout classically presents as an acute inflammatory monoarthritis. The first metatarsophalangeal joint is often involved ("podagra"), but any joint of the lower extremity can be affected and occasionally gout will present as a monoarthritis of the wrist or finger. The spectrum of gout also includes nephrolithiasis, gouty nephropathy, and aggregated deposits of sodium urate (tophi) in cartilage, tendons, synovial membranes, and elsewhere.

Signs and Symptoms

- Fever, intense pain, erythema, warmth, swelling, and inflammation of involved joints.

Laboratory Tests

- Elevated serum uric acid levels; leukocytosis.

Other Diagnostic Tests

- Observation of MSUs in synovial fluid or a tophus.
- For patients with long-standing gout, radiographs may show asymmetric swelling within a joint on or subcortical cysts without erosions.

A decline in the urinary excretion of uric acid to a level below the rate of production leads to hyperuricemia and an increased miscible pool of sodium urate. Almost all the urate in plasma is freely filtered across the glomerulus. The concentration of uric acid appearing in the urine is determined by multiple renal tubular transport processes in addition to the filtered load. Evidence favors a four-component model including glomerular filtration, tubular reabsorption, tubular secretion, and postsecretory reabsorption.

Approximately 90% of filtered uric acid is reabsorbed in the proximal tubule, probably by both active and passive transport mechanisms. There is a close linkage between proximal tubular sodium reabsorption and uric acid reabsorption, so conditions that enhance sodium reabsorption (eg, dehydration) also lead to increased uric acid reabsorption. The exact site of tubular secretion of uric acid has not been determined; this too appears to involve an active transport process. Postsecretory reabsorption occurs somewhere distal to the secretory site. **Table 93-2** lists the drugs that decrease renal clearance of uric acid through modification of filtered load or one of the tubular transport processes. By enhancing renal urate reabsorption, insulin resistance is also associated with gout.

TABLE 93-2 Drugs Capable of Inducing Hyperuricemia and Gout

Diuretics	Ethanol	Ethambutol
Nicotinic acid	Pyrazinamide	Cytotoxic drugs
Salicylates (<2 g/day)	Levodopa	Cyclosporine

The pathophysiologic approach to the evaluation of hyperuricemia requires determining whether the patient is overproducing or underexcreting uric acid. This can be accomplished by placing the patient on a purine-free diet for 3 to 5 days and then measuring the amount of uric acid excreted in the urine in 24 hours. As it is very difficult to maintain a purine-free diet for several days, this test is done infrequently in clinical practice. Nevertheless, when it is performed, individuals who excrete more than 600 mg on a purine-free diet may be considered overproducers. Hyperuricemic individuals who excrete less than 600 mg of uric acid per 24 hours on a purine-free diet may be classified as underexcreters of uric acid. On a regular diet, excretion of more than 1,000 mg per 24 hours reflects overproduction; less than this is probably normal.

CLINICAL PRESENTATION

1 Gout is diagnosed clinically by symptoms rather than laboratory tests of uric acid. In fact, asymptomatic hyperuricemia discovered incidentally generally requires no therapy because many individuals with hyperuricemia will never experience an attack of gout. These patients should still be encouraged to implement lifestyle measures to reduce serum urate concentrations.

Acute Gouty Arthritis

A classic acute attack of gouty arthritis is characterized by rapid and localized onset of excruciating pain, swelling, and inflammation. The attack is typically monoarticular at first, most often affecting the first metatarsophalangeal joint (great toe) and then, in order of frequency, the insteps, ankles, heels, knees, wrists, fingers, and elbows. In one half of initial attacks, the first metatarsophalangeal joint is affected, a condition commonly referred to as *podagra* (**Fig. 93-2**). Up to 90% of patients with gout will experience podagra at some point in the course of their disease.[2]

FIGURE 93-2

Acute gout attack of the first metatarsophalangeal joint. *(Reproduced with permission from Imboden J, Hellmann DB, Stone JH. Current Rheumatology Diagnosis and Treatment, 2nd ed. New York: McGraw-Hill, 2004:316.)*

Atypical presentations of gout also occur. For elderly patients, gout can present as a chronic polyarticular arthritis that can be confused with rheumatoid arthritis or osteoarthritis. Additionally, the onset of gout may be less dramatic than the typical acute attack and have fewer clinical findings.[13] Multiple small joints in the hands may be involved, especially in elderly women.[10] **Table 93-3** summarizes the different clinical manifestations of gout.

TABLE 93-3 Clinical Manifestations of Gout

	Monoarticular arthritis
Classic acute gout ("podagra")	Frequently attacks the first metatarsophalangeal joint, although other joints of the lower extremities are also frequently involved
Interval gout	Affected joint is swollen, erythematous, and tender Asymptomatic period between attacks
Tophaceous gout	Deposits of monosodium urate crystals in soft tissues Complications include soft tissue damage, deformity, joint destruction, and nerve compression syndromes such as carpal tunnel syndrome
Atypical gout	Polyarthritis affecting any joint, upper or lower extremity May be confused with rheumatoid arthritis or osteoarthritis
Gouty nephropathy	Nephrolithiasis Acute and chronic renal impairment

The predilection of acute gout for peripheral joints of the lower extremity is probably related to the low temperature of these joints combined with high intra-articular urate concentration. Synovial effusions are likely to occur transiently in weight-bearing joints during the course of a day with routine activity. At night, water is reabsorbed from the joint space, leaving behind a supersaturated solution of monosodium urate, which can precipitate attacks of acute arthritis. Attacks generally begin at night with the patient awakened from sleep by excruciating pain.

The development of crystal-induced inflammation involves a number of chemical mediators causing vasodilation, increased vascular permeability, complement activation, and chemotactic activity for polymorphonuclear leukocytes.[14] Phagocytosis of urate crystals by the leukocytes results in rapid lysis of cells and a discharge of lysosomal and proteolytic enzymes into the cytoplasm. The ensuing inflammatory reaction is associated with intense joint pain, erythema, warmth, and swelling. Fever is common, as is leukocytosis. Untreated attacks may last from 3 to 14 days before spontaneous recovery.

Although acute attacks of gouty arthritis may occur without apparent provocation, a number of conditions may precipitate an attack. These include stress, trauma, alcohol ingestion, infection, surgery, rapid lowering of serum uric acid by ingestion of uric acid-lowering agents, and ingestion of certain drugs known to elevate serum uric acid concentrations (see Table 93-2). Other crystal-induced arthropathies that may resemble gout on clinical presentation are caused by calcium pyrophosphate dihydrate crystals (pseudogout) and calcium hydroxyapatite crystals, which are associated with calcific periarthritis, tendinitis, and arthritis.[14,15,16,17] Acute flares of gouty arthritis may occur infrequently, but over time the interval between attacks may shorten if appropriate measures to correct hyperuricemia are not undertaken. Later in the disease, tophaceous deposits of MSUs in the skin or subcutaneous tissues may be found. These tophi can be anywhere but are often found on the hands, wrists, elbows, or knees. It is estimated to take 10 or more years for tophi to develop.

Diagnostic Evaluation

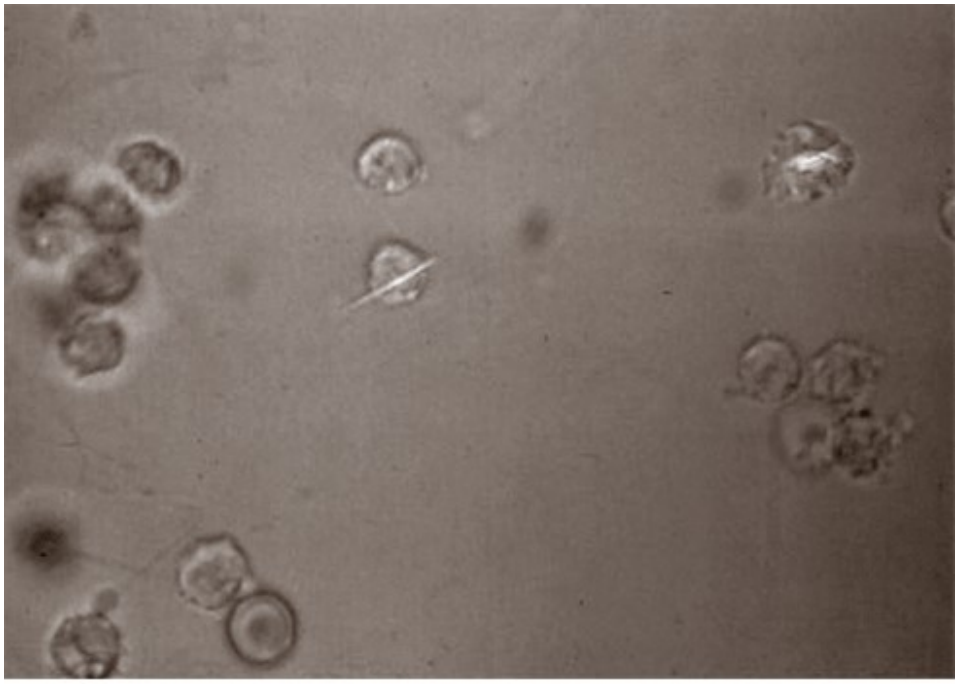
Table 93-4 lists the differential diagnosis of an acute monoarthritis.[18,19] A definitive diagnosis of gout requires aspiration of synovial fluid from the affected joint and identification of intracellular crystals of monosodium urate monohydrate in synovial fluid leukocytes.[2] Identification of MSUs is highly dependent on the experience of the observer. Crystals are needle-shaped, and when examined under polarizing light microscopy, they are strongly negatively birefringent (**Fig. 93-3**). Crystals can be observed in synovial fluid during asymptomatic periods.[20] If an affected joint is tapped, the resulting synovial fluid may have white cells and appear purulent. Such findings should always raise the question of infection. If any clinical features of infection are present, such as high fever, elevated white blood cell count, multiple joints affected, or an identified source of infection, proper diagnosis and treatment are critical. Patients with gout can have septic arthritis. Diabetes, alcohol abuse, and advanced age increase the likelihood of septic arthritis.

TABLE 93-4 Differential Diagnosis of Acute Monoarthritis

1. Pseudogout (pyrophosphate crystal-related arthritis)
2. Palindromic rheumatism
3. Seronegative inflammatory arthritis
4. Trauma or hemarthrosis
5. Septic arthritis
6. Cellulitis
7. Type II dyslipidemia
8. Unrelated hyperuricemia (as in psoriasis, hypertension) when joint pain is not caused by gout

FIGURE 93-3

Urate crystal ingested by a polymorphonuclear leukocyte in synovial fluid. *(Reproduced with permission from Imboden J, Hellmann DB, Stone JH. Current Rheumatology Diagnosis and Treatment, 2nd ed. New York: McGraw-Hill, 2004:317.)*



In lieu of obtaining a synovial fluid sample from an affected joint to inspect for urate crystals, the clinical triad of inflammatory monoarthritis, elevated serum uric acid level, and response to colchicine can be used to diagnose gout. However, this approach has limitations, including a failure to recognize atypical gout presentations and the fact that serum uric acid levels can be normal or even low during an acute gout attack.[2,5,21] In addition, use of colchicine as a diagnostic tool for gout is limited by lack of sensitivity and specificity for the disease. Other conditions such as psoriatic arthritis, sarcoidosis, and Mediterranean fever can respond to colchicine therapy. For patients with long-standing gout, radiographs may show punched-out marginal erosions and secondary osteoarthritic changes; however, in an acute first attack radiographs will be unremarkable.[19,22] The presence of chondrocalcinosis on radiographs may indicate pseudogout. Some studies have recently examined the use of magnetic resonance imaging and computed tomography to obtain images for patients with gout; however, this is not currently considered part of normal practice. **Table 93-5** shows the European League Against Rheumatism (EULAR) evidence-based diagnostic principles.[22]

TABLE 93-5 EULAR Evidence-Based Recommendations for Gout: Diagnostic Principles

1. In acute attacks the rapid development of severe pain, swelling, and tenderness that reaches its maximum within just 6-12 hours, especially with overlying erythema, is highly suggestive of crystal inflammation though not specific for gout

2. For typical presentations of gout (such as recurrent podagra with hyperuricemia), a clinical diagnosis alone is reasonably accurate but not definitive without crystal confirmation

3. Demonstration of MSU crystals in synovial fluid or tophus aspirates permits a definitive diagnosis of gout

4. A routine search for MSU crystals is recommended in all synovial fluid samples obtained from undiagnosed inflamed joints
5. Identification of MSU crystals from asymptomatic joints may allow definite diagnosis in intercritical periods
6. Gout and sepsis may coexist. When septic arthritis is suspected, gram staining and culture of synovial fluid should still be performed, even if MSU crystals are identified
7. While the most important risk factor for gout, serum uric acid levels do not confirm or exclude gout, as many people with hyperuricemia do not develop gout, and during acute attacks serum levels may be normal
8. Renal uric acid excretion should be determined in selected gout patients, especially those with a family history of young onset gout, onset of gout under age 25 years, or with renal calculi
9. Although radiographs may be useful for differential diagnosis and may show typical features in chronic gout, they are not useful in confirming the diagnosis of early or acute gout
10. Risk factors for gout and associated comorbidity should be assessed, including features of the metabolic syndrome (obesity, hyperglycemia, hyperlipidemia, hypertension)

EULAR, The European League Against Rheumatism; MSU, monosodium urate.

Data from Reference 22.

Recently, the American College of Rheumatology (ACR) and EULAR jointly developed recommendations for the classification of gout for the purpose of assisting in identifying subjects potentially eligible for enrollment into clinical trials of gout treatments.[23] Although they specifically state the recommendations should not be used clinically to diagnose gout, the classification system may be a useful reference when evaluating a patient presenting with symptoms suggestive of gout. The recommendations include a point-based system that includes clinical, laboratory, and imaging information, which can be used when a patient presents with at least one episode of swelling, pain, or tenderness in a peripheral joint or bursa but has no evidence of MSU crystals. An online calculator is available at http://goutclassificationcalculator.auckland.ac.nz/.

Uric Acid Nephrolithiasis

Clinicians should be suspicious of hyperuricemic states for patients who present with kidney stones, as nephrolithiasis occurs in approximately 15% of patients with gout.[24] The frequency of urolithiasis depends on serum uric acid concentrations, acidity of the urine, and urinary uric acid concentration. Typically, patients with uric acid nephrolithiasis have a urinary pH of less than 6. Uric acid has a negative logarithm of the acid ionization constant of 5.5. Therefore, when the urine is acidic, uric acid exists primarily in the unionized, less soluble form. At a urine pH of 5, urine is saturated at a uric acid level of 15 mg/dL (0.89 mmol/L). When the urine pH is 7, the solubility of uric acid in urine is increased to 200 mg/dL (11.9 mmol/L).[1] For patients with uric acid nephrolithiasis, urinary pH typically is less

than 6 and frequently less than 5.5. When acidic urine is saturated with uric acid, spontaneous precipitation of stones may occur.

Other factors that predispose individuals to uric acid nephrolithiasis include excessive urinary excretion of uric acid and highly concentrated urine. The risk of renal calculi approaches 50% in individuals whose renal excretion of uric acid exceeds 1,100 mg/day (6.5 mmol/day). In addition to pure uric acid stones, hyperuricosuric individuals are at increased risk for mixed uric acid–calcium oxalate stones and pure calcium oxalate stones. Uric acid stones are usually small, round, and radiolucent. Uric acid stones containing calcium are radiopaque.[25]

Gouty Nephropathy

There are two types of gouty nephropathy: acute uric acid nephropathy and chronic urate nephropathy.[2] In acute uric acid nephropathy, acute renal failure occurs as a result of blockage of urine flow secondary to massive precipitation of uric acid crystals in the collecting ducts and ureters. This syndrome is a well-recognized complication for patients with myeloproliferative or lymphoproliferative disorders and is a result of massive malignant cell turnover, particularly after initiation of chemotherapy.

Chronic urate nephropathy is caused by the long-term deposition of urate crystals in the renal parenchyma. Microtophi may form, with a surrounding giant-cell inflammatory reaction. A decrease in the kidneys' ability to concentrate urine and the presence of proteinuria may be the earliest pathophysiologic disturbances. Hypertension and nephrosclerosis are common associated findings. Although renal failure occurs in a higher percentage of gouty patients than expected, it is not clear if hyperuricemia per se has a harmful effect on the kidneys. The chronic renal impairment seen in individuals with gout may result largely from the coexistence of hypertension, diabetes mellitus, and atherosclerosis.

Tophaceous Gout

Tophi (urate deposits) are uncommon in the general population of gouty subjects and are a late complication of hyperuricemia. The most common sites of tophaceous deposits for patients with recurrent acute gouty arthritis are the base of the fingers, olecranon bursae, ulnar aspect of the forearm, Achilles tendon, knees, wrists, and hands (**Fig. 93-4**).[2] Eventually, even the hips, shoulders, and spine may be affected. In addition to causing obvious deformities, tophi may damage surrounding soft tissue, cause joint destruction and pain, and even lead to nerve compression syndromes including carpal tunnel syndrome.

TREATMENT

Desired Outcomes

The goals in the treatment of gout are to terminate the acute attack, prevent recurrent attacks of gouty arthritis, and prevent complications associated with chronic deposition of urate crystals in tissues. These can be accomplished through a combination of pharmacologic and nonpharmacologic methods, including focused patient education efforts. The first-ever ACR evidence- and consensus-based guidelines for the management of gout were published in 2012.[26,27] These guidelines provide specific recommendations for treatment of acute gout attacks, management of hyperuricemia in gout, and anti-inflammatory prophylaxis of acute gout during initiation of urate-lowering therapy (ULT). These guidelines will be discussed throughout the remainder of the treatment section of this chapter. **Tables 93-6** and **93-7** summarize dosing and monitoring information for available pharmacotherapy used in management and prevention of gout.

TABLE 93-6 Pharmacotherapy of Acute Gout, Anti-Inflammatory Prophylaxis during Initiation of Urate-Lowering Therapy and Hyperuricemia in Gout[a]

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Acute Gout					
NSAIDs					
Etodolac	Lodine, various	300 mg twice daily	300-500 mg twice daily		In general, not recommended in patients with advanced renal

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Acute Gout					
Fenoprofen	Nalfon, various	400 mg three times daily	400-600 mg three to four times daily		disease as NSAID use may decrease renal function; Use with caution in patients with mild to moderate renal impairment
Ibuprofen	Advil, various	400 mg three times daily	400-800 mg three to four times daily		
Indomethacin	Indocin	50 mg three times daily	50 mg three times daily initially until pain is tolerable then rapidly reduce to complete cessation		
				Severe renal impairment (GFR <25 mL/min [0.42 mL/s]): 100 mg maximum daily dose	
Ketoprofen	Orudis, various	75 mg three times daily or 50 mg four times daily	50-75 mg three to four times daily	Mildly impaired renal function: 150 mg maximum daily dose	
				Impaired liver function with serum albumin <3.5 g/dL (<35 g/L): 100 mg maximum daily dose	
Naproxen	Naprosyn, various	750 mg followed by 250 mg every 8 hours until the attack has subsided		Not recommended in severe renal impairment (creatinine clearance <30	

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Acute Gout					
				mL/min [<0.5 mL/s])	
Piroxicam	Feldene	20 mg once daily or divided twice daily			
Sulindac	Clinoril	200 mg twice a day	150-200 mg twice daily for 7-10 days		
Celecoxib	Celebrex	800 mg followed by 400 mg on day one then 400 mg twice daily for 1 week			Option for patients with GI contraindications to nonselective NSAIDs; unclear risk-to-benefit ratio at this time due to cardiovascular concerns
Oral colchicine	Colcrys	1.2 mg initially, followed by 0.6 mg 1 hour later		See Table 94-8	Dose adjustment recommended when used with selected CYP3A4 and P-glycoprotein inhibitors
Corticosteroids					
Oral		0.5 mg/kg prednisone equivalent daily for 5-10 days followed by discontinuation or 0.5 mg/kg daily for 2-5 days followed by tapering for 7-10 days	30-60 mg prednisone equivalent once daily for 3-5 days, then taper in 5-mg decrements spread over 10-14 days until discontinuation		The use of an oral methylprednisolone dose pack may be considered
Intramuscular		Triamcinolone acetonide 60 mg IM once; methylprednisolone 100 mg IM once	Triamcinolone acetonide 60 mg IM once; methylprednisolone 100-150 mg IM daily for 1-2 days		Administration of intramuscular triamcinolone is to be followed by oral prednisone or prednisolone

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Acute Gout					
Intra-articular	Kenalog	Triamcinolone acetonide 10 mg (large joints), 5 mg (small joints)	Triamcinolone acetonide 10-40 mg (large joints), 5-20 mg (small joints)		Intraarticular administration is acceptable when only one to two joints involved and should be used in combination with NSAIDs, colchicine, or oral corticosteroids
Corticotropin	H.P. Acthar Gel	40 units IM or SC every 72 hours	40-80 units IM or SC every 24-72 hours		Contraindicated for IV administration
Interleukin-1 inhibitors					Reserve use for refractory cases
Anakinra	Kineret	100 mg SC daily for 3 days			
Canakinumab	Ilaris	Single dose 150 mg SC			
Anti-Inflammatory Prophylaxis during Initiation of Urate-Lowering Therapy					
NSAIDs			Lowest effective dosage		
Oral colchicine	Colcrys	0.6 mg daily	0.6 mg once or twice daily	See Table 93-8	
Prednisone or prednisolone		≤10 mg daily			Second-line therapy; recommended only if colchicine and NSAIDs are both contraindicated, ineffective or not tolerated
Interleukin-1 inhibitors					Reserve use for refractory cases Studied for 16-week duration
Rilonacept	Arcalyst	320 mg loading dose followed by 160 mg weekly (SC)			
Canakinumab	Ilaris	Single SC dose (50 mg-300 mg) or four			

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Acute Gout					
		times weekly SC dosing (50 mg—50 mg—25 mg—25 mg)			
Hyperuricemia in Gout					
Xanthine oxidase inhibitors					
Allopurinol	Lopurin, Zyloprim	100 mg daily	100-800 mg daily to achieve serum urate concentration <6 mg/dL (<357 µmol/L)	Start at dose of 50 mg daily for patients with a glomerular filtration rate <30 mL/min/1.73 m2 (<0.29 mL/s/m2)	
Febuxostat	Uloric	40 mg daily	40-80 mg/daily	No dosage adjustment necessary for patients with mild-moderate renal dysfunction (creatinine clearance 30-89 mL/min [0.5-1.49 mL/s])	
				Insufficient data in patients with creatinine clearance <30 mL/min (<0.5 mL/s)	
Uricosurics					
Probenecid	Probalan	250 mg twice daily for 1 week	500-2,000 mg/day (target serum urate concentration <6 mg/dL [<357 mol/L])	Not recommended if creatinine clearance <50 mL/min (<0.83	

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Acute Gout					
				mL/s)	
Other					
Pegloticase	Krystexxa	8 mg IV every 2 weeks			Optimal treatment duration has not been established
Lesinurad	Zurampic	200 mg once daily in combination with a xanthine oxidase inhibitor		Not recommended if creatinine clearance <45 mL/min (<0.75 mL/s) Not studied in patients with severe hepatic disease Contraindicated in tumor lysis syndrome and Lesch-Nyhan Syndrome	Should be used in combination with a xanthine oxidase inhibitor due to increased risk of acute renal failure with lesinurad monotherapy Use is not recommended in patients taking allopurinol doses <300 mg daily (normal renal function) or <200 mg daily (creatinine clearance <60 mL/min)

CYP, cytochrome P; GFR, glomerular filtration rate; IM, intramuscular; IV, intravenous; NSAID, nonsteroidal anti-inflammatory drug; SC, subcutaneous.

[a]Agents available in the United States.

TABLE 93-7 Drug Monitoring

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
NSAIDs	Renal dysfunction, gastritis (worse with concurrent aspirin), fluid retention, blood pressure elevation	Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis	Avoid for patients with peptic ulcer disease, active bleeding Use caution in congestive heart failure, dehydration, renal impairment

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
		Toxic Blood pressure Renal function Edema Dark stools	Consider coadministration with a proton-pump inhibitor when used long term for patients at risk for GI bleeding
Systemic corticosteroids	GI upset, increased appetite, nervousness/restlessness, transient glucose intolerance, fluid retention, blood pressure elevation	Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis Toxic Glucose levels in patients with diabetes	Limit duration of therapy in patients with diabetes
Intra-articular corticosteroids	Injection pain, rebound arthritis	Therapeutic Resolution of pain Toxic Signs of rebound arthritis (pain relief followed by reemergence of pain)	Avoid if joint sepsis cannot be ruled out
Corticotropin	Increased appetite, nervousness/restlessness, transient glucose intolerance, fluid retention, blood pressure elevation	Therapeutic Resolution of pain	Requires intact pituitary–adrenal axis Less effective for patients receiving long-term oral corticosteroid therapy
Colchicine	Dose-dependent GI adverse effects (diarrhea, nausea, vomiting), rare myelosuppression, and reversible neuromyopathy	Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis	

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
		Toxic GI symptoms Complete blood count Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis	
Interleukin-1 inhibitors	Injection site reaction, neutropenia, immune hypersensitivity reaction, infectious disease, malignancy	Toxic Neutrophil count (prior to initiation, monthly for the first 3 months of therapy then after 6, 9, and 12 months of therapy) Temperature (periodically to detect infection)	Safety for use in acute gout and gout prophylaxis during initiation of urate-lowering therapy has not yet been established; not FDA approved for use in gout
Allopurinol	Rash, potential for fatal hypersensitivity syndrome	Therapeutic Serum urate level Reduced frequency of gout attacks Toxic Rash Renal function	Can be used in both urate overproduction and urate underexcretion
Febuxostat	Liver enzyme elevation, nausea, arthralgias, and rash	Therapeutic Serum urate level Reduced frequency of gout attacks Toxic	Can be used in both urate overproduction and urate underexcretion

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Probenecid	Urolithiasis	Liver function tests Renal function Therapeutic Serum urate level Reduced frequency of gout attacks Toxic Renal function	Useful in urate underexcretion Avoid for patients with history of urolithiasis
Pegloticase	Acute gout attack during treatment initiation, anaphylaxis, GI symptoms (constipation, nausea, vomiting), chest pain, nasopharyngitis	Therapeutic Serum urate levels Reduced frequency of gout attacks Toxic Signs/symptoms of anaphylaxis following infusion	Reserved for patients with gout refractory to conventional therapies Can be used in both urate overproduction and urate underexcretion
Lesinurad	Acute gout attack during treatment initiation, headache, GERD, major adverse cardiovascular events have been observed although a causal relationship has not been established	Therapeutic Serum urate levels Reduced frequency of gout attacks Toxic Renal function	Reserved for patients with hyperuricemia associated with gout who do not achieve target serum uric acid levels with conventional therapies Can be used in both urate overproduction and urate underexcretion Must be used in combination with a xanthine oxidase inhibitor due to increased risk of acute renal failure with monotherapy

FDA, Food and Drug Administration; GERD, gastroesophageal reflux disease; GI, gastrointestinal;

NSAID, nonsteroidal anti-inflammatory drug.

Acute Gouty Arthritis

Nonpharmacologic Therapy

There are limited effective nonpharmacologic therapies for an acute gout attack; therefore, they are recommended strictly as adjunctive treatment.

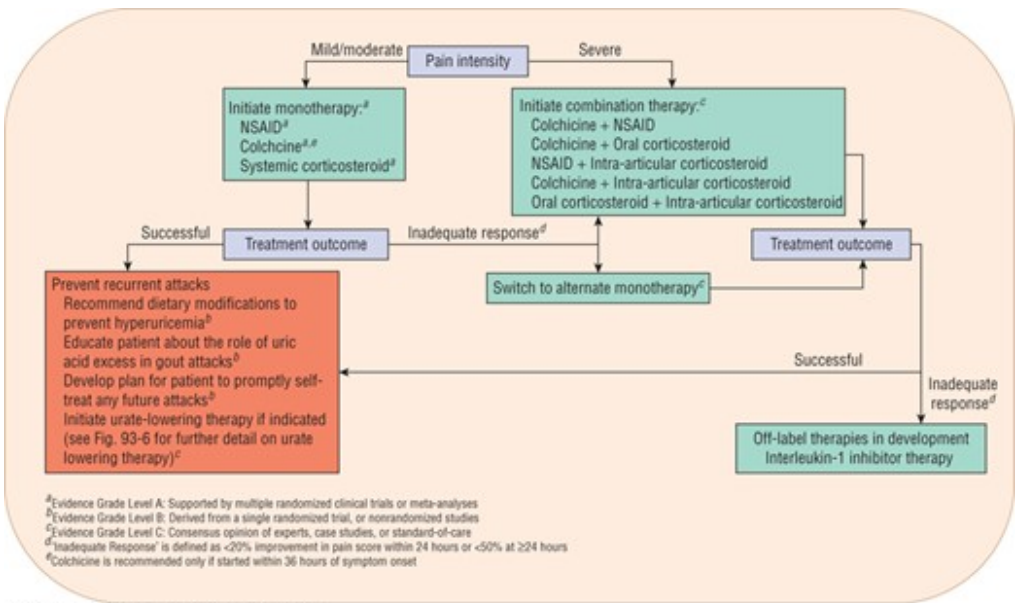
Local ice application is the most effective.[27] In one small study, adjunctive ice application resulted in significantly greater pain reduction in those receiving the therapy compared with those not treated with ice (difference of 3.33 cm on a 10-cm visual analog pain scale, $P = 0.021$).[28] Complementary and alternative medicines, including flaxseed and celery root, are not recommended in ACR guidelines.[27]

Pharmacologic Therapy

2 For most patients, acute attacks of gouty arthritis may be treated successfully with nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, or colchicine. The ACR guidelines recognize these three modalities as first-line monotherapy for the treatment of acute gout. Treatment should commence within 24 hours of the onset of an attack. In more severe cases, those affecting multiple joints or causing higher intensity pain, combination or investigational drug therapy may be indicated (**Fig. 93-5**).[27]

FIGURE 93-5

Algorithm for management of an acute gout attack.



Nonsteroidal Anti-Inflammatory Drugs

NSAIDs are a mainstay of therapy for acute attacks of gouty arthritis because of their excellent efficacy and minimal toxicity with short-term use. Indomethacin has been historically favored as the NSAID of choice for acute gout flares, but there is little evidence to support one NSAID as being more efficacious than another. Three agents (indomethacin, naproxen, and sulindac) have US Food and Drug Administration (FDA)-approved labeling for the treatment of gout, although several others are likely to be effective.[27] Although choice of NSAID is not an important determinant of therapeutic success, timing of pharmacotherapy is. It is critical that therapy is initiated within 24 hours of acute gout attack onset and continued until complete resolution.[27] Following resolution of the attack, tapering of NSAID therapy may be considered, especially in patients with comorbidities such as hepatic or renal insufficiency where prolonged therapy would be undesirable.[27] Resolution of an acute attack for most patients generally occurs within 5 to 8 days after initiating therapy.

All NSAIDs have the potential to cause similar adverse effects. The most common areas affected include the GI system (gastritis, bleeding, perforation), kidneys (renal papillary necrosis, reduced creatinine clearance), cardiovascular system (sodium and fluid retention, increased blood pressure), and central nervous system (CNS) (impaired cognitive function, headache, dizziness). Caution should be exercised when using NSAIDs for individuals with a history of peptic ulcer disease, congestive heart failure, uncontrolled hypertension, renal insufficiency, coronary artery disease, or who are concurrently receiving anticoagulants or antiplatelets. Patients with active peptic ulcer disease, uncompensated congestive heart failure, severe renal impairment, or a history of hypersensitivity to aspirin or other NSAIDs should not be prescribed an NSAID.

Selective cyclooxygenase-2 (COX-2) inhibitors present a potentially better tolerated alternative to nonselective NSAIDs in patients with GI issues.[29] Specific COX-2 inhibitors, etoricoxib and lumiracoxib, have demonstrated efficacy in the treatment of acute gout in numerous controlled trials; however, these agents are not available in the United States. One study has established effectiveness of high-dose celecoxib (1,200 mg on day 1 followed by 400 mg twice daily thereafter) in the treatment of acute gout, but concerns regarding the cardiovascular risk of COX-2 inhibitors must be considered when using these agents (see Chapter 90, Osteoarthritis, for further discussion of COX-2 inhibitors).[30,31] The ACR guidelines recommend celecoxib as an option for patients unable to take NSAIDs but note that the risk-to-benefit ratio of celecoxib use in acute gout is unclear.[27]

Corticosteroids

Corticosteroids have historically been reserved for treatment of acute gout flares when contraindications to other therapies exist, largely due to lack of evidence from controlled clinical trials. However, more recent evidence indicates that corticosteroids are equivalent to NSAIDs in the treatment of acute gout flares.[32,33] They can be used either systemically or by intra-articular injection. The ACR guidelines recommend that the number of joints involved be considered when choosing the route of corticosteroid administration. If only one or two joints are involved, either intraarticular or oral corticosteroids are recommended. If an attack is polyarticular, systemic therapy is necessary.[27] A hypothetical risk for a rebound attack upon steroid withdrawal exists; therefore, gradual tapering is often employed when discontinuing steroid therapy. The ACR guidelines suggest two different dosing strategies for oral corticosteroid therapy (prednisone or prednisolone) in the treatment of acute gout:

(a) 0.5 mg/kg daily for 5 to 10 days followed by abrupt discontinuation or (b) 0.5 mg/kg daily for 2 to 5 days followed by tapering for 7 to 10 days. The guidelines also support the use of a methylprednisolone dose pack for acute treatment of gout, a 6-day regimen that starts with 24 mg on day 1 and decreases by 4 mg each day.[27] Intra-articular administration of triamcinolone acetonide in a dose of 20 to 40 mg may be useful in treating acute gout limited to one or two joints. Injection should be done under an aseptic technique in a joint determined not to be infected. Per ACR guideline recommendations, intra-articular corticosteroid therapy should be used in conjunction with either an NSAID, colchicine, or oral corticosteroid therapy; however, case reports suggest that this therapeutic approach may be as effective as monotherapy.[27,34] A single intramuscular injection of a long-acting corticosteroid, such as methylprednisolone, followed by oral corticosteroid therapy is recognized as a reasonable therapeutic approach to the treatment of acute gout by the ACR guidelines.[27] Alternatively, intramuscular corticosteroid monotherapy may be considered in patients with multiple affected joints who are unable to take oral therapy.

The adverse effects of corticosteroids are generally dose and duration dependent. Short-term use for treatment of acute attacks is generally well tolerated. Corticosteroids should be used with caution for patients with diabetes as they can increase blood sugar. In addition, patients with a history of GI problems, bleeding disorders, cardiovascular disease, and psychiatric disorders should be monitored closely. Long-term corticosteroid use should be avoided because of the risk for osteoporosis, hypothalamic–pituitary axis suppression, cataracts, and muscle deconditioning that can occur with their use.

Corticotropin, or adrenocorticotropic hormone (ACTH), which stimulates the adrenal cortex to produce cortisol and corticosterone, can be administered in acute gout. Doses of 40 to 80 United States Pharmacopeia (USP) units are given intramuscularly every 6 to 8 hours for 2 to 3 days, and then discontinued. Studies with ACTH are limited, but it appears to provide similar efficacy to systemic antiinflammatory doses of corticosteroids.[35] When administered alone or in combination with colchicine, ACTH may provide earlier efficacy compared with indomethacin but with fewer adverse effects.[36] Because the studies have several limitations, the regimen should be considered only as an alternative, especially for patients with comorbidities where other regimens are contraindicated.[37] Examples of patients where ACTH has been used safely when other first-line gout therapies were contraindicated include those with congestive heart failure, chronic renal failure, and history of GI bleeding.[38] The ACR guidelines support the use of ACTH in the treatment of acute gout in patients unable to take oral medications.[27]

Colchicine

3 Colchicine is an antimitotic drug that is highly effective at relieving acute attacks of gout.[39] When begun within the first 24 hours of an acute attack, colchicine produces a response in two-thirds of patients within hours of administration.[40] If the initiation of colchicine is delayed; however, the probability of success with the drug diminishes substantially. For this reason, the ACR guidelines advocate use of colchicine for treatment of acute gout only if started within 36 hours of attack onset.[27]

Although it is a highly effective therapy, oral colchicine can cause dose-dependent GI adverse effects,

including nausea, vomiting, and diarrhea. Other important non-GI adverse effects include neutropenia and axonal neuromyopathy, which may be worsened for patients taking other myopathic drugs such as β-hydroxy-β-methylglutaryl-coenzyme A reductase inhibitors (statins) or for those with renal insufficiency.

Colchicine was used for many years as an unapproved drug with no FDA-approved prescribing information, dosage recommendations, or drug interaction warnings. More recently, the FDA approved a 0.6-mg tablet of colchicine (Colcrys®) for oral use. Data submitted in support of the safety and efficacy of colchicine in acute gout flares demonstrated that a substantially lower dose of colchicine (1.2 mg initially, followed by 0.6 mg 1 hour later) was as effective as higher doses traditionally used (continued hourly dosing until symptoms subside or GI symptoms become intolerable).[41] These findings suggest that prior use of high-dose colchicine regimens, may unnecessarily expose patients to increased toxicity with no additional efficacy.[42] In addition to the new low-dose regimen, the ACR guidelines also suggest that colchicine 0.6 mg once or twice daily can be started 12 hours following the initial 1.2 mg dose and continued until the acute attack resolves.[27] This off-label dosing recommendation is based upon pharmacokinetic data that suggest that colchicine levels begin to decline 12 hours after administration.[41]

Comprehensive review of postmarketing safety data revealed an increased risk of adverse events for patients receiving colchicine administered concurrently with P-glycoprotein or cytochrome P450 3A4 inhibitors (eg, clarithromycin or cyclosporine) (**Table 93-8**).[43,44,45,46] These interactions are thought to result in an increased colchicine concentration. Colchicine should also be used carefully for patients with renal and hepatic insufficiency. Refer to Table 93-8 for colchicine dosing recommendations in these special situations.

TABLE 93-8 Colchicine Dosing in Special Situations/Colchicine Drug Interactions

	Treatment of Acute Gout Flares	Prophylaxis of Gout Flares
Renal Impairment[a]		
Mild/moderate (creatinine clearance = 30-80 mL/min [0.5-1.33 mL/s])	Dose adjustment not required	Dose adjustment not required
Severe (creatinine clearance <30 mL/min [<0.5 mL/s])	Dose adjustment not required; treatment course should be repeated no more than once every 2 weeks	0.3 mg daily (starting dose)
Dialysis	Single 0.6 mg dose; treatment course should not be repeated more than once every 2 weeks	0.3 mg twice weekly (starting dose)
Hepatic Impairment[b]		
Mild/moderate	Dose adjustment not required	Dose adjustment not required
Severe	Dose adjustment not required; treatment course should be repeated no more than once every	Dose reduction should be considered

[a]Treatment of gout flares with colchicine is not recommended in patients with renal impairment who are receiving colchicine for prophylaxis.

[b]Treatment of gout flares with colchicine is not recommended in patients with hepatic impairment who are receiving colchicine for prophylaxis.

IV colchicine has resulted in fatalities and is no longer available.[47]

Hyperuricemia in Gout

Nonpharmacologic Therapy

Following treatment and resolution of the intense pain associated with an acute gout attack, the focus shifts to the prevention of future episodes. Recurrent gout attacks can be prevented by maintaining low uric acid levels. Although both nonpharmacologic and pharmacologic efforts to maintain low uric acid levels are critical in the management of gout, trials have shown high rates of nonadherence with ULT.[48] A likely explanation for this lack in patient adherence is the silent nature of intercritical gout (the period of time between two gout attacks). Patient education, therefore, is a critical first step in the management of hyperuricemia.[26,49] Education should address the recurrent nature of the disease and reinforce the objective of each lifestyle/dietary modification and medication therapy recommended.

Weight loss through caloric restriction and exercise should be promoted in all patients with gout and hyperuricemia, as this may enhance renal excretion of urate.[50] Restriction of alcohol intake is of great importance, as this is closely correlated with gout attacks.[51,52] Acute ingestions of alcohol cause lactic acidemia, which reduces renal urate excretion, and long-term alcohol intake promotes production of purines as a by-product of the conversion of acetate to acetyl coenzyme A in the metabolism of alcohol.[53] The ACR guidelines recommend limiting alcohol use in all gout patients and avoidance of any alcohol during periods of frequent gout attacks and in those with advanced gout under poor control.[26] The ACR guidelines also recommend limiting consumption of high-fructose corn syrup and purine-rich foods (organ meats and some seafood), which have been linked to uric acid elevation, and encourage the consumption of vegetables and low-fat dairy products, which have been shown to have urate-lowering effects.[26,54,55,56,57,58,59]

Another strategy to lower uric acid before initiating urate-lowering pharmacotherapy is to evaluate a patient's medication list for potentially unnecessary drugs that may elevate uric acid levels (see Table 93-2). These include thiazide and loop diuretics, calcineurin inhibitors, niacin, and low-dose aspirin. The ACR guidelines consider the potential elimination of uric acid-elevating medications as a baseline recommendation for all gout patients with hyperuricemia; however, the benefit of thiazide diuretics in

the treatment of hypertension and of low-dose aspirin in cardiovascular disease prevention is specifically noted.[26]

The presence of gout should not be a contraindication to the use of thiazide diuretics in hypertensive patients, although clinicians should be aware that diuretics are independent risk factors for gout and can increase serum uric acid levels.[9] It may be important to avoid using diuretics if other agents can be used to control blood pressure, particularly if the patient has had frequent gout attacks or continues to have an elevated serum uric acid level despite appropriate therapy for gout. The ACR guidelines specifically recommend against discontinuing low-dose aspirin used for cardiovascular prevention in patients with gout, since aspirin's effect on elevating serum uric acid is negligible.[26]

Pharmacologic Therapy

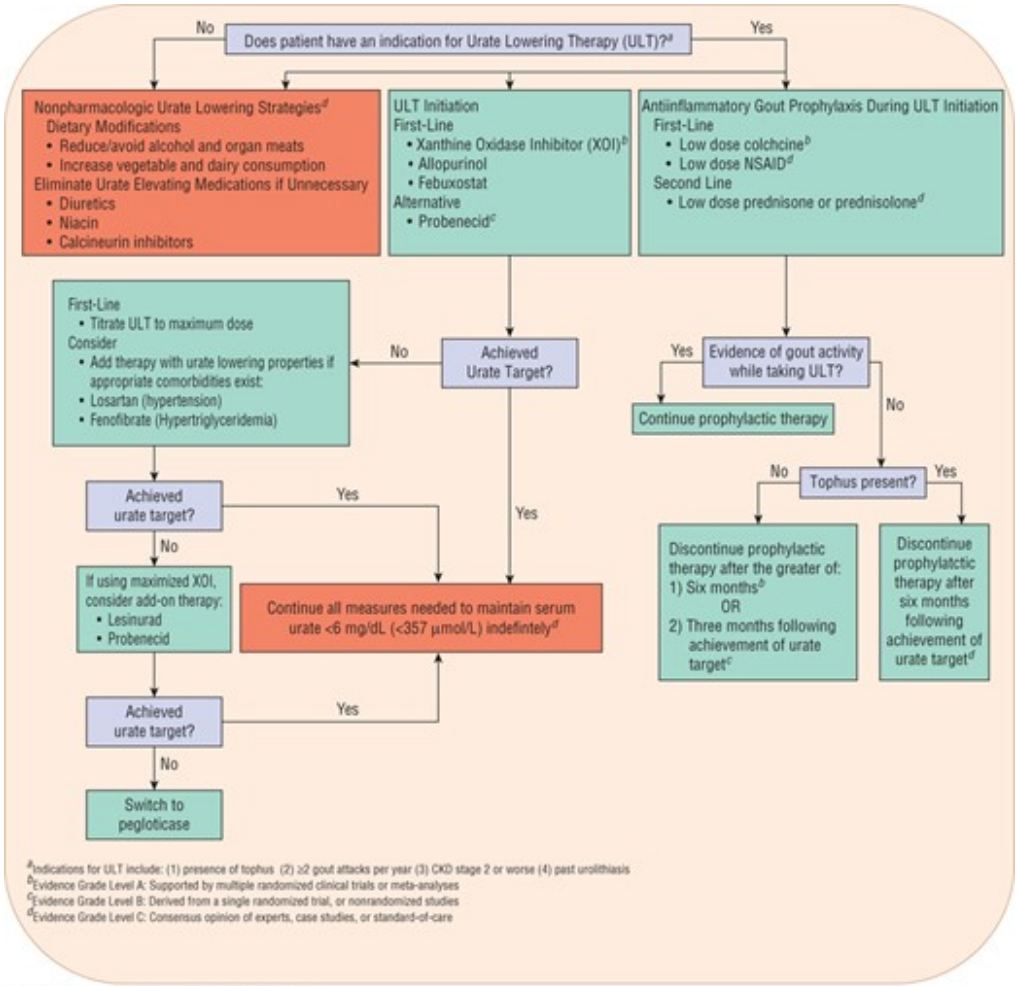
4 After the first attack of acute gouty arthritis, a decision to institute prophylactic urate-lowering pharmacotherapy must be considered. This decision should carefully balance risk and benefit. Prophylactic pharmacotherapy has been found to be cost-effective if patients have two or more attacks per year, even if the serum uric acid concentration is normal or only minimally elevated.[60,61]

5 Consistent with this finding, the ACR guidelines recognize the occurrence of two or more gout attacks per year as an indication for pharmacologic ULT.[26] Other indications include the presence of one or more tophus, chronic kidney disease (stage 2 or worse), and a history of urolithiasis.[26]

Pharmacologic ULT can be started during an acute gout attack if appropriate antiinflammatory prophylaxis has been initiated[26] (see "Anti-inflammatory Gout Prophylaxis during Initiation of Pharmacologic Urate-Lowering Therapy" section and **Fig. 93-6** for more detail). The goal of initiating ULTs is to achieve and maintain a serum uric acid concentration of less than 6 mg/dL (357 µmol/L), and preferably below 5 mg/dL (297 µmol/L) if signs and symptoms of gout persist.[26,62] Urate lowering should be prescribed for long-term use, as intermittent administration has been less effective in controlling gouty attacks.[26,63] Reduction of serum urate concentrations can be accomplished pharmacologically by decreasing the synthesis of uric acid (xanthine oxidase inhibitors) or by increasing the renal excretion of uric acid (uricosurics).

FIGURE 93-6

Algorithm for management of hyperuricemia in gout.



The ACR guidelines provide a step-wise approach in the treatment of hyperuricemia in gout[26] (see Fig. 93-6). Within this strategy, xanthine oxidase inhibitors are recommended as first-line therapy. Probenecid, a potent uricosuric therapy, is recommended as an alternative first-line therapy in patients with a contraindication or intolerance to xanthine oxidase inhibitor therapy. In refractory cases, combination therapy including a xanthine oxidase inhibitor plus an agent with uricosuric properties (probenecid, losartan, or fenofibrate) is suggested. Finally, in severe cases in which the patient cannot tolerate or is not responding to other therapies, pegloticase is recommended.

Xanthine Oxidase Inhibitors

Xanthine oxidase inhibitors reduce uric acid by impairing the ability of xanthine oxidase to convert hypoxanthine to xanthine and xanthine to uric acid. Because they are efficacious for prophylaxis in both underexcreters and overproducers of uric acid, xanthine oxidase inhibitors are the most widely prescribed agents for the long-term prevention of recurrent attacks of gout. For nearly 40 years, allopurinol was the only agent available in the United States; a second xanthine oxidase inhibitor (febuxostat; Uloric) reached the US market in 2009.

Allopurinol is an effective urate-lowering agent,[64] but up to 5% of patients are unable to tolerate it because of adverse effects and long-term adherence with allopurinol is low.[48,65] Mild adverse effects

such as skin rash, leukopenia, GI problems, headache, and urticaria can occur with allopurinol administration. More severe adverse reactions including severe rash (toxic epidermal necrolysis, erythema multiforme, or exfoliative dermatitis), hepatitis, interstitial nephritis, and eosinophilia reportedly occur in approximately 1:1,000 patients and are associated with a 20% to 25% mortality.[26] In a large population-based study in Taiwan, including almost 500,000 patients using allopurinol for the first time, the annual incidence rate of allopurinol hypersensitivity was 4.68 per 1,000 patients. Risk factors associated with the development of allopurinol hypersensitivity included female gender, age above 60 years, initial starting dose of allopurinol exceeding 100 mg/d, renal disease, cardiovascular disease, and use of allopurinol for treatment of asymptomatic hyperuricemia.[66]

As evidence has linked higher starting doses of allopurinol with an increased incidence of allopurinol hypersensitivity syndrome, conservative initial dosing is important.[67] ACR guidelines recommend that allopurinol be started at a dose no greater than 100 mg daily in patients with normal renal function and at a dose no greater than 50 mg daily in patients with chronic kidney disease (stage 4 or worse).[26] This conservative initial dosing strategy is intended to avoid allopurinol hypersensitivity syndrome and also prevent acute gout attacks common during initiation of ULT.

In clinical practice, allopurinol is often arbitrarily capped at a dose of 300 mg/d, resulting in achieving serum urate target concentration of less than 6.0 mg/dL (less than 357 µmol/L) in fewer than 50% of patients.[68,69,70] In patients with renal impairment, the maximum daily dose of allopurinol is typically reduced even further; however, this recommendation comes from a non-evidence-based algorithm and is therefore not supported by the ACR guidelines.[26,71] Ideally, the dose of allopurinol should be gradually titrated every 2 to 5 weeks up to a maximum dose of 800 mg/day until the serum urate target is met, in patients with and without renal impairment.[26] When the dose of allopurinol is maximized beyond 300 mg/day, patients should be educated about the signs and symptoms of a serious reaction, including pruritus and rash. These patients should also undergo routine monitoring for elevation of hepatic enzymes and signs of eosinophilia.[26]

Similar to allopurinol, febuxostat lowers serum urate concentrations in a dose-dependent manner.[72,73] In clinical trials, 40 mg/day of febuxostat was noninferior to conventionally dosed allopurinol (300 mg/day) in achieving the primary endpoint of serum urate concentration less than 6 mg/dL (less than 357 µmol/L), while 80 mg/day of febuxostat was more effective. The incidence of gout flares occurring during long-term follow-up is similar for both drugs.[74] Febuxostat is well tolerated, with adverse events mostly limited to nausea, arthralgias, and minor liver transaminase elevations.

One criticism of the studies comparing allopurinol and febuxostat is that a fixed dose of allopurinol was used, rather than titrating the dose to achieve the targeted serum urate level. An advantage of febuxostat is that it has been studied in patients with mild-to-moderate hepatic and renal impairment (creatinine clearances of 30-89 mL/min [0.50-1.49 mL/s]) and does not require dose adjustment in these patients.

Uricosuric Drugs

Uricosuric drugs increase the renal clearance of uric acid by inhibiting postsecretory renal proximal

tubular reabsorption of uric acid. The drug used most widely to increase uric acid excretion is probenecid. Several other uricosuric drugs are available in Europe, but not in the United States.

Uricosuric therapies, through their action to increase the elimination of uric acid, cause marked uricosuria and may cause stone formation. Probenecid, specifically, has been associated with a 9% to 11% risk of urolithiasis.[26,69,75] For this reason, patients with a history or urolithiasis should not use potent uricosuric drugs, such as probenecid.[26] The maintenance of adequate urine flow and alkalinization of the urine during the first several days of uricosuric therapy may help diminish the possibility of uric acid stone formation.[26]

Probenecid is given initially at a dose of 250 mg twice a day for 1 to 2 weeks and then 500 mg twice a day for 2 weeks. Thereafter, the daily dose is increased by 500 mg increments every 1 to 2 weeks until satisfactory control is achieved or a maximum dose of 2 g is reached. In addition to urolithiasis, major adverse effects associated with uricosuric therapy include GI irritation, rash and hypersensitivity, and precipitation of acute gouty arthritis. A disadvantage of uricosurics is that salicylates may interfere with this mechanism and result in treatment failure; however, low doses (325 mg/day or less) of enteric-coated aspirin may be used cautiously. In addition, probenecid can inhibit the tubular secretion of other organic acids; thus, increased plasma concentrations of penicillins, cephalosporins, sulfonamides, and indomethacin can occur.

6 Uricosuric drugs are contraindicated for patients who are allergic to them, for patients with impaired renal function [a creatinine clearance less than 50 mL/min (less than 0.83 mL/s)], and for patients who are overproducers of uric acid; for such patients, a xanthine oxidase inhibitor should be used.

Lesinurad

Lesinurad (Zurampic) is the first FDA-approved selective uric acid reabsorption inhibitor (SURI). It works by inhibiting urate transporter 1 (URAT1), a transporter found in the proximal renal tubule. Inhibition of URAT1 results in uric acid excretion.

In one 4-week randomized controlled trial, the addition of lesinurad 200 mg, 400 mg, or 600 mg to daily allopurinol therapy (200-600 mg) demonstrated efficacy in reducing serum uric acid in patients with gout and an inadequate response to allopurinol therapy (defined as serum uric acid more than or equal to 6 mg/dL on more than or equal to 2 occasions more than or equal to 2 weeks apart while on allopurinol 200-600 mg daily for more than or equal to 6 weeks).[76] Patients taking 200 mg, 400 mg, and 600 mg of lesinurad achieved serum uric acid reduction of 16%, 22% and 30%, respectively, compared to 3% with placebo ($P < 0.0001$ for all comparisons).[76] Adverse effects noted with lesinurad therapy included serum creatinine elevation, elevated lipase, increased creatinine kinase, and urticaria.[76]

Lesinurad is approved as combination therapy with a xanthine oxidase inhibitor (including allopurinol and febuxostat) for treatment of hyperuricemia associated with gout in patients who have not achieved target serum uric acid levels with xanthine oxidase inhibitor monotherapy. Because lesinurad works by increasing renal uric acid secretion, it has been associated with adverse renal events,

particularly when used as monotherapy.[77] Lesinurad carries a black box warning which highlights the increased risk of acute renal failure when used in the absence of xanthine oxidase inhibitor therapy. Lesinurad has been studied in combination with xanthine oxidase inhibitor therapy in three placebo-controlled trials for up to 12 months.[77] Although other doses have been studied, the only approved dose of lesinurad is 200 mg daily due to increased risk of renal events when used at higher doses.[77] Lesinurad should not be used in patients with creatinine clearance less than 45 mL/min.[77]

Because the ACR gout guidelines were published prior to the approval of a URAT1 inhibitor, lesinurad's place in therapy is not well established. Given lesinurad's ease of use (once daily oral tablet) and, thus far, reasonable safety profile, the medication may serve as first-line add-on therapy for the treatment of hyperuricemia in patients with gout who are unable to achieve target serum uric acid levels despite maximization of xanthine oxidase inhibitor therapy.[77] Limitations to widespread use may include high cost, given market exclusivity until patent expiration, and renal adverse events. Given the lack safety data beyond 12 months of use, postmarketing surveillance will also be important in guiding future use.

Pegloticase

Pegloticase (Krystexxa) is a pegylated recombinant uricase that works to reduce serum uric acid by converting uric acid to allantoin, a water-soluble and easily excreted substance.

In two 6-month randomized controlled trials, biweekly pegloticase therapy demonstrated efficacy in reducing serum uric acid and resolving tophi in patients with severe gout and hyperuricemia (uric acid more than or equal to 8 mg/dL [more than or equal to 476 µmol/L]) who failed or had a contraindication to allopurinol therapy.[78] Severe gout referred to patients who met at least one of the following criteria: (a) three or more gout flares within the most recent 18 months, (b) one or more tophi, or (c) joint damage due to gout. Far more patients receiving pegloticase therapy compared with placebo achieved the primary outcome, maintenance of uric acid less than 6 mg/dL (less than 357 µmol/L) for at least 80% of the time during months 3 and 6 of the trial (42% vs 0%; $P < 0.001$).

Although clearly efficacious, pegloticase has several drawbacks that limit widespread use. One is the route of administration. The biweekly IV infusions of pegloticase must be given over no less than 2 hours, a potential inconvenience to many patients. Furthermore, given potential infusion-related allergic reactions, patients must be treated with antihistamines and corticosteroids before therapy. Cost is another major consideration. Pegloticase is estimated to cost more than $5,000 per month, not including administration costs associated with an IV infusion.[79] This represents a significantly greater cost burden compared with other ULT.[79]

The ideal duration of pegloticase therapy is currently unknown. Other ULTs, xanthine oxidase inhibitors for example, are typically used indefinitely in patients with gout and hyperuricemia. Immunogenicity issues associated with pegloticase therapy may limit the duration with which pegloticase therapy may be used effectively. In the previously cited 6-month pegloticase trials, 134 of 150 patients developed pegloticase antibodies that, for most patients, resulted in a loss of efficacy by month 4.[78]

Given these many limitations and the narrow patient population in which the drug has been studied, pegloticase is an agent of last resort that should be reserved for patients with refractory gout who are

unable to take or have failed all other ULTs.

Miscellaneous Urate-Lowering Agents

Lipid-lowering agents, in particular fenofibrate, can also be prescribed for patients with gout. Although dyslipidemia is common in gout patients, the fibrates are believed to exert their effects as an ancillary benefit by increasing the clearance of hypoxanthine and xanthine, leading to a sustained reduction in serum urate concentrations. Reductions of 20% to 30% in urate levels are observed with fenofibrate use.[80,81] Importantly, fenofibrate does not appear to not cause an acute gout flare when initiated and is well tolerated overall.[82,83]

Losartan, an angiotensin II receptor antagonist, has also demonstrated benefit in reducing serum urate concentrations independent of angiotensin receptor antagonism.[84] Losartan inhibits renal tubular reabsorption of uric acid and increases urinary excretion, and this effect seems to be a unique property of losartan that is not shared with other angiotensin II receptor antagonists.[85] In addition, it alkalinizes the urine, which helps reduce the risk for stone formation.

The ACR guidelines support the use of fenofibrate or losartan in combination with a xanthine oxidase inhibitor in patients with refractory disease.[26]

Anti-Inflammatory Gout Prophylaxis during Initiation of Pharmacologic Urate-Lowering Therapy

7 Initiation of ULT can prompt an acute attack of gout due to remodeling of urate crystal deposits in joints as a result of rapid lowering of urate concentrations.[27] The frequency of this phenomenon is inconsistently reported in clinical trials and may occur in as many of 75% of patients initiating ULT or as few as 25%.[86] Prophylactic antiinflammatory pharmacotherapy is often recommended to prevent gout attacks and, secondarily, to assist in ensuring patient acceptance of and adherence with ULT. The ACR guidelines recommend low-dose oral colchicine (0.6 mg twice daily) and low-dose NSAIDs (eg, naproxen 250 mg twice/day) as first-line prophylactic therapies, with stronger evidence supporting use of colchicine.[27] Low-dose corticosteroid therapy (eg, less than or equal to 10 mg/day prednisone) is recommended as an alternative in patients with intolerance, contraindication, or lack of response to first-line therapy.[27] Continuation of pharmacologic prophylaxis is recommended for at least 3 months after achieving target serum uric acid or 6 months total, whichever is longer. For patients with one or more tophi, prophylactic therapy should be continued for 6 months following achievement of serum urate target[27] (see Fig. 93-6).

Given the considerable duration of therapy required for acute gout prophylaxis during initiation of ULT, adverse effects of the pharmacologic agents employed must be seriously considered. Although the risk for gastric ulceration and bleeding is relatively small with short-term NASID therapy normally employed when treating acute gout flares, administration of a proton-pump inhibitor or other acid-suppressing therapy is indicated to protect from NSAID-induced gastric problems for patients on long-term prophylactic therapy.[27] Prolonged corticosteroid therapy is clearly linked to many severe adverse effects (ie, hyperglycemia, cushing syndrome, fluid retention, hypertension, osteoporosis,

glaucoma, depression/euphoria) and, as suggested above, is not appropriate for first-line therapy for this reason.

Cost is another major consideration when selecting prophylactic pharmacotherapy given the need for an extended duration of therapy (6 months of therapy compared to approximately 1 week for acute gout treatment). While improved dosing recommendations resulted from the recent availability of an FDA-approved colchicine product, the research efforts that provided this additional information have come with a price. Market exclusivity rights were granted to the manufacturer of Colcrys and the resulting lack of competition has caused the price of the medication to increase from approximately $0.09 per tablet to more than $5 per tablet.[87] The cost of this brand name colchicine, if not covered by insurance, is a potential challenge to therapy for certain patients. To date there have been no formal pharmacoeconomic studies evaluating colchicine in comparison to other therapies for antiinflammatory prophylaxis during ULT initiation; however, NSAIDs and corticosteroids may present more affordable options for patients.

Clinical Controversy…

It is unclear if the benefit of long-term anti-inflammatory prophylaxis during initiation of ULT outweighs the risk in patients with gout and multiple comorbidities. Harms of extended-course NSAIDs in patients with renal impairment or GI disease, for example, may preclude use of the therapy, leaving only low-dose, daily colchicine as a costly alternative. Patients and providers must balance the risk of gout recurrence against the risk and/or cost of prophylactic therapy.

Investigational Drugs

Prior to the release of febuxostat in 2009 and pegloticase in 2010, several decades passed without the release of a new pharmacotherapeutic agent for the treatment of gout. Given the increased prevalence of gout and the presence of both treatment intolerance and treatment refractory cases, several new agents are currently under investigation.[88]

Interleukin-1 Inhibitors

During acute gout attacks, urate crystals elicit an inflammatory response that triggers the production of interleukin-1 (IL-1).[89] This finding has led to the investigational use of IL-1 inhibitors in the treatment and prevention of acute gout.

In small trials, two IL-1 inhibitors, anakinra and canakinumab, have demonstrated efficacy in the treatment of acute gout.[90,91,92,93,94] Neither is approved for treatment of acute gout by the FDA, and their use remains off-label. The ACR guidelines suggest that anakinra 100 mg subcutaneously daily for 3 days or single-dose canakinumab 150 mg subcutaneously can be considered for treatment of severe acute gout attacks refractory to other treatments. However, due to a lack of randomized controlled trials and an uncertain risk-to-benefit ratio, the guidelines note that the role of IL-1 inhibitors in the treatment of acute gout is unclear.[27]

Limited evidence also suggests efficacy of IL-1 inhibitors in the prevention of acute gout during the

first 16 weeks of ULT initiation (subcutaneous rilonacept 320 mg loading dose followed by 160 mg weekly and subcutaneous canakinumab single dose [50-300 mg] or four times weekly dosing [50 mg—50 mg—25 mg—25 mg]).[95,96,97] Given the limited evidence and lack of FDA approval for this indication, the ACR guidelines do not provide a recommendation for the use of IL-1 inhibitors for anti-inflammatory prophylaxis during initiation of ULT.

Clinical Controversy…

IL-1 inhibitors have demonstrated efficacy in treating and preventing acute gout. Given limited clinical trial data, however, these agents currently lack FDA approval for use in the management of gout. They may serve as safe and effective treatment options for patients with intolerances to traditional gout medications or in patients with treatment refractory disease. More evidence is needed to determine exactly where these agents fit in the armamentarium available for gout management.

Other Investigational Agents

Several investigational agents intended to be used for the management of gout are at various stages of development. Additional URAT1 inhibitors, to follow lesinurad, are currently in development (RDEA3170, levotofisopam, arhalofenate).[98] Arhalofenate also suppresses the production of IL-1β which may potentially lead to a reduction in gout flares in addition to urate lowering.[98,99] Other novel mechanisms of action include purine nucleoside phosphorylase (PNP) inhibition (ulodesine) and glucose transporter 9 (GLUT9) inhibition (tranilast).[96,97] Continued research will ultimately define the role of these agents in the management of gout and hyperuricemia.

Nephrolithiasis

8 The medical management of uric acid nephrolithiasis includes hydration sufficient to maintain a urine volume of 2 to 3 L/day, alkalinization of urine, avoidance of pne-rich foods, moderation of protein intake, and reduction of urinary uric acid excretion.

Maintenance of a 24-hour urine volume of 2 to 3 L with an adequate intake of fluids is desirable for all gout patients, but especially for those with excessive uric acid excretion (more than 1 g/day [more than 6 mmol/day]). Alkalinizing agents should be used with the objective of making the urine less acidic. Urine pH should be maintained at 6 to 6.5. In this pH range, up to 85% of uric acid will be in the form of the soluble urate ion.

Reduction of urine acidity is usually accomplished by the administration of potassium bicarbonate or potassium citrate 60 to 80 mEq/day (mmol/day).[100,101] Administration of alkali via sodium salts is a less desirable option for two reasons. First, the sodium-induced volume expansion will increase sodium excretion and can secondarily cause hypercalcemia because calcium passively follows the reabsorption of sodium in the proximal tubule and loop of Henle. In the presence of uric acid, the resultant hypercalcemia can lead to calcium oxalate stone formation. Second, older patients with uric acid kidney stones may also have hypertension, congestive heart failure, or renal insufficiency. Because of these conditions, they should not be overloaded with alkalinizing sodium salts or unlimited fluid intake, as these can worsen these conditions.

Acetazolamide, a carbonic anhydrase inhibitor, produces rapid and effective urinary alkalinization and sometimes is used in conjunction with alkali therapy. When a 250-mg dose of acetazolamide is given at bedtime, the excretion of acidic urine in the early morning hours is avoided. The usual tachyphylaxis (rapid tolerance) to this drug is obviated by a daily repletion dose of bicarbonate.

Since the advent of xanthine oxidase inhibitors, a low-purine, low-protein diet for the patient with uric acid nephrolithiasis is no longer as critical as it once was; however, it is still advisable to instruct the patient to avoid foods rich in purine and to limit protein to no more than 90 g/day. Such a diet is still palatable and reduces appreciably the amount of uric acid in the urine.

The mainstay of drug therapy for recurrent uric acid nephrolithiasis is xanthine oxidase inhibitors. They are effective in reducing both serum and urinary uric acid levels, thus preventing the formation of calculi. Xanthine oxidase inhibitors are recommended as prophylactic treatment for patients who will receive cytotoxic agents for the treatment of lymphoma or leukemia. The marked increase in uric acid production associated with cytolysis of a neoplasm predisposes a patient to the development of uric acid nephrolithiasis.

Uric Acid Lowering in the Absence of Gout

Asymptomatic Hyperuricemia

Questions are often raised regarding the indication for drug therapy for asymptomatic hyperuricemia. The purported benefits include prevention of acute gouty arthritis, tophi formation, nephrolithiasis, and chronic urate nephropathy. The first three complications are easily controlled should they develop; therefore, antihyperuricemic therapy is not warranted to prevent these conditions. The prevention of urate nephropathy might be a stronger indication because it is irreversible even with proper treatment. Available data indicate, however, that gouty nephropathy is extremely rare in the absence of clinical gout, and evidence that elevation of uric acid by itself may cause renal disease is weak and inconclusive. As discussed previously, renal impairment associated with hyperuricemia is very rare in the absence of concurrent hypertension and atherosclerosis. In addition, it is unclear whether uric acid-lowering therapy protects renal function in such individuals. Thus, the routine treatment of asymptomatic hyperuricemia on the grounds of reducing renal complications is presently not recommended.

Uric Acid and Cardiovascular Risk

The relationship between elevated serum urate concentrations and cardiovascular disease is controversial. In observational studies, hyperuricemia has been shown to be a risk factor for ischemic heart disease.[102,103,104,105] However, hyperuricemia is also associated with other known risk factors for cardiovascular disease, such as diabetes mellitus, dyslipidemia, and hypertension, and the individual contribution of hyperuricemia on the risk for cardiovascular disease is difficult to separate from these associated factors. Recently, a 12-year follow-up of the Health Professionals Study revealed a 28% higher risk of death from all causes, 38% higher risk of cardiovascular disease death, 55% higher risk of death from coronary heart disease, and a 59% higher risk of nonfatal myocardial infarction for men with a self-reported history of gout compared with those without this reported history.[106] These

associations remained significant even after adjusting for age, body mass index, smoking, family history of myocardial infarction, and comorbidities such as diabetes and hypertension. To date, this study is the only one providing prospective data that implicate gout as an independent risk for coronary heart disease.

Given the epidemiologic relationship between uric acid and cardiovascular risk, the potential effects of urate lowering on various cardiovascular parameters have been investigated in a number of small trials. Effects on blood pressure and vasculature are one of the mechanisms studied. In one recent trial, the addition of allopurinol in blacks receiving chlorthalidone further improved clinic blood pressure control (4.3 mm Hg mean decrease in systolic blood pressure after 4 weeks of therapy).[107] Similar effects on blood pressure have been demonstrated with allopurinol in other clinical studies.[108,109,110] The mechanism by which allopurinol may decrease blood pressure is not clear but may be mediated through decreases in oxidative stress brought on as a result of inhibiting oxidant generation during the reaction between hypoxanthine and xanthine with xanthine oxidase.[107] Of note, febuxostat has also been shown to decrease oxidative stress in small clinical trials.[111,112]

While empirically initiating ULT in patients with asymptomatic hyperuricemia and elevated cardiovascular risk may seem attractive on the basis of epidemiologic studies and small prospective trials using surrogate markers, no studies have provided clear evidence that drug treatment of asymptomatic hyperuricemia or gout reduces cardiovascular morbidity and mortality. At this time, it is premature to implement therapy for patients with asymptomatic hyperuricemia in the absence of a history of gout. Risks of therapy must also be considered, such as the increased incidence of allopurinol hypersensitivity syndrome when allopurinol is used for the treatment of asymptomatic hyperuricemia. Whether or not ULT is implemented, efforts should be directed toward aggressive management of cardiovascular risk factors in all patients with hyperuricemia.

Clinical Controversy…

While asymptomatic hyperuricemia is not generally treated, some clinicians choose to initiate treatment on the basis that it may reduce the risks of vascular disease, including hypertension, cerebrovascular disease, and kidney disease. Allopurinol has been associated with decreases in blood pressure in recent trials; however, a defined mechanism has not been established. Given the lack of randomized controlled trials demonstrating improved cardiovascular outcomes with allopurinol use in patients with asymptomatic hyperuricemia, the benefit of treatment in this setting is unclear. Furthermore, adverse effects must be considered, such as the increased risk of allopurinol hypersensitivity syndrome.

Personalized Pharmacotherapy

While the ACR guidelines provide clear recommendations regarding use of pharmacotherapy in the management of gout and hyperuricemia, application of these recommendations requires personalization to fit the needs of a specific patient. When making therapeutic choices for an individual, it is critical to evaluate the adverse effect profile of a particular pharmacotherapeutic agent while considering a patient's baseline risk for those unwanted effects. This involves an analysis of patient demographics and comorbidities.[13]

Allopurinol hypersensitivity syndrome is perhaps the most concerning adverse effect of all potential side effects associated with gout therapies, given the high mortality rate associated with this reaction. As such, it would be ideal if patients at high risk for developing this syndrome could be screened for and, consequently, guided to alternative therapy. Recent research has identified a genetic link in certain populations that increases risk for the development of allopurinol hypersensitivity syndrome. Korean patients with chronic kidney disease (stage 3 or worse), Han Chinese patients, and Thai patients have been identified as being at increased risk for allopurinol hypersensitivity syndrome if found to have a specific genotype (HLA-B*5801 positive).[112,113,114] The ACR guidelines recommend that HLA-B*5801 testing be considered before allopurinol initiation in these specific subpopulations; for those found to be positive, alternative therapy should be used.[26]

Certain comorbidities may warrant dose adjustment of some gout therapies or, in certain instances, complete avoidance of certain medications. For example, patients with renal impairment should, in general, avoid NSAID therapy and must receive colchicine at reduced doses. Patients with GI disease should also avoid NSAID therapy and may not be able to tolerate colchicine therapy and, therefore, may find most success with corticosteroid therapy. In addition to comorbidities, polypharmacy and cost considerations may affect treatment decisions in an individual patient. Refer to **Table 93-9** for an overview of important factors to consider when personalizing pharmacotherapy for an individual patient with gout.

TABLE 93-9 Personalized Pharmacotherapy in Gout

Conditions and Situations	Limitations to Pharmacotherapy	Alternative Therapies
Renal insufficiency	NSAIDs may lead to exacerbation of renal insufficiency	Consider reduced-dose colchicine or corticosteroids for short-term treatment of acute gout
		Consider reduced-dose colchicine for prophylaxis during initiation of urate-lowering therapy
	Uricosuric therapy is ineffective in patients with renal insufficiency	Consider allopurinol or febuxostat
	Lesiurad is not indicated in patients with renal insufficiency	Consider allopurinol or febuxostat for first-line urate lowering therapy; consider pegloticase for refractory cases
	Colchicine may cause GI upset and diarrhea	Consider corticosteroids for treatment of acute gout
		If monoarticular, consider joint injection
GI disease	NSAIDs may cause GI bleeding or ulceration	Consider gastroprotection with coadministration of proton-pump inhibitor when NSAID therapy is used
		Consider colchicine or corticosteroids for treatment of acute gout

Conditions and Situations	Limitations to Pharmacotherapy	Alternative Therapies
Congestive heart failure	NSAIDs may cause a congestive heart failure exacerbation	Consider low-dose colchicine for prophylaxis during initiation of urate-lowering therapy Consider colchicine for treatment of acute gout
	Concurrent use of diuretic may increase serum urate	Consider colchicine for prophylaxis during initiation of urate-lowering therapy If diuretic remains necessary, consider initiating urate-lowering therapy Consider losartan as a therapy for congestive heart failure given its uricosuric properties
Hypertension	Diuretics may increase uric acid	Consider losartan as alternative or additional antihypertensive therapy given its uricosuric properties Consider addition of urate-lowering therapy if diuretic remains necessary
	NSAIDs may worsen blood pressure control	Consider colchicine or corticosteroids for treatment of acute gout Consider colchicine for prophylaxis during initiation of urate-lowering therapy Reduce the dose of colchicine used for the treatment and prophylaxis of acute gout
Polypharmacy	CYP3A4 inhibitors and P-glycoprotein inhibitors interact with colchicine leading to elevated colchicine levels	Consider NSAIDs or corticosteroids for treatment of acute gout Consider NSAIDs for prophylaxis during initiation of urate-lowering therapy
	Added pharmacotherapy may be undesirable in a patient with a large medication burden	Consider losartan as urate-lowering therapy in patients with comorbid hypertension Consider fenofibrate as urate-lowering therapy in patients with hypertriglyceridemia
Financial limitations	Febuxostat and colchicine are considerably more costly compared with other gout treatments	Consider allopurinol as urate-lowering therapy Consider NSAIDs or corticosteroids for treatment of acute gout

Conditions and Situations	Limitations to Pharmacotherapy	Alternative Therapies
		Consider NSAIDs for prophylaxis of gout during initiation of urate-lowering therapy

CYP, cytochrome P; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug.

Evaluation of Therapeutic Outcomes

Follow-up of patients with gout depends on the frequency of attacks and on the medications used to treat symptoms. For a patient who is experiencing a first attack of gout, long-term therapy is generally not indicated. As previously mentioned, the ACR guidelines recommend that urate-lowering pharmacotherapy be started only after two or more attacks of gout in 1 year, because the treatment is long-term and relatively expensive, the drugs used are potentially toxic, and adherence for patients without symptoms is generally poor.[26,61,65] Patients having a first attack should be educated about the likelihood of recurrence and what to do if another attack occurs. Approximately 60% of patients have a second attack within the first year, and 78% have a second attack within 2 years. Only 7% of patients do not have a recurrence within a 10-year period.[115]

Baseline blood work for patients receiving hypouricemic medications chronically should include renal function (serum creatinine, blood urea nitrogen), liver enzymes (aspartate aminotransferase, alanine aminotransferase), complete blood count, and electrolytes. There is generally no need to recheck these laboratory parameters for patients undergoing acute therapy with an NSAID or colchicine of limited duration. However, for patients requiring long-term therapy or prophylaxis, they should be rechecked every 6 to 12 months or as clinically indicated. For patients suspected of having an acute attack of gouty arthritis, it is reasonable to check a serum uric acid level, particularly if it is not the first attack and a decision is to be made regarding initiation of prophylactic therapy. However, clinicians should be mindful that acute gouty arthritis can occur in the presence of normal serum uric acid concentrations.[6] During titration of ULT, uric acid should be monitored every 2 to 5 weeks; once the urate target is achieved, uric acid should be monitored every 6 months.[26] This monitoring regimen is recommended not only to ensure appropriate dosing of ULT, but also to serve as an assessment of patient adherence given the known adherence issues with ULTs. Because of the high rates of comorbidities associated with gout, including diabetes mellitus, chronic kidney disease, hypertension, obesity, myocardial infarction, heart failure, and stroke, elevated uric acid levels or gout should prompt evaluations for signs of cardiovascular disease and the need for appropriate risk reduction measures.[116] Additionally, clinicians should look for a possible correctable cause of hyperuricemia, such as medications (eg, thiazide and loop diuretics, niacin, calcineurin inhibitors), obesity, malignancy, and alcohol abuse. Patients should be encouraged to exercise, lose weight, reduce alcohol intake, reduce consumption of syrup-sweetened sodas and increase consumption of low-fat dairy foods and vegetables, and have periodic follow-up to address progress on these goals.

CONCLUSION

Hyperuricemia may lead to acute arthritis, chronic gout, or kidney stones or to no sequelae at all. Asymptomatic hyperuricemia may not need to be treated, although lifestyle modifications (eg, weight loss, reduction of alcohol intake, control of blood pressure) should be encouraged to help reduce serum urate and overall cardiovascular health.

Acute gouty arthritis responds well to short courses of NSAIDs, colchicine, or corticosteroids to treat the underlying inflammatory condition. The management of uric acid nephrolithiasis includes hydration and alkalinization of the urine. Prevention of recurrent gouty arthritis or recurrent nephrolithiasis and treatment of chronic gout require hypouricemic therapy with either a uricosuric drug or xanthine oxidase inhibitor. Xanthine oxidase inhibitors are effective in both underexcreters and overproducers of uric acid, making them the hypouricemic drugs of choice for most patients with gout. Finally, anti-inflammatory prophylaxis with low-dose colchicine or NSAID therapy is indicated during the initiation of ULT to prevent the development of acute gout due to rapid mobilization or urate.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACR	American College of Rheumatology
ACTH	adrenocorticotropic hormone
CNS	central nervous system
COX-2	cyclooxygenase-2
EULAR	European League Against Rheumatism
FDA	Food and Drug Administration
GI	gastrointestinal
GLUT9	glucose transporter 9
HGPRT	hypoxanthine-guanine phosphoribosyltransferase
IL-1	interleukin-1
MSU	monosodium urate
NSAID	nonsteroidal anti-inflammatory drug
PNP	purine nucleoside phosphorylase
PRPP	phosphoribosyl pyrophosphate (synthetase)
SURI	selective uric acid reabsorption inhibitor
ULT	urate-lowering therapy
URAT1	urate transporter 1
USP	United States Pharmacopeia

Chapter 94: Glaucoma

Richard G. Fiscella; Timothy S. Lesar; Ohoud A. Owaidhah; Deepak P. Edward

INTRODUCTION

KEY CONCEPTS

- 1 Primary open-angle glaucoma (POAG) or ocular hypertension (OHT) is more prevalent outside Asia than primary angle closure glaucoma (PACG).
- 2 In any form of glaucoma, reduction of intraocular pressure (IOP) is essential.
- 3 IOP is a very important risk factor for glaucoma, but the most important considerations are progression of glaucomatous changes in the back of the eye (optic disk and nerve fiber layer) and visual field changes when diagnosing and monitoring for POAG or OHT.
- 4 Optic nerve changes often occur before visual field changes are exhibited.
- 5 Recent studies demonstrate that reduction in IOP prevents progression or even onset of glaucoma.
- 6 Newer medications simplify treatment regimens for patients. Prostaglandin analogs are considered the most potent topical medications for reducing IOP and flattening diurnal variations in IOP.
- 7 Local adverse events are common with topical glaucoma medications, but patient education and reinforcing adherence are essential to prevent glaucoma progression.

The glaucomas are a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Increased intraocular pressure (IOP) is thought to play an important role in the pathogenesis of glaucoma, but it is not a diagnostic criterion for glaucoma. Consistently high IOP without signs or symptoms of glaucoma is called ocular hypertension (OHT).

Two major types of glaucoma have been identified: open angle and closed angle. Open-angle glaucoma (OAG) accounts for the great majority of cases in North America, while primary angle

closure glaucoma (PACG) is more prevalent in Asia. Either type can be a primary inherited disorder, congenital, or secondary to disease, trauma, or drugs and can lead to serious complications. Both primary and secondary glaucomas may be caused by a combination of open-angle and closed-angle mechanisms (**Table 94-1**). Patients with consistently high IOP, or patients with clinical findings suspicious of early glaucomatous changes are called "glaucoma suspects."[1,2,3,4,5,6]

TABLE 94-1 General Classification of Glaucoma

I. Primary glaucoma

A. Open angle

B. Angle closure

1. With pupillary block

2. Without pupillary block

II. Secondary glaucoma

A. Open angle

2. Trabecular

3. Post-trabecular

B. Angle closure

1. Without pupillary block

2. With pupillary block

III. Congenital glaucoma

BASIC CONCEPTS

Aqueous Humor Dynamics and Intraocular Pressure

An understanding of IOP and aqueous humor dynamics will assist the reader in understanding the drug therapy of glaucoma.[1,2,3]

Aqueous humor is formed in the ciliary body and its epithelium (**Figs. 94-1** and **94-2**) through both filtration and secretion. Because ultrafiltration depends on pressure gradients, blood pressure and IOP changes influence aqueous humor formation. Osmotic gradients produced by active secretion of sodium and bicarbonate and possibly by other solutes such as ascorbate from the ciliary body

epithelial cells into the aqueous humor result in movement of water from the pool of ciliary stromal ultrafiltrate into the posterior chamber, forming aqueous humor. Carbonic anhydrase (primarily isoenzyme type II), α- and β-adrenergic receptors, and sodium- and potassium-activated adenosine triphosphatases are found on the ciliary epithelium and appear to be involved in this secretion of the solutes sodium and bicarbonate.

FIGURE 94-1

Anatomy of the eye.

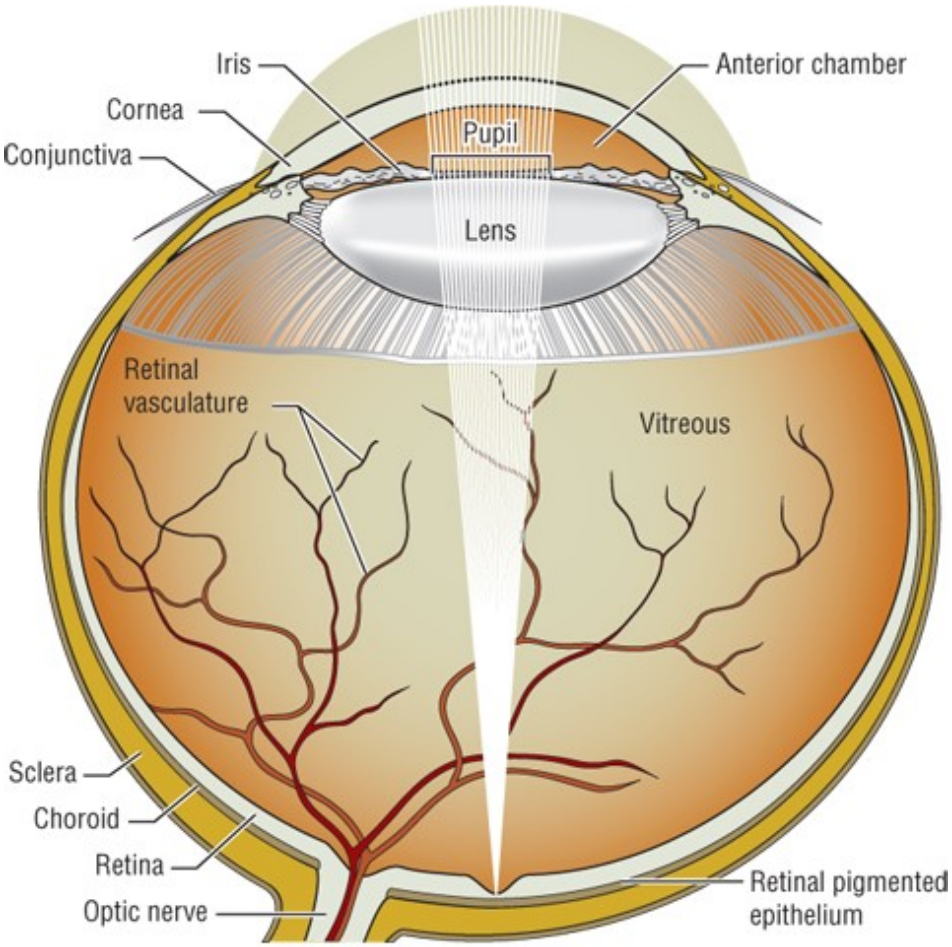

FIGURE 94-2

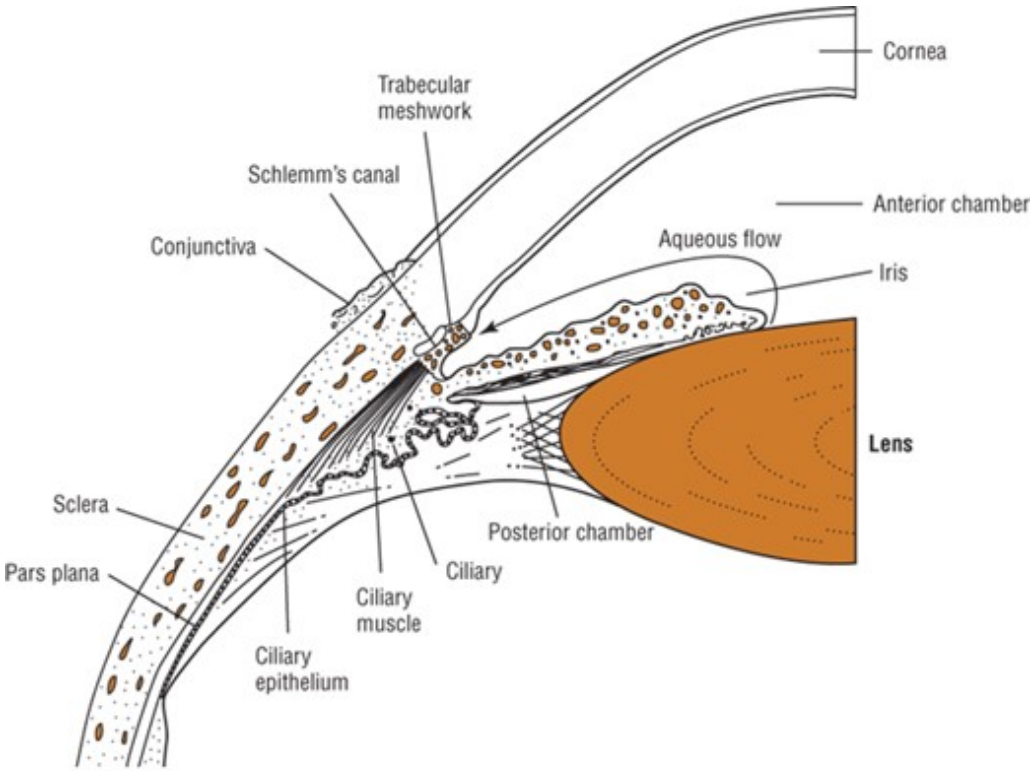
Anterior chamber of the eye and aqueous humor flow.



Receptor systems controlling aqueous inflow have not been elucidated fully. Pharmacologic studies suggest that β-adrenergic agents increase inflow, whereas α_2-adrenergic blocking, β-adrenergic blocking, dopamine-blocking, carbonic anhydrase-inhibiting, melatonin-1 agonist, and adenylate cyclase-stimulating agents decrease aqueous inflow. Aqueous humor produced by the ciliary body is secreted into the posterior chamber at a rate of approximately 2 to 3 µL/min. The pressure in the posterior chamber produced by the constant inflow pushes the aqueous humor between the iris and lens and through the pupil into the anterior chamber of the eye (see Fig. 94-2).[1,3,7,8,9]

Aqueous humor in the anterior chamber leaves the eye by two routes: (a) filtration through the trabecular meshwork (conventional outflow) to the Schlemm's canal (80% to 85%) and (b) through the ciliary body and the suprachoroidal space (uveoscleral outflow or unconventional outflow). Cholinergic agents such as pilocarpine appear to increase outflow by physically opening the meshwork pores secondary to ciliary muscle contraction. Prostaglandins are thought to result in remodeling of extracellular matrix in the meshwork, thereby increasing outflow. The uveoscleral outflow of aqueous humor is increased by prostaglandin analogs and β- and α_2-adrenergic agonists. Constant inflow of aqueous humor from the ciliary body and resistance to outflow result in an IOP great enough to produce an outflow rate equal to the inflow rate (see Fig. 94-2). Novel adenosine receptor agonists, cannabinoids, serotonin agents, and dopamine agonists also increase aqueous humor outflow and reduce IOP.[1,2,3,4,7,8,9]

The median IOP measured in large populations is 15.5 ± 2.5 mm Hg (2.1 ± 0.3 kPa); however, the distribution of pressures around the mean is skewed to the right (toward higher readings). IOP is not constant and changes with pulse, blood pressure, forced expiration or coughing, neck compression,

and posture. Gender, general health, and lifestyle (eg, smoking) are some of the factors that may have a long-term effect on IOP.[1,2,3,4,5,6] The amount of caffeine in 1 cup of caffeinated coffee (182 mg) increases IOP by about 1 mm Hg (0.1 kPa) after 90 minutes, this increase in IOP is not clinically relevant. Patients who have thinner corneas have had laser refractory eye surgery (LASIK), or have had cataract surgery demonstrate falsely low IOP readings. IOP is measured by tonometry: indentation tonometry, applanation tonometry, or a noncontact method using an air pulse. Newer methods of tonometery include the Pascal tonometer, IcareTM rebound tonometer, and a contact lens-based investigational device that can remotely monitor 24-hour IOP changes from baseline.[10,11,12] These methods may result in slightly different pressure readings. IOPs consistently greater than 21 mm Hg (2.8 kPa) are found in 5% to 8% of the general population. The incidence increases with age, such that "abnormal" (ie, >22 mm Hg [>2.9 kPa]) IOP is found in 15% of those 70 to 75 years of age. Intermittently very high IOP (>40 mm Hg [>5.3 kPa]) is found in patients with PACG.[5] The increased IOP in all types of glaucoma results from the decreased facility for aqueous humor outflow. Aqueous humor production in primary open-angle glaucoma (POAG) is normal.[1,2,3,4,5,6]

Intraocular pressure demonstrates considerable circadian variation (often referred to as *diurnal* IOP or the IOP during the daily 24-hour cycle) primarily because of changes in the rate of aqueous humor formation. This circadian variation results in a minimum IOP at approximately 6 pm and a maximum IOP at awakening, although some studies suggest that both healthy and glaucoma patients may have their highest IOP at night after falling asleep.[1,2,3] Low systemic blood pressure in conjunction with high IOPs (decreased ocular perfusion pressure) at night can result in optic nerve head damage. Generally, the circadian IOP variation is less than 3 to 4 mm Hg (0.4 to 0.5 kPa); however, it may be greater for patients with glaucoma. This circadian variation and the poor relationship of IOP with visual loss make measurement of IOP a poor screening test for glaucoma. Controlling circadian increases in IOP is thought to be important in prevention of disease progression. Prostaglandin analogs and carbonic anhydrase inhibitors (CAIs) reduce nocturnal IOP, whereas β-blockers and alpha-2 adrenergic agents have minimal effects.[1,3,13]

Although increased IOP within any range is associated with a higher risk of glaucomatous damage, it is both an insensitive and nonspecific diagnostic and monitoring tool. Of individuals with IOP between 21 and 30 mm Hg (2.8 and 4.0 kPa), only 0.5% to 1% per year will develop optic disk changes and visual field loss (ie, glaucoma) over 5 to 15 years. However, more subtle retinal damage, such as alteration of color vision or decreased contrast sensitivity, occurs in a higher percentage of patients with IOPs greater than 21 mm Hg (2.8 kPa), and the incidence of visual field defects increases to as high as 28% in individuals with IOPs above 30 mm Hg (4.0 kPa). The risk of developing glaucoma increases with older age, family history of glaucoma, lower ocular perfusion pressure, lower blood pressure, thinner central cornea, optic disk hemorrhage, larger cup-to-disk ratio, and specific visual fields findings. For patients with preexisting optic nerve damage, the worse the existing damage, the more sensitive the eye is to a given IOP. As many as 20% to 30% of patients with glaucomatous visual field loss have an IOP of less than 21 mm Hg (2.8 kPa) (called *normal-tension glaucoma*, referring to the normal IOP). Thus the absolute IOP is a less-precise predictor of optic nerve damage. More direct measurements of therapeutic outcome, such as optic disk examination and visual field evaluation, also must be used as monitors of disease progression. Taking the above factors into consideration, glaucoma medications that provide maximal reduction of IOP over 24

hours and have minimal influence on blood pressure may be advantageous in treating glaucoma patients.[1,2,3,4,5,14,15,16,17,18]

Optic Disk and Visual Fields

The optic disk is the portion of the optic nerve ophthalmoscopically visible as it leaves the eye. It consists of approximately 1 million retinal ganglion nerve cell axons, blood vessels, and supporting connective tissue structures (lamina cribrosa). The small depression within the disk is termed the *cup* (**Fig. 94-3**). A normal physiologic cup does not extend beyond the optic nerve rim and has a varying diameter of less than one-third to one-half that of the disk (cup-to-disk ratio: 0.33 to 0.5). **Table 94-2** lists the common alterations of the optic disk found in glaucoma. These disk changes result from optic nerve axonal degeneration and remodeling of the supporting structures. As the nerve axons die, the cup becomes larger in relation to the whole disk. A loss of retinal nerve fiber layer might be visualized in glaucoma patients with detectable visual field loss. This pattern of changes is consistent with visual field losses and loss of visual sensitivity seen in glaucoma.[1,2,3,4] Damage to the optic nerve can be documented by optic disk photographs, and disease stability or progression may be monitored by examining sequential photographs. Newer methods of assessing damage to the retinal nerve fiber layer and optic disk have been described. These include scanning laser polarimetry (GDX), confocal laser ophthalmoscopy (Heidelberg retinal tomography, or HRT), and optical coherence tomography (OCT). These methods offer the ability to assess the damage to the optic nerve quantitatively.

FIGURE 94-3

Normal fundus of the eye and optic disk and cup.

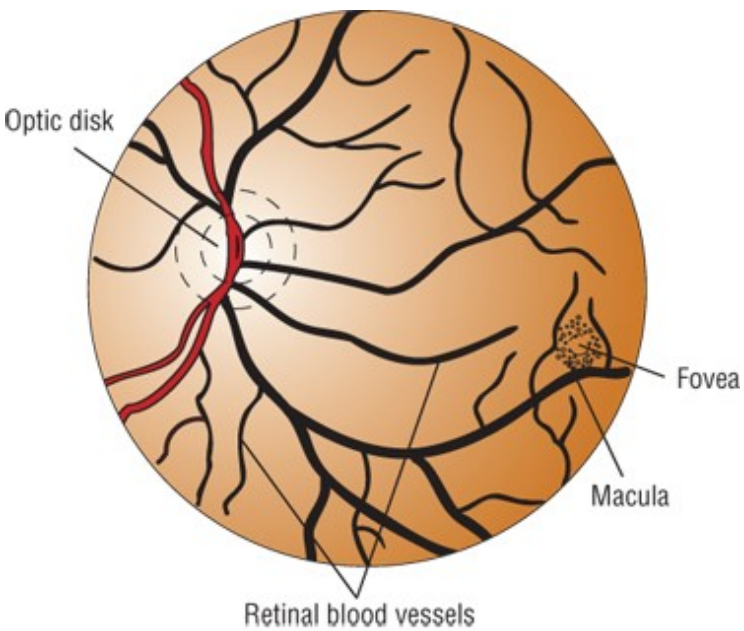


TABLE 94-2 Optic Disk and Visual Field Findings

Optic disk
Cup-to-disk ratio >0.5
Progressive increase in cup size
Cup-to-disk ratio asymmetry >0.2
Vertical elongation of the cup
Excavation of the cup
Increased exposure of lamina cribrosa
Pallor of the cup
Splinter hemorrhages
Cupping to edge of disk
Notching of the cup (usually superior or inferior)
Nerve fiber defects
Visual field findings
General peripheral field constriction
Isolated scotomas (blind spots)
Nasal visual field depression (“nasal step”)
Enlargement of blind spot
Large arc-like scotomas
Reduced contrast sensitivity
Reduced peripheral acuity
Altered color vision

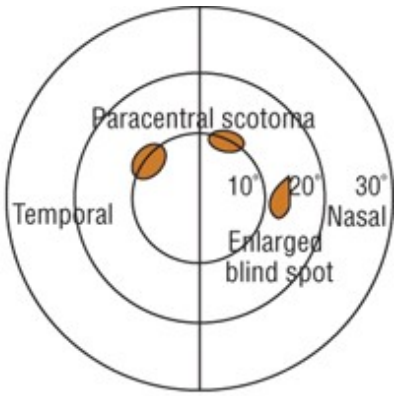
Determination of the visual field allows assessment of optic nerve damage and is an important monitoring parameter in treatment. However, visual field changes typically lag behind optic disk changes, and a loss of 25% to 35% of retinal ganglion cells is usually required before detectable visual field defects are noted. The peripheral visual field is measured using a visual field instrument called a *perimeter*. Characteristic visual field loss occurs in glaucoma (**Fig. 94-4**; see also Table 94-2), but loss of central visual acuity usually does not occur until late in the disease. Other indicators, such as color vision changes and contrast sensitivity, may allow earlier and more sensitive detection of

glaucomatous changes.[1,2,3,4]

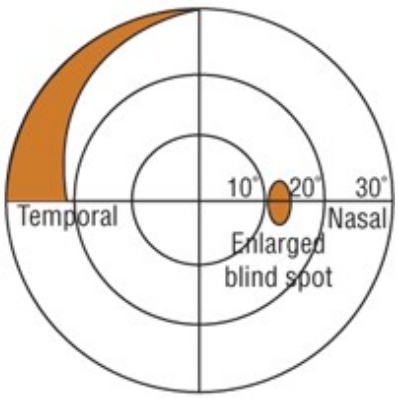
FIGURE 94-4

Schematic of the progression of visual field loss in glaucoma.

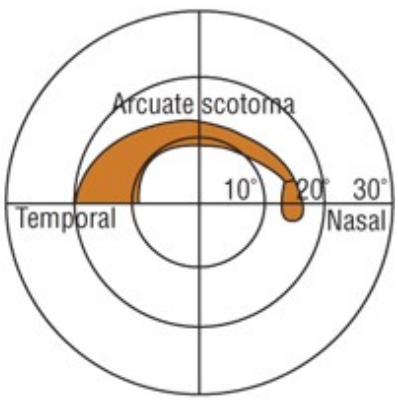
Field loss near central field
(paracentral)



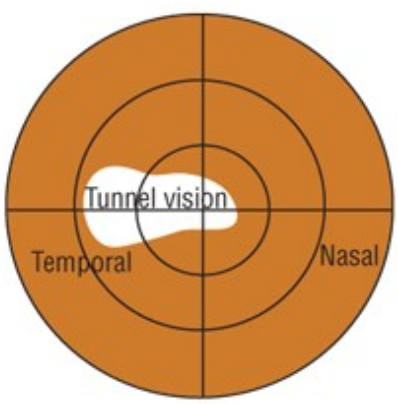
Nasal field loss
(nasal scotoma or step)

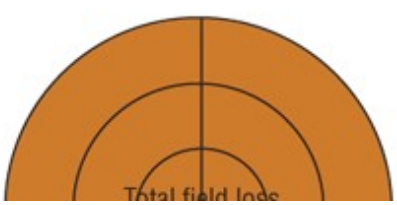


Field loss in midperiphery
(arcuate scotoma)



Sparing of central fixation
(tunnel vision)





Genetics

Glaucoma is often inherited as a complex multifactorial disease, but it can also be inherited as a Mendelian autosomal-dominant or autosomal-recessive trait form. The common age-related adult-onset glaucoma, like POAG, although containing heritability of some significance, is more complex and is influenced by environmental factors. Genetic studies have more clearly defined the underlying molecular events responsible for the Mendelian forms of the disease. However, the chromosome locations identified may play some factor in the more complex forms. A number of major gene loci associated with POAG have been identified. The molecular mechanism of how mutations in any of these genes result in increased IOP with loss of visual field has not been elucidated. The future of genetic studies in glaucoma will include discovery of new glaucoma genes, determination of clinical phenotypes associated with these genes and mutations, understanding how environmental factors interact, and developing a database that can be used for further testing.

Genome-wide association studies have identified new loci that are associated with clinically relevant optic disk parameters, including the optic disk area and vertical cup-disk ratio. Genes associated with chronic angle closure glaucoma (ACG) have also been identified. Improved understanding of the genetic origins of POAG may lead to new diagnostic tools and therapies that target the underlying causes of the disease.[1,2,3,4,19,20,21]

Epidemiology of Ocular Hypertension, Glaucoma Suspects, and Open-Angle Glaucoma

1 Overall, OHT occurs in 4.5% of non-Hispanic whites in the United States. The frequency increases to 7.7% of those older than 79 years.[22,23,24,25] The number of glaucoma suspects (ie, those with consistently high IOP or suspicious eye findings) is thought to be 3-6 million individuals in the United States. Left untreated, approximately 2% of glaucoma suspects will progress to glaucoma each year.[1,2,3,4,14,15,16,17,18,24,25]

Open-angle glaucoma is the second leading cause of blindness, affecting up to 4 million individuals in the United States and up to 70 million individuals worldwide. It is estimated that more than 135,000 persons in the United States and about 6-7 million in the world have glaucoma-related bilateral blindness. The prevalence rate varies with age, race, diagnostic criteria, and other factors. In the United States, OAG occurs in 1.5% of the population older than 30 years of age, 1.3% of whites and 3.5% of blacks. Recent study data have also suggested that the prevalence of OAG and OHT is also high among Latinos of Mexican ancestry, with approximately 4.74% and 3.56% of people affected, respectively.[20]

The incidence of OAG increases with increasing age. The incidence of the disease for patients 80 years of age is 3% in whites and 5% to 8% in blacks. In addition to increased IOP, older age, and ethnicity, the risk of glaucoma increases with family history, thinner central corneal thickness, lower ocular perfusion pressure, type 2 diabetes, myopia, and certain genetic mutations.[1,2,3,4,5,21,22,23,24,25]

Etiology of Open-Angle Glaucoma

2 The specific cause of glaucomatous optic neuropathy is presently unknown. Previously, increased IOP was considered to be the sole cause of the damage; however, it is now recognized that IOP is only one of many factors associated with the development and progression of glaucoma. Increased susceptibility of the optic nerve to ischemia (a reduced or dysregulated blood flow), excitotoxicity, autoimmune reactions, and other abnormal physiologic processes are likely additional contributory factors. The final outcome of these processes is believed to be apoptosis of the retinal ganglion cells, which results in axonal degeneration and finally permanent loss of vision. POAG may represent a number of distinct diseases or conditions that simply manifest the same symptoms. Susceptibility to visual loss at a given IOP varies considerably; some patients do not demonstrate damage at high IOPs, whereas other patients have progressive visual field loss despite an IOP in the normal range (normal-tension glaucoma).[1,2,3,4,6]

Although IOP poorly predicts which patients will have visual field loss, the risk of visual field loss clearly increases with increasing IOP within any range. In fact, recent studies demonstrate that lowering IOP, no matter what the pretreatment IOP, reduces the risk of glaucomatous progression or may even prevent the onset to early glaucoma in patients with OHT.[1,2,3,4,6,14,15,16,17,18]

The mechanism by which a certain level of IOP increases the susceptibility of a given eye to nerve damage remains controversial. Multiple mechanisms are likely to be operative in a spectrum of combinations to produce the death of retinal ganglion cells and their axons in glaucoma. Pressure-sensitive astrocytes and other cells in the optic disk supportive matrix may produce changes and remodeling of the disk, resulting in axonal death. Vasogenic theories suggest that optic nerve damage results from insufficient blood flow to the retina secondary to the increased perfusion pressure required in the eye, dysregulated perfusion, or vessel wall abnormalities, and results in degeneration of axonal fibers of the retina. Another theory suggests that the IOP may disrupt axoplasmal flow at the optic disk.[1,2,3]

Recently, focus on the mechanisms of the retinal ganglion cell apoptosis and the role of excessive glutamate and nitric oxide found in glaucoma patients has broadened the focus of drug therapy research to include evaluation of agents that act as neuroprotectants. Such agents may be particularly useful for patients with normal-pressure glaucoma, in whom pressure-independent factors may play a relatively larger role in disease progression. These agents would target risk factors and underlying pathophysiologic mechanisms of disease other than IOP.[2,8,13,14,15,26,27,28,29]

CLINICAL PRESENTATION Glaucoma General

- Glaucoma can be detected in otherwise asymptomatic patients, or patients can present with characteristic symptoms, especially vision loss. POAG is a chronic, slowly progressive disease found primarily in patients older than 50 years of age, whereas PACG is more typically associated with symptomatic acute episodes or may be slowly progressive as with POAG

Symptoms

- POAG: None until substantial visual field loss occurs

- PACG: Nonsymptomatic or prodromal symptoms (blurred or hazy vision with halos around lights that is caused by a hazy, edematous cornea, and occasionally headache) may be present. Acute episodes produce symptoms associated with a cloudy, edematous cornea, ocular pain, or discomfort, nausea, vomiting, abdominal pain, and diaphoresis

Signs

- POAG: Disk changes and visual field loss (see Table 94-2); IOP can be normal or elevated (>21 mm Hg [>2.8 kPa])

  Mild: Optic disk abnormalities with normal visual field with standard perimetry

  Moderate: Optic disk changes plus visual field abnormalities in one hemifield that are not within 5 degrees of central visual fixation

  Severe: Optic disk changes with visual field loss in both hemifields and loss within 5 degrees of central fixation and abnormalities in at least one hemifield

- Acute ACG: Acute hyperemic conjunctiva, cloudy cornea, shallow anterior chamber, and occasionally an edematous and hyperemic optic disk; IOP is generally elevated markedly (40 to 90 mm Hg [5.3 to 12.0 kPa]) when symptoms are present

- Chronic ACG (CACG): Disk changes and visual field loss (see Table 94-2); IOP can be normal or elevated (>21 mm Hg [>2.8 kPa])

Laboratory Tests

- None

Other Diagnostic Tests

- Emerging tests include OCT, retinal nerve fiber analyzers, and confocal scanning laser tomography of the optic nerve

Pathophysiology of Open-Angle Glaucoma

3 As stated previously, optic nerve damage in POAG can occur at a wide range of IOPs, and the rate of progression is highly variable. Patients may exhibit pressures in the 20 to 30 mm Hg (2.7 to 4.0 kPa) range for years before any disease progression is noticed in the optic disk or visual fields. That is why POAG is often referred to as the “sneak thief of sight.”

Clinical Presentation of Open-Angle Glaucoma

Primary open-angle glaucoma is a bilateral, often asymmetric, genetically determined disorder constituting 60% to 70% of all glaucomas and 90% to 95% of primary glaucomas in the United States (see Clinical Presentation of Glaucoma above). An increased IOP is not required for diagnosis of POAG. Symptoms do not present until substantial visual field constriction occurs. Central visual acuity

typically is maintained even in the late stages of the disease. Even though POAG is a bilateral disease, it may have greater IOP and progression and severity in one eye. As such, each eye is treated individually.[1,2,3,4,6]

4 Detection and diagnosis involve evaluation of the optic disk and retinal nerve fiber layer, assessment of the visual fields, and measurement of IOP. The presence of characteristic disk changes and visual field loss with or without increased IOP confirms the diagnosis of glaucoma. Typical disk changes and field loss occurring at an IOP of less than 21 mm Hg (2.8 kPa) account for 20% to 30% of patients and are referred to as *normal-tension glaucoma*. Elevated IOP (>21 mm Hg [>2.8 kPa]) without disk changes or visual field loss is observed in 5% to 7% of individuals (*glaucoma suspects*) and is referred to as *OHT*. New technologies, such as OCT, retinal nerve fiber analyzers, or confocal scanning laser tomography of the optic nerve head, may allow early identification of signs of glaucomatous retinal changes in ocular hypertensives, thus allowing for earlier initiation of therapy.[1,2,3,4,5]

Secondary OAG has many causes, including exfoliation syndrome, pigmentary glaucoma, systemic diseases, trauma, surgery, ocular inflammatory diseases, and medications. A system for classifying secondary glaucomas into pretrabecular, trabecular, and post-trabecular forms has been proposed. This classification allows drug therapy to be chosen on the basis of the pathogenic mechanism involved. In pretrabecular forms, a normal meshwork is covered and does not permit aqueous humor outflow. Trabecular forms of secondary glaucoma result from either an alteration of meshwork or an accumulation of material in the intertrabecular spaces. The post-trabecular forms result primarily from disorders causing increased episcleral venous blood pressure.[1]

Prognosis of Open Angle Glaucoma

5 In most cases of POAG, the overall prognosis is excellent when it is discovered early and treated adequately. Even patients with advanced visual field loss can have continued visual field loss reduced if the IOP is maintained at low enough pressures (often <10 to 12 mm Hg [<1.3 to 1.6 kPa]). Medications will control IOP successfully in 60% to 80% of patients over a 5-year period. Progression of visual field loss still occurs in 8% to 20% of patients despite reaching standard therapy IOP goals. However, for untreated patients and for those who fail to achieve target IOP reduction, up to 80% have continued visual field loss. Estimates of progression to bilateral blindness in treated patients range from 4% to 22%. Compared with placebo, each 1 mm Hg (0.1 kPa) in IOP reduction reduces risk of disease progression by at least 10%.[1,2,3,4,14,15,16,17,18] After 2 years, visual field loss occurred in 25.6% of placebo patients compared with 15.2% of those treated with latanoprost.[18] Thus, the keys to medical treatment of POAG are an effective, well-tolerated drug regimen, close monitoring of therapy, and adherence.[1,2,3,4]

Epidemiology of Primary Angle Closure Glaucoma

The incidence of PACG varies by the ethnic group, with a higher incidence in individuals of Inuit, Chinese, and Asian-Indian descent. Incidence rates of 1% to 4% have been reported in these

populations.[1,2] Because of the high frequency of PACG in populous Asia, PACG accounts for approximately one-third of glaucoma worldwide. PACG accounts for a disproportionately high proportion of blindness (estimated at up to 50%) worldwide.[1,2,3,5,30]

Etiology of Primary Angle Closure Glaucoma

In North America, PACG accounts for a minority of primary glaucomas. When severe ACG occurs, it may need to be treated as an emergency to avoid visual loss. PACG results from mechanical blockage of the (usually normal) trabecular meshwork by the peripheral iris. Partial or complete blockage of the meshwork occurs intermittently, potentially resulting in extreme fluctuations between normal IOP with no symptoms and very high IOP with symptoms of acute PACG. Between attacks of PACG, the IOP is usually normal unless the patient has concomitant POAG or nonreversible blockage of the meshwork with synechiae ("creeping" angle closure) that develops over time in the narrow-angle eye. PACG occurs in patients with inherited shallow anterior chambers (often seen in small eyes), which produce a narrow angle between the cornea and iris or tight contact between the iris and lens (pupillary block). The presence of a narrow angle is determined mainly by visualization of the angle by gonioscopy. Other tests for PACG involve provocation of an angle-closure-induced IOP increase. These tests, which attempt to produce angle closure through mydriasis (darkroom test or mydriasis test) or gravity (prone test), are rarely performed in the clinical setting.

Two major types of classic, reversible PACG have been described: PACG with pupillary block and PACG without pupillary block. PACG with pupillary block results when the iris is in firm contact with the lens. This produces a relative block of aqueous flow through the pupil to the anterior chamber (pupillary block), resulting in a bowing forward of the iris, which blocks the trabecular meshwork. PACG with pupillary block occurs most commonly when the pupil is in mid-dilation. In this position, the combination of pupillary block and relaxed iris allows the greatest bowing of the iris; however, angle closure may occur during miosis or mydriasis.

Primary angle closure glaucoma can occur without significant pupillary block for patients with an abnormality called a *plateau iris*. The ciliary processes in these cases are situated anteriorly, which indent the iris forward and cause closure of the trabecular meshwork, especially during mydriasis. The mydriasis produced by anticholinergic drugs or any other drug results in precipitation of both types of PACG glaucoma, whereas drug-induced miosis may produce pupillary block.[1,2,3,5,30]

Pathophysiology of Primary Angle Closure Glaucoma

The mechanism of IOP elevation in PACG is more clear than that of POAG. In PACG, a physical blockage of trabecular meshwork is present. In many cases, single or multiple episodes of high IOP that in some patients may exceed 40 mm Hg (5.3 kPa) and result in optic nerve damage. Very high IOP (>60 mm Hg [>8.0 kPa]) may result in permanent loss of visual field within a matter of hours to days.

One type of CAG, known as "creeping" angle closure, occurs in patients with narrow angles in which the iris adheres to the trabecular meshwork and may result in continuously increased IOP in ranges

more similar to those of POAG, and the clinical behavior is similar to POAG, with individuals differing in the degree and rapidity of visual loss from any given elevated IOP.[1,30]

Clinical Presentation of Angle Closure Glaucoma

Most patients with untreated PACG typically experience intermittent nonsymptomatic or prodromal symptoms brought on by precipitating events (see Clinical Presentation of Glaucoma above). Increased IOP during such prodromal episodes is not great enough or long enough to produce the other symptoms of a full-blown attack. Such prodromal attacks last 1 to 2 hours, at which time pupillary block is broken by further mydriasis or miosis, or when miosis or mydriasis occurs in patients with plateau iris. The rate at which IOP increases may be a determinant of when full-blown symptoms occur. Visual fields demonstrate generalized constriction or typical glaucomatous defects as seen in POAG. In approximately 25% of patients, severe attacks may occur and if prolonged, total loss of vision may occur if the IOP is high enough. Tonometry reveals IOPs as high as 40 to 90 mm Hg (5.3 to 12.0 kPa). Patients who have developed adhesions between the iris and meshwork (anterior synechiae) may have chronic IOP elevation with intermittent spikes of high IOP when angle closure occurs.[1,2,30]

Drug-Induced Glaucoma

A number of medications are associated with increased IOP or carry labeling that cautions against use of the medication in glaucoma patients. The potential for a medication to produce or worsen glaucoma depends on the type of glaucoma and whether the patient is treated adequately.[1,2,3,4,31] Patients with treated, controlled POAG are at minimal risk of induction of an increase in IOP by systemic medications with anticholinergic properties or vasodilators; however, for patients with untreated glaucoma or uncontrolled POAG, the potential of these medications to increase IOP should be considered. Topical anticholinergic agents used to produce mydriasis may result in an increase in IOP. Potent anticholinergic agents such as atropine or homatropine are most likely to increase IOP. Weaker anticholinergics, such as tropicamide, that produce less cycloplegia are less likely to increase IOP and are favored, along with phenylephrine, when mydriasis is desired for POAG patients. Inhaled, nasal, topical, or systemic glucocorticoids may increase IOP for both normal individuals and patients with POAG.

Patients with POAG appear to be particularly susceptible to glucocorticoid-induced increases in IOP. Glucocorticoids reduce the facility of aqueous humor outflow through the trabecular meshwork. The decreased facility of outflow appears to result from the accumulation of extracellular material blocking the trabecular channels. The potential of a glucocorticoid to increase IOP is related to its anti-inflammatory potency and intraocular penetration. Thus, patients should be treated with the lowest potency and dose and for the shortest time possible when steroids are indicated.

For patients predisposed to CAG (ie, narrow anterior chambers), angle closure may be produced by any drug that causes mydriasis (eg, anticholinergics). A wide range of sulfa compounds causes idiosyncratic reactions that result in anterior choroidal effusions with anterior movement of the iris and lens, resulting in angle closure. The topical use of anticholinergics or sympathomimetic agents

most likely will result in angle closure. Systemic and inhaled anticholinergic and sympathomimetic agents also must be used with caution in such patients. As discussed previously, potent miotic agents such as echothiophate may produce angle closure by increasing pupillary block. **Table 94-3** lists the drugs associated with potentiation of glaucoma.

TABLE 94-3 Drugs That May Induce or Potentiate Increased Intraocular Pressure

Open-angle glaucoma
Ophthalmic corticosteroids (high risk)
Systemic corticosteroids
Nasal/inhaled corticosteroids
Fenoldopam
Ophthalmic anticholinergics
Succinylcholine
Vasodilators (low risk)
Cimetidine (low risk)
Closed-angle glaucoma
Topical anticholinergics
Topical sympathomimetics
Systemic anticholinergics
Heterocyclic antidepressants
Low-potency phenothiazines
Antihistamines
Ipratropium
Benzodiazepines (low risk)
Theophylline (low risk)
Vasodilators (low risk)
Systemic sympathomimetics (low risk)
CNS stimulants (low risk)

Serotonin-selective reuptake inhibitors

Imipramine

Venlafaxine

Topiramate

Tetracyclines (low risk)

Carbonic anhydrase inhibitors (low risk)

Monoamine oxidase inhibitors (low risk)

Topical cholinergics (low risk)

TREATMENT

Glaucoma Suspects and Ocular Hypertension

Treatment of the patient with possible glaucoma (OHT; ie, patients with IOP >22 mm Hg [>2.9 kPa]) is less controversial with the recent results of the Ocular Hypertensive Treatment Study (OHTS) than it was in the past.[14] The OHTS helped to identify risk factors for treatment. Patients with IOPs higher than 25 mm Hg (3.3 kPa), vertical cup-to-disk ratio of more than 0.5, and central corneal thickness of less than 555 µm are at greater risk for developing glaucoma. Risk factors such as family history of glaucoma, black, Latino/Hispanic ethnicity, severe myopia, and patients with only one eye must also be taken into consideration when deciding which individuals need treatment.

Patients without risk factors typically are not treated and are monitored for the development of glaucomatous changes. The use of risk calculators has been suggested as a means of determining who are at greatest risk in developing glaucoma. It is hoped that with future improvement in such calculators, one would be able to tailor treatment to those at greatest risk for developing glaucoma.

Patients with significant risk factors usually are treated with a well-tolerated topical agent such as a prostaglandin analog or β-blocking agent. Other options include a α_2-agonist (brimonidine) or a topical CAI, depending on individual patient characteristics. Therapy may be initiated in one eye to assess tolerance and efficacy; however, because each eye may respond differently to medications as well as possible contralateral effects, IOP response may be compared with baseline in individual eyes.

The goal of therapy is to lower the IOP to a level associated with a decreased risk of optic nerve damage, usually at least a 20%, if not a 25% to 30% decrease from the baseline IOP. Greater decreases may be required in high-risk patients or those with higher initial IOPs. Drug therapy should be monitored by measurement of IOP, examination of the optic disk, assessment of the visual fields, and evaluation of the patient for drug adverse effects and compliance with therapy. Patients who are unresponsive to or intolerant of a drug should be switched to an alternative agent rather than given an additional drug. Partial responders may be treated with combinations of well-tolerated topical

medications (prostaglandins, β-blockers, brimonidine or a CAI). Use of multiple combinations of topical agents or when first-line agents fail to reduce IOP depends on the risk-to-benefit assessment of each patient. Some clinicians prefer to discontinue all medications for patients who fail to respond adequately to simple topical therapy, closely monitor for development of disk changes or visual field loss, and treat again when such changes occur.[6] The cost, inconvenience of frequent adverse effects of multiple-combination therapies, pilocarpine, dipivefrin, cholinesterase inhibitors, and oral CAIs generally result in an unfavorable risk-to-benefit ratio for glaucoma suspect patients.[1,2,3,4,6,32,33,34,35]

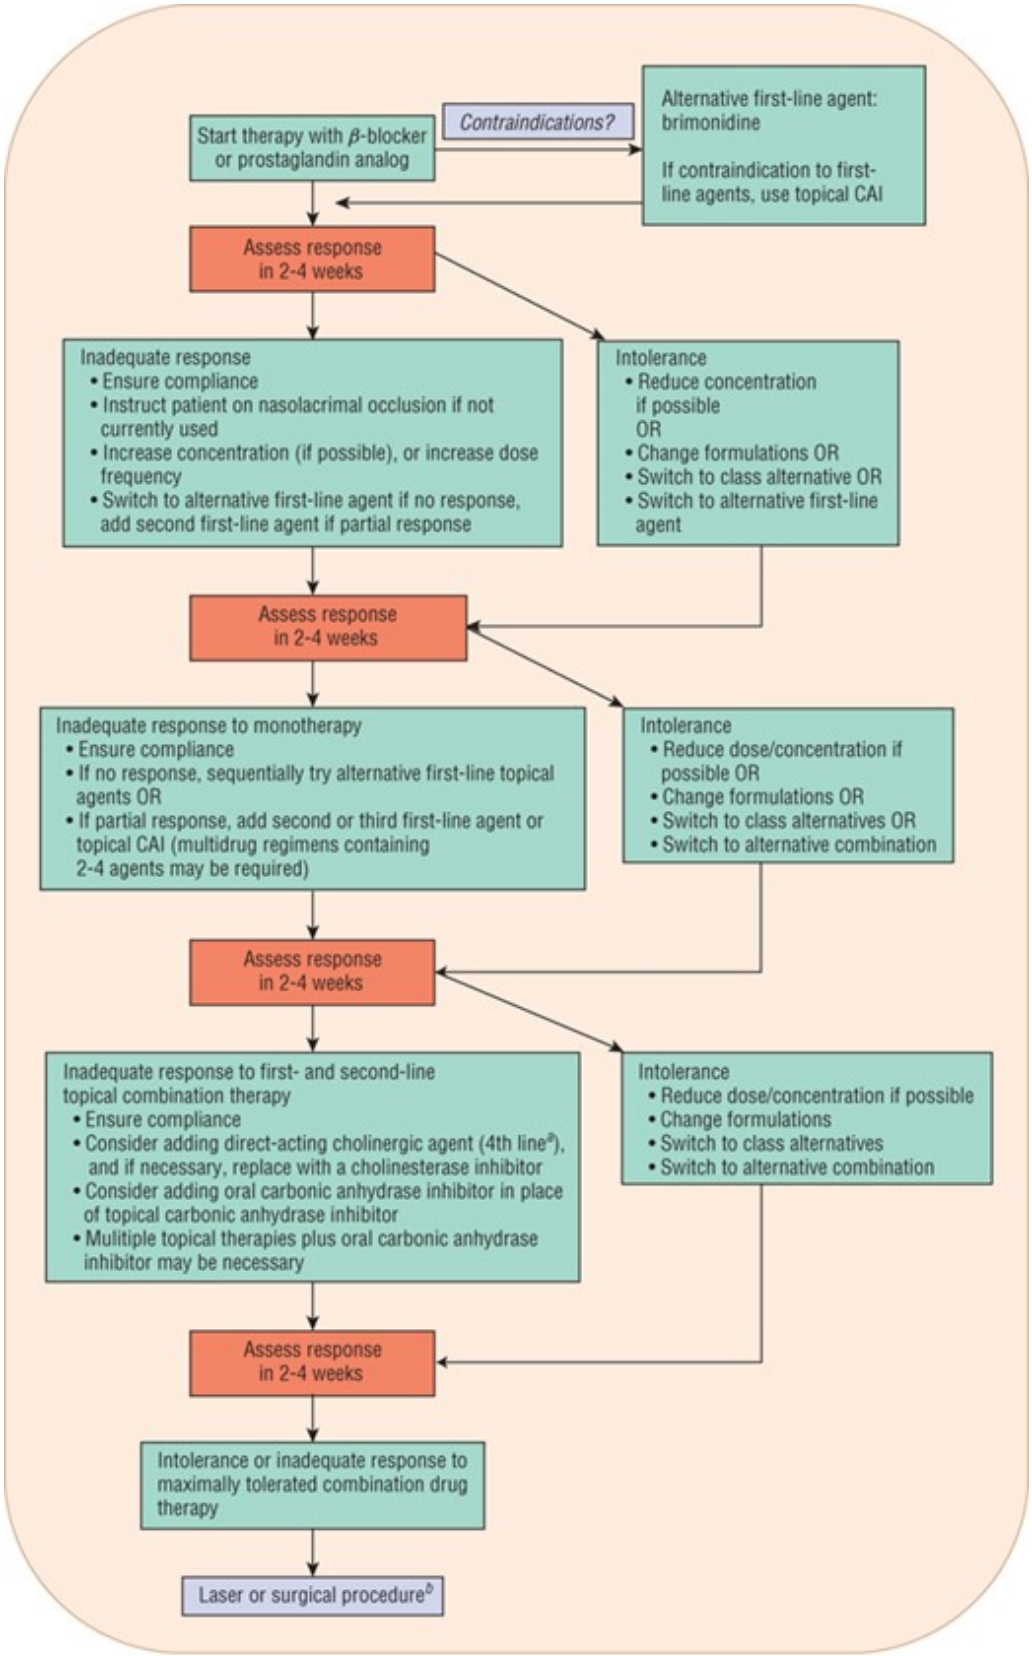
TREATMENT

Open-Angle Glaucoma

All patients with elevated IOP and characteristic optic disk changes and/or visual field defects not caused by other factors (ie, glaucoma by definition) should be treated. Recent findings that one in five patients with "normal" IOP and glaucomatous retinal nerve findings (ie, normal-tension glaucoma) do not have progression of visual field loss if left untreated have prompted recommendations to monitor normal-tension glaucoma patients without immediate threat of loss of central vision and to treat only when progression is documented. Some controversy exists as to whether the initial therapy of glaucoma should be surgical trabeculectomy (filtering procedure), argon or selective laser trabeculectomy, or medical therapy.[1,2,3,4,32,33,34,35,36,37,38,39,40,41,42,43,44] Presently, drug therapy remains the most common initial treatment modality. Drug therapy of patients with documented glaucomatous change with either elevated or normal IOP is initiated in a stepwise manner (**Fig. 94-5**), starting with a single, well-tolerated topical agent. The goal of therapy is to prevent further visual loss. A "target" IOP is chosen based on a patient baseline IOP and the amount of existing visual field loss. Typically, an initial target IOP reduction of 25-30% is desired. Greater reductions may be desired for patients with very high baseline IOPs or advanced visual field loss. Patients with normal baseline IOPs (normal-tension glaucoma) may have target IOPs of less than 10 to 12 mm Hg (1.3 to 1.6 kPa).[1,2,3,4]

FIGURE 94-5

Algorithm for the pharmacotherapy of open-angle glaucoma. [a]Fourth-line agents not commonly used any longer or commercially unavailable. [b]Most clinicians believe the laser procedure should be performed earlier (eg, after three-drug maximum, poorly adherent patient). (CAI, carbonic anhydrase inhibitor.)



Clinical Controversy…

How much should the IOP be reduced for patients who may have POAG? Although the major clinical

trial (OHTS[3]) required a 20% reduction in IOP for patients with OHT, many clinicians believe a further lowering of IOP may be more beneficial in preventing the progression of OHT to glaucoma. The American Academy of Ophthalmology Preferred Practice Guidelines suggest 20% to 30% IOP lowering. It remains to be seen if a more aggressive approach earlier in the treatment of the POAG suspect would be more beneficial.

Pharmacotherapeutic Approach

Medications most commonly used to treat glaucoma are the prostaglandin analogs, nonselective β-blockers, brimonidine (a α_2-agonist), the topical CAIs, and the fixed combination products of timolol/dorzolamide, timolol/brimonidine, brimonidine/brinzolamide, or timolol/prostaglandins (marketed outside the United States).[1,2,3,4,32,33,34,35]

The prostaglandin analogs are often recommended as first-line therapy. They offer once-daily dosing, better IOP reduction, better 24-hour IOP control, good tolerance, and availability of lower-cost generics (see Fig. 94-5). The topical β-blockers have a long history of successful use, providing a combination of clinical efficacy and general tolerability. Brimonidine and topical CAIs are also well tolerated and effective agents, but often considered second-line agents (to prostaglandins and β-blockers).[1,2,3,4] Therapy optimally is started as a single agent, and may be started in one eye (except for patients with very high IOP or advanced visual field loss) to evaluate drug efficacy and tolerance, although response may differ between contralateral eyes. Monitoring of therapy should be individualized. Initial check for IOP response to therapy is typically done 4 to 6 weeks after the medication is started. Once IOPs reach acceptable levels, the IOP is monitored every 3 to 4 months or longer if there is prolonged control (over 6-12 months) without progression. More frequent monitoring is necessary if the IOP target is not achieved, disease progression is noted, and after any change in drug therapy.[1,2,3,4,6]

Clinical Controversy...

The American Academy of Ophthalmology has not designated any agent as the drug of choice for initiation of glaucoma treatment. In recent years, many clinicians have used the prostaglandin analogs because they are dosed once daily and achieve the best pressure reduction and are available as less expensive generic products.

Visual fields and disk changes are typically monitored every 6-12 months or earlier if the glaucoma is unstable or there is suspicion of disease worsening. Patients should always be questioned regarding adherence to and tolerance of prescribed therapy. Initial IOP response does not predict long-term IOP control, as tachyphylaxis to IOP reduction and or disease progression may occur.

The value of an agent with which the patient has shown a drop in IOP following an initial response can be measured by discontinuing the medication completely and determining if an increase in IOP occurs. Patients responding to but intolerant of initial therapy may be switched to another drug. For patients failing to respond to an initial drug, a switch to an alternative agent should be considered. If only a partial response occurs, addition of another topical drug to be used in combination is a

possibility. A number of drugs or drug combinations may need to be tried before an effective and well-tolerated regimen is identified.

Prostaglandin agonists, β-blockers, brimonidine, CAIs, and pilocarpine may be used in various combinations. Adding a second drug generally results in a less-than-additive reduction in IOP. Using more than one drop per dose does not improve response but rather increases the likelihood of adverse effects and the cost of therapy. When using more than one medication, separation of drop instillation of each agent by at least 5 minutes is suggested to provide optimal ocular absorption.

Combination products reduce the number of daily doses, possibly improving adherence and preventing washout effect seen when a second medication is administered too soon after the initial medication. Use of combination products also reduces exposure to ophthalmic preservatives. Ocular surface disease (OSD) secondary to glaucoma therapy will often manifest as superficial punctate keratitis, tear-film instability or allergy.[45] In-vivo and animal studies have demonstrated the toxic effects of preservatives—benzalkonium chloride in particular—through various mechanisms. However, extrapolating these results to clinical use is difficult because these studies must control for effects such as blinking, tear dilution and turnover, and buffering capabilities of the human eye. While many crossover clinical trials show benefit to preservative-free therapies, many other studies demonstrate no improvement. Patients with medication-related OSD may try treatment with artificial tears, anti-inflammatory therapy, or possibly preservative-free therapy if feasible.

The IOP response to ocular hypotensive medication may vary with corneal thickness. The response might be better in those with normal or thin corneas than in those with thicker structures.

Because of the frequency of adverse effects, dipivefrin, carbachol, topical cholinesterase inhibitors, and oral CAIs are considered last-line agents to be used for patients who fail less-toxic combination topical therapy.

Nonpharmacologic Therapy: Laser and Surgical Procedures

When drug therapy fails, is not tolerated, or is excessively complicated, surgical procedures such as laser trabeculoplasty (argon or selective) or a surgical trabeculectomy (filtering procedure) may be performed to improve outflow. Laser trabeculoplasty is usually an intermediate step between drug therapy and trabeculectomy. The newer selective laser trabeculoplasty (SLT) procedure has demonstrated similar IOP reduction as argon laser trabeculoplasty (ALT) and may be repeatable. Recent studies have demonstrated good efficacy for this procedure in comparison with medical treatment options for POAG. Procedures with higher complication rates, such as those involving placement of draining tubes or destruction of the ciliary body (cyclodestruction), may be required when other methods fail (see Fig. 94-2).[1,2,3,4]

Surgical methods for reduction of IOP involve the creation of a channel through which aqueous humor can flow from the anterior chamber to the subconjunctival space (filtering bleb), where it is reabsorbed by the vasculature. A major reason for failure of the procedure is healing and scarring of the site. The use of aqueous shunts or valves to manage glaucoma has been increasing, and the results of a recent study have demonstrated improved safety and efficacy of these devices. However,

glaucoma surgery is still plagued with the shortcomings despite modifications and improvements over the past century, including potentially vision-threatening complications such as hypotony, wound leaks, and infections.[38,39,46] Minimally invasive glaucoma surgery (MIGS) uses microincisions and implants that reduce IOP by targeting various areas of the outflow pathway.[46] These can either be approached from inside the eye (ab-interno) (eg, iStent, Hydrus, Trabectome, suprachoroidal shunts) or outside the eye (ab-externo) (eg, canaloplasty, Gold micro shunt, and Stegman Canal Expander).[46]

Modification of the healing process to maintain patency is possible with the use of antiproliferative agents. The antiproliferative agents 5-fluorouracil and mitomycin C are used for patients undergoing glaucoma-filtering surgery to improve success rates by reducing fibroblast proliferation and consequent scarring. Although used most commonly for patients with increased risk for suboptimal surgical outcome (after cataract surgery and a previous failed filtering procedure), use of these agents also improves success in low-risk patients.[38,39,46] A standardized formulation of mitomycin C (MMC) that is prepacked in a kit with a fixed dose and concentration was approved by FDA in 2012 and is commercially available under the name "Mitosol."

TREATMENT

Acute Angle Closure Crisis (AACC)

The goal of initial therapy for acute acute angle closure crisis (AACC) with high IOP is rapid reduction of the IOP to preserve vision and to avoid surgical or laser iridectomy on a hypertensive, congested eye. Iridectomy (laser or surgical) is the definitive treatment of PACG; it produces a hole in the iris that permits aqueous humor flow to move directly from the posterior chamber to the anterior chamber, opening up the block at the trabecular meshwork. Drug therapy of an AACC typically involves administration one or more topical antiglaucoma medications including miotics (eg, pilocarpine), secretory inhibitors (β-blockers, α_2-agonist, or topical/systemic CAIs), or a prostaglandin agonist.[5,30] The miosis produced by pilocarpine pulls the peripheral iris away from the meshwork. However, miotics may worsen angle closure by increasing pupillary block and producing anterior movement of the lens because of drug-induced accommodation. The aqueous secretory inhibitors and pilocarpine may not be effective due to ischemia of the ciliary body and pupillary sphincter, respectively. During this time, the urge to use excessive amounts of topical agents must be resisted. A hyperosmotic agent such as mannitol or glycerin may be needed to temporarily reduce IOP and restore response to the topical agents.

An osmotic agent also is commonly administered because these drugs produce the most rapid decrease in IOP. Oral glycerin 1 to 2 g/kg can be used if an oral agent is tolerated; if not, IV mannitol 1 to 2 g/kg should be used. Osmotic agents reduce IOP by withdrawing water from the eye secondary to the osmotic gradient between the blood and the eye. These drugs are among the first-line agents in the short-term treatment of an AACC or other forms of acute very high IOP elevations. Topical corticosteroids often are used to reduce the ocular inflammation and reduce the development of synechiae in PACG eyes. Patients failing therapy altogether will require an emergency iridectomy. Once the IOP is controlled, iridectomy is performed on the affected eye as well as the

contralateral eye (if narrow angles are present).

Peripheral iridectomy essentially "cures" primary PACG without significant synechiae. Long-term drug therapy is not used unless IOP remains high because of the presence of synechiae blocking the trabecular meshwork or concurrent POAG. In such cases, the pharmacotherapeutic approach is essentially identical to that for the POAG patient, or laser or surgical procedures are performed.[1,2,5,30]

PHARMACOLOGIC AGENTS USED IN GLAUCOMA

Prostaglandin Analogs

The prostaglandin analogs, including latanoprost, travoprost, bimatoprost, and tafluprost, reduce IOP by increasing the uveoscleral and, to a lesser extent, trabecular outflow of aqueous humor. Some differences in receptor sites and mechanisms of action may exist between the two prostaglandins (latanoprost and travoprost) and the prostamide (bimatoprost). However, both classes appear to produce collagen changes matrix in the ciliary body and trabecular meshwork. Bimatoprost may be slightly more effective in lowering IOP, getting a larger percentage of patients to lower IOPs, and for patients unresponsive to latanoprost. If the patient does not respond to one prostaglandin agonist, a switch to another may be beneficial.[37,40,41] Generic forms of some prostaglandin analogs are now available, reducing the cost to patients for these agents. Tafluprost is available as a preservative-free solution, which may be useful in patients intolerant of common ophthalmic preservatives or those with corneal surface disorders.

Reduction in IOP with once-daily doses of prostaglandin analogs (a 25% to 35% reduction) is often greater than that seen with timolol 0.5% twice daily. In addition, nocturnal control of IOP is improved compared with timolol.[2,40,41] Interestingly, administration of prostaglandin analogs twice daily may reduce the IOP similarly to once-daily dosing. The drugs are administered at nighttime, although they are probably as effective if given in the morning.

Prostaglandin analogs are well tolerated and produce fewer systemic adverse effects than timolol. Local ocular tolerance generally is good, but ocular reactions such as punctate corneal erosions and conjunctival hyperemia do occur. Local intolerance occurs in 10% to 25% of patients with these agents.[1,2,3,9,33,34,35]

With prostaglandin analogs, altered iris pigmentation occurs in 15% to 30% of patients, particularly those with mixed-color irises (blue-brown, green-brown, blue-gray-brown, or yellow-brown eyes), which become browner in color over 3 to 12 months. The change in iris pigmentation will often appear within 2 years, and long-term consequences of this pigment change appear to be mostly cosmetic but irreversible upon discontinuation. Hypertrichosis is common and reverses upon discontinuation of the drug. Hyperpigmentation around the lids and lashes has also been reported and appears to reverse upon discontinuation. Loss of periorbital fat has been reported; this may lead to apparent enophthalmos and sunken eye especially when agents are used unilaterally.

Topical prostaglandin analogs may produce rates of corneal thinning that are slightly higher than

ongoing age-related changes. This effect is unlikely to be clinically relevant.[7,8,9,33,34,35]

These agents have occasionally been associated with uveitis, and caution is recommended for patients with ocular inflammatory conditions. Cases of cystoid macular edema and worsening of herpetic keratitis have been reported.

Prostaglandin analogs can be used in combination with other antiglaucoma agents for additional IOP control because of their unique mechanism of action. Given their excellent efficacy and side-effect profile, prostaglandin analogs provide effective monotherapy or adjunctive therapy for patients who are not responding to or tolerating other agents. Long-term studies demonstrate these agents are safe, efficacious, and well tolerated in glaucoma therapy.[4,7,8,9,33,34,35] Various fixed combination prostaglandin products, often with timolol, are available in Canada and other countries.

β-Blocking Drugs

The topical *β*-blocking agents are one of the most commonly used antiglaucoma medications (**Table 94-4**). *β*-Blockers lower IOP by 20% to 30% with a minimum of local ocular adverse effects. *β*-blockers have minimal effects on nocturnal IOP. These are commonly one of the agents of first choice—along with prostaglandin analogs—in treating POAG if no contraindications exist.[1,2,3,4,9,33,34,35]

TABLE 94-4 Topical Drugs Used in the Treatment of Open-Angle Glaucoma

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
***β*-Adrenergic Blocking Agents**						
Betaxolol	Relative β_1-selective	Generic	Solution	0.5	One drop twice a day	All reduce aqueous production of ciliary body
		Betoptic-S	Suspension	0.25	One drop twice a day	
Carteolol	Nonselective, intrinsic sympathomimetic activity	Generic	Solution	1	One drop twice a day	
Levobunolol	Nonselective	Betagan	Solution	0.25, 0.5	One drop twice a day	
Metipranolol	Nonselective	OptiPranolol	Solution	0.3	One drop twice a	

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
					day	
Timolol	Nonselective	Timoptic, Betimol, Istalol	Solution	0.25, 0.5	One drop every day—one to two times a day	
		Timoptic-XE	Gelling solution	0.25, 0.5	One drop every day[a]	
Adrenergic Agonists						
Non-specific Adrenergic Agent						
Dipivefrin**	Epinephrine prodrug	Propine	Solution	0.1	One drop twice a day	Increased aqueous humor outflow
α_2-Adrenergic Agonists						
Apraclonidine	Specific α_2-agonists	Iopidine	Solution	0.5 (U.D.), 1	One drop two to three times a day	Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow; only brimonidine has primary indication
Brimonidine		Alphagan P	Solution	0.2 (generic) 0.15 (brand/generic), 0.1	One drop two to three times a day	
Cholinergic Agonists Direct Acting						

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
Carbachol**	Irreversible	Carboptic, Isopto Carbachol	Solution	1.5, 3	One drop two to three times a day	All increase aqueous humor outflow through trabecular meshwork
Pilocarpine	Irreversible	Isopto Carpine, Pilocar	Solution	0.5, 1, 2, 4, 6	One drop two to three times a day	
					One drop four times a day	
		Pilopine HS**	Gel	4	Every 24 hours at bedtime	
Cholinesterase Inhibitors						
Echothiophate**		Phospholine Iodide	Solution	0.125	Once or twice a day	
Carbonic Anhydrase Inhibitors						
Topical						
Brinzolamide	All carbonic anhydrase inhibition	Azopt	Suspension	1	Two to three times a day	All reduce aqueous humor production of ciliary body
Dorzolamide		Trusopt Generic	Solution	2	Two to three times a day	
Systemic						
Acetazolamide		Generic	Tablet	125 mg, 250 mg	125-250 mg two	

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
					to four times a day	
			Injection	500 mg/vial	250-500 mg	
		Diamox Sequels	Capsule	500 mg	500 mg twice a day	
Methazolamide		Generic	Tablet	25 mg, 50 mg	25-50 mg two to three times a day	
Prostaglandin Analogs						
Latanoprost	Prostanoid agonist	Xalatan	Solution	0.005	One drop every night	Increases aqueous uveoscleral outflow and to a lesser extent trabecular outflow
Bimatoprost	Prostamide agonist	Lumigan	Solution	0.01, 0.03	One drop every night	
Travoprost	Prostanoid agonist	Travatan Z	Solution	0.004	One drop every night	
Tafluprost	Prostanoid agonist	Zioptan	Preservative free solution	0.0015	One drop every night	
Combinations						
Timolol–dorzolamide		Cosopt Generic	Solution	Timolol 0.5 dorzolamide 2	One drop twice daily	Reduce aqueous production
Timolol–brimonidine		Combigan	Solution	Timolol 0.5 brimonidine 0.2	One drop twice daily	Reduce aqueous production and

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
						increase uveoscleral outflow
Brinzolamide–brimonidine		Simbrinza		Brinzolamide 1 brimonidine 0.2	One drop three times daily	Reduce aqueous production and increase uveoscleral outflow
Timolol-latanoprost***		Xalacom	Solution	Timolol 0.5 latanoprost 0.005	One drop every night	All reduce aqueous production and increase uveoscleral outflow
Timolo-travoprost***		Duotrav	Solution	Timolol 0.5 travoprost 0.004	One drop every night	
Timolol-bimatoprost***		Ganfort	Solution	Timolol 0.5 Bimatoprost 0.03	One drop every night	

[a]Use of eyelid closure (ELC) technique for 5 minutes will increase the drug availability and reduce potential for local and systemic side effects.

**Often used as fourth-line agents; limited or no commerical availability.

***Not available in U.S.

The β-blocking agents produce ocular hypotensive effects by decreasing the production of aqueous humor by the ciliary body without producing substantial effects on aqueous humor outflow facility. The mechanism by which β-blockers decrease aqueous humor inflow remains controversial, but it is most frequently attributed to β_2-adrenergic receptor blockade in the ciliary body.

Five ophthalmic β-blockers are presently available: timolol, levobunolol, metipranolol, carteolol, and betaxolol. Timolol, levobunolol, and metipranolol are nonspecific β-blocking agents, whereas betaxolol is a relatively β_1-selective agent. Carteolol is a nonspecific blocker with intrinsic sympathomimetic activity. Despite differences in potency, selectivity, lipophilicity, and intrinsic

sympathomimetic activity, the five agents reduce IOP to a similar degree, although betaxolol has been reported to produce somewhat less lowering of IOP than timolol and levobunolol. Levobunolol, which possesses α-adrenergic effects, may be more effective than timolol and betaxolol in reducing IOP elevations after cataract surgery and may be more effective in controlling IOP than other agents when given as aqueous solutions on a once-daily schedule (up to 70% of patients). Timolol in the form of a gel-forming solution (Timoptic-XE) provides equivalent IOP control with once-daily administration when compared with the same concentration of the aqueous solution administered twice daily. The choice of a specific *β*-blocking agent generally is based on differences in adverse effect potential, individual patient response, and cost. Treatment with topical *β*-blockers may result in tachyphylaxis (short-term escape and long-term drift) in 20% to 25% of patients. The mean IOP reduction from baseline may be smaller for patients receiving topical *β*-blockers with concurrent systemic *β*-blockers.[9,33,34,35]

Local adverse effects with *β*-blockers usually are tolerable, although stinging on application occurs commonly, particularly with betaxolol solution (less with betaxolol suspension) and metipranolol. Other local effects include dry eyes, corneal anesthesia, blepharitis, blurred vision, and, rarely, conjunctivitis, uveitis, and keratitis. Some local reactions may be a result of preservatives used in the commercially available products. Switching from one agent to another or switching the type of formulation may improve tolerance in patients experiencing local adverse effects.

Systemic effects are the most important adverse effects of *β*-blockers. Drug absorbed systematically may produce decreased heart rate, reduced blood pressure, negative inotropic effects, conduction defects, bronchospasm, CNS effects, and alteration of serum lipids and may block the symptoms of hypoglycemia. The β_1-specific agents' betaxolol and possibly carteolol (as a consequence of intrinsic sympathomimetic activity) are less likely to produce the systemic adverse effects caused by *β*-adrenergic blockade, such as the cardiac effects and bronchospasm, but a real risk still exists. The use of timolol as a gel-forming liquid or betaxolol as a suspension allows for administration of fewer drugs per day and, therefore, reduces the chance for systemic adverse effects compared with the aqueous solutions.

Because of their systemic adverse effects, all ophthalmic *β*-blockers should be used with caution for patients with pulmonary diseases, sinus bradycardia, second- or third-degree heart block, congestive heart failure, atherosclerosis, diabetes, and myasthenia gravis, as well as for patients receiving oral *β*-blocker therapy. Use of the nasolacrimal occlusion (ELC; see Patient Education below for description) technique during administration reduces the risk or severity of systemic adverse effects, as well as optimizes response. Overall, *β*-adrenergic blocking agents are well tolerated by most patients, and most potential problems can be avoided by appropriate patient evaluation, drug choice, and monitoring of drug therapy. For patients failing or having an inadequate response to single-drug therapy with a *β*-blocking agent, the addition of a topical CAI, prostaglandin analog, or the α_2-adrenergic receptor agonist brimonidine usually will result in additional IOP reduction.[1,2,3,4,5,9,33,34,35]

α_2-Adrenergic Agonists

Brimonidine and the less lipid-soluble and less receptor-selective apraclonidine are α_2-adrenergic agonists structurally similar to clonidine. Apraclonidine is indicated and brimonidine is effective for prevention or control of postoperative or postlaser treatment increases in IOP. Brimonidine has a primary indication in OAG and is considered a second-line agent (often after a prostaglandin or β-blocker) or adjunctive agent. Apraclonidine is generally used only over the short term after ocular surgery due to high incidence of loss of control of IOP (tachyphylaxis) and a more severe and prevalent ocular allergy rate.

α_2-Agonists reduce IOP by decreasing the rate of aqueous humor production (some increase in uveoscleral outflow also occurs with brimonidine). The drugs reduce IOP by 18% to 27% at peak (2 to 5 hours) and by 10% at 8 to 12 hours. Comparative trials demonstrate a reduction in IOP similar to that obtained with 0.5% timolol. Use of brimonidine 0.2% every 8 to 12 hours appears to provide maximum IOP-lowering effects in long-term use. Use of ELC (see Patient Education below) may improve response and allow the longer dosing frequency (ie, every 12 hours). These agents have minimal effects on nocturnal IOP. Combinations of α_2-agonists with β-blockers, prostaglandin analogs, or CAIs produce additional IOP reduction.

An allergic-type reaction characterized by lid edema, eye discomfort, foreign-object sensation, itching, and hyperemia occurs in approximately 30% of patients with apraclonidine. Brimonidine produces this adverse effect in up to 8% of patients. This reaction commonly necessitates drug discontinuation. Systemic adverse effects with brimonidine include dizziness, fatigue, somnolence, dry mouth, and possibly a slight reduction in blood pressure and pulse. α_2-Agonists should be used with caution for patients with cardiovascular diseases, renal compromise, cerebrovascular disease, and diabetes, as well as in those taking antihypertensives and other cardiovascular drugs, monoamine oxidase inhibitors, and tricyclic antidepressants.

Brimonidine is also contraindicated in infants because of apneic spells and hypotensive reactions. In terms of overall efficacy and tolerability, brimonidine approximates that achieved with β-blockers.[1,2,3,4,9,33,34,35]

Brimonidine Purite 0.15% or 0.1% is a formulation of brimonidine in a lower concentration than the original product that contains a less corneal-toxic preservative than the commonly employed benzalkonium chloride. The newer formulations are as effective as the original because the more neutral pH of brimonidine Purite (0.15% pH 7.2; 0.1% pH 7.7) allows for higher concentrations of brimonidine in the aqueous humor with a similar reduction in IOP and a reduced incidence of ocular allergy.

A randomized clinical trial of topical brimonidine 0.2% twice daily preserved visual field better than treatment with topical timolol maleate 0.5% in patients with OAG and statistically normal IOP.[26] The IOP-lowering efficacy was similar between the two medications, suggesting that this finding was consistent with a non-IOP-related mechanism, possibly a neuroprotective action. However, validation of a neuroprotective role for brimonidine requires further research to confirm these results.[26,27] The combination product timolol 0.5% and brimonidine 0.2% (Combigan) may provide additional IOP lowering than either agent alone.[42]

Clinical Controversy...

Many animal trials demonstrate that brimonidine has excellent neuroprotective properties. Some clinicians believe that one of the major advantages of using brimonidine lies in its potential neuroprotective properties. However, neuroprotection has not been demonstrated in human trials, although a recent study produced the most clinically relevant data to date.[26,43]

Carbonic Anhydrase Inhibitors

Topical Agents

Carbonic anhydrase inhibitors reduce IOP by decreasing ciliary body aqueous humor secretion. CAIs appear to inhibit aqueous production by blocking active secretion of sodium and bicarbonate ions from the ciliary body to the aqueous humor.[1,2,9,33] The topical CAIs dorzolamide and brinzolamide, are well tolerated and are considered second line (after prostaglandins and β-lockers) for monotherapy or adjunctive therapy of POAG and OHT. These drugs reduce IOP by 15% to 26%.

Topical CAIs generally are well tolerated. Local adverse effects include transient burning and stinging, ocular discomfort and transient blurred vision, tearing, and, rarely, conjunctivitis, lid reactions, and photophobia. A superficial punctate keratitis occurs in 10% to 15% of patients. Brinzolamide produces more blurry vision but is less stinging than dorzolamide. Systemic adverse effects are unusual despite the accumulation of drug in red blood cells. Because of their favorable adverse-effect profile, topical CAIs provide a useful alternative agent for monotherapy or adjunctive therapy for patients with inadequate response to or who are unable to use other agents. The drugs may add additional IOP reduction for patients using other single or multiple topical agents. The usual dose of a topical CAI is one drop every 8 to 12 hours. Administration every 12 hours produces somewhat less IOP reduction than administration every 8 hours. Use of ELC should optimize response to CAI given at any interval.[1,2,3,9,33] The combination product timolol 0.5% and dorzolamide 2% (Cosopt) is dosed twice daily and produces equivalent IOP lowering to each product dosed separately. Both dorzolamide and timolol/dorzolamide (Cosopt) are now available as generic formulations. The combination product brimonidine 0.2% and brinzolamide 1% (Simbrinza) is dosed three times daily.

Systemic CAI Agents

Systemic CAIs are indicated for patients failing to respond to or tolerate maximum topical therapy. Systemic and topical CAIs should not be used in combination because no data exist concerning improved IOP reduction, and the risk for systemic adverse effects is increased. Oral CAIs reduce aqueous humor inflow by 40% to 60% and IOP by 25% to 40%. The available systemic CAIs (see Table 94-4) produce equivalent IOP reduction but differ for potency, adverse effects, dosage forms, and duration of action. Despite their excellent effects on elevated IOP of any etiology, the systemic CAIs frequently produce intolerable adverse effects. As a result, CAIs are considered third-line agents in the treatment of POAG and often used for short-term administration to lower IOP.

On average, only 30% to 60% of patients are able to tolerate oral CAI therapy for prolonged periods. Intolerance to CAI therapy results most commonly from a symptom complex attributable to systemic

acidosis and including malaise, fatigue, anorexia, nausea, weight loss, altered taste, depression, and decreased libido. Other adverse effects include renal calculi, increased uric acid, blood dyscrasias, diuresis, and myopia. Elderly patients do not tolerate CAIs as well as younger patients. The available CAIs produce the same spectrum of adverse effects; however, the drugs differ in the frequency and severity of the adverse effects listed.

Carbonic anhydrase inhibitors should be used with some caution in patients with sulfa allergies (all CAIs, topical or systemic, contain sulfonamide moieties, although cross-sensitivity is thought to be very low), sickle cell disease, respiratory acidosis, pulmonary disorders, renal calculi, electrolyte imbalance, hepatic disease, renal disease, diabetes mellitus, or Addison's disease. Concurrent use of a CAI and a diuretic may rapidly produce hypokalemia. High-dose salicylate therapy may increase the acidosis produced by CAIs, whereas the acidosis produced by CAIs may increase the toxicity of salicylates.[1,2,3,4,9,33,34,35]

Parasympathomimetic Agents

The parasympathomimetic (cholinergic) agents reduce IOP by increasing aqueous humor trabecular outflow. The increase in outflow is a thought to be a result of physically pulling open the trabecular meshwork secondary to ciliary muscle contraction, thereby reducing resistance to outflow. These agents may actually reduce uveoscleral outflow. Their use as primary or even adjunctive agents in the treatment of glaucoma has decreased significantly because of local ocular adverse effects and/or frequent dosing requirements.

Pilocarpine, the parasympathomimetic agent of choice in POAG, is available as an ophthalmic solution and a hydrophilic polymer gel (see Table 94-4). Pilocarpine produces similar (20% to 30%) reductions in IOP as those seen with β-blocking agents. Pilocarpine in POAG is initiated as 1% solution, one drop three to four times daily. The use of ELC improves response and reduces the need for an every-6-hour dosing frequency. The use of one drop of 2% pilocarpine every 6 to 12 hours and ELC provides optimal response in many patients. Both drug concentration and frequency may be increased if IOP reduction is inadequate. Patients with darkly pigmented eyes frequently require higher concentrations of pilocarpine than do patients with lightly pigmented eyes. Concentrations of pilocarpine above 4% rarely improve IOP control in patients.

Pilocarpine 4% gel (Pilopine HS) once daily is equivalent to treatment with pilocarpine solution 4% four times daily or timolol 0.5% twice daily. Ocular adverse effects of pilocarpine include miosis, which decreases night vision and vision in patients with central cataracts. Visual field constriction may be seen secondary to miosis and should be considered when evaluating visual field changes in a glaucoma patient. Pilocarpine ciliary muscle contraction produces accommodative spasm, particularly in young patients still able to accommodate (prepresbyopic). Pilocarpine may also produce frontal headache, brow ache, periorbital pain, eyelid twitching, and conjunctival irritation or injection early in therapy, which tends to decrease in severity over 3 to 5 weeks of continued therapy.

Cholinergics produce a breakdown of the blood-aqueous humor barrier and may result in a worsening of an ocular inflammatory reaction or condition. Systemic cholinergic adverse effects of pilocarpine—such as diaphoresis, nausea, vomiting, diarrhea, cramping, urinary frequency,

bronchospasm, and heart block—may be seen. Other adverse effects associated with direct-acting miotics include retinal tears or detachment, allergic reaction, permanent miosis, cataracts, precipitation of CAG, and, rarely, miotic cysts of the pupillary margin.

Carbachol is a potent direct-acting miotic agent; its duration of action is longer than that of pilocarpine (8 to 10 hours) because of resistance to hydrolysis by cholinesterases. This drug also may act as a weak inhibitor of cholinesterase. Patients with an inadequate response to or intolerance of pilocarpine as a result of ocular irritation or allergy frequently do well on carbachol. The ocular and systemic adverse effects of carbachol are similar to but more frequent, constant, and severe than those of pilocarpine.[33] Clinical use of carbachol is limited.

Echothiophate is a cholinesterase inhibitor, is used in the treatment of POAG. It is a long-acting, relatively irreversible agent (limited commercial availability; see Table 94-4). This agent is a potent inhibitor of pseudocholinesterase, but also inhibits true cholinesterase. Because of the serious ocular and systemic toxic effects of echothiophate, it is reserved primarily for patients who are either not responding to or are intolerant of other therapy. Because of its cataractogenic properties, most ophthalmologists use this agent only for patients without lenses (aphakia) and for patients with artificial lenses (pseudophakia). The ocular and periocular parasympathomimetic adverse effects are more common and more severe than with pilocarpine or carbachol.

In addition to the parasympathomimetic effects, echothiophate may produce severe fibrinous iritis (particularly with the irreversible inhibitors), synechiae, iris cysts, conjunctival thickening, occlusion of the nasolacrimal ducts, and cataracts. The inhibition of systemic pseudocholinesterase by echothiophate decreases the rate of succinylcholine hydrolysis, resulting in prolonged muscle paralysis. Echothiophate should be discontinued at least 2 weeks before procedures in which succinylcholine is used.

The role of echothiophate in glaucoma is limited by its frequency and potential toxicity. For phakic patients, cholinesterase inhibitors should be administered only if intolerance or failure results with other antiglaucoma medications. Echothiophate has been shown to provide additional IOP-lowering effects when used with β-blockers, CAIs, and sympathomimetic (adrenergic) agents. As with all agents for glaucoma, therapy should be initiated with lower concentrations of these agents. A once-daily administration frequency should be used for most patients unless very high IOP is present.

Use of ELC likely improves response, reduces systemic adverse effects, and should be performed by all patients administering echothiophate. The drug should be used with caution for patients with asthma, retinal detachments, narrow angles, bradycardia, hypotension, heart failure, Down's syndrome, epilepsy, parkinsonism, peptic ulcer, and ocular inflammation, as well as in those receiving cholinesterase inhibitor therapy for myasthenia gravis or exposure to carbamate or organophosphate insecticides and pesticides.

Dipivefrin

The mechanism of action by which dipivefrin (an epinephrine prodrug) lowers IOP has not been fully elucidated; however, a β_2-receptor–mediated increase in outflow facility through the trabecular

meshwork and the uveoscleral route appears to be the primary mechanism. Compared with β-blockers or miotics, dipivefrin is less effective for reducing IOP. With the advent of the better-tolerated and more-efficacious agents to treat glaucoma, the clinical use of epinephrines has decreased dramatically and commercial availability discontinued.

A factor limiting the usefulness of dipivefrin is the high frequency of local ocular adverse effects. Tearing, burning, ocular discomfort, brow ache, conjunctival hyperemia, punctate keratopathy, allergic blepharoconjunctivitis, rare loss of eyelashes, stenosis of the nasolacrimal duct, and blurred vision may occur. Prolonged use (>1 year) may result in deposition of pigment (adrenochrome) in the conjunctiva and cornea. Pigment also may deposit in soft contact lenses, turning them black. Dipivefrin may produce mydriasis (particularly when combined with a β-blocker) and may precipitate acute CAG in patients with narrow anterior chambers. A transient increase in IOP may occur with initial therapy, particularly for patients not using other antiglaucoma medications. A relative contraindication to the use of dipivefrin is aphakia (ie, after cataract removal) or lens dislocation because of the development of swelling of the macular portion of the retina. The edema is dose dependent and disappears with drug discontinuation.

Systemic adverse effects of dipivefrin include headache, faintness, increased blood pressure, tachycardia, arrhythmias, tremor, pallor, anxiety, and increased perspiration. Dipivefrin should be used with caution for patients with cardiovascular diseases, cerebrovascular diseases, aphakia, CAG, hyperthyroidism, and diabetes mellitus, as well as for patients undergoing anesthesia with halogenated hydrocarbon anesthetics. Using ELC with dipivefrin will improve therapeutic response and reduce the risk of systemic adverse effects.[9,33,34,35]

Future Drug Therapies

It is hoped that new agents, improved formulations, and novel approaches to the reduction of IOP and other methods of prevention of glaucomatous visual field loss will provide more effective and better-tolerated therapies. Most areas of glaucoma development continue to focus on drugs that reduce IOP by either reducing aqueous production or increasing outflow. Classes of medication in development include the Rho kinase inhibitors (ROCK), which induce changes in the trabecular meshwork and thereby reduce impedance to aqueous outflow. These agents may also possess neuroprotective effects and produce an increase in ocular blood flow. Other classes of drugs in development include adenosine-1 receptor agonists, cannabinoids, serotonin agonists, dopamine agonists, nitric oxide/carbon dioxide modulators, and hydroxysteroid dehydrogenase inhibitors. Agents with dual ROCK inhibition and norepinephrine transport inhibition are in later clinical phase trials. Agents that are neuroprotective and act through mechanisms other than IOP reduction are also in development and are likely to be part of glaucoma therapy in the future.[7,8,27]

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of drug therapy for the patient with glaucoma is to preserve visual function through reduction of IOP to a level at which no further optic nerve damage occurs. Because of the poor relationship between IOP and optic nerve damage, no specific target IOP exists. Indeed, drugs

used to treat glaucoma may act in part to halt visual field loss through mechanisms separate from or in addition to IOP reduction, such as improvements in retinal or choroidal blood flow. Often a 25% to 30% reduction is desired, but greater reductions (40% to 50%) may be desired for patients with initially high IOPs. For patients with glaucoma, an IOP of less than 21 mm Hg (2.8 kPa) generally is desired, with progressively lower target pressures needed for greater levels of glaucomatous damage. Even lower IOPs (possibly even below 10 mm Hg [1.3 kPa]) are required for patients with very advanced disease, those showing continued damage at higher IOPs, and those with normal-tension glaucoma and pretreatment pressures in the low to middle teens. The IOP considered acceptable for a patient is often a balance of desired IOP and acceptable treatment-related toxicity and of patient quality of life.

PATIENT EDUCATION

7 An important consideration for patients failing to respond to drug therapy is adherence. Poor adherence or nonadherence occurs in 25% to 60% of glaucoma patients.

A large percentage of patients also fail to use topical ophthalmic drugs correctly. Patients should be taught the following procedure:

1. Wash and dry the hands; shake the bottle if it contains a suspension.
2. With a forefinger, pull down the outer portion of the lower eyelid to form a “pocket” to receive the drop.
3. Grasp the dropper bottle between the thumb and fingers with the hand braced against the cheek or nose and the head held upward.
4. Place the dropper over the eye while looking at the tip of the bottle; then look up and place a single drop in the eye.
5. The lids should be closed (but not squeezed or rubbed) for 5 minutes after instillation. This increases the ocular availability of the drug and reduces systemic absorption.
6. Recap bottle and store as instructed.

Note that many patients are physically unable to administer their own eye drops without assistance. ELC also should be used to improve ocular bioavailability and reduce systemic absorption.[1,2,3,4] The patient induces ELC for 5 minutes by gently closing the eyes. ELC decreases nasolacrimal drainage of drug, thereby decreasing the amount of drug available for systemic absorption by the nasopharyngeal mucosa. The use of ELC may improve drug response significantly, reduce adverse effects, and allow less-frequent dosing intervals and the use of lower drug concentrations.

Use of more than one drop per dose increases costs, does not improve response significantly, and may increase adverse effects. When two drugs are to be administered, instillations should be separated by at least 5 minutes (preferably 10 minutes) to prevent the drug administered first from being washed out. The patient should be taught not to touch the dropper bottle tip with eye, hands,

or any surface.

Adherence to glaucoma therapy usually is inadequate, and it always should be considered as a possible cause of drug therapy failure. Assessment of adherence by healthcare providers generally is poor; so all patients should be encouraged continually to administer prescribed therapy diligently as instructed. To improve adherence, the patient, family, and care providers should be fully informed of the expectations of therapy and the need to continue therapy despite a lack of symptoms. Possible adverse effects of the medication and ways to reduce them should be discussed. Adherence will be improved by good communication, simplified and well tolerated dosing regimens, reminder devices, education, close monitoring, and individualized care planning.[1,2,3,4,6,44]

CONCLUSION

The glaucomas are a group of primary and secondary diseases whose management presents a considerable challenge to the clinician. Successful therapy requires rational use of antiglaucoma medications and patient adherence to the selected regimen, combined with conscientious monitoring for adverse effects and disease progression. The reward for successful therapy is considerable—the maintenance of vision. The overview of the clinical findings, pathology, and drug therapy presented in this chapter provides the clinician with the fundamentals necessary to understand and treat glaucoma.

Chapter 95: Allergic Rhinitis

J. Russell May

INTRODUCTION

KEY CONCEPTS

- 1 Allergic rhinitis is a common disease. Prevention measures and treatment are justified in most cases because of the potential for complications.
- 2 Because an immune response to allergens results in release of inflammatory mediators that cause allergic rhinitis symptoms, patients must understand the rationale for proper timing and administration of prophylactic regimens.
- 3 Avoidance of allergens is difficult and it may be impractical to expect full success.
- 4 Antihistamines offer an effective option for treating both seasonal and persistent allergic rhinitis.
- 5 Intranasal steroids are highly effective in patients who use them properly.
- 6 While immunotherapy is the only disease-modifying treatment of allergic rhinitis, expense, potential risks, and the major time commitment required make patient selection critical.

Allergic rhinitis involves inflammation of the nasal mucous membrane. In a sensitized individual, allergic rhinitis occurs when inhaled allergenic particles contact mucous membranes and elicit a specific response mediated by immunoglobulin E (IgE). This acute response involves the release of inflammatory mediators and is characterized by sneezing, nasal itching, and watery rhinorrhea, often associated with nasal congestion. Itching of the throat, eyes, and ears frequently accompanies allergic rhinitis.

Allergic rhinitis may be regarded as seasonal allergic rhinitis, commonly known as *hay fever*, or persistent allergic rhinitis (formerly known as perennial rhinitis). Seasonal rhinitis occurs in response to specific allergens usually present at predictable times of the year, during plants' pollination (typically the spring or fall). Seasonal allergens include pollen from trees, grasses, and weeds. Persistent allergic rhinitis is a year-round disease caused by nonseasonal allergens, such as house dust mites, animal dander, and molds, or multiple allergic sensitivities. It typically results in less variable, chronic symptoms. Many patients have a combination of these two types of allergic rhinitis, with symptoms year-round and seasonal exacerbations.

EPIDEMIOLOGY

1 Allergic rhinitis is one of the most common diseases affecting adults and is the most common chronic disease in children in the United States, generating $2 to $5 billion in direct healthcare cost each year.[1] Sensitization to inhaled allergens is increasing with a prevalence of 15% to 30% in the United States.[2] Patients may be limited in their ability to carry out normal daily functions; higher levels of general fatigue, mental fatigue, anxiety, depressive disorders, and learning disabilities (secondary to sleep loss and fatigue) are possible.

In addition, the impact of allergic rhinitis goes well beyond these CNS issues. Allergic rhinitis is associated with several other serious medical conditions, including asthma, chronic rhinosinusitis, otitis media, nasal polyposis, respiratory infections, and orthodontic malocclusions.

ETIOLOGY

The development of allergic rhinitis is determined by genetics, allergen exposure, and the presence of other risk factors. A family history of allergic rhinitis, atopic dermatitis, or asthma suggests that rhinitis is allergic. The risk of developing allergic disease appears to increase if one parent is atopic and further increases if two are allergic; however, small sample sizes and the lack of reproducibility prevent generalization.[3]

Allergen exposure is another necessary factor. For allergic rhinitis to occur, an individual must be exposed over time to a protein that elicits the allergic response in that individual. Many potential sufferers never develop symptoms because they do not come into contact with the allergen that would produce symptoms in them.

Evidence suggests microbial exposure in the first years of life could help prevent allergic disease by stimulating a nonatopic immune response.[4] Farm children are exposed to higher concentrations of endotoxin, derived from cell walls of gram-negative bacteria, in barns and dust around the farmhouse. Consumption of nonpasteurized farm milk may cause further exposure. These observations have led to the idea that allergic disease could be prevented by proactively increasing exposure to harmless bacteria early in life (see Alternative Treatment Options below). This could explain why positive skin tests indicating allergen sensitization have been observed more frequently for people in higher socioeconomic classes and for people who live in suburban areas.

Other predisposing factors include an elevated serum IgE (>100 international units/mL [kIU/L]) before the age of 6 years, eczema, and heavy exposure to secondhand cigarette smoke.[5]

Allergens

Allergens that produce seasonal rhinitis include protein components of airborne pollen grains, often enzymes, from a variety of trees, grasses, and weeds. Ragweed and grass pollen are the most common offenders in the United States; however, this varies with the geographic region. In general, tree pollens cause symptoms in the spring, grass pollens cause symptoms in the late spring and summer, and weed pollens are the culprits from late summer through fall. Patients who are hypersensitive to all three may have overlapping problem periods and may be described as having perennial rhinitis when they are actually experiencing prolonged seasonal rhinitis. For this reason and the fact that most patients with seasonal problems are sensitive to at least some of the perennial allergens, there is little practical difference between the two types of allergic rhinitis. To complicate matters further, the antigenic components of many grasses —including fescue, Kentucky bluegrass, orchard, redtop, and timothy—cross-react extensively. By contrast, most tree allergens are antigenically distinct. Trees with allergenic pollen include ash, beech, birch, cedar, hickory, maple, oak, poplar, and sycamore. Flowering plants that depend on insect pollination do not cause allergic rhinitis because their pollen is too heavy and sticky and is not carried in the air.

Smaller mold spores are also important but cause allergy much less frequently. Various spores are present year-round; however, mold growth on decaying vegetation increases seasonally. Just walking through uncut fields or raking leaves can increase exposure. Thus, mold spores can be responsible for both perennial and seasonal allergies.

Indoor allergens are always present. Most important among these are house-dust mite fecal proteins, animal dander, cockroaches, and certain mold species. Dust mite levels are on the rise, possibly because of the construction of energy-efficient homes and offices with reduced ventilation and increased humidity, use of wall-to-wall carpeting, and the popularity of cool-water detergents and cold-water washing.[3]

PATHOPHYSIOLOGY

Knowledge of nasal physiology aids in the understanding of allergic rhinitis. The nose performs three “air conditioning” functions to prepare incoming gases for the lungs. During the fraction of a second that air is in the nose, it is heated, humidified, and cleaned. The cleaning process plays a role in the development of allergic rhinitis. As the air passes through the nose, the turbulence throws particulate matter against a mucous blanket. The rhythmic movements of the nasal cilia cause the mucous blanket to move posteriorly at approximately 9 mm/min, where it is eventually swallowed; thus, trapped foreign particles are removed via the GI tract and do not reach the lungs. It also concentrates foreign protein material into the posterior nasopharynx, where lymph tissues identify them and produce most of the allergic antibody that drives allergic rhinitis.

The vascular tissue in the nose is erectile. Stimulation of sympathetic fibers causes vasoconstriction, reduction in erectile tissue size and the size of the membranes and turbinates, and airway widening. Parasympathetic stimulation causes opposite effects.

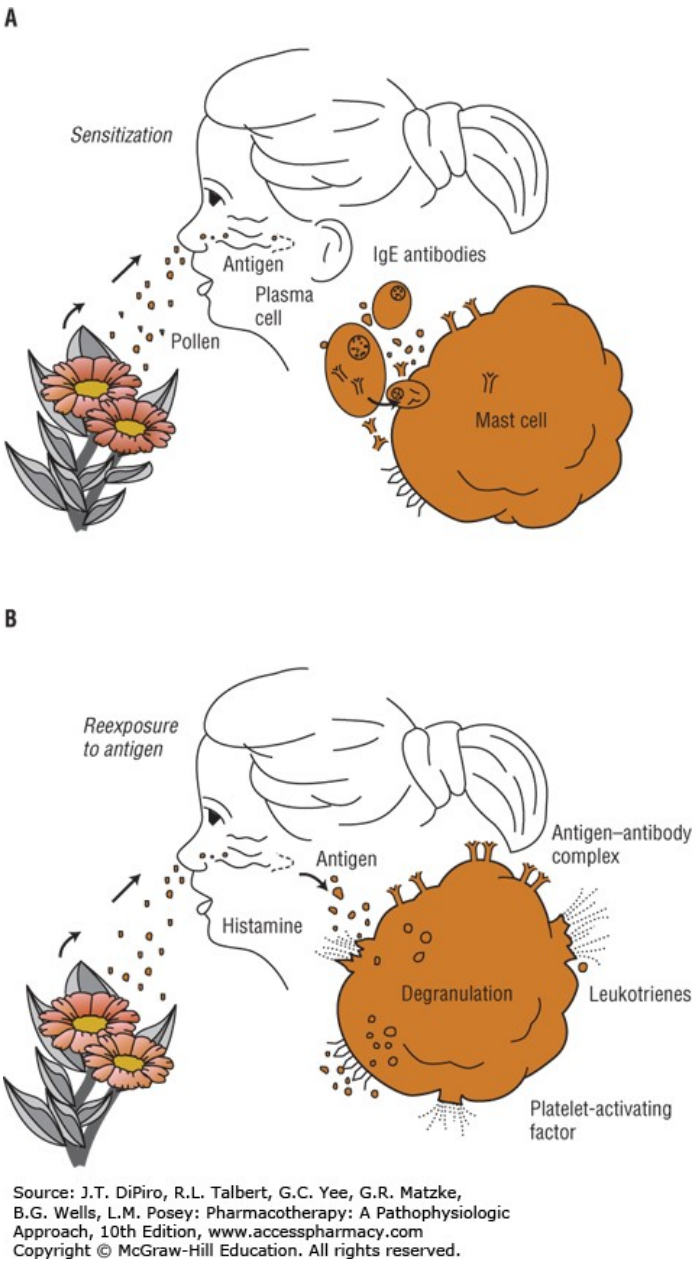
Mast cells, in the nasal membranes, participate in the regulation of nasal patency by releasing mediators such as histamine. These are described below.

Immune Response to Allergens

Allergic reactions in the nose are mediated by antigen–antibody responses when allergens interact with specific IgE molecules bound to nasal mast cells and basophils. In allergic people, these cells are increased in both number and reactivity. During inhalation, airborne allergens enter the nose and are processed by lymphocytes, which produce antigen-specific IgE, thereby sensitizing genetically predisposed hosts to those agents. Upon nasal re-exposure, IgE bound to mast cells interacts with airborne allergen, triggering release of inflammatory mediators in vastly increased quantities (**Fig. 95-1**).[6]

FIGURE 95-1

Allergen sensitization and the allergic response. *A*. Exposure to antigen stimulates IgE production and sensitization of mast cells with antigen-specific IgE antibodies. *B*. Subsequent exposure to the same antigen produces an allergic reaction when mast cell mediators are released.



Both immediate and late-phase reactions are observed after allergen exposure. The immediate reaction occurs within seconds to minutes, resulting in the rapid release of preformed mediators and newly generated mediators from the arachidonic acid cascade as the mast cell membrane is disturbed (**Table 95-1**). These mediators of immediate hypersensitivity include histamine, some leukotrienes, prostaglandin D_2, tryptase, and kinins.[6] In addition, the mast cell has been found to be a source of several cytokines that probably are relevant to the chronicity of the mucosal inflammation that characterizes allergic rhinitis.[7] Sensory nerve stimulation produces itching, and sneezing occurs via reflex stimulation of efferent vagal pathways. Neuropeptides substance P and calcitonin gene-related peptide from nonadrenergic, noncholinergic nerves affect vascular engorgement directly and via modulation of sympathetic tone. Histamine produces rhinorrhea, itching, sneezing, and obstruction, with the obstruction only partially blocked by H_1- or H_2-blocking agents.[8] Nasal obstruction is also caused by kinins, prostaglandin D_2, and leukotrienes C_4/D_4. Kinins, when directly administered, produce pain rather than itching.[9] These inflammatory mediators also produce vasodilation, increased vascular permeability, and production of increased nasal secretions.[10]

TABLE 95-1 Mast Cell Mediators

Mediators	Effects

Mediators	Effects
Preformed and rapidly released	
Histamine	Stimulates irritant receptors
	Pruritus
	Vascular permeability
	Mucosal permeability
	Smooth muscle contraction
Neutrophil chemotactic factor	Influx of inflammatory cells
Eosinophil chemotactic factor	Influx of inflammatory cells
Kinins	Vascular permeability
N-α-tosyl L-arginine methyl esterase	Vascular permeability
Newly generated	
Leukotrienes	Smooth muscle contraction
	Vascular permeability
	Mucus secretion
	Chemotaxis
	Neutrophil chemotaxis
Thromboxanes	Smooth muscle spasm
Platelet-activating factor	Mucus secretion
	Airway permeability
	Chemotaxis
	Vascular permeability
Granule matrix contents	
Heparin	Antiinflammatory
Tryptase	Protein hydrolysis
Kallikrein	Protein hydrolysis

Four to eight hours after the initial exposure to an allergen, a late-phase reaction occurs symptomatically in 50% of allergic rhinitis patients.[11] This response, thought to be caused by cytokines released primarily by mast cells and thymus-derived helper lymphocytes, is characterized by profound infiltration and activation of migrating cells. This inflammatory response likely is responsible for the persistent, chronic symptoms of allergic rhinitis, including nasal congestion. The inflamed mucosa becomes hyperresponsive, a state characterized by exacerbation of nasal reactions to nonspecific or irritant triggers. In this state, the patient also reacts to increasingly lower amounts of the same allergen.[12] The process also causes significant increases in nonspecific irritability (as seen in asthma) and the notion among patients that they have become "allergic to everything."

CLINICAL PRESENTATION

The patient with allergic rhinitis typically complains of clear rhinorrhea, paroxysms of sneezing, nasal congestion, postnasal drip, and pruritic eyes, ears, nose, or palate. Symptoms of allergic conjunctivitis are associated more frequently with seasonal than perennial allergic rhinitis, because a majority of the perennial allergens, such as dust mites and molds, are indoors, where air velocity is too low for substantial deposition of allergenic particles on the conjunctivae. However, with heavy exposure from animal or mold allergens, allergic conjunctivitis can be pronounced.

Symptoms secondary to the late-phase reaction, predominantly nasal congestion, begin 3 to 5 hours after antigen exposure and peak at 12 to 24 hours. Subsequent symptoms, both allergic and irritant, are elicited more easily because of the priming effect. For instance, a ragweed-sensitive patient, when exposed to ragweed pollen out of season, responds with modest symptoms and may be very tolerant of irritants such as air pollution or tobacco smoke. During the ragweed season, however, when the nasal mucosa is already inflamed, exposure to small doses of pollen or to irritants to which the patient is usually tolerant elicits a response clinically indistinguishable from the patient's allergy.

Diagnostic Considerations

Allergic rhinitis is distinguished from other causes of rhinitis by a thorough history, physical examination, and certain diagnostic tests. The medical history consists of a careful description of symptoms, environmental factors and exposures, results of previous therapy, use of other medications, previous nasal injuries, previous nasal or sinus surgery, family history, and the presence of other medical problems and

medications. Historical identification of specific causative allergens may be difficult. For example, a reaction induced by mowing the lawn may not be caused by grass pollens but may be caused by the disturbance of various weeds, molds, or other plants in the lawn. With perennial allergic rhinitis, the cause-effect and temporal relationships are less clear, making the diagnosis of specific causes more difficult, especially with such covert allergens as house dust mites and molds.

In children, physical examination may reveal allergic shiners—a transverse nasal crease caused by repeated rubbing of the nose—and adenoidal breathing. Pale, bluish, edematous nasal turbinates coated with thin, clear secretions are characteristic of a purely allergic reaction. Tearing, conjunctival injection and edema, and periorbital swelling may be present. Physical findings are generally less clear-cut for adults.

Nasal scrapings will provide a representative sample of cells infiltrating the nasal mucosa and can be helpful in supporting the diagnosis.[13] Microscopic examination of the nasal smear from an allergic individual typically will show numerous eosinophils. The blood eosinophil count may be elevated in allergic rhinitis, but it is nonspecific and has limited usefulness.[14]

Allergy testing can help determine whether a patient's rhinitis is caused by an allergen. Immediate-type hypersensitivity skin tests are used for the diagnosis of allergic rhinitis. These include skin tests performed by the percutaneous route, where the diluted allergen is pricked or scratched into the skin surface, or by the intradermal route, where a small volume (0.01 to 0.05 mL) of diluted allergen is injected between the layers of skin. Percutaneous tests are more commonly performed and are safer and more generally accepted, with intradermal tests reserved for patients requiring confirmation in special circumstances.

In all allergy testing, a positive control (histamine) and a negative control are essential for correct interpretation. After 15 minutes of the application of the allergen, the site is examined for a positive reaction (defined as a wheal-and-flare reaction). Because correct testing is done with extremely minute doses, undetectable by nonsensitized individuals, this reaction is evidence of the presence of mast cell-bound IgE specific to the allergen tested. Many, but not all, common allergens are available as standardized allergenic extracts.

Antihistamines and a few other medications interfere with the wheal-and-flare reaction. First-generation antihistamines should be stopped at least 3 to 5 days before testing, and second-generation, nonsedating antihistamines should be stopped for 10 days before testing.[15] Medications with antihistamine properties (eg, sympathomimetic agents, phenothiazines, and tricyclic antidepressants) should be discontinued if possible before skin testing.

The radioallergosorbent test (RAST) was the first commonly used method for detecting IgE antibodies in the blood that are specific for a given allergen. Several other quantitative assays that include a reference curve calculated against standardized IgE are available. These tests are highly specific but may be slightly less sensitive than percutaneous tests.

Complications

Not only is allergic rhinitis aggravating, it frequently leads to further complications, particularly if the patient does not receive adequate treatment. Symptoms of untreated rhinitis may lead to disturbed sleep, chronic malaise, fatigue, and poor work or school performance. Patients often are plagued by loss of smell or taste, with sinusitis or polyps underlying many cases of allergy-related hyposmia. Postnasal drip with cough, hoarseness, and even vocal polyps also can be bothersome.

The role of allergic rhinitis in the development of acute otitis media or chronic middle ear effusion is often less clear. Children with allergic rhinitis appear to be at greater risk of these conditions because of nasal obstruction and negative middle ear pressure. Hearing problems in children related to middle ear effusion may lead to delayed development of language in young children or to school problems in older children.

Permanent facial disfigurement can result from chronic allergic rhinitis.[16] The chronic edema and venous stasis may contribute to the development of a high-arched, V-shaped palate. Mouth breathing caused by nasal obstruction can be responsible for dental malocclusion and orthodontic problems. Constant upward rubbing of the nose (allergic salute) can cause a transverse crease across the lower nose; nasal congestion often leads to venous pooling and dark circles under the eyes known as *allergic shiners*.

Allergic rhinitis is clearly associated with asthma. The prevalence of asthma in patients without rhinitis is less than 2%, while the prevalence of asthma in patients with rhinitis is 10% to 40%.[17] It is not known if allergic rhinitis is an early clinical manifestation of asthma or if the nasal disease itself is causative for asthma.

Recurrent sinusitis and chronic sinusitis are relatively common complications of allergic rhinitis. The structure of the mucus blanket breaks down, with decreased water production by serous glands, leaving hair cells trapped in the thicker mucus layer. This greatly reduces the clearance of trapped bacteria and offers ideal breeding grounds for the bacteria. Nasal polyps are less common but nonetheless bothersome; they require specific therapy but may improve with management of the underlying allergic state. Epistaxis also can be a problem; it is related to mucosal hyperemia and inflammation.

TREATMENT

A number of options exist for the treatment of allergic rhinitis, both nonpharmacologic and pharmacologic. Many of the pharmacologic options are available over-the-counter requiring that patients receive guidance in the selection process by a healthcare professional to obtain the most appropriate therapy. Both over-the-counter and prescription choices must be guided by patient-specific symptomatology and patient characteristics as described in this chapter.

Desired Outcomes

The therapeutic goal for patients with allergic rhinitis is to minimize or prevent symptoms and prevent long-term complications. This goal should be accomplished with no or minimal adverse medication effects and reasonable medication expenses. The patient should be able to maintain a normal lifestyle, including participating in outdoor activities, yard work, and playing with pets as desired.

General Approach to Treatment

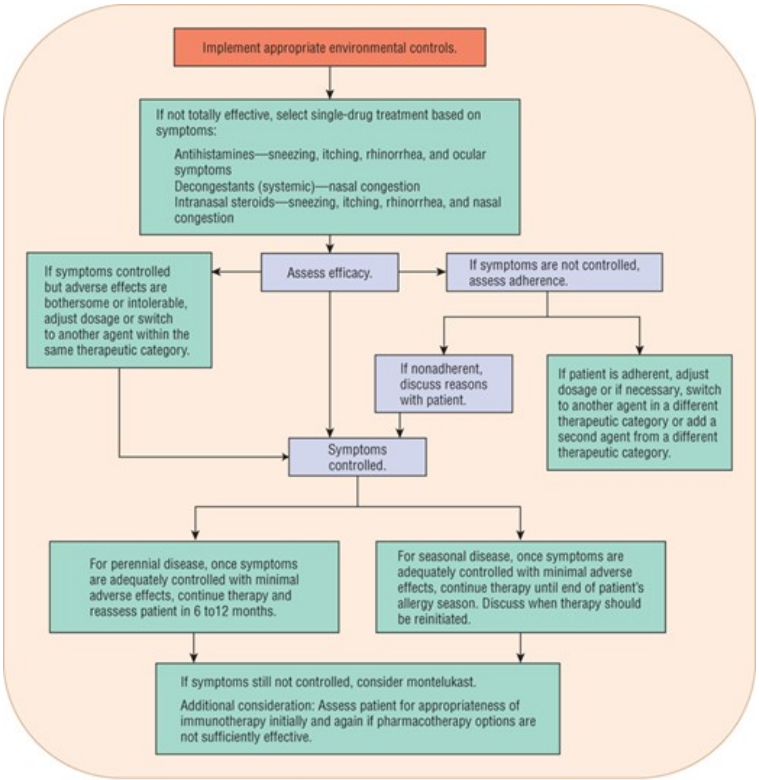
Once the causative allergens and the specific symptoms are identified, management consists of three possible approaches: (a) allergen avoidance, (b) pharmacotherapy for prevention or treatment of symptoms, and (c) specific immunotherapy. The pharmacotherapy for symptoms approach includes several options that are based on patient-specific information (**Table 95-2**). **Figure 95-2** depicts an algorithm for treatment options.

TABLE 95-2 Pharmacotherapeutic Options for Allergic Rhinitis

Medication Classes	Symptoms Controlled	Comments
Antihistamines		
Systemic	Sneezing, rhinorrhea, itching, conjunctivitis	For seasonal allergic rhinitis, begin treatment before allergen exposure. Nonsedating agents should be tried first. If ineffective or too expensive for the patient, the older agents may be used. For perennial allergic rhinitis, use an intranasal steroid as an alternative to or in combination with systemic antihistamines
Ophthalmic	Conjunctivitis	Logical addition to nasal steroids if ocular symptoms are present
Intranasal	Sneezing, rhinorrhea, nasal pruritus	Option for seasonal allergic rhinitis. Warn patients of potential drowsiness
Decongestants		
Systemic	Nasal congestion	Only needed when nasal congestion is present
Topical	Nasal congestion	Only needed when nasal congestion is present. Do not exceed 3-5 days
Intranasal corticosteroids	Sneezing, rhinorrhea, itching, nasal congestion	For seasonal allergic rhinitis, an option when congestion is present. Must begin therapy before allergen exposure. Excellent choice for perennial rhinitis
Mast cell stabilizers	See comments	Prevents symptoms; therefore, for seasonal allergic rhinitis, use before offending allergen's season starts. For perennial rhinitis, improvement may not be seen for up to 1 month
Intranasal anticholinergics	Rhinorrhea	Reserve for use when above therapies fail or cannot be tolerated
Leukotriene receptor antagonists	See comments	When combined with antihistamines, more effective than antihistamines alone. May be used as monotherapy in children with asthma and coexisting allergic rhinitis

FIGURE 95-2

Treatment algorithm for allergic rhinitis.



Nonpharmacologic Therapy

Avoidance of offending allergens is the most direct method of preventing allergic rhinitis, but it is often the most difficult to accomplish, especially for perennial allergens. Mold growth can be reduced by maintaining household humidity below 50% and removing obvious growth with bleach or disinfectant. Patients sensitive to animals will benefit most by removing pets from the home;[18] however, most animal lovers are reluctant to comply with this approach. Dog and cat allergens may produce symptoms in sensitized individuals.[7] After removing a cat from the home, it may take as long as 20 weeks for the home to reach allergen levels of a pet-free home. Washing cats weekly may reduce allergens but studies are inconclusive.[7] Some dogs display antigens more profusely than do others; clinically, a sensitized person may tolerate one animal better than another.

Evidence to support avoidance measures for house dust mites suggests that accepted notions for reducing exposure have little practical effect.[18] While some evidence shows allergen levels can be reduced by washing bedding on a hot cycle, replacing carpets with hard flooring and using vacuum cleaners with HEPA filters, there is no documented evidence for a clinical benefit. Only encasing bedding in impermeable covers has some clinical benefit in children but not adults. Future studies are needed to determine if environmental control of allergens may be helpful in forestalling further rhinitis and preventing later asthma.

General recommendations have been made to prevent poor air quality in homes.[19] Steps include avoiding wall-to-wall carpeting, using moisture control to prevent the accumulation of molds, and controlling sources of pollution such as cigarette smoke. Patients with seasonal allergic rhinitis should keep windows closed and minimize time spent outdoors during pollen seasons. Immediate hair washing and change of clothes are recommended upon returning indoors. Use of fans that direct outside air into the house should be avoided. Filter masks can be worn while gardening or mowing the lawn. Avoidance of upholstery and stuffed toys in the bedroom are easy steps to accomplish. **Table 95-3** summarizes recommendations for environmental control. These measures are intended to be a part of a comprehensive treatment strategy that will likely include pharmacotherapy and, in selected cases, immunotherapy.

TABLE 95-3 Environmental Controls to Prevent Allergic Rhinitis

Pollens

- Keep windows and doors closed during pollen season
- Avoid fans that draw in outside air
- Use air conditioning

- If possible, eliminate outside activities during times of high pollen counts
- Shower, shampoo, and change clothes following outdoor activity
- Use a vented dryer rather than an outside clothesline

Molds

- Use similar controls as above
- Avoid walking through uncut fields, working with compost or dry soil, and raking leaves
- Clean indoor moldy surfaces
- Fix all water leaks in home
- Reduce indoor humidity to <50% if possible

House dust mites

- Encase mattress, pillow, and box springs in an allergen-impermeable cover
- Wash bedding in hot water weekly
- Remove stuffed toys from bedroom
- Minimize carpet use and upholstered furniture
- Reduce indoor humidity to <50%, if possible

Animal allergens (if removal of pet is not acceptable)

- Keep pet out of patient's bedroom
- Isolate pet from carpet and upholstered furniture
- Wash pet weekly

Cockroaches

- Keep food and garbage in tightly closed containers
- Take out garbage regularly
- Clean up dirty dishes promptly
- Use roach traps

Other recommendations

- Do not allow smoking around the patient, in the patient's house, or in the family car
- Minimize the use of wood-burning stoves and fireplaces

Data from reference 3.

Clinical Controversy…

While avoidance steps are logical, there is little existing evidence that environmental control measures provide clinical benefit. Controlled trials that identify the efficacy of environmental controls on measurable allergic rhinitis endpoints need to be performed.

Other suggested measures for preventing allergic rhinitis include breastfeeding infants and avoidance of exposure to tobacco smoke.[18] Exclusive breastfeeding for the first 3 months of life may help prevent allergies. Avoidance of environmental tobacco smoke (ie, passive smoking) by children and pregnant woman may also reduce the development of allergies and has been strongly recommended. However, the evidence for both these recommendations is minimal.

Pharmacologic Therapy

Table 95-4 summarizes the most recent guidelines for treatment of allergic rhinitis with levels of evidence for each treatment strategy.[1] Therapeutic modalities for treating allergic rhinitis are generally directed at relief of symptoms as previously described in Table 95-2. Antihistamines and decongestants (both oral and topical) generally are used first in treating allergic rhinitis with medications. Several options in these two categories are available without a prescription, but patients will need sound advice to make appropriate choices. Knowledge of pathophysiology and the inflammatory state has led to prophylactic therapy for those with more severe disease using agents such topical steroids. However, in attempting to assess the evidence supporting any particular therapy, clinicians have difficulty interpreting the medical literature for a variety of reasons, including lack of uniformity in the research methodologies, inappropriate drug controls, and failure to identify types of rhinitis in study subjects (perennial vs seasonal and allergic vs nonallergic).

TABLE 95-4 Evidence-Based Treatment Recommendations for Allergic Rhinitis

Recommendation	Level of Evidence[a]
Environmental factors	B
*Avoidance of known allergens	
*Environmental controls (removal of pets, air filters)	
*May consider this approach as *optional*.	
Note: Even though good evidence exists, this may be hard to achieve.	
See text for limitations of this approach.	
Nasal steroids	A
*Benefits include symptom control, improved quality of life, better sleep, cost-saving if used as monotherapy, targeted local effect. Patient preference will play a large role.	
Oral antihistamines	A
*Second generation (nonsedating) agents should be used in patients with primary complaints of sneezing and itching. Relief of eye symptoms, OTC status and the availability of lower cost generics may be advantages.	
Intranasal antihistamines	A
*Evidence is strong but studies were of short duration. May consider these agents as *optional*.	
Oral leukotriene receptor antagonists	D
*Clinicians should not recommend these agents as primary therapy for allergic rhinitis	
*Patients with allergic rhinitis and asthma may benefit from this therapy	
Combination therapy	Variable
*Oral antihistamines and oral decongestants: several studies show benefit but must be weighed against potential risks: increased insomnia, headache, dry mouth, nervousness, and increased blood pressure. Tolerance may develop with long-term use of oral decongestants.	
*Oral antihistamines and intranasal steroids: no evidence to support the combination.	
*Intranasal steroids and intranasal antihistamines: For patients who tolerate a nasal agent but have inadequate control of symptoms with a single agent, this combination is an effective option.	
*Intranasal steroids and topical decongestants: Combination more effective than intranasal therapy alone however, see text regarding risk of rhinitis medicamentosa.	
Immunotherapy	A
*Recommended in patients who have inadequate response to with pharmacologic therapy with or without environmental controls	
*See text for information on sublingual versus subcutaneous therapy	

[a] Levels of evidence: A, a strong recommendation or recommendation based on excellent evidence where benefits clearly outweigh harms. B, a strong recommendation or recommendation based on good evidence that benefits outweighs harms. C, recommendation where evidence is not as strong or high quality evidence is impossible to obtain. D, an optional therapy for some patients but quality of evidence is suspect, or no recommendation because there is a lack of pertinent evidence and an unclear balance between benefits and harm. For each level of evidence, see comments for further clarification of recommendations.

Antihistamines

4 Histamine (H_1)-receptor antagonists are competitive antagonists to histamine. They bind to H_1 receptors without activating them, preventing histamine binding and action. Second-generation antihistamines may also affect components of the inflammatory response such as histamine release, generation of adhesion molecules, and influx of inflammatory cells. Although it was once thought that the older antihistamines had no antiinflammatory action, some were shown to have these effects as early as the 1950s.[20] Antihistamines are available in oral, ophthalmic, and intranasal dosage forms.

The oral antihistamines are the most commonly used and can be divided into two major categories: nonselective (first generation) and peripherally selective (second generation). Nonselective agents are commonly referred to as *sedating antihistamines*, and peripherally selective agents are referred to as *nonsedating antihistamines*. These generalizing terms can be misleading. Individual agents should be judged on their specific characteristics because variation within these broad categories exists. Also, the nonsedating claim is only valid when the agents are used at recommended doses.[21] This is of particular concern as some of these antihistamines are available without a prescription. The mechanism for sedation is not well understood, but its central effect depends on the drugs' ability to cross the blood–brain barrier. Most older antihistamines are lipid soluble and cross this barrier easily. The peripherally selective agents have little or no central or autonomic nervous system effects. **Table 95-5** lists common antihistamines, their chemical classifications, their relative potential for causing sedation, and their relative anticholinergic effects.

TABLE 95-5 Relative Adverse-Effect Profiles of Antihistamines

Medications	Relative Sedative Effects	Relative Anticholinergic Effects
Alkylamine class, nonselective		
Brompheniramine maleate	Low	Moderate
Chlorpheniramine maleate	Low	Moderate
Dexchlorpheniramine maleate	Low	Moderate
Ethanolamine class, nonselective		
Carbinoxamine maleate	High	High
Clemastine fumarate	Moderate	High
Diphenhydramine hydrochloride	High	High
Phenothiazine class, nonselective		
Promethazine hydrochloride	High	High
Piperidine class, nonselective		
Cyproheptadine hydrochloride	Low	Moderate
Phthalazinone class, peripherally selective		
Azelastine (nasal only)	Low to none	Low to none
Bepotastine (ophthalmic only)	Low to none	Low to none
Piperazine class, peripherally selective		
Cetirizine	Low to moderate	Low to none
Levocetirizine	Low to moderate	Low to none
Piperidine class, peripherally selective		
Desloratadine	Low to none	Low to none
Fexofenadine	Low to none	Low to none
Loratadine	Low to none	Low to none
Olopatadine (nasal only)	Low to none	Low to none

Antihistamines are much more effective in preventing the actions of histamines and essentially do not reverse these actions once they have taken place. Reversal of symptoms is largely caused by the anticholinergic properties of these drugs. This activity is responsible for the drying effect of antihistamines, which reduces the problem of nasal, salivary, and lacrimal gland hypersecretion. Antihistamines antagonize increased capillary permeability, wheal-and-flare formation, and itching.

In general, the antihistamines are well absorbed, have large volumes of distribution, and are metabolized by the liver. Serum half-lives vary considerably between patients. In addition, the therapeutic effects of these agents are more prolonged than might be predicted by their half-lives.

Drowsiness is usually the chief complaint of patients who take antihistamines. It can interfere with a patient's ability to drive a car or operate machinery and may interfere with the patient's ability to function adequately at the workplace. Remember that these problems can also be a reflection of the disease itself. For this reason, many recommend the use of peripherally selective agents as first-line treatment for any patient who is at high risk for the development of adverse events. This includes patients with renal or hepatic impairment, those with small weights (for whom adult doses may provide larger-than-recommended doses on a milligram-per-kilogram basis), patients with

preexisting CNS or cardiac disorders, patients who require higher doses, and patients who have shown a tendency to overuse nonprescription or prescription medications.[20]

The sedative effects of antihistamines can be useful for patients who suffer from sleeplessness caused by the symptoms of allergic rhinitis. In these patients, a bedtime dose may prove beneficial. However, they may cause residual daytime sedation, decreased alertness, and performance impairment.

The logic of preferentially using the second-generation agents is not clear-cut. A meta-analysis of performance-impairment trials did not show a clear and consistent distinction between diphenhydramine and the peripherally selective agents.[22] Another study showed that tolerance to sedation secondary to diphenhydramine developed by day 4 of treatment, becoming indistinguishable from placebo,[23] but sedation must be distinguished from impairment since the two are not equivalent. Despite this evidence, guidelines recommend the nonsedating agents.[1,18]

Anticholinergic (drying) effects contribute to the agents' therapeutic efficacy, but they also cause most adverse effects. Dry mouth, difficulty in voiding urine, constipation, and potential cardiovascular effects may be troublesome. Keep in mind that the differences may be small. Patients with a predisposition to urinary retention (eg, older men and those on concurrent anticholinergic therapy) should use antihistamines with caution. Caution also should be used for patients with increased intraocular pressure, hyperthyroidism, and cardiovascular disease.

Other adverse effects of oral antihistamines include loss of appetite (and paradoxically, weight gain with increased appetite), nausea, vomiting, and epigastric distress.

Antihistamines are only fully effective when taken approximately 1 to 2 hours before anticipated exposure to the offending allergen. This must be discussed with patients who face exposure daily during a pollen season and with those who have indoor perennial allergens where daily scheduled use is necessary. If tolerance develops to the therapeutic effect, a change to an agent in a different chemical class is usually effective.

Patients should be counseled about the proper use of antihistamines. Adverse effects, especially drowsiness, should be emphasized. Patients should be warned against taking other CNS depressants, including the use of alcohol. Patients should be told not to take a double dose when a dose is missed. Taking the antihistamine with meals or at least a full glass of water will help prevent GI adverse effects such as nausea, vomiting, and epigastric distress. Patients should check with their healthcare professional and read labels before taking nonprescription medications. Many cold products and sleep aids contain antihistamines. Patients should be instructed not to use more than one antihistamine at a time. **Table 95-6** lists the recommended dosages of the commonly used agents with their prescription status.

TABLE 95-6 Medication Dosing for Allergic Rhinitis

Drugs	Brand Names	Dosages	Special Population Doses	Other
Antihistamines				
Oral				
Nonselective:				
Chlorpheniramine maleate	Various	Plain: 4 mg every 6 hours	Pediatrics: 6-12 years: 2 mg every 6 hours 2-5 years: 1 mg every 6 hours	OTC Available as liquid
		Sustained release: 12 mg every 12 hours	Pediatrics: 6-12 years: 0.67 mg every 12 hours	OTC
Clemastine fumarate	Tavist	1.34 mg every 8 hours	Pediatrics: 5 mg/kg per day divided every 8 hours (up to 25 mg per dose)	OTC Available as liquid
Diphenhydramine hydrochloride	Benadryl and others	25-50 mg every 8 hours	Pediatrics: 6-12 years: 10 mg once daily 2-5 years: 5 mg once daily	OTC Available as liquid
Peripherally selective:				
Loratadine	Alavert/Claritin	10 mg once daily	Pediatrics: 2-11 years: 30 mg twice daily	OTC Available as liquid
Fexofenadine	Allegra	60 mg twice daily or 180 mg once daily	Pediatrics: 1-5 years: 2.5 mg daily may increase to twice daily	OTC Available as liquid
Cetirizine	Zyrtec	5-10 mg once daily	6-12 months: 2.5 mg once daily Pediatrics: 6-11 years: 2.5 mg in the evening 6 months to 5 years: 1.25 mg in the evening	OTC Available as liquid
Levocetirizine	Xyzal	5 mg at bedtime		
Nasal				
Azelastine	Astopro	One to two sprays twice daily	Pediatrics: 5-11 years one spray twice daily	
Olopatadine	Patanase	Two sprays twice daily	Pediatrics: 6-11 years: one spray twice daily	
Ophthalmic				
Bepotastine	Bepreve	One drop twice daily		
Decongestants				
Oral				
Pseudoephedrine	Various	60 mg every 4-6 hours	Pediatrics: 6-12 years: 30 mg every 4-6 hours 4-5 years: 15 mg every 4-6 hours	OTC Available as liquid
		Sustained release: 120 mg every 12 hours Controlled release: 240 mg once daily		
Phenylephrine	Various	10-20 mg every 4 hours	Pediatrics: 6-12 years: 5 mg every 4 hours 4-6 years: 2.5 mg every 4 hours	OTC Available as liquid
Nasal				
Oxymetazoline	Various	Two to three sprays twice daily		OTC
Phenylephrine	Various	Two to three sprays every 4 hours	Pediatrics: >12 years: use 0.25-0.5% two to three sprays every 4 hours 6-12 years: use 0.25% two to three sprays every 4 hours 2-6 years: use 0.125% one drop every 2-4 hours	OTC
Nasal steroids				
Beclomethasone	Beconase AQ Qnasl	One to two inhalations in each nostril twice daily (Beconase AQ) Two inhalations (160 mcg) in each nostril once daily (Qnasl)	Pediatric: Beconase AQ: 6-11 years: one inhalation in each nostril twice daily Qnasl: 4-11 years: one inhalation (40 mcg) in each nostril once daily	
Budesonide	Rhinocort Aqua	One spray each nostril daily (up to maximum of four sprays each nostril daily)		
Flunisolide	Various	Two sprays in each nostril twice daily	Pediatrics: 6-14 years: two sprays in each nostril twice daily	
Fluticasone	Flonase Veramyst	Two sprays in each nostril once daily	Pediatrics: >4 years: one spray in each nostril daily (Flonase) 2-11 years: one spray in each nostril daily (Veramyst)	OTC
Mometasone	Nasonex	Two sprays in each nostril daily	Pediatrics: 2-11 years: one spray in each nostril daily	
Triamcinolone	Nasacort	Two sprays in each nostril daily (reduce to one spray when symptoms controlled)	Pediatrics: 2-11 years: one spray in each nostril once daily	OTC
Other nasal medications				
Cromolyn	Nasalcrom	One spray in each nostril three to four times a day	Pediatrics: >2 years, same as adult dose	OTC
Ipratropium	Atrovent	Two sprays in each nostril two to four times per day	Pediatrics: 5-11 years: two sprays in each nostril two to three times a day	
Montelukast	Singulair	Oral: 10 mg once daily	Pediatrics: 6-23 months: 4 mg (oral granules) once daily 2-5 years: 4 mg once daily (chewable or granules) 6-14 years: 5 mg once daily (chewable)	

Many patients respond to and tolerate the older agents quite well. Because many of the older agents are available generically, they are much less expensive. Patient cost for many of the older nonprescription agents is less than $5 for a 30-day supply, compared with more than $20 for some of the nonprescription selective agents and more than $70 for the selective prescription-only products. Although cost is a concern, patient safety should be the first consideration.

The selective agents have moved ahead of the nonselective choices in a recent survey of pharmacist recommended over-the-counter antihistamines.[24] Among the 2 million antihistamine recommendations, the top three were loratadine (41%), cetirizine (33%), and fexofenadine (15%) followed by the nonselective agents diphenhydramine (9%) and chlorpheniramine (2%).

For seasonal and persistent allergic rhinitis, the intranasal antihistamine azelastine is available. The 0.1% product can be used in children for seasonal allergies, while the 0.15% product is labeled for adults only for either type of allergic rhinitis. Despite this labeling, recent guidelines favor the use of the intranasal route for seasonal but not persistent allergic rhinitis.[18] Azelastine has been used successfully for patients who did not respond to loratadine.[25] Using the nasal route offers an alternative to switching to another oral antihistamine. Patient satisfaction has been varied because while the product produces rapid symptom relief, patients complain of drying effects, headache, and diminished effectiveness over time. Patients should be warned of the medication's potential to produce drowsiness, as its systemic availability is approximately 40%.[26,27] Olopatadine, another intranasal antihistamine, may cause less drowsiness as it is a selective H_1-receptor antagonist.

Allergic conjunctivitis, often associated with allergic rhinitis, can be treated with ophthalmic antihistamines such as levocabastine or bepotastine. Because systemic antihistamines usually are also effective for allergic conjunctivitis, one of these ophthalmic agents is a logical addition to nasal steroids when ocular symptoms occur, and it is an acceptable approach for patients whose only symptoms involve the eyes or to add for those whose symptoms persist on oral treatment.

Decongestants

Topical and systemic decongestants are sympathomimetic agents that act on adrenergic receptors in the nasal mucosa, producing vasoconstriction. Decongestants shrink swollen mucosa and improve ventilation. When nasal congestion occurs with allergic rhinitis, decongestants work well in combination with antihistamines.

Topical Decongestants

Topical decongestants are applied directly to swollen nasal mucosa via drops or sprays. **Table 95-7** lists the common topical decongestants and their durations of action. The use of these agents results in little or no systemic absorption.

TABLE 95-7 Duration of Action of Topical Decongestants

Medications	Durations of Action (hours)
Short acting	
Phenylephrine hydrochloride	Up to 4
Intermediate acting	
Naphazoline hydrochloride	2-6
Tetrahydrozoline hydrochloride	
Long acting	
Oxymetazoline hydrochloride	Up to 12
Xylometazoline hydrochloride	

Because these agents are extremely effective and are available to patients without a prescription, they are widely used. However, prolonged use of these agents (for more than 3 to 5 days) can result in a condition known as *rhinitis medicamentosa*, or *rebound vasodilation*, with even more severe congestion. Patients who develop this condition use increasingly more spray more often with less response. Although the methods used to treat this "addiction" have not been studied formally, several are used commonly. Abrupt cessation works, but it is difficult because of rebound congestion that may leave the patient congested for several days or weeks. Sleeping may become difficult. Nasal steroids have been used successfully, but they take several days to work. Weaning the patient off topical decongestants can be accomplished by decreasing the dosing frequency or the concentration over several weeks. Combining the weaning process with nasal steroids may prove useful. Ultimately, the success of any plan depends on the patient's resolve and clear understanding of the importance of stopping the drug to end the problem.

Other adverse effects of topical decongestants include burning, stinging, sneezing, and dryness of the nasal mucosa.

Patients should be counseled on the use of topical decongestants to prevent rhinitis medicamentosa. Patients should be instructed to use as small a dose as possible as infrequently as possible and only when absolutely necessary (eg, at bedtime to aid in falling asleep). Duration of therapy always should be limited to 5 days or less.

Systemic Decongestants

Oral decongestants are not as effective on an immediate basis as the topical agents, but their effects sometimes last longer and they cause less local irritation. In addition, rhinitis medicamentosa is not a problem with oral agents. The most commonly used agent is pseudoephedrine. Table 95-6 lists the usual doses for the regular and sustained-release versions. The use of phenylephrine is increasing because of regulations related to pseudoephedrine described below.

Concerns of safety have greatly limited the systemic decongestant options. Legal requirements for the sale of pseudoephedrine were put into place to combat the misuse of the drug as a component in making methamphetamine. Pseudoephedrine must now be sold behind the counter, and the monthly amount a patient can purchase is limited. Until this requirement, pseudoephedrine was the most frequently used systemic decongestant, and it was considered the safest. Doses of 180 mg have been shown to produce no measurable change in blood pressure or heart rate.[28] In higher doses (210 to 240 mg), pseudoephedrine has raised both blood pressure and heart rate.[29] Pseudoephedrine can cause mild CNS stimulation, even at therapeutic doses. Stroke, related to use of oral decongestants such as pseudoephedrine, can occur in patients with hypertension and/or vasospasm.[30] Although stroke complications seem to be associated with higher-than-recommended doses, there is also a stroke risk when these agents are taken properly. Severe hypertensive reactions can occur when pseudoephedrine is given concomitantly with monoamine oxidase inhibitors. Hypertensive patients should, unless necessary, avoid systemic decongestants.

Combination Products

Numerous products combine an antihistamine with a decongestant. While the combination may be rational because of the different mechanisms of action, remember that antihistamines must be taken on a regular schedule, but decongestants should only be used when needed. Both nonselective and peripherally selective antihistamines are available in such combinations. As mentioned previously, patients should read labels to avoid therapeutic duplication. Consideration should be given to how often and how severely the patient is congested before recommending these combinations. Only a short course of a combination product should be used.

Nasal Steroids

6 Nasal steroids are an excellent choice for treating perennial rhinitis, and can be useful in seasonal rhinitis, especially if begun in advance of symptoms. Nasal steroids appear to be effective with minimal adverse effects. Some believe that nasal steroids should be recommended as initial therapy over antihistamines because of their high level of efficacy when used properly and along with avoidance of allergens.[18] Multiple mechanisms are involved with the effects of nasal steroids on the nasal mucosa: reducing inflammation by reducing mediator release, suppressing neutrophil chemotaxis, reducing intracellular edema, causing mild vasoconstriction, and inhibiting mast cell-mediated late-phase reactions. Table 95-6 lists the available nasal steroids and their usual doses.

Topical steroids produce only minor adverse effects, most commonly sneezing, stinging, headache, and epistaxis. Despite concerns about safety of systemic steroids, nasal steroids have been found to have no significant association with hypothalamic–pituitary axis suppression, cataract formation, glaucoma, or bone mineral density changes in the doses used for allergic rhinitis. Growth suppression remains a question with some evidence showing that nasal steroids with higher bioavailability (eg, beclomethasone) may have a greater growth-suppression effect than less bioavailable agents.[31] These findings require more study. Most likely, all currently available nasal steroids are safe in the majority of patients, and their clinical benefits outweigh any small growth suppressive effect. Other concerns include local infections with *Candida albicans*, which occur rarely.

The therapeutic benefits of topical steroids are not immediate, and they are not decongestants. Patients need to understand this to ensure cooperation and continuation of therapy. Some patients notice improvement in a few days, but peak responses may not be observed for 2 to 3 weeks. Once a response is achieved, the dosage may be reduced. Blocked nasal passages should be cleared with a decongestant or saline irrigation before administration to ensure adequate penetration of the spray. Patients should be advised to avoid sneezing or blowing their noses for at least 10 minutes after administration. Topical steroids should not be used for patients with nasal septum ulcers or recent nasal surgery or trauma.

One additional benefit of nasal steroids in treating allergic rhinitis in individuals with asthma and upper airway conditions is that they may confer some protection against exacerbations of asthma, leading to fewer emergency room visits. The overall relative risk for an emergency visit among asthma patients who received intranasal steroids was 0.7.[32] No effect was seen for patients receiving antihistamines.

Other Inhalant Medications

Cromolyn sodium and ipratropium bromide offer two additional approaches for treating allergic rhinitis. While neither of these agents appears in the latest treatment guidelines, they are mentioned here for completeness. Cromolyn sodium is a mast cell stabilizer. Increased interest in this product has resulted from it becoming available without a prescription. Ipratropium bromide is an anticholinergic agent that may be useful in perennial allergic rhinitis.

Cromolyn sodium nasal spray is used for the symptomatic prevention and treatment of allergic rhinitis. It curtails antigen-triggered mast cell degranulation and release of the mediators of allergic reactions, including histamine. Cromolyn sodium has no direct antihistaminic, anticholinergic, or antiinflammatory properties. Similarly to topical steroids, the most common adverse effects—sneezing and nasal stinging—result from local irritation. Dosing information is given in Table 95-6. Cromolyn sodium must cover the entire nasal lining; therefore, patients should be instructed to clear nasal passages before administration. Inhaling gently through the nose during administration aids in this process. Dosing must be repeated at 6-hour intervals to maintain the effect.

For seasonal rhinitis, treatment with cromolyn sodium should be initiated just before the usual start of the offending allergen's season and continued throughout the season. In perennial rhinitis, the effects may not be seen for 2 to 4 weeks; therefore, antihistamines or decongestants may be needed during this initial phase of therapy. As cromolyn sodium begins to work, the need for these medications should decrease.

Ipratropium nasal spray is an anticholinergic agent that exhibits antisecretory properties when applied locally. It provides symptomatic relief of rhinorrhea associated with allergic and other forms of chronic rhinitis. Dosing information is given in Table 95-6. The optimal dose should be determined based on the specific patient's symptoms and response. Adverse effects are mild, with the most common being headache, nosebleeds, and nasal dryness.

Immunotherapy

6 Experience with immunotherapy has reached the one-century mark, as the first report of the successful use of grass pollen extract injections to treat allergic rhinitis was published in 1911.[33] Until recently, immunotherapy was only available for subcutaneous injection. Sublingual dosage forms for a very limited number of allergens are now available in the United States. The therapy was first called *desensitization*; however, this did not seem appropriate because skin reactivity sometimes remained. The name was later changed to *hyposensitization*. Although this term is still used today, *immunotherapy* is used more commonly and is less confusing.

Immunotherapy is the process of administering doses of antigens responsible for eliciting allergic symptoms into a patient with the hope of inducing tolerance to the allergen when natural exposure occurs. Several mechanisms have been proposed to explain the beneficial effects of immunotherapy, including induction of IgG-blocking antibodies, reduction in specific IgE (long-term), reduced recruitment of effector cells, altered T-cell cytokine balance (a shift from T-helper type 1 to T-helper type 2), T-cell anergy, and alteration of regulatory T-cell actvitiy.[34]

Immunotherapy is moderately expensive, has significant potential risks, and requires a major time commitment from the patient. However, the cost of immunotherapy may be covered by insurance, including Medicaid. Long-term savings can be realized since decades of treatment with medication can be averted through successful immunotherapy. Candidates for immunotherapy should have significant symptoms unsuccessfully controlled by avoidance and pharmacotherapy or should stand to benefit in other significant ways, such as with asthma. Immunotherapy may postpone the onset of asthma or possibly even prevent it.[35] Patients who are unable to tolerate the adverse effects of properly managed drug therapy also should be considered. Patients must be committed to the necessary regular office visits required to complete a course of subcutaneous therapy over several years.

The effectiveness of immunotherapy for seasonal allergic rhinitis appears to be better than that seen with perennial rhinitis, in part because it is more difficult to determine which allergen is responsible for perennial symptoms, and it is more often due to multiple sensitizations. Effectiveness has been shown in a number of clinical studies using a variety of pollen extracts, even for patients with severe disease resistant to pharmacotherapy.[35] Specific immunotherapy for house dust mites has had good results in appropriately selected patients, but more study is needed. Data indicate that for some patients 3 years of immunotherapy may be sufficient to give lasting benefit;[36] however, many require longer treatment. Sublingual and local nasal specific immunotherapy may offer acceptable alternatives to the traditional subcutaneous route in some patients.[18]

The selection of antigens should be based on patient history and skin test results. Numerous regimens for administration of selected allergens have been suggested. In the beginning of subcutaneous immunotherapy, very dilute solutions are given initially one to two times per week. The concentration is increased until the maximum tolerated or highest planned or effective dose is achieved. This maintenance dose is continued in slowly increasing intervals over several years, depending on clinical response. In light of the present understanding of the immunologic results of immunotherapy, it should be given year-round rather than seasonally.

Sublingual immunotherapy is available for ragweed and certain grass allergies. Because the types of allergens are limited, patient selection should be done carefully to ensure that those receiving this route of immunotherapy are the most likely to benefit. The products are started 12 weeks before the allergen season and continued throughout the season. The first dose is administered in the physician's office to allow observation of the patient for 30 minutes for hypersensitivity reactions. The patient places the tablet under the tongue where it dissolves. Patients should not swallow for at least 1 minute. After the first dose is administered without incident, patients can take immunotherapy at home. However, patients must be prescribed an autoinjectable epinephrine.

Adverse reactions can occur with subcutaneous immunotherapy and range from mild to life threatening. Among the most common are

mild local reactions, consisting of induration and swelling at the site of the injection. These may be immediate or delayed. Other more serious reactions (eg, generalized urticaria, bronchospasm, laryngospasm, and vascular collapse) occur rarely; deaths can result from anaphylactic reactions. Severe reactions are treated with epinephrine as well as other modalities recommended for anaphylaxis. Because of this potential risk, subcutaneous immunotherapy must not be given without adequate direct observation in a medical facility. With sublingual immunotherapy, the most common reactions are pruritus of the mouth, ears, and tongue, throat irritation, and mouth edema.

Several patient types are poor candidates for immunotherapy, including patients with any medical condition that would compromise the ability to tolerate an anaphylactic-type reaction, patients with impaired immune systems, and patients with a history of nonadherence to therapy.

Clinical Controversy…

Since few patients suffer from hypersensitivity to a single allergen type, will the sublingual immunotherapy be helpful to patients with allergies to other grass or weed pollens than those contained in the currently available products?

Leukotriene Receptor Antagonists

Leukotriene receptor antagonists inhibit the cysteinyl leukotriene receptor. The cysteinyl leukotrienes are one type of inflammatory mediators released from mast cells in allergy. Montelukast is approved for the treatment of perennial allergic rhinitis in children as young as 6 months and for seasonal allergic rhinitis in children as young as 2 years. Montelukast is considered a third choice behind antihistamines and nasal steroids.[18]

Studies published to date show leukotriene receptor antagonists to be no more effective than peripherally selective antihistamines and less effective than intranasal steroids. However, when combined with antihistamines, they are more effective than the antihistamine alone.[37] In children with mild persistent asthma and coexisting allergic rhinitis, montelukast as monotherapy has been recommended.[1] Table 95-6 lists dosage regimens.

Alternative Treatment Options

A few other alternative options have been suggested for treatment of allergic rhinitis. As mentioned earlier in this chapter, microbial exposure in the early years of life could help prevent allergic disease by favoring a nonatopic immune response.[4] However, the use of probiotics may be limited to treatment or prevention of childhood eczema as available evidence shows little benefit in allergic airway diseases.[41] Butterbur, with the active ingredient petasin that exhibits antileukotriene and antihistamine activity, has shown some success but is not recommended for most patients.[18,42] Acupuncture is listed as an optional therapy in the latest guidelines, but high-quality evidence supporting the intervention is not available.[1]

Personalized Pharmacotherapy

The two primary pharmacotherapy options for the treatment of allergic rhinitis in adults and children are antihistamines and intranasal steroids. Patient preference should play a role when selecting between these two options. While limited evidence supports intranasal steroids over antihistamines, some patients may prefer simple oral therapy. Either choice requires clear patient counseling to ensure appropriate timing of therapy and expectations of effect.

For patients (both adults and children) who are not immunocompromised, have a high likelihood for adherence, and have adequate insurance and/or financial resources, subcutaneous specific immunotherapy is an excellent choice for treatment of seasonal allergic rhinitis and allergic rhinitis secondary to house dust mites. In some children, immunotherapy may prevent development of asthma. Sublingual immunotherapy may be beneficial to patients who are sensitive only to ragweed or certain types of grasses.

For patients experiencing an exacerbation of nasal congestion as part of their allergic rhinitis picture, decongestants can be used short term.

Leukotriene receptor antagonists should not be recommended as primary therapy for allergic rhinitis; however, patients with allergic rhinitis and asthma may benefit from this therapy.

Cromolyn is another alternative that is effective, but many patients may find its frequent daily dosing (up to six times daily) difficult.

A drug monitoring summary is shown in **Table 95-8**. Intranasal and ophthalmic antihistamines may be helpful for specific symptoms not relieved by first-line choices. An intranasal anticholinergic such as ipratropium is specifically useful for rhinorrhea.

TABLE 95-8 Monitoring of Medications for Allergic Rhinitis

Drug	Adverse Reaction	Monitoring Parameter	Comments
Antihistamines	Drowsiness	Caution patient about the potential for	Do not mix with alcohol or other CNS depressants

Drug	Adverse Reaction	Monitoring Parameter	Comments
		drowsiness, even with nonsedating and intranasal products	
	Gastrointestinal effects	Counsel patient to take with a meal or full glass of water	Switching to an antihistamine with less anticholinergic effects may be necessary
	Anticholinergic effects	Watch for dry mouth and difficulty with urination. Caution patient about other medications with anticholinergic effects	
Decongestants		Watch for decreased response to topical agent	Avoid prolonged use (>3-5 days)
Topical	Rebound vasodilation	Watching for burning, stinging, sneezing, and dryness of mucosa	Self-limiting due to short-term use. May try nasal saline for dryness.
	Local irritation		
Systemic	Hypertension	If used in a patient with hypertension, monitor blood pressure regularly and discontinue if the pressure increases	Usually not an issue for patients without preexisting hypertension. Use lowest effective dose
	CNS stimulation		Use lowest effective dose
		Usually mild but discuss with patient	
Nasal steroids	Local effects such as sneezing, stinging, and epistaxis	These effects may vary among products	
Other intranasal agents	Local effects such as sneezing, burning, or coughing	Usually mild but tell patient to report bothersome symptoms	If patient cannot tolerate local reactions, choose an alternative agent
Cromolyn			
Ipratropium	Headache, nosebleeds, and nasal dryness	Usually mild, tell patient to report bothersome symptoms	If patient cannot tolerate local reactions, choose an alternative agent
Montelukast	Behavioral changes	Monitor for mood and behavioral changes including suicidal ideation	Rare but should be monitored
Immunotherapy, SC	Local reactions	Watch for induration or swelling at site of injection	Anaphylaxis rare, but should only be given under direct medical supervision with epinephrine available
Immunotherapy, SL	Allergic reactions Pruritis of ear, oral itching, mouth edema, throat irritation	Monitor for signs of anaphylaxis Caution patient about these reactions as they are fairly common.	First dose giving in physician's office so patient can be observed for 30 minutes. Prescription must be accompanied by a prescription for an epinephrine autoinjector.

More supportive evidence is needed to determine which patients, if any, would benefit from the other alternative options mentioned earlier.

Evaluation of Therapeutic Outcomes

With allergic rhinitis, major outcomes include the effect of the disease on a patient's life, the efficacy and tolerability of treatment, and patient satisfaction. Consideration must be given to how the condition is affecting the patient's job or school performance, family and social interactions, and other aspects of quality of life. Drug therapy should prevent or minimize symptoms with few adverse effects. The patient should not have difficulty obtaining needed medication for financial or other reasons. Patients should be questioned about their satisfaction with the management of their allergic rhinitis. The management should result in minimal disruption to their lives.

Methods for assessing patient-reported outcomes and health-related quality of life in clinical trials related to allergy have been recommended.[43] These tools go beyond measuring improvement in symptoms and include such items as sleep quality, nonallergic symptoms (eg, fatigue, poor concentration, and others), emotions, and participation in a variety of activities. How well each of the current treatment modalities performs and how they compare in improving patient outcomes remain to be determined.

Clinicians caring for allergic rhinitis patients should develop a comprehensive pharmaceutical care plan that addresses several areas. Discuss and agree on therapeutic end points for allergic rhinitis, including the patient's acceptable level of symptom relief, onset of symptom relief expectations, and seasonal starts and stops. Discuss adverse drug reaction self-monitoring and prevention based on treatment selection. Assess patient attitude toward adherence to and persistence with oral, ocular, intranasal, or immunologic therapies. Ensure proper matching of treatment to symptoms and intervene with the prescriber if necessary. Conduct seasonal or annual review with patient.

The therapeutic goal for all patients with allergic rhinitis is to minimize or prevent symptoms. Evaluation of success is accomplished primarily through the discussions with the patient, in whom both relief of symptoms and tolerance of drug therapy must be discussed.

CONCLUSION

Allergic rhinitis is a common disease with symptoms ranging from mild to severe. If avoidance measures are unsuccessful, allergic rhinitis should be treated to improve quality of life and prevent long-term complications. Timing of treating is essential. Treatment regimens should be individualized based on patient symptoms and response. Care should be taken to correctly identify allergy as the cause of the patient's rhinitis before committing them to chromic treatment.

Chapter 96: Acne Vulgaris

Debra Sibbald

INTRODUCTION

KEY CONCEPTS

- 1 Acne is a highly prevalent disorder affecting many adolescents and adults.
- 2 The etiology of this complex disease originates from multiple causative and contributory factors. The diagnosis is based on the patient's history and clinical presentation.
- 3 Elements of pathogenesis involve defects in epidermal keratinization, androgen secretion, sebaceous function, bacterial growth, inflammation, and immunity.
- 4 Acne vulgaris is a chronic disorder which cannot be "cured." Goals of treatment and prevention include control and alleviation of symptoms by reducing the number and severity of lesions, slowing progression, limiting disease duration and recurrence, prevention of long-term disfigurement associated with scarring and hyperpigmentation and avoidance of psychologic suffering. Targeting goals may increase patient adherence to therapy.
- 5 The most critical target for treatment is the microcomedone. Minimizing or reversing follicular occlusion will arrest the pathogenic acne cascade and involves combining treatment measures to target all pathogenic elements.
- 6 Nondrug measures are aimed at long-term prevention and treatment. Patients should eliminate aggravating factors, maintain a balanced, low-glycemic load diet, and control stress. Cleanse twice daily with mild soap or soapless cleanser, and use only oil-free cosmetics. Comedone extraction in approximately 10% of patients produces immediate cosmetic improvement. Shave infrequently as possible, using a sharp blade or electric razor.
- 7 First-, second-, and third-line therapies should be appropriate for the severity and staging of the clinical presentation and directed toward control and prevention.
- 8 Treatment regimens should be tapered over time, adjusting to response. Combine the

smallest number of agents at the lowest possible dosages to ensure efficacy, safety, avoidance of resistance, and patient adherence.

- 9 Once control is achieved, maintenance regimens should be simplified to continue with some suppressive therapy. Therapy must be continued beyond 8 weeks: efficacy is assessed through comedonal and inflammatory lesion (IL) count, control or progression of severity, and management of associated anxiety or depression. Safety end points include monitoring for treatment adverse effects.

- 10 Motivate the patient to continue long-term therapy through empathic and informative counseling.

In this chapter, I review the latest developments in understanding acne vulgaris and its treatment. The contents provide an analysis of the physiology of the pilosebaceous unit; the epidemiology, etiology, and pathophysiology of acne; relevant treatment with nondrug measures; and comparisons of pharmacologic agents, including drugs of choice recommended in best-practice guidelines. Options include a variety of alternatives such as retinoids, antimicrobial agents, hormones, and light therapy. Formulation principles are discussed in relation to drug delivery. Patient assessment, general approaches to individualized therapy plans, and monitoring evaluation strategies are presented.

EPIDEMIOLOGY

1 Acne vulgaris is a chronic disease and the most common one treated by dermatologists. The lifetime prevalence of acne approaches 90%, with the highest incidence in adolescents. Prevalence data available from the European Union, United States, Australia, and New Zealand show that acne affects 80% of individuals between puberty and 30 years of age, depending on the method of lesion counting (50%-95% prevalence range reported for adolescents and 20%-30% prevalence range for ages 20-40).[1] Other studies have reported acne in 28% to 61% of school children aged 10 to 12 years; 79% to 95% of those 16 to 18 years of age; and even in children aged 4 to 7 years. If mild manifestations were excluded and only moderate or severe manifestations were considered, the frequency in epidemiological studies in Western industrialized countries was still 20% to 35%.[2,3,4,5]

The onset of acne vulgaris during puberty occurs at a younger chronologic age in girls than boys (12% age 25-58 vs 3% in males of the same age) and periodic premenstrual flares may continue until menopause. It is triggered in children by the initiation of androgen production by the adrenal glands and gonads, and it usually subsides after the end of growth. However, to some degree, most patients continue to have symptoms into their mid-20s, and there is evidence that the duration of acne may last into middle age for most women, recorded in 54% of women and 40% of men older than 25 years of age.[6] In puberty, acne is often more severe in boys in about 15% of cases, which is tenfold greater than in girls. Women often have more severe forms during adulthood. When untreated, acne usually lasts for several years until it spontaneously remits. After the disease has ended, scars and dyspigmentation are not uncommon permanent negative outcomes.

Genetic factors have been recognized; there is a high concordance among identical twins, and there

is also a tendency toward severe acne in patients with a positive family history of acne.

There are believed to be no gender differences in acne prevalence, although such differences are often reported and may represent social biases. In urban clinics, there is a clear preponderance of girls seeking treatment. There is also a perception that acne is less prevalent in rural populations. This is supported by the data from Varanasi, India, where 21.35% of boys (13-18 years) from rural areas had acne versus 37.5% of those from the urban areas.[7]

An international group of epidemiologists, community medicine specialists, and anthropologists have questioned whether acne might be predominantly a disease of Western civilization.[8] They assert that since acne vulgaris is nearly universal in westernized societies (afflicting 79%-95% of the adolescent population), one causative factor might be the Western glycemic diet. While this hypothesis is based on the observation that primitive societies subsisting on traditional (low glycemic) diets have no acne, the theory awaits validation and acceptance by the dermatologic community.

ETIOLOGY

2 Acne is a multifactorial disease. Genetic, racial, hormonal, dietary, and environmental factors have been implicated in its development. Its psychologic impact can be severe.

Four major etiologic factors are involved in the development of acne: increased sebum production, due to hormonal influences; alteration in the keratinization process and hyperproliferation of ductal epidermis; bacterial colonization of the duct with *Propionibacterium acnes*; and production of inflammation with release of inflammatory mediators in acne sites. These are reviewed in the Pathophysiology section later in this chapter.

The role of heredity in acne has not been clearly defined; however, there is a significant tendency toward more serious involvement if one or both parents had severe acne during their youth.

Environmental factors play a major role in determining the severity and extent of acne and may influence the choice of topical treatments. Heat and humidity may induce comedones; pressure or friction caused by protective devices such as helmets, shoulder pads, or pillows, and excessive scrubbing or washing can exacerbate existing acne by causing microcomedones to rupture. Pressure may cause acne lesions to form in patients who do not have acne vulgaris: this variant is called *mechanical acne*. Friction, wool, or other rough textured fabrics and occlusive clothing may also be mechanical irritants. Hair styles that are low on the forehead or neck may cause excessive sweating and occlusion, exacerbating acne. In most cases acne is worse in winter and improves during the summer, suggesting a salutary effect of sunlight. However, in some cases, exposure to sunlight worsens the disease.[9] Studies examining the relationship between tobacco smoking and acne show inconsistent results; however, dermatologists have begun to counsel people to quit tobacco smoking as a potential auxiliary treatment for acne.

The importance of psychologic factors in this prolonged and capricious condition has been repeatedly stressed. Two-thirds of affected teenagers wish that they could speak with their physician their healthcare provider about acne, but only one-third actually do. Emotions, such as intense anger

and stress, can exacerbate acne, causing flares or increasing mechanical manipulation: picking, excoriating, or pinching lesions sometimes subconsciously or in sleep. This is probably the result of increased glucocorticoid secretion by the adrenal glands, which appears to potentiate the effects of androgens.[10]

Dietary influences are the focus of current investigations. In the past, acne was not felt to be influenced by diet, but patients could restrict certain foods they perceived exacerbate acne (chocolate, cola drinks, milk and milk products).[11,12] These recommendations, which still persist in some guidelines, are based on one or two poorly designed studies conducted more than 40 years ago. They have largely been discounted by well-designed current studies. A discussion of the issues surrounding dietary influences is elaborated in the Clinical Controversy on Diet box.

Clinical Controversy… Diet and Acne

The role of dietary influences in acne continues to be disputed in the literature with increasing attention and vigor. Evidentiary studies are currently in progress to elaborate associations between various dietary influences and presentation of acne, following the dismissal of over-interpreted 40-year-old, poorly designed studies that disavowed potential effects of dietary ingestions on acne.[162,163] Researchers are examining nutritional factors both as factors in acne development as well as potential treatment modalities.

Beginning in 2005, a series of studies have linked consumption of dairy products with acne, perhaps due to natural hormonal components and/or other bioactive molecules in milk.[164,165] Acne has been positively associated with the reported quantity of milk ingested, particularly skim milk.[166] The Nurses Health Study, which included 47,355 women, used retrospective data on diet during high school and found an association between acne and the intake of milk. The authors suggest that natural hormonal components of milk and/or other bioactive molecules in milk could exacerbate acne.[167]

Other studies suggest that insulin-like growth factor (IGF), increased by ingestion of high glycemic loads, may play a role in acne.[168,169] Lactoferrin-enriched fermented milk ameliorates acne vulgaris with a selective decrease of triacylglycerols in skin surface lipids.[167] Lactoferrin is a whey milk protein that has a prominent activity against inflammation. When administered as a dietary supplement on a twice-daily regimen in mild-to-moderate acne vulgaris, it may lead to an overall improvement in acne lesion counts in the majority of affected adolescents and young adults.[170]

The strongest evidence points to a high glycemic load (HGL) diet as a significant factor in acne. In a well-designed randomized controlled trial, a significant reduction in acne was seen in patients who eliminated high glycemic index foods. Patients who consumed a low-glycemic-load diet, compared with a conventional HGL diet, had improvements of facial acne after 12 weeks. Accompanying changes in physical and endocrinologic parameters suggest that decreases in total energy intake, body weight, and indices of androgenicity and insulin resistance may also be associated with observed improvements in acne.[171] Other studies showed correlations between increases in the ratio of saturated to monounsaturated fatty acids and acne lesion counts and increased sebum outflow.

This suggests a possible role of desaturase enzymes in sebaceous lipogenesis and the clinical manifestation of acne; these require further investigation.[172] Another study reported an improvement in acne and insulin sensitivity in low-glycemic-load diets compared with controls, suggesting nutrition-related lifestyle factors play a role in the etiology of acne. Independent effects of weight loss versus dietary intervention need to be isolated.[173] In an Australian study, no cases of acne were reported in participants who consumed low glycemic load diets.[166]

In 2015, a survey reported results of a French questionnaire of individuals (age 15-24) reporting or not reporting acne with associated epidemiological variables using univariate and multivariate analysis. Daily consumption of chocolate and sweets was independently and highly associated with acne (odds ratio 2.38), as was regular use of cannabis (odds ratio 2.88) whereas smoking tobacco (>10 cigarettes daily) was highly protective. Respective roles of sugar, lipids, and milk were not investigated.[174]

A systematic review of dietary influences on acne suggests that a possible role of dietary factors cannot be dismissed, as studies to date have not been sufficiently large or robust. While still controversial, diet is thought to play a role in the development or progression of acne vulgaris and further studies are ongoing. Investigations reviewing antioxidants from nutritional and topical sources and probiotics, as potential acne-fighting agents are now proceeding in early stages.[166]

PATHOPHYSIOLOGY

3 The pathogenesis of acne progresses through the following four major stages:

1. Increased sebum production by the sebaceous gland
2. *P. acnes* follicular colonization (and bacterial lipolysis of sebum triglycerides to free fatty acids)
3. Release of inflammatory mediators
4. Increased follicular keratinization

Improved understanding of acne development on a molecular level suggests that acne is a disease that involves both innate and adaptive immune systems and inflammatory events. Receptors that regulate sebaceous lipid metabolism work in concert with receptors regulating epidermal growth and differentiation. Acne can be considered as a model of immune-mediated chronic inflammatory skin disease: an innate immune response that is not able to control *P. acnes* followed by a Th1-mediated adaptive immune response that becomes self-maintaining independently from *P. acnes* itself.[13]

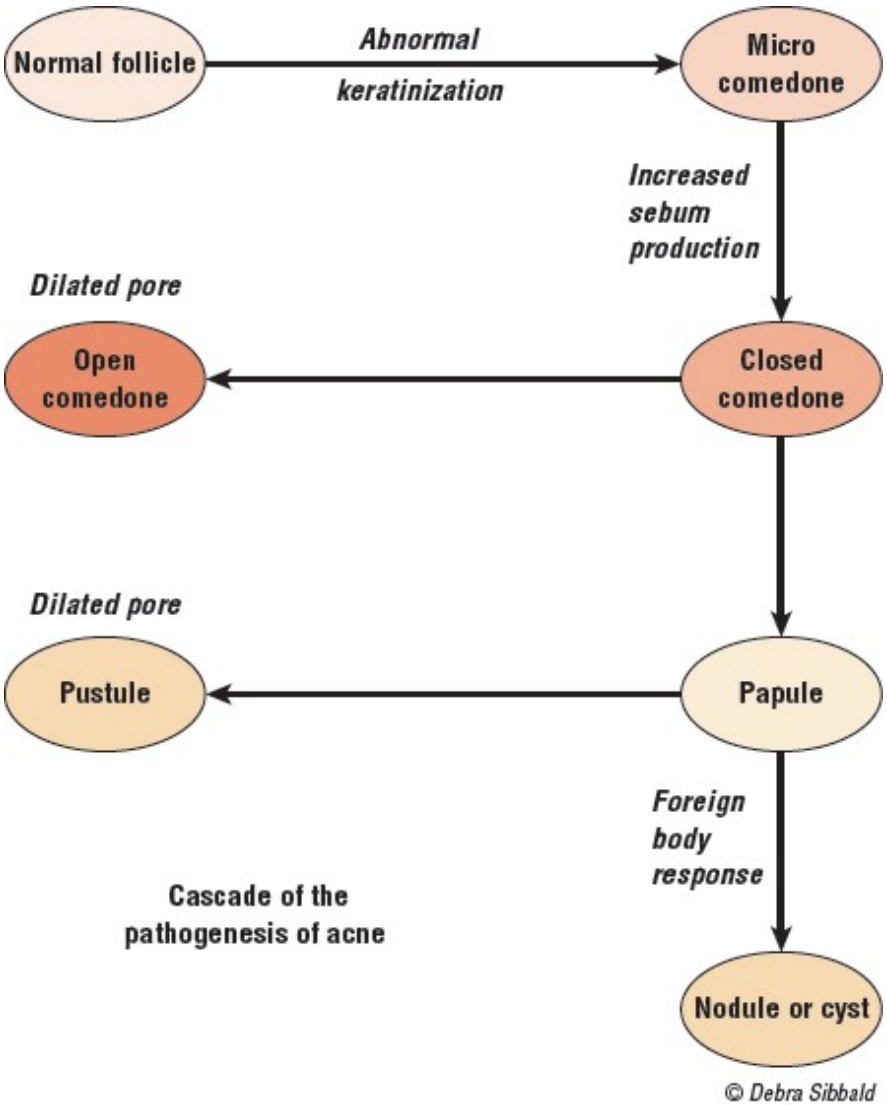
Acne usually begins in the prepubertal period, when the adrenal glands mature, and progresses as androgen production and sebaceous gland activity increase with gonad development.

As shown in **Fig. 96-1**, acne results from the development of an obstructed sebaceous follicle, called a *microcomedone*. Sebaceous glands increase their size and activity in response to circulating androgens. Most patients with acne do not overproduce androgens (with some exceptions); instead,

they have sebaceous glands that are hyperresponsive to androgens.[14] Patients with acne have a significantly greater number of lobules per gland compared with unaffected individuals.

FIGURE 96-1

Cascade of the pathogenesis of acne.



Sebaceous lipids are regulated by peroxisome proliferator-activated receptors, which act in concert with retinoid X receptors to regulate epidermal growth and differentiation as well as lipid metabolism. Sterol response element-binding proteins mediate the increase in sebaceous lipids formation induced by insulin-like growth factor-1. Substance P receptors, neuropeptidases, α-melanocyte stimulating hormone, insulin-like growth factor (IGF)-1R and corticotropin-releasing hormone (CRH)-R1 are also involved in regulating sebocyte activity as are ectopeptidases. The sebaceous gland also acts as an endocrine organ in response to changes in androgens and other hormones. Oxidized squalene can stimulate hyperproliferative behavior of keratinocytes, and

lipoperoxides produce leukotriene B4, a powerful chemoattractant.[14] The composition of sebum is changed, with a reduction in linoleic acid. The growth of keratinocytes changes. The infrainfundibulum increases its keratinization of cells with hypercornification and development of the microcomedone, the primary lesion of both noninflammatory and inflammatory acne.[13] Cells adhere to each other in an expanding mass, which forms a dense keratinous plug. In particular androgens, hormones could be a stimulus to pilosebaceous duct hypercornification. Sebum, produced in increasing amounts by the active gland, becomes trapped behind the keratin plug and solidifies, contributing to open or closed comedone formation.

Interleukin-1-α upregulation contributes to the development of comedones independently of colonization with *P. acnes*. A relative linoleic acid deficiency has also been described.[14]

A prominent role is played by the follicular colonization by *P. acnes*. *P. acnes* displays several activities which promote the development of acne lesions, including the promotion of follicular hyperkeratinization; the induction of sebogenesis; and the stimulation of an inflammatory response by the secretion of proinflammatory molecules and by the activation of innate immunity, followed by a *P. acnes*-specific adaptive immune response. In addition, *P. acnes*-independent inflammation mediated by androgens or by a neurogenic activation, followed by the secretion in the skin of proinflammatory neuropeptides, can occur in acne lesions.[13]

The pooling of sebum in the follicle provides ideal substrate conditions for proliferation of the anaerobic bacterium *P. acnes*, generating a T cell response, which results in inflammation.[15] *P. acnes* produces a lipase that hydrolyzes sebum triglycerides into free fatty acids. These free fatty acids may trigger the changes that lead to an increase in keratinization and microcomedone formation.[16,17] This closed comedone, or whitehead, is the first clinically visible lesion of acne. It takes approximately 5 months to develop. The closed comedone is almost completely obstructed to drainage and has a tendency to rupture.[18,19,20]

As the plug extends to the upper canal and dilates its opening, an open comedone, or blackhead, is formed. Its dark color is not due to dirt but to either oxidized lipid and melanin or to the impacted mass of horny cells. The cylindrically shaped, open comedone is very stable and may persist for a long time as soluble substances and liquid sebum escape more easily. Acne that is characterized by open and closed comedones is termed *noninflammatory acne*.

Acne produces chemotactic factors and promotes the synthesis of tumor factor-α and interleukin-1β. Cytokine induction by *P. acnes* occurs. Both recruitment of polymorphs into the follicle during the inflammatory process and release of *P. acnes*-generated chemokines lead to pus formation. The pus eventually bursts on the surface with resolution of the inflammation or into the dermis. *P. acnes* also produces enzymes that increase the permeability of the follicular wall, causing it to rupture, releasing keratin, hair, and lipids and irritating free fatty acids into the dermis. Several different types of inflammatory lesions (ILs) may form, including pustules, nodules, and cysts and may lead to scarring.

Hyperpigmentation and scarring are two sequelae of acne. A time delay of up to 3 years between acne onset and adequate treatment correlates to degree of scarring and emphasizes the need for

early therapy.[11,12]

CLINICAL PRESENTATION: Signs and Symptoms Lesion Type: Acne Vulgaris Can be Noninflammatory or Inflammatory

- Noninflammatory acne is characterized by open and closed comedones that develop from the subclinical microcomedo
- The closed comedo is visible as a 1-2 mm whitehead most easily seen when the skin is stretched. It is often inconspicuous with no visible follicular opening
    - Is the first clinical sign of acne
    - Has a tendency to rupture
- The open comedo, or blackhead, is larger, approximately 2-5 mm and is dark-topped with contents extruding
    - Is relatively stable
- Inflammatory acne is traditionally characterized as having papulopustular and/or nodular lesions which may arise from the microcomedo or from noninflammatory clinically apparent lesions
    - A pustule is formed from a superficial aggregation of neutrophils
        - Appears as a raised white lesion filled with pus, usually less than 5 mm in diameter
        - Superficial pustules usually resolve within a few days without scarring
- A nodule is produced through deeper, dermal, inflammatory infiltration
    - Is the most severe variant of acne
    - Appears as warm, tender, firm lesions, with a diameter of 5 mm or greater
    - May be suppurative or hemorrhagic within the dermis, may involve adjacent follicles and sometimes extend down to fat
- Cysts are suppurative nodules named because they resemble inflamed epidermal cysts
    - Cystic acne may show double comedones, resulting from prior inflammation and fistulous links between neighboring sebaceous units
- Progression of ILs:
    - Pustules and cysts often rupture spontaneously and drain a purulent or bloody but odorless discharge[21]

- Inflammatory lesions may itch as they erupt and can be tender or painful. Nodules may develop exudative sinus tracts resulting in tissue destruction
- Often resolution of these lesions leaves erythematous or pigmented macules that can persist for months or longer, especially in dark-skinned individuals
- Nodules and deep lesions may result in scarring

Regions of Involvement

- Acne lesions can occur anywhere on the body apart from the palms and soles
  - Are usually located on the face, back, neck, shoulders, and chest
  - May extend to buttocks or extremities
  - One or more anatomic areas may be involved in any given patient
  - The pattern of involvement, once present, tends to remain constant
  - Comedones frequently have a midfacial distribution in childhood and when evident early, are indicative of a poor prognosis
- Skin, scalp, and hair are frequently oily

Severity Grading Taxonomies

FDA Investigator Global Assessment 2005[22,24]

Favorite Table | Download (.pdf) | Print

Type 1	Almost clear: rare noninflammatory lesions (NIL) with no more than 1 papule
Type 2	Mild, some NIL but no more than a few papules/pustules
Type 3	Moderate: many NIL, some ILs, no more than 1 nodule
Type 4	Severe: up to many NIL and IL, but no more than a few nodular lesions

European Union Guidelines Clinical Classification:[14]

Favorite Table | Download (.pdf) | Print

I	Comedonal acne
II	Mild-moderate papulopustular (MMPP) acne
III	Severe papulopustular acne, moderate nodular acne (*this level combines FDA types 3 and 4, above*)
IV	Severe nodular acne, conglobate acne (*this is an additional level cf. the FDA types above*)

Diagnostic and Assessment Considerations

Favorite Table | Download (.pdf) | Print

Palliating factors	Sunlight

Provoking factors	Premenstrual flares, humid environments, excessive sweating; exposure to chemicals; occlusive clothing; friction; oily cosmetics; manual manipulation; stress
Associated symptoms	Itch, pain, fever
Medical conditions	May contribute to or coexist with acne, including endocrine factors (eg, irregular menses, hirsutism, alopecia), pregnancy, atopy
Allergies	May cause acne symptoms, or present a contraindication to therapy
Medication history	Products may cause or interact with acne signs and symptoms
Social habits	Diet, or smoking (see clinical controversies)
Family history	Genetic predisposition to acne
Psychosocial issues	Assess global and disease specific quality of life (QOL) indicators or health-state utilities

CLINICAL PRESENTATION AND DIAGNOSTIC CONSIDERATIONS

To correctly diagnose acne vulgaris, the clinician considers patient assessment, which includes distinguishing all the presenting signs and symptoms of the clinical presentation, reviewing diagnostic and assessment considerations (see Clinical Presentation box), as well as considering psychosocial issues, differential diagnosis, and the possibility of drug-induced acne.

Psychosocial Issues

Assessment of acne's impact on QOL is an important consideration in clinical decision-making. The negative impact of facial acne is one of the primary motivators for patients to seek and to adhere to treatment.[23] Specific QOL indicators represent patients' perceptions of and reactions to their health. Assessing QOL impairment in patients with acne may aid in management by evaluating psychologic impact, which may not correlate with clinical severity; aid in detection of depression or need for psychologic care; and improve therapeutic outcomes.

Acne adversely affects all aspects of QOL. In addition to documentation regarding acne-specific QOL impairment, acne impact on general health and psychologic status has been assessed for relationship between sociodemographic variables, disease severity and mental status on QOL of acne sufferers. In a report of 195 cases, acne impact on health status was worse compared to other chronic diseases. Authors concluded acne is not a minor disease in comparison with other chronic conditions. Age of onset is capable to influence general health quality (GHQ status) which in turn affects QOL.[25]

Examples of global scales that have been used to evaluate acne include Skindex[26] and Dermatology QOL Index[27] examples of acne specific scales include the Acne-specific QOL questionnaire[28] and the Acne QOL Scale.[29] The Acne QOL Scale was developed to measure the impact of facial acne across four domains (acne symptoms, role-emotional, self-perception, and role-social) of health-related QOL. Health-state utilities (such as time trade-off [TTO]) are quantitative measures of patient

preferences of health outcomes ranging from 0 (death) to 1 (perfect health) and can be used in clinical trials as outcome measures of treatment effects. TTO utilities for acne in the range of 0.94 to 0.96 can be compared with those of other diseases (eg, 0.92 for epilepsy, 0.94 for myopia), and help to identify the impact of acne on self-perception and psychologic functioning.[30]

Differential Diagnosis

Acne vulgaris is rarely misdiagnosed. The conditions most commonly mistaken for acne vulgaris include rosacea, perioral dermatitis, gram-negative folliculitis, and drug-induced acne.[31]

Acne rosacea (adult acne) is a chronic, progressive relapsing condition occurring after age 30 years in fair-complexioned persons. The diagnosis is clinical and based on history and physical findings. There are four subtypes: erythemato-telangietactic changes (erythema, flushing, telangiectasia [spider veins], stinging and burning); progressing to papular-pustular changes (ILs, with edema, papules, and pustules on central facial areas such as nose, cheeks, chin, and forehead); phymatous changes (thickened skin and prominent pores on nose, ears, chin, and eyelids; and ocular changes (foreign body sensation, dryness, burning, eyelid erythema).

Rosacea has key differences from acne vulgaris. Onset is not linked to androgens or endocrine changes; and comedones are not usually present. Aggravating factors include endogenous triggers: ingestion of alcohol, spicy foods, or hot drinks (especially those containing caffeine); smoking; and exogenous triggers: overexposure to sunlight; exposure to temperature extremes, heat and humidity, friction, irritating cosmetics, and steroids. Treatment may include antibiotics, particularly doxycycline (low, antiinflammatory dose) or erythromycin, topical metronidazole, pimecrolimus or azelaic acid as well as agents to reduce erythema (alpha adrenergics).[32]

Perioral dermatitis occurs primarily in young women and adolescents and is characterized by erythema, scaling, and papulopustular lesions commonly clustered around the nasolabial folds, mouth, and chin. The cause is unknown.[33]

Gram-negative folliculitis (*Proteus, Pseudomonas, Klebsiella*) may complicate acne, with a sudden change to pustules or large inflammatory cysts occurring after long-term treatment of acne with oral antibiotics. Folliculitis may be caused by staphylococci. There is a sudden onset of superficial pustules around the nose, chin, and cheeks. Patients with suspected folliculitis should be referred.[34]

Several conditions include acne vulgaris as a characteristic component, and understanding the mechanisms involved in these syndromes provides insight into the pathogenesis of acne. These include polycystic ovary syndrome (elevated androgen levels); PAPA syndrome (pyogenic arthritis, pyoderma gangrenosum, acne; early onset arthritis with increased inflammatory activity), and SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis syndrome; sterile inflammatory arthro-osteitis, with *P. acnes* as a possible trigger).[15]

Drug-Induced Acne

In addition to the conditions induced by drugs that were presented in Chapter 23, acneiform

eruptions can also be caused by medications. Systemic corticosteroids can cause a pustular inflammatory form of acne, especially on the trunk. Onset is abrupt at 2 to 6 weeks after initiation of therapy. Acne has also been associated with most of the potent topical steroids, but not with hydrocortisone, which lacks the ability to inhibit protein synthesis. Discontinuation of the steroid results in an initial worsening of appearance due to removal of the anti-inflammatory action of the steroid itself. Caution patients about this reaction, which can be subdued through judicious use of topical hydrocortisone.[33,34,35,36]

Antiepileptics and tuberculostatics are the most commonly implicated in drug-induced acne, followed by lithium. Other heavy metals inducing acne include cobalt (in vitamin B_{12}).[37] Halogens, especially an excess of iodide in seafood, salt, and health foods, can exacerbate acne. In addition, halogens can provoke de novo acne lesions in individuals who have increased external exposure often due to occupational contact, or pool or hot tub disinfection; this variant is called *chloracne*.

In addition, certain minor ingredients in cosmetics have been implicated in cosmetic acne, including isopropyl myristate, cocoa butter, and fatty acids.

TREATMENT

The first step in determining a safe and efficacious treatment regimen for acne vulgaris is to establish desired outcomes for the patient, regarding both short- and long-term goals.

Desired Outcomes (Goals of Treatment)

4 Acne vulgaris is treated as a chronic disease, as it demonstrates typical chronicity characteristics: manifests as either acute outbreaks or slow onset; patterns of recurrence or relapse; a prolonged course; and psychologic and social impact. There are two governing principles: the chronic nature warrants early and aggressive treatment, and maintenance therapy is often needed for optimal outcomes.

Acne requires long-term control. This must be stressed with the patient to encourage adherence to lengthy treatment regimens, which address management of current symptoms and signs and preventive measures.

Basic goals of treatment include alleviation of symptoms by reducing the number and severity of lesions (objective and subjective grading) and improving appearance, slowing progression, limiting duration and recurrence, prevention of long-term disfigurement associated with scarring and hyperpigmentation, and avoidance of psychologic suffering.

A significant percentage change in lesion counts is desirable: most patients empirically validate a margin of 10% to 15% reduction in facial lesion counts as appropriate. Patient global self-assessment of acne improvement is a primary outcome.

General Approach to Treatment

5 The most critical treatment target is the microcomedone. Eliminating follicular occlusion will arrest the whole acne cascade. Nondrug and pharmacologic treatment and preventive measures should be directed toward cleansing, reducing triggers and combination therapy targeting all four pathogenic mechanisms. Combination therapy is often more effective than single therapy, and may decrease side effects and minimize resistance or tolerance to individual treatments.

The approach to acne management is largely determined by:

1. Severity index
2. Lesion type: predominantly noninflammatory or inflammatory
3. Treatment preferences including patient choices
4. Cost implications
5. Skin type and/or ethnic group
6. Patient age
7. Adherence
8. Response to previous therapy
9. Presence of scarring
10. Psychologic effects
11. Family history of persistent acne

Topical therapy is the standard of care for mild-to-moderate acne. Those with moderate-to-severe acne will require systemic therapy.

Topical treatments only work where applied. To reduce new lesion development, they require application to the whole affected area rather than individual spots. Most cause initial skin irritation, which may result in nonadherence or discontinuation. Irritation can be minimized by starting with lower strengths and gradually increasing frequency or dose. Where irritation persists, changing formulation from alcoholic solutions to washes, gels, or more moisturizing creams or lotions might help.

6 7 First-line, second-line, and third-line therapies should be selected and altered as appropriate for the severity and staging of the clinical presentation. Treatment is directed at control, not cure. Regimens should be tapered over time, adjusting to response. Combine the smallest number of agents at the lowest possible dosages to ensure efficacy, safety, avoidance of resistance, and patient adherence. Once control is achieved, simplify the regimen but continue with some suppressive therapy. As it takes 8 weeks for a microcomedone to mature, therapy must be continued beyond this duration to assess efficacy.[35] Most topical preparations may be used for years as needed.

Lesions typically recur for years. Microcomedones significantly decrease during therapy but rebound almost immediately after therapy is discontinued. The strategy for treating acne includes an induction phase followed by a maintenance phase, further supported by adjunctive treatments and/or cosmetic routines. Routine maintenance therapy involves regular use of appropriate agents to ensure remission and reduce potential for recurrence of visible lesions.

For successful long-term treatment, maintenance therapy must be tolerable, appropriate for the patient's lifestyle and convenient, continuing months to years, depending on age. Education about pathophysiology of acne and the psychosocial benefits of clearer skin are compelling reasons for patient adherence to consistent therapy to sustain remission.

Nonpharmacologic Therapy

8 9 Encourage patients with acne to discontinue or avoid aggravating factors, maintain a balanced, low-glycemic-load diet and control stress. Evidence shows that by being empathic and informative during counseling, the health professional may motivate the patient to continue long-term therapy.[8,9,32] One of the first approaches to nondrug management of acne is attention to cleansing techniques. Shaving recommendations, comedone extraction, dietary considerations, issues relating to ultraviolet light, and prevention of cosmetic acne should be reviewed with patients.

Cleansing

Cleansers are indicated in all patients with acne. However, washing too frequently in an attempt to remove surface oils is not likely helpful, as surface lipids do not affect acne. Contributory lipids are deep in the follicle and are not removed through washing. Antiseptic cleansers, while producing a clean, refreshed feeling, remove only surface dirt, oil, and aerobic bacteria. They do not affect *P. acnes*. Patients should wash no more than twice daily with a mild, nonfragranced opaque or glycerin soap or a soapless cleanser.

Soapless cleansers are an alternative to soaps.[38] Soaps are the most widely used cleansing products, but do not lend themselves to efficient delivery of active drug. Two main disadvantages exist. As soaps are rinsed off, the deposit of active agent is small, and the high pH required in soaps may degrade some active ingredients and be less tolerable on sensitive skin. Soaps produce a drying effect on the skin due to detergent action. As medicated cleansers require increased contact time, this drying action is pronounced, especially with peeling agents.

Cleansers often contain surfactant systems to remove fat from the skin surface. The oil is dispersed from the skin into the surfactant system; however, the active ingredient is sometimes trapped and removed upon rinsing. The balance between cleanliness and drying or irritation should also be taken into account. Most patients prefer products with foaming action, and these must contain additional secondary surfactants to enhance the foam and condition the skin.

There is no evidence that any particular washing regimen is superior. Evidence-based studies on the use of cleanser or medicated cleansers are lacking or poorly designed with small numbers of patients.[39] Avoid cream-based cleansers. Scrubbing should be minimized to prevent follicular

rupture.

Because the acid pH of skin has an antimicrobial effect, it has been proposed that lowering lesional surface pH (with products such as Herpifix, marketed in Europe) may be correlated to the number of acne lesions. Studies are planned.

Synthetic polyester cleansing sponges abrade the skin surface, removing superficial debris. Considering the structure of comedones, they are unlikely to unseat these lesions. Sponges are available in soft or coarse textures, with or without soap. Circular or rubbing motions will increase irritation. Instruct patients to use single, gentle, continuous strokes on each side of the face, from the midline out toward the ears.

Cationic-bond strips are activated by water. As the strip dries, the cationic-bond binds the anionic dirt and oil in the pores and removes it when the strip is peeled off.

Shaving

Males should try electric and safety razors to determine which is more comfortable for shaving. When using a safety razor, the beard should be softened with soap and warm water or shaving gel. Shaving should be done as lightly and infrequently as possible, using a sharp blade and being careful to avoid nicking lesions. Strokes should be in the direction of hair growth, shaving each area only once.

Comedone Extraction

Comedone extraction has not been widely tested in clinical trials despite long-standing clinical use; however, it is painless and results in immediate cosmetic improvement. Pretreatment with a peeler for 4 to 6 weeks often facilitates the procedure.[36] Following cleansing with hot water, a comedone extractor is placed over the lesion and gentle pressure applied until the contents are expressed. This removes unsightly lesions, preventing progression to inflammation. A correctly sized extractor allows the central keratin plug to extrude through the opening. The small end of a plastic eye dropper, with bulb removed, may also be used. These instruments should be cleaned with alcohol after each use. Some initial reddening may be apparent. If the contents are not expressed with modest pressure, patients should not continue since improper extraction may further irritate the skin. A physician should be consulted if this technique is too difficult for the patient to manage. Since the follicle is difficult to remove completely, comedones may recur between 25 and 50 days following expression. Fewer than 10% of comedone extractions are a complete success, but the process is useful when done properly.[21]

Comedo removal may be helpful in the management of comedones resistant to other therapies. While the procedure cannot affect the clinical course of the disease, it can improve the patient's appearance, which may encourage adherence with the treatment program.

Ultraviolet Light

Although ultraviolet light was recommended in the past for desquamation, the practice is no longer

advisable because of the well-established carcinogenic and photoaging effects of ultraviolet exposure. Moreover, inflamed skin is more susceptible to the damaging effects of ultraviolet light. Patients taking tretinoin may show heightened sensitivity.[40]

Before exposure to sunlight, patients with acne should apply sunscreens (sun protection factor [SPF] 15) in alcohol or oil-free bases and avoid using the acnegenic benzophenones. Sunscreen should be applied as the first product.

Prevention of Cosmetic Acne

Persistent low-grade acne is frequently caused by heavy cosmetic use in women after their mid-20s. Adolescent acne in younger women may be exacerbated with makeup overuse. The problem is perpetuated when resultant blemishes are concealed with more cosmetics.

Patients should be advised to discontinue oil-containing cosmetics and avoid cosmetic multistep regimens applying various cream-based cleansers and cover-ups. These are commercially advertised and often available with promotional bonuses through Internet shopping. Three-step basic systems usually combine medicated and nonmedicated ingredients. Their cosmetic names may not make apparent therapeutic agents are included. Initial steps usually involve cleansers, in lotions or creams, which may contain a multitude of unnecessary ingredients, including medicated peelers, oils, fragrances, and preservatives. Active ingredients including salicylic acid, sulfur, or benzoyl peroxide are often included in subtherapeutic or low doses. The second step is generally a water- or alcohol-based "toner" or "refresher" which might contain medicated mild comedolytic agents such as α-hydroxy acids (eg, glycolic acid), or even a humectant such as glycerin. The final product, often called intensive or repairing solutions, usually contains the lowest strength of peelers such as benzoyl peroxide, sulfur, or salicylic acid; plus potentially sensitizing fragrances and preservatives; or oil-soluble sunscreens not identified on the label. Bases may have significant oil content. There may be additional products such as masks or spot treatments that supplement the base routine of three steps. Multiple-step cosmetic programs are often costly, and should be avoided in favor of simple cleansers and more effective single-ingredient peelers at optimal concentrations.

The term *noncomedogenic* may refer to either water-based vehicles or products that are free of substances known to induce comedones. They are not necessarily oil-free. Water-based cosmetics may contain significant amounts of oil in the form of undiluted vegetable oils, lanolin, fatty acid esters (butyl stearate, isopropyl myristate), fatty acids (stearic acid), fatty acid alcohols, cocoa butter, coconut oil, red veterinary petrolatum, and sunscreens containing benzophenones. Water-based products are more likely to contribute to pore blockage than oil-free products.

Oil-free makeups are well-tolerated and lipstick, eye shadow, eyeliner, eyebrow pencils, and loose face powders are relatively innocuous. Heavier, oil-based preparations, particularly moisturizers and hairsprays, clog pores and accelerate comedone formation.[41]

Patients should restrict cosmetic use including makeup, moisturizers, or sunscreens to products labeled oil-free rather than water-based. Cover-up cosmetics for acne are available in several skin tones and in lotion and cream forms. They often contain peeling agents, antibacterial agents, or

hydroquinone. Most contain sulfur. They may be applied as cosmetics two or three times daily, over the entire face or to individual lesions. Because the spread time of oil-free makeup is decreased, best results are achieved if applied to one-quarter of the face at a time. Topical medication should be applied after gentle cleansing and a foundation lotion may be used sparingly as a concealer.[42,43,44]

Because the action of most therapeutic acne agents is to dry the skin, the use of nonspecific moisturizers is counterproductive. Active agents, such as α-hydroxy acids (glycolic, lactic, pyruvic, and citric acids), may be present in a cosmetic formulation, since they reduce corneocyte adhesion.[45] Patients with acne should be restricted to oil-free α-hydroxy acid products unless absolutely necessary because of treatment with strong drying agents or isotretinoin.

Cosmetics, if correctly prescribed, may improve the performance of the therapy, whereas wrong procedures and/or inadequate cosmetics may worsen acne. Clinicians should make informed decisions about the role of various cosmetics and to identify the appropriate indications and precautions. The choice of the most effective product should take into consideration the ongoing pharmacologic therapy and acne type/severity as well.[46]

Vehicles

The formulation of an acne vehicle must consider the technical characteristics of maintaining and delivering the drug in an active state together with the need for an elegant product that the patient will enjoy using, so that it is more likely to be applied as required and deliver the full benefit. Physically and chemically, the vehicle will be used with one or more of the following goals: reduce excess oil, control bacteria associated with acne, reduce the effects of hyperkeratinization, and unclog pores. Performance, safety, and stability should be maximized while addressing technical and commercial factors.

Immiscible liquids might be delivered in oil-in-water or water-in-oil emulsions. In addition to having undesirable oil content, these vehicles also contain humectants, thickeners, preservatives, and fragrance, all of which may be problematic.

Solutions are simpler formulations. They are often used as the soaking liquid for fibrous cloth wipe products. The shelf-life depends upon whether multiple wipe packages are resealable, and whether the solvent volatility will affect storage, active agent availability or cause crystallization. Solutions are used mainly with topical antibiotics, which are often dissolved in specific types of alcohol. Although some antibiotics are only soluble in ethyl alcohol, isopropyl alcohol is generally better able to remove oil from the skin surface and is preferred for nonmedicated vehicles. Solutions and washes can be more easily applied to large areas such as the back.[47]

Non-greasy solutions, gels, lotions, and creams should be selected as bases for topical acne preparations. Lotions and creams will contain some oil-phase ingredients. Discourage moisturizers and oil-based products. Lotions are slightly less drying than gels, and creams are more emollient. Gels are very useful as they are mixtures of water or alcohol and totally oil free. Many gels contain ethanol or isopropyl alcohol. Propylene glycol is sometimes present in small amounts to add viscosity and lessen the drying effects of strong peeling agents. Gels are drying but may cause a burning

irritation in some patients and may prevent certain kinds of cosmetics from adhering to the skin.[41] Propylene glycol gels are easy to apply and dry without a visible or sticky film. Nonalcoholic gels may be so effective and less drying than alcoholic solutions. Alcoholic or acetone gels are usually more drying and provide better penetration of the active ingredient.

Consider the patient's skin type and preferences in the choice of vehicle for topical agents. Patients with oily skin often prefer vehicles with higher proportions of alcohol (solutions and gels), while those with dry or sensitive skin prefer nonirritating lotions and creams. Hydrating and emollient products are often recommended to patients using drying treatment therapies, such as isotretinoin, to control adverse effects and improve adherence to treatment. Lotions can be used with any skin type and can be easily spread over hair-bearing skin, but will cause burning or dryness if they contain propylene glycol. Compatibility of vehicles and agents with cosmetics should also be considered.

The importance of vehicle effects in topical therapy has been demonstrated in placebo effect literature.[48] The percent contribution of vehicle (placebo) toward efficacy of reduction of lesions counts of eight commonly prescribed topical preparations at the end of 10 to 12 weeks of daily administration has been reported as a mean value of 55% (range 35%-82%).

How to Use Topical Preparations

Topical preparations should not be applied to individual lesions but to the whole area affected by acne to prevent new lesions from developing. Care should be advised in applying around the eyelid, mouth, and neck (to avoid chafing). Lotions should be applied with a cotton swab once or twice a day after washing or at bedtime if they leave a visible residue. Skincare products may cause skin dryness and redness particularly at the early stages of the treatment. Should this occur, the product should be applied more infrequently, the treatment should be stopped for a while or another topical product tried. To reduce irritation a topical vehicle with high water content may be applied over the medicinal product after a few minutes; the irritation usually subsides as the skin becomes accustomed to the topical skincare product.

Psychologic Approaches, Hypnosis, and Biofeedback

The psychologic effects of acne may be profound. The American Academy of Dermatology expert workgroup unanimously concluded that effective acne treatment can improve the emotional outlook of patients.[49] There is weak evidence of the possible benefit of biofeedback-assisted relaxation and cognitive imagery.[50,51]

Dressings

A pilot double-blind, randomized study of 20 patients has shown some benefit of treatment with a hydrocolloid acne dressing when compared with tape dressings for improving mild-to-moderate inflammatory acne vulgaris. Results showed greater reduction over 3 to 7 days in the overall severity of acne and inflammation, along with greater improvement in redness, oiliness, dark pigmentation, and sebum casual level. Less ultraviolet B light reaches the skin surface with the hydrocolloid dressing

in place.[52,53]

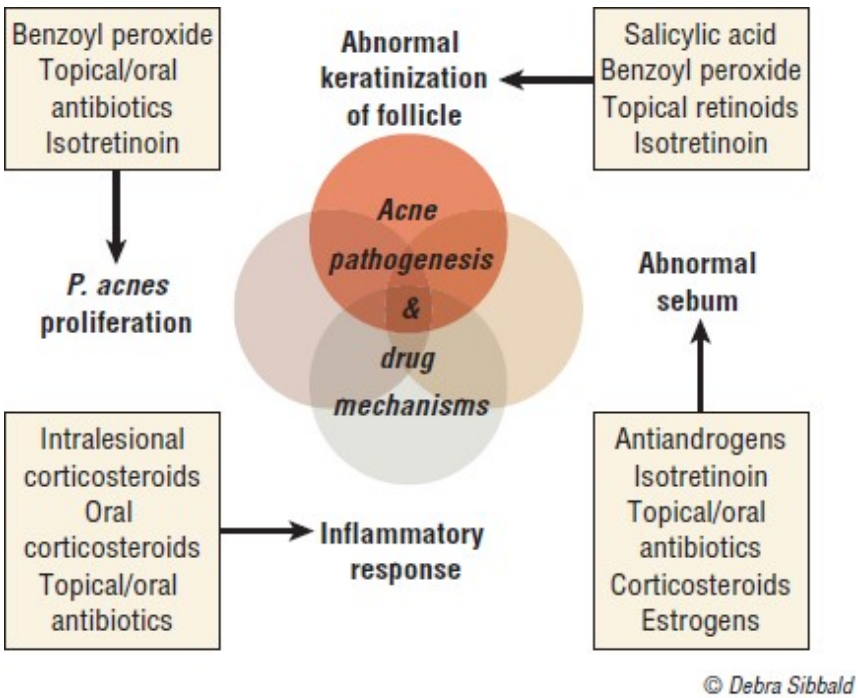
Pharmacologic Therapy

Successful pharmacologic therapy must address one of the four mechanisms involved in the pathogenesis of acne. There are numerous agents available that prove one or more of these actions and are therefore effective (Table 96-2). However, the choice of active pharmacologic therapy depends on severity.

Mechanisms of drug action relating to acne pathogenesis are illustrated in **Fig. 96-2**.

FIGURE 96-2

Acne pathogenesis and drug mechanisms.



Drug Treatments of First Choice

There is concordance among key opinion leaders in different settings regarding recommendations for drugs of choice for management of acne (the Global Alliance,[54] European Guidelines[14]).

For comedonal, noninflammatory acne, active agents of first choice include those that correct the defect in keratinization by producing exfoliation most efficaciously. Topical retinoids, in particular, adapalene, can be recommended as drugs of choice.[14,54] Benzoyl peroxide or azelaic acid can be considered, as alternatives (lower strength recommendation)[14,54] or a change could be made to an alternate topical retinoid. Limitations can apply that may necessitate the use of a treatment with a

lower strength of recommendation as a first-line therapy (eg, financial resources and reimbursement limitations, legal restrictions, availability, drug licensing). Because the comedone is the initial lesion even in inflammatory acne, these agents are used to correct the defect in keratinization in all cases of acne.

For mild-to-moderate papulopustular inflammatory acne, it is important to reduce the population of *P. acnes* in the follicle and the generation of its extracellular products and inflammatory effects. Either the fixed-dose combination adapalene and benzoyl peroxide or the fixed-dose combination of clindamycin and benzoyl peroxide are strongly recommended as first choice therapy (high strength recommendation).[14,54] As alternatives, a different topical retinoid used with a different topical antimicrobial agent could be advised, with or without benzoyl peroxide. Azelaic acid or benzoyl peroxide can also be recommended (medium strength recommendation). In case of more widespread disease, a combination of a systemic antibiotic with adapalene can be recommended for the treatment of moderate papulopustular acne.

Low-strength recommendations are offered as considerations for treatment in the event of limitations that apply in selecting a first-choice agent. The choices would be blue light monotherapy, fixed-dose combination of erythromycin and tretinoin, fixed-dose combination of isotretinoin and erythromycin, or oral zinc. In case of more widespread disease, a combination of a systemic antibiotic with either benzoyl peroxide or with adapalene in fixed combination with benzoyl peroxide can be considered.[14]

For severe papulopustular or moderate nodular acne, oral isotretinoin monotherapy is strongly recommended as the drug of first choice (high strength recommendation). As alternatives, medium strength recommendations can be given for systemic antibiotics in combination with adapalene, with the fixed-dose combination of adapalene and benzoyl peroxide or in combination with azelaic acid.[14,54] In the event of limitations to use of these agents, considerations could be given to oral antiandrogens in combination with oral antibiotics or topical treatments, or systemic antibiotics in combination with benzoyl peroxide (low strength recommendation).

For nodular or conglobate acne, monotherapy with oral isotretinoin is strongly recommended as the drug of first choice (high strength recommendation).[14] As alternative agents, systemic antibiotics in combination with azelaic acid can be recommended (medium strength recommendation). If limitations exist to use of these agents, consideration could be given to oral antiandrogens in combination with oral antibiotics, systemic antibiotics in combination with adapalene, benzoyl peroxide, or the adapalene-benzoyl peroxide fixed-dose combination (low strength recommendation).[14]

For maintenance therapy for acne, the most recommended agents are topical retinoids. The most extensively studied maintenance treatment (four controlled trials) has been adapalene regimens.[14] Other published options include tazarotene or tretinoin. In general, maintenance therapy is begun after a 12-week induction and continues for 3 to 4 months. Continuing improvement using this schema is achieved, with relapse occurring when patients stop treatment, suggesting a longer duration of maintenance therapy is likely to be beneficial. Topical azelaic acid is an alternative to

topical retinoids for acne maintenance therapy, with advantageous efficacy and safety profiles for long-term therapy. To minimize antibiotic resistance, long-term therapy with antibiotics is not recommended as an alternative to topical retinoids. If an antimicrobial effect is desired, the addition of benzoyl peroxide to topical retinoid therapy is preferred.

Published Guidelines

In general, recommendations should be based on critical appraisal and interpretation of the literature combined with clinical experience. There is considerable heterogeneity in the acne literature. The large number of products and product combinations, and the scarcity of comparative studies, has led to disparate opinions and few recommendations are evidence-based. Various evidence-based guidelines, available from multiple American, Canadian, European, Scandinavian, and South African sources from 2005 to 2015, do not provide concordance or clarity on all issues.

The 2012 European Guidelines for the Treatment of Acne focus primarily on major treatments, include use of light and laser therapy (see Clinical Controversy on Light Therapy box), but do not review general management issues such as psychologic determinants, scarring, diet, and so forth.[14] Where relevant, specific information from multiple sources will be integrated into the therapy section that follows.

Clinical Controversy… Light Therapy

Increasingly, "diverse" light therapies (using various wavelengths) as convenient acne treatments with few[147] or temporary[148,149] adverse effects are reported. Conclusions based on outcomes with light therapy are contradictory.

Light therapies for acne are believed to work by killing *P. acnes* and by damaging and shrinking sebaceous glands, reducing sebum output. Light therapies may be used once or twice weekly as a course of 6 to 10 treatments, with each irradiation lasting 10 to 20 minutes.[149] *P. acnes* produce endogenous porphyrins that absorb light to form highly reactive singlet oxygen, which destroys the bacteria.[149] Since porphyrins have peak absorption at blue light wavelengths, blue light is often used to treat acne. Red light is also absorbed by porphyrins and can penetrate deeper into the skin,[150] where it may directly affect inflammatory mediators. Other light therapies attempt to selectively target and damage sebaceous glands directly, reducing their size and thus sebum output.[151] These include infrared lasers, low-energy pulsed dye lasers, and radiofrequency devices.[149]

Photodynamic therapy (PDT) uses specific light-activating creams, which are absorbed into the skin and amplify the response to light therapy but tend to produce more severe adverse effects. There are concerns that PDT may interfere with the skin's natural immune mechanisms[152,153] and cause long-term skin damage.

Previously, treatment was not available universally, but accessed privately via dermatologists or clinics, and expensive. Light therapies are increasingly popular among consumers and home-use blue light therapy is now available. Patients find it easier to comply with light treatments because of their short duration.

Medical science continues to debate whether light of different wavelengths is effective.[149] To date, very few trials compare light therapy with conventional acne treatments. The European evidence-based guidelines for the treatment of acne evaluated existing light therapies and concluded published evidence is still very scarce and standardized treatment protocols and widespread experience are still lacking. They were unable to make a recommendation for or against treatment of comedonal, MMPP or severe papulopustular/nodular acne with monotherapy visible light, visible or infrared wavelength lasers, or intense pulsed light or PDT, due to lack of or conflicting or insufficient evidence. Blue light has a low strength recommendation as a consideration for MMPP.[14]

An ongoing Cochrane review protocol continues to investigate the current state of evidence for use of light therapy in acne.[154]

In 2015, a summary report on light-based intervention therapies for acne rosacea was published.[155] In 106 studies, of 8-12 weeks, in 13,631 people age 40-50 with moderate to severe rosacea, there was low quality evidence for laser and intense pulsed light therapy. Laser therapy and intense pulsed light therapy were both effective for the treatment of telangiectasia, but only limited data was reported. Pulsed dye laser was more effective than yttrium-aluminium-garnet (Nd:YAG) laser based on one study, and it appeared to be as effective as intense pulsed light therapy (both low quality evidence).

An expert committee of the American Academy of Dermatology convened in 2007 to define guidelines for acne therapy and identify nine clinical questions to structure the primary issues in diagnosis and management (**Table 96-1**).[49] These guidelines address the management of adolescent and adult patients presenting with acne but not the consequences of disease, including the scarring, postinflammatory erythema, or postinflammatory hyperpigmentation. The use of light and laser therapy was not addressed in the guidelines. In 2009, The Global Alliance to Improve Outcomes in Acne updated their 2003 recommendations to review new information about pathophysiology and treatment and included current published data on relevant issues. They provided seven summary statements, most of which are based primarily on expert opinion (level V evidence) because of a lack of studies or different designs and methodologies of existing studies (evidence from published studies constitute levels I to IV).[54]

TABLE 96-1 Guidelines for Managing Acne Vulgaris

Clinical Question Issues	Recommendation	Strength of Recommendation[a]	Level of Evidence[a]
I			
Systems for the grading and classification of acne	Use a grading/classification system	B	II
IIa			
Role of microbiologic testing	Do microbiologic testing	B	II
IIb			
Role of endocrinologic testing	Do endocrinologic testing	A	I
III			

Clinical Question Issues	Recommendation	Strength of Recommendation[a]	Level of Evidence[a]
	Retinoids	A	I
Use of specific agents for topical therapy	Benzoyl peroxide	A	I
	Antibiotics	A	I
	Other agents	A	I
IV			
	Tetracyclines	A	I
Efficacy and safety of systemic antibiotics	Macrolides	A	I
	Trimethoprim-sulfamethoxazole	A	I
V			
	Contraceptive agents	A	I
Efficacy and safety of hormonal agents	Spironolactone	B	II
	Antiandrogens	B	II
	Oral corticosteroids	B	II
VI			
Efficacy and safety of isotretinoin	Isotretinoin	A	I
VII			
Efficacy and safety of miscellaneous therapy	Intralesional steroids	C	III
	Chemical peels	C	III
	Comedo removal	C	III
VIII			
Efficacy and safety of complementary therapy	Herbal agents	B	I
	Psychologic approaches	C	III
	Hypnosis/biofeedback	B	II
IX			
Efficacy and safety of dietary restrictions[b]	Effect of diet	B	II

[a]An expert panel of the American Academy of Dermatology developed these clinical recommendations using the best available evidence. The panel rated evidence using the Strength of Recommendation Taxonomy (SORT), which uses this three-point scale:

I. Good quality patient-oriented evidence.

II. Limited quality patient-oriented evidence.

III. Other evidence including consensus guidelines, extrapolations from bench research, opinion, or

case studies.

Similarly, recommendations were ranked as follows:

A. Recommendation based on consistent and good quality patient-oriented evidence.

B. Recommendation based on inconsistent or limited quality patient-oriented evidence.

C. Recommendation based on consensus, opinion, or case studies.

[b]See Clinical Controversy: Dietary Influences

Used with permission from Mills OH, Kligman AM. Comedogenicity of sunscreens. Experimental observations in rabbits. Arch Dermatol *1982;18(6):417-419*.

The Alliance consensus statements were as follows:[54]

1. Acne should be approached as a chronic disease.
2. Strategies to limit antibiotic resistance are important in acne management.
3. Combination retinoid-based therapy is first-line therapy for acne.
4. More data are needed to define the role of laser and light therapy in acne.
5. Topical retinoids should be first-line agents in acne maintenance therapy.
6. Early, appropriate treatment is best to minimize potential for acne scars.
7. Assess adherence via verbal interview or use of a simple tool.

General Information Regarding Efficacy and Safety

The guidelines and recommendations of the American Academy of Dermatology considered the efficacy and safety of various treatments, such as topical agents, systemic antibacterial agents, hormonal agents, isotretinoin, miscellaneous therapies, complementary and alternative therapies, and dietary restriction, based on levels of evidence and best clinical practice.[49] More specific information about the efficacy and safety of each of these specific modalities is outlined below in sections on each individual agent.

Alternative Drug Treatments

Complementary and Alternative Medications People with acne often turn to complementary and alternative medicine (CAM), such as herbal medicine, acupuncture, and dietary modifications, because of their concerns about the adverse effects of conventional medicines. Although these products might be well tolerated, very limited data exist regarding their safety and efficacy.

A systematic review of CAM treatments for acne in 2006 identified 15 randomized controlled trials

covering diverse approaches such as *Aloe vera*, pyridoxine, fruit-derived acids, kampo (Japanese herbal medicine), and ayurvedic herbal treatments.[55] Although mechanisms of potential benefit for some were biologically plausible, the included studies were of poor quality and inconclusive.

Another systematic review of seventeen traditional Chinese medicine randomized controlled trials found some benefit for acupuncture with moxibustion that was better than Western medicines, but the quality of included studies was limited.[55,56]

A review of studies published from 2007 to 2010 showed most studies were level of evidence grade D. Two studies of grade A concluded that topical tea tree oil 5% gel and gluconolactone are efficacious in mild-to-moderate acne, with the latter agent comparable with benzoyl peroxide 5%. No data supported these claims, and one study predated the review dimensions (published in 1992). Tea tree oil contains terpinen-4-ol, which appears to have some antimicrobial activity. One grade B study compared tea tree oil 5% against benzoyl peroxide 5% without placebo and concluded tea tree oil provided slower relief but less discomfort.[57]

A systematic review of four randomized controlled trials of tea tree oil in 2000 did not find conclusive evidence of benefit.[58] Tea tree oil continues to be studied for its efficacy and safety in acne.[59,60]

There is increasing interest in the use of CAM as adjuvant or single therapies: in America, 7% or people report using a complementary medicine, and 2% report seeing a complementary medicine practitioner.[61] Traditional Chinese medicine has been widely used to treat acne for many years, based on a diagnosis from a traditional Chinese medicine perspective according to the different syndromes of acne.

The Cochrane collaboration undertook a systematic review to assess the effectiveness and safety of any CAM in the management of acne vulgaris, reported in 2015.[60] This included 35 studies, with a total of 3,227 participants in parallel-group randomized controlled trials (or the first phase data of randomized cross-over trials) of any kind of CAM, compared with no treatment, placebo, or other active therapies, in people with a diagnosis of acne vulgaris. The primary outcome was improvement of clinical signs assessed through skin lesion counts. Some evidence from single studies showed low-glycemic load diet, tea tree oil, and pollen bee venom (PBV) may have an effect on reducing total skin lesion counts and acne severity scores. However, small sample sizes and poor methodological quality limited the strength of the evidence. Evidence from other existing randomized controlled trials does not support the use of herbal medicine, acupuncture, or wet-cupping therapy for the treatment of acne vulgaris. The evidence for a secondary outcome (number of participants with remission) for herbal medicine versus antibiotic was uncertain. Two trials reported QOL showed the benefit of herbal medicine compared with western drugs. The Cochrane review cautioned that there is a lack of evidence from the review of 31 studies to support the use of other CAMs, such as aloe vera, copaiba essential oil, dried fruit of Berberis vulgaris, or seaweed oligosaccharides for the treatment of this condition. Most studies were done in a traditional Chinese medicine context; therefore, results might be less generalizable to western medicine.

The review highlights potential adverse effects from herbal medicine (dizziness, dry mouth, nausea, diarrhea, or stomach upset); acupuncture (pain, itchiness, or redness) and tea tree oil gel (pruritus,

dryness, burning sensations, and skin flaking).

The use of botanical preparations which are nonstandardized should be discouraged in favor of traditional quality-controlled preparations that have evidence of efficacy. The lack of appropriate data, absence of quality assessment, and inconsistencies in search methodology suggest that CAM cannot be recommended for acne therapy at this time.

Glycolic Acid Another agent considered as an alternative therapy for acne vulgaris is glycolic acid. The efficacy and tolerability of a 0.1% retinaldehyde/6% glycolic acid combination (Diacneal) has been evaluated for mild-to-moderate acne vulgaris.[62] Physician and patient ratings of acne symptom severity and tolerance performed at baseline and months 1, 2, and 3 showed mean numbers of papules, pustules, and comedones were significantly reduced from month 1 on, demonstrating that glycolic acid is effective and well tolerated in mild-to-moderate acne vulgaris.

Both glycolic acid-based, salicylic acid or salicylic acid derivative-based, (eg, lipohydroxyacid) and amino fruit acid-peeling preparations have been used in the treatment of acne. There is very little evidence from clinical trials published in peer-reviewed literature supporting the efficacy of peeling regimens.[49] Topical corneolytics, including retinaldehyde/glycolic acid or lactic acid, induce a comedolytic effect and may also facilitate skin absorption of topical drugs.[46] Further research on the use of peeling in the treatment of acne needs to be conducted to establish best practices for this modality.

Hydroquinone To control pigmentation, hydroquinone, which reversibly damages melanocytes, has been used as a hypopigmenting agent in concentrations of 2% to 4%, in preparations of clear or tinted gels, which are more drying, and as vanishing or opaque, flesh-tinted creams, with or without α-hydroxy acids or sunscreens. Hydroquinone causes fading of epidermal but not dermal pigmentation. Onset of response is usually 3 to 4 weeks, and the depigmentation lasts for 2 to 6 months but is reversible. While effective in the removal of melanin, hydroquinone has been clinically found to be a possible carcinogen and causes a blue-black discoloration known as ochronosis.[63]

After considering new data and information on the safety of hydroquinone, the U.S. Food and Drug Administration (FDA) issued a proposed ruling in 2006 about hydroquinone products. The FDA proposed reversing earlier rules that hydroquinone is generally recognized as safe and effective. The FDA has not yet issued a final ruling on the status of nonprescription hydroquinone, and many physicians consider a ban unnecessary, given the lack of convincing evidence of carcinogenic risk to humans and the rarity of ochronosis occurrence.

Treatment of Scarring Drug and nonmeasures for scar resolution are important in acne vulgaris because many patients are scarred despite adequate treatment. For patients with mild scarring, nonprescription α-hydroxy acids may be used, while severe scarring may be corrected with other treatment modalities that require consultation with a dermatologist. Dermabrasion, local or subcuticular excision, collagen implants, chemical peels (eg, 70% glycolic acid, trichloroacetic acid) and laser therapy have been used to improve scarring. Atrophic scars can be treated with laser resurfacing. Usually the scar is not completely removed, but a more cosmetically acceptable result is achieved. Keloids and hypertrophic scars can be treated with intralesional triamcinolone, cryotherapy,

topical steroids, and silicone sheeting. Surgical options for scars include excision, augmentation with collagen or fat, chemical peels, subcision, and injection of autologous fibroblasts.

Special Populations

About 20% of young infants (2-3 months of age) develop papules, pustules, and less commonly closed or open comedones, primarily on the cheeks, due to placental transfer of maternal androgens (neonatal acne). The acne subsides within a few months with regular maturation. Boys are affected more often than girls because of a transient increase in testosterone secretion during the third and fourth month of intrauterine life. *Malassezia* spp. may be involved in pathogenesis.[21] Resolution occurs without therapy.[64] Infants with neonatal acne may have more severe teenage acne.[21]

The treatment of acne in children is similar to that in adults. Because topical therapies may be more irritating in children, initiation with low concentrations is preferred. Systemic treatments should be reserved for more extensive cases. Erythromycin is preferred over tetracyclines for children younger than 9 years of age because tetracyclines can affect growing cartilage and teeth.

Although treatment is with isotretinoin has numerous potential minor adverse effects in patients of all ages, an uncommon complication in young patients is premature epiphyseal closure. This generally occurs when isotretinoin is administered in high doses, thus limiting long-term therapy.

Selecting appropriate treatment in pregnant women can be challenging because many acne therapies are teratogenic; all topical and especially oral retinoids should be avoided. Oral therapies, such as tetracyclines and antiandrogens, are also contraindicated in pregnancy. Topical and oral treatment with erythromycin may be considered.

Acne in skin of color is an increasing problem, presenting unique challenges. Although combination therapy is now the standard of care in acne, concerns exist with the increased potential irritation and dryness in skin of color. Although individual medications can be titrated or applied at different times of day to avoid irritation, this is not always practical or desirable. There is a paucity of clinical studies that evaluate the safety and efficacy of acne medications in skin of color. One study has examined susceptibility to irritation in Fitzpatrick skin types I to III versus types IV to VI and found subjects with darker skin were not more susceptible and tolerability was comparable across the two groups. Hispanic subjects were not more susceptible to irritation compared with total study groups.[65]

Drug Class Information

This section reviews the pharmacology and mechanisms as related to pathophysiology for pharmacologic options recommended in the guidelines for mild, moderate, and severe acne. It will also review evidence of efficacy and safety as well as kinetics, interactions, dosing, and administration when relevant.

Exfoliants (Peeling Agents) Exfoliants induce continuous mild drying and peeling by primary irritation, damaging the superficial layers of the skin, and inciting inflammation. This stimulates mitosis, thickening the epidermis, and increasing horny cells, scaling, and erythema. A decrease in

sweating results in a dry, less oily surface and may superficially resolve pustular lesions.

In the past, a rabbit model was used to study the efficacy of topical exfoliants in retarding tar-induced comedone formation and accelerating their loss (comedolysis). In this animal model, retinoic acid (tretinoin) was most active, compared with benzoyl peroxide and salicylic acid, which were respectively less active. Data from peer-reviewed literature regarding the efficacy of sulfur, resorcinol, sodium sulfacetamide, aluminum chloride, and zinc are limited. Traditional nonprescription exfoliants, including phenol, resorcinol, beta-naphthol, sulfur, Vleminckx solution, and sodium thiosulfate, are weak or ineffective. These agents are not comedolytic given that they affect the superficial epidermis rather than the hair canal. They have been supplanted by superior effective agents. Linoleic acid-rich phosphatidylcholine combined with 4% nicotinamide is suggested as an emulsion treatment that may be effective in normalization of follicular hyperkeratinization, and also provide anti-inflammatory effects.[66,67]

Resorcinol This phenol derivative is less keratolytic than salicylic acid. It is noted to be both bactericidal and fungicidal. Products containing resorcinol 1% to 2% have been used for acne, often in combination with other peeling agents such as sulfur or salicylic acid. The FDA considers resorcinol 2% and resorcinol monoacetate 3%, in combination with sulfur 3% to 8%, to be safe and effective and that the combination may enhance the activity of sulfur. However, the FDA is not convinced that resorcinol and resorcinol acetate are safe and effective when used as single ingredients, and has placed such products in category II (not generally recognized as safe and effective, or misbranded).[67]

Resorcinol is an irritant and sensitizer and should not be applied to large areas of the skin or on broken skin. It produces a reversible, dark brown scale on some dark-skinned individuals.

Protective packaging is important as resorcinol is reactive to light and oxygen. It has good solubility in both water and alcohol and is heat stabile Thus, it is incorporated into a variety of products, including emulsions.[68]

Salicylic Acid Salicylic acid, a β-hydroxy acid, has been used for many years for the treatment of acne, although few well-designed trials of its safety and efficacy exist. It is a natural ingredient in many plants such as willow tree or willow bark, and penetrates the pilosebaceous unit. It has comedolytic activity, although the concentrations in commercial preparations (<2%-3%) are generally low. While concentrations less than 2% may actually increase keratinization, concentrations between 3% and 6% are keratolytic, softening the horny layer and producing shedding of scales. Its mechanism remains unresolved, attributed to either reduced cohesion of corneocytes or shedding of epidermal cells, rather than breakdown of keratin.

Salicylic acid has no effect on the mitotic activity of normal epidermis and does not influence disordered cornification.[69] It may also provide mild antibacterial value, as it is active against *P. acnes*. It also offers slight anti-inflammatory activity at concentrations ranging from 0.5% to 5%. Its efficacy against comedones helps to prevent development of inflamed lesions, thus providing a delayed efficacy.[70]

Salicylic acid is effective. As a peeling agent, its relative strength compared with others in this class

varies according to the model used in measurement. It is slightly *less* potent than equal-strength benzoyl peroxide when measured with the rabbit ear animal model, and slightly *more* potent when measured with a biologic microcomedone model.[70] Its anti-inflammatory properties may help dry ILs.[68] Its comedolytic properties are considered less potent than topical retinoids. It is often used when patients cannot tolerate a topical retinoid because of skin irritation.[71]

Its keratolytic effect may enhance the absorption of other agents. Salicylic acid is a mild irritant and may cause some degree of local skin peeling and discomfort (burning or reddening). It is not a sensitizer. Although the FDA recognizes salicylic acid as safe and effective, the compound offers no advantages over more modern topical agents such as benzoyl peroxide.[67,69,71]

Salicylic acid products are often used as first-line therapy for mild acne because of their widespread availability without a prescription. They are often available in alcohol–detergent impregnated pads as well as washes, bars, and semisolid vehicles. Lower concentrations are sometimes combined with sulfur to produce an additive keratolytic effect. Concentrations up to 5% to 10% can be used for acne, beginning with a low concentration and increasing as tolerance to the irritation develops. However, the maximum strength allowed in nonprescription acne products is 2%. In high concentrations of 20% to 30% in hydroethanolic vehicles, salicylic acid, either alone or in combination, can be used as a peeling agent for comedonal acne and hyperpigmentation. It has been shown to extrude closed and open comedones several days after peel, but it must be applied under strict control to offer this adjunctive benefit when treating acne vulgaris.[72]

Sulfur Sulfur medications often lessen the severity of acne, presumably because of keratolytic and antibacterial action. Sulfur helps to resolve comedones by an exfoliant action. Its popularity is due to its ability to quickly resolve pustules and papules, mask and conceal lesions (similar to a thick foundation lotion), and produce irritation leading to skin peeling and mild antibacterial action. Sulfur is used in the precipitated or colloidal form in concentrations of 2% to 10%, because it is practically insoluble in water and must be well dispersed. Its stability depends on effective maintenance of the dispersion.[68] Sulfur compounds (eg, sulfides, thioglycolates, sulfites, thiols, cysteines, and thioacetates) are also available and somewhat weaker. Sulfur can cause slight ophthalmic and dermatologic irritation, and patients should be cautioned to avoid eye contact. Use should be discontinued if excessive irritation results. Although it is often combined with salicylic acid or resorcinol to increase its effect, its use is limited by its offensive odor and the availability of more effective agents.[73]

Sulfur has met the criteria of the FDA Advisory Review Panel for nonprescription topical acne products and is considered safe and effective when used alone, although its antibacterial effects were not recognized by this panel. Sodium thiosulfate, zinc sulfate, and zinc sulfide were not considered safe and effective.

Topical Retinoids Normal epithelial cell differentiation is a vitamin A-dependent process, and currently, the most powerful peeling agents are related retinoid compounds. The effectiveness of topical retinoids in the treatment of acne is well documented. There is no consensus about the relative efficacy of currently available topical retinoids (tretinoin, adapalene, tazarotene) and oral

isotretinoin. The rationale for the use of topical retinoids is based on their ability to target key stages in the development of the disease; the agents act by binding to specific nuclear receptors, reducing inflammation, and inhibiting sebocyte proliferation and differentiation, which reduces sebum production.

These agents act to reduce obstruction within the follicle and therefore are useful in the management of both comedonal and inflammatory acne. As a group, the retinoids are highly active peelers as they reverse abnormal keratinocyte desquamation.[74] They improve acne vulgaris by inhibiting microcomedone formation, diminishing the number of mature comedones and subsequently, ILs. They also normalize follicular epithelium maturation and desquamation. The third-generation retinoids (ie, adapalene and tazarotene) are receptor specific. Topical retinoids, unlike isotretinoin, do not decrease production of sebum, but primarily decrease inflammation, normalize keratinocyte differentiation, and increase keratinocyte proliferation and migration.[74]

Retinoids facilitate acne clearance through secondary effects of loosening and decreasing corneocytes. This increases skin permeability, facilitates absorption of other agents, such as antimicrobials or benzoyl peroxide, and increases penetration of oral antibiotics into the follicular canal. As a result, the overall duration of antibiotic treatment decreases, and the possibility of resistance lessens. Therefore, combination products with oral or topical antimicrobials are available for increased efficacy, faster onset of effects, decreased total antibiotic use and risk of resistance, and shorter duration of treatment.[74] Retinoids may also improve and prevent postinflammatory hyperpigmentation often seen in people with darker complexions who have acne.

Retinoic acid (vitamin A acid or tretinoin) is a powerful exfoliant that slows the desquamation process, reducing numbers of both microcomedones and comedones.[16] It is not to be used in pregnant women because of risk to the fetus. Gels and creams are less irritating than solutions.

Adapalene is a stable, fast-acting, antiacne treatment that has significant anti-inflammatory and comedolytic properties.[74,75,76,77,78] It causes epidermal and follicular epithelium hyperplasia, increased desquamation, keratinocyte differentiation, and loosening of corneocyte connections. Its anti-inflammatory effect is due to the inhibition of oxidative metabolism of arachidonic acid and inhibition of chemotactic reponses.[78] It is better at reducing ILs and total lesion count[78] and causes less local irritation because of its mechanisms and receptor specificity than tretinoin or tazarotene.[74,75,76,77,78,79,80,81] Release from lotions and hydroalcoholic gels is more effective than from creams and aqueous gels and a microsphere gel formulation may be less irritating.[74,80] It is a good first-line therapy for colder climates or in patients with sensitive skin.[63]

Adapalene is generally regarded as the topical retinoid of first choice for both treatment and maintenance therapy, as it is as effective but less irritating than other topical retinoids.[42,54] It is available in fixed-dose combinations in specialized gel vehicles with benzoyl peroxide to increase the efficacy in comparison with monotherapies. This strategy allows for the synergy of adapalene effects on normalizing desquamation with reduction of inflammation due to benzoyl peroxide action against *P. acnes*.

Tazarotene is also a specific agent with superior efficacy to parent retinoids, reducing both noninflammatory and ILs.[74] While its exact mechanism is unknown, it is thought to activate retinoid receptors and thereby affect keratinocyte differentiation, and inhibit proinflammatory transcription factors to decrease cell proliferation and inflammation.[74] It penetrates skin but accumulates in the upper dermis. It is as effective as adapalene in reducing noninflammatory and IL counts when applied half as frequently. Compared with tretinoin, it is as effective for comedonal and more effective for ILs when applied once daily.[82,83,84] Tazarotene foam, 0.1% has been studied as an alternative vehicle to the gel with less systemic absorption and is a safe and effective formulation.[85,86] Tazarotene is not degraded by sunlight.[16]

The retinoid class includes the systemic agent isotretinoin, which has effects on comedogenesis and sebum control, and is reviewed below under Anti-sebum Agents.

Retinoids tend to produce remissions that are maintained for extended periods of time, provided the accompanying irritation does not impede patient adherence. However, such adverse effects including erythema, xerosis, burning, and desquamation are issues for many patients. The concentration and/or vehicle of any particular retinoid may decrease tolerability.[75,76] Most retinoids are unstable and insoluble in water.

Topical retinoids are not teratogenic; however, tretinoin should be used cautiously in pregnancy and tazarotene is contraindicated. Tretinoin and adapalene are in FDA category C, while tazarotene, based on large-surface-area use in psoriasis (see Chapter 78), is in FDA category X.[21]

Skin type and age may influence tolerability in addition to choice of vehicle. Oily skin may be more resistant, and darker skin is more prone to postinflammatory hyperpigmentation due to retinoid dermatitis. To decrease irritation, start with the lowest concentration and increase as tolerated. Application of retinoids should be at night, a half hour after cleansing, starting with every other night for 1 to 2 weeks to adjust to irritation. Short contact time starting with 2 minutes and adding 30 seconds per dose can be advised for patients with sensitive skin or in the winter, discontinuing and resuming after a 3-day rest if undue irritation results. Doses can be increased only after beginning with 4 to 6 weeks of the lowest concentration and least irritating vehicle. Gels and creams are less irritating than solutions. Adapalene and tazarotene are photoirritants (not photosensitizers), and sun avoidance and sunscreen use are imperative.[74]

Overall, topical retinoids are the cornerstone of acne treatment and provide safe, effective, and economical means of treating all but the most severe cases of acne vulgaris. They should be the first step in moderate acne, alone or in combination with antibiotics and benzoyl peroxide, reverting to retinoids alone for maintenance once adequate results are achieved. Their lack of effect in inducing bacterial resistance enables long-term maintenance of remission.

A Cochrane systematic evidence-based assessment of all issues regarding acne treatment with topical retinoids is planned to establish optimal treatment regimens, compare efficacy and tolerability of combination therapy, assess effect on *P. acnes* resistance, and evaluate safety.[84]

Antibacterial Agents Choices for antibacterial therapy include benzoyl peroxide, prescription topical

and systemic antibiotics, and combination products. These drugs kill *P. acnes* and inhibit the production of proinflammatory mediators by organisms that are not killed.[16]

Benzoyl Peroxide Benzoyl peroxide is a bactericidal agent that has proven effective in the treatment of acne. Because of concerns of resistance, it is often used in the management of patients treated with oral or topical antibiotics. It has the ability to prevent or eliminate the development of *P. acnes* resistance.

Benzoyl peroxide is a derivative of coal tar and was first used for acne vulgaris in the mid-1960s, becoming popular once stable formulations aimed at its heat-lability were developed in the mid-1970s.[79] These preparations are the single most useful group of topical nonprescription drugs. Used alone or in combination, benzoyl peroxide is the standard of care for mild-to-moderate papular-pustular acne.[14,54] It is an agent of first choice when combined with adapalene for most patients with mild-to-moderate inflammatory acne vulgaris and a second choice alternative for patients with noninflammatory comedonal acne.[14,54] A systematic review of 22 trials using benzoyl peroxide for acne vulgaris provided evidence that it reduces acne-lesion count, although high quality evidence is not robust enough for firm conclusions.[87]

Benzoyl peroxide is well absorbed through the stratum corneum and concentrates in the pilosebaceous unit.[88] It has three principle actions useful in both noninflammatory and inflammatory acne. It produces powerful anaerobic antibacterial activity due to slow release of oxygen, thereby acting against gram-positive and gram-negative bacteria, yeasts, and fungi. This nonspecific antibacterial mechanism does not induce resistance with long-term use.[88] It has a rapid (within 2 hours) bactericidal effect that lasts at least 48 hours. As a result, it may decrease the number of inflamed lesions within 5 days. As an indirect effect, it induces suppression of sebum production; it does not reduce skin surface lipids, but is effective in reducing free fatty acids, which are comedogenic agents and triggers of inflammation.[88] Topical benzoyl peroxide 5% lowers free fatty acids 50% to 60% after daily application for 14 days, and decreases aerobic bacteria by 84% and anaerobic bacteria (primarily *P. acnes*) by 98%.

It also produces comedolysis. While earlier rabbit model studies showed a benzoyl peroxide effect greater than that of salicylic acid, these animal comedones were not physiologic but induced by tar. More recent studies using native microcomedones show an anticomedogenic effect that is only comparatively slight, compared with tretinoin or salicylic acid.[89,90,91]

Finally, a supplementary benefit of benzoyl peroxide is an indirect anti-inflammatory action, which is due either to its antibacterial or oxidizing effects. This has been reported in several studies and thus can be used to support treatment of predominantly inflamed lesions.[88] The drug's antiacne effect is augmented by increased blood flow, dermal irritation, local anesthetic properties, and promotion of healing.[92,93,94,95] Because the primary effect of benzoyl peroxide is antibacterial, it is most effective for inflammatory acne. Many patients with noninflammatory comedonal acne will respond to its peeling action.

Benzoyl peroxide is available in a variety of preparations including gel, washes, lotions, and creams.

There is no clear superiority of different preparations in terms of effectiveness. Newer delivery systems to enhance efficacy and tolerability are also being investigated.

Cleansers containing benzoyl peroxide are available as nonprescription liquid washes and solid bars of various strengths. The desquamative and antibacterial effectiveness in a soap or wash is minimized by limited contact time and removal with proper rinsing. Stable lotions are available in 2.5%, 5%, and 10%. Alcohol and acetone gels facilitate bioavailability and may be more effective, while water-based vehicles are less irritating and better tolerated. Paste vehicles are stiffer and more drying than ointments or creams, which facilitate absorption and allow the active ingredients to stay localized.

Concentrations of 2.5%, 5%, and 10% in a water-based gel have been compared with the vehicle alone. The 2.5% formulation is equivalent to the 5% and 10% formulation in reducing the number of ILs. The lower strength may not be as effective a peeler compared to higher strengths, which is due to an irritancy reaction. Thus, irritant side effects with the 2.5% gel are less frequent than with the 10% gel but are equivalent to the 5% gel. The lowest concentration of benzoyl peroxide should be used for treating patients with easily irritated skin and may lessen irritation when used in combination topical therapy with comedolytic agents.

Benzoyl peroxide may bleach hair, bedsheets, and clothing. It produces a mild primary irritant dermatitis that subsides with continued use and is more likely to occur in those with fair complexions, a tendency to irritancy, or propensity to sunburn. This irritation is dependent on the concentration and the vehicle, being higher with alcoholic gels compared with emulsion bases.[88] There are rare reports of contact allergic dermatitis. Cross-reactions with other sensitizers, notably Peruvian balsam and cinnamon, are well established. It may cross-sensitize to other benzoic acid derivatives such as topical anesthetics. Concomitant use of an abrasive cleanser may initiate or enhance sensitization.[96]

Another side effect is body odor from breakdown of the benzoyl peroxide that remains on clothing and bedsheets.

There is no indication that the normal use of benzoyl peroxide in the treatment of acne is associated with an increased risk of facial skin cancer. Although links have been made in experiments with mice, human relevance has not been established. The weak in vitro genotoxic potential is not manifested in vivo based on a lack of initiating or complete carcinogenic activity.[88] Overall, the cutaneous use of benzoyl peroxide is relatively safe, and is recognized by the FDA as category III, which means that more information is required to make a final determination of safety and efficacy for nonprescription use.[97,98,99,100] Safety is also confirmed by the American Academy of Dermatology and the German Best Guideline Acne (BGA) Monograph.[88]

Benzoyl peroxide has been used in combination with other antiacne medications, such as sulfur and chlorhydroxyquinoline, or in formulations with urea to facilitate drug delivery. No significant improvement has been demonstrated.

Benzoyl peroxide has also been combined with prescription agents to improve efficacy, reduce dosing strengths, decrease irritation, and reduce resistance of antibiotics.[101,102,103,104]

Benzoyl peroxide is often combined with topical retinoid for an antimicrobial effect or used in conjunction with an antimicrobial. It reduces the likelihood of antibiotic resistance. For long-term maintenance therapy, it is recommended as a highly efficient bactericidal agent to be added to a topical retinoid.[54]

The benefits in efficacy and tolerability of combining topical antibiotics with benzoyl peroxide over using either as monotherapy have been demonstrated in several trials, most in combination with clindamycin. Combination with erythromycin show advantages over oral tetracycline monotherapy.[105]

The adjunctive use of clindamycin/benzoyl peroxide gel with tazarotene cream promotes greater efficacy and may also enhance tolerability. Increased tolerability might be attributed to emollients in the clindamycin/benzoyl peroxide gel formulation.[106] A patented gel formulation of benzoyl peroxide 5%/clindamycin phosphate 1% (clindamycin) containing dimethicone and glycerin was studied both as a monotherapy and in combination with topical retinoid use. Certain additives, such as silicates and specific humectants, reduced irritation by maintaining barrier integrity.[107]

All single-agent preparations of benzoyl peroxide are now available without prescription. Recommend the weakest concentration (2.5%) in a water-based formulation, for anyone with a history of skin irritation, or who must use combination therapy.[107] There are many suggested routines to initiate therapy. One is to gently cleanse the skin and apply the preparation for 15 minutes the first evening, avoiding the eyes and mucous membranes. A mild stinging and reddening will appear. Each evening the time should be doubled until the product is left on for 4 hours and subsequently all night. Dryness and peeling will appear after a few days. Once tolerance is achieved, the strength may be increased to 5% or the base changed to the acetone or alcohol gels, or to paste. Alternatively, benzoyl peroxide can be applied for 2 hours for four nights, 4 hours for four nights, and then left on all night. It is important to wash the product off in the morning. Other drying agents should be discontinued. Patients with very sensitive skin or demonstrated sensitivity to benzoyl peroxide should not use the product, and it should be discontinued if irritation becomes severe upon use. Contact with eyes, lips, or mouth should be avoided.

A sunscreen is recommended if benzoyl peroxide is used. To avoid interactions, apply the sunscreen during the day and the benzoyl peroxide at night.

Comparison of Salicylic Acid and Benzoyl Peroxide Although both salicylic acid and benzoyl peroxide are used for mild-to-moderate acne, their mechanisms differ and therefore different types of acne respond to each. Benzoyl peroxide is a strong antibacterial agent, while salicylic acid acts primarily through keratolysis.

Studies have shown salicylic acid to be equal or slightly superior to benzoyl peroxide in reducing number of comedones and subsequently number of ILs. Any superiority salicylic acid demonstrates is likely because it interferes with an earlier step in pathogenesis—formation of the primary lesion of acne, the microcomedone.[69,71] However, studies of the compound did not use identical formulations. Instead, they compared salicylic acid cleansers to benzoyl peroxide washes and salicylic acid solutions to benzoyl peroxide creams. The effect of different bases is critical in determining differences in

efficacy and therefore comparability of action since the base itself has an effect and influences penetration and duration of action.

In summary, the two products have similar efficacy, with salicylic acid noted as stronger in terms of retarding comedone formation. Benzoyl peroxide, as an antibacterial with some peeling effects, is considered the nonprescription and cosmetic gold standard for milder versions of the condition, used alone or in combination to increase efficacy and improve tolerability; however, salicylic acid is included in many of these products because of the perception of efficacy and safety for comedonal acne of type 1 or milder presentation.[70]

Topical Antibacterials The value of topical antibiotics in the treatment of acne has been investigated in many clinical trials. In addition to reduction of *P. acnes* as the primary mechanism for efficacy in acne, certain antibiotic drugs are also potent anti-inflammatory agents via other mechanisms.

Macrolides, including topical erythromycin and topical clindamycin, have been demonstrated to be effective and are well-tolerated, well-established acne treatments. However, they have become less effective since the early 1990s because of resistance by *P. acnes*.[108] Decreased sensitivity of *P. acnes* to these antibiotics can limit the use of either drug as a single therapeutic agent. Resistant strains are usually resistant to all of the macrolides. Addition of benzoyl peroxide or topical retinoids to the macrolide antibiotic regimen is more effective than monotherapy and mitigates against survival of resistant *P. acnes* populations.

Clindamycin is the preferred macrolide because of potent action, lack of absorption, and its limited systemic use because it can cause pseudomembranous colitis when given orally or by injection. It is available as a single ingredient topical preparation and can also be combined with benzoyl peroxide. A topical fixed-dose clindamycin phosphate 12% and benzoyl peroxide 30% combination gel once daily was more effective and twice daily at least as effective as clindamycin alone twice daily, with an early onset of action and an acceptable safety and tolerability profile.[109] Erythromycin is available alone and in combination with retinoic acid or benzoyl peroxide. Some topical antibiotic–benzoyl peroxide combinations require refrigeration.[49] Other topical antibiotics that are being studied include fluoroquinolones, such as 1% nadifloxacin cream, but are not available in the American market. Research approaches for developing new antibiotics against *P. acnes* include combining ribosomal effects of aminoglycosides molecules with bacteria-selective membrane-permeabilizing abilities in one drug.[110]

Oral Antibacterials Systemic antibiotics are a standard of care in the management of moderate and severe acne and treatment-resistant forms of inflammatory acne. There is evidence to support the use of tetracycline, doxycycline, minocycline, erythromycin, trimethoprim–sulfamethoxazole, trimethoprim, and azithromycin. Studies do not exist for the use of ampicillin, amoxicillin, or cephalexin. However, any antibiotic that can reduce the *P. acnes* population in vivo and interfere with the organism's ability to generate inflammatory agents should be effective.[49] Although erythromycin is effective, use should be limited to those who cannot use one of the tetracyclines (ie, pregnant women or children under 8 years of age because of the potential for damage to the skeleton or

teeth). Ciprofloxacin, trimethoprim-sulfamethoxazole, and trimethoprim alone are also effective in instances where other antibiotics cannot be used or for patients who do not respond to conventional treatment.[67,111] A comparison of azithromycin with doxycycline reported doxycycline is a better option for treatment of acne vulgaris.[112]

The tetracycline antibiotic family has multiple modes of action, well-understood antibacterial effects, and anti-inflammatory effects that target an additional aspect of pathogenesis.[108,111,113] Agents, such as tetracycline, minocycline, and doxycycline, are used only as systemic agents. Through calcium chelation, they inhibit neutrophil and monocyte chemotaxis. Concentrations below the antibiotic threshold still inhibit inflammation, and improve both acne vulgaris and acne rosacea.

Tetracycline is no longer the drug of choice in this family; its disadvantages include diet-related effects on absorption and the drug's lower anti-inflammatory and antibacterial activity.

The incidence of significant adverse effects with oral antibiotic use is low. However, adverse effect profiles may be helpful for each systemic antibiotic used in the treatment of acne. Vaginal candidiasis may complicate the use of all oral antibiotics.[49] Doxycycline is very commonly a photosensitizer especially at higher doses.

Minocycline has been associated with pigment deposition in the skin, mucous membranes, and teeth, particularly among patients receiving long-term therapy and/or higher doses of the medication. In some cases this is irreversible. Pigmentation occurs most often in acne scars, anterior shins, and mucous membranes. Minocycline may cause dose-related dizziness, which resolves with dose titration; urticaria; hypersensitivity syndrome, autoimmune hepatitis, a systemic lupus erythematosus-like syndrome; and serum sickness-like reactions.[49,108]

The Cochrane collaboration has conducted a review into the efficacy and safety of minocycline, examining 39 randomized controlled trials. These studies show that minocycline is an effective treatment for moderate to severe inflammatory acne but present no evidence to support the first-line use of minocycline in acne treatment. The drug is more lipophilic, may act more quickly, and can be taken once daily. However, people treated with minocycline are at a significantly greater risk of developing an autoimmune syndrome than those given tetracycline or no treatment.[114]

The majority of oral antibiotic course durations follow guidelines. Costs of antibiotic therapy are reported lower for shorter courses and those using generic medications.[115]

Bacterial resistance to antibiotics is an increasing problem particularly because therapy is directed at control over a long period of time.[108] The development of strains with unidentified mutations suggest new mechanisms of resistance are evolving. Combined resistance to clindamycin and erythromycin is much more common than resistance to tetracycline.[14] Use of topical antibiotics can lead to resistance largely confined to the skin of treated sites, whereas oral antibiotics can lead to resistance in commensal flora at all body sites. Resistance is more common in patients with moderate-to-severe acne and in countries with high outpatient antibiotic sales. Resistance is disseminated primarily by person-to-person contact, and thus the spread occurs frequently.

There have been an increasing number of reports of systemic infections caused by resistant *P. acnes* in non-acne patients after surgery. A transmission of factors conferring resistance to bacteria other than *P. acnes* has been described.

The most likely effect of resistance is to reduce the clinical efficacy of antibiotic-based treatment regimens to a level below that in patients with fully susceptible flora. This has been shown as a decreased clinical efficacy of topical erythromycin in clinical trials; there is no evidence to date of this effect in treatments with oral tetracycline or topical clindamycin.

Studies on *P. acnes* resistance have highlighted the need for treatment guidelines to restrict the use of antibiotics to limit the emergence of resistant strains. Patients with less severe forms of acne should not be treated with oral antibiotics, and where possible such therapy should be limited to the shortest feasible duration (eg, 6-8 weeks). Local patterns of resistance should be considered.[105] The use of systemic antibiotics should be limited (both indication and duration) and topical antibiotic monotherapy should be avoided.

There should be early use of combination therapy with retinoids. Often, when oral antibiotics are combined with topical agents, the antibiotic may be discontinued after 6 months of therapy.[116] Nearly 70% of patients with acne require antibiotics for 12 weeks or less if aggressive retinoid therapy is used during that time.[108]

Another potential strategy that had been suggested is to eliminate the use of antibiotics and combine other topical agents. Neither retinoids nor benzoyl peroxide creates selective pressure for resistance and is one combination option. Although this approach has been evaluated for efficacy and safety, there is limited evidence of its effect on microbial resistance. In one open label study of adapalene and benzoyl peroxide, baseline counts of antibiotic resistant strains of *P. acnes* were reduced by week 4.[54,105]

The high sensitivity of *P. acnes* to acidified nitrite suggests a useful role in the treatment of antibiotic resistant acne. Nitric oxide and its intermediates diffuse as well as oxygen, and would be expected to penetrate the ILs well. The newly developed topical nitric oxide-releasing agent holds potential in limiting antibiotic resistance.[117] Further work to optimize the pharmacokinetic delivery of nitric oxide releasers could increase bactericidal effectiveness.[118]

Stricter cross-infection control measures are recommended when assessing acne. Any topical or systemic antibiotic therapy should be combined when possible with broad-spectrum antibacterial agents such as benzoyl peroxide. In addition, isotretinoin use should be initiated earlier in indicated patients, rather than prolonging antibiotic courses.[14]

Azelaic Acid Azelaic acid possesses activity against all four pathogenic factors that produce acne. It has anti-inflammatory and antibacterial activities. Azelaic acid also normalizes keratinization, which accounts for its anticomedogenic effect. It is a competitive inhibitor of mitochondrial oxidoreductases and of 5-α-reductase, inhibiting the conversion of testosterone to 5-dehydrotestosterone. It also possesses bacteriostatic activity to both aerobic and anaerobic bacteria including *P. acnes*. Azelaic acid is an antikeratinizing agent, displaying antiproliferative cytostatic effects on keratinocytes and

modulating the early and terminal phases of epidermal differentiation.[119] It may produce hypopigmentation. Inhibition of thioredoxin reductase by azelaic acid provides a rationale for its depigmenting property.

Azelaic acid 20% cream is used in the treatment of mild-to-moderate inflammatory acne, has an excellent safety profile with minimal adverse effects, and is well-tolerated in comparison with other acne treatments. The most common adverse effects, occurring in approximately 1% to 5% of patients, are pruritus, burning, stinging, and tingling. Adverse reactions are generally transient and mild in nature. Other adverse reactions, such as erythema, dryness, rash, peeling, irritation, dermatitis, and contact dermatitis, have been reported in less than 1% of patients.[119]

Azelaic acid has been shown effective in clinical trials studied with topical 2% erythromycin, topical 5% benzoyl peroxide gel, and topical 0.05% tretinoin cream in the treatment of mild-to-moderate inflammatory acne. However, the agent has limited efficacy, compared with other antiacne therapies.[49] It is an alternative to first choice therapy for comedonal and all types inflammatory acne, particularly in combination.[14] It is an alternative to topical retinoids for maintenance therapy as its efficacy and safety profile are advantageous for long-term therapy.[14]

Azelaic acid should be applied twice a day, in the morning and evening. A majority of patients with ILs may experience an improvement in their acne within 4 weeks of beginning treatment. However, treatment may be continued over several months, if necessary.

Azelaic acid is in a pregnancy category B and should only be used in pregnant women if medically necessary. Patients with dark complexions should be monitored for early signs of hypopigmentation.

Dapsone Topical dapsone 5%, a synthetic sulfone, is a recently introduced treatment for acne available as a topical gel. Sulfones have both anti-inflammatory and antibacterial properties, and may be used in sulfonamide-allergic patients.

Dapsone's utility is attributable to its anti-inflammatory and antimicrobial properties that improve both inflammatory and noninflammatory acne, with more prominent effects occurring in ILs. Short- and long-term safety and efficacy have been demonstrated.[120,121]

Topical dapsone gel 5% was shown to be safe, minimally irritating, and effective after 12 weeks in the treatment of mild-to-moderate inflammatory facial acne in 101 adult women with sensitive skin.[122] The response to dapsone 5% gel appears to be influenced by gender, with female patients experiencing a significantly greater reduction in acne lesion counts and a significantly higher clinical success rate following 12 weeks of treatment.[123]

Topical dapsone is a novel addition to the treatment armamentarium, especially for patients exhibiting sensitivities or intolerance to conventional antiacne agents.[124]

Topical dapsone 5%, alone or in combination, with adapalene 0.1% or benzoyl peroxide 4% has been shown to be safe and efficacious, but may be more irritating than other topical agents.[125,126]

Intralesional Steroids Intralesional corticosteroid injections are effective in the treatment of individual inflammatory acne nodules. The effect of intralesional injection with corticosteroids is a well-established and recognized treatment for large ILs. Cystic acne improved in patients receiving intralesional steroids.[49]

Systemic absorption of steroids may occur with intralesional injections. Adrenal suppression was observed in one study. The injection of intralesional steroids may be associated with local atrophy. Lowering the concentration and/or volume of steroid may minimize these complications.

Anti-sebum Agents No topical agents directly influence the production of sebum. Systemic drugs that influence sebum production include high-dose estrogens, antiandrogens (cyproterone acetate), spironolactone, and the retinoid isotretinoin. Antioxidants, such as sodium l-ascorbyl-2-phosphate 5%, may act to prevent the oxidation of sebum and studies are in preliminary stages.

Oral antiandrogens, such as spironolactone and cyproterone acetate, can also be useful in the treatment of acne. While flutamide can be effective, hepatotoxicity limits its use. There is no evidence to support the use of finasteride. There are limited data to support the effectiveness of oral corticosteroids in the treatment of acne. Oral corticosteroid therapy is of temporary benefit in patients who have severe inflammatory acne. In patients who have well-documented adrenal hyperandrogenism, low-dose oral corticosteroids may be useful in treatment of acne.[49]

Oral Contraceptives Estrogen-containing oral contraceptives can be useful in the treatment of acne in some women. Those currently approved by the FDA for the management of acne contain norgestimate with ethinyl estradiol and norethindrone acetate with ethinyl estradiol. There is good evidence and consensus opinion that other estrogen-containing oral contraceptives are also equally effective.[49]

The Cochrane collaboration conducted a review in 2012 to determine the effectiveness of combination oral contraceptives (COCs) for the treatment of facial acne compared with placebo or other active therapies. Thirty-one trials with a total of 12,579 women were reviewed.[126]

Combination oral contraceptive use reduced inflammatory and noninflammatory facial lesion counts, severity grades, and self-assessed acne in nine placebo comparison trials, according to the review. Progestins included levonorgestrel, norethindrone acetate, norgestimate, drospirenone, dienogest, and chlormadinone acetate. There were fewer clear differences in trials that compared varying progestin types, showing no superiority, little differences, or conflicting results. No conclusions could be reached regarding the effect of a COC compared with an antibiotic because there was only one underpowered trial.[126]

Most studies assessed women over six treatment cycles, which might not be adequate for a chronic condition like acne. In two trials, patients were more likely to discontinue because of adverse events. Thus even if COCs improve acne, women might not be willing to accept long-term use for acne because of other side effects.

The review concluded that COCs should be considered for women with acne who also want an oral

contraceptive.

A meta-analysis review of 32 randomized controlled trials comparing use of antibiotics to oral contraceptive agents for acne compared with placebo, concluded that although antibiotics may be superior at 3 months, oral contraceptive agents are equivalent to antibiotics at 6 months in reducing acne lesions and, may be a better first-line alternative to systemic antibiotics for long-term acne management in women.[127]

There is a need for more research into comparative effectiveness of COCs in randomized control trials, and into the acceptability and need for long-term use of COCs for acne.[126]

Spironolactone At higher doses, spironolactone is an antiandrogenic compound. Dosages of 50 mg to 200 mg have been shown to be effective in acne. Spironolactone may cause hyperkalemia, particularly when higher doses are prescribed or when there is cardiac or renal compromise. It occasionally causes menstrual irregularity. A 5% spironolactone gel, studied in patients with increased sebum secretion, resulted in a decrease in the total acne lesions with no significant efficacy under the acne severity index.[128]

Cyproterone Acetate Cyproterone combined with ethinyl estradiol (in the form of an oral contraceptive) has been found effective in the treatment of acne in females. Higher doses have been found more effective than lower doses. No cyproterone/estrogen-containing oral contraceptives are approved for use in the United States.[126]

Oral Corticosteroids Oral corticosteroids have two potential modes of activity in the treatment of acne. One study demonstrated that low-dose corticosteroids suppress adrenal activity in patients who have proven adrenal hyperactivity.[129] Expert opinion is that short courses of higher dose oral corticosteroids may be beneficial in patients with highly inflammatory disease.

Oral Isotretinoin Isotretinoin revolutionized the treatment of acne, yet its use and availability are increasingly complex. The risk of potential adverse effects must be weighed against its ability to prevent lifelong and permanent physical and psychologic scarring.[130]

A good understanding of this agent's mechanisms and adverse effects is important. Oral isotretinoin is a natural metabolite of vitamin A. Its mechanism is elusive, as it does not bind to retinoid receptors. It has been shown to reduce sebogenesis and may also inhibit sebaceous gland activity, growth of *P. acnes*, inflammation, and improve follicular epithelial differentiation.[131] Systemic isotretinoin exerts a primary effect on comedogenesis, causing a decrease in size and reduction in formation of new comedones.[16] Isotretinoin is the only drug treatment for acne that produces prolonged remission.

Oral isotretinoin is approved for the treatment of severe recalcitrant nodular acne. Oral isotretinoin is also useful for the management of less severe acne that is treatment-resistant (unresponsive to adequate treatment, reasonable courses of antibiotic, or combination peelers and antibiotics administered for 6 weeks to 3 months) or that is producing either physical or psychologic scarring.[49]

The teratogenic effects of oral retinoid therapy are well documented. Because of its teratogenicity

and the potential for many other adverse effects, this drug should be prescribed only by those physicians knowledgeable in its appropriate administration and monitoring. Female patients of child-bearing potential must only be treated with oral isotretinoin if they are participating in the approved pregnancy prevention and management program (ie, iPLEDGE). Two different forms of contraception must be started 1 month before and continue at least 1 month (but normally 4 months) after therapy and pregnancy monitoring undertaken before, during, and after therapy.[130]

The efficacy of conventional isotretinoin treatment (0.5-1.0 mg/kg/day for 16-32 weeks, reaching a cumulative dose of 120 mg/kg) for acne has been well established. The approved dosage of isotretinoin is 0.5 to 2.0 mg/kg/day. The drug is usually given over a 20-week course.

Initial flaring can be minimized with a beginning isotretinoin dose of 0.5 mg/kg/day or less. There are many reports regarding the efficacy of low-dose and intermittent isotretinoin treatment. Lower doses can be used for longer time periods, with a total cumulative dose of 120 to 150 mg/kg or the dose can be lowered to 20 mg on alternate days after an initial 2 months of therapy with higher dosage.[132,133,134] Reports suggest that low-dose regimens are superior to other regimens (conventional or intermittent) in terms of patient satisfaction, tolerability, and efficacy for patients with moderate acne. In patients with severely inflamed acne, an even greater initial dose reduction may be required. In the most severe cases of acne, consideration of pretreatment with oral corticosteroids may also be appropriate. Some patients experience a relapse of acne after the first course of treatment with isotretinoin. Relapses are more common in younger adults or when lower doses are used.

Drug absorption is greater when the drug is taken with food. One novel formulation is less dependent on the presence of fat in the gut for absorption.[135] When used, drying agents must be discontinued and replaced with moisturizers.

Because isotretinoin is a vitamin A derivative, it interacts with many of the biologic systems of the body, and consequently has a significant pattern of adverse effects. The pattern is similar to that seen in hypervitaminosis A. Side effects include those of the mucocutaneous (most common), musculoskeletal, and ophthalmic systems, as well as headaches and central nervous system effects. Most of the adverse effects, such as cheilitis, and dry nose, eyes, and mouth, are temporary and resolve after the drug is discontinued.[130] Laboratory monitoring during therapy should include triglycerides, cholesterol, transaminases, and complete blood counts.

Mood disorders, depression, suicidal ideation, and suicides have been reported sporadically in patients taking this drug. A causal relationship has not been established. These symptoms are quite common in adolescents and young adults, the age range of patients who are likely to receive isotretinoin. This issue and other key unresolved considerations regarding isotretinoin continue to be the subject of investigations and are discussed as a Clinical Controversy in this chapter.

Clinical Controversy… Accutane Considerations

After almost three decades of experience with oral isotretinoin, the published data and opinion of experts still differ with respect to its use as first-line or reserve therapy, optimal dosing, and risk of

depression. The 2012 European Guidelines for the treatment of acne noted conflicting viewpoints from major opinion leaders.[14] It is important to put into perspective issues surround its responsible and informed use.[130]

Some directives persist in reserving isotretinoin use only for severe acne, nodular or conglobate acne that has not responded to appropriate antibiotics and topical therapy.[156] For many reasons, other experts recommend that isotretinoin should be considered the first-choice therapy for severe acne, given its clinical effectiveness, prevention of scarring, and quick improvement of a patient's QOL, including minimizing depression. This position suggesting delaying the use of oral isotretinoin, the most effective choice, poses an ethical problem. Although comparative trials are missing, clinical experience confirms relapse rates after isotretinoin treatment are the lowest among available therapies.[14,157,158]

Evidence on best dosage, including cumulative dosage, is rare and partly conflicting for isotretinoin. In most trials, the higher doses associated with better response rates have less favorable safety/tolerability profiles. Attempts to determine the cumulative dose necessary to obtain an optimal treatment response and low relapse rate have not yet yielded sufficient evidence for a strong recommendation. Current expert opinion recommends for severe cases, a starting dosage of 0.3 to 0.5 mg/kg daily and for conglobate acne, a dose of 0.5 mg/kg daily or higher. Duration of therapy should be until a recommended cumulative dose of 120 mg/kg is reached, or at least 6 months. For insufficient response, prolong treatment. Opinions vary on whether or not to restrict use to patients under 12 years and whether to avoid lasers, peelers or wax epilation for at least 6 months after discontinuation of therapy.[14,159]

The causal relationship between the use of isotretinoin and risk of depression continues to be scrutinized with no consensus. The issue is complex as depression and suicidal ideation occur with severe acne in the absence of isotretinoin.

There are instances in which withdrawal of isotretinoin has resulted in improved mood, and reintroduction of isotretinoin has resulted in the return of mood changes. Treatment of severe acne with isotretinoin is often associated with mood improvement.[49] There is epidemiologic evidence that the incidence of these events is less in patients treated with isotretinoin than in an age-matched general population. There is also evidence that the risk of depressed mood is no greater during isotretinoin therapy than during therapy of an age-matched acne group treated with conservative therapy.[49]

A systematic review published in 2005 did not find any evidence to support worsening of depression after use, and some depressive scores improved with use, but nine of these studies had limitations.[160] A retrospective cohort study in Sweden found attempted suicide increased in users, but an increased risk was present before treatment. An increased risk of attempted suicide was present 6 months after isotretinoin, suggesting patients should be monitored for suicidal behavior after treatment discontinuation.[161]

The current literature is insufficient to support a meaningful causative association, but important

study limitations exist. In the absence of definitive evidence, an idiosyncratic effect cannot be excluded. Prescribers of isotretinoin are advised to note prior psychiatric symptoms, monitor patients at each visit for early recognition, and advise patients about a possible risk of depression and suicidal behavior.[14,160,161]

This disputed association remains an important area for future research.

Pharmacologic Cleansing Options

Medicated Soaps and Washes Medicated soaps, washes, and foams may contain topical antiseptics such as triclosan; peeling agents such as salicylic acid, sulfur; antimicrobials such as benzoyl peroxide, clindamycin, or azelaic acid, alone or in combination in low concentrations. They may be nonprescription or prescription status.[136] Most washes should remain on the skin from 15 seconds to 5 minutes followed by thorough rinsing. This limits the amount of time the active ingredient is in contact with the skin. Other cleansers are applied after washing and left on the skin without rinsing.

Quaternary ammonium compounds are cationic detergents that are inactivated quickly in the presence of organic material such as sebum. The duration of action of these products is short.

Bacteriostatic soaps, such as hexachlorophene, carbanilides, and salicylanilides (halogenated hydroxyphenols), may alter normal flora or be acnegenic. Few ordinary soaps induce acne. However, acne patients are particularly susceptible to comedogenic contactants, and if these soaps are applied several times daily for long periods, they may become troublesome.

Soaps containing coal tar, which can induce folliculitis, are not indicated for acne.

In a very small group of patients in an 8-week, double-blind, randomized clinical trial, a combination cleanser containing triclosan, azelaic acid, and salicylic acid produced a greater histopathologic decrease in inflammatory response compared with a nonmedicated cleanser, but there was no significant difference in NILs in either group.[136] A rebound tendency was noted for the nonmedicated cleanser with respect to ILs at 4 weeks. Authors concluded that nonmedicated cleansers were an easier and cheaper way of managing patients with mild acne.

Chlorhexidine inhibits in vitro growth of *P. acnes*.[137] A 4% chlorhexidine gluconate preparation in a detergent base has been shown to be as effective as benzoyl peroxide washes in patients with mild acne, and both preparations reduced the number of inflammatory and NILs after 8 and 12 weeks, compared with vehicle alone.[138]

Alcohol-detergent medicated pads, impregnated with salicylic acid 0.5%, have reduced ILs and open comedones in mild-to-moderate acne. This type of medication is less abrasive, not rinsed off, and convenient.[139]

Alcohol-detergent wipes, swabs, or “pledgets” impregnated with antibiotics, such as clindamycin or lincomycin, are available. The antibiotic is deposited in low concentrations on the surface of the skin, and may not penetrate to the depths of the pilosebaceous duct. Although patients may like the

convenience and perception of using an active agent, they should not be recommended over simple cleansing.

Abrasives consist of finely divided particles of fused aluminum or plastic together with cleansing and wetting agents. Abrasives peel and remove surface debris and may assist resorption of papules and pustules. Despite vigorous rubbing, removal of comedones is not accomplished. Particles containing active agents, such as sodium tetraborate decahydrate, dissolve on use, and their abrasiveness is therefore limited.[139] The effectiveness of an abrasive cleanser with and without polyethylene granules showed no difference in results in patients with mild-to-moderate acne. These products are not indicated in most cases but may be used in a patient who responds empirically.[140]

Personalized Pharmacotherapy

The individualized treatment of certain patient groups, including infants, children, pregnant women, and persons of color, is described under Special Populations.

Providers and patients must also weigh costs and drug availability in choosing a treatment regimen. One study showed that the average total cost of treatment per episode across all age groups is US $689.06.[141] Topical retinoids and fixed-dose combination therapies are in general more expensive than benzoyl peroxide preparations. A retrospective analysis investigated adherence to oral antibiotic guideline recommendations and opportunities for cost-savings. Of 17,448 courses, 84.5% aligned with duration guidelines, although 69.0% of courses did not include concomitant topical retinoid therapy. Costs of antibiotic therapy were lower for shorter courses and those using generic medications. Mean savings of $592.26 per person could result if prolonged courses met guidelines.[142]

Laser treatments and cosmetic procedures are also very costly. The economics of long-term maintenance therapy should be borne in mind when selecting a regimen. Patients should not spend large amounts on herbals and botanicals, as well as home remedies, given the lack of current good evidence to support their use. As acne is a chronic disease extending over many years, total cost implications are important and affect adherence and response.

Other practical considerations include the need for refrigeration of some products such as antibiotics. Local patterns of resistance should be kept in mind in choosing antibiotics. Extent and area of lesion involvement when large or inaccessible (eg, the back or trunk) as well as ease of application may determine the choice of route between topical and systemic therapy. The natural skin predilection toward oiliness versus dryness may dictate the choice of vehicle. Dietary interactions should be born in mind with certain drugs such as oral tetracycline. Sunscreens will need to be used with photosensitizers, and applied as the first topical agent.

Regimens that may require more frequency of application may be difficult for students or patients whose occupation limits flexibility. The frequency of primary nonadherence to acne treatment has been characterized in terms of the complexity of multidrug acne regimens. Overall, 27% of patients did not fill all their prescriptions: with 1, 2, or 3 or more treatments, 9%, 40%, and 31%, respectively, did not fill all their prescriptions. Authors concluded some patients may not complete acne treatment

because 1 or more of their medications were never obtained. Primary adherence to an acne treatment regimen is better when only 1 treatment is prescribed.[143] History of poor adherence because of intolerance of topical treatments may be countered by reducing the strength of treatment, using a different preparation of the drug, or switching to an alternative topical agent that causes less irritation.

EVALUATION OF THERAPEUTIC OUTCOMES

10 Provide a monitoring framework for patients with acne. Parameters should be monitored by the patient and recorded in a diary. Therapy should be appropriately tapered in response to improvement or resolution. The healthcare professional should be responsible for ensuring that the treatment plan remains on schedule and is effective with no adverse effects. The patient should be contacted within 2 to 3 weeks to determine progress.

Acne is poorly understood by adolescents. These patients often lack knowledge of the cause of the disorder and aggravating factors, indications for self-care versus prescription treatment, expected onset of effect, sequence of the healing process, duration of treatment, appropriate application of topical agents, maximal achievable effects, expected adverse effects, safety concerns, and the benefit to QOL. Clinicians should review patient understanding of each of these important factors to ensure patient adherence. There is often a need to supplement counseling sessions with written materials to which the patient can refer at home.

Good adherence is the key to treatment success. Other strategies to increase adherence include use of once-daily regimens, online follow-up visits, and remote digital imaging for ongoing lesion assessment.[141,144,145] A randomized controlled trial compared the effectiveness of automated online counseling to standard web-based education on improving acne knowledge. While both models had a significant increase in knowledge from baseline, after 12 weeks, mean improvement in knowledge was higher in the automated counseling group than in the standard website group. The automated counseling website group rated their educational material more useful and more enjoyable to view than did the standard website group. Internet-based patient education appears to be an effective method of improving acne knowledge among adolescents.[146]

Monitoring of the Pharmaceutical Care Plan

Tables 96-2, **96-3**, **96-4** provide a guide for monitoring patients with acne. Table 96-2 outlines individual drugs, their most common adverse effects, parameters to monitor, and issues to note. Table 96-3 outlines general effectiveness and safety end points, monitoring parameters, and degree of change and timeframes for short- and long-term outcomes. Table 96-4 is a guide for monitoring acne patients with consideration to the severity grading of acne types I through IV.

TABLE 96-2 Monitoring of Medications Used in Acne Treatment and Maintenance Therapy

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Exfoliants			
Resorcinol	Irritant and sensitizer	Degree and/or changes in signs or symptoms of irritancy (redness, discomfort, peeling, skin breakdown, or dermatitis).	Should not be applied to large areas of the skin or on broken skin.
Sulfur	Avoid eye contact —slight ophthalmic and skin irritation	Degree and/or changes in signs or symptoms of irritancy (redness, discomfort, peeling, skin breakdown, or dermatitis). Use should be discontinued if excessive irritation results.	
Salicylic acid	Mild irritant—burning and reddening, local skin peeling	Degree and/or changes in signs or symptoms of irritancy (redness, discomfort, peeling, skin breakdown, or dermatitis).	Begin with a low concentration and increase as tolerance develops. Not a sensitizer.
Retinoids			
Isotretinoin	Side effects: mucocutaneous (most common), musculoskeletal, and ophthalmic systems. Common: dryness of mucus membranes (lips, mouth, eyes, nose) dry skin, itching, hair loss, thirst, back pain, myalgia, headaches, and central	Test for pregnancy twice before starting. Contraceptive measures must be started 1 month prior, continued during the 2 months of treatment and for at least 1 month after stopping treatment (but	Drying agents must be discontinued. Sun avoidance strategies and sunscreen use recommended. Vitamin A supplementation. Use moisturizers (lip balm, nasal moisturizers, eye lubricants, temp removal of contacts). Most adverse effects, such as cheilitis, and dry nose, eyes and

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
		normally 4 months). Laboratory monitoring during therapy should include triglycerides, cholesterol, transaminases, and complete blood counts (before, during and after treatment).	
	nervous system effects. Increased cholesterol. Teratogenic. Sun sensitivity. Depression and suicide—controversial.	Degree and/or changes in signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis). Degree and/or changes in signs or symptoms of irritancy to mucous membranes (mouth, nose, eyes). Instances of headache or central nervous system symptoms. Note prior psychiatric symptoms, monitor patients at each visit for early recognition of changes in mood or psychological well-being (before, during, and after	mouth, are temporary and resolve after the drug is discontinued. Advise patients about a possible risk of depression and suicidal behavior.

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
		treatment).	
Tretinoin/Retinoic acid	Common: erythema, dryness, burning, photosensitization. Rare: true contact allergy. Use cautiously in pregnancy. (Irritation: tazarotene > retinoic acid > adapalene)	Degree and/or changes in signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis). Skin changes in areas of sun exposure —dermatitis or hives.	Additive effects with concomitant topical drying medications; products with high concentrations of alcohol, astringents, abrasive soaps, etc. Gels and creams are less irritating than solutions. Sun avoidance strategies and sunscreen use recommended.
Adapalene	Side effects include erythema, xerosis, burning and desquamation. Less irritation than other retinoids. Photoirritation or sensitization.	Degree and/or changes in signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis). Skin changes in areas of sun exposure —dermatitis or hives.	Less photosensitivity than other agents. Sun avoidance strategies and sunscreen use recommended.
Tazarotene	Side effects include irritation, erythema, xerosis, burning and desquamation.	Skin changes in areas of sun exposure —dermatitis or hives.	Contraindicated in pregnancy due to the large surface area. Short contact therapy, 1-5 minutes every other night, gradually increasing to overnight advocated for dosing in patients with sensitive skin. Oily complexions may tolerate twice daily, short contact time.
Topical Antimicrobial Agents			

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
	Dryness and peeling appear after a few days; erythema; burning; pruritus.	Once tolerance is achieved, the strength may be increased to 5% or the base changed to the acetone or alcohol gels, or to paste.	Increased skin irritation or drying effect with other medications, soaps, and cosmetics with strong drying effect.
	Rare reports of contact allergic dermatitis.		
	May bleach hair and clothing.		
Benzoyl peroxide	Body odor, odor on clothes and bedsheets.	Degree and/or changes in signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis).	Chemically incompatible with retinoic acid.
	Irritation is concentration dependent—most frequent with 10% gel.		Cross-reactions with other sensitizers, such as Peruvian balsam, cinnamon, and other benzoic acid derivatives (topical anesthetics).
	Irritation from gels used as vehicles —water-based < alcohol = acetone	Hives.	
Clindamycin	Erythema, peeling, itching, dryness and burning	Signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis).	
Oral Antibiotics			
Erythromycin	Gastrointestinal upset (nausea, vomiting, diarrhea)	If gastrointestinal adverse effects occur, monitor hydration	Drug interactions: Inhibits CYP1A2 and CYP3A4: carbamazepine, cyclosporine, theophylline, and warfarin.
	Vaginal candidiasis	Vaginal discharge	Safe in pregnant women and children.
Tetracyclines	Gastrointestinal intolerance: (tetracycline > erythromycin > doxycycline =	Vaginal discharge. Skin changes in areas of sun exposure	Contraindicated in pregnant women or in children younger than 9 years of age. Absorption decreased by food,

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
	minocycline)		
	Vaginal candidiasis Photosensitivity is dose-dependent (doxycycline > tetracycline).	—dermatitis or hives.	chelated by antacids and milk. To be taken on an empty stomach.
		Vaginal discharge.	
		Skin changes in areas of sun exposure —dermatitis or hives.	
Minocycline	Drug-induced lupus. Pigment changes in skin, mucous membranes, and teeth. Hepatitis. Urticaria. Dose-related dizziness (resolves with dose titration). Autoimmune hepatitis and hypersensitivity syndrome.	Changes or discoloration of skin, teeth, or mucous membranes. Monitor degree of dizziness as dose is titrated. Signs of hypersensitivity syndrome: fever, dermatitis, blistering reactions; systemic symptoms such as malaise, changes in blood pressure, or renal function.	Contraindicated in pregnant women or in children younger than 9 years of age. Decreased gastrointestinal absorption with Fe, Ca, Mg, Al. Sun avoidance strategies and sunscreen use recommended.
Doxycycline	Gastrointestinal upset. Photosensitizer (especially at higher doses).	If gastrointestinal side effects occur, monitor hydration. Skin changes in areas of sun exposure —dermatitis or hives.	Contraindicated in pregnant women or in children younger than 9 years of age. Sun avoidance strategies and sunscreen use recommended.

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Antisebum			
Combination oral contraceptives	Breakthrough bleeding, headache. Serious: venous thromboembolism, hepatotoxicity.	Spotting or bleeding.	Oral antibiotics may decrease contraceptive efficacy—(significance controversial).
Spironolactone	Common: hyperkalemia, menstrual irregularity, gynecomastia, breast tenderness	Menstrual signs. Breast changes.	
Antiinflammatory			
Azelaic acid	Primary: pruritus, burning, stinging, and tingling Other: erythema, dryness, rash, peeling, irritation, dermatitis, and contact dermatitis in less than 1% of patients	Skin changes in areas of sun exposure—dermatitis or hives	Adverse reactions are generally transient and mild in nature.
Dapsone	Short- and long-term safety and efficacy demonstrated. Peeling, dryness, and erythema.	Skin changes in areas of sun exposure—dermatitis or hives	Does not induce phototoxicity or photoallergy in human dermal safety studies. Medications such as rifampin, anticonvulsants, trimethoprim/sulfamethoxazole, and St. John's wort may increase formation of dapsone hydroxylamine (toxicity).

Al, aluminum; Ca, calcium; Fe, iron; Mg, magnesium.

TABLE 96-3 Monitoring Therapy for Acne: Parameters and Frequency

Person Responsible and Frequencies for Monitoring:

Patient: daily while on drug therapy; Pharmacist: every 4-8 wk of therapy or next pharmacy visit

Parameter	Time Frame/Degree of Change	Actions

Short-Term Effectiveness End Points (Acne Resolution/Control)		
Lesion count	Decrease by 10-25% within 4-8 wk, with control, or more than a 50% decrease within 2-4 mo	If end points not achieved, refer to a physician for further therapy.
Comedones	Resolve by 3-4 mo	
Inflammatory lesions	Resolve within a few weeks	
Anxiety, depression	Achieve control or improvement within 2-4 mo	
Long Term		
Progression of severity	No progression of severity	If end points not achieved, refer to a physician for further therapy.
Recurrent episodes	Lengthening of acne-free periods throughout therapy	
Scarring or pigmentation	No further scarring or pigmentation throughout therapy	
Safety End Points (Treatment Side Effects)		
Dermatitis, increased dryness, gastrointestinal upset, photosensitivity	No adverse effects	Refer to a physician for alternate therapy, dose reduction, discontinuation or additive palliative treatment or preventative measures for adverse effects.

TABLE 96-4 Monitoring Care Plans for Acne Types I through IV

Acne Type	Description	Suggested Options	Follow-up Action If Patient Responds	Follow-up Action If Patient Does Not Respond in 3 Months	Adjustment in Therapy If Patient Does Not Respond Adequately to Previous Action
Type I	Mainly comedones with an occasional small inflamed papule or pustule; no scarring present	Topical retinoid is the drug of choice; can also consider benzoyl peroxide or salicylic acid	Continue until lesions are completely cleared and then stop or taper therapy	Treat as Type II acne	
Type II	Comedones and more numerous papules and pustules (mainly	Topical retinoid plus benzoyl peroxide, topical or antibiotic	Continue until lesions are completely cleared and then stop or	Treat as Type III acne	

Acne Type	Description	Suggested Options	Follow-up Action If Patient Responds	Follow-up Action If Patient Does Not Respond in 3 Months	Adjustment in Therapy If Patient Does Not Respond Adequately to Previous Action
	facial); mild scarring		taper therapy		
Type III	Numerous comedones, papules and pustules, spreading to the back, chest and shoulders, with an occasional cyst or nodule; moderate scarring	Systemic antibiotic plus topical retinoid, or benzoyl peroxide	Oral antibiotics typically are prescribed for daily use over 4-6 mo, with subsequent tapering and discontinuation as acne improves. Other agents can also be stopped or tapered at this time	Add oral contraceptive or antiandrogen (women only)	Oral isotretinoin (except in women who are or who may become pregnant); consider safety end points (potential adverse effects) before initiating therapy
Or					
Type IV	Numerous large cyst on the face, neck and upper trunk; severe scarring	Systemic antibiotic plus topical retinoid, and benzoyl peroxide ± oral contraceptive or antiandrogen (females only)	Oral antibiotics typically are prescribed for daily use over 4-6 mo, with subsequent tapering and discontinuation as acne improves Other agents can also be stopped or tapered at this time	If no response after 3-6 mo, oral isotretinoin (except in women who are or who may become pregnant). Consider safety end points (potential adverse effects) before initiating therapy	

CONCLUSION

Considerable gaps remain in the understanding of acne, despite all that is known about the pathogenesis of acne and the mechanisms of effective drugs for controlling its symptoms, progression, and complications at structural, biochemical, and physiologic levels. It is still not possible to precisely define the cause of one of the most common skin diseases, nor is it possible to identify a cure for a condition that affects a very large proportion of the global population.

Chapter 97: Psoriasis

Rebecca M. Law; Wayne P. Gulliver

INTRODUCTION

KEY CONCEPTS[1]

- 1 Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients.
- 2 Psoriasis is a progressive T-lymphocyte–mediated systemic inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition and precipitating "trigger" factors play a role in the "march of psoriasis." This march of innate and adaptive immune responses results in clinical expressions (eg, keratinocyte proliferation) and is possibly responsible for psoriatic comorbidities.
- 3 Diagnosis of psoriasis is usually based on recognition of the characteristic psoriatic lesion and not based on laboratory tests.
- 4 Treatment goals for patients with psoriasis are to minimize signs such as plaques and scales, alleviate symptoms such as pruritus, reduce the frequency of flare-ups, ensure appropriate treatment of associated comorbid conditions such as psoriatic arthritis (PsA) or clinical depression, and minimize treatment-related morbidity.
- 5 Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies.
- 6 Nonpharmacologic alternatives such as stress reduction and the liberal use of moisturizers may be very beneficial and should always be considered and initiated when appropriate.
- 7 Pharmacologic alternatives for psoriasis include topical agents, phototherapy, and systemic agents (both traditional agents and newer biologic response modifiers).
- 8 Pharmacologic therapy is generally guided by the severity of disease, advancing from

topical agents to phototherapy to systemic agents as needed.

- 9 Rotational therapy (ie, rotating systemic drug interventions) is a means to minimize drug-associated toxicities. However, continuous treatment has replaced rotational or sequential therapy and is now the standard of care for many dermatologists.

- 10 Some biologic response modifiers (BRMs) have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. BRMS are often used for moderate-to-severe psoriasis and may be first-line therapy especially if comorbidities exist.

Psoriasis is a chronic disease that waxes and wanes. It is never cured, and it is now known to be associated with multiple comorbidities including heart disease, diabetes, and the metabolic syndrome. The signs and symptoms of psoriasis may subside totally (go into remission) and then flare-up again (exacerbation). Triggers include stress, seasonal changes, and some drugs. Disease severity may vary from mild to disabling. Psoriasis imposes a burden of disease that extends beyond the physical dermatologic manifestations.

1 Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients. Thus, management of this condition is necessarily long-term and multifaceted, and management modalities may change according to the severity of illness at the time.[1]

EPIDEMIOLOGY

Psoriasis is likely the most common immune-modulated inflammatory disease in North America and Europe, as it is thought to affect 17 million people, or approximately 2% of the population.[2,3] Worldwide prevalences vary between 0.1% and 3%, with reasons for variation ranging from racial to geographic and environmental.[3] Climate, sun exposure, and ethnicity are thought to affect prevalence, but correlation between latitude and prevalence is weak.[4] Prevalences higher than 3% have been reported occasionally in Canada and the United States. Lower frequencies of between 0.4% and 0.7% are seen for people of African and Asian descent.[4,5] Of interest is the fact that psoriasis is seldom seen in North and South American aboriginal Indians. It affects males and females equally.[3,6] The majority of patients (approximately 75%) have onset before the age of 40,[3] but psoriasis has been observed at birth and as late as the ninth decade of life.[3] Prevalence increases are roughly linear over the life course (about 0.12% at age 1 to 1.2% at age 18).[4] Many studies report two peak ages of onset: at 20 to 30 and 50 to 60 years.[3,5]

ETIOLOGY

2 Psoriasis is a T-lymphocyte–mediated systemic inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition

coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions. This has been called the "march of psoraisis"[2,6] to reflect the innate and adaptive immune responses that are present. This march leads to expressions of psoriasis with keratinocyte proliferation being central to the clinical presentation of psoriasis, and is likely responsible for various comorbidities as a consequence of the chronic inflammation associated with psoriasis.[2,4] For example, there is an association between psoriasis and cardiovascular disease, which appears to be an ongoing, two-way interplay.[2,6] The concept is that systemic inflammation enhances insulin resistance, causing endothelial dysfunction, leading to atherosclerosis and coronary events.[7]

Genetics

Dermatologists have recognized the familial tendencies of psoriasis for many years. Monozygotic twins have a concordance rate in the 80% range. Rates of family history in a psoriasis family range between 36% and 91%.[8,9] A study using the founder population of Newfoundland and Labrador noted that more than 80% of the patients had a positive family history.

There are psoriasis susceptibility genes and variants that reside on various chromosomes. The psoriasis susceptibility locus 1 (*PSORS1*) on chromosome 6p is a key gene locus, accounting for up to 50% of disease heritability.[4] In 2009, studies of the Newfoundland and Labrador population confirmed that major histocompatibility complex antigen (HLA)-Cw6 and tumor necrosis factor (TNF)-α as major psoriasis susceptibility genes, along with interleukin (IL)-23 loci that had previously been reported.[3,10] The findings have been confirmed in multiple populations worldwide.[11] Currently, roughly 40 additional loci are thought to be associated with psoriasis.[4] Corresponding genes to these loci are involved in pathogenesis pathways in the immune system (adaptive and innate). There appears to be a general role for T cells and a specific role for TH17 lymphocytes in psoriasis pathogenesis and as indicators of psoriasis risk.[4]

Predisposing Factors and Precipitating Factors

Injury to the skin, infection, drugs, smoking, alcohol consumption, obesity, and psychogenic stress have been implicated in the development of psoriasis. Examples of these precipitating factors include a horsefly bite causing skin trauma (known as the *Koebner phenomenon*),[12] a viral or streptococcal infection, or the use of β-adrenergic blockers.[13] Factors exacerbating preexisting psoriasis include drugs[13] (eg, lithium, nonsteroidal anti-inflammatory drugs [NSAIDs], antimalarials such as chloroquine, β-adrenergic blockers, fluoxetine, and withdrawal of corticosteroids), and psoriatic patients commonly have exacerbations during times of stress.[1,4,13] Smoking cigarettes has been shown in two international studies to be a risk factor for psoriasis.[14] Lifestyle intervention to mitigate risk factors has been recommended.[15]

PATHOPHYSIOLOGY

Psoriasis is a common chronic inflammatory disease that involves both adaptive and innate

immunity.[4] The interaction between dermal dendritic cells, activated T cells of the TH-1, TH-17 lineage in concert with a multitude of cytokines and growth factors are responsible for the epidermal hyperplasia and dermal inflammation that is seen in the skin of patients with psoriasis. Cross-talk between the innate and adaptive immune systems mediated by cytokines including TNF-α, interferon gamma, and IL-1 is a major research focus.[4]

Comorbidities

It is well documented that psoriasis patients have significant associated comorbidities.[2,4,6] Psoriatic arthritis (PsA) is one of the most common and well-known extracutaneous manifestations of disease. Other associated comorbidities include the metabolic syndrome, other immune-mediated disorders such as Crohn disease, multiple sclerosis, and some psychological illnesses (anxiety, depression, and alcoholism).[16] Also, malignancies such as cutaneous T-cell lymphoma are associated with psoriasis, and melanoma and nonmelanoma skin cancer are associated with psoriasis treatments.

The National Psoriasis Foundation published a clinical consensus on psoriasis comorbidities with recommendations for screening and addressing issues such as cardiovascular risk, metabolic syndrome, and obesity.[17] The importance of screening for comorbidities in psoriasis patients cannot be overemphasized: Nearly half of the psoriatic patients older than age 65 have at least three comorbidities, (with two-thirds of this patient population having two or more comorbidities).[18] The presence of a specific comorbidity in a patient with psoriasis may influence the choice of pharmacotherapy.

PsA usually develops after the onset of psoriasis,[3] typically 10 years later.[16] However, 10% to 15% of patients report that the PsA appeared first.[3] The prevalence of PsA in psoriatic patients is about 30% but varies by disease severity.[16] In one US study, the prevalences were 14% for patients with mild psoriasis, 18% for those with moderate psoriasis, and 56% for patients with severe psoriasis.[19] TNF-α and HLA-Cw6 are linked to both PsA and psoriasis.[20] Although immunomodulating treatments for psoriasis (such as methotrexate [MTX] or TNF-α inhibitors) are useful for PsA, NSAIDs effective for joint symptoms of PsA may exacerbate psoriasis.

The metabolic syndrome is a cluster of risk factors including abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance or glucose intolerance, prothrombotic state, and proinflammatory state.[17] Patients with psoriasis are at increased risk of developing the metabolic syndrome.[4,17] The syndrome is a strong predictor of cardiovascular diseases, stroke, and diabetes.[17,21,22] Patients with this syndrome are three times as likely to have a myocardial infarction (MI) or stroke, twice as likely to die from the MI or stroke, and five times as likely to develop type 2 diabetes.[17] A 2010 retrospective analysis of pooled data from three clinical trials (M02-528, CHAMPION, and REVEAL) showed that patients with psoriasis have a 28% and 12% increased 10-year risks of coronary heart disease (CHD) and stroke, respectively.[22]

Patients with psoriasis also have a decreased life expectancy and increased rates of mortality. Psoriasis is an independent risk factor for atherosclerosis, especially for younger patients with severe

disease.[17] A 2006 study found that a relative risk (RR) of death for a 30-year-old person with severe psoriasis was 3.10, after controlling for traditional cardiovascular risk factors (eg, age, gender, hypertension, dyslipidemia, diabetes mellitus, smoking, body mass index [BMI], C-reactive protein [CRP], and family history of cardiovascular disease).[17,23] Three epidemiologic meta-analyses identified increased cardiovascular mortality risk (RR: 1.39, 1.37, 1.2) and stroke (RR 1.56, 1.59, and 1.21) for psoriatic patients.[4]

Types of Psoriasis

Plaque psoriasis, also known as *psoriasis vulgaris*, is the most common type of psoriasis (**Table 97-1**) and is seen in about 90% of psoriasis patients. Clinical presentation of plaque psoriasis is given in **Table 97-2**.

TABLE 97-1 Phenotypic Classifications of Psoriasis

Plaque (also known as psoriasis vulgaris)
Flexural and/or intertriginous (also known as inverse psoriasis)
Seborrheic
Scalp
Acrodermatitis of Hallopeau
Palm and/or soles (also known as palmar/plantar psoriasis)
Generalized pustular psoriasis
Guttate
Erythrodermic

TABLE 97-2 Clinical Presentation of Plaque Psoriasis

Signs and Symptoms of Plaque Psoriasis	
Lesions (plaques)	Erythematous
	Red-violet in color
	At least 0.5 cm in diameter
	Well demarcated—clearly distinguished from normal skin
	Typically covered by silver, flaking scales
Skin involvement	Either as single lesions at predisposed areas (eg, knees, elbows) or generalized over a wide BSA
	Mild psoriasis: ≤5% BSA involvement
	Moderate psoriasis: PASI ≥8 (higher in trials of biologics)
	Severe psoriasis: The rule of tens: PASI ≥10 or DLQI ≥10 or BSA ≥10% (in some phototherapy trials, BSA ≥20% used as lower limit)

Signs and Symptoms of Plaque Psoriasis

	Categories in the European consensus: Mild psoriasis: BSA ≤10 and PASI ≤10 and DLQI ≤10. Moderate-to-severe psoriasis: (BSA >10 or PASI >10) and DLQI >10
Pruritus	More than 50% of patients with psoriasis have associated pruritus May be severe in some patients and may require treatment to minimize excoriations from constant scratching
Other associated concerns	Lesions may also be physically debilitating or socially isolating. Potential comorbidities: PsA, depression, hypertension, obesity, diabetes mellitus, Crohn disease, anxiety, alcoholism

BSA, body surface area; DLQI, Dermatology Life Quality Index; PASI, Psoriasis Area and Severity Index; PsA, psoriatic arthritis.

Data from reference 14.

Up to 30% of patients with psoriasis have associated PsA.[4] Although nail involvement (psoriatic onychodystrophy) can occur with any type of psoriasis, it is seen in up to 90% of patients with PsA.[14] Fingernails are involved in about 50% of all patients with psoriasis and toenails are involved in 35% of patients.[14]

DIAGNOSTIC CONSIDERATIONS

3 The diagnosis of psoriasis is a diagnosis based on recognition of the characteristic psoriatic lesion and not on laboratory tests. Diagnostic testing is rarely performed as a biopsy may be suggestive but is not diagnostic of psoriasis.

Psoriasis is traditionally classified into mild, moderate, or severe disease. In 2011, a European consensus (19 countries) formalized the definition of disease severity and treatment goals and defined plaque psoriasis severity as two main categories: mild versus moderate-to-severe. This became the basis for defining treatment goals in the 2015 European guidelines.[24,25] Both classification systems are in use today. In clinical practice, assessment of the severity of disease includes both an objective evaluation of the extent and symptoms as well as a subjective evaluation of the impact of disease on the patient's quality of life.[14] Assessment typically includes measures of symptom and involvement such as body surface area (BSA), Psoriasis Area and Severity Index (PASI), or Physician's Global Assessment (static PGA), as well as quality-of-life measures such as the Dermatology Life Quality Index (DLQI) or the Short Form (SF-36) Health Survey.[14]

Classification of psoriasis as mild, moderate, or severe disease is generally based on BSA or PASI measurements (see Table 97-2). Practically, to give a rough estimate of BSA involvement, palm size is approximately 1% BSA, head and neck involvement is approximately 10% BSA, both upper limbs approximately 20% BSA, trunk involvement (front and back) approximately 30% BSA, and both lower limbs approximately 40% BSA.

TREATMENT

Treatment of psoriasis is based on managing the underlying pathophysiology. Agents that modulate the abnormal immune response, such as topical corticosteroids (TCS) and biologic response modifiers (BRMs), are important treatment strategies for psoriasis. Topical therapies that affect cell turnover, such as retinoids, are also effective for psoriasis. In addition, nonpharmacologic therapies are effective adjuncts and should be considered for all patients with psoriasis. A treatment regimen should always be individualized, taking into consideration severity of disease, patient responses, and tolerability to various interventions. Furthermore, if comorbidities exist, they must be taken into treatment considerations and managed early. Optimal psoriasis care needs to maintain a focus on the patient's overall health-related quality of life.

Desired Outcomes

4 Goals of treatment for the patient with plaque psoriasis include the following[1]:

- Minimizing or eliminating the visible signs of psoriasis, such as plaques and scales
- Alleviating pruritus and minimizing excoriations
- Reducing the frequency of flare-ups
- Ensuring appropriate treatment of associated comorbid conditions such as PsA, hypertension, dyslipidemia, diabetes, or clinical depression
- Screening for and managing lifestyle factors that may trigger exacerbations (eg, stress, smoking, obesity)[26]
- Minimizing nonspecific triggers such as mild trauma (scratching, piercings, tattoos), sunburn, chemical irritants, environmental/work place factors[4]
- Providing guidance or counseling as needed (eg, stress-reduction techniques, smoking cessation programs)
- Avoiding or minimizing adverse effects from treatments used (topical, phototherapy, and/or systemic)
- Providing cost-effective therapy
- Maintaining or improving the patient's quality of life

Evaluation of Therapeutic Outcomes

Successful management of psoriasis should include not only clearance of skin lesions, which may take weeks to months depending on the severity of disease, but also control of associated conditions such as itching, and, importantly, comorbidities, including dyslipidemia, hypertension, PsA, and clinical depression. The ultimate goal is to provide enough control of this chronic disease and its

comorbidities, (if present) so that the patient's quality of life (QOL) is minimally affected.

The 2011 European consensus defined induction and maintenance phases and provided separate treatment goals for induction and maintenance.[24,25] The induction phase is defined as the first 16 weeks of treatment for drugs with a rapid induction to remission (such as adalimumab or infliximab), extending the phase to 24 weeks of treatment for less rapidly effective drugs (such as MTX or etanercept).[25] To be considered successful therapy, a treatment regimen should result in a reduction of PASI greater than or equal to 75%, or PASI of 50% to 75% coupled with a DLQI less than 5.[25] Otherwise, treatment modifications should be considered. Treatment goals should be assessed at 10 to 16 weeks and then every 8 weeks thereafter.[25] It is important to treat beyond clearing visible skin lesions. In fact, a European consensus lead author writes, "Psoriasis is the first dermatological inflammatory disorder where the goal is to manage skin lesions and associated diseases."[26] Comorbidities and trigger factors must be managed as early as possible.

General Approach

5 Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies. Nonpharmacologic management strategies are important and should be used for all patients with psoriasis, regardless of the severity of disease. Pharmacologic therapies are always tailored to the individual patient with psoriasis, and different treatment strategies would be used depending on psoriatic disease severity, presence or absence of comorbid illnesses, and any special considerations such as hepatic or renal dysfunction.

Nonpharmacologic Therapy

6 Nonpharmacologic alternatives may be very beneficial and should always be considered and initiated when appropriate.[1] These include stress-reduction strategies, moisturizers, oatmeal baths, and skin protection using sunscreens.[27]

In particular, stress reduction has been shown to improve both the extent and severity of psoriasis, and includes methods such as guided imagery and stress-management clinics. Liberal use of nonmedicated moisturizers, applied ad lib, helps maintain skin moisture, reduces skin shedding, controls associated scaling, and may reduce pruritus. Oatmeal baths further reduce pruritus and with regular use may minimize the need for systemic antipruritic drugs.

Sunscreens, preferably with a sun protection factor (SPF) of 30 or more, should be regularly used because sunburns can trigger an exacerbation of psoriasis. Irritation to the skin should be minimized —harsh soaps or detergents should not be used. Cleansing should be done with tepid water and preferably with lipid-free and fragrance-free cleansers.[1,27]

For patients with comorbidities such as dyslipidemia, obesity, or cardiovascular disease, cessation of nicotine and alcohol consumption, diet control, and increasing physical activity are all important interventions.[2,26]

Pharmacologic Therapy

7 Pharmacologic alternatives for psoriasis are topical agents, phototherapy, and systemic agents, including biologic response modifiers (BRMs).

Drug Treatments of First Choice

8 For limited or mild to moderately severe disease, topical treatments are the usual standard of care, with phototherapy and photochemotherapy used in moderate-to-severe cases. For patients presenting with extensive or moderate-to-severe disease, systemic therapies with or without the use of topical treatments are the usual standard of care. Newer systemic treatments such as BRMs may be the treatments of choice, especially for patients with comorbidities such as PsA or if traditional systemic treatments (such as MTX or cyclosporine) are contraindicated. Once the disease is under control, it would be important to step down to the least potent, least toxic agent(s) that maintain control. 9 Sequential therapy and rotational therapy may minimize drug-associated toxicities; however, continuous treatment is now the standard of care for many dermatologists. Different treatment algorithms are used, depending on the severity of the plaque psoriasis (**Figs. 97-1** and **97-2**).[1]

Published Guidelines or Treatment Protocols

There are treatment guidelines for both Canada and the United States.[14,28,29,30,31,32,33,34,35] All US guidelines are endorsed by the American Academy of Dermatology or the National Psoriasis Foundation, and Canadian guidelines are endorsed by the Canadian Dermatology Association. In Europe, guidelines from the British Association of Dermatologists[36] and a European 19-country consensus have been published.[24,25] These guidelines represent the current standards of care.

Topical Therapies

Approximately 80% of patients with psoriasis have mild-to-moderate disease,[30] and the majority of these patients can be treated with topical therapies alone.[30] Individualized approaches are essential because of the wide variation in patients' presentations, their psychosocial health, and their personal opinions as to what would be acceptable treatment.[14] Topical therapies include corticosteroids, vitamin D_3 analogs, retinoids, anthralin, and coal tar. In addition, topical calcineurin inhibitors may be useful for difficult-to-treat sites such as the intertriginous areas or the face.[4] These are generally efficacious and safe for this patient population. Topical agents are also used as adjunctive therapy for patients with more extensive disease who are being treated concurrently with phototherapy or systemic agents.

To determine the quantity of topical agents required, the fingertip unit[37] can be used. One fingertip unit is approximately 500 mg,[30,37] which is sufficient to cover one hand (front and back) or about 2% BSA.[38] The trunk (front and back) is about 30% BSA; to cover the entire trunk once, about 15 fingertip units, or 7,500 mg (7.5 g), would be required.

In a 2012 systematic review of topical and phototherapies for psoriasis by dermatologists in France, nine recommendations based on evidence and expert opinion are offered. However, quality literature was limited, and the recommendations relating to optimal steroid use and optimal first-line treatment for psoriasis did not reach 80% consensus.[37]

Corticosteroids

Topical corticosteroids have been the mainstay of therapy for the majority of patients with psoriasis for over half a century. They are generally well tolerated, although adverse effects can occur, including systemic ones on occasion. **Table 97-3** provides a summary of topical corticosteroid formulations—including ointments, creams, gels, foams, lotions, sprays, shampoos, tape, and solutions[30]—and potencies.

TABLE 97-3 Topical Corticosteroid Potency Chart

Potency Rating	Corticosteroid—Topical Preparations
Class 1: Superpotent	Betamethasone dipropionate 0.05% ointment (Diprolene and Diprosone ointment)
	Clobetasol propionate 0.05% lotion/spray/shampoo/foam (Clobex lotion/spray/shampoo, OLUX-E foam)
	Clobetasol propionate 0.05% cream and ointment (Cormax, Temovate, Dermovate)
	Desoximetasone 0.25% spray (Topicort)
	Fluocinonide 0.1% cream (Vanos)
	Halobetasol propionate 0.05% cream, lotion, and ointment (Ultravate)
	Flurandrenolide tape 4 mcg/cm^2 (Cordran)
Class 2: Potent	Amcinonide 0.1% ointment (Cyclocort ointment)
	Betamethasone dipropionate 0.05% cream/gel (Diprolene cream, gel, and Diprosone cream)
	Desoximetasone 0.25% cream, ointment (Topicort)
	Diflorasone diacetate 0.05% ointment (Florone, Psorcon)
	Fluocinonide 0.05% cream, gel, ointment (Lidex)
	Halcinonide 0.1% cream (Halog)
Class 3: Upper mid-strength	Amcinonide 0.1% cream (Cyclocort cream)
	Betamethasone valerate 0.1% ointment (Betnovate/Valisone ointment)

Potency Rating	Corticosteroid—Topical Preparations
	Diflorasone diacetate 0.05% cream (Psorcon cream)
	Fluticasone propionate 0.005% ointment (Cutivate ointment)
	Mometasone furoate 0.1% ointment (Elocon ointment)
	Triamcinolone acetonide 0.5% cream and ointment (Aristocort)
Class 4: Mid-strength	Betamethasone valerate 0.12% foam (Luxiq)
	Clocortolone pivalate 0.1% cream (Cloderm)
	Desoximetasone 0.05% cream, ointment, and gel (Topicort LP)
	Fluocinolone acetonide 0.025% ointment (Synalar ointment)
	Fluocinolone acetonide 0.2% cream (Synalar-HP)
	Flurandrenolide 0.05% ointment (Cordran)
	Hydrocortisone valerate 0.2% ointment (Westcort ointment)
	Mometasone furoate 0.1% cream (Elocon cream)
	Triamcinolone acetonide 0.1% ointment (Kenalog)
Class 5: Lower mid-strength	Betamethasone dipropionate 0.05% lotion (Diprosone lotion)
	Betamethasone valerate 0.1% cream and lotion (Betnovate/Valisone cream & lotion)
	Desonide 0.05% lotion (DesOwen)
	Fluocinolone acetonide 0.01% shampoo (Capex shampoo)
	Fluocinolone acetonide 0.025%, 0.03% cream (Synalar cream)
	Flurandrenolide 0.05% cream and lotion (Cordran)
	Fluticasone propionate 0.05% cream and lotion (Cutivate cream and lotion)
	Hydrocortisone butyrate 0.1% cream (Locoid)
	Hydrocortisone valerate 0.2% cream (Westcort cream)
	Prednicarbate 0.1% cream (Dermatop)
	Triamcinolone acetonide 0.1% cream and lotion (Kenalog cream and lotion)
Class 6: Mild	Alclometasone dipropionate 0.05% cream and ointment (Aclovate)
	Betamethasone valerate 0.05% cream and ointment
	Desonide 0.05% cream, ointment, gel (DesOwen, Desonate, Tridesilon)
	Desonide 0.05% foam (Verdeso)
	Fluocinolone acetonide 0.01% cream and solution (Synalar)
	Fluocinolone acetonide 0.01% FS oil (Derma-Smoothe)
Class 7: Least Potent	Hydrocortisone 0.5%, 1%, 2%, 2.5% cream, lotion, spray, and ointment (various brands)

Data from The National Psoriasis Foundation—Mild Psoriasis: Steroid potency chart, http://www.psoriasis.org/netcommunity/sublearn03_mild_potency. Rosso JD, Friedlander SF.

Corticosteroids: Options in the era of steroid-sparing therapy. J Am Acad Dermatol 2005;53:S50-S58; Leung DYM, Nicklas RA, Li JT, et al. Disease management of atopic dermatitis: An updated practice parameter. Ann Allergy Asthma Immunol 2004;93:S1-S17.

The choice of vehicle affects corticosteroid potency: Ointments, being the most occlusive, enhance drug penetration and provide the most potent formulations. However, patients may prefer a less greasy formulation, such as a cream or lotion for daytime use, although they may be willing to apply the more effective ointment-based corticosteroid during the night.[30] Providing additional occlusion will increase drug penetration of a topical preparation, resulting in enhanced potency. For example, flurandrenolide cream and lotion are potency class 5, but flurandrenolide tape was found to have higher efficacy than diflorasone diacetate ointment (potency class 1).[30,39,40]

Despite their widespread use, there have been few large-scale, randomized placebo-controlled corticosteroid trials and even fewer head-to-head comparisons with other therapies. The most comprehensive review to date is the analysis of topical psoriasis therapies done in 2002 but recent studies aren't included so this review was already somewhat out of date when published.[14,41] This systematic review found that all topical corticosteroid treatments considered were efficacious and significantly better than placebo; and that the highest potency corticosteroids were the most efficacious, followed by vitamin D_3 analogs.[14] The French group in 2012 found variable efficacy in their systematic review, noting that recommendations about topical steroid use should be mostly based on expert opinion, and that maintenance intermittent treatment may prolong remission.[42]

Corticosteroids have anti-inflammatory, antiproliferative, immunosuppressive, and vasoconstrictive effects.[30] These are mediated through a variety of mechanisms. Mechanisms of action include binding to intracellular corticosteroid receptors and regulation of gene transcription (in particular those which code for proinflammatory cytokines).[30]

Appropriate use of topical corticosteroids should include an assessment of disease severity and disease location as well as knowledge of the patient's preference and age. Lower potency corticosteroids should be used for infants and for lesions on the face, intertriginous areas, and areas with thin skin. For other areas of the body in adults, mid- to high-potency agents are generally recommended as initial therapy.[30] The highest potency corticosteroids are generally reserved for patients with very thick plaques or recalcitrant disease, such as plaques on palms and soles. The use of potency class 1 corticosteroids should be limited to a duration of 2 to 4 weeks,[30] recognizing that the risk of cutaneous and systemic side effects increases with continued use.

Cutaneous adverse effects include skin atrophy, acne, contact dermatitis, hypertrichosis, folliculitis, hypopigmentation, perioral dermatitis, striae, telangiectases, and traumatic purpura.[14,30] Systemic adverse effects have been reported not only with superpotent corticosteroids but also with extended or widespread use of mid-potency agents.[30] Systemic adverse effects include hypothalamic–pituitary–adrenal (HPA) axis suppression and less commonly Cushing syndrome, osteonecrosis of the femoral head, cataracts, and glaucoma.[30] All topical corticosteroids are pregnancy category C.[30]

Tachyphylaxis can occur with prolonged use, although its clinical significance is difficult to verify.[14] It

is recommended that the frequency of use be gradually reduced once clinical response is seen, although there are no established tapering regimens.[30] The French group recommended twice-weekly maintenance therapy.[37] Other approaches include transitioning to weaker potency agents or combination with other nonsteroidal topical therapies.[30] Pulse dosing has also been used to minimize tachyphylaxis and adverse effects.[43]

Vitamin D_3 Analogs

Topical vitamin D_3 analogs include calcipotriol (calcipotriene), calcitriol (the active metabolite of vitamin D), and tacalcitol. Only calcipotriol is currently available in the United States[30] and Canada.[14] Other analogs currently under study include maxacalcitol and becocalcidiol.[30] Their mechanisms of action include binding to vitamin D receptors, which results in inhibition of keratinocyte proliferation and enhancement of keratinocyte differentiation.[14,30] They also inhibit T-lymphocyte activity.[14]

The efficacy of calcipotriol for patients with mild psoriasis is well established in randomized double-blind placebo-controlled (DBPC) trials. In head-to-head comparison studies with other topical agents, calcipotriol was found to be more effective than anthralin (dithranol)[44] and comparable or slightly more effective than potency class 3 (upper mid-strength) topical corticosteroid ointments such as betamethasone valerate 0.1% ointment.[14,45,46] In an analysis of topical psoriasis therapies done in 2002,[41] calcipotriol was found to be as effective as all but the most potent topical corticosteroids.[14] Combination therapy with a topical steroid is particularly effective[47] and is discussed later in the chapter.

Vitamin D_3 analogs are generally well tolerated and have a good safety profile in comparison with other topical therapies.[47] They are considered the safest long-term topical treatments.[4] Cutaneous adverse effects most commonly include a mild irritant contact dermatitis; others include burning, pruritus, edema, peeling, dryness, and erythema.[14,30] These adverse effects may be mitigated with continued use.[30] Systemic adverse effects, including hypercalcemia and parathyroid hormone suppression, are rare unless patients are using more than the recommended maximum of 5 mg calcipotriol (100 g of calcipotriol 50 mcg/g cream or ointment) per week[14,30] or if there is underlying renal disease or impaired calcium metabolism.[30] When applied sparingly over a BSA of less than 30%, the risk of hypercalcemia is remote.[37]

Calcipotriol is pregnancy category C. It is inactivated by ultraviolet A (UVA) light thus it should be applied after rather than before UVA light exposure.[30]

Retinoids

Tazarotene is a topical retinoid that acts through the following mechanisms: normalizing abnormal keratinocyte differentiation, diminishing keratinocyte hyperproliferation, and clearing the inflammatory infiltrate in the psoriatic plaque.[14,30] It is effective in clearing psoriatic plaque lesions and achieving remission.

In a placebo-controlled trial of tazarotene 0.1% and 0.05% gels for patients with plaque psoriasis, tazarotene provided a 50% or greater improvement in 63% (0.1% gel) and 50% (0.05% gel) of patients, respectively, after 12 weeks of use.[48] The therapeutic benefit appears to be maintained for 12 weeks after cessation of therapy.[48] Later clinical trials with tazarotene 0.1% and 0.05% creams versus a placebo vehicle provided similar findings.[49] The 2012 systematic review similarly found that about 50% of patients experienced a 50% or more improvement with no difference in formulations.[37]

Adverse effects of tazarotene include a high incidence of irritation at the site of application, a dose-dependent effect.[14] This results in burning, itching, and erythema, which can occur in lesional and perilesional skin.[30] Irritation may be reduced by using the cream formulation, lower concentration, alternate-day application, or short-contact (30-60 minutes) treatment.[30] Ad lib use of moisturizers is also beneficial. Tazarotene is also potentially photosensitizing, due to thinning of the epidermis that can occur with continued use.[30]

Tazarotene is pregnancy category X and should not be used in women of childbearing age unless effective contraception is being used.

Anthralin

Anthralin is not as commonly used as other topical therapies currently available for psoriasis; however, there are situations where its use is appropriate and efficacious. It has a direct antiproliferative effect on epidermal keratinocytes,[1,14] normalizing keratinocyte differentiation.[30] Although the exact mechanism of action is unknown, it may have a direct effect on mitochondria[30,50] and reduce the mitotic activity. It also prevents T-lymphocyte activation.[30] Small placebo-controlled studies demonstrated efficacy for anthralin used continuously or as very short contact (1 minute of treatment).[30]

Currently, short-contact anthralin therapy (SCAT) is usually the preferred regimen, where the anthralin ointment is applied only to the thick plaque lesions for 2 hours or less and then wiped off.[1,30] Because lesions are generally well demarcated, zinc oxide ointment or a nonmedicated stiff paste should be applied to the surrounding normal skin to protect it from irritation and burning. Anthralin should be used with caution, if at all, on the face and intertriginous areas because of the risk of severe skin irritation.[30]

Concentrations for SCAT range from 1% to 4% or as tolerated; concentrations for continuous anthralin therapy vary from 0.05% to 0.4%. Note the 10-fold concentration differences. Aside from significant and often severe skin irritation, other adverse effects include folliculitis and allergic contact dermatitis, but these are uncommon.

Anthralin is pregnancy category C. People who handle the dry anthralin powder should avoid skin contact (eg, by wearing gloves while compounding).[1]

Coal Tar

Coal tar was one of the earliest agents used to treat psoriasis. It is keratolytic and may have antiproliferative and anti-inflammatory effects.[1] Coal tar formulations include crude coal tar and tar distillates (liquor carbonis detergens) in ointments, creams, and shampoos. Because of limited efficacy coupled with patient acceptance and compliance issues, coal tar preparations are less commonly used today, especially in North American and European[37] countries.

A 2007 comparative study in Thailand reported that betamethasone valerate was significantly more effective than coal tar.[14,51] Although coal tar may have similar efficacy as calcipotriol, it has a slower onset of action.[14] In addition, coal tar has an unpleasant odor and will stain clothing; thus, it may be cosmetically unappealing to patients.

Adverse effects include folliculitis, acne, local irritation, and phototoxicity.[14] It is carcinogenic in animals, but for humans no convincing data have emerged regarding carcinogenicity with topical use.[30]

Coal tar concentrations as used in psoriasis treatments (0.5%-5%) are considered safe by the Food and Drug Administration (FDA).[33] However, occupational exposure to coal tar, especially in very high concentrations such as coal tar used in industrial paving,[33] was reported to increase the risk of lung cancer, scrotal cancer, and skin cancer.[30,33] The risk of teratogenicity when used in pregnancy is likely to be small, if it exists.[30]

Salicylic Acid

Salicylic acid has keratolytic properties and has been used in various formulations including shampoos or bath oils for patients with scalp psoriasis. In combination with topical corticosteroids, it enhances steroid penetration thus increasing efficacy. It should not be used in combination with ultraviolet B (UVB) light phototherapy because of a filtering effect that may reduce efficacy. Systemic absorption and toxicity can occur, especially when applied to more than 20% BSA or when used in patients with renal impairment.

Avoid the use of salicylic acid in children. However, it may be used for limited and localized plaque psoriasis in pregnancy.[30]

Calcineurin Inhibitors

Topical calcineurin inhibitors such as pimecrolimus 1% cream (Elidel) are used for the treatment of inflammatory skin diseases such as atopic dermatitis.[52,53,54] Pimecrolimus was found to be effective for plaque psoriasis when used under occlusion[53] and also effective for patients with moderate-to-severe inverse psoriasis (intertriginous areas are affected).[54] Because this cream is less irritating than calcipotriol and also avoids steroid adverse effects such as skin atrophy, it may be a useful alternative for patients with lesions in intertriginous areas or on the face.[4]

Phototherapies and Photochemotherapy

Phototherapy has been used for treating psoriasis for years and is still an important treatment modality today. It has been known for centuries that some skin diseases improve with sun exposure, and clinical studies with phototherapies have been reported since the late 19th century.[28] Phototherapy consists of using nonionizing electromagnetic radiation, either UVA or UVB, as light therapy to treat psoriatic lesions.[55]

UVB is given alone as either broadband or narrowband UVB (NB-UVB), currently with NB-UVB being the preferred method. UVB is also given as photochemotherapy with topical agents such as crude coal tar (Goeckerman regimen)[55] or anthralin (Ingram regimen) for enhanced efficacy.[28]

UVA is generally given with a photosensitizer, such as an oral psoralens, to enhance efficacy—this regimen is known as PUVA (photochemotherapy with oral methoxypsoralen and ultraviolet A light).[55]

With respect to comparative efficacy, NB-UVB is more efficacious than broadband UVB, but may be slightly less effective than PUVA.[28,56] PUVA is very effective in the majority of patients, with the potential for long remissions.[28] A meta-analysis showed that more patients are still clear at 6 months with PUVA versus with NB-UVB.[56] However, because of greater availability of UVB treatment centers, more evidence available now of the efficacy of UVB treatments for psoriasis (in particular, NB-UVB), and especially the increasing concerns about PUVA toxicities (including skin cancers), phototherapy for psoriasis currently uses UVB or NB-UVB where available. Failure of NB-UVB may justify PUVA therapy.[55]

UVB interferes with protein and nucleic acid synthesis, leading to decreased proliferation of epidermal keratinocytes.[28] UVA has similar effects on epidermal keratinocytes. However, because of deeper penetration into the dermis, it also has effects on dermal dendritic cells, fibroblasts, endothelial cells, mast cells, and skin-infiltrating inflammatory cells including granulocytes and T lymphocytes.[28]

Adverse effects of phototherapy include erythema, pruritus, xerosis, hyperpigmentation, and blistering, especially with higher dosages. It should be used with caution for patients with photosensitivity concerns, and drug interactions include photosensitizing medications such as tetracyclines. Patients must be provided with eye protection during UVB, NB-UVB, or PUVA treatments, and for 24 hours[55] or the remainder of the day[28] after PUVA treatments. In addition, patients receiving PUVA therapy may experience gastrointestinal symptoms such as nausea or vomiting, which may be minimized by taking the oral psoralens with food or milk.[28] For patients also receiving oral retinoids plus PUVA (RE-PUVA), the UVA dose should be reduced by one-third.[28] Long-term PUVA use can lead to photoaging and the development of PUVA lentigines. Psoralens bind to proteins in the lens of the eye; thus, there is a potential for increased cataract formation.

Furthermore, although UVB has a theoretical risk of photocarcinogenesis, the risk is significantly higher with PUVA and is dose related.[28,55] A meta-analysis reported a 14-fold increase in the incidence of squamous cell carcinoma (SCC) in patients receiving high-dose PUVA when compared with low-dose PUVA, with SCC of the male genitalia particularly elevated.[28,57] PUVA may also increase

the risk of basal cell carcinoma and possibly melanoma,[28] which may occur 15 years after the first treatment.[55] Thus, the use of phototherapy or photochemotherapy is contraindicated in patients with a history of melanoma or multiple nonmelanoma skin cancers.

Targeted phototherapy using excimer lasers that selectively target psoriatic lesions without affecting normal skin is an option being studied and early results appear promising, although blistering and burning of treated lesions are more common, and long-term safety has not been established.[28]

Systemic Therapies

Systemic therapies are the mainstay of treatment for patients with moderate-to-severe psoriasis, with topical therapies remaining as useful adjuncts. However, as discussed below under combination therapies, topical calcipotriol and betamethasone dipropionate ointment may provide sufficient disease control for some patients.[14,58] Conversely, a subset of patients with limited disease may have debilitating symptoms, and the use of systemic therapies would be warranted.[29] Systemic therapies include the following traditional agents: acitretin, cyclosporine, MTX, mycophenolate mofetil (MMF), and hydroxyurea; as well as the newer BRMs, specifically adalimumab, alefacept, etanercept, infliximab, ustekinumab, and secukinumab.

Acitretin

In the 1980s, etretinate became the first oral retinoid, or vitamin A acid derivative, available for the treatment of psoriasis. It has since been replaced by acitretin, its active metabolite.

Retinoids may be less effective than MTX or cyclosporine when used as monotherapy,[4] although the initial response may be more rapid than MTX for patients with severe inflammatory forms of psoriasis. Currently, acitretin is more commonly used in combination with topical calcipotriol or phototherapy.[14,29] Its efficacy appears to be dose dependent.[29] Although low-dose acitretin (25 mg/day) is safer and better tolerated than higher-dose (50 mg/day) therapy,[14] low-dose acitretin is not recommended as monotherapy.[4]

Common adverse effects of acitretin include hypertriglyceridemia and mucocutaneous adverse effects such as dryness of the eyes, nasal and oral mucosa, chapped lips, cheilitis, epistaxis, xerosis, brittle nails, and burning or sticky skin.[14,29] Less commonly, "retinoid dermatitis" may occur. Ophthalmologic changes include photosensitivity, decreased color vision and impaired night vision.[24] GI adverse effects including hepatitis and jaundice are rare with liver enzyme elevations usually being transient.[24] Periungual pyogenic granulomas are sometimes seen after long-term use of acitretin.[29] Rarely, skeletal abnormalities—such as disseminated idiopathic skeletal hyperostosis (DISH) syndrome—may occur.[14]

All retinoids are teratogenic and are pregnancy category X, including topical retinoids. Acitretin should not be used for women of childbearing age unless they are able and willing to use effective birth control not only for the duration of acitretin therapy but also for at least 2 years after

discontinuing the agent.[14,24,29] Blood donation (men and women) is not permitted during and for at least 1 year after treatment.[24] Ethanol should be avoided during therapy and for 2 months after drug discontinuation because it causes the transesterification of acitretin to etretinate, which has a much longer elimination half-life.

Cyclosporine

Cyclosporine is a systemic calcineurin inhibitor. The more bioavailable microemulsion formulation, Neoral, was approved by the FDA in 1997 for the treatment of psoriasis and rheumatoid arthritis.[32]

Cyclosporine is efficacious for both inducing remission and as maintenance therapy for patients with moderate-to-severe plaque psoriasis. It is also effective in treating pustular, erythrodermic, and nail psoriasis.[32] The 2009 Canadian Guidelines recommended that cyclosporine be normally reserved for intermittent use in periods up to 12 weeks for most patients with psoriasis,[14] although other recommendations are for periods of 1 year or up to 2 years.[32] Risk of toxicity increases with treatment duration: intermittent short-course therapy (less than 12 weeks) is preferable since this appears to significantly reduce the risk of nephrotoxicity as compared with continuous therapy.[14,24,32]

In comparative randomized controlled trials (RCTs), cyclosporine was significantly more effective than etretinate[59] and similar or slightly better in efficacy than MTX.[14,32,60] After inducing remission, maintenance therapy using low doses (1.25-3.0 mg/kg/day) may prevent relapse.[32] The dose should always be titrated to the lowest effective dose for maintenance. In one placebo-controlled study, the relapse rate was 42% for patients on 3.0 mg/kg/day versus 84% for patients on placebo.[61] For patients discontinuing cyclosporine, a gradual taper of 1 mg/kg/day each week may prolong the time before relapse, as compared with abrupt discontinuation.[29,32] Abrupt discontinuation resulted in a dramatic rebound of psoriasis in a few cases.[14] Because more than half of patients discontinuing cyclosporine will relapse within 4 months, patients should be provided with appropriate alternative treatments shortly before or after discontinuing cyclosporine therapy.[32]

Adverse effects of cyclosporine include cumulative renal toxicity, hypertension, and hypertriglyceridemia. The latter two are particularly significant for patients with prior elevation of diastolic blood pressure or triglycerides.[14] Hypertriglyceridemia can occur in up to 15% of patients with psoriasis who are treated with cyclosporine, although this effect is generally reversible upon cessation of therapy.[29]

The risk of SCC and other nonmelanoma skin cancers increases with duration of treatment[14] and with prior PUVA treatments.[29] Thus, although continuous therapy for up to 2 years may be efficacious,[32] it should be used only in a subset of patients[14] in whom renal function is monitored with annual determinations of glomerular filtration rate (GFR) and monthly measurements of blood pressure and creatinine clearance, with more frequent measurements during the initial 6 weeks of treatment.[14]

Baseline blood pressure, serum creatinine, serum urea nitrogen, triglycerides, complete blood count

(CBC), uric acid, potassium, and magnesium should be obtained before initiating therapy, every 2 weeks for the first 12 weeks of therapy, and monitored monthly thereafter during therapy.[14,32] If the serum creatinine increases to 25% above the patient's baseline on 2 occasions (2 weeks apart), the cyclosporine dosage needs to be decreased by 25% to 50% and serum creatinine rechecked as often as every other week for 1 month. If the serum creatinine does not return to within 10% of the patient's baseline value, a further dose decrease of 25% to 50% should be considered. If the value continues to be greater than10% above the patient's baseline value, consider discontinuing cyclosporine therapy.[32] (Note: A 25% above-baseline cutoff for dosage reduction is the manufacturer's recommendation; the National Psoriasis Foundation consensus guidelines continue to recommend a 30% cutoff).[32] Age-appropriate malignancy screens should also be done, and patients should be seen for dental examinations at least yearly because of the risk of gingival hyperplasia.[32]

As a cytochrome P450 isoenzyme 3A4 (CYP3A4) substrate, cyclosporine has significant drug interactions. Serum concentration monitoring is not routinely needed for patients with psoriasis because doses used are lower than in transplant recipients, although monitoring may be advisable for patients taking interacting drugs.

Drugs that can increase cyclosporine concentrations include calcium channel blockers (verapamil, diltiazem, and nicardipine), amiodarone, thiazide diuretics, macrolide antibiotics, allopurinol, oral contraceptives, ezetimibe, selective serotonin reuptake inhibitors (fluoxetine, sertraline), fluoroquinolones (ciprofloxacin, norfloxacin), antifungals (ketoconazole, itraconazole, fluconazole, voriconazole), and cimetidine.[32] Grapefruit juice will also increase cyclosporine concentrations.

Drugs that can reduce cyclosporine concentrations include anticonvulsants (carbamazepine, oxcarbazepine, phenobarbital, phenytoin, valproic acid), rifampin, efavirenz, and St. John's wort.[32]

Conversely, cyclosporine may also affect the drug levels of some drugs. Concurrent use of potentially interacting drugs should be avoided when possible.

Methotrexate

For decades, MTX has been the mainstay of systemic therapy for patients with moderate-to-severe psoriasis. It has direct anti-inflammatory benefits due to its effects on T-cell gene expression and also has cytostatic effects.[14] It is more efficacious than acitretin and similar or slightly less efficacious than cyclosporine.[14,34]

Although it also has a significant adverse effects profile, MTX is generally considered a safer alternative than cyclosporine unless there are preexisting contraindications such as liver disease. In some head-to-head clinical studies more patients dropped out of the cyclosporine treatment arms due to adverse effects.[29,34] While BRMs are undoubtedly more efficacious, they are much more costly, and some insurance companies require an inadequate response or intolerance to MTX (the gold standard) as a prerequisite for approving their use.[34] In a recent placebo-controlled comparative study with adalimumab (CHAMPION), the efficacy of MTX was 36% versus 80% for adalimumab and 19% for placebo.[62] Adalimumab also provided a more rapid response; however, the duration of

remission is unclear.

Initial doses of 7.5 to 15 mg/week may be increased to 20 to 25 mg/week if the response is inadequate at 8 to 12 weeks, with appropriate adverse effect monitoring. MTX can be used continuously for years or decades with sustained benefits.[14] MTX inhibits folate biosynthesis; and the use of folate supplementation during prolonged MTX therapy as seen in dermatology remains controversial.[29,34]

Clinical Controversy… Folate Supplementation for MTX Therapy

Although some experts recommend folate supplementation for all patients receiving MTX for psoriasis, others add folate only when patient issues occur, such as gastrointestinal adverse effects or early bone marrow toxicity (as manifested by an increased mean corpuscular volume) that can be caused by megaloblastic anemia. Lack of folate supplementation has also been listed as a risk factor for hepatotoxicity from MTX use. One small 2006 placebo-controlled study in patients with psoriasis suggested that folate supplementation may result in a slight decrease in efficacy of treatment, but the study methodology has been questioned. A 2013 Cochrane review of folic acid and folinic acid for patients with rheumatoid arthritis who were on MTX also addressed this concern but found that supplementation did not appear to affect MTX efficacy while reducing some MTX side effects such as GI symptoms. (Available at: http://onlinelibrary.wiley.com/doi/10.1002/14651858.CD000951.pub2/full)

The most significant adverse effect is cumulative liver toxicity; and total lifetime dose of MTX must be monitored. Traditionally, patients received a pretreatment liver biopsy and subsequent biopsies when a cumulative dose of 1.5 g is reached. Liver biopsy is the gold standard for assessing histological changes and provides an invasive marker of liver fibrosis. Currently, it is recognized that pretreatment liver biopsies may not be practical or appropriate in all cases[14,34] and that baseline liver biopsies only be considered for patients with a history of significant liver disease.[34] It has also been recommended that a baseline liver biopsy be delayed for 2 to 6 months so that medication efficacy and tolerability can first be established[34] (ie, intention to continue with MTX use). Risk factors for hepatotoxicity from MTX include the following: a history of or current alcohol consumption, persistent abnormal liver chemistry studies, history of liver disease including chronic hepatitis B or C, family history of inheritable liver disease, history of significant exposure to hepatotoxic drugs or chemicals, diabetes mellitus, obesity, and hyperlipidemia.[29,34] For patients without preexisting risk factors for hepatotoxicity, it is recognized that they would likely have a low risk of fibrosis and would not require a baseline liver biopsy; furthermore, consideration can be made to continue MTX treatment for these patients without biopsies at all, to perform a liver biopsy after 3.5 to 4.0 g total cumulative dose, or to switch therapy to an alternate drug at that point.[29,34]

There are noninvasive markers of liver fibrosis, in particular the procollagen type III N-terminal peptide (P3NP or PIIINP) serum level, and the 2015 European recommendation for MTX monitoring is PIIINP determination before starting MTX and every 3 months thereafter.[24] However, a systematic review and meta-analysis of the diagnostic accuracy of non-invasive markers of liver fibrosis in patients with psoriasis taking MTX reported that: (1) the likelihood ratios for P3NP were suboptimal for it to be considered a "good test" and (2) liver function tests (LFTs) demonstrate low diagnostic

accuracy for the detection of fibrosis; and the conclusion was that the clinical utility of LFTs, P3NP and liver ultrasound is poor, and that if these tests are used in isolation, a significant proportion of patients with liver fibrosis may remain unidentified.[63] Thus MTX monitoring recommendations currently differ between continents.

Other adverse effects include significant nausea, pulmonary toxicity, pancytopenia, acute myelosuppression, megaloblastic anemia, and a small but significant increase in lymphoma.[14] Although rare, pancytopenia can occur anytime with the use of low-dose weekly MTX and even after single doses of MTX.[29] Informing patients about the early symptoms of pancytopenia (dry cough, nausea, fever, dyspnea, cyanosis, stomatitis/oral symptoms, and bleeding) may aid early detection.[24] MTX is an abortifacient and is teratogenic (pregnancy category X) and should not be used in pregnancy. After MTX therapy is discontinued, it is recommended that men continue an effective birth control for 3 months (as one cycle of spermatogenesis is 74 days), and women should be on effective birth control for at least one ovulatory cycle.[14,29]

Significant drug interactions include serum albumin binding interactions with salicylates, phenytoin, sulfonamides/trimethoprim, ciprofloxacin, and thiazide diuretics, potentially increasing toxicity. Drugs that can reduce MTX renal elimination (such as acidic drugs, including salicylates or vitamin C) will also increase serum MTX levels and hence increase toxicity. In addition, drugs with hepatotoxic potential may pose an additive risk with MTX use.[29]

Systemic Therapy with Biologic Response Modifiers

10 Some BRMs have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. In general, because of their immunomodulatory effects, there is an increased risk of infection with most of these agents, including serious infections such as sepsis, new-onset or reactivation of tuberculosis (TB), and opportunistic infections such as histoplasmosis, cryptococcosis, aspergillosis, candidiasis, and pneumocystis. The use of live or live-attenuated vaccines during therapy is generally contraindicated. Currently, BRMs are often considered for patients with moderate-to-severe psoriasis when other systemic agents are inadequate or relatively contraindicated. BRMs are sometimes recommended for first-line therapy, alongside conventional systemic agents, for patients with moderate-to-severe psoriasis; however, in practice, drug access due to cost considerations may be a limiting factor. BRMs may be appropriate/preferred as first-line therapy if comorbidities exist. For example, BRMs such as infliximab or adalimumab would be an appropriate treatment option for patients with both plaque psoriasis and active PsA. BRMs currently available for treatment of psoriasis include adalimumab, alefacept, etanercept, infliximab, ustekinumab, and secukinumab.[64,65]

Currently, a number of RCTs describe short-term efficacy of various BRMs for psoriasis but few long-term studies are available. A recent 3-year open-label extension of a 1-year adalimumab phase 3 trial (REVEAL) has demonstrated sustained response with continuous use in initial PASI 75 responders, as discussed below.[66] More clinical evidence has enabled the development of guidelines in an attempt to optimize BRM therapies for psoriasis.[24,25,31,65] The current European consensus

recommends either adalimumab or infliximab with etanercept as a suggested alternative,[24] but these guidelines are incomplete as newer BRMs such as secukinumab have not been included.[25,31]

Tumor Necrosis Factor-α Inhibitors

Dysregulation of TNF-α production is associated with various inflammatory conditions, including rheumatoid arthritis, inflammatory bowel disease, ankylosing spondylitis, PsA, and psoriasis.[66,67,68] Elevated TNF-α levels are seen in both the affected skin and serum of patients with psoriasis; and these elevated levels have a significant correlation with psoriasis severity.[31] The biologic agents etanercept, adalimumab, and infliximab are TNF-α inhibitors which are effective for psoriasis and PsA.[41]

There are safety concerns common to TNF-α inhibitors, mainly from observations made through their use in rheumatoid arthritis and inflammatory bowel disease and more recently psoriasis.[66,67,68] One concern is an increased risk of infections, most commonly upper respiratory tract infections, and less commonly serious infections including sepsis, new-onset or reactivation TB, and opportunistic infections such as histoplasmosis, cryptococcosis, aspergillosis, candidiasis, and pneumocystis.[14,31,66,67,68] There have been reports of serious pulmonary and disseminated histoplasmosis, coccidioidomycosis, and blastomycosis infections,[69,70] sometimes with fatal outcomes when these infections were not consistently recognized and promptly treated in the patients taking TNF-α inhibitors.[69]

A second concern is the development or worsening of autoimmune diseases such as peripheral and central demyelinating disorders including multiple sclerosis and drug-induced lupus-like syndromes.[14,31] A third concern is the potential increased risk of malignancies such as lymphoma,[14,31] melanoma, and nonmelanoma skin cancer.[31] A fourth concern is the potential for other cutaneous adverse effects including vasculitis, granulomatous reactions, cutaneous infections, psoriasiform eruptions, and infusion or injection site reactions.[67] Flares of pustular psoriasis have been reported primarily for patients undergoing treatment for nondermatologic conditions such as rheumatoid arthritis.[14]

There is also a concern about chronic heart failure (CHF): there have been rare reports of worsening congestive heart failure (CHF) and new-onset CHF; TNF inhibitors are contraindicated in patients with preexisting moderate-to-severe CHF (NYHA class III/IV),[24,31] and those with milder CHF should have their TNF-α inhibitors withdrawn at the onset of new symptoms or worsening of preexisting CHF.[31]

Although the above are safety concerns common to etanercept, adalimumab, and infliximab, their safety profiles are not identical. For example, the risk for TB appears lowest with etanercept and highest with infliximab.[14] Nonetheless, they are contraindicated in patients with active TB.[24] Patients should be evaluated for active or latent TB before therapy and considered for a yearly PPD.[14,31] CBC and LFTs are also recommended before and periodically during therapy.[24] In addition, pretreatment C-reactive protein (CRP), hepatitis serology (HBV, HCV), and HIV testing have been recommended.[24]

They are pregnancy category B and safe to use in pregnancy.[31] (Some manufacturers have cautioned that, since these drugs cross the placenta, infants exposed in utero may be at higher risk of infections and live vaccines would be contraindicated for several months after birth.[70])

Adalimumab is a human monoclonal antibody that provides rapid and efficacious control of psoriasis.[31] Clinical trials in patients with moderate-to-severe psoriasis have shown dramatic results. A 2006 12-week RCT with open-label extension to 52 weeks showed significant improvement within 1 week of therapy, with complete or nearly complete clearance in some patients, and clinical benefits were maintained for at least 1 year with continuous therapy for most patients.[14,71]

A 2008 52-week RCT (REVEAL) with an initial 16-week double-blind placebo-controlled (DBPC; period A) phase followed by a 17-week open-label phase (period B) followed by a 19-week DBPC phase (period C) showed a 71% PASI 75 response for adalimumab treated patients versus 7% for placebo-treated patients at week 16. All patients received open-label adalimumab from weeks 17 through 32. At week 33, patients achieving PASI 75 were rerandomized to adalimumab or placebo; patients achieving PASI 50 but less than 75 were continued on open-label adalimumab; and therapy for patients with PASI less than 50 was discontinued. At week 52, 5% of patients rerandomized to adalimumab lost adequate response versus 28% of patients rerandomized to placebo. Adalimumab was continued at 40 mg every other week. The study showed that adalimumab can produce rapid and dramatic results which can be sustained on continued use, in patients with moderate-to-severe psoriasis.[72]

Additional 3-year open-label extension study for patients in REVEAL showed that in patients with sustained initial PASI 75 responses, adalimumab efficacy was maintained for more than 3 years of continuous therapy and maintenance was best at PASI 100. Some patients with PASI less than 75 in REVEAL also achieved long-term PASI 75 responses.[66]

For comparative studies, as discussed in the MTX section, a head-to-head study showed that adalimumab was significantly more efficacious than MTX.[62]

Adalimumab is given as 80 mg subcutaneously in the first week, then 40 mg the following week, and thereafter 40 mg every other week continuously.[14,24,31,70] More frequent dosing has been explored.[14]

Adverse effects in adalimumab clinical trials including the 3-year extension were similar to those already described for this class of BRMs (ie, TB and other opportunistic infections such as candidiasis, CHF, malignancies including nonmelanoma skin cancer that may be related to psoriasis, and allergic reactions).[66,70,71,72]

Etanercept was one of the earliest BRMs available on the market for use in inflammatory diseases. It has demonstrated efficacy for rheumatoid arthritis. It was approved for use in PsA in the United States in June 2002 and approved in 2004 for use in moderate-to-severe psoriasis. It is also approved for treatment of juvenile rheumatoid arthritis and ankylosing spondylitis. Thus, as opposed to some of the other BRMs approved for psoriasis, etanercept has been extensively used in rheumatology

both for adults and children.

The dosing of etanercept in psoriasis differs from its other indications, reflective of the dosing regimens found to be effective for psoriasis in clinical trials. Etanercept is used continuously, given as 50 mg subcutaneously twice weekly for the first 12 weeks, followed by 25 mg twice weekly[14] or 50 mg once weekly.[24,31] Significant improvement was seen in about 50% of patients in clinical trials by week 12 and more than 50% of participants by week 24; with continuing therapy, weaker responders continued to improve for up to 1 year.[14,29,73] Continuing therapy using 50 mg twice weekly regimens are being explored and may provide greater benefit.[14] Etanercept was efficacious in children and adolescents (aged 4-17 years) with plaque psoriasis dosed at 0.8 mg/kg (maximum 50 mg) once weekly.[74]

Infliximab also received approval for rheumatologic diseases before psoriasis and was on the market before adalimumab. Infliximab may be more efficacious than etanercept. A 2011 open-label study showed that psoriatic patients with an inadequate response to etanercept had rapid and sustained improvement when switched to infliximab.[75] Unlike etanercept or adalimumab, infliximab is a chimeric antibody with both murine and human components; thus, antibodies to the drug can develop, resulting in infusion reactions.[31] Regular therapy rather than intermittent dosing on an as-needed basis may minimize this occurrence.[31] The standard dosing regimen is three IV infusions of 5 mg/kg given over a 6-week induction period, followed by regular infusions every 8 weeks.[31]

Clinical response is seen rapidly. In a randomized controlled phase III trial, 80% of patients responded by week 10 (after three doses of infliximab); however, the response dropped to about 50% by week 50.[76,77] Rare reports of serious adverse events, including fatal cases of hepatosplenic T-cell lymphomas, have been associated with infliximab use.[28] Other rare instances of cholecystitis and autoimmune hepatitis, which may be a class effect for TNF-α inhibitors, have also been reported.[14]

Alefacept

Alefacept was the first BRM to receive approval for the treatment of psoriasis, in January 2003 in the United States and in October 2004 in Canada. Over the years, it has accumulated an extensive and reassuring safety record, with no evidence of increased incidence of infections, cancers, or any other serious adverse events beyond background levels. The exception is that CD4 T lymphocytes can be depleted, and CD4 cell counts must be monitored.[14,78]

In comparison with other BRMs, alefacept monotherapy provides only limited control of psoriasis, and as discussed later, it is often explored in combination regimens to enhance response.[14] However, even with monotherapy, long periods of near-complete remission can be seen occasionally.[14]

Dosing is intended to be intermittent. Alefacept is given for a 12-week course, then repeated only when the loss of control becomes unacceptable (up to two more courses per year may be given).[14] Maximal response was generally seen by 6 to 8 weeks in responders, and currently there is no measure to predict which patients will respond.[31]

Ustekinumab

This is an IL-12/23 monoclonal antibody approved for the treatment of psoriasis in adults 18 years or older with moderate-to-severe plaque psoriasis.[24] It selectively targets IL-12 and IL-23, two cytokines that play a role in the pathogenesis of psoriasis.[4,24] It binds to their shared p40 protein subunit thus preventing interaction with their cell surface IL-12Rβ 1receptor.[79] This shared binding may allow ustekinumab to exert its clinical effects in both psoriasis and PsA through interruption of the TH1 and TH17 cytokine pathways, central to both disease conditions.[79] Clinical response appears to be related to serum ustekinumab levels achieved.[79] In a comparison with etanercept, ustekinumab was significantly more efficacious (ACCEPT clinical trial).[79]

Ustekinumab can provide a rapid response that is seen within 2 weeks of initiating treatment.[79,80,81] Two large randomized placebo-controlled trials (PHOENIX 1 and PHOENIX 2) demonstrated clinical efficacy of ustekinumab, with approximately 70% of patients achieving 75% skin clearance after two doses and maintaining the response for 1 year with continued treatment.[79,80,81] The improvements were dramatic. Ustekinumab was also significantly more efficacious than etanercept (ACCEPT clinical trial).[79]

The impact of ustekinumab on patients' health-related QOL was evaluated in the PHOENIX 2 trial.[82] Patients showed a significant improvement not only in skin-related QOL, but also in symptoms of anxiety and depression (as assessed by the Hospital Anxiety and Depression Scale).[82] The subset of patients with PsA in PHOENIX 1 and PHOENIX 2 also showed significant improvement in QOL, anxiety, and depression.[83]

Weight-based dosing rather than fixed-dose was found to be clinically significant for efficacy in PHOENIX 1 and PHOENIX 2—heavier patients required a higher dose.[84] Serum ustekinumab concentrations were also affected by weight.[84] Dosing is 45 mg for patients weighing 100 kg (220 lb) or less, and 90 mg for those of higher weights. Ustekinumab is administered subcutaneously at weeks 0 and 4, then every 12 weeks as maintenance therapy.[79]

Cumulative 3-year safety data from PHOENIX 1 and 2, and ACCEPT have also been published.[85,86] Common adverse effects include upper respiratory infections, headache, fatigue, pruritus, back pain, injection site reactions, and arthralgia, with the most common events being headache and nasopharyngitis.[85] Ustekinumab does not appear to exacerbate atopic diseases.[85] Serious adverse effects include those seen with other BRMs, including serious tubercular, fungal, viral infections, and cancers. No evidence of a dose-response to infection rates was seen.[86] Serious infections and malignancy rates did not increase with long-term ustekinumab treatment up to 3 years.[85,86] In addition, a reversible posterior leukoencephalopathy syndrome (RPLS) has been reported.[67]

Secukinumab

This is a fully human immunoglobulin (IgG)1κ monoclonal antibody that selectively binds and inhibits IL-17A, a proinflammatory cytokine, thus inhibiting the release of chemokines and other

proinflammatory mediators. It was approved in the United States in January 2015 and in Canada in May 2015 for treatment of moderate-to-severe plaque psoriasis in adult patients who are candidates for systemic therapy or phototherapy.[87]

The approval was based on the results of four RCTs evaluating a total of more than 2,000 patients. Secukinumab was shown to induce a rapid response with clinically significant greater PASI rates by week 12, and with continued treatment was associated with sustained high responses through week 52.[88] Recommended dosing regimen is 300 mg (as two subcutaneous injections of 150 mg) at weeks 0, 1, 2, 3 followed by maintenance dosing starting at week 4.[87] Adverse effects from clinical trials commonly included nasopharyngitis, headache, upper respiratory tract infection, diarrhea, and uncommonly included neutropenia and detection of anti-secukinumab antibodies.[87,88]

Other BRMs are being investigated. BRMs with promising clinical trial results include ixekizumab and brodalumab (two other BRMs targeting IL-17) and tofacitinib (an oral agent that inhibits Janus kinase and currently used in treatment of rheumatoid arthritis). Thus there appears to be many more *needed* biologics in the near future for this disease.

Combination Therapies

Combination therapies may be beneficial in the management of plaque psoriasis: generally to either enhance efficacy or minimize toxicity. As shown in Figs. 97-1 and 97-2, combinations can include two topical agents, a topical agents plus phototherapy, a systemic agent plus topical therapy, a systemic agent plus phototherapy, two systemic agents used in rotation, or a systemic agent and a BRM. Rotational therapy is not commonly used in practice, and the use of a BRM added to a systemic agent is still under investigation.

The combination of a topical corticosteroid and a topical vitamin D_3 analog is particularly useful. This was shown in several studies to be efficacious and safe, with less skin irritation than monotherapy with either agent, and the combination product containing calcipotriol and betamethasone dipropionate ointment has demonstrated efficacy in RCTs for patients with relatively severe psoriasis.[14,30] The combination may also be steroid sparing.[30]

The combination of retinoids with phototherapy has also been shown to increase efficacy. Because retinoids may be photosensitizing and increase the risk of burning after ultraviolet (UV) light exposure, doses of phototherapy should be reduced to minimize adverse effects. An RCT with tazarotene and broadband UVB not only showed significant enhancement of UVB efficacy but also reduced the number of UVB treatment sessions needed for response.[28,30,89] The combination of acitretin and broadband UVB reduced the number of needed treatments, compared with UVB alone.[14,90] Acitretin with NB-UVB (RE-UVB) was highly effective for patients with difficult-to-control psoriasis.[30,91] The combination of acitretin and PUVA (RE-PUVA) also showed greater efficacy than monotherapy with either agent.[28,92] RE-PUVA can be used to achieve clearance with up to a twofold reduction in total UV exposure.[14] Phototherapy has also been used with other topical agents, such as UVB with coal tar (Goeckerman regimen)[55] to increase treatment response, because coal tar is also photosensitizing.

Cyclosporine and calcipotriol/betamethasone dipropionate in combination is superior to cyclosporine alone.[24] Cyclosporine may also be successfully used with SCAT; however, it should not be used with PUVA due to reduced efficacy and the potential increase risk of cutaneous malignancies.[32]

The combination of MTX and UVB appears to be synergistic.[29,34] There is also consensus/evidence that MTX in combination with a BRM such as etanercept may be beneficial.[24]

BRMs used in combination with other therapies are being explored. Some beneficial combinations have been found. Alefacept and NB-UVB in combination significantly reduced the number of UVB treatments needed with clearance seen in 43% of patients within 12 weeks.[14,93] Infliximab given concurrently with immunosuppressive agents such as MTX or azathioprine may result in a lower incidence of infusion reactions to infliximab.[31] MTX in combination with adalimumab or infliximab is widely used in rheumatology and low-dose MTX (eg, 7.5-10 mg once per week) is likely sufficient to reduce formation of anti-drug-antibodies and increase the respective trough levels of adalimumab or infliximab.[24]

Alternative Drug Treatments

Mycophenolate Mofetil

(MMF) is a systemic agent occasionally used for patients with resistant cases of moderate-to-severe psoriasis.[14] This is currently not an approved indication in either Canada or the United States.

A few reports and small studies are available describing the efficacy of MMF when used as monotherapy or adjuvant therapy.[94] In addition, one small study evaluated the switch for eight patients with severe psoriasis from cyclosporine to MMF after a washout period of 2 to 4 weeks. On cyclosporine, seven of these patients had deteriorating renal function and hypertension, and one experienced loss of efficacy.[95] After the switch to MMF, there was significant loss of psoriasis control in five of the eight patients but also significant improvement in renal function for six patients.[94,95]

Conversely, another small study evaluated the sequential use of MMF followed by cyclosporine in eight patients with moderate-to-severe psoriasis.[96] There was significant improvement with MMF in all patients, and all patients further improved when switched to cyclosporine.[96]

MMF has some uncommon but significant adverse effects, including increased incidence of opportunistic infections such as cytomegalovirus, cryptococcosis, candidiasis, and *Pneumocystis jirovecii*.[94] Cases of progressive multifocal leukoencephalopathy have also been reported.[92] There may be an associated risk of malignancy.[97]

Hydroxyurea

Hydroxyurea is an antimetabolite usually used for cancer treatments, but it has also been used in the systemic treatment of psoriasis for more than 30 years.[14,29] It is still occasionally tried for patients

with recalcitrant severe psoriasis, although BRMs may be a better option for these patients.

Hydroxyurea has been compared with MTX for patients with moderate-to-severe psoriasis.[98] Weekly regimens showed greater efficacy for MTX with a faster clearance rate, although hydroxyurea was also efficacious. The authors concluded that weekly doses of hydroxyurea may be an alternative to MTX for patients experiencing intolerable MTX side effects or have reached the recommended cumulative dose.[98]

Adverse effects of hydroxyurea include significant bone marrow suppression, lesional erythema, localized tenderness, and reversible hyperpigmentation.[14,98]

Complementary and Alternative Medicines

The use of complementary and alternative medicine (CAM) among patients with psoriasis is common, with a prevalence of 43% to 69% in various studies.[99] Most of these patients use herbs, special diets, or dietary supplements in conjunction with their usual antipsoriatic medications and not as replacements. Most patients do not discuss CAM use with their physicians.[99]

A 2009 systematic review of RCTs found that, although there is a large body of literature on CAM use in psoriasis, the quality of most studies was relatively low.[99] CAM agents and interventions with documented clinical efficacy in psoriasis include *Mahonia aquifolium*, fish oil, climatotherapy (Dead Sea salts), and stress reduction techniques.

Mahonia aquafolium (Oregon grape, Mountain grape, or barberry but *not* European barberry) is an evergreen native to southern British Columbia, western Oregon, and northern Idaho. The rhizome and root contain berberine as the primary active constituent. Berberine is an alkaloid that inhibits keratinocyte growth and reduces keratinocyte proliferation, and it also has antibacterial and antifungal activities. In at least two clinical trials *Mahonia aquifolium* was efficacious in reducing disease severity: In one randomized placebo-controlled study a *Mahonia aquifolium* 10% preparation applied topically twice daily resulted in a significant improvement in the PASI score and the Quality of Life Index (QLI), compared with placebo.[100] Adverse effects in clinical trials included rash, burning sensation, redness, and itching.

Fish oil contains two important long-chain polyunsaturated fatty acids—eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). EPA and DHA are omega-3 fatty acids. They act as substrates competing with arachidonic acid for cyclooxygenase and lipoxygenase, thus reducing the production of proinflammatory molecules in psoriatic plaques.[99] Several randomized placebo-controlled and/or comparative trials for patients with psoriasis have demonstrated efficacy of fish oils. One study comparing EPA plus etretinate to etretinate monotherapy found significantly greater efficacy with the combination of EPA plus etretinate.[101]

Climatotherapy refers to the practice of traveling to the Dead Sea and sunbathing and/or bathing in the sea—the beneficial effects are likely from the high salinity of the sea and UV rays.[99] Several studies have demonstrated efficacy, including two studies using saline spa baths. One study used

highly concentrated (25%-27%) saline spa baths plus UVB compared with UVB alone, and the other used low concentrated (4.5%-12%) saline spa bath plus UVB again compared with UVB alone. In both studies the clinical response was significantly better with the saline spa bath plus UVB combination.[99,102,103]

Stress-reduction techniques have inconsistently shown some benefit. One randomized study demonstrated that both meditation or meditation and imagery were efficacious as adjunctive treatments for patients with scalp psoriasis.[104] A second randomized study for patients with psoriasis receiving either UVB or PUVA therapy showed that the addition of a mindfulness-based stress-reduction audiotape played during light treatments reduced response times for patients receiving UVB but not PUVA therapy.[105] This confirmed the belief that psychological stress plays a role in psoriasis. More recently, in a case-control study of risk factors during the year before the onset of psoriasis, stressful life events were found to be significant.[106,107]

Personalized Pharmacotherapy

Despite the availability of good quality evidence and clinical practice guidelines, patients with psoriasis are still often undertreated or inappropriately managed.[25] A 2007 study in the United States involving 1,657 patients from National Psoriasis Foundation surveys found that 40% of patients with psoriasis were receiving no current treatment; of those, 27% had psoriasis involving greater than 10% BSA.[108] In addition, those receiving care may be undertreated.[108] Early access to care and adherence may also be issues.

Patient-specific therapies that take into consideration comorbid illnesses, adherence, and pharmacoeconomic issues in addition to the patient's psoriatic manifestations and responses to treatments are important, and will ultimately improve the quality of care. Treatment goals need to be defined for both short-term and long-term management time frames.[25] Without optimizing patient care, the concern is that patients with poorly managed psoriasis may follow a "diminished" life course compared with the course they might have taken if they did not have psoriasis, as the disease has significant psychological, social, and economic impacts in addition to its physical manifestations.[109]

To this end, a current focus is defining frameworks[109] and specific treatment goals[24,25] for implementation of practice guidelines, as described earlier in this chapter. The reader is encouraged to review the noted references for further information.

Special Populations

Psoriasis in Children

Pediatric psoriasis is more often attributable to direct precipitating factors such as skin trauma, infections, drugs, or stress.[14,110] Compared with adults, plaque lesions in children are often smaller, thinner, and less scaly, which can make diagnosis more difficult. Face and flexures are more commonly involved than for adults. Psoriatic diaper rash can occur up to age 2. PsA is rare.[14]

Topical treatment is the standard of care for children with psoriasis, with topical corticosteroids often the treatment of first choice.[14] Other useful pharmacologic therapies include calcipotriol and anthralin; calcipotriol with or without topical corticosteroids has also been recommended as treatment of first choice[111] because it produces minimal adverse effects.[14] Since children's skin is thinner and better hydrated than that of adults, they are at higher risk of drug absorption leading to systemic adverse effects. The lowest potency corticosteroid that provides control should be used, and it should be tapered as the lesions improve. If long-term calcipotriol is used, monitoring of ionized calcium is recommended because of the risk of hypercalcemia.[14]

Systemic therapies are reserved for children with severe and recalcitrant psoriasis.[14,111] MTX can provide near to complete clearance[111] and has been safely used to control severe childhood psoriatic episodes and then withdrawn as lesions improve.[14] Regular monitoring for liver and blood toxicity is required.[14] The BRM etanercept was studied in a randomized placebo-controlled trial of 211 children and adolescents (4-17 years) with moderate-to-severe plaque psoriasis. It significantly reduced disease severity; however, four serious adverse events occurred (ovarian cyst requiring removal, gastroenteritis, gastroenteritis-associated dehydration, and left basilar pneumonia).[112] Etanercept has been studied in children with polyarticular juvenile rheumatoid arthritis without new safety concerns emerging.[14]

Phototherapy should be used with caution, especially for younger children, because of long-term carcinogenic risks and phototoxicities. For older children and adolescents with severe, extensive, or treatment-resistant disease, UVB may be a treatment option.[14]

Psoriasis in Pregnancy

Hormonal changes in pregnancy can improve symptoms for patients with plaque psoriasis. In one study, 55% of patients showed improvements during pregnancy.[14,113] For patients with more than 10% BSA involvement who reported improvement, lesions decreased by more than 80% during pregnancy.[113] This appeared to correlate with high estrogen but not progesterone levels.[113] Thus, some pregnant women may require minimal treatment for their psoriasis.

Some antipsoriatic drugs have significant teratogenic risks, placing them in pregnancy category X. Thus, women of childbearing potential must use effective birth control during therapy, and may need to continue effective contraception after discontinuing therapy for a period of time, as discussed in detail throughout this chapter. In addition, drugs listed as pregnancy category C may carry known teratogenic risks in animal studies or have limited available data for use in pregnancy.

UVB has been considered the safest treatment for extensive psoriasis during pregnancy. It is recommended for patients with widespread disease not controlled by topical agents. One problem with this therapy is an increased potential for reactivation of herpes simplex, which may be transmitted to the infant at delivery.[14]

For more detailed information about antipsoriatic drugs in pregnancy, a systematic, drug-by-drug

review of case reports and case-control studies is available.[114] The 2009 Canadian Guidelines provides a drug-by-drug summary of recommendations for topical agents, phototherapy, and systemic agents in pregnancy.[14] The 2015 European S3 Guidelines provides a discussion about most appropriate treatments for women with a wish for pregnancy in the near future, and which treatments to avoid.[24]

Psoriasis in the Elderly

Age-related changes in organ function/drug clearance and greater drug sensitivity increase the risk of adverse drug events for elderly patients with psoriasis.

MTX is hepatotoxic and should be used with caution in the elderly. Cyclosporine has nephrotoxic potential and may also increase blood pressure. Both drugs have significant drug interactions, and polypharmacy, common in older patients, make management of interactions challenging.

In addition, older patients may have preexisting comorbidities, such as hyperlipidemia and metabolic syndrome, and this may further limit drug use. Adalimumab appears equally efficacious in older patients (older than 65 years) who may have higher incidences of hypertension, hyperlipidemia, depression, obesity, and diabetes.[115] Adverse effects profiles were similar between subgroups (various weights and comorbidities) with no significant differences in serious adverse events.[115] Topical psoriasis treatments are often prescribed for elderly patients as first-line therapy[14]; however, even with topicals, adverse effects—including systemic ones—can occur with greater frequency in these patients.[14]

Psoriasis in Patients with a History of Solid Tumors

As discussed throughout this chapter, many antipsoriatic therapies carry significant cancer risks. PUVA, systemic therapies such as cyclosporine, and some BRMs are associated with increased risks of oncologic disorders.

A systematic review of the risk of malignancy associated with therapies for moderate-to-severe psoriasis confirmed the following[97]: PUVA is associated with an increased risk of cutaneous SCC and malignant melanoma; UVB is a much safer therapeutic modality than PUVA; cyclosporine increases risks of lymphoma, internal malignancies, and skin cancers; MTX may be associated with increased melanoma and Epstein–Barr virus–associated lymphomas; MMF may be associated with lymphoproliferative disorders; and the malignancy risk may be increased for biologic agents, especially the TNF-α inhibitors.[97]

The 2009 Canadian guidelines recommend that TNF-α inhibitors be used with caution for patients with a history of malignancy or existing malignancies, and the T-cell modulator alefacept is contraindicated for these patients.[14]

Pharmacoeconomic Considerations

10 The wide gap in costs of agents for psoriasis makes economics and availability of insurance or other coverage important considerations in formulating a therapeutic plan.

Currently, the expensive BRMs are often considered for patients with moderate-to-severe psoriasis when less expensive systemic agents are inadequate or relatively contraindicated. BRMs have also been recommended as first-line therapy, alongside conventional systemic agents, for patients with moderate-to-severe psoriasis; however, in practice, drug access secondary to cost considerations can limit use. These agents may be needed early, though, for some patients with comorbidities.

A recent pharmacoeconomic analysis of BRMs in the treatment of psoriasis suggests that the cost-to-benefit ratio for BRMs may be favorable.[68] There are also cost differences among the BRMs. Of the TNF-α inhibitors, etanercept is the least costly, followed by adalimumab than infliximab.[116] However, etanercept is less efficacious. Adalimumab (at doses of 40 mg every other week) is significantly less costly than ustekinumab, with similar efficacies, in patients with suboptimal response to etanercept.[117]

CONCLUSION

Psoriasis is a lifelong illness with no known cure. Significant comorbidities may coexist. Treatment should be patient-specific, with consideration given to disease severity, patient risk factors, age, and comorbidities. Newer treatment modalities, including numerous BRMs, are now parts of the armamentarium available in the management of this disease.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

BMI	body mass index
BRM	biologic response modifier
BSA	body surface area
CAM	complementary and alternative medicine
CBC	complete blood count
CHD	coronary heart disease
CHF	chronic heart failure
CRP	C-reactive protein
CYP3A4	cytochrome P450 isoenzyme 3A4
DBPC	double-blind placebo-controlled
DHA	docosahexaenoic acid
DISH	disseminated (or diffuse) idiopathic skeletal hyperostosis
DLQI	Dermatology Life Quality Index
EPA	eicosapentaenoic acid

FDA	Food and Drug Administration
GFR	glomerular filtration rate
HLA-C	major histocompatibility complex antigen
HPA	hypothalamic–pituitary–adrenal
IL	interleukin
LFT	liver function test
MI	myocardial infarction
MMF	mycophenolate mofetil
MTX	methotrexate
NSAIDs	nonsteroidal antiinflammatory drugs
NB-UVB	narrowband ultraviolet B (311 nm ultraviolet B light)
PASI	Psoriasis Area and Severity Index
PGA	Physician's Global Assessment
PsA	psoriatic arthritis
PUVA	psoralens with ultraviolet A light
QLI	Quality of Life Index
QOL	quality of life
RCT	randomized controlled trial
RE-PUVA	retinoid plus PUVA (as combination therapy)
RE-UVB	retinoid plus NBUVB (as combination therapy)
RPLS	reversible posterior leukoencephalopathy syndrome
RR	relative risk
SCAT	short-contact anthralin therapy
SCC	squamous cell carcinoma
SF-36	Short Form Health Survey
SPF	sun protection factor
TB	tuberculosis
TNF-α	Tumor necrosis factor-α
UV	ultraviolet
UVA	ultraviolet A (315 to 400 nm ultraviolet A light)
UVB	ultraviolet B, or broadband UVB (28 to 315 nm ultraviolet B light)

Chapter 98: Atopic Dermatitis

Rebecca M. Law; Po Gin Kwa

INTRODUCTION

KEY CONCEPTS

- 1 Atopic dermatitis (AD) is a chronic skin disorder involving inflammation associated with intense pruritus, a hallmark symptom. Management of AD must always include appropriate management of the associated pruritus.
- 2 AD is associated with other atopic diseases such as asthma and allergic rhinitis in the same patient or family. The three conditions are known as the *atopic triad*.
- 3 The prevalence of AD appears to have increased two- to threefold in many developed and developing countries during the last three decades. Recent data indicate age and country or regional differences, with some countries showing no change or even a decrease. Rural areas appear to have lower prevalence rates.
- 4 There are genetic and environmental factors in the pathogenesis and pathophysiologic manifestations of AD. The inheritance pattern is not straightforward. More than one gene may be involved in the disease, with the filaggrin gene (*FLG*) being a key player. Other genes coding for specific cytokines are also involved.
- 5 AD usually presents in infants and young children. The clinical presentation differs somewhat depending on the age of the patient.
- 6 Secondary bacterial skin infections are common in patients with AD and must be promptly treated.
- 7 Management of AD must always include appropriate nonpharmacologic management of any controllable environmental factors, such as avoidance of identified triggers. These may include aeroallergens (eg, mold, grass, pollen), foods (eg, peanuts, eggs, tomatoes), chemicals (eg, detergents, soaps), clothing material (eg, wool, polyester), temperature (eg, excessive heat), and humidity (eg, low humidity).

- 8 Nonpharmacologic management of AD entails managing the symptoms associated with pruritus and encouraging appropriate skin care habits such as proper bathing techniques and the copious use of moisturizers, which is a standard of care.
- 9 Topical corticosteroids (TCS) are the drugs of first choice for AD.
- 10 Topical calcineurin inhibitors (tacrolimus and pimecrolimus) are alternate treatment options for adults and children older than 2 years.
- 11 Phototherapy is a second-line treatment when TCS and topical calcineurin inhibitors fail.
- 12 This chronic illness has substantial socioeconomic impact. The cost may be magnified by undertreatment.

1 Atopic dermatitis (AD) is a chronic, pruritic inflammatory skin disease. It is often referred to as *eczema*, which is a general term for several types of skin inflammation. AD is the most common type of eczema (**Table 98-1**).[1] Pruritus is the hallmark symptom and presentation and is responsible for much of the disease burden borne by patients and their families.[2]

TABLE 98-1 Types of Eczema (Dermatitis)[1]

- **Allergic contact eczema (dermatitis):** A red, itchy, weepy reaction where the skin has come into contact with a substance that the immune system recognizes as foreign, such as poison ivy or certain preservatives in creams and lotions.
- **Atopic dermatitis:** A chronic skin disease characterized by itchy, inflamed skin.
- **Contact eczema (dermatitis):** A localized reaction that includes redness, itching, and burning where the skin has come into contact with an allergen (an allergy-causing substance) or with an irritant such as an acid, cleaning agent, or other chemical.
- **Dyshidrotic eczema:** Irritation of the skin on the palms of hands and soles of the feet characterized by clear, deep blisters that itch and burn.
- **Neurodermatitis:** Scaly patches of the skin on the head, lower legs, wrists, or forearms caused by a localized itch (such as an insect bite) that become intensely irritated when scratched.
- **Nummular eczema:** Coin-shaped patches of irritated skin—most common on the arms, back, buttocks, and lower legs—that may be crusted, scaling, and extremely itchy.
- **Seborrheic eczema:** Yellowish, oily, scaly patches of skin on the scalp, face, and occasionally other parts of the body.
- **Stasis dermatitis:** A skin irritation on the lower legs, generally related to circulatory problems.

2 This form of dermatitis is commonly associated with a personal or family history of other atopic disorders, such as allergic rhinitis and asthma[2] (collectively known as the *atopic triad*). AD has been considered the start of the "atopic march"[2]; however, the association with other atopic conditions is multifactorial and complex, since this progression does not happen in all cases.[2] The disease can have periods of exacerbation, or flare-ups, followed by periods of remission. These flare-ups may be disruptive to the patient's quality of life and may affect the entire family. Disease flare-ups are difficult to manage and may be complicated by secondary infections. About one-half (estimate up to 65%) of cases in children first manifest before age 1 year[1,2,3,4]; these cases are termed *early onset atopic dermatitis*.[5] Onset of AD is most common between 3 and 6 months of age.[2] Approximately 85% to 90% of patients develop symptoms before age 5 years.[2]

Among children with AD, 10%-30% will have the skin condition in adulthood.[2] However, onset after age 30 years is much less common and is often caused by exposure to harsh or wet conditions[1] such as repeated skin trauma or exposure to harsh chemicals.

EPIDEMIOLOGY

3 The prevalence of AD is generally said to have increased two- to threefold in developed and developing countries during the past three decades.[5] In developed countries, an estimated 15% to 30% of children and 2% to 10% of adults are affected.[5,6] The prevalence appears to be increasing worldwide, as earlier prevalence rates were estimated at 10% to 15% in children.[4]

3 The largest international study of the prevalence of AD found both age and country differences in prevalence rates.[7] This international study was the International Study of Asthma and Allergies in Childhood (ISAAC), which was conducted in three phases.[8] The strength of this study was the use of a uniformly validated methodology which allowed a direct comparison of results from pediatric populations worldwide.[9] ISAAC Phase One included 700,000 children from 156 centers in 56 countries between 1992 and 1998. ISAAC Phase Two studied allergic causes from 30 centers in 22 countries. ISAAC Phase Three repeated a multicountry cross-sectional survey (1999-2004) and included 187,943 children between ages 6 and 7 years from 64 centers in 35 countries and 302,159 adolescents between ages 13 and 14 years from 105 centers in 55 countries. For children aged 6 to 7 years, most countries showed an increase of two standard deviations (SDs) in mean annual prevalence over a 5- to 10-year period. In contrast, for adolescents aged 13 to 14 years, the trends differ from country to country. Large increases in prevalence were seen in developing countries (eg, Mexico, Chile, Kenya, and Algeria, and seven countries in Southeast Asia). But in other countries with formerly very high prevalences, the mean annual prevalence in eczema symptoms has either leveled off or decreased. Most of the largest decreases (SD more than or equal to 2) in prevalence were reported from developed countries in northwest Europe, (eg, the United Kingdom, Ireland, Sweden, Germany) and New Zealand.[7] The ISAAC study has suggested that a maximum prevalence plateau of approximately 20% has emerged.[7,8]

There were no differences according to the sex of the study participant, or with gross national income

at a country level.[7] This is consistent with other reports that AD affects men and women at approximately the same rate.[1] There appears to be a lower prevalence of AD in rural areas when compared with urban areas,[2] suggesting a link to the *hygiene hypothesis*,[10,11] which postulates that the absence of early childhood exposure to infectious agents increases susceptibility to allergic diseases.[10,11,12] In contrast, children attending daycare centers before 3 months of age have less atopy and asthma in later childhood,[11,12] and areas with diffuse and chronic helminth infestations have a low prevalence of allergic diseases.[12] In addition, a European birth cohort study involving 1,133 newborns showed that children born to farm families had a lower prevalence of sensitization to seasonal inhaled allergens such as grass pollen.[11,13] Maternal exposure during pregnancy (ie, prenatal exposure) to animal sheds correlated with the lower prevalence rate in the farm children. However, there were no differences in prevalence related to inhaled perennial allergens. Parasitic infections decreased the risk of allergen sensitization.[11] A recent systematic review reported that exposures to endotoxin, farm animals, and dogs may protect against AD.[14]

Although reported risk factors associated with higher prevalence include urban environment, higher socioeconomic status, higher level of family education, a family history of AD, female gender (after age 6 years), and smaller family size.[8] However, more recent studies are conflicting. There are no consistent findings that higher socioeconomic status or male/female gender affect the risk of AD.[2] Urban living does appear to increase the risk of AD, but studies attempting to identify causative environmental agents have been inconclusive.[2] Strongly associated risk factors include a family history of AD, and the loss of function mutations in the *FLG* gene.[2]

ETIOLOGY

4 AD is a complex genetic disease that arises from gene–gene and gene–environment interactions. There are two major groups of genes involved. First, there are the genes encoding for epidermal or other epithelial structural proteins. Second, there are genes encoding for the major elements of the immune system.[5]

The inheritance pattern is not straightforward. More than one gene is likely involved in the disease. There is an increased risk for a child to have AD if there is a family history of other atopic diseases, such as hay fever or asthma. The risk of AD is two- to threefold higher in children with one atopic parent and three- to fivefold higher if both parents are atopic.[2] Studies of identical twins show that a person whose identical twin has AD is seven times more likely to have AD than someone in the general population.[1] And a person whose fraternal twin has AD is three times more likely to have AD than someone in the general population.[1] Another estimate is 80% concordance in monozygous twins and 20% in heterozygous twins.[10]

Thus, genetic predispositions to developing AD exist. Specifically, there are several possible genes on the chromosomes 3q21, 1q21, 16q, 17q25, 20p, and 3p26. Of these chromosomes, 1q21 has the highest linkage region. This region has a family of epithelium-related genes called the epidermal differentiation complex.[5] One of these genes, the filaggrin gene (*FLG*), on chromosome 1q21.3,

encodes for profilaggrin which degrades to filaggrin proteins.[2] Filaggrin proteins playkey roless in epidermal differentiation, including terminal differentiation of the epidermis and formation of the skin barrier (including the stratum corneum).[2,15] Filaggrin breakdown products are natural moisturizers and contribute to epidermal hydration and barrier function.[2] Mutations or deficiency of *FLG* results in an abnormality in permeability barrier function.[15] Patients with AD who carry *FLG* mutations have more persistent disease, a higher incidence of skin infections with herpes virus (eczema herpeticum) and a greater risk for multiple allergies.[15] However, many patients with AD have no known *FLG* mutations, and conversely, about 40% of people with *FLG* null alleles do not develop AD.[2,15]

Epidermal barrier dysfunction is a prerequisite for the penetration of high-molecular-weight allergens in pollens, house dust mite products, microbes, and food.[5] In mice studies, this barrier abnormality lowers irritability thresholds, and enhanced cutaneous allergen penetration.[15] In humans, two common *FLG* variants (*R501X* and *2282de14*) with an estimated combined allele frequency of about 6% have been identified in individuals of European descent.[16] Eighteen other less common variants have also been identified in Europeans, with an additional 17 mutations restricted to individuals of Asian descent.[16] Each of these variants leads to nonsense mutations which either prevent or severely diminish the production of filaggrin in the epidermis.[16] Mutations of *FLG* seem to occur mainly in early onset AD patients and may be associated with the development of asthma in patients with AD.[5,16] However, *FLG* mutations are identified in only 30% of European patients with AD; implying that other genetic mutations affecting other epidermal structures may be important (eg, changes in the cornified envelope proteins involucrin and loricrin, or lipid composition).[5]

4 There are other genes encoding for the immune system that may be associated with AD, especially those found on chromosome 5q31-33.[5] These genes code for cytokines that regulate IgE synthesis. Cytokines are produced by helper T cells (TH_0, TH_1, TH_2, TH_3).[11] T-helper type 1 (TH_1) cells produce cytokines that suppress immunoglobulin E (IgE) production (eg, interferon-γ and interleukin-12 [IL-12]).[5] T-helper type 2 (TH_2) cells produce cytokines that increase IgE production (eg, IL-5 and IL-13).[5,17] In patients with AD, there is an imbalance between TH_1 and TH_2 immune responses. These patients are genetically predisposed to TH_2 predominance, seen as increased TH_2 cell activity.[2,5,9,17] Increased TH_2 activity causes the release of IL-3, IL-4, IL-5, IL-10, and IL-13, resulting in blood eosinophilia, increased total serum IgE, and increased growth and development of mast cells.[2,5,11,17,18] This is seen in the initial and acute phase of AD.[9] In addition, these cytokines affect the maturation of B cells and cause a genomic rearrangement in these cells that favors isotype class switching from immunoglobulin M (IgM) to IgE.[5] As discussed below, epidermal Langerhans cells (LC) and dendritic cells (DC) with high-affinity IgE receptors uptake allergens and mediate the inflammatory response.[11]

In summary, *FLG* deficiency alone can provoke a barrier abnormality in the epidermis and predispose to the development of dermatitis by enhancing allergen absorption through the skin.[19] Furthermore, there appears to be complex relationships, including genetic and nongenetic risk factors, that modify

an individual's susceptibility to allergic disease.[20] Complex genetic factors contribute to the increased susceptibility to AD (*FLG* mutations and gene–gene interactions). These, along with environmental factors such as food allergens[21] (gene–environment interactions), result in the pathophysiologic changes and clinical presentations associated with AD.

PATHOPHYSIOLOGY

The initial mechanisms that trigger inflammatory changes in the skin in patients with AD are unknown. Neuropeptides, irritation, or pruritus-induced scratching may be causing the release of proinflammatory cytokines from keratinocytes. Alternatively, allergens in the epidermal barrier or in food[21] may cause T-cell mediated but IgE-independent reactions. Allergen-specific IgE is not a prerequisite.[5] Characteristic features in pathophysiology are skin barrier dysfunction, and immune deviation toward TH_2 with subsequent increased IgE.[10] The disease is further complicated by microbial colonization with pathologic organisms resulting in increased susceptibility for skin infections.[10]

As discussed above, skin barrier dysfunction plays a critical role in the development of AD,[10,11,15,,22] with loss of function mutations in *FLG* being a major risk factor.[15,22] Other factors may include a deficiency of skin barrier proteins, increased peptidase activity, lack of certain protease inhibitors, and lipid abnormalities.[22] There must be epidermal barrier dysfunction for high-molecular-weight allergens in pollens, house dust mite particles, microbes, and foods to penetrate the skin barrier. Atopic skin has reduced antimicrobial peptides (AMPs). AMPs are normally produced by keratinocytes, sebocytes, and mast cells, and they form a chemical shield on the surface of the skin. Reduced AMPs result in a diminished antimicrobial barrier, which correlates with increased susceptibility to infections and superinfections seen in these patients.[23]

On penetration of the epidermal barrier, allergens are met by DCs. DCs are antigen-presenting cells populating the skin, respiratory tract, and mucosa of the gastrointestinal (GI) tract (ie, at the front line of pathogen entry).[24] DCs then enhance TH_2 polarization, resulting in increased production of IgE. Keratinocytes in the skin of patients with AD also produce high levels of an IL-7–like protein, which again drives dendritic cells to enhance TH_2 polarization. Epidermal DCs in patients with AD bear IgE and express its high-affinity receptor (FcεRI).[25,16,27] Total serum IgE is often elevated in patients with AD,[1,2,18] especially during an exacerbation.

However, on initial presentation, patients with early onset AD generally do not have increased total serum IgE levels (ie, there is no detectable IgE-mediated allergic sensitization). IgE-mediated allergic sensitization may occur several weeks or months after the initial AD lesions appear. Although in some children—mostly girls—this sensitization never occurs.[5] Furthermore, elevated total serum IgE is not specific to AD and can be associated even with nonatopic conditions.[2]

Other potential biomarkers currently discovered include serum CD30, macrophage-derived chemoattractant (MDC), IL-12, -16, -18, and -31, and thymus and activation-regulated chemokine

(TARC); however, to date none of them have shown reliable sensitivity nor specificity for clinical use.[2]

Predisposing Factors

Several factors can predispose patients to development of AD. These include climate, infection, genetics, environmental aeroallergens, and food.

Hot and extremely cold climates are both poorly tolerated by patients with this condition. Dry weather, common in the winter, causes increased skin dryness. Hot weather causes increased sweating, resulting in pruritus.

Patients with AD are commonly colonized by *Staphylococcus aureus* bacteria. Clinical infections with *S aureus* frequently cause flare-ups of AD.

As discussed previously, genetics plays a role in AD. Family history of AD is a strong risk factor.

Exposure to environmental aeroallergens is another risk factor. Dust mites, pollens, molds, cigarette smoke, and dander from animal hair or skin may worsen the symptoms of AD.[1,18]

The role of food as antigens in the pathogenesis of AD is still not fully understood.[15,21] Preliminary results (mostly animal studies) indicate that defects in the skin and gut barrier function may facilitate sensitization to food allergens.[21] Small amounts of environmental foods (low-dose exposure from foods on tabletops, hands, dust) may penetrate the skin barrier and be taken up by LCs, leading to TH_2 responses and IgE production.[28] However, early high-dose oral food consumption induces oral tolerance. The timing and balance of cutaneous and oral exposure determines whether a child will have allergy or tolerance.[28] Increased serum IgE antibodies to a particular food is evidence of sensitization to a food and is consistent with although not proof of a food allergy.[1,29] Eczema may frequently be a manifestation of food allergy,[28] and patients with AD have a higher prevalence of food allergy than those in the general population.[1] Conversely, there is a belief that food allergy may be caused by AD, and in most patients with coexisting AD and food allergy, AD precedes the food allergy. (The assumption is that AD is a causal risk factor for asthma and systemic allergen sensitization in the context of *FLG* mutations.[15]) Regardless, the two conditions coexist, and the likelihood of an infant or child with AD also having food allergy or allergies must be kept in mind.[29]

There is a known epidermal barrier dysfunction in AD, allowing for increased low-level skin permeability to allergenic foods. Certain foods may trigger acute reactions, including urticaria and anaphylaxis. The most commonly reported allergenic foods are eggs, milk, peanuts, wheat, soy, tree nuts, shellfish, and fish.[1] Individual food allergies, such as peanut allergy, have increased in prevalence in the past decade;[28,29] new food allergies may also be increasing in prevalence, particularly kiwi allergy[28,30] and sesame seed allergy.[28,31] Allergies to seafood, peanuts, and nuts are more likely to persist into adulthood, while allergies to milk, eggs, wheat, and soy generally resolve by late-childhood.[21] Consistent with the oral tolerance concept, early results from recent studies using sublingual and oral immunotherapy to specific food allergens (eg, milk or peanut) appear to indicate that it may be possible to induce oral tolerance, and that it may be possible to desensitize

children to some allergenic foods.[32] Nine to 12 months of immunotherapy was needed to observe the beneficial effect and "the present evidence does not warrant routine recommendation" by the AAD.[33] Injectable allergen-specific immunotherapy is also being studied.[33] National Institute of Allergy and Infectious Diseases (NIAID) suggests limited food allergy testing (ie, cow's milk, eggs, wheat, soy, peanut) if a child younger than 5 years has moderate to severe AD and persistent disease despite optimal therapy.[29,33] For more information about management of food allergies the reader is directed to the 2010 NIAID-sponsored expert panel's report, available at www.niaid.nih.gov.[29]

CLINICAL PRESENTATION

Diagnosis of AD is generally based on clinical presentation (**Table 98-2**).[1] There is currently no objective diagnostic test or reliable biomarker for the clinical confirmation of AD.[1,2] On occasion, skin biopsy specimens or other tests (eg, total and/or allergen-specific serum IgE, potassium hydroxide preparation, patch testing, and/or genetic testing) may be used to rule out other diseases or associated skin conditions.[2] *FLG* gene mutations may be associated with persistent and more severe AD as well as early onset cases.[22]

TABLE 98-2 Skin Features Associated with Atopic Dermatitis[1]

- **Atopic pleat (Dennie-Morgan fold):** An extra fold of skin that develops under the eye.
- **Cheilitis:** Inflammation of the skin on and around the lips.
- **Hyperlinear palms:** Increased number of skin creases on the palms.
- **Hyperpigmented eyelids:** Eyelids that have become darker in color from inflammation or hay fever.
- **Ichthyosis:** Dry, rectangular scales on the skin.
- **Keratosis pilaris:** Small, rough bumps, generally on the face, upper arms, and thighs.
- **Lichenification:** Thick, leathery skin resulting from constant scratching and rubbing.
- **Papules:** Small raised bumps that may open when scratched and become crusty and infected.
- **Urticaria:** Hives (red, raised bumps) that may occur after exposure to an allergen, at the beginning of flares, or after exercise or a hot bath.

Clinical Controversy…

Although it has traditionally been thought that food allergies are a predisposing factor for the development of AD, some clinicians are now thinking that AD may be the predisposing factor for the development of food allergies in an individual. Often the signs and symptoms of AD appear before the food allergies.

5 AD follows a relapsing course.[33,34] Studies reviewing the natural course of the disease usually describe the disease pattern as persistent, intermittent, or in remission.[8] A 2004 study found that 43% were in complete remission after age 2 years, with 19% having persistent disease and 38% an intermittent pattern.[8]

The clinical presentation of AD differs depending on the age of the patient. In infancy, the earliest onset of AD usually occurs between 3 and 6 months of age, with 60% of patients develop symptoms within the first year of life, and 85% to 90% will have developed symptoms before the age of 5 years.[1,2] The initial presentation in infancy is an erythematous, papular skin rash that may first appear on the cheeks and chin as a patchy facial and that can then progress to red, scaling, oozing skin.[1] The rash shows a centrifugal distribution affecting the malar region of the cheeks, forehead, scalp, chin, and behind the ears while sparing the central areas (ie, the nose and paranasal creases). Lesions occur in the flexor surfaces, such as antecubital and popliteal fossae. Over the next few weeks and as the infant becomes more mobile and begins crawling, the lesions spread to the extensors of the lower legs, and eventually the entire body may be involved, with sparing of the groin, axillary region, and the nose.[1,2,34] These lesions are associated with uncontrollable itchiness, and the infant will become irritable and may try to rub his or her face to relieve the itch. Scratching may occur quite early, and infants with AD may scratch themselves continuously, even during sleep.[2] Sleep disruption occurs in up to 60% of children with AD, increasing to 80% or more during exacerbations.[2] Excessive rubbing or scratching may result in excoriation and development of secondary infections.

In childhood, the skin often appears dry, flaky, rough, cracked, and may bleed because of scratching. With repeated scratching and rubbing the skin becomes lichenified. Lichenification, usually localized to the flexural folds of the extremities, is characteristic of childhood AD in older children and in adults.[34] Lichenification signifies repeated rubbing of the skin and is seen mostly over the folds, bony protuberances, and forehead.[34] Excoriations and crusting are also commonly seen, along with secondary infections. Sometimes increased folds are seen underneath the eyes (so-called Dennie–Morgan folds).[34] Lesions are still most commonly seen in the flexor surfaces of the body, particularly the flexural creases of the antecubital and popliteal fossae.[34]

Sleep disturbances also occur. One study reported that there are both brief and longer awakenings associated with scratching episodes that affect sleep efficiency in school-age children with AD.[35]

In adulthood, lesions are more diffuse with underlying erythema. The face is commonly involved and may be dry and scaly. Lichenification may again be seen. A brown macular ring around the neck, representing a localized deposit of amyloid, is typical but not always present.[34]

Although no objective diagnostic test confirms the presence of AD,[1,2] some signs, symptoms, and other factors are commonly used in its diagnosis. These include pruritus, early age of onset, eczematous skin lesions that vary with age, chronic and relapsing courses, dry and flaky skin, IgE reactivity, family or personal history of asthma or hay fever, or other atopic diseases (**Tables 98-3** and **98-4**).[2,34] In addition, allergy skin testing may be helpful in identifying factors that trigger flares of AD.[1] Negative results may help rule out certain substances as triggers; however, positive results may

be unrelated to disease activity, and false positives are common.[1]

TABLE 98-3 Clinical Features in the Diagnosis of Atopic Dermatitis[2]

Essential Features (Must Be Present):

- Pruritus
- Eczema (acute, subacute, chronic)
    - Typical morphology and age-specific patterns
        - Facial, neck, external involvement (infants, children)
        - Flexural lesions (any age group)
        - Sparing of groin and axillary regions
    - Chronic or relapsing history

Important Features (Seen in Most Cases, Supports the Diagnosis of AD):

- Early age of onset
- Atopy
    - Personal/family history
    - IgE reactivity
- Xerosis

TABLE 98-4 Major and Minor Signs and Symptoms of Atopic Dermatitis[1]

Major Indicators

- Pruritus (intense itching)
- Characteristic rash in locations typical of the disease
- Chronic or repeatedly occurring symptoms
- Personal or family history of atopic disorders (eczema, hay fever, asthma)

Selected Minor Indicators

- Early age of onset
- Dry skin that may also have patchy scales or rough bumps

- Increased serum IgE
- Numerous skin creases on the palms
- Hand or foot involvement
- Inflammation around the lips
- Nipple eczema
- Susceptibility to skin infection
- Positive allergy skin tests

1 Pruritus is a quintessential feature of AD, and a diagnosis cannot be made if there is no history of itching.[1,2,3,4,34] Scratching and rubbing itchy atopic skin further irritates the skin, increases inflammation, and exacerbates itchiness.[3] Atopic skin can itch during sleep. This nighttime itching is a problem for many infants and children with the disease, since there is no conscious control of scratching during sleep.[1,2,18] Pruritus is the symptom that most affects the health-related quality of life for most patients with AD. In studies, more than 50% of patients rated their pruritus as very bothersome or extremely bothersome, and reported that they often or always experienced intolerable symptoms.[34]

Pruritus can be triggered by a variety of factors. The most common triggers of itch have been reported as heat and perspiration (96%), wool (91%), emotional stress (81%), certain (usually vasodilatory) foods (49%), alcohol (44%), upper respiratory infections (36%), and house dust mites (more than 35%).[34,35]

Once pruritus occurs, the surrounding normally nonpruritic skin area (whether inflamed or noninflamed) may be very sensitive and react to light stimuli and begin itching (allokinesis). Allokinesis is typical of AD.[34,35] As a result of allokinesis, patients with AD may experience pruritic attacks when their skin is touched accidentally by mechanical factors such as clothing, especially wool products.[35]

Elevated serum IgE may be seen, consistent with the genetically predetermined dominance of TH_2 cytokines causing increased IgE. In addition, increased serum IgE antibodies to a particular food, consistent with a food allergy, is common in patients with AD. Serum-based tests for allergen-specific IgE (formerly a radioallergosorbent test referred to as RAST) are used to screen for allergy to a specific substance or substances.[33] (Currently, most laboratories use large autoanalyzers that rely on fluorescent or chemiluminesent labels rather than radiolabels to identify reactions, so RAST does not describe the technique used). In some cases, allergen-specific IgE tests may be used to monitor immunotherapy or to see if a child has outgrown a specific allergy. The negative predictive value is high (greater than 95%) but the specificity and positive predictive value are low (40%-60%).[33] Negative results help rule out a food allergy, whereas positive (elevated) allergen-specific IgE test

results only signify sensitization and require clinical correlation and confirmation.[33] The level of IgE may not correlate with the severity of an allergic reaction, and the IgE level may remain elevated for years after an allergy has been outgrown.

A clinically useful set of criteria for the diagnosis of AD is as follows: atopy, pruritus, eczema, and altered vascular reactivity.[18,35]

COMPLICATIONS

6 Patients with AD are prone to skin infections. Atopic skin is drier and the stratum corneum has weakened protective abilities; combined with the abnormal skin barrier function and immune defense, there is an increased risk of secondary bacterial skin infections with staphylococci or streptococci, and viral infections such as herpes simplex or even fungal infections.[1,2] Constant scratching to relieve pruritus may cause excoriations, further compromising the integrity of the skin barrier. *S. aureus* is a common cause of secondary bacterial infections in AD.[10] Binding of *S aureus* is enhanced by skin inflammation as seen in AD. Many patients with AD are colonized with *S. aureus* and may have exacerbations after skin infections of this organism.[10] Secondary bacterial infections may present as yellowish crusty lesions and should be promptly treated. Oral (systemic) antibiotics are generally more effective than topical treatment.[1]

Patients with AD are also more prone to disseminated infections with herpes simplex or vaccinia virus. Severe viral infections such as eczema herpeticum or eczema vaccinatum might be linked to the severity of atopy. Smallpox vaccination is contraindicated in patients with AD.

TREATMENT

Desired Outcomes

In treating patients with AD, clinicians generally have the following clinical goals in mind:

1. Provide symptomatic relief—control the itching.
2. Control the AD.
3. Identify and, when possible, eliminate triggers and environmental aeroallergens.
4. Identify and minimize predisposing factors for exacerbations including any stressors.
5. Prevent future exacerbations.
6. Provide any social and psychological support needed for the patient, family, and caregivers.
7. Minimize or prevent adverse events from medications and other treatment modalities.
8. Treat to cure any secondary skin infections, if present.

Successful management of AD should include not only clearance of skin lesions, which may take days to weeks depending on the severity of disease, but also control of the itch, minimizing or eliminating triggers, monitoring the patient to minimize or prevent adverse events from medications or other treatment modalities, and providing adequate social and psychological support for the patient, family, and caregivers.

The ultimate goal is to provide enough control of this chronic disease so that future exacerbations are prevented, thus ensuring that the patient's quality of life is minimally affected by AD. Because the course of the disease evolves over time, management strategies may change.

7 Both nonpharmacologic and pharmacologic therapies are important in managing the signs and symptoms of AD. Nonpharmacologic strategies include identifying and minimizing or eliminating preventable risk factors, such as known triggers and allergens, as well as appropriate skin care.

Treatment guidelines and protocols for AD are available. These are listed in **Table 98-5**.

Nonpharmacologic Therapy

8 Nonpharmacologic approaches to the treatment of infants and children with AD include the following[1,36]:

1. Apply moisturizers frequently throughout the day. Moisturizers are a standard of care for AD and there is strong evidence that their use can reduce disease severity and the need for pharmacologic intervention.[36]
2. Give lukewarm baths. Currently there is insufficient evidence for AD patients to recommend the addition of oils, emollients, or most other additives to bath water, or the use of acidic spring water.[36]
3. Apply moisturizer immediately after bathing. Currently there is no standard for the frequency or duration of bathing appropriate for those with AD.[36]

4. Use nonsoap cleansers (which are neutral to low pH, hypoallergenic, fragrance free). Limited use.[36]

5. Use wet-wrap therapy (with or without topical corticosteroid) during flare-ups for patients with moderate to severe AD. "Wet wrap" is applying damp tubular elasticized bandages and occlusive dressing to the limbs—this promotes skin hydration and absorption of emollients and TCS,[11] reducing disease severity and water loss.[11,36]

6. Keep child's fingernails filed short.

7. Select clothing made of soft cotton fabrics, not polyester.

8. Consider using sedating antihistamines at bedtime to reduce scratching at night.

9. Keep the child cool; avoid situations in which overheating occurs.

10. Learn to recognize skin infections and seek treatment promptly.

11. Attempt to distract the child with activities to keep him or her from scratching during the day.

12. Identify and remove irritants and allergens.

Hydration is crucial, and adequate skin hydration is a fundamental part of managing AD.[3,36] Transepidermal water loss is greater in atopic skin than in normal skin. Thus, any measures to improve skin moisturization, such as liberal use of moisturizers, would be beneficial. Moisturizers are a standard of care and may be steroid-sparing.[10,36,37,38,39,40] They are useful for both prevention and maintenance therapy.[10,36,39,40] They can be categorized based on their specific effects on the skin:

1. Occlusives: These agents provide an oily layer on the skin surface to slow transepidermal water loss, increasing the moisture content of the stratum corneum. These are the best moisturizers for patients with AD.[3]

2. Humectants: In the stratum corneum, these agents increase the water-holding capacity. However, they are not useful in patients with AD because they have a stinging effect on open skin.[3]

3. Emollients: These agents smooth out the surface of the skin by filling the spaces with droplets of oil. These are the least effective moisturizers.[3]

Note that the term "emollients" is sometimes more broadly used to mean all nonmedicated moisturizers, including occlusives.[37,38] Usual active ingredients in moisturizers include mineral oil, petrolatum, ceramide, and urea. Ceramide was shown to improve pruritus and sleep in pediatric patients with AD.[38] Ceramide-containing over-the-counter (OTC) moisturizers and prescription emollient devices (PEDs) with distinct ratios of lipids mimic endogenous compositions. However, to date these have not shown superiority in AD.[36]

The humidity in the home should be kept at or above 50% and the room temperature kept on the cool side.[18]

Appropriate skin care is crucial in preventing flare-ups.[1] A daily skin care routine should include the following[18]:

1. Using scent-free moisturizers liberally as needed each day. Large quantities can be used.

2. Bathing in lukewarm water (never hot) for 5 to 10 minutes.[36] once or twice daily.[3,36,37] Adding a capful of emulsifying oil[10] may help the body retain moisture; baths are better than showers. Bathing daily for 10 to 20 minutes may be desirable as long as a thick moisturizer is applied afterward.[37] A 20-minute soak followed by immediate application of topical anti-inflammatory agents (eg, TCS) without towel drying is known as the "soak and smear" technique and is useful when the topical anti-inflammatory agent alone is inadequate.[36] Bathing twice daily during disease flares may also be a useful method for enhancing skin penetration of topical therapies and for debridement of crusting and staphylococcal colonization.[37]

3. The skin should be lightly towel dried (pat to dry, avoid rubbing or brisk drying).[1,37,38]

4. A scent-free moisturizer should then be applied while the skin is still moist or slightly damp (eg, within 3 minutes of towel drying).[3,37] Some fragrance-free moisturizers include Aveeno Baby Soothing Relief Moisture Cream, Cetaphil, Neutrogena Hand Cream, and Vanicream products. Lotions may be used on the scalp and other hairy areas and for mild dryness on the face, trunk, and limbs; creams are more occlusive than lotions; ointments are the most occlusive and can be used for drier, thicker, or more scaly areas.[3] Occlusive moisturizers are best.[3]

5. Using nonsoap skin cleansers[1] may cause less skin irritation. Lipid- and fragrance-free skin cleansers may be particularly advantageous (eg, Cetaphil Gentle Skin Cleanser, Free and Clear Liquid Cleanser, Spectro Derm Cleanser). Aquanil, Dove, Neutrogena, and pHisoderm sensitive skin products have also been recommended as low-irritant products, and some are lipid free.

6. Avoiding alcohol-containing topical products including lotions, swabs, and wipes, as they may be drying.

7. Clothing should be double-rinsed. Mild detergents should be used to wash clothing, with no bleach or fabric softener.[3]

Pharmacologic Therapy

Topical Corticosteroids

9 *Topical corticosteroids* (TCS) are the standard of care to which other treatments are compared.[10,11,36,37,38,39,40] They remain the drug treatment of choice for AD. However, despite their extensive use, supporting data are limited regarding optimal corticosteroid concentrations, duration

and frequency of therapy, and quantity of application.[10,36] The use of long-term intermittent application of TCS was beneficial and safe in two randomized controlled trials (RCTs); however, independent studies of other formulations are needed.

To maximize the anti-inflammatory benefit and minimize adverse effects, the choice of TCS should be matched with the severity and site of disease.[3] Low-potency TCS, such as hydrocortisone 1%, are suitable for the face, and medium-potency TCS, such as betamethasone valerate 0.1%, may be used for the body.[3] For longer-duration maintenance therapy, low-potency TCS are recommended.[36] Mid-strength and high-potency TCS should be used for short-term management of exacerbations.[36] Currently there is no established optimum regimen for controlling flare-ups—starting with a short burst of high-potency TCS to rapidly control active disease followed by a rapid taper in potency is equally acceptable as using the lowest-potency agent thought to be needed then adjusting upward if treatment fails.[36] Although twice-daily application is the usual clinical practice, there is some evidence of efficacy with once-daily use of some potent TCS.[36] Daily TCS applications are recommended until the inflammatory lesions are significantly improved—which may take up to several weeks at a time. Once control is achieved, either (a) stop the TCS and use moisturizers alone until the next flare-up, or (b) apply a TCS once or twice weekly to areas of the patient's body where frequent/repeated flare-ups occur—this method has reduced rates of relapse for those patients who experience frequent flare-ups at the same body sites.[36] Ultrahigh- and high-potency TCS, such as betamethasone dipropionate 0.05% or clobetasone propionate 0.05%, are typically reserved for short-term treatment of lichenified areas in adults.[39] Short-term treatments mean brief periods of 1 to 2 weeks.[37,38] After the lesions have cleared or significantly improved, a lower-potency agent (the least potent TCS that is effective)[36] should be used for maintenance when necessary.[39] Potent fluorinated TCS should be avoided not only on the face, but also the genitalia and the intertriginous areas, and in young infants. (For a corticosteroid potency comparison chart, see Table 97-2 in Chapter 97, or visit the National Psoriasis Foundation Web site at https://www.psoriasis.org/about-psoriasis/treatments/topicals/steroids/potency-chart.)

It is also important to remember that altering the local environment through hydration and/or occlusion (eg, wet-wrap therapy)[11] as well as changing the vehicle[41] may alter the absorption and effectiveness of the TCS.[10] Some vehicles are better suited for certain body areas,[41] such as a lotion for the scalp and hairy areas. Foams may be more cosmetically pleasing to some patients, as they easily disappear into the skin. The surface area of the skin involved and the skin thickness also play a role. In addition, tachyphylaxis is a clinical concern, but there is little experimental documentation.

Adverse effects of TCS may be systemic in nature, and they are directly related to the steroid potency, duration of use, and other factors as discussed above. Local adverse effects include striae and skin atrophy, perioral dermatitis, acne, rosacea, telangiectasias, purpura, focal hypertrichosis, and allergic contact dermatitis (often related to the vehicle).[36,42] The potential for systemic adverse effects is related to the potency of the TCS, the site of application, the occlusiveness of the preparation, the percentage of body surface area covered, and the duration of use. Potential systemic effects include hypothalamic-pituitary-adrenal (HPA) axis suppression, infections, hyperglycemia, cataracts, glaucoma, and growth retardation (in children).[1,18,36,37,38,42] However, growth retardation may also

be related to the chronicity of the illness rather than to TCS use or dietary factors.[3] Although less likely, systemic adverse effects can occur with low-potency TCS. For example, a phase II study of a mild-potency corticosteroid (desonide 0.05% foam) in children and adolescents 3 months to 17 years showed that 4% (3 of 75) of patients experienced mild reversible HPA-axis suppression after a 4-week treatment period.[43]

When TCS therapy has failed for efficacy or safety reasons, numerous agents and interventions can be used as alternative or add-on therapy in patients with AD.

Topical Calcineurin Inhibitors

10 Topical immunomodulators such as the calcineurin inhibitors tacrolimus ointment (Protopic) and pimecrolimus cream (Elidel) have been shown to reduce the extent, severity, and symptoms of AD in adults and children.[10,36,39,40] Calcineurin inhibitors inhibit the activation of key cells involved in AD, including T cells and mast cells, blocking the production of proinflammatory cytokines and mediators.[36] Tacrolimus also decreases the number and costimulatory ability of epidermal dendritic cells.[36] Pimecrolimus has more favorable lipophilic characteristics and, in animal studies, appears to preferentially distribute to the skin as opposed to the systemic circulation.[44] Both tacrolimus ointment and pimecrolimus cream are approved for AD in adults and children older than 2 years.[10,36,39,40,44] Although clinical trials conducted in younger infants (eg, 2 to 23 months old) also showed significant efficacy without appreciable adverse effects, use in children younger than 2 years is not FDA-approved.[45] Tacrolimus 0.03% ointment is approved for moderate to severe AD for ages 2 years and older, with the 0.1% ointment limited to ages 16 years and older; pimecrolimus 1% cream is approved for mild-to-moderate AD for ages 2 years and older.[45] There is limited data comparing TCS with tacrolimus or pimecrolimus.

Because of continuing concerns regarding a possible risk of cancer with tacrolimus and pimecrolimus,[45] both drugs are recommended for use as second-line treatments for short-term and noncontinous chronic use in AD,[10,36,37,38,39,40] when the continued use of TCS is ineffective or inadvisable.[36,37] They may be appropriate in patients with corticosteroid-related adverse effects, patients with large body-surface areas of disease, patients unresponsive to TCS, or other reasons where treatment with TCS is inadvisable.[3] Children and adults with a weakened or compromised immune system should not be treated with these agents.[36] Unlike TCS, calcineurin inhibitors can be used on all body locations for prolonged periods,[3,10,11] although episodic use is recommended. They may be used as twice-weekly long-term therapy for maintenance.[11] Skin atrophy does not occur.[11,36] They may be used as steroid-sparing agents (sequentially or concomitantly with TCS) although clinical trial data are limited.[36]

The most common adverse effect of topical calcineurin inhibitors is transient discomfort (burning sensation) at the application site.[3,36] There is a potential for local skin carcinogenesis as seen in animal studies, or for systemic effects if high blood levels are reached (eg, increased susceptibility to infections due to immunosuppressive effects).[45] Because there is a possible risk of cutaneous

malignancy,[3,36,37] sun protection is recommended.[3,11,18,37,45] Patients should be encouraged to apply a high sun protection factor (SPF) broad-spectrum sunblock daily to all exposed skin (eg, SPF 30 or higher); and this counseling should especially be emphasized for those patients with the highest risk of developing skin cancer, including patients with red hair and/or Fitzpatrick skin types I and II, and patients receiving phototherapy or using tanning beds.[45]

Topical calcineurin inhibitors are very effective in relieving the associated pruritus. Both tacrolimus and pimecrolimus significantly relieve pruritus even after the first few days of treatment in both children and adults (studies report relief after just 3 days).[10]

Clinical Controversy...

With topical calcineurin inhibitors, there is a potential for local skin carcinogenesis as seen in animal and in vitro studies. In addition, pigmented melanocytic lesions have been seen in treated areas, raising concern about melanoma.[43] The FDA has a black box warning for both tacrolimus ointment and pimecrolimus cream about their potential cancer risk, but no causal relationship has been proven between use of a topical calcineurin inhibitor and the development of lymphoma or nonmelanoma skin cancer.[43]

Phototherapy

11 Phototherapy is effective for AD and is recommended[10,11,37,38,39,40] as second-line treatment when the disease is not controlled by TCS and/or tacrolimus or pimecrolimus ointment.[46,47] Phototherapy may be steroid-sparing, allowing for the use of lower-potency TCS, or even eliminating the need for maintenance TCS in some cases. Phototherapy can be used for acute or maintenance therapy in children and adults with AD.[47] Phototherapy may also help prevent secondary bacterial skin infections, commonly seen in patients with AD. However, in a few patients, phototherapy may worsen the AD; it is not recommended in patients whose disease flares up when exposed to sunlight. Relapse following cessation of therapy frequently occurs.[10]

Phototherapy may consist of either ultraviolet light therapy alone, or ultraviolet light therapy alongside drug or topical ointment (commonly called photochemotherapy). Psoralens plus ultraviolet A light (PUVA) is one type of photochemotherapy. The photosensitizer (psoralens) is administered either orally or in a bath immediately prior to ultraviolet A (UVA) light therapy. Topical ointments (such as crude coal tar) may also be used concomitantly with ultraviolet light therapy (eg, crude coal tar + ultraviolet B [UVB] light).

Ultraviolet lamps include UVA (315-400 nm), UVA1 (340-400 nm), broadband UVB (BB-UVB) (280-315 nm), and narrowband UVB (NB-UVB) (311 nm). Phototherapies used for AD have included PUVA, high- or medium-dose UVA1, BB-UVB, and NB-UVB.[10,46] Currently, no definitive recommendation can be made to differentiate between the various phototherapies.[47] NB-UVB is more effective than BB-UVB therapy and is generally the most commonly recommended light treatment and it has a better side-effects profile than UVA or PUVA.[10,47] BB-UVB may not effectively treat the scalp and skinfold areas. Medium-dose UVA1 is very effective for patients with an acute exacerbation of severe

AD; however, the effect may be relatively short-lived and symptoms may recur within 3 months of stopping therapy.[46] Currently, medium-dose UVA1 is considered similar in efficacy as NB-UVB; and high-dose UVA1 is preferred in severe cases when available.[10] There is weaker evidence supporting the use of PUVA in AD[46] and it is not first choice.[10]

Patients need to wear eye protection during ultraviolet (UV) light therapy to prevent damage to the retina. Short-term adverse effects include erythema, skin pain, skin burning or sunburn, pruritus, and pigmentation.[47] Long-term adverse effects include premature aging of the skin (photoaging), lentigines, photosensitive eruptions, folliculitis, photo-onycholysis, herpes simplex virus (HSV) reactivation, facial hypertrichosis, and skin cancer.[46,47] For example, PUVA has been associated with squamous cell carcinoma and possibly melanoma, which may occur years after PUVA therapy has ceased.[46] UVA therapy may also cause cataract formation.[47]

Coal Tar

Although tar preparations had been widely used for AD and have been recommended as alternative topical therapy, few RCTs support their efficacy.[36] Their anti-inflammatory properties are not well characterized, and part of the improvement with the agent may be the result of a placebo effect, which can be significant in AD.

Coal tar products are also staining and malodorous, although newer products may be more cosmetically acceptable. They are not recommended on acutely inflamed skin, since this may result in additional skin irritation.

The use of coal tar in pregnancy has not been studied. Few data are available about tar excretion into breast milk; in addition, safety in children has not been established.[48] Adverse effects include tar folliculitis, acneiform eruptions, irritant dermatitis, burning, stinging, photosensitivity, and a risk of tar intoxication if used extensively in a young child.[48] Although animal studies showed that tar components can be converted to carcinogenic and mutagenic entities, there is inconclusive epidemiologic evidence supporting the claim that human use of topical tar preparations in dermatology leads to skin cancer.[48]

Clinical Controversy…

Animal studies showed that coal tar components can be converted to carcinogenic/mutagenic entities, and tar keratoses (small nodules that develop from cutaneous tar exposure) have the potential to regress, fall off, or develop into a squamous cell carcinoma. However, there is inconclusive epidemiologic evidence supporting the claim that human use of topical tar preparations in dermatology leads to skin or internal cancers such as bladder cancer or lymphoma.[48]

Other Topical Therapies

Patients with moderate to severe AD who have frequent bacterial infections may benefit from dilute bleach baths with intranasal mupirocin—one study showed enhanced clinical improvement.[36]

Systemic Therapies

Systemic therapies for the treatment of AD are generally not well-studied. Small case series or open studies are available for some agents, but few well-conducted RCTs exist. Agents described in published papers have included systemic corticosteroids, cyclosporine, interferon-γ, azathioprine, methotrexate, mycophenolate mofetil, intravenous immunoglobulin (IVIG), and biologic response modifiers.[10,47] Systemic therapies are indicated in AD care only for the subset of adult and pediatric patients in whom optimized topical regimens and/or phototherapy do not adequately control the disease, or where the quality of life is substantially affected.[47]

Systemic corticosteroids although often used for rapid disease suppression, are generally not recommended due to an unfavorable risk-benefit profile.[11,37,38,39,40,47] Short courses of oral corticosteroids may lead to atopic flares/rebound.[11,47] *Cyclosporine* is effective for severe, recalcitrant AD,[10,11,47] but its usefulness is limited by significant side effects, including hypertension and nephrotoxicity. There is also the potential for significant drug–drug and drug–food (eg, grapefruit juice) interactions. It should be reserved for short-term use in adults or children with severe refractory disease.[11,47] Maximal benefit is usually seen after 2 to 6 weeks of use and relapse may occur quickly after cessation of therapy.[10,11,46,47] Treatment durations currently recommended are 6 to 9 months[11] and up to 1 year—this is off label use.[47] In a meta-analysis of eight RCTs, cyclosporine was more efficacious than placebo, with reduced body surface area, erythema, sleep loss, and glucocorticoid use. However, all scores were back to pretreatment levels 8 weeks after ending cyclosporine therapy.[10]

Recombinant interferon-γ may be effective in a subset of patients with AD.[10] It may be an alternative for refractory AD (adults and children).[47] Two randomized placebo-controlled trials in patients with severe AD demonstrated significant improvement in symptoms.[49,50] Short-term adverse effects, such as headache, myalgias, and chills, occurred in substantial proportions of study patients. Transient liver transaminase elevations and granulocytopenia have also occurred.[51] There is no recommended optimal dose[47]; some recommend that a higher dose of this agent be used initially followed by a lower dosage during maintenance therapy.[46]

Azathioprine,[47,52] *methotrexate*,[47,53] *mycophenolate mofetil*,[47] and *IVIG* have shown efficacy in small case series or open-label studies primarily in adults with recalcitrant AD. There are two RCTs with azathioprine as monotherapy which showed efficacy, improving both quality of life and AD.[47,52] Additional RCTs are needed. Oral methotrexate, with a long history of pediatric use for various inflammatory conditions, appeared to be effective in a case series of children (aged 2-16 years) with severe AD[53] and has also shown efficacy in adults.[47]

Biologic response modifiers, unlike for psoriasis, are currently not approved for AD. The safety and efficacy of various biologic response modifiers in patients with AD have been studied,[51] mostly in case reports, small case series, or open-label studies with a limited number of patients. Theoretically, using protein-based therapies is inherently risky in a patient population more prone to developing IgE sensitization to protein antigens than the general population. Type 1 immediate hypersensitivity

reactions such as anaphylaxis could result, and patients with severe disease are potentially the patients at greatest risk of anaphylaxis. None has been reported in the published literature, which detail 261 patients with AD treated with various biologics,[51] but these numbers are too small to generalize their findings to larger numbers of people or specific populations.

More specifically, the tumor necrosis factor (TNF)-*α* inhibitors infliximab and etanercept appeared effective in a few patients but not others, and adverse events have included infusion reactions with flushing and dyspnea, urticaria, and recurrent skin infections of methicillin-resistant *S aureus*. Similarly, omalizumab, rituximab, and alefacept have been shown in a few case reports and small case series to be somewhat effective. A case report series of omalizumab plus IVIG showed significant clinical improvement.[54] However, an RCT with omalizumab showed no clinical improvement in AD despite reducing IgE levels.[47]

Additional research is needed to determine the therapeutic potential and safety of biologics in patients with AD.[47,51]

Oral antihistamines are used widely, however, there is mixed evidence of efficacy in AD control.[47] There is some evidence that oral sedating antihistamines used at night may benefit patients with poor sleep due to pruritus.[11,47]

Complementary and Alternative Therapies

Traditional Chinese herbal therapy has been studied in placebo-controlled trials and appeared to provide temporary benefit for patients with severe AD. However, the effectiveness may wear off despite continued treatment, and long-term toxicity is unknown.[10,55]

Probiotics of various types have been studied in several RCTs with mixed results. One study group reported that prenatal and postnatal exposure for 6 months to *Lactobacillus rhamnosus GG* halved the frequency of AD at 2, 4, and 7 years but had no effect on atopic sensitization. Other study groups also administered lactobacilli, including *L rhamnosus GG*, but with mixed results. A recent placebo-controlled study comparing *Bifidobacterium lactis* and *L rhamnosus HN001* found that *L rhamnosus HN001* may be effective in preventing the development of AD in high-risk infants, but not *Bifidobacterium*. However, one study showed that *Lactobacillus acidophilus* supplementation actually increased the sensitization rate (40% vs 24%) and led to more IgE-associated AD.[56] More research is needed about the role of probiotics in prevention and treatment of AD.[56] Because of inconsistent evidence probiotic use is not recommended at this time.[33]

Immunotherapy using allergen-specific desensitization techniques in controlled settings for patients with AD may also be beneficial, and much research is ongoing including RCTs. A recent review and meta-analysis of immunotherapy in AD patients showed significant efficacy.[11,57] More research is also needed to adequately assess the role of homeopathy, hypnotherapy, acupuncture, massage therapy, and biofeedback therapy in the treatment of AD.

PERSONALIZED PHARMACOTHERAPY

12 AD may have significant implications not only for the patients themselves, but also their families and caregivers.

In 2006, an international study of 2,002 patients and caregivers from eight countries addressed the effect of AD on the lives of patients and society.[58] This European study found that, on average, patients experienced nine flares per year, with those having severe disease experiencing more flares and taking significantly longer to clear. The flares were associated with disturbed sleep, and 86% of patients avoided at least one type of everyday activity. Schoolwork performance and productivity were negatively affected. Patients missed an average of 2.5 days of school or work per year, and an analysis of adult patient performance at work and occupational absence showed that the social cost of lost productivity could amount to more than 2 billion Euros per year across the European Union. There were also emotional consequences; half of the patients experienced depression or unhappiness about their condition, and one-third reported that AD had eroded their self-confidence. In addition, concern about adverse effects from topical corticosteroid treatments resulted in poor adherence to therapy. On average, patients endured the symptoms of AD without initiating specific treatment 47% of the time they had an exacerbation. Approximately one-half of the respondents were concerned about using TCS, and 58% restricted them to particular sites, 39% used them less frequently or for shorter time periods than prescribed, and 66% used them as a last resort. The study concluded that AD is "an undertreated disease that has a significant, yet mostly avoidable, negative effect on patients, their caregivers, and society."[58]

Thus, healthcare professionals play an integral role in providing patient and caregiver education about this disease and specific treatment plans. The importance of adequate and appropriate education for the patient, family, and caregivers about AD and its management cannot be overemphasized. Patients should be involved in their own care whenever possible.

CONCLUSION

AD is a chronic skin condition that generally presents at an early age. It affects the patient, family, and caregivers. Nonpharmacologic management strategies are important in treatment; these include appropriate skin care, hydration, avoidance of triggers, and psychosocial support. Pharmacologic treatment emphasizes topical corticosteroids as the standard of care. Patient and caregiver education about AD and treatment strategies is critical to minimize nonadherence. Successful outcomes result when patients and caregivers are partners with healthcare professionals in the management of this chronic disease.

Chapter e99: Dermatologic Drug Reactions and Common Skin Conditions

Rebecca M. Law; David T. S. Law

INTRODUCTION

KEY CONCEPTS

- 1 The skin is the largest organ of the human body. It performs many vital functions such as (a) protecting the body against injury, physical agents, and ultraviolet radiation; (b) regulating body temperature; (c) preventing dehydration, thus helping to maintain fluid balance; (d) acting as a sense organ; and (e) acting as an outpost for immune surveillance. Skin also has a role in vitamin D production and absorption.

- 2 Age-related factors affect the epidermis and dermis. Pediatric skin is thinner and better hydrated, which enhances topical drug absorption and potential drug toxicities. Elderly skin is drier, thinner, and more friable, which may predispose to external insults.

- 3 Patients presenting with a skin condition should be interviewed thoroughly regarding signs and symptoms, urgency, other subjective complaints, and medication history. The skin eruption should be carefully assessed to help distinguish between a disease condition and a drug-induced skin reaction.

- 4 Drug-induced skin reactions can be irritant or allergic in nature.

- 5 Allergic drug reactions can be classified into exanthematous, urticarial, blistering, and pustular eruptions. Exanthematous reactions include maculopapular rashes and drug hypersensitivity syndrome. Urticarial reactions include urticaria, angioedema, and serum sickness-like reactions. Blistering reactions include fixed drug eruptions, Stevens-Johnson's syndrome, and toxic epidermal necrolysis. Pustular eruptions include acneiform drug reactions and acute generalized exanthematous pustulosis. Other drug-induced skin reactions include hyperpigmentation and photosensitivity.

- 6 Not all skin reactions are drug induced.

- 7 Contact dermatitis is a common skin disorder caused either by an irritant or an allergic sensitizer.
- 8 The first goals of therapy in the management of contact dermatitis involve identification, withdrawal, and avoidance of the offending agent. A thorough history, including work history, must be carefully reviewed for potential contactants.
- 9 Other goals of therapy for contact dermatitis include providing symptomatic relief, implementing preventative measures, and providing coping strategies and other information for patients and caregivers.
- 10 Diaper dermatitis is most often seen in infants, although the condition may also be seen in older adults who wear diapers for incontinence. Management includes frequent diaper changes, air drying, gentle cleansing, and using barriers.
- 11 Skin cancers include squamous cell carcinoma, basal cell carcinoma, and malignant melanoma.

1 Skin is an essential part of the body. Although it is not commonly thought of as such, skin is an organ. In fact, it is the human body's largest organ, with an average surface area of about 1.8 m^2.[1] The organ system that includes the skin is known as *the integumentary system*.

The human skin consists of an outer epidermis and an inner dermis. The epidermis primarily provides protection from the environment and performs a critical barrier function—keeping in water and other vital substances and keeping out foreign elements. The dermis is a connective tissue layer that primarily provides resiliency and support for various skin structures and appendages such as sweat glands, sebaceous glands, hair, and nails.

Because the skin surface is such a visible part of the body, changes that are slow or subtle often go unnoticed. Slowly enlarging and evolving moles or dry skin conditions can go undetected even though such changes can be life threatening in some cases (eg, malignancy). Health professionals who have direct contact with patients should be able to distinguish between common self-treatable skin lesions and common skin lesions that must be seen and treated professionally, such as melanoma and squamous cell carcinoma.

Skin infections and infestations are not covered in this chapter but are discussed in Chapter 110. Acne, psoriasis, and atopic dermatitis are discussed in Chapters 96 to 98.

STRUCTURE AND FUNCTIONS OFTHE SKIN

The integumentary system comprises the epidermis and dermis. The epidermis, which is derived from ectoderm, is further divided into four layers: *stratum basale* (basal layer), *stratum spinosum* (prickle cell layer), *stratum granulosum* (granular layer), and *stratum corneum* (horny layer). The *stratum corneum* is the outermost layer of skin and is primarily responsible for the barrier function. The

epidermis is thick on the palms and soles and thin on other parts of the body, with some variations. For example, the palms and soles contain sweat glands but lack sebaceous glands, which are found almost everywhere else in the skin, with the highest concentration on the face and trunk areas. Sebaceous glands and small hair follicles together form pilosebaceous units, which originate in the dermis and have follicular ducts extending through the epidermis to the skin surface. Sebaceous glands produce sebum, a lipid-like substance.[1] (Increased production by sebaceous glands is partially responsible for acne.[2])

Skin cells are called keratinocytes. They produce keratin, a protein network that gives epithelial cells resilience to mechanical stress. Keratinocytes begin at the *stratum basale* as box-shaped basal cells. As the cells mature, they migrate toward the skin surface, elongating and flattening as they divide and differentiate, ending as corneocytes in the *stratum corneum*. Corneocytes are flattened keratinocytes containing keratin tonofibrils (filaments composed of keratin and keratohyalin granules). They are often termed *dead* because they do not contain nuclei and are not capable of mitosis. Each cell covers a much larger surface area as a corneocyte compared with its basal origin. Overlapping corneocytes provide for the skin barrier.[1] (Note that abnormal keratinocyte activity accounts for some skin diseases. For example, psoriasis is associated with increased keratinocyte cell turnover, and acne is partially caused by increased keratin production.[2])

Melanocytes are pigment-producing cells in the *stratum basale*. They produce melanin, a yellow–brown/black pigment. Melanin granules are spread out into a protective layer in the *stratum corneum*, reducing ultraviolet (UV) penetration into the skin. UV radiation causes human skin to increase both melanin production and keratinocyte proliferation as a protective effort.[1]

The skin surface is normally covered with a hydrolipid film composed of sweat, oils (sebaceous lipids and free fatty acids), corneocytes, protein decomposition products, and transepidermal water. Some of these are natural moisturizing factors that help the skin retain water. Thus, the hydrolipid film is a permeability barrier that keeps the skin supple.[1]

Because of the presence of lactic acid and various amino acids from sweat, free fatty acids from sebum, and amino acids from shedding corneocytes, human skin is normally acidic, generally with a pH of 5.5 to 6. Bacteria thrive in an alkaline environment. As a result, the skin also functions as a protective acid mantle against invasion by pathogenic bacteria and fungi.[1]

The dermis, which is derived from mesoderm, is a much thicker layer that contains nerve endings and blood vessels. It is made up of collagen and elastin, which provide support for various skin structures and appendages. Eccrine (sweat) glands, hair follicles, sebaceous glands, and arrector pili muscles originate in the dermis. Subcutaneous tissue (adipose tissue with nerves and blood vessels) lies beneath the dermis.[1]

Skin is also involved in regulating body temperature, preventing dehydration, acting as a sense organ, and playing a role in vitamin D production and absorption.

Age-Related Changes and Other Skin-Related Considerations

2 Age-related changes in the structure and functions of the epidermis and dermis are important.

In general, pediatric skin contains more water and is thinner, allowing for enhanced topical drug absorption in both the rate and amount of drug absorbed. This increases the potential for drug toxicities. Increased topical absorption and toxicity have been reported with the use of rubbing alcohol, boric acid powders, and hexachlorophene emulsions and soaps in infants and young children. Even drugs that are not normally used topically may be systemically absorbed. For example, a theophylline gel (17 mg spread over an area of 2 cm in diameter) applied to the abdomens of premature infants produced therapeutic serum theophylline concentrations.[3]

Well-hydrated, unbroken skin provides maximal protection against microbial invaders. Aged skin tends to be drier, thinner, and more friable, which increases susceptibility to external insults. In addition, the healing time after skin injury may be prolonged in aged skin. UV radiation is associated with accelerated skin aging and skin cancers (eg, malignant melanoma and basal cell carcinoma). Skin should be constantly protected from UV damage by the use of sunscreens that block both UVA and UVB, with a sun protection factor (SPF) of at least 15, preferably 30 or higher. Sunscreens should be applied 20 min before sun exposure and reapplied after sweating or swimming.

It should not be surprising that skin health is related to overall health. Exercise and adequate sleep along with maintaining a healthy, well-balanced diet are key factors. Ample daily fluid intake and regular use of moisturizers are important for skin hydration. Malnourishment can cause a patient to become immunocompromised, which may adversely affect the ability of the skin to act as a barrier. Nutritional deficiencies can cause skin problems, including dry skin. Specific food allergies can cause skin reactions (eg, rashes and hives). Patients with atopic dermatitis often have multiple food sensitivities and allergies, resulting in hives and skin rashes and/or systemic manifestations. For skin cleansing, soapless cleansers may be preferable to soap because they may cause less skin irritation. Repeated and frequent exposure to soap or other cleansers that cause cumulative irritation (eg, with surfactants and emulsifiers) can result in irritant contact dermatitis.

PATIENT ASSESSMENT

When patients present with dermatologic disorders, including a suspected cutaneous adverse drug reaction (ADR), a standard approach to assessment should be used.[4,5] Skin disorders range from the inconsequential to life-threatening; it is essential that the clinician be able to distinguish between them. A standard approach to assess the patient is especially important for nonprescribing pharmacists who must decide whether to recommend nonprescription therapies or refer patients to physicians, nurse practitioners, or physician assistants, to further evaluate symptoms and decide whether a supervising physician or dermatologist should be involved.

Patient History: Questions to Ask

3 With all skin conditions, including possible ADRs, a comprehensive patient history is important. Activities include questioning and physically assessing the patient to obtain the following information:

1. Signs and Symptoms

    a. *Onset*. When did the lesions first appear? It is important to distinguish between an acute and a chronic condition.

    b. *Progression*. Are the lesions improving or worsening or spreading? If lesions are worsening, how quickly are the lesions becoming more severe or widespread? Are the lesions changing and if so, how? Enlargement or increasing density of lesions (often to the point where multiple lesions coalesce) would be indications of worsening. Also, in most cases the more quickly the evolution, the more urgent the situation.

    c. *Timeframe*. Did the occurrence of skin lesions correlate temporally with the use of any medications? This may help to distinguish between a drug-induced condition and a disease-related condition.

    d. *Location(s) and description of the lesions*. Specific details about where the lesions occur and what they look like will help to identify the type of skin condition. For example, plaque psoriasis is usually diagnosed in this manner and not through laboratory means. However, for conditions such as skin cancers,[6] a skin biopsy may be needed to establish a definitive histopathologic diagnosis.

    e. *Presenting symptoms*. Is there pruritus? Are the lesions painful? Is there a fever? Pruritus is a common symptom for various skin conditions (eg, atopic dermatitis, allergic and irritant contact dermatitis, psoriasis, bullous pemphigoid, lichen planus, and pityriasis rosea) as well as systemic conditions (eg, chronic renal failure, hepatobiliary diseases, malignancy, and parasitosis) and drug reactions[7] (ie, it is a nonspecific symptom). However, keep in mind that a sudden onset of pruritus, (particularly in the paraoral region, palms, or plantae, or on the scalp), is one of the most important prodromal symptoms in anaphylaxis.[8] Fever is another nonspecific symptom that is of great importance in assessing skin conditions and reactions, as its presence heralds systemic involvement (ie, not just confined to the skin). Most severe cutaneous drug-induced reactions are preceded or accompanied by fever[9]; thus, fever should be regarded as a warning sign of a potentially serious condition. In fact, fever and neutrophilia are the diagnostic criteria for acute generalized exanthematous pustulosis (AGEP).[9] On the other hand, drug fever may be the only manifestation of a drug hypersensitivity reaction.

    f. *Previous occurrence*. Has the patient presented with similar lesions before? If so, that may be extremely helpful in establishing a diagnosis and deciding on a course of treatment.

2. Urgency

    a. *Severity, area, and extent of skin involvement*. If a large area of the body is involved or if signs of severe disease such as skin sloughing or hives (and in some cases, if the face is involved) are present, more urgent treatment may be required, and an immediate referral to a physician would be appropriate if the patient was first seen by another health

professional such as a pharmacist. In some cases, a dermatology consult or an emergency hospital admission would be needed.

b. *Signs of a systemic or generalized reaction or disease condition*. If there is any indication that the patient has a systemic disease condition, whether drug induced or disease related, and particularly if the patient is febrile (as discussed above), this generally indicates a more urgent situation requiring immediate medical attention. For example, erythrodermic psoriasis is distinguishable from plaque psoriasis and would require immediate medical care. (See Chapter 97 for details about psoriasis.)

3. Medication History

a. *Temporal correlation*. Is the patient using any medication that could potentially cause the observed skin condition? Temporal correlation with medication use is important in evaluating for a potential drug-induced skin reaction. Although possible, drug-induced skin reactions do not generally begin after the offending agent has already been discontinued. However, for some medications it is possible for the patient to have used the offending drug for months to years before a skin reaction occurs.

b. *Previous exposure*. If the patient had presented with similar skin lesions previously, was the patient taking the same or similar medication(s) at that time? If so, did the skin lesions improve after drug discontinuation?

c. *Nonprescribed drugs and other products*. Ensure that the medication history is complete and comprehensive. In particular, use of any over-the-counter (OTC) medications or natural health products (NHP) or supplements should be specifically asked about, as they may be the culprit in a cutaneous ADR. For example, OTCs such as nonsteroidal anti-inflammatory drugs (NSAIDs) are common offenders.[4]

4. Differential Diagnosis

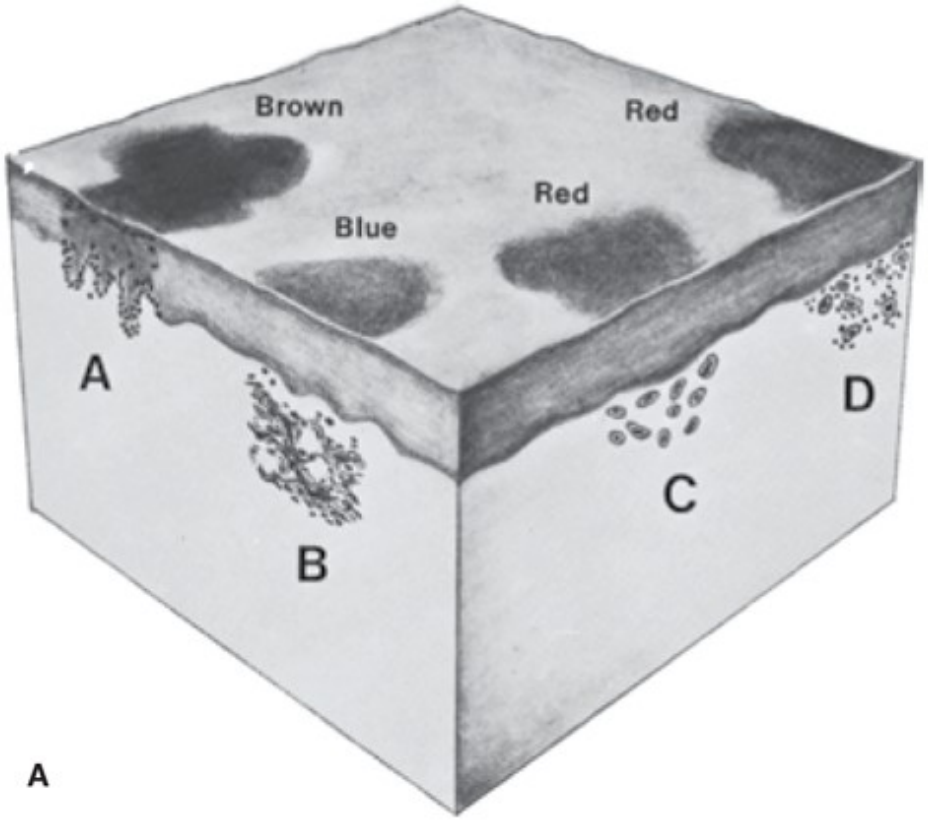
a. Is this a disease-related problem, a drug-induced problem, or a food allergy? What other possible diseases or conditions might present in this manner? It is not possible to provide a thorough discussion about differential diagnoses of skin lesions in this chapter. The reader should be aware that there are differential diagnoses for each type of skin lesion. For example, besides drugs (eg, antimalarials, cyclophosphamide, clofazimine, busulfan, and 5-fluorouracil), other causes of hyperpigmentation include Wilson's disease, malabsorption syndromes, lymphomas, porphyria cutanea tarda, neurofibromatosis, Albright's syndrome, physical trauma, and others.[10] Besides drugs (eg, aspirin, NSAIDs, penicillins, sulfonamides, and opiates), other causes of urticaria include infection (viral, bacterial, fungal, and parasitic), insect stings, foods and food additives, cold, pressure, dermatographism, and cholinergic stimulation (exercise, hot shower, and emotional stress), hereditary C1 inhibitor deficiency, and others.[11]

Lesion Assessment

As discussed briefly in the following section, the appearance of skin lesions can give some clues as to their causes. Lesions may be categorized as macules (**Fig. e99-1**), papules (**Fig. e99-2**), nodules (**Fig. e99-3**), blisters (**Fig. e99-4**), or plaque and lichenification (**Fig. e99-5**).

FIGURE e99-1

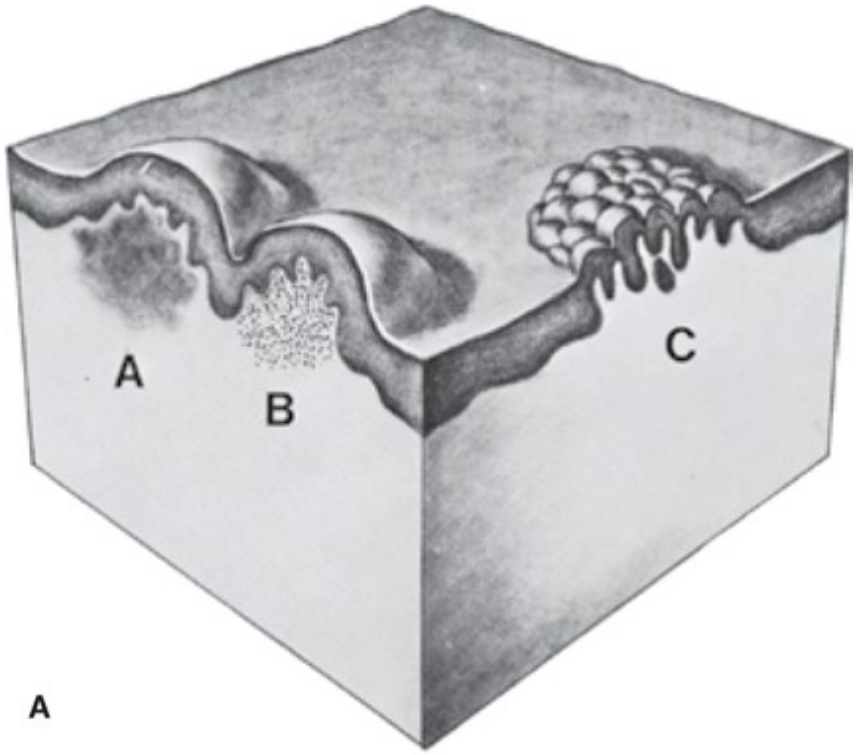
Macules are circumscribed, flat lesions of any shape or size that differ from surrounding skin because of their color. *A*. Macules may be the result of hyperpigmentation (*a*), hypopigmentation, dermal pigmentation (*b*), vascular abnormalities, capillary dilation (erythema) (*c*), or purpura (*d*). *B*. The clinical appearance of a drug reaction that has produced an eruption consisting of multiple, well-defined red macules of varying size that blanch upon pressure (diascopy) and are thus a result of inflammatory vasodilation. *(Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18.)*



A

FIGURE e99-2

Papules are small, solid, elevated lesions that are usually < 1 cm in diameter. The major portion of a papule projects above the plane of the surrounding skin. *A*. Papules may result, for example, from metabolic deposits in the dermis (*a*), from localized dermal cellular infiltrates (*b*), and from localized hyperplasia of cellular elements in the dermis and epidermis (*c*). Papules with scaling are referred to as papulosquamous lesions, as in psoriasis (see Chapter 78). *B*. Clinical examples of papules. The examples are two well-defined and dome-shaped papules of firm consistency and brownish color, which are dermal melanocytic nevi. *C*. Multiple, well-defined and coalescing papules of varying size are seen. Their violaceous color, glistening surface, and flat tops are characteristic of lichen planus. *(Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18.)*



A

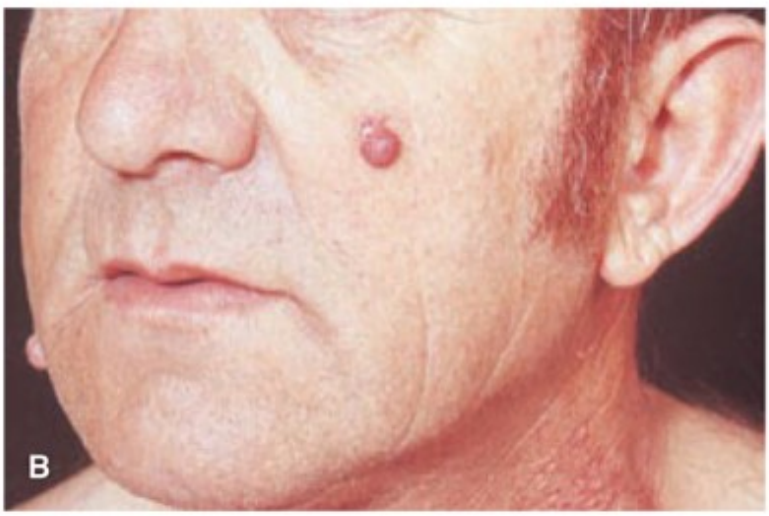


FIGURE e99-3

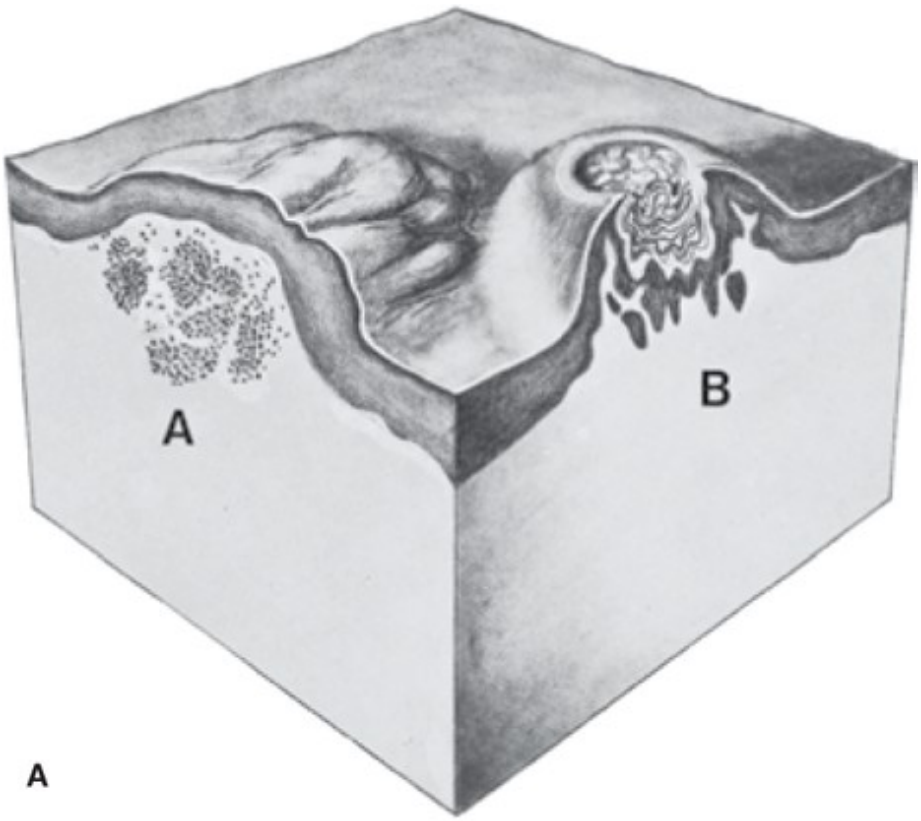
Nodules are palpable, solid, round, or ellipsoidal lesions. Depth of involvement or substantive palpability, rather than diameter, differentiates a nodule from a papule. *A*. Nodules may extend into the dermis or subcutaneous tissue (*a*) or be located in the epidermis (*b*). *B*. A well-defined, firm nodule with a smooth and glistening surface through which telangiectasia (dilated capillaries) can be seen; there is central crusting indicating tissue breakdown and thus incipient ulceration (nodular basal cell carcinoma). *C*. Multiple nodules of varying size can be seen (melanoma metastases). *(Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18.)*



A

FIGURE e99-4

Vesicles and bullae are the technical terms for blisters. Whereas vesicles are circumscribed lesions that contain fluids, bullae are vesicles that are larger than 0.5 cm in diameter. *A.* Whereas subcorneal vesicles (*a*) result from fluid accumulation just below the stratum corneum, spongiotic vesicles (*b*) result from intercellular edema. *B.* Multiple translucent subcorneal vesicles are extremely fragile, collapse easily, and thus lead to crusting (arrows). These lesions are staphylococcal impetigo. *(Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18.)*

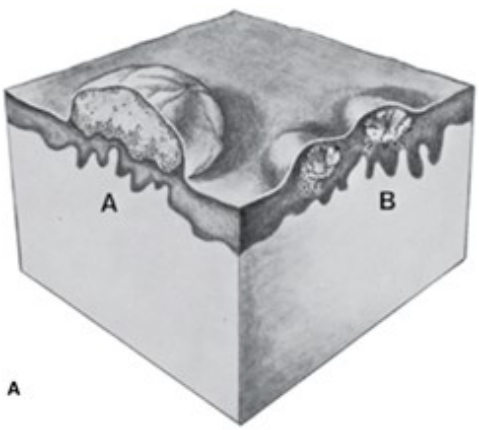


FIGURE e99-5

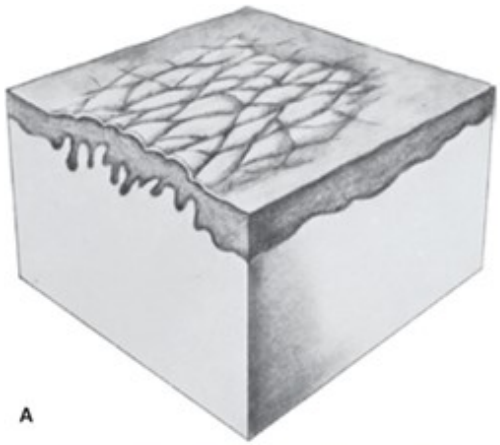
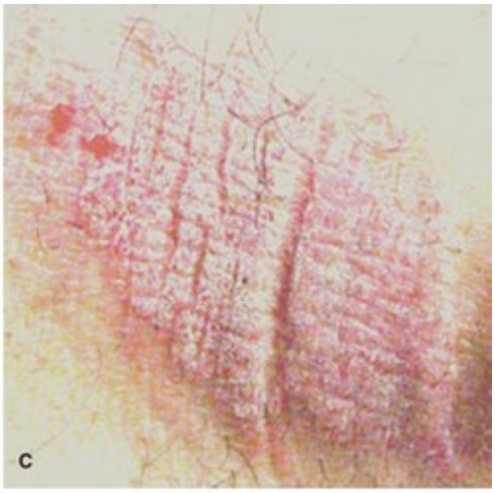
A. Plaque is a mesa-like elevation that occupies a relatively large surface area relative to its height above the skin surface. *B*. Well-defined, reddish, scaling plaques can coalesce to cover large areas of the back and buttocks, with some regression in the center as is common in psoriasis (see Chapter 78). *C*. Lichenification, a thickening of the skin and accentuation of skin, can result from repeated rubbing. It develops frequently in patients with atopy and occurs in eczematous dermatitis and other conditions associated with pruritus. Lesions of lichenification are not as well defined as most plaques and often show signs of scratching, such as excoriations and crusts. *(Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18, and Garg Amit, Levin Nikki A, Bernhard Jeffrey D. Structure of Skin Lesions and Fundamentals of Clinical Diagnosis. In: Wolff K, Goldsmith LA, Katz SI, Gilchrest B, Paller AS, Leffell DJ, eds. Fitzpatrick's Dermatology in General Medicine, 7th ed. http://www.accessmedicine.com/content.aspx?aID=2965385.)*





Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

However, some skin conditions may cause more than one type of lesion. For example, patients with acne vulgaris may present with macules, papules, nodules, or a combination of these. Another example is psoriasis—the most common type is plaque psoriasis noted by discrete, well-defined plaques; however, there are other types of psoriasis such as guttate or erythrodermic with varying lesions. Wheals developing as a result of a drug reaction may present as papules or plaques. In contrast, some skin conditions present with a characteristic lesion. For example, lichenification is a thickening of the skin usually caused by chronic rubbing or scratching and can be seen in patients with chronic pruritus or atopic dermatitis.

DRUG-INDUCED CUTANEOUS REACTIONS

The skin is among the most common organs of manifestation for adverse reactions (ADR) and accounts for at least 15% to 20% of all ADRs.[4,8] An estimated 636,000 cutaneous ADR-related health care visits occur in the US annually.[12] Some patients may be more prone to developing hypersensitivity ADRs and risk factors include the following[8]: prior drug reaction (inducing

drug-specific antibodies), multiple drug therapy or intermittent/repeated use of the same drug (vs continuous therapy), some concurrent illnesses (eg, HIV, Epstein-Barr virus, and CMV), dosage/serum drug level increases (eg, IV vancomycin administration rate), topical route of administration (more immunogenic than subcutaneous > intramuscular > oral > IV), certain genetic factors (eg, certain HLA-B alleles predispose for drug allergies), and certain comorbidities (eg, asthma).

Types of Drug-Induced Skin Reactions

4 Drug-induced skin reactions can be irritant or allergic in origin.

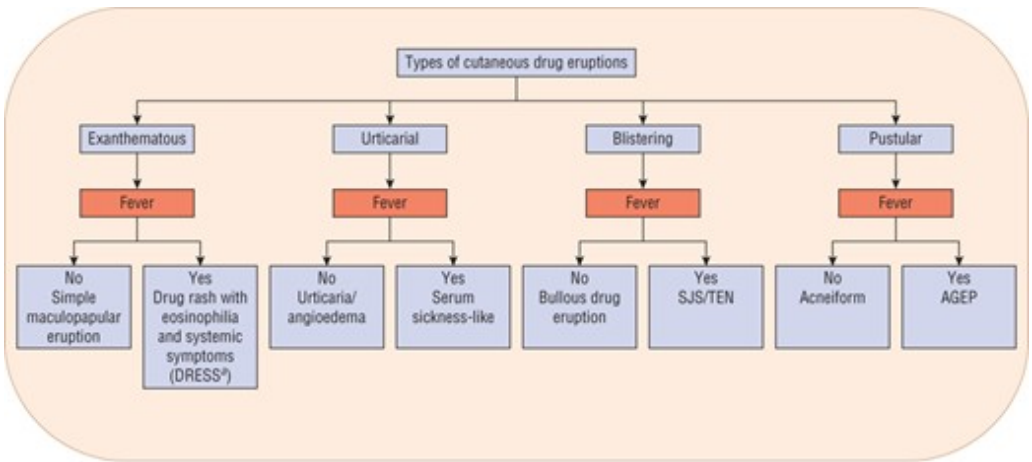
Irritant reactions are localized. Examples include chemical vaginitis, such as those resulting from vaginal douches, spermicides, and imidazoles; and vesication, produced by drug extravasation, as with agents such as anthracyclines.

Allergic reactions depend on inducing an immune response from the host; thus, the reaction may be systemic rather than limited to skin manifestations.

5 Allergic drug reactions can be classified as exanthematous, urticarial, blistering, or pustular eruptions (**Fig. e99-6**).[13] Skin reactions accompanied by fever are generally more serious systemic disorders. These may be life threatening in some cases, although afebrile skin reactions are not always minor (eg, urticaria and angioedema). Severe cutaneous adverse reactions to drugs (SCARs) include Stevens-Johnson syndrome/toxic epidermal necrolysis (SJS/TEN) and drug reaction with eosinophilia and systemic symptoms (DRESS), which are further discussed below. Recently, genetic associations between specific HLA alleles and SCARs have been discovered; this is an area of ongoing research.[14]

FIGURE e99-6

Types of cutaneous drug eruptions. (AGEP, acute generalized exanthematous pustulosis; SJS, Stevens-Johnson's syndrome; TEN, toxic epidermal necrolysis.) *(Adapted from Knowles, S. Drug-Induced Skin Reactions, Table 3, Description of Drug Eruptions. In: Compendium of Therapeutic Choices for Minor Ailments, 2nd ed. Ottawa (ON): Canadian Pharmacists Association; © 2016.)*



Maculopapular skin reaction is an afebrile exanthematous eruption that is considered the most commonly encountered allergic skin reaction. Signs and symptoms of a maculopapular skin rash include erythematous macules and papules that may be pruritic. No fever, blisters, or pustules are present. The lesions usually begin within 7 to 10 days after starting the offending medication and generally resolve within 7 to 14 days after drug discontinuation. Because this is a delayed hypersensitivity reaction, it is possible that the offending agent is already discontinued (eg, a 10-day antibiotic treatment course) before skin manifestation (eg, on day 12).[9] However, in a previously sensitized patient, the onset may be earlier (within 2-3 days). The lesions may spread and become confluent. Usual drug culprits include penicillins, cephalosporins, sulfonamides, and some anticonvulsant medications.

Drug hypersensitivity syndrome (DHS) is an exanthematous eruption accompanied by fever, lymphadenopathy, and multiorgan involvement (including the kidneys, liver, lung, bone marrow, heart, and brain). Signs and symptoms usually begin 1 to 4 weeks after starting the offending drug, and the reaction may be fatal if not promptly treated.

This condition is also known as drug reaction with eosinophilia and systemic symptoms (DRESS). It is more commonly referred to by the acronym DRESS, although DHS is also used.[9]

Usual drug culprits include allopurinol, sulfonamides, some anticonvulsants (barbiturates, phenytoin, carbamazepine, and lamotrigine), and dapsone. For patients taking allopurinol, several factors increase the risk of serious skin reactions: renal impairment, hypertension, and use of thiazide diuretics or excessive allopurinol doses (ie, not dose adjusted for renal impairment).[15,16]

Urticaria and angioedema are simple eruptions that are caused by drugs in about 5% to 10% of cases. Other causes include foods (likely the most significant offenders) and physical factors such as cold or pressure, infections, and exposure to latex. The condition may also be idiopathic.

Urticaria has been called the cutaneous manifestation of anaphylaxis. It is an IgE-related (type 1) allergic reaction that may be the first symptom of an emerging anaphylactic reaction. A prodrome of pruritus that suddenly occurs (especially on the scalp, around the mouth, and on palms and soles) may precede the appearance of visible lesions; this is a sign of imminent anaphylaxis.[8] Urticaria is characterized by hives, extremely pruritic red raised wheals; angioedema; and mucous membrane swelling. Early symptoms of angioedema of the tongue and larynx include the urge to clear the throat, hoarseness, and throat "tightness." Urticarial symptoms typically occur within minutes (anaphylactic) to hours (anaphylactoid) (**Fig. e99-7**). Individual lesions typically last less than 24 h, but new lesions may continually develop.

FIGURE e99-7

A. Wheals are rounded or flat-topped papules or plaques that are characteristically evanescent, disappearing within hours. An eruption consisting of wheals is termed *urticaria* and usually itches. *B*. Wheals may be tiny papules 3 to 4 mm in diameter, as in cholinergic urticaria. *C*. Alternatively, wheals may present as large, coalescing plaques, as in allergic reactions to penicillin or other drugs or alimentary allergens. *(Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick*

TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18.)

Offending drugs include penicillins and related antibiotics, aspirin, sulfonamides, x-ray contrast media, opiates, and others. Latex allergy is linked to the natural rubber latex (NRL) proteins, which bind with human IgE and result in contact urticaria, asthma, and anaphylaxis.[17] Latex allergy is common in health care workers.[18] Aside from latex gloves and medical products, other sources of NRL proteins include rubber insoles of shoes, balloons, inflatable mattresses, and poinsettia plants.

Serum sickness-like reactions are complex urticarial eruptions presenting with fever, rash (usually urticarial), and arthralgias, usually within 1 to 3 weeks after starting the offending drug. This is not a true serum sickness, and the patient does not have immune complex formation, vasculitis, or renal lesions.[12]

Fixed drug eruptions are simple eruptions presenting as pruritic, red, raised lesions that may blister. Symptoms can include burning or stinging. Lesions may evolve into plaques.[12] These so-called "fixed" drug eruptions recur in the same area each time the offending drug is given. Lesions appear within minutes to days and disappear within days, leaving hyperpigmented skin for months (**Fig. e99-8**). Usual drug culprits include tetracyclines, barbiturates, sulfonamides, codeine, phenolphthalein, acetaminophen, and NSAIDs.[9]

FIGURE e99-8

Hyperpigmentation. This patient exhibits a striking amiodarone-induced, slate-gray pigmentation of the face. The blue color (ceruloderma) is caused by deposition of a brown pigment in the dermis contained in macrophages and endothelial cells. *(Reproduced with permission from Lapeere H, et al. Chapter 75. Hypomelanoses and Hypermelanoses. In: Goldsmith LA, et al., eds. Fitzpatrick's Dermatology in General Medicine, 8e. New York, NY: McGraw-Hill; 2012.)*

Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Stevens-Johnson's syndrome (SJS) and *toxic epidermal necrolysis* (TEN) are complex blistering eruptions that, together with erythema multiforme (EM), are known as acute bullous disorders. They are histologically similar and have been considered part of an "EM spectrum of diseases."[19] EM may be considered a dermatologic disorder not associated with a drug reaction, whereas SJS and TEN are immune complex or cell-mediated allergic responses to offending agents, including drugs.[19,20] Because of their histologic similarity, in the past SJS and TEN have been considered either distinct disorders or progressions of the same disorder based on the percentage of skin area involved. They are now considered variants of the same disorder but distinct from EM, and these two entities are often discussed together as SJS/TEN.[19] Genetic associations between some drug causes of SJS/TEN and HLA alleles have been identified. For example, carbamazepine-induced SJS/TEN is associated

with HLA-B*15:02, with this allele being specific for the carbamazepine-induced activation of cytotoxic T cells that release granulysin, a mediator responsible for the epidermal sloughing in SJS/TEN.[14]

SJS/TEN: are rare, severe, and life-threatening conditions with an acute onset (within 7-14 days of drug exposure). Patients present with generalized tender or painful bullous formation with accompanying systemic signs and symptoms, including fever, headache, and respiratory symptoms, that rapidly deteriorate. Lesions show rapid confluence and spread, resulting in extensive epidermal detachment and sloughing.[19] This may result in marked loss of fluids; drop in blood pressure; electrolyte imbalances; and secondary infections, including *Staphylococcus epidermidis* and methicillin-resistant *Staphylococcus aureus (MRSA)*. Usual drug culprits include sulfonamides, penicillins, some anticonvulsants (hydantoins, carbamazepine, barbiturates, and lamotrigine), NSAIDs, and allopurinol. In children, a pooled analysis using data from two multicenter international case–control studies confirmed the following drug risk factors for SJS/TEN anti-infective sulfonamides, phenobarbital, carbamazepine, and lamotrigine. In addition, acetaminophen use is suspected to increase the risk.[20] However, cases in children only represented 10% of the population in both studies because the incidence of SJS/TEN increases with age.[20]

Acneiform drug reactions are simple pustular eruptions caused by medications that induce acne (whiteheads or blackheads). The onset is usually about 1 to 3 weeks. Common drug culprits include corticosteroids, androgenic hormones, some anticonvulsants, isoniazid, and lithium. Topical acne treatments can be used to manage symptoms if the offending drug cannot be discontinued or replaced.

Acute generalized exanthematous pustulosis (AGEP) is a complex pustular eruption characterized by acute onset (within days after starting the offending drug), fever, diffuse erythema, and many pustules. About 50% of patients have other cutaneous lesions, and 25% may have mucosal erosions. Generalized desquamation occurs 2 weeks later.[12] Usual drug culprits include β-lactam antibiotics, macrolides, and calcium channel blockers.

Other Drug-Induced Skin Reactions

Hyperpigmentation of the skin (**Fig. e99-8**) may be related to increased melanin (eg, hydantoins), direct deposition (eg, silver, mercury, tetracyclines, and antimalarials), or other mechanisms (some cytotoxic drugs, such as 5-fluorouracil, may cause banding on nails or tracking along veins).

Photosensitivity reactions (**Fig. e99-9**) may be phototoxic or photoallergic. Drugs that induce phototoxic reactions absorb UVA light, resulting in skin damage. Severity tends to be proportional to the drug dose. Usual drug culprits include amiodarone, tetracyclines, sulfonamides, psoralens, and coal tar.

FIGURE e99-9

Photosensitivity. Severe solar damage of the face revealing both telangiectasias and actinic keratoses

at different stages in development, including flat, pink macules and hyperkeratotic papules. *(Reproduced with permission from Duncan KO, et al. Chapter 113. Epithelial Precancerous Lesions. In: Goldsmith LA, et al., eds. Fitzpatrick's Dermatology in General Medicine, 8e. New York, NY: McGraw-Hill; 2012.)*

Drug-induced photoallergic reactions result from UVA transformation of medications into allergens. In this syndrome, skin damage may occasionally spread beyond sun-exposed skin. These reactions require sensitization to the offending drug and are not dose related. Usual drug culprits include sulfonamides, sulfonylureas, thiazides, NSAIDs, chloroquine, and carbamazepine.

Management and Prevention of a Drug-Induced Skin Reaction

6 The first rule of thumb in managing skin reactions is to remember that not all are drug induced. In clinical practice, a diagnosis of drug-induced skin reaction is often a diagnosis of exclusion (ie, the diagnosis is reached after other possible diagnoses have been ruled out). Potential foods and other causes have to be thoroughly investigated, and a detailed patient interview is important, as discussed earlier. Consistent with the assessment for any ADR, the likelihood of a drug-induced skin reaction should be categorized as probable, possible, or not probable (unlikely). It may not be possible to categorize a drug-induced skin reaction as definite because this requires rechallenge with the potentially offending agent, and this should not be done with most reactions. Reactions are often unpredictable ADRs unrelated to the normal pharmacologic effects of the drug. Fortunately, unpredictable ADRs (eg, allergic, idiosyncratic, and carcinogenic) usually affect only a small percentage of patients.

If a drug-induced skin reaction is suspected, the most important treatment in nearly all cases is discontinuing the suspected drug as quickly as possible and avoiding the use of potential cross-sensitizers. In most instances, that is the only specific treatment required. In severe cases, a short course of systemic corticosteroids may be needed. In a few instances, it may be possible to continue the offending drug and "treat through" the reaction[12] (eg, ampicillin-associated maculopapular skin rash).

The next step is to control symptoms associated with the drug reaction (eg, pruritus). Furthermore, any signs or symptoms of a systemic or generalized reaction may require additional supportive therapies specific to the severity and type of signs and symptoms seen. For high fevers, an antipyretic such as acetaminophen is more appropriate than aspirin or an NSAID because these may exacerbate skin lesions for some reactions. Depending on the type of skin reaction, the affected skin condition may take days to weeks or months to resolve.

For patients with life-threatening SJS/TEN, supportive measures such as maintenance of adequate blood pressure and fluid and electrolyte balance, use of broad-spectrum antibiotics and vancomycin for secondary infections, and IV immunoglobulin (IVIG) may all be appropriate. IVIG has been shown to halt disease progression, decrease mortality and enhance recovery in patients with SJS or TEN.[19,20,21] The use of corticosteroids for SJS/TEN is somewhat controversial; although they may curb disease progression, they may also increase the risk of infection and thus contribute to increased mortality.[19] If used, relatively high initial doses followed by rapid tapering as soon as disease progression halts is indicated.[19] Refer to the Drug-Induced Skin Reactions case in the *Pharmacotherapy Casebook* to further explore management.

Patient education should be provided. Advice to the patient should include information about the suspected drug and potential drugs to avoid in the future and which drugs may be used. Potential cross-sensitizers should be identified. For patients with photosensitivity reactions, information should be provided about preventive measures such as the use of sunscreens and sun avoidance (see Fig. e99-9). For patients with severe reactions (eg, anaphylaxis), information about MedicAlert programs may be appropriate. Genetic predisposition has not been established for most drug-induced reactions, but for SCARs such as SJS/TEN or DRESS, the risk may be higher in first-degree relatives of affected patients.

COMMON SKIN DISORDERS

Contact Dermatitis

7 Contact dermatitis is defined as an inflammation of the skin caused by irritants or allergic sensitizers.[22] It describes and includes all skin reactions resulting from direct contact of the skin or mucous membranes with an exogenous agent, which may be a "foreign" molecule such as a drug or chemical, UV light, or temperature.[22]

The skin or mucous membranes may react nonimmunologically or immunologically to an exogenous agent, resulting in either an irritant or allergic skin reaction as described earlier. However, the

distinction between an allergic contact dermatitis (ACD) and irritant contact dermatitis (ICD) has become increasingly blurred; the two types may and often do coexist.[22,23] The most reliable method for diagnosing ACD is the patch test (discussed below).[22,23] ICD is often a diagnosis of exclusion, as in cases when patch test results for ACD are negative.[22]

Furthermore, an exogenous dermatitis can be superimposed on an endogenous skin eruption such as acne.[22] Irritant effects may be considerably enhanced by occlusion. Contact dermatitis must also be distinguished from atopic dermatitis and other dermatologic conditions such as dyshidrotic dermatitis, lichen simplex dermatitis, acne rosacea, and other conditions. (See Chapter 98 for a discussion on atopic dermatitis.)

Contact dermatitis is a common skin problem for which 5.7 million physician visits are made per year.[22] Almost any of the more than 85,000 chemicals in the world environment may be a skin irritant, and more than 3,700 substances have been identified as contact allergens.[22] Although all age groups may be affected, ACD is rare in the first years of life (<10 years), but the rate of occurrence in older children may exceed that in adults.[22]

The prevalences of ACD to individual allergens is similar in children and adults; allergens include nickel, fragrances, *Toxicodendron* (formerly known as *Rhus*), and rubber chemicals.[22] There may be a slight female preponderance, presumably caused by exposure to specific contactants in jewelry and cosmetics.[22]

The clinical presentation of contact dermatitis is that of an eczematous inflammation with erythema, vesicles, papules, crusting, fissuring, or scaling (**Figs. e99-10** and **e99-11**). The area may itch, burn, or sting and may be extremely pruritic. The severity may range from a mild, short-lived condition to a severe and persistent condition but is rarely life threatening.[22] The gross and histologic appearances of ICD and ACD are often similar and may be difficult to distinguish.[22] However, the rash or lesion for ICD is frequently localized, but for ACD, it may extend beyond the borders of the exposed area of contact, and the reaction may rarely become systemic (eg, latex allergy).

FIGURE e99-10

Acute dermatitis caused by poison ivy. Note the linear arrangement of lesions typical of phytodermatitis acquired by inadvertent contact with the plant. The severe vesiculobullous reaction is typical for urushiol, an oily poisonous irritant found in *Toxicodendron* spp. *(Reprinted with permission from Belsito DV. Allergic contact dermatitis. In: Freedberg IM, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:1167.)*

FIGURE e99-11

A. This patient has allergic chronic dermatitis involving the dorsal aspects of the hands and the distal forearms but with minimal involvement of the palms. In this case, contact dermatitis is secondary to use of thiuram present in rubber gloves prescribed for treatment of a irritant hand dermatitis. *B*. This patient, a florist, has allergic contact dermatitis as a consequence of exposure to tuliposide A, the allergen in Peruvian lilies (*Alstroemeria* spp.). Note the more prominent involvement of the palms of the dominant hand. *(Reprinted with permission from Belsito DV. Allergic contact dermatitis. In: Freedberg IM, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:1167.)*

Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

ICD is generally a multifactorial response involving contact with a substance that chemically abrades, irritates, or otherwise damages the skin; cellular damage in ICD occurs via T cells (activated by irritant or innate mechanisms) releasing proinflammatory cytokines.[22] ACD is the clinical manifestation of contact hypersensitivity;[24] skin allergens tend to be low-molecular-weight molecules (haptens) that become immunogenic after conjugation with skin proteins, resulting in a complex series of interactions that involve antigen-presenting Langerhans or other dendritic cells or $CD4^+$ and $CD8^+$ T cells,[22] including interleukin-17-producing T_H17 cells.[24]

Because ACD is immunologically mediated, the patient may have tolerated exposure to the offending agent for some time, making it more difficult to pinpoint the culprit. Furthermore, the reaction may continue to develop for some time after the offending agent is removed.

8 The first goal of therapy in the management of contact dermatitis involves identifying, withdrawal, and avoidance of the offending agent. An algorithmic diagnostic and management approach has been developed.[23] A thorough history, including work history, must be carefully reviewed for potential contactants. Nonwork activities such as hobbies (eg, painting, gardening, camping, and fishing) may be additional potential sources of exposure. Patch testing is the gold standard for identifying a contact allergen,[22,23] but it is impractical to test an unlimited number of allergens.

Standard panels of allergens have been designed and validated by collaborative research dermatologic societies; however, these may account for only 25% to 30% of the most relevant contact allergens.[22] Many patients need additional testing, customized patch tests may be needed, depending on the patient's exposure history.[22] Additional tests (eg, repeated open application test and provocative use test) may sometimes be needed to confirm a causal relationship.[23]

The most common causes of occupational contact dermatitis are chromium (leather exposure); rubber and rubber additives (gloves); nickel (work tools and metal working); food ingredients, including intact proteins (for food processing workers); fertilizers and pesticides (for farmers); and handwashing (disinfectants, irritants in soaps).[22]

The most common cause of plant dermatitis is *Toxicodendron (Rhus)* dermatitis. This genus includes poison ivy, poison oak, and poison sumac. These plants contain the offender urushiol oil, one of several oleoresins that are sensitizers and irritants. Urushiol oil is also found in mango skin, cashew nut oil, ginkgo (female) leaves, Japanese lacquer, and Indian marking ink.[22]

Cosmetics and personal hygiene products, such as hair conditioners and shampoos, nail polishes and hardeners, mascara, foundations, antiperspirants and deodorants, and toothpastes, may all contain potential causes of contact dermatitis. The most important classes are fragrances, preservatives, formulation excipients, glues, and sunblocks[22]; fragrances are among the most common causes of contact dermatitis in the United States.[22]

9 The second goal of therapy in contact dermatitis is to provide symptomatic relief while decreasing skin lesions. The affected skin may require supportive treatment such as the use of cold

compresses to sooth and cleanse the skin or topical corticosteroids to help resolve the inflammatory process. Compresses are applied to wet or oozing lesions, removed, remoistened, and reapplied every few minutes for a 20- to 30-min period. Calamine lotion or Burow solution (aluminum acetate) may be soothing.

Topical corticosteroids are considered the mainstay of treatment, and patients with ACD respond better than those with ICD. Generally, higher potency corticosteroids are used initially, switching to medium- or lower-potency corticosteroids as the condition improves.[22] Refer to the Topical Corticosteroid Potency Chart in Chapter 97 Psoriasis (Table 97-3) for specific examples.

Other treatments may be effective. Tacrolimus ointment has been shown to be effective for nickel-induced ACD in a small randomized placebo-controlled clinical trial.[25] Oatmeal baths and oral first-generation antihistamines may provide relief for excessive itching. If the affected areas are already dry or hardened (eg, lichenification), wet dressings applied as soaks (without removal for up to 20-30 min) will soften and hydrate the skin (these should not be used for acute exudating lesions because the skin area may become macerated, further damaging its barrier function).

The third goal of contact dermatitis therapy is to implement preventive measures. Prevention involves both primary and secondary measures.

Primary prevention may be done in the workplace by initiating surveillance programs and educating workers about proper skin care and chemical exposure.

Secondary prevention involves the use of moisturizers to prevent dryness and fissuring of the skin. The efficacy of barrier creams is controversial.[22] The damaged skin may need to be protected against secondary infections, at least until the acute stage subsides. Debris, produced by oozing, scaling, or crusting, should not be allowed to accumulate. Rarely, some workers may have persistent dermatitis despite removal of offenders, and a small number of workers change jobs because of severe recalcitrant occupational contact dermatitis.[22]

A final goal of therapy is to provide patient and caregiver information and support, helping them to develop coping strategies for contact dermatitis, as required.

Diaper Dermatitis

10 Diaper dermatitis, more commonly known as diaper rash, is most often seen in infants, although the condition may also be seen in older adults who wear diapers for incontinence. It is an acute inflammatory dermatitis affecting the buttocks, genital, and perineum regions that are covered by a diaper. The rash is erythematous, and severe rashes may have vesicles or oozing erosions. The rash may be infected by *Candida* species and present with confluent red plaques, papules, and pustules.

Management of diaper dermatitis includes frequent diaper changes, air drying (removing the diaper for as long as practical), gentle cleansing (preferably with nonsoap cleansers and lukewarm water), and the use of barriers. Commercial diaper wipes containing fragrance or alcohol should be avoided. Zinc oxide has astringent and absorbent properties and provides an effective barrier. Petrolatum also

provides a water-impermeable barrier but has no absorbent ability and may trap moisture.

Patients with candidal (yeast) diaper rash should be treated with a topical antifungal agent which is then covered by a barrier product. Imidazoles are the treatment of choice for this type of diaper rash. After the rash subsides, the antifungal agent should be stopped and the barrier product continued to prevent recurrence.

In severe inflammatory diaper rashes, a very low-potency topical corticosteroid (hydrocortisone 0.5%-1%) may be used for short periods of 1 to 2 weeks.

Skin Cancers

Actinic keratoses are precursors to the development of skin cancers. UV radiation (with UVA a greater risk than UVB) may induce abnormal keratinocyte changes. These present as actinic keratoses. These lesions can develop into squamous cell or basal cell carcinomas.

Actinic keratoses are most often found in elderly fair-skinned patients and on chronically sun-exposed areas, such as hands, forearms, head, and neck.

11 Skin cancers include squamous cell carcinoma, basal cell carcinoma, and malignant melanoma.

Squamous cell carcinoma (SCC) is a skin cancer most commonly seen in older patients (**Fig. e99-12**). Risk factors include fair complexion, prolonged sun exposure, UV radiation (including PUVA [psoralens plus UVA] used for treatment of psoriasis), and long-term immunosuppression (including the use of biologic response modifiers for treatment of conditions such as psoriasis). Most SCCs present as firm, flesh-colored, or erythematous papules or plaques. Treatment is primarily via surgical excision.

FIGURE e99-12

Squamous cell carcinoma. This case of squamous cell carcinoma must be differentiated in diagnosis from chondrodermatitis nodularis helicis, which, unlike carcinoma, is painful. *(Reproduced with permission from Grossman D, David J. L. Chapter 114. Squamous Cell Carcinoma. In: Goldsmith LA, et al., eds. Fitzpatrick's Dermatology in General Medicine, 8e. New York, NY: McGraw-Hill; 2012.)*

Basal cell carcinoma (BCC) is a very common skin disorder (**Fig. e99-13**). BCC most commonly presents as a pigmented nodule on the head and neck. Treatment may vary based on histology and may involve surgical excision as well as the use of topical agents such as imiquimod, or antineoplastic agents such as 5-fluorouracil.

FIGURE e99-13

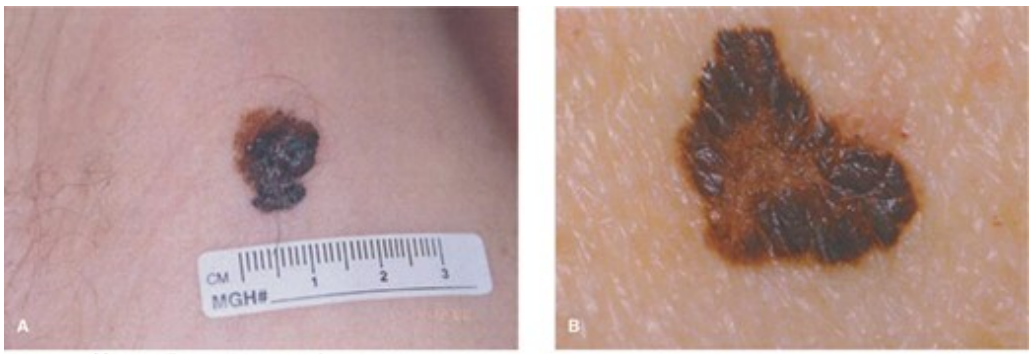
Basal cell carcinoma. *A*. Basal cell carcinoma, nodular type. *B*. An ulcerated nodular basal cell carcinoma. *(Reprinted with permission from Carucci JA, Leffell DJ. Basal cell carcinoma. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:749.)*

Malignant melanoma, unless detected early and excised, often produces systemic metastases. Its incidence has increased over the past few decades, with an estimated one in 65 Americans developing melanoma during their lifetimes.[26]

A changing mole is often a harbinger of melanoma. These are detected by skin examination; dermatologists often have melanoma clinics for this purpose. Moles are examined for asymmetry, irregular borders, variegated colors, and size (**Fig. e99-14**). Full-body skin examinations are important in screening for melanoma because it can occur anywhere on the skin.[26]

FIGURE e99-14

Melanomas. These two superficial spreading melanomas illustrate the ABCDs of melanoma. *A*, Asymmetry. The lesions are not symmetrical and often have irregular borders. *B*, Border. Note the highly irregular, uneven, and notched border. *C*, Color. The color is variegated with different shades of brown, black, and tan. *D*, Diameter. The diameter is usually (but not always) more than 6 mm in melanomas. *(Reprinted with permission from Langley RGB, Barnhill RL, Mihm MC Jr, et al. Neoplasms: Cutaneous melanoma. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:925.)*



Other risk factors include prolonged sun exposure and the ability to tan, family history, and drug treatments such as PUVA or biologic response modifiers used for psoriasis.

Suspicious pigmented lesions should be fully excised as soon as possible rather than biopsied; malignant melanomas are best diagnosed and microstaged with an excisional biopsy of the entire lesion.[27] Delayed diagnosis of malignant melanoma directly affects patient survival adversely.[26] Treatment may also include systemic antineoplastic therapy, such as temozolomide or dacarbazine for metastatic melanoma.

SPECIAL PATIENT POPULATIONS

Certain signs or symptoms relating to skin disorders may need to be assessed and/or managed differently in specific patient populations such as the pregnant woman. Pharmacists and primary care providers should be aware of these situations before deciding to recommend OTC products—in some cases, a referral to a medical practitioner or specialist is needed. If in doubt, a referral is prudent.

Pregnancy

Pruritus affects up to 20% of pregnant women and may affect sleep and quality of life.[28] Pruritic skin disorders unique to pregnancy include intrahepatic cholestasis of pregnancy (ICP), pruritic urticarial papules and plaques of pregnancy (PUPPP), pemphigoid gestationis (PG), and atopic eruption of pregnancy.[28,29]

ICP presents as a sudden onset of severe pruritus that begins on palms and soles then quickly

becomes more generalized, with *no rash*; the pruritus may worsen at night.[28] This *should not* be managed with dry skin care, and the patient should be immediately referred to her physician. ICP is caused by elevated serum bile acids; the treatment is ursodeoxycholic acid. ICP has been associated with adverse fetal outcomes including preterm labor and fetal death.[28]

PUPPP are pruritic, erythematous, urticarial papules and plaques that often begin in abdominal stretch marks then spread to buttocks and thighs, sparing the umbilicus.[28] This is a self-limiting condition that resolves spontaneously after delivery; low-potency topical corticosteroids can be recommended to provide relief.[28]

PG is a bullous disorder that presents with intense pruritus followed by pruritic, erythematous, urticarial papules, and plaques that subsequently blister. Lesions are clustered around the umbilicus and may spread to the extremities but sparing the face, palms, and soles.[28] This is a self-limiting condition that presents after the 20th week of gestation but may appear postpartum.[28] Treatment is usually with systemic corticosteroids to control the blisters; thus, a referral is appropriate.[28]

Atopic eruption of pregnancy describes many benign pruritic conditions of pregnancy that occur in patients with a history of atopy. These can usually be managed with short courses of topical corticosteroids.[28]

Children

Chronic pruritus is associated with many skin disorders in children including chronic spontaneous urticaria (CSU), psoriasis (Chapter 97), and atopic dermatitis (AD; Chapter 98), in which pruritus is a hallmark symptom. Although the differential diagnoses and specific discussions are beyond the scope of this chapter, it must be emphasized that adequate control of the pruritus is important in each condition. For example, children with AD and chronic pruritus may be at increased risk for anxiety, depression, and attention deficit hyperactivity disorder.[30]

The quality of life of the children and their caregivers are affected by these conditions. Management strategies include identifying and minimizing causative factors in addition to dry skin care and pharmacotherapy with topical corticosteroids and/or other agents. Oral antihistamines have limited efficacy in AD but may be useful in some children with histaminergic pruritus associated with CSU.[30]

CONCLUSION

This chapter provided coverage about the skin and associated age-related changes, lesion assessment and recognition, drug-induced skin reactions, contact dermatitis, diaper dermatitis, and briefly discussed common skin cancers and special populations. Other common skin disorders are covered in the chapters on acne (see Chapter 96), psoriasis (see Chapter 97), and atopic dermatitis (see Chapter 98). Skin and soft tissue infections (see Chapter 110) and parasitic diseases (see Chapter e115) are detailed in other chapters of this text.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACD	allergic contact dermatitis
AD	atopic dermatitis
ADR	adverse drug reaction
AGEP	acute generalized exanthematous pustulosis
BCC	basal cell carcinoma
CSU	chronic spontaneous urticaria
DHS	drug hypersensitivity syndrome
EM	erythema multiforme
DRESS	drug reaction with eosinophilia and systemic symptoms
HLA	human leukocyte antigen
ICD	irritant contact dermatitis
ICP	intrahepatic cholestasis of pregnancy
IVIG	IV immunoglobulin
MRSA	methicillin-resistant *Staphylococcus aureus*
NRL	natural rubber latex
NSAID	nonsteroidal anti-inflammatory agent
OTC	over-the-counter medication
PG	pemphigoid gestationis
PUPPP	pruritic, urticarial papules and plaques of pregnancy
PUVA	psoralens + ultraviolet A light
SCARs	severe cutaneous adverse reactions to drugs
SCC	squamous cell carcinoma
SJS	Stevens-Johnson syndrome
SPF	a sun protection factor
TEN	toxic epidermal necrolysis
UV	ultraviolet
UVA	ultraviolet A

Chapter 100: Anemias

Kristen Cook

INTRODUCTION

KEY CONCEPTS

- 1 Anemia is a group of diseases characterized by a decrease in either hemoglobin (Hb) or the volume of red blood cells (RBCs), which results in decreased oxygen-carrying capacity of the blood. Anemia is defined by the World Health Organization (WHO) as Hb less than 13 g/dL (less than 130 g/L; less than 8.07 mmol/L) in men and less than 12 g/dL (less than 120 g/L; less than 7.45 mmol/L) in women.

- 2 Acute-onset anemias are most likely to present with tachycardia, lightheadedness, and dyspnea. Chronic anemia often presents with weakness, fatigue, headache, vertigo, and pallor.

- 3 Iron-deficiency anemia (IDA) is characterized by decreased levels of ferritin (most sensitive marker) and serum iron, as well as decreased transferrin saturation. Hb and hematocrit decrease later. RBC morphology includes hypochromia and microcytosis. Most patients are adequately treated with oral iron therapy, although parenteral iron therapy is necessary in selected patient populations.

- 4 Vitamin B_{12} deficiency, a macrocytic anemia, can be due to inadequate intake, malabsorption syndromes, and inadequate utilization. Anemia caused by lack of intrinsic factor, resulting in decreased vitamin B_{12} absorption, is called *pernicious anemia*. Neurologic symptoms can be present and can become irreversible if the vitamin B_{12} deficiency is not treated promptly. Oral or parenteral therapy can be used for replacement.

- 5 Folic acid deficiency, a macrocytic anemia, results from inadequate intake, decreased absorption, and increased folate requirements. Treatment consists of oral administration of folic acid, even for patients with absorption problems. Adequate folic acid intake is essential in women of childbearing age to decrease the risk of neural tube defects in their children.

- 6 Anemia of inflammation (AI) is a newer term used to describe both anemia of chronic disease and anemia of critical illness. AI is a diagnosis of exclusion. It results from chronic

inflammation, infection, or malignancy and can occur as early as 1 to 2 months after the onset of the disease. The serum iron level usually is decreased, but in contrast to IDA, the serum ferritin concentration is normal or increased. Treatment is aimed at correcting the underlying pathology. Anemia of critical illness occurs within days of acute illness.

- 7 Anemia is one of the most prevalent clinical problems in the elderly, although not an inevitable complication of aging. Low Hb concentrations are not "normal" in the elderly. Anemia is associated with an increased risk of hospitalization and mortality, reduced quality of life, and decreased physical functioning in the elderly.

- 8 IDA is a leading cause of infant morbidity and mortality. Age- and sex-adjusted norms must be used in the interpretation of laboratory results for pediatric patients. Primary prevention of IDA is the goal. A therapeutic trial of oral iron is the standard of care.

Anemia affects a large part of the world's population. According to the World Health Organization (WHO), almost 1.6 billion people (25% of the world's population) are anemic. Anemia is defined by the WHO as hemoglobin (Hb) less than 13 g/dL (less than 130 g/L; less than 8.07 mmol/L) in men or less than 12 g/dL (less than 120 g/L; less than 7.45 mmol/L) in women. In the United States, about 3.5 million Americans have anemia based on self-reported data from the National Center for Health Statistics. It is estimated that millions of people are unaware they have anemia, making it one of the most underdiagnosed conditions in the United States. Iron deficiency is the leading cause of anemia worldwide, accounting for as many as 50% of cases.[1] Recent data show that the overall prevalence of anemia has declined in the United States in preschool-aged children and women of childbearing age over the past 20 years, but the prevalence of iron deficiency anemia (IDA) did not change significantly in these same groups. The reasons for these changes remain unclear.[2] Although nutritional deficiencies occur less often in the United States, obesity surgery, which can cause deficiencies, is becoming increasingly common. Gastric bypass may result in folate, vitamin B_{12}, and iron deficiencies. Prevalence data are confounded by the lack of a standardized definition of anemia and lack of screening guidelines for most populations. The United States Preventive Services Task Force (USPSTF) guidelines for pregnant women recommend routine screening for IDA.

Anemia is not an innocent bystander because it can affect both length and quality of life. Retrospective observational studies of hemodialysis patients and heart failure patients suggest that anemia is an independent risk factor for mortality.[3] In addition, anemia significantly influences morbidity in patients with end-stage renal disease, chronic kidney disease, and heart failure.[4] Anemia is associated with psychomotor and cognitive abnormalities in children. Similarly, anemia is associated with cognitive dysfunction in patients with renal failure or cancer, and among community-dwelling elders.[5] Anemia during pregnancy is associated with increased risk for low birth weights, preterm delivery, and perinatal mortality.[6] Maternal IDA may be associated with postpartum depression in mothers and poor performance by offspring on mental and psychomotor tests. Global goals of treatment in anemic patients are to alleviate signs and symptoms, correct the underlying etiology, and prevent recurrence of anemia.

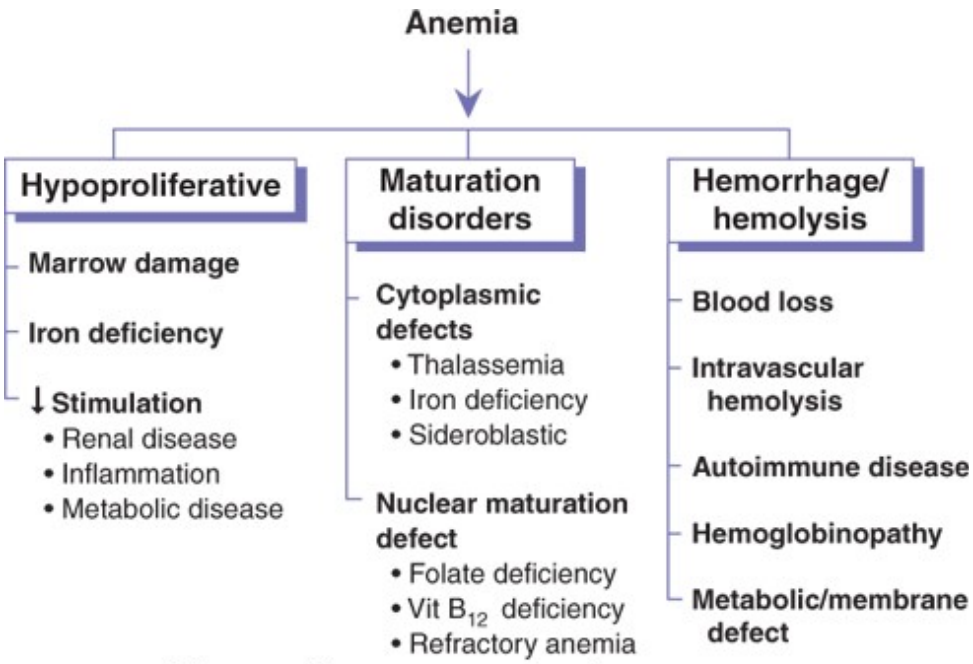
1 Anemia is a group of diseases characterized by a decrease in either Hb or circulating red blood

cells (RBCs), resulting in reduced oxygen-carrying capacity of the blood. Anemia can result from inadequate RBC production, increased RBC destruction, or blood loss. It can be a manifestation of a host of systemic disorders, such as infection, chronic renal disease, or malignancy. Because anemia is a sign of underlying pathology, rapid diagnosis of the cause may be essential.

The functional classification of anemia is shown in **Fig. 100-1**. This chapter focuses on the most common causes of anemia—IDA, anemia associated with vitamin B_{12} or folic acid deficiency, and anemia of inflammation (AI) (eg, anemia of chronic disease [ACD]). Some of the other causes of anemia are addressed in other chapters.

FIGURE 100-1

Functional classification of anemia. Each of the major categories of anemia (hypoproliferative, maturation disorders, and hemorrhage/hemolysis) can be further subclassified according to the functional defect in the several components of normal erythropoiesis.



Characteristic changes in the size of RBCs seen in erythrocyte indices can be the first step in the morphologic classification and understanding of the anemia. Anemia can be classified by RBC size as macrocytic, normocytic, or microcytic. Vitamin B_{12} deficiency and folic acid deficiency both are macrocytic anemias. An example of a microcytic anemia is iron deficiency, whereas a normocytic anemia may be associated with recent blood loss or chronic disease. More than one etiology of anemia can occur concurrently. Inclusion of the underlying cause of the anemia makes diagnostic terminology easier to understand (eg, microcytic anemia secondary to iron deficiency).

Microcytic anemias are a result of a quantitative deficiency in Hb synthesis, usually due to iron deficiency or impaired iron utilization. As a result, erythrocytes containing insufficient Hb are formed.

Microcytosis and hypochromia are the morphologic abnormalities that provide evidence of impaired Hb synthesis.

Macrocytic anemias can be divided into megaloblastic and nonmegaloblastic anemias. The type of macrocytic anemia can be distinguished microscopically by peripheral blood smear examination. Megaloblasts are distinctive cells that express a biochemical abnormality of retarded DNA synthesis, resulting in unbalanced cell growth. Megaloblastic anemias may affect all hematopoietic cell lines. The most common causes of megaloblastic anemia are vitamin B_{12} and folate deficiency. Nonmegaloblastic macrocytic anemias may arise from liver disease, hypothyroidism, hemolytic processes, and alcoholism. Hemolytic anemias often are macrocytic, reflecting the increased numbers of circulating reticulocytes, which are larger on average than mature red cells.

MATURATION AND DEVELOPMENT OF RED BLOOD CELLS

In adults, RBCs are formed in the marrow of the vertebrae, ribs, sternum, clavicle, pelvic (iliac) crest, and proximal epiphyses of the long bones. In children, most bone marrow space is hematopoietically active to meet increased RBC requirements.

In normal RBC formation, a pluripotent stem cell yields an erythroid burst-forming unit. Erythropoietin (EPO) and cytokines such as interleukin-3 and granulocyte–macrophage colony-stimulating factor stimulate this cell to form an erythroid colony-forming unit in the marrow (**Fig. 100-2**). During this process, the nucleus becomes smaller with each division, finally disappearing in the normal erythrocyte. Hb and iron are incorporated into the gradually maturing RBC, which eventually is released from the marrow into the circulating blood as a reticulocyte. The maturation process usually takes about 1 week. The reticulocyte loses its nucleus and becomes an erythrocyte within several days. The circulating erythrocyte is a nonnucleated, nondividing cell. More than 90% of the protein content of the erythrocyte consists of the oxygen-carrying molecule Hb. Erythrocytes have a normal survival time of 120 days.[7]

Stimulation of Erythropoiesis

The hormone EPO, 90% of which is produced by the kidneys, initiates and stimulates the production of RBCs. Erythropoiesis is regulated by a feedback loop. The main mechanism of action of EPO is to prevent apoptosis, or programmed cell death, of erythroid precursor cells and allow their proliferation and subsequent maturation. A decrease in tissue oxygen concentration signals the kidneys to increase the production and release of EPO into the plasma, which increases production and maturation of RBCs. Under normal circumstances, the RBC mass is kept at an almost constant level by EPO matching new erythrocyte production to the natural rate of loss of RBCs. A summary of erythropoiesis is shown in **Fig. 100-3**. Early appearance of large quantities of reticulocytes in the peripheral circulation (reticulocytosis) is an indication of increased RBC production.[7]

Synthesis of Hemoglobin

Hb contains a protein component with two α-chains and two β-chains. Each chain is linked to a heme group consisting of a porphyrin ring structure with an iron atom chelated at its center, which is capable of binding oxygen. The initial step in the synthesis of heme from the substrate succinyl CoA and glycine requires the presence of pyridoxine phosphate (vitamin B_6) as a catalyst. Following its synthesis in the cytoplasmic mitochondria of the RBC, heme diffuses into the extramitochondrial space, where it combines with the completed α- and β-chains and forms Hb. When hemolytic destruction of RBCs exceeds marrow production capacity and anemia develops, the Hb value decreases to a steady-state level at which production is equal to destruction.

Incorporation of Iron into Heme

Iron is an essential part of Hb. The specific plasma transport protein transferrin delivers iron to the bone marrow for incorporation into the Hb molecule. Transferrin enters cells by binding to transferrin receptors, which circulate and then attach to cells needing iron. Fewer transferrin receptors are present on the surface of cells that do not need iron, thus preventing iron-replete cells from receiving excess iron.[8]

Circulating transferrin normally is about 30% saturated with iron. Transferrin delivers extra iron to other body storage sites, such as the liver, marrow, and spleen, for later use. This iron is stored within

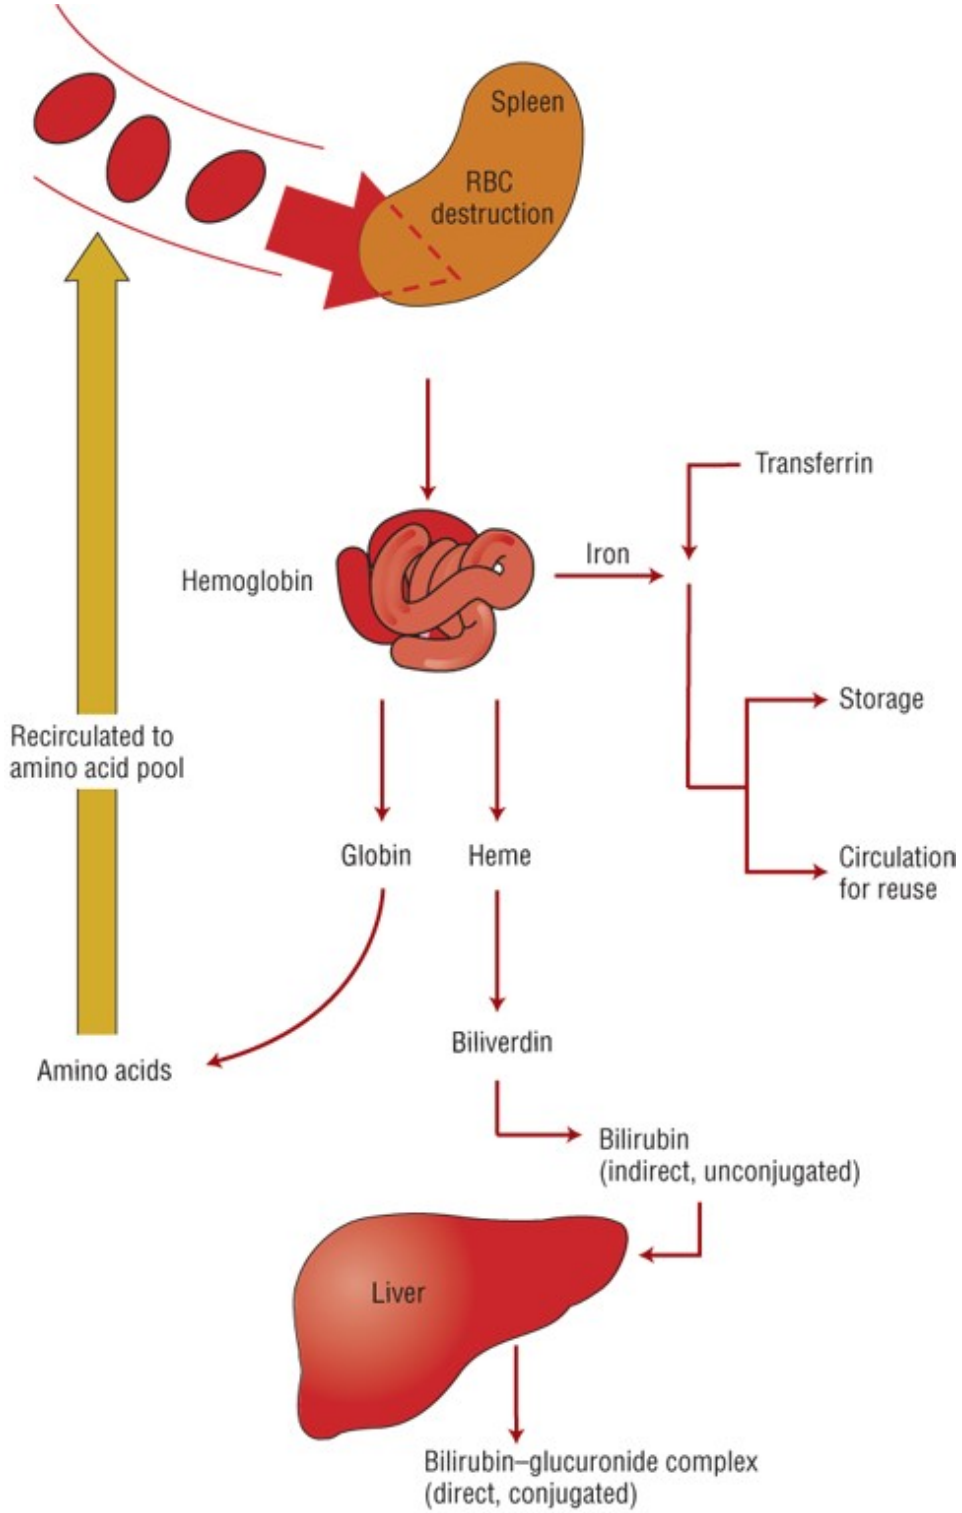
macrophages as ferritin or hemosiderin. Ferritin consists of a Fe^{3+} hydroxyphosphate core surrounded by a protein shell called *apoferritin*. Hemosiderin can be described as compacted ferritin molecules with an even greater iron-to-protein shell ratio. Physiologically it is a more stable, but less available, form of storage iron. Since total body iron storage is generally reflected by ferritin levels, low serum levels of ferritin provide strong evidence of IDA.[9]

Normal Destruction of Red Blood Cells

Phagocytic breakdown destroys older blood cells, primarily in the spleen but also in the marrow (**Fig. 100-4**). Amino acids from the globin chains return to an amino acid pool; heme oxygenase acts on the porphyrin heme structure to form biliverdin and to release its iron. Iron returns to the iron pool to be reused, although biliverdin is further catabolized to bilirubin. The bilirubin is released into the plasma, where it binds to albumin and is transported to the liver for glucuronide conjugation and excretion via bile. If the liver is unable to perform the conjugation, as occurs with intrinsic liver disease or oversaturation of conjugation enzymes by excessive cell hemolysis, the result is an elevated *indirect* (unconjugated) bilirubin. If the biliary excretion pathway for conjugated bilirubin is obstructed, an elevated *direct* bilirubin results. Comparison of direct and indirect bilirubin values helps to determine if the defect in bilirubin clearance occurs before or after bilirubin enters the liver. The Hb in RBCs destroyed by intravascular hemolysis becomes attached to haptoglobin and is carried back to the marrow for processing in the normal manner.[10]

FIGURE 100-4

Destruction of red blood cells (RBCs).



DIAGNOSIS OF ANEMIA

General Presentation

History, physical examination, and laboratory testing are used in the evaluation of the patient with

anemia. The workup determines if the patient is bleeding and investigates potential causes of the anemia, such as increased RBC destruction, bone marrow suppression, or iron deficiency. Diet can also be important in identifying causes of anemia. Additionally, information about concurrent nonhematologic disease states and a drug history are essential when evaluating the cause of the anemia (Chapter e103). History of blood transfusions and exposure to toxic chemicals also should be obtained.

Presenting signs and symptoms of anemia depend on its rate of development and the age and cardiovascular status of the patient. Severity of symptoms does not always correlate with the degree of anemia. Healthy patients may acclimate to very low Hb concentrations if the anemia develops slowly. Mild anemia often is associated with no clinical symptoms and may be found incidentally upon obtaining a complete blood count (CBC) for other reasons. The signs and symptoms in elderly patients with anemia may be attributed to their age or concomitant disease states. The elderly may not tolerate levels of Hb in the same way that younger persons do. Similarly, patients with cardiac or pulmonary disease may be less tolerant of mild anemia. Premature infants with anemia may be asymptomatic or have tachycardia, poor weight gain, increased supplemental oxygen needs, or episodes of apnea or bradycardia.

2 Anemia of rapid onset is most likely to present with cardiorespiratory symptoms such as palpitations, angina, orthostatic lightheadedness, and breathlessness due to decreased oxygen delivery to tissues or hypovolemia in those with acute bleeding. The patient also may have tachycardia and hypotension.

If onset is more chronic, presenting symptoms may include fatigue, weakness, headache, orthopnea, dyspnea on exertion, vertigo, faintness, sensitivity to cold, pallor, and loss of skin tone. Traditional signs of anemia, such as pallor, have limited sensitivity and specificity and may be misinterpreted. With chronic bleeding, there is time for equilibration within the extravascular space, so faintness and lightheadedness are less common.

Possible manifestations of IDA include glossal pain, smooth tongue, reduced salivary flow, pica (compulsive eating of nonfood items), and pagophagia (compulsive eating of ice). These symptoms are not likely to appear unless the anemia is severe.

Neurologic findings in vitamin B_{12} deficiency may precede hematologic changes. Early neurologic findings may include numbness and paraesthesias. Ataxia, spasticity, diminished vibratory sense, decreased proprioception, and imbalance may occur later as demyelination of the dorsal columns and corticospinal tract develop. Vision changes may result from optic nerve involvement. Psychiatric findings include irritability, personality changes, memory impairment, depression, and infrequently, psychosis.

Anemia associated with folate deficiency is typically macrocytic but, unlike B_{12} deficiency, occurs without neurological symptoms. Although the symptoms of anemia will improve with folate replacement and a partial hematologic response will occur, the neurologic manifestations of vitamin B_{12} deficiency will not be reversed with folic acid replacement therapy and consequently may progress or become irreversible if not treated appropriately.

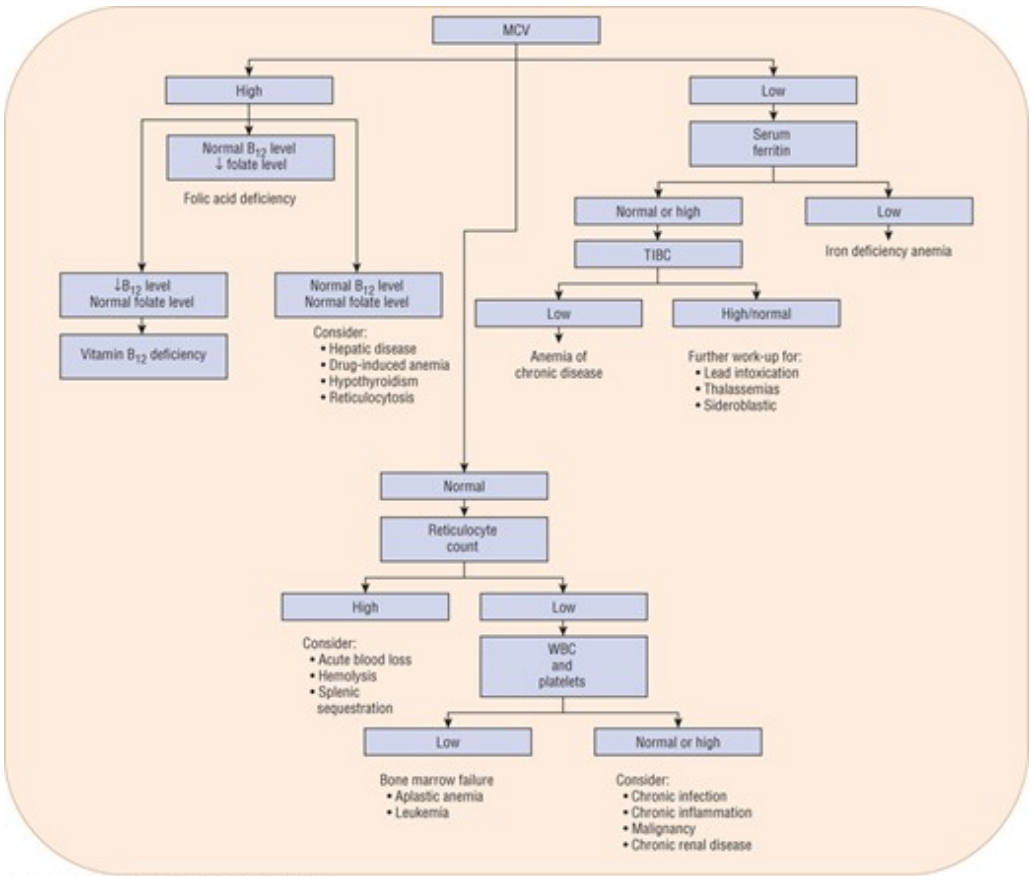
Laboratory Evaluation

The initial evaluation of anemia involves a CBC (including RBC indices), reticulocyte index, and possibly an examination of a stool sample for occult blood. The results of the preliminary evaluation determine the need for other studies, such as examination of a peripheral blood smear. Based on laboratory test results, anemia can be categorized into three functional defects: RBC production failure (hypoproliferative), cell maturation ineffectiveness, or increased RBC destruction or loss (see Fig. 100-1).

Figure 100-5 shows a broad, general algorithm for the diagnosis of anemia based on laboratory data. There are many exceptions and additions to this algorithm, but it can serve as a guide to the typical presentation of common types and causes of anemia. The algorithm is less useful in the presence of more than one cause of anemia.

FIGURE 100-5

General algorithm for diagnosis of anemias (↓, decreased; MCV, mean corpuscular volume; TIBC, total iron-binding capacity; and WBC, white blood cells).



Hemoglobin

Values given for Hb represent the amount of Hb per volume of whole blood. The higher values seen

in males are due to stimulation of RBC production by androgenic steroids, whereas the lower values in females reflect the decrease in Hb as a result of blood loss during menstruation. The Hb level can be used as a very rough estimate of the oxygen-carrying capacity of blood. Hb levels may be diminished because of a decreased quantity of Hb per RBC or because of a decrease in the actual number of RBCs.

CLINICAL PRESENTATION Anemia General

- Patients may be asymptomatic or have vague complaints
- Patients with vitamin B_{12} deficiency may develop neurologic consequences
- In AI, signs and symptoms of the underlying disorder often overshadow those of the anemia

Symptoms

- Decreased exercise tolerance
- Fatigue
- Dizziness
- Irritability
- Weakness
- Palpitations
- Vertigo
- Shortness of breath
- Chest pain
- Neurologic symptoms in vitamin B_{12} deficiency

Signs

- Tachycardia
- Pale appearance (most prominent in conjunctivae)
- Decreased mental acuity
- Increased intensity of some cardiac valvular murmurs
- Diminished vibratory sense or gait abnormality in vitamin B_{12} deficiency

Laboratory Tests

- Hemoglobin, hematocrit, and RBC indices may remain normal early in the disease and then decrease as the anemia progresses
- Serum iron is low in IDA and AI
- Ferritin levels are low in IDA and normal to increased in AI
- Total iron binding capacity is high in IDA and is low or normal in AI
- Mean cell volume is elevated in vitamin B_{12} deficiency and folate deficiency
- Vitamin B_{12} and folate levels are low in their respective types of anemia
- Homocysteine is elevated in vitamin B_{12} deficiency and folate deficiency
- Methylmalonic acid is elevated in vitamin B_{12} deficiency

Hematocrit

Expressed as a percentage, hematocrit (Hct) is the actual volume of RBCs in a unit volume of whole blood. In general, it is about three times the Hb value (when Hb is expressed in g/dL). An alteration in this ratio may occur with abnormal cell size or shape and often indicates pathology. A low Hct indicates a reduction in either the number or the size of RBCs or an increase in plasma volume.

Red Blood Cell Count

The RBC count is an indirect estimate of the Hb content of the blood; it is an actual count of RBCs per unit of blood.

Red Blood Cell Indices

Wintrobe indices describe the size and Hb content of the RBCs and are calculated from the Hb, Hct, and RBC count. RBC indices, such as mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH), are single mean values that do not express the variation that can occur in cells.

Mean Cell Volume

MCV represents the average volume of RBCs. It may reflect changes in MCH. Cells are considered macrocytic if they are larger than normal, microcytic if they are smaller than normal, and normocytic if their size falls within normal limits. Folic acid and vitamin B_{12} deficiency anemias yield macrocytic cells, whereas iron deficiency and thalassemia are examples of microcytic anemias. When IDA (decreased MCV) is accompanied by folate deficiency (increased MCV), the overall MCV may be normal. Failure to understand that the MCV represents an average RBC size creates the potential for overlooking some causes of the anemia.

Mean Cell Hemoglobin

MCH is the amount of Hb in a RBC, and usually increases or decreases with the MCV. Two morphologic changes, microcytosis and hypochromia, can reduce MCH. A microcytic cell contains less Hb because it is a smaller cell, while a hypochromic cell has a low MCH because of the decreased concentration of Hb present in the cell. Cells can be both microcytic and hypochromic, as seen with IDA. The MCH alone cannot distinguish between microcytosis and hypochromia. The most common cause of an elevated MCH is macrocytosis (eg, vitamin B_{12} or folate deficiency).

Mean Cell Hemoglobin Concentration

The concentration of Hb per volume of cells is the mean cell Hb concentration (MCHC). Because MCHC is independent of cell size, it is more useful than MCH in distinguishing between microcytosis and hypochromia. A low MCHC indicates hypochromia; a microcyte with a normal Hb concentration will have a low MCH but a normal MCHC. A decreased MCHC is seen most often in IDA.

Total Reticulocyte Count

The total reticulocyte count is an indirect assessment of new RBC production. It reflects how quickly immature RBCs (reticulocytes) are produced by bone marrow and released into the blood. Reticulocytes circulate in the blood about 2 days before maturing into RBCs. About 1% of RBCs are normally replaced daily, representing a reticulocyte count of 1%. The reticulocyte count in normocytic anemia can differentiate hypoproliferative marrow from a compensatory marrow response to an anemia. A lack of reticulocytosis in anemia indicates impaired RBC production. Examples include iron deficiency, B_{12} deficiency, anemia of chronic disease (ACD), malnutrition, renal insufficiency, and malignancy. A high reticulocyte count may be seen in acute blood loss or hemolysis. The reticulocyte index can aid in determining the functional classification of an anemia (see Fig. 100-5).

Red Blood Cell Distribution Width

The higher the red blood cell distribution width (RDW), the more variable is the size of the RBCs. The RDW increases in early IDA because of the release of large, immature, nucleated RBCs to compensate for the anemia, but this change is not specific for IDA. The RDW also can be helpful in the diagnosis of a mixed anemia. A patient can have a normal MCV yet have a wide RDW. This finding indicates the presence of microcytes and macrocytes, which would yield a “normal” average RBC size. The use of RDW to distinguish IDA from ACD is not recommended.

Peripheral Blood Smear

The peripheral blood smear can supplement other clinical data and help establish a diagnosis. Peripheral blood smears provide information on the functional status of the bone marrow and defects in RBC production. Additionally, it provides information on variations in cell size (anisocytosis) and shape (poikilocytosis). Automated blood counters, used for the CBC, can flag specific RBC changes that can be confirmed by a peripheral blood smear. Blood smears are placed on a microscope slide and stained as appropriate. Morphologic examination includes assessment of size, shape, and color. The extent of anisocytosis correlates with increased range of cell sizes.

Poikilocytosis can suggest a defect in the maturation of RBC precursors in the bone marrow or the presence of hemolysis.

Serum Iron

The level of serum iron is the concentration of iron bound to transferrin. Transferrin is normally about one-third bound (saturated) to iron. The serum iron level of many patients with IDA may remain within the lower limits of normal because a considerable amount of time is required to deplete iron stores. Serum iron levels show diurnal variation (higher in the morning, lower in the afternoon), but this variation is probably not clinically significant in timing of levels.[9] Since serum iron levels are decreased by infection and inflammation, serum iron levels are best interpreted in conjunction with the total iron binding capacity. The serum iron level decreases with IDA and ACD and increases with hemolytic anemias and iron overload.

Total Iron-Binding Capacity

An indirect measurement of the iron-binding capacity of serum transferrin, total iron-binding capacity (TIBC) evaluation is performed by adding an excess of iron to plasma to saturate all transferrin with iron. Each transferrin molecule can carry two iron atoms. Normally, about 30% of available iron-binding sites are filled. With this laboratory test, all binding sites are filled to measure TIBC; the excess (unbound) iron is then removed and the serum iron concentration determined. Unlike the serum iron level, the TIBC does not fluctuate over hours or days. TIBC usually is higher than normal when body iron stores are low. The finding of a low serum iron level and a high TIBC suggests IDA. The TIBC is actually a measurement of protein serum transferrin, which can be affected by a variety of factors. Patients with infection, malignancy, inflammation, liver disease, and uremia may have a decreased TIBC and a decreased serum iron level, which are consistent with the diagnosis of ACD.

Percentage Transferrin Saturation

The ratio of serum iron level to TIBC indicates transferrin saturation. It reflects the extent to which iron-binding sites are occupied on transferrin and indicates the amount of iron readily available for erythropoiesis. It is expressed as a percentage, as described in the following formula:

$$\text{Transferrin saturation} = \frac{\text{serum iron}}{\text{TIBC}} \times 100$$

Transferrin normally is 20% to 50% saturated with iron. In IDA, transferrin saturation of 15% or lower is commonly seen.[10] Transferrin saturation is a less sensitive and specific marker of iron deficiency than are ferritin levels.

Serum Ferritin

The serum concentration of ferritin (storage iron) is proportional to total iron stores and therefore is the best indicator of iron deficiency or iron overload. Ferritin levels indicate the amount of iron stored

in the liver, spleen, and bone marrow cells. Low serum ferritin levels are virtually diagnostic of IDA. In contrast, serum iron levels may decrease in both IDA and ACD. Since serum ferritin is an acute phase reactant, chronic infection or inflammation can increase its concentration independent of iron status, masking depleted tissue stores. This limits the utility of the serum ferritin if the level is normal or high for a chronically ill patient. For these patients, iron, even if present in these tissue stores, may not be available for erythropoiesis.

Soluble Transferrin Receptor

The soluble transferrin receptor (sTfR) assay is a laboratory test considered a sensitive, early, highly quantitative marker of iron depletion. The sTfR concentration is inversely correlated with tissue iron stores, and elevated levels are predictive of iron deficiency. Unlike ferritin, the sTfR is not an acute phase reactant; so its level remains normal for patients with chronic disease. It may be a useful test for distinguishing ACD from IDA.[9] The major limitation of this test is that it is not widely available in many laboratories.

Folic Acid

The results of folic acid measurements vary depending on the assay method used. Decreased serum folic acid levels (less than 4 ng/mL [less than 9 nmol/L]) indicate a folate deficiency megaloblastic anemia that may coexist with a vitamin B_{12} deficiency anemia. Erythrocyte folic acid levels are less variable than serum levels because they are slow to decrease in an acute process such as drug-induced folic acid deficiency and slow to increase with oral folic acid replacement. In addition, erythrocyte folic acid levels have the theoretical advantage of less susceptibility to rapid changes in diet and alcohol intake. Limitations with sensitivity and specificity do exist with measurements of erythrocyte folate. If the serum folate concentration is normal for a patient with suspected folate deficiency, then the erythrocyte folate level should be measured.[11]

Vitamin B_{12}

Low levels (less than 200 pg/mL [less than 148 pmol/L]) of vitamin B_{12} (cyanocobalamin or cobalamin) indicate deficiency. However, a deficiency may exist prior to the recognition of low serum levels. Serum values are maintained at the expense of vitamin B_{12} tissue stores. Vitamin B_{12} and folate deficiency may overlap, thus serum levels of both vitamins should be determined. Vitamin B_{12} levels may be falsely low with folate deficiency and pregnancy.[12]

Schilling Test

This test used to be the “gold standard” for assessing vitamin B_{12} absorption. Due to its cost, unavailable test components, and complexity, the test is rarely used today. Tests to replace it are under investigation.[13]

Homocysteine

Vitamin B_{12} and folate both are required for conversion of homocysteine to methionine. Increased serum homocysteine may suggest vitamin B_{12} or folate deficiency. Homocysteine levels also can be elevated in patients with vitamin B_6 deficiency, renal failure, hypothyroidism, or a genetic defect in cystathionine β-synthase.[14]

Methylmalonic Acid

A vitamin B_{12} coenzyme is needed to convert methylmalonyl coenzyme A to succinyl coenzyme A. Patients with vitamin B_{12} deficiency have increased concentrations of serum methylmalonic acid (MMA), which is a more specific marker for vitamin B_{12} deficiency than homocysteine. MMA levels are not elevated in folate deficiency because folate does not participate in MMA metabolism. Levels of both MMA and homocysteine usually are elevated prior to the development of hematologic abnormalities and reductions in serum vitamin B_{12} levels.[12] MMA levels must be interpreted cautiously for patients with renal disease and hypovolemia because the levels may be elevated due to decreased urinary excretion.

IRON-DEFICIENCY ANEMIA

Epidemiology

Iron deficiency is the most common nutritional deficiency in developing and developed countries. Data from the National Health and Nutrition Examination Survey (NHANES) indicate the prevalence of IDA in young children and women of childbearing age is 1.2% and 4.5%, respectively.[2] The normal ranges for Hb and Hct are so wide that a patient may lose up to 15% of RBC mass and still have a Hct within the normal range. Therefore, iron deficiency may precede the appearance of anemia.

Iron Balance

The normal iron content of the body is about 3 to 4 g. Iron is a component of Hb, myoglobin, and cytochromes. About 2 g of the iron exists in the form of Hb, and about 130 mg exists as iron-containing proteins such as myoglobin. About 3 mg of iron is bound to transferrin in plasma, and 1,000 mg of iron exists as storage iron in the form of ferritin or hemosiderin. The rest of the iron is stored in other tissues such as cytochromes.[9] Due to the toxicity of inorganic iron, the body has an intricate system for iron absorption, transport, storage, assimilation, and elimination. Hepcidin is a regulator of intestinal iron absorption, iron recycling, and iron mobilization from hepatic stores. It is a peptide hormone made in the liver, distributed in plasma, and excreted in urine. Hepcidin inhibits efflux of iron through ferroportin. Hepcidin synthesis is increased by iron loading and inflammation and decreased by iron deficiency and erythropoietic activity. Hepcidin is induced during infections and inflammation, which allows iron to sequester in macrophages, hepatocytes, and enterocytes.[15] As a result, hepcidin is likely an important mediator of AI. Hepcidin is usually suppressed in IDA.[16] Hepcidin testing is not routinely available.[17]

Most people lose about 1 mg of iron daily. Menstruating women can lose up to 0.6% to 2.5% more

per day. Pregnancy requires an additional 700 mg of iron and a blood donation can result in as much as 250 mg of iron loss[18]; these patients are at higher risk for deficiency.

Iron is best absorbed in its ferrous (Fe^{2+}) form. The normal daily Western diet contains mainly the ferric (Fe^{3+}) nonabsorbed form. After iron is ionized by stomach acid and then reduced to the Fe^{2+} state, it is absorbed primarily in the duodenum, and to a smaller extent in the jejunum, via intestinal mucosal cell uptake. Subsequently, it is transferred across the cell into the plasma. Iron absorption is not directly proportional to iron intake. Rather as physiologic iron levels decrease, GI absorption of iron increases.

The daily recommended dietary allowance for iron is 8 mg in adult males and postmenopausal females and 18 mg in menstruating females. Children require more iron because of growth-related increases in blood volume, and pregnant women have an increased iron demand brought about by fetal development. In the absence of hemochromatosis, iron overload does not occur, because only the amount of iron lost per day is absorbed. The amount of iron absorbed from food depends on the body stores, the rate of RBC production, the type of iron provided in the diet, and the presence of any substances that may enhance or inhibit iron absorption.

Heme iron, which is found in meat, fish, and poultry, is about three times more absorbable than the nonheme iron found in vegetables, fruits, dried beans, nuts, grain products, and dietary supplements. Gastric acid and other dietary components such as ascorbic acid increase the absorption of nonheme iron. Dietary components that form insoluble complexes with iron (phytates, tannates, and phosphates) decrease absorption. Phytates, a natural component of grains, brans, and some vegetables, can form poorly absorbed complexes and partially explain the increased prevalence of IDA in poorer countries, where grains and vegetables compose a disproportionate amount of the normal diet. Polyphenols bind iron and decrease nonheme iron absorption when large amounts of tea or coffee are consumed with a meal. Although the mechanism is unknown, calcium inhibits absorption of both heme and nonheme iron. Finally, because gastric acid improves iron absorption, patients who have undergone a gastrectomy or have achlorhydria have decreased iron absorption.[19]

Etiology

Iron deficiency results from prolonged negative iron balance, which can occur due to increased iron demand or hematopoiesis, increased loss, or decreased intake/absorption. The onset of iron deficiency depends on an individual's initial iron stores and the imbalance between iron absorption and loss. Multiple etiologic factors usually are involved. Certain groups at higher risk for iron deficiency include children younger than 2 years, adolescent girls, pregnant/lactating females, and those older than 65 years. Patients older than 65 years of age with IDA should be considered for testing for occult GI bleeding.[18] Blood loss must initially be considered a cause of IDA in adults. Blood loss may occur as a result of many disorders, including trauma, hemorrhoids, peptic ulcers, gastritis, GI malignancies, arteriovenous malformations, diverticular disease, copious menstrual flow, nosebleeds, and postpartum bleeding. In less industrialized nations, the risk of IDA is largely related to dietary factors.

The USPSTF recommends routine screening for IDA in all pregnant women.[20] The USPSTF has concluded that evidence is insufficient to recommend for or against routine iron supplementation for nonanemic pregnant women.[18] However, iron deficiency in pregnant women is so common that the Centers for Disease Control and Prevention (CDC) guidelines recommend initiation of low-dose iron supplements or prenatal vitamins with 30 mg/day of iron at each woman's first prenatal visit.

Medication history, specifically regarding recent or past use of iron, alcohol, corticosteroids, warfarin or other anticoagulants, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs), is a vital part of the history to assess bleeding risk. Other possible causes of hypochromic microcytic anemia include AI, thalassemia, sideroblastic anemia, and heavy metal (mostly lead) poisoning (see Fig. 100-4).

Pathophysiology

Iron is vital to the function of all cells. Without iron, cells lose their capacity for electron transport and energy metabolism. Iron deficiency usually is the result of a long period of negative iron balance. Manifestations of iron deficiency occur in three stages. In the initial stage, iron stores are reduced without reduced serum iron levels and can be assessed with serum ferritin measurement. The stores allow iron to be utilized when there is an increased need for Hb synthesis. Once stores are depleted, there still is adequate iron from daily RBC turnover for Hb synthesis. Further iron losses would make the patient vulnerable to anemia development. In the second stage, iron deficiency occurs when iron stores are depleted, and Hb is above the lower limit of normal for the population but may be reduced for a given patient. This can be determined by serial CBC measurements. Findings include reduced transferrin saturation and increased TIBC. The third stage occurs when the Hb falls to less than normal values.

Laboratory Findings

3 Abnormal laboratory findings for patients with IDA generally include low serum iron and ferritin levels and high TIBC. In the early stages of IDA, RBC size is not changed. Low ferritin concentration is the earliest and most sensitive indicator of iron deficiency. However, ferritin may not correlate with iron stores in the bone marrow because renal or hepatic disease, malignancies, infection, or inflammatory processes may increase ferritin values.[9] Hb, Hct, and RBC indices usually remain normal in early stages. In the later stages of IDA, Hb and Hct fall below normal values, and a microcytic hypochromic anemia develops. Microcytosis may precede hypochromia, as erythropoiesis is programmed to maintain normal Hb concentration in preference to cell size. As a result, even slightly abnormal Hb and Hct levels may indicate significant depletion of iron stores and should not be ignored. In terms of RBC indices, MCV is reduced earlier in IDA than Hb concentration.

Transferrin saturation (ie, serum iron level divided by the TIBC) is useful for assessing IDA. Low values may indicate IDA, although low serum transferrin saturation values also may be present in inflammatory disorders. The TIBC may help to differentiate the diagnosis in these patients: TIBC levels that are elevated can suggest IDA, while values that are low represent inflammatory disease.

TREATMENT

Iron Deficiency Anemia (Desired Outcomes)

The outcomes for all types of anemia in this chapter include: reversal of hematologic parameters to normal, return of normal function and quality of life, and prevention or reversal of long-term complications such as neurologic complications of vitamin B_{12} deficiency.

Dietary Supplementation and Oral Iron Preparations

The severity and cause of IDA determine the approach to treatment. Treatment is focused on replenishing iron stores. Because iron deficiency can be an early sign of other illnesses, treatment of the underlying disease may aid in the correction of iron deficiency.

Treatment of IDA usually consists of dietary supplementation and administration of oral iron preparations. Foods high in iron are listed in **Table 100-1**. Iron is best absorbed from meat, fish, and poultry. These foods as well as certain iron-fortified cereals can help treat IDA. Orange juice and other ascorbic acid-rich foods can be included with meals to increase absorption. Milk and tea reduce absorption and should be consumed in moderation. In most cases of IDA, oral administration of iron therapy with soluble Fe^{2+} iron salts is appropriate.

TABLE 100-1 Good Sources of Iron

Food	Serving Size	Amount (mg)
Ready to eat cereal, 100% fortified	3/4 cup (180 mL)	18
Instant plain oatmeal, fortified	1 cup (240 mL)	11
Wheat germ	1 oz (28g)	2.6
Broccoli	1 medium stalk	2.1
Baked potato	1 medium	2.7
Raw tofu	1/2 cup (120 mL)	4
Lentils	1/2 cup (120 mL)	3.3
Beef chuck	3 oz (85g)	3.2

Fe^{2+} sulfate, succinate, lactate, fumarate, glutamate, and gluconate are absorbed similarly. The addition of copper, cobalt, molybdenum, or other minerals provides no advantage but increases cost of the product. Iron is best absorbed in the reduced Fe^{2+} form, with maximal absorption occurring in the duodenum, primarily due to the acidic medium of the stomach. Slow-release, sustained-release, or enteric coated iron preparations do not undergo sufficient dissolution until they reach the small intestine. In the alkaline environment of the small intestine, iron tends to form insoluble complexes, which significantly reduces absorption. The dose of iron replacement therapy depends on the patient's ability to tolerate the administered iron. Tolerance of iron salts improves with a small initial dose and gradual escalation to the full dose. For patients with IDA, the generally recommended dose is about 150 to 200 mg of elemental iron daily, usually in two or three divided doses to maximize tolerability. If patients cannot tolerate this daily dose of elemental iron, smaller amounts of elemental iron (eg, single 325 mg tablet of Fe^{2+} sulfate) usually are sufficient to replace iron stores, although at a slower rate. **Table 100-2** lists the percentage of elemental iron of commonly available iron salts.

Iron preferably is administered at least 1 hour before meals because food can interfere with iron absorption. Many patients must take iron with food because they experience GI upset when iron is administered on an empty stomach.

TABLE 100-2 Oral Iron Products

Iron Salt	Percent Elemental Iron	Common: Formulations and Elemental Iron Provided
Ferrous sulfate	20	60-65 mg/324-325 mg tablet 60 mg/5 mL syrup 44 mg/ 5 mL elixir 15 mg/1 mL
Ferrous sulfate (exsiccated)	30	65 mg/200 mg tablet 50 mg/160 mg tablet
Ferrous gluconate	12	38 mg/325 mg tablet 28-29 mg/240-246 mg tablet
Ferrous fumarate	33	66 mg/200 mg tablet 106 mg/324-325 mg tablet

Clinical Controversy…

The treatment of patients who are found to be iron deficient, but do not have anemia, can improve fatigue or physical performance. Ferritin is typically used to measure deficiency in these studies. It is currently unknown whether these deficient patients should have a trial of iron therapy to improve symptoms.

Adverse reactions to therapeutic doses of iron are primarily GI in nature and consist of dark discoloration of feces, constipation or diarrhea, nausea, and vomiting. GI side effects usually are dose related and are similar among iron salts when equivalent amounts of elemental iron are administered. Dark stools do not interfere with testing for occult blood in the GI tract. Administration of smaller amounts of iron with each dose or administration with meals may minimize these adverse effects. Histamine-2 blockers or proton-pump inhibitors reduce gastric acidity and may impair iron absorption. **Table 100-3** lists drug interactions with iron.

TABLE 100-3 Iron Salt–Drug Interactions

Drugs That Decrease Iron Absorption	Object Drugs Affected by Iron
Al-, Mg-, and Ca^{2+}-containing antacids	Levodopa ↓ (chelates with iron) Methyldopa ↓ (decreases efficacy of methyldopa)
Tetracycline and doxycycline	

Drugs That Decrease Iron Absorption	Object Drugs Affected by Iron
	Levothyroxine ↓ (decreased efficacy of levothyroxine)
Histamine$_2$ antagonists	Penicillamine ↓ (chelates with iron)
Proton-pump inhibitors	Fluoroquinolones ↓ (forms ferric ion quinolone complex)
Cholestyramine	Tetracycline and doxycycline ↓ (when administered within 2 hours of iron salt)
	Mycophenolate ↓ (decreases absorption)

Failure to respond to appropriate treatment regimens necessitates reevaluation of the patient's condition. A "therapeutic trial of iron" approach will occasionally be used to confirm a presumptive diagnosis of IDA. Common causes of treatment failure include poor patient adherence, inability to absorb iron, incorrect diagnosis, continued bleeding, or a concurrent condition that impairs full reticulocyte response. Even when iron deficiency is present, response may be impaired when a coexisting cause for anemia exists. Rarely a patient has diminished ability to absorb iron, most often due to previous gastrectomy, such as gastric bypass surgery, or celiac disease. Regardless of the form of oral therapy used, treatment should continue for 3 to 6 months after the anemia is resolved to allow for repletion of iron stores and to prevent relapse. Patients should be instructed to store oral iron out of reach of children and pets as small amounts can result in a fatal overdose. Products containing more than 30 mg of elemental iron are required to be packaged as individual dosage units to prevent toxicity. Treatment for acute iron poisoning is discussed in Chapter e9.

Parenteral Iron Therapy

Indications for parenteral iron therapy include intolerance to oral, malabsorption, and nonadherence. Patients with significant blood loss who refuse transfusions and cannot take oral iron therapy also may require parenteral iron therapy. Parenteral iron therapy should also be considered, possibly first line, in patients with inflammatory bowel disease and those with gastric bypass/gastric resection due to poor oral absorption.[21] Parenteral iron therapy is also used for patients with chronic kidney disease (see Chapter 44), especially those undergoing hemodialysis, and for some cancer patients receiving chemotherapy on erythropoiesis-stimulating agents (ESAs; Chapter 127). Five different parenteral iron preparations currently available in the United States are iron dextran, sodium ferric gluconate, iron sucrose, ferumoxytol, and ferric carboxymaltose (Table 44-10). They differ in their molecular size, pharmacokinetics, bioavailability, and adverse effect profiles. Although toxicity profiles of these agents differ, clinical studies indicate that each is efficacious. Iron dextran parenteral preparations have been associated with more anaphylactic reactions and this product requires a test dose prior to full dose administration. Fatal reactions have also occurred in patients who tolerated the test dose. Iron dextran and ferumoxytol products have black box warnings in their labeling regarding severe allergic reactions. The safety profile of parenteral iron is largely assessed by spontaneous reports to the FDA and observational studies. All parenteral iron preparations carry a risk for anaphylactic reactions but likely to a lesser extent than iron dextran.[22,23] The FDA

recommends that resuscitation equipment and trained staff be available during administration of all iron dextran preparations. A concern with parenteral iron is that iron may be released too quickly and overload the ability of transferrin to bind it, leading to free iron reactions that can interfere with neutrophil function. The following formula can be used to estimate the total dose of parenteral iron needed to correct anemia:

$$\text{Dose of iron (mg)} = \text{whole blood hemoglobin deficit (g/dL)} \times \text{body weight (lb) or}$$
$$\text{Dose of iron (mg)} = \text{whole blood hemoglobin deficit (g/L)} \times \text{body weight (kg)} \times 0.22$$

An additional quantity of iron to replenish stores should be added (about 600 mg for women and 1,000 mg for men).[9]

Iron dextran, a complex of Fe^{3+} hydroxide and the carbohydrate dextran, contains 50 mg of iron per milliliter and can be given via the intramuscular or IV route. Different brands of iron dextran are available and differ in their molecular weight. They are not interchangeable. The intramuscular route is no longer used routinely and requires Z-tract injection technique.[24]

Methods of IV administration include multiple slow injections of undiluted iron dextran solution or an infusion of a diluted preparation. This latter method often is referred to as total dose infusion.

Total replacement doses of IV iron dextran have been given as a single dose, but this method of administration is not FDA approved. A test dose still is required. Patients who receive total dose infusions are at higher risk for adverse reactions, such as arthralgias, myalgias, flushing, malaise, and fever. Other adverse reactions of iron dextran include staining of the skin, pain at the injection site, allergic reactions, and rarely anaphylaxis. Patients with preexisting immune-mediated diseases, such as active rheumatoid arthritis or systemic lupus erythematosus, are considered at high risk for adverse reactions because of their hyperreactive immune response.

Sodium ferric gluconate is a complex of iron bound to one gluconate and four sucrose molecules in a repeating pattern. Its molecular weight is 289 to 440 kDa. Sodium ferric gluconate is available in an aqueous solution. No direct transfer of iron from the Fe^{3+} gluconate to transferrin occurs. The complex is taken up quickly by the mononuclear phagocytic system and has a half-life of about 1 hour in the bloodstream. Sodium ferric gluconate appears to produce fewer anaphylactic reactions than iron dextran does. Adverse effects of sodium ferric gluconate include cramps, nausea, vomiting, flushing, hypotension, intense upper gastric pain, rash, and pruritus.[26]

Iron sucrose is a polynuclear iron (III) hydroxide in sucrose complex with a molecular weight of 34 to 60 kDa. Following IV administration of iron sucrose, the iron is released directly from the circulating iron sucrose to transferrin and is taken up by the mononuclear phagocytic system and metabolized. The half-life is about 6 hours, with a volume of distribution similar to that of iron dextran. Iron sucrose injection should not be administered concomitantly with oral iron preparations because it will reduce the absorption of oral iron.[27] Adverse effects include leg cramps and hypotension.

Ferumoxytol was FDA-approved in 2009 to treat iron deficiency in adults with chronic kidney disease

who are on or off dialysis. Typical dosing is 510 mg IV dose followed by a second 510 mg dose 3 to 8 days later. The dose can be readministered after 1 month if anemia persists. No test dose is required but anaphylaxis can occur and patients should be observed for at least 30 minutes after each dose. A black box warning was also added in 2015 due to case reports of fatal and nonfatal anaphylactic reactions to the product. It should not be used in patients who previously had an allergic reaction to other iron preparations.[28]

Ferric carboxymaltose is the newest approved parenteral iron product, receiving FDA approval in 2013. The approval of this product was delayed due to hypophosphatemia seen in clinical trials. No additional warnings were required and no clinical issues related to hypophosphatemia have been reported. This product received approval for treatment of IDA in those who have failed oral iron therapy or who have intolerance for oral therapy. It is also approved for chronic kidney disease patients not on hemodialysis.[29]

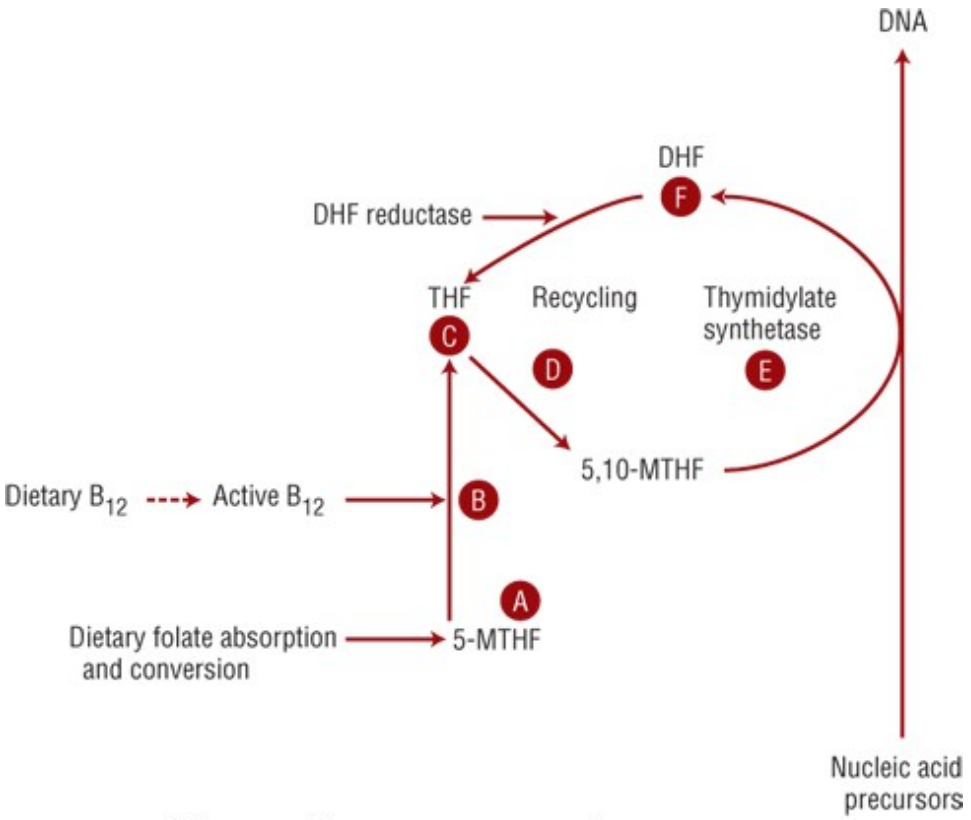
Increased risk for infection is a concern with parenteral iron preparations because iron is a growth factor for some bacteria, but a recently published meta-analysis concluded that IV iron does not increase risk for infection.[30] Parenteral iron products are discussed in more detail in Chapter 44.

MEGALOBLASTIC ANEMIAS

Macrocytic anemias are divided into megaloblastic and nonmegaloblastic anemias. Macrocytosis, as seen in megaloblastic anemias, is caused by abnormal DNA metabolism resulting from vitamin B_{12} or folate deficiency. It also can be caused by administration of various drugs, such as hydroxyurea, zidovudine, cytarabine, methotrexate, azathioprine, 6-mercaptopurine, and cladribine. In vitamin B_{12}- or folate-deficiency anemia, megaloblastosis results from interference with folic acid- and vitamin B_{12}-interdependent nucleic acid synthesis in the immature erythrocyte. The rate of RNA and cytoplasm production exceeds the rate of DNA production. The maturation process is impaired, resulting in immature large RBCs (macrocytosis). RNA and DNA synthesis depend on a series of reactions catalyzed by vitamin B_{12} and folic acid because of their role in the conversion of uridine to thymidine. As shown in **Fig. 100-6**, dietary folates are absorbed in this process and converted to 5-methyl-tetrahydrofolate (A), which then is converted via a B_{12}-dependent reaction (B) to tetrahydrofolate (C). After gaining a carbon, tetrahydrofolate is converted to 5,10-methyl-tetrahydrofolate (D), a folate cofactor used by thymidylate synthetase (E) in the biosynthesis of nucleic acids. The 5,10-methyl-tetrahydrofolate cofactor is converted to dihydrofolate (F) during biosynthesis. Dihydrofolate reductase normally reduces dihydrofolate back to tetrahydrofolate (C), which can again pick up a carbon and be recycled to produce more 5,10-methyl-tetrahydrofolate (D).

FIGURE 100-6

Drug-induced megaloblastosis (DHF, dihydrofolate; 5-MTHF, 5-methyl-tetrahydrofolate; 5,10-MTHF, 5,10-methyl-tetrahydrofolate; THF, tetrahydrofolate).



Although vitamin B_{12} and folate deficiency are common causes of macrocytosis, other possible causes must be considered if these deficiencies are not found. Other causes of macrocytosis include (1) a shift to immature or stressed RBCs as seen in reticulocytosis, aplastic anemia, and pure RBC aplasia; (2) a primary bone marrow disorder such as myelodysplastic syndromes, congenital dyserythropoietic anemias, and large granular lymphocyte leukemia; (3) lipid abnormalities as seen with liver disease, hypothyroidism, or hyperlipidemia; and (4) unknown mechanisms resulting from alcohol abuse and multiple myeloma. Macrocytosis is the most typical morphologic abnormality associated with excessive alcohol consumption. Even with adequate folate and vitamin B_{12} levels and the absence of liver disease, patients with high alcohol intake may present with an alcohol-induced macrocytosis. Cessation of alcohol ingestion results in resolution of the macrocytosis within a couple of months.

Vitamin B_{12} Deficiency Anemia

The prevalence of vitamin B_{12} deficiency anemia in the United States is unknown. Risk increases with age.[31] The use of gastric acid-suppressing agents, which may inhibit cobalamin release from food, is associated with an increased risk. Older adults in the United States have a high prevalence (up to 15%) of elevated MMA levels and associated low or low-normal vitamin B_{12} levels, likely due to atrophic gastritis and malabsorption of food-bound vitamin B_{12}.[31]

Etiology

4 The three major causes of vitamin B_{12} deficiency are inadequate intake, malabsorption syndromes, and inadequate utilization. Inadequate dietary consumption of vitamin B_{12} is rare. It usually occurs only in patients who are strict vegans and their breast-fed infants, chronic alcoholics, and elderly patients who consume a "tea and toast" diet because of financial limitations or poor dentition. Decreased vitamin B_{12} absorption can occur with loss of intrinsic factor by autoimmune mechanisms (such as pernicious anemia, in which gastric parietal cells are selectively damaged), chronic atrophic gastritis, or stomach surgery. One of the most frequent causes of low serum B_{12} levels results from the inability of vitamin B_{12} to be cleaved and released from proteins in food because of inadequate gastric acid production. Treatment of *Helicobacter pylori* may improve vitamin B_{12} status because this bacterial infection is a cause of chronic gastritis.[32] Vitamin B_{12} deficiency may occasionally result from overgrowth of bacteria in the bowel that use vitamin B_{12} or from injury or removal (from Crohn's disease or small bowel surgery, respectively) of ileal receptor sites where vitamin B_{12} and the intrinsic factor complex are absorbed. Blind loop syndrome, Whipple disease, Zollinger–Ellison syndrome, tapeworm infestations, intestinal resections, tropical sprue, surgical resection of the ileus, pancreatic insufficiency, inflammatory bowel disease, advanced liver disease, tuberculosis, and Crohn's disease may contribute to the development of vitamin B_{12} deficiency.[31] Metformin may reversibly decrease B_{12} absorption, likely due to its effects on the intestinal mucosa in the ileum. It rarely causes anemia on its own but can contribute to deficiency. Proton pump inhibitors and histamine 2 receptor antagonists may also contribute to vitamin B_{12} deficiency because an acidic environment is needed for vitamin B_{12} to be absorbed in the GI tract from food.[33] A recent study suggested that these medications have a greater effect on deficiency in those who have taken them for 2 or more years.[33]

Pathophysiology

Vitamin B_{12} works closely with folate in the synthesis of building blocks for DNA and RNA, is essential in maintaining the integrity of the neurologic system, and plays a role in fatty acid biosynthesis and energy production. It is a water-soluble vitamin obtained exogenously by ingestion of meat, fish, poultry, dairy products, and fortified cereals. The body stores several years of vitamin B_{12}, of which about 50% is in the liver. The recommended daily allowance is 2 mcg in adults and 2.6 mcg in pregnant or breast-feeding women. The average western diet provides 5 to 15 mcg of vitamin B_{12} daily, of which 1 to 5 mcg is absorbed.[31] Vitamin B_{12} deficiency usually takes several years to develop following vitamin deprivation.

Once dietary cobalamin enters the stomach, pepsin and hydrochloric acid release the cobalamin from animal proteins. The free cobalamin then binds to R-protein, which is released from parietal and salivary cells. In the duodenum, the cobalamin-R-protein complex is degraded, releasing free cobalamin. The cobalamin then binds with intrinsic factor that serves as a cell-directed carrier protein similar to transferrin for iron. This complex attaches to mucosal cell receptors in the distal ileum, the intrinsic factor is discarded, and the cobalamin is bound to transport proteins (transcobalamin I, II, and III). The cobalamin bound to transcobalamin II is secreted into the circulation and is taken up by the liver, bone marrow, and other cells. Most circulating cobalamin is bound to transcobalamin I and

transcobalamin III. Passive diffusion is an alternate pathway for vitamin B_{12} absorption independent of intrinsic factor or an intact terminal ileum and accounts for about 1% of vitamin B_{12} absorption.[31]

Vitamin B_{12} deficiency can cause neurologic and hematologic complications. These usually start with bilateral paraesthesia in extremities; deficits in proprioception and vibration can also be present. If not treated, this can progress to ataxia, dementia-like symptoms, psychosis, and vision loss. In children prolonged deficiency can lead to poor brain development.[13,34] Patients with unexplained neuropathies should be evaluated for vitamin B_{12} deficiency.

Laboratory Findings

In macrocytic anemias, MCV is elevated greater than 100 fL, but some patients deficient in vitamin B_{12} may have a normal MCV. If there is a coexisting cause of microcytosis, the MCV may not be elevated.[30] Mild leukopenia and thrombocytopenia are often present because abnormal DNA synthesis can affect all blood cell lines. A peripheral blood smear demonstrates macrocytosis accompanied by hypersegmented polymorphonuclear leukocytes (one of the earliest and most specific indications of this disease), oval macrocytes, anisocytosis, and poikilocytosis. Serum lactate dehydrogenase and indirect bilirubin levels may be elevated as a result of hemolysis or ineffective erythropoiesis.[13] Other laboratory findings include a low reticulocyte count, low serum vitamin B_{12} level (less than 200 pg/mL [less than 148 pmol/L]), and low Hct.

In the early stages of vitamin B_{12} deficiency, classic signs and symptoms of megaloblastic anemia may not be evident, and serum levels of vitamin B_{12} may be within normal limits. Therefore, measurement of MMA and homocysteine may be useful because these parameters are typically the first to change. Because MMA and homocysteine are involved in enzymatic reactions that depend on vitamin B_{12}, a deficiency in vitamin B_{12} leads to accumulation of these metabolites. Elevations in MMA are more specific for vitamin B_{12} deficiency. Homocysteine is also elevated in several other situations including folate deficiency, chronic renal disease, alcoholism, smoking, use of steroid or cyclosporine therapy, and smoking.[34] Low levels of vitamin B_{12} result in hyperhomocysteinemia, which some studies have reported to be an independent risk factor for cerebrovascular, peripheral vascular, coronary, and venous thromboembolic disease.[35]

Blood levels of vitamin B_{12} should be drawn for all patients with suspected vitamin B_{12} deficiency. Vitamin B_{12} values less than 200 pg/mL (less than 148 pmol/L) are suggestive of B_{12} deficiency. Some patients with clinical B_{12} deficiency manifesting as neurological disease may have normal hematological parameters.

Clinical Controversy…

Subclinical vitamin B_{12} deficiency is sometimes used with vitamin B_{12} levels 200 to 300 pg/mL (148-221 pmol/L).[36] A general multivitamin does not typically contain enough vitamin B_{12} to normalize levels in deficient persons. Whether to treat patients in this range is not clear in the absence of neurologic symptoms.

A Schilling test may theoretically be performed to diagnose pernicious anemia, but the usefulness of this test is questionable and rarely alters the clinical management of the vitamin B_{12} deficiency. The Schilling test was once performed to determine whether replacement of vitamin B_{12} should occur via an oral or parenteral route, but evidence now shows that oral replacement is as efficacious as parenteral supplementation because of the vitamin B_{12} absorption pathway independent of intrinsic factor.[31,37]

TREATMENT

Vitamin B_{12} Deficiency Anemia

The goals of treatment for vitamin B_{12} deficiency include reversal of hematologic manifestations, replacement of body stores, and prevention or resolution of neurologic manifestations. Early treatment is of paramount importance because neurologic damage may be irreversible if the deficiency is not detected and corrected within months. In addition to replacement therapy, any underlying etiology that is treatable, such as bacterial overgrowth, should be corrected. Indications for starting oral or parenteral therapy include megaloblastic anemia or other hematologic abnormalities and neurologic disease from deficiency.[34] Those with borderline low levels of B_{12} but no hematologic abnormalities should be followed at yearly intervals.[34] Patients should be counseled on the types of foods high in vitamin B_{12} content such as fortified cereals as seen in **Table 100-4**. Orally administered vitamin B_{12} can be used effectively to treat pernicious anemia because of the previously discussed alternate pathway of passive absorption, independent of intrinsic factor.[14] Daily oral doses (1,000-2,000 mcg) of vitamin B_{12} is as effective as intramuscular administration in achieving hematologic and neurologic responses.[31,37] If vitamin B_{12} levels are marginally low and either MMA or both MMA and homocysteine levels are elevated, administration of 1,000 mcg of oral vitamin B_{12} daily should be strongly considered.[38] Timed-release preparations of oral cobalamin should be avoided.[39] Nonprescription 1,000 mcg cobalamin tablets are available, among several other strengths. A commonly used initial parenteral vitamin B_{12} regimen consists of daily injections of 1,000 mcg of cyanocobalamin for 1 week to saturate vitamin B_{12} stores in the body and resolve clinical manifestations of the deficiency. Thereafter, it can be given weekly for 1 month and monthly thereafter for maintenance. The series of daily parenteral injections may be omitted if administration is difficult or inconvenient. In this case the parenteral injection is then given weekly, sometimes for a longer than 1 month. Parenteral therapy is preferred for patients exhibiting neurologic symptoms until resolution of symptoms and normalization of hematologic indices because the most rapid-acting therapy is necessary.[40] When patients are converted from the parenteral to the oral form of cobalamin, 1,000 mcg of oral cobalamin daily can be initiated on the due date of the next injection. Vitamin B_{12} should be continued for life in patients with pernicious anemia.

TABLE 100-4 Good Sources of Vitamin B_{12}

Food	Serving Size	Amount (mcg)
Beef liver, cooked	3 oz (85g)	70
Breakfast cereal, fortified (100%)	3/4 cup (180 mL)	6

Food	Serving Size	Amount (mcg)
Rainbow trout, cooked	3 oz (85g)	3.5
Sockeye salmon, cooked	3 oz (85g)	4.9
Beef, cooked	3 oz (85g)	2.1
Breakfast cereal, fortified (25%)	¾ cup (180 mL)	1.5
Clams, cooked	3 oz (85g)	84.1
Oysters, breaded and fried	6 pieces	1
Tuna, canned in water	3 oz (85g)	2.5
Milk	1 cup (240 mL)	1.2
Yogurt	8 oz (230g)	1.1

In addition to the oral and parenteral forms, vitamin B_{12} is available as a nasal spray for patients in remission following intramuscular vitamin B_{12} therapy who have no nervous system involvement. The nasal spray is administered once weekly. Intranasal administration should be avoided for patients with nasal diseases or those receiving medications intranasally in the same nostril. Patients should not administer the spray 1 hour before or after ingestion of hot foods or beverages, which can impair cobalamin absorption. The efficacy of the nasal spray formulation has not been well studied, and it should be used for maintenance therapy only after hematologic parameters have normalized.

Potential adverse effects with vitamin B_{12} replacement therapy are rare. Uncommon side effects include hyperuricemia and hypokalemia due to marked increase in potassium utilization during production of new hematopoietic cells.

Folic Acid Deficiency Anemia

Epidemiology

Folic acid deficiency is one of the most common vitamin deficiencies occurring in the United States, largely because of its association with excessive alcohol intake and pregnancy.

Etiology

5 Major causes of folic acid deficiency include inadequate intake, decreased absorption, and increased folate requirements. Poor eating habits make this deficiency more common in elderly patients, teenagers whose diets consist of “junk food,” alcoholics, food faddists, the impoverished, and those who are chronically ill or demented. Folic acid absorption may decrease for patients who have malabsorption syndromes or those who have received certain drugs. In alcoholics with poor dietary habits, alcohol interferes with folic acid absorption, interferes with folic acid utilization at the cellular level, and decreases hepatic stores of folic acid.

Increased folate requirements may occur when the rate of cellular division is increased, as seen in pregnant women; patients with hemolytic anemia, myelofibrosis, malignancy, chronic inflammatory disorders such as Crohn’s disease, rheumatoid arthritis, or psoriasis; patients undergoing long-term

dialysis; burn patients; and adolescents and infants during their growth spurts. This hyperutilization eventually can lead to anemia, particularly when the daily intake of folate is borderline, resulting in inadequate replacement of folate stores.

Several drugs have been reported to cause a folic acid deficiency. Some drugs (eg, azathioprine, 6-mercaptopurine, 5-fluorouracil, hydroxyurea, and zidovudine) directly inhibit DNA synthesis. Other drugs are folate antagonists; the most toxic is methotrexate (other examples include pentamidine, trimethoprim, and triamterene). A number of drugs (eg, phenytoin, phenobarbital, and primidone) antagonize folate via poorly understood mechanisms but are thought to reduce vitamin absorption by the intestine (see Chapter e103). Since folic acid doses as low as 1 mg/day may affect serum phenytoin levels, routine folic acid supplementation is not generally recommended. The decline in phenytoin concentration usually occurs within the first 10 days and may decrease phenytoin levels by 15% to 50%.[41] Alcohol can also interfere with folic acid and vitamin B_{12} absorption likely through its effects on the intestinal mucosa.[33]

Pathophysiology

Folic acid is a water-soluble vitamin readily destroyed by cooking or processing. It is necessary for the production of DNA and RNA. It acts as a methyl donor to form methylcobalamin, which is used in the remethylation of homocysteine to methionine. Because humans are unable to synthesize sufficient folate to meet total daily requirements, they depend on dietary sources. Major dietary sources of folate include fresh, green leafy vegetables, citrus fruits, yeast, mushrooms, dairy products, and animal organs such as liver and kidney. Most folate in food is present in the polyglutamate form, which must be broken down into the monoglutamate form prior to absorption in the small intestine. Once absorbed, dietary folate must be converted to the active form tetrahydrofolate through a cobalamin-dependent reaction. In 1997, the United States mandated that grain products be fortified with folic acid in an attempt to increase the dietary intake of folate. This amount of supplementation was chosen to decrease the incidence of neural tube defects without masking occult vitamin B_{12} deficiency.
