As a result of grain product fortification, neural tube defect frequency has decreased by 25% to 30%.[42] Although body demands for folate are high because of high rates of RBC synthesis and turnover, the minimum daily requirement is 50 to 100 mcg. In the general population, the recommended daily allowance for folate is 400 mcg in nonpregnant females, 600 mcg for pregnant females, and 500 mcg for lactating females.[38] Because the body stores about 5 to 10 mg of folate, primarily in the liver, cessation of dietary folate intake can result in deficiency within 3 to 4 months.

Laboratory Findings

It is of paramount importance to rule out vitamin B_{12} deficiency when folate deficiency is suspected. Laboratory changes associated with folate deficiency are similar to those seen in vitamin B_{12} deficiency, except vitamin B_{12} and MMA levels are normal. Serum folate levels decrease to less than 3 ng/mL (7 nmol/L) within a few days of reduced dietary folate intake. The RBC folate level (less than150 ng/mL [less than 340 nmol/L]) also declines, and levels remain constant throughout the life

span of the erythrocyte.[12] If serum or erythrocyte folate levels are borderline, serum homocysteine usually is increased with a folic acid deficiency. If serum MMA levels also are elevated, vitamin B_{12} deficiency must be ruled out given that folate does not participate in MMA metabolism.

TREATMENT

Folic Acid Deficiency Anemia

Therapy for folic acid deficiency consists of administration of exogenous folic acid to induce hematologic remission, replace body stores, and resolve signs and symptoms. In most cases, 1 mg daily is sufficient to replace stores, except in cases of deficiency due to malabsorption, in which case doses of 1 to 5 mg daily may be necessary. Parenteral folic acid is available but rarely necessary. Synthetic folic acid is almost completely absorbed by the GI tract and is converted to tetrahydrofolate without cobalamin. Therapy should continue for about 4 months if the underlying cause of the deficiency can be identified and corrected to allow for clearance of all folate-deficient RBCs from the circulation. Foods high in folic acid should also be encouraged in the diet as seen in **Table 100-5**. Long-term folate administration may be necessary in chronic conditions associated with increased folate requirements. Low-dose folate therapy (500 mcg daily) can be administered when anticonvulsant drugs produce a megaloblastic anemia so that discontinuation of anticonvulsant therapy may not be necessary. Adverse effects have not been reported with folic acid doses used for replacement therapy. It is considered nontoxic at high doses and is rapidly excreted in the urine.

TABLE 100-5 Good Sources of Folate

Food	Serving	Amount (mcg)
Beef liver	3 oz (85g)	215
Cereal, 25% fortified	½-1½ cups (120-360 mL)	100-400
Lentils, cooked	1/2 cup (120 mL)	180
Chickpeas	1/2 cup (120 mL)	141
Asparagus	1/2 cup (120 mL)	132
Spinach, cooked	1/2 cup (120 mL)	131
Pasta, enriched	1/2 cup (120 mL)	83
Kidney beans	1/2 cup (120 mL)	46
White rice, cooked	1/2 cup (120 mL)	90
Tomato juice	1 cup (240 mL)	48
Brussels sprouts	1/2 cup (120 mL)	78
Orange	1 medium	47

Although megaloblastic anemia during pregnancy is rare, the most common cause is folate deficiency. The condition usually manifests as an underweight premature infant and suboptimal health of the mother. Periconceptional folic acid supplementation is recommended to decrease the occurrence and recurrence of neural tube defects, specifically anencephaly and spinal bifida. Folic acid supplementation at a dose of 400 mcg daily is recommended for all women. Women who have previously given birth to offspring with neural tube defects or those with a family history of neural

tube defects should ingest 4 mg daily of folic acid.[41,42,43] Higher levels of folic acid supplementation should not be attained via ingestion of excess multivitamins because of the risk for fat soluble vitamin toxicity.[43] Prenatal vitamins usually have a higher amount of folic acid as compared with general multivitamins to ensure adequate supplementation is attained. It is essential that women in their childbearing years maintain adequate folic acid intake.

ANEMIA OF INFLAMMATION

Epidemiology

6 AI is a newer term used to describe both ACD and anemia of critical illness. This new term was developed to reflect the inflammatory process that underlies both of those types of anemia. The onset of anemia of critical illness is quicker, over days, and typically occurs in a hospital setting. ACD has a similar mechanism, but it develops over months to years from a chronic condition. AI is one of the most common forms of anemia seen clinically, particularly among the elderly. It is especially important in the differential diagnosis of iron deficiency. ACD is associated with common disease states that may mimic the symptoms of anemia, which causes the diagnosis of ACD to sometimes be overlooked in the outpatient setting. Anemia of critical illness is a common complication in critically ill patients and is found almost universally in this patient population.[44]

Etiology

The diagnosis of AI usually is one of exclusion. It is important to exclude IDA as the true or competing etiology. Various conditions associated with ACD may predispose patients to blood loss (malignancy, GI blood loss from treatments with aspirin, NSAIDs, or corticosteroids). ACD is often observed in patients with diseases that last longer than 1-2 months, although it can occur in conditions with a more rapid onset of several weeks, such as pneumonia. ACD tends to be a mild (Hb greater than 9.5 g/dL [greater than 95 g/L; greater than 5.90 mmol/L]) or moderate (Hb greater than 8 g/dL [greater than 80 g/L; greater than 4.97 mmol/L]) anemia.[45] Anemia associated with human immunodeficiency virus (HIV), autoimmune conditions, cancer, and heart failure are common forms of ACD. The degree of anemia in ACD is generally reflects the severity of underlying disease. **Table 100-6** lists common diseases associated with ACD.

TABLE 100-6 Diseases Causing Anemia of Inflammation

Common causes
Chronic infections
Tuberculosis
Other chronic lung infections (eg, lung abscess, bronchiectasis)
Human immunodeficiency virus

- Subacute bacterial endocarditis
- Osteomyelitis
- Chronic urinary tract infections

- Chronic inflammation
  - Rheumatoid arthritis
  - Systemic lupus erythematosus
  - Inflammatory bowel disease
  - Inflammatory osteoarthritis
  - Gout
  - Other (collagen vascular) diseases
  - Chronic inflammatory liver diseases

- Malignancies
  - Carcinoma
  - Lymphoma
  - Leukemia
  - Multiple myeloma

Less common causes

- Alcoholic liver disease
- Congestive heart failure
- Thrombophlebitis
- Chronic obstructive pulmonary disease
- Ischemic heart disease

Factors that may contribute to anemia in critically ill patients include sepsis, frequent blood sampling, surgical blood loss, immune-mediated functional iron deficiency, decreased production of endogenous EPO, reduced RBC life span, and active bleeding, especially in the GI tract. A combination of these factors often exists, creating an anemic state over days. Additional comorbid factors include coagulopathies and nutritional deficits such as poor oral intake and altered absorption of vitamins and minerals, including iron, vitamin B_{12}, and folate.[46] Deleterious effects of anemia

include an increased risk of cardiac-related morbidity and mortality, especially for patients with known cardiovascular disease. Persistent tissue hypoxia can result in cerebral ischemia, myocardial ischemia, multiple organ deterioration, lactic acidosis, and death. Consequences of anemia in critically ill patients may be enhanced because of the increased metabolic demands of critical illness. Weaning anemic patients from mechanical ventilation may be more difficult.[47]

Pathophysiology

AI is a response to stimulation of the cellular immune system by various underlying disease processes. AI is an anemia that traditionally has been associated with infectious or inflammatory processes, tissue injury, and conditions associated with release of proinflammatory cytokines. The pathogenesis of AI is multifactorial and is characterized by a blunted EPO response to anemia, an impaired proliferation of erythroid progenitor cells, and a disturbance of iron homeostasis. Increased iron uptake and retention occur within cells. The RBCs have a shortened life span, and the bone marrow's capacity to respond to EPO is inadequate to maintain normal Hb concentration. The cause of this defect is uncertain but appears to involve blocked release of iron from cells in the bone marrow. Iron availability to erythroid progenitor cells then is limited. Various cytokines, such as interleukin-1, interferon-γ, interleukin-6, and tumor necrosis factor released during illness may inhibit the production or action of EPO or the production of RBCs.[45] These cytokines also upregulate hepcidin, which blocks iron release from storage cells.[48] Hepcidin also decreases duodenal absorption of iron.[45]

Laboratory Findings

No definitive test can confirm the diagnosis of AI. The practitioner should maintain a high index of suspicion for any patient with a chronic inflammatory or neoplastic disease. AI may coexist with IDA and folic acid deficiency because many patients with these conditions have poor dietary intake or GI blood loss. Examination of the bone marrow reveals an abundance of iron, suggesting that the release mechanism for iron is the central defect. Patients with AI usually have a decreased serum iron level, but unlike patients with IDA, their serum ferritin level is normal or increased and their TIBC is decreased. Transferrin saturation is typically decreased. AI usually is normocytic and normochromic with mildly depressed Hb. Patients with concurrent AI and IDA usually have microcytes and a more severe anemia. **Table 100-7** shows lab values seen in AI and IDA. Erythrocyte survival may be reduced for patients with AI, but a compensatory erythropoietic response does not occur. A low reticulocyte count indicates underproduction of RBCs.[45] As discussed in the IDA section, hepcidin levels are not routinely used for diagnosis but would likely be elevated in a patient with ACD.[49]

TREATMENT

Anemia of Inflammation

Treatment of AI depends somewhat on the underlying etiology. Guidelines exist for management of anemia for patients with cancer or chronic kidney disease (see Chaps. 44 and 127). Although the goals of therapy should include treating the underlying disorder and correcting reversible causes of anemia, accomplishment of these goals may not totally reverse hematologic and physiologic abnormalities. Iron is effective only if iron deficiency is present. During inflammation, oral or parenteral iron therapy may not be as effective. Absorption is impaired because of downregulation of ferroportin and iron diversion mediated by cytokines.[45] Because iron is a required nutrient for proliferating microorganisms, supplementation may theoretically increase the risk of infections. Iron therapy should be reserved for those patients with an established iron deficiency.[45]

RBC transfusions are effective but should be limited to situations in which oxygen transport is inadequate due to concomitant medical problems. Transfusions are typically considered for those with severe anemia (Hb less than 7 to 8 g/dL [less than 70 to 80 g/L; less than 4.34 to 4.97 mmol/L]). Transfusion risks may include transmission of blood-borne infections, development of autoantibodies, transfusion reactions, and iron overload.

ESAs have been used to stimulate erythropoiesis for patients with AI since a relative EPO deficiency exists for the degree of anemia. Two agents are available: recombinant epoetin alfa and recombinant darbepoetin alfa. Although both agents share the same mechanism of action, darbepoetin alfa has a longer half-life and can be administered less frequently. Although these agents are sometimes used to treat AI, they are not FDA-approved for this indication. Patients with chronic disease may have a relatively impaired response to ESAs. The initial dosage of epoetin alfa and darbepoetin alfa are typically 50 to 100 units per kilogram three times per week and 0.45 mcg per kilogram once weekly, respectively. These doses are typical starting doses for those with chronic kidney disease. Response to ESAs varies depending on dose and cause of the anemia. Higher doses may be needed to overcome hyporesponsiveness. ESA treatment is effective when the marrow has an adequate supply of iron, cobalamin, and folic acid.

Iron deficiency can occur in patients treated with ESAs; so close monitoring of iron levels is necessary. Some patients develop “functional” iron deficiency, in which the iron stores are normal but the supply of iron to the erythroid marrow is less than necessary to support the demand for RBC production. Therefore, many practitioners routinely supplement ESA therapy with oral or IV iron therapy. Potential toxicities of exogenous ESA administration include increases in blood pressure, nausea, headache, fever, bone pain, and fatigue. Less common adverse effects include seizures, thrombotic events, and allergic reactions such as rashes and local reactions at the injection site. If ESAs are used, the

practitioner must monitor to ensure the patient's Hb does not exceed 12 g/dL (120 g/L; 7.45 mmol/L) with treatment or that Hb does not rise greater than 1 g/dL (greater than 10 g/L; greater than 0.62 mmol/L) every 2 weeks since both of these events have been associated with increased mortality and cardiovascular events.[50] Tumor progression with these agents can also occur and is discussed in Chapter 127. Further discussion of dosing guidelines and potential adverse outcomes of ESA treatment in populations for which treatment is FDA approved are discussed in Chapters 44 and 127.

Patients who are critically ill require the necessary substrates of iron, folic acid, and vitamin B_{12} for RBC production. Parenteral iron is generally preferred in this population because patients often are undergoing enteral therapy or because of concerns regarding inadequate iron absorption. The disadvantage of parenteral therapy is the theoretical risk of infection.

Pharmacologic doses of ESAs have been used to treat the anemia of critical illness. Few randomized controlled trials have evaluated the role of ESAs in critically ill patients, and the results of these trials have not consistently shown a decrease in transfusion requirements in ESA-treated patients.[51] Further investigation is necessary to determine the effectiveness of ESAs in critically ill patients. These agents are not FDA approved in this setting.

Many critically ill patients receive RBC transfusions despite the inherent risks associated with transfusions. Stored RBCs may not function as well as endogenous blood. Although RBC transfusions may increase oxygen delivery to tissues, cellular oxygen may not increase.[52] Transfusion practices in ICUs vary, and clinicians use different Hb concentrations as thresholds for administering transfusions. The decision to use transfusions must consider the risks, including transmission of infections; volume overload, especially for patients with renal or heart failure; iron overload; and immune-mediated reactions such as febrile reactions, hemolysis, and anaphylaxis. The clinician also must consider administrative, logistic, and economic factors, including the shortage of blood supplies.

The recognition of hepcidin in the regulation of iron homeostasis and its role in ACD has led to interest in new agents targeted at hepcidin, including direct hepcidin antagonists and other novel agents.[49]

ANEMIA IN THE ELDERLY

Epidemiology

7 One of the most common clinical problems observed in the elderly is anemia. Anemia is a prevalent and increasing problem in the elderly, with about 20% of people 85 years and older affected.[53] Elderly patients with the highest incidence of anemia are those who are hospitalized, followed by residents of nursing homes and other institutions, with an estimated rate of 31% to 40%.[54] Although the incidence of anemia is high in the elderly, anemia should not be regarded as an inevitable outcome of aging. The body's set point of Hb does not fall with age. An underlying cause can be identified in about two-thirds of older patients. Undiagnosed and untreated anemia has been associated with adverse outcomes, including all-cause hospitalization, hospitalization secondary to

cardiovascular disease, and all-cause mortality.[55] Anemia is an independent predictor of death and major clinical adverse events in elderly patients with stable symptomatic coronary artery disease.[56] Anemia can exacerbate neurologic and cognitive conditions and can adversely influence quality of life and physical performance in the elderly.[57] Anemia may be an indication of serious diseases such as cancer.

Pathophysiology

Aging is associated with a progressive reduction in hematopoietic reserve, which makes individuals more susceptible to developing anemia in times of hematopoietic stress.[58] Dysregulation of proinflammatory cytokines, most notably interleukin-6, may inhibit EPO production or interact with EPO receptors.[59] Although Hb levels may remain normal, the diminished marrow reserve leaves the elderly patient more susceptible to other causes of anemia. Renal insufficiency, which also is common in elderly patients, may reduce the ability of the kidneys to produce EPO. Older patients often have a normal creatinine level but a diminished glomerular filtration rate. Myelodysplastic syndromes are another common cause of anemia in the elderly, but most anemia cases in the elderly are multifactorial.

Etiology

In the acute care setting, the top three causes of anemia in the elderly are chronic disease (35%), unexplained cause (17%), and iron deficiency (15%), whereas in community-based outpatient clinics, the most common causes are unexplained (36%), infection (23%), and chronic disease (17%).[60] Another common problem in the elderly is vitamin B_{12} deficiency. The most common causes of clinically overt vitamin B_{12} deficiency are food/cobalamin malabsorption (more than 60% of cases) and pernicious anemia (15%-20% of cases).[61]

One often-overlooked major factor that may contribute to anemia in the older population is nutritional status. Cognitive and functional impairments in the older population may create barriers for patients to obtain and prepare a nutritious diet. Nutritional deficiencies that are not severe enough to affect the hematopoietic system in the younger population may contribute to anemia in the elderly. Edentulous or infirm elderly who may be too ill to prepare their meals are at risk for nutritional folate deficiency. Risk factors for inadequate folate intake in the elderly include low caloric intake, inadequate consumption of fortified cereals, and failure to take a vitamin/mineral supplement. However, unlike cobalamin levels, folate levels often increase rather than decline with age. High folic acid intake can occur if the elderly patient regularly uses a supplement and consumes fortified cereals.[62,63]

Bleeding with resultant iron deficiency in the elderly may be due to carcinoma, peptic ulcer, atrophic gastritis, drug-induced gastritis, postmenopausal vaginal bleeding, or bleeding hemorrhoids. Elderly women have a much lower incidence of IDA compared with younger, menstruating women. Until proven otherwise, iron deficiency in the elderly should be considered a sign of chronic blood loss. Steps should be taken to rule out bleeding, especially from the GI or female reproductive tract. AI is

more common in the elderly, as diseases that contribute to AI such as cancer, infection, and rheumatoid arthritis are more prevalent in this population.

Laboratory Findings

For practical purposes, it is best to use usual adult reference values and WHO criteria for laboratory tests in the elderly. Anemia in elderly persons usually is normocytic and mild, with Hb values ranging between 10 and 12 g/dL (100-120 g/L; 6.21-7.45 mmol/L) in most anemic patients.[53] Evaluation of an elderly patient should be similar to strategies described previously for younger adults, perhaps with more emphasis on identifying occult blood loss and vitamin B_{12} deficiency. Vitamin B_{12} deficiency may be present even when plasma levels of vitamin B_{12} are within the normal range, but elevated MMA levels will reveal the deficiency. A refractory macrocytic anemia in the elderly should raise suspicion of a myelodysplastic syndrome.

TREATMENT

Anemia in the Elderly

Treatment of anemia in the elderly is the same as that described for each type of anemia discussed in this chapter. With IDA it is essential to treat the underlying cause, if known (ie, bleeding), and administer iron supplementation. Lower doses of iron supplementation are often recommended in the elderly (eg, 325 mg of ferrous sulfate once daily) to decrease the incidence of GI adverse effects, which can lead to additional morbidity and poor adherence. The goal of treatment of AI is resolution of the underlying cause, although curing the underlying chronic illness for elderly patients can be difficult. Routine treatment with ESAs is not currently standard of care for AI in the elderly.

ANEMIA IN PEDIATRIC POPULATIONS

Epidemiology

7 IDA is a leading cause of infant morbidity and mortality around the world.[64] Data from NHANES III indicated that 9% of children ages 12 to 36 months in the United States had iron deficiency and 3% had IDA.[65,66] Lack of a normal Hb at birth directly affects nonstorage iron and increases the risk of IDA in the first 3 to 6 months of life. African American or Hispanic-American children have a higher incidence of anemia.[67] Requirements for iron absorption peak during puberty. An anemia of prematurity can occur 3 to 12 weeks after birth in infants younger than 32 weeks' gestation and spontaneously resolves by 3 to 6 months. The prevalence of vitamin B_{12} deficiency has been identified as 1 in 1,255 for levels less than 100 pg/mL (less than 74 pmol/L) and 1 in 200 for levels less than 200 pg/mL (less than 148 pmol/L), with the lowest levels in non-Hispanic whites.[68]

Pathophysiology

In contrast to anemias in adults, which tend to be manifestations of a broader underlying pathology,

anemias in the pediatric population are more often due to a primary hematologic abnormality. The amount of iron present at birth depends on gestational length and weight. A decrease in EPO production results in a physiologic anemia peaking at 2 months.[69] Iron stores from birth are mostly depleted by 6 months of age.

Etiology

The age of the child can yield some clues regarding the etiology of the anemia. The optimal amount of nutritional iron and folate required varies among individuals based on life-cycle stages. Two peak periods place children at risk of developing IDA. The first peak occurs during late infancy and early childhood, when children undergo rapid body growth, have low levels of dietary iron, and exhaust stores accumulated during gestation. The second peak occurs during adolescence, which is associated with rapid growth, poor diets, and onset of menses in girls. Some studies suggest that overweight children are at significantly higher risk for IDA. Proposed factors include genetic influences; physical inactivity, leading to decreased myoglobin breakdown and lower amounts of released iron into the blood; and inadequate diet with limited intake of iron-rich foods.[70]

Conditions in the newborn period that can lead to IDA include prematurity and insufficient dietary intake. Premature infants are at increased risk for IDA because of their smaller total blood volume, increased blood loss through phlebotomy, and poor GI absorption. Factors leading to unbalanced iron metabolism in infants include insufficient iron intake, early introduction of cow's milk, intolerance of cow's milk, medications, and malabsorption. Dietary deficiency of iron in the first 6 to 12 months of life is less common today because of the increased use of iron supplementation during breast-feeding and use of iron-fortified formulas. Iron deficiency becomes more common when children change to regular diets.

When screening for iron deficiency in young children, a careful dietary history can help identify children at risk. High iron needs and the tendency to eat fewer iron-containing foods contribute to the etiology of iron deficiency during adolescence.

Other causes of microcytic anemia include thalassemia, lead poisoning, and sideroblastic anemia. Use of homeopathic or herbal medications and exposure to paint or certain cooking materials may place children at risk for lead exposure. Normocytic anemias in children include infection with human parvovirus B19 and glucose-6-phosphate dehydrogenase (G6PD) deficiency. Macrocytic anemias are caused by deficiencies in vitamin B_{12} and folate, chronic liver disease, hypothyroidism, and myelodysplastic disorders. Folic acid deficiency usually is due to inadequate dietary intake, but human milk and cow's milk provide adequate sources. Folic acid deficiency may be seen in infants and children who primarily consume goat's milk or health food milk alternatives, or in children with insufficient intake of green leafy vegetables. Vitamin B_{12} deficiency due to nutritional reasons is rare but may occur due to a congenital pernicious anemia.

Laboratory Findings

When evaluating laboratory values for pediatric patients, the clinician must use age- and

sex-adjusted norms. It is important to know that many blood samples are capillary samples, such as heel or finger sticks, which may have slightly different results than venous samples. The USPSTF has concluded that evidence is insufficient to recommend for or against routine screening for IDA in asymptomatic, low risk, children aged 6 to 12 months. Hb is a sensitive test for iron deficiency, but it has low specificity in childhood anemias. If an abnormality is found, a CBC should be ordered to evaluate MCV and determine whether the anemia is microcytic, normocytic, or macrocytic. A peripheral blood smear and reticulocyte count also may be helpful. The peripheral blood smear can indicate the etiology based on RBC morphology, and the reticulocyte count helps differentiate between decreased RBC production and increased RBC destruction or loss. Other laboratory tests include serum iron, ferritin, TIBC, and transferrin saturation. Mild hereditary anemias may produce a mild hypochromic microcytic anemia that can be confused with IDAs. The RDW may be high with iron deficiency and is more likely to be normal with thalassemia. Laboratory features of anemia of prematurity include normocytic normochromic cells, low reticulocyte count, low serum EPO concentrations, and decreased RBC precursors in bone marrow. Laboratory diagnosis of vitamin B_{12} and folate deficiency in children is similar to that of adults.

TREATMENT

Anemia in Pediatric Populations

Primary prevention of IDA in infants, children, and adolescents is the most appropriate goal because delays in mental and motor development are potentially irreversible. In 2006, the USPSTF published revised recommendations to screen and supplement iron deficiency in the United States, focusing on children and pregnant women.[17] The USPSTF recommends routine iron supplementation for asymptomatic children aged 6 to 12 months who are at increased risk for IDA. Fair evidence was found that iron supplementation (eg, iron-fortified formula or iron supplements) might improve neurodevelopmental outcomes in children at risk for IDA. The quality of evidence of benefit for children 6 to 12 months of age not at risk for IDA was poor.

Interventions likely to prevent anemia include diverse foods with bioavailable forms of iron, food fortification for infants and children, and individual supplementation. Routine screening for iron deficiency in nonpregnant adolescents is recommended only for those with risk factors, which include vegetarian diets, malnutrition, low body weight, chronic illness, or history of heavy menstrual blood loss.

For infants aged 9 to 12 months with a mild microcytic anemia, the most cost-effective treatment is a therapeutic trial of iron. Fe^{2+} sulfate at a dose of 3 to 6 mg/kg/day of elemental iron divided once or twice daily between meals for 4 weeks is recommended. In children who respond, iron should be continued for two more months to replace storage iron pools, along with dietary intervention and patient education.[71] Parenteral iron therapy has a limited role and is rarely necessary.

For the macrocytic anemias in children, folate can be administered in a dose of 1 mg daily. However, vitamin B_{12} deficiency due to congenital pernicious anemia requires lifelong vitamin B_{12} supplementation. Dose and frequency should be titrated according to clinical response and laboratory values. No data regarding the use of oral vitamin B_{12} supplementation in children are

available.

PERSONALIZED PHARMACOTHERAPY

In the treatment of the anemias discussed in this chapter, personalized pharmacotherapy is important in a few populations. When treating IDA, the elderly should be treated with lower doses of oral iron therapy. This typically is once daily dosing with ferrous sulfate 325 mg. Patients with immune-mediated disease are at higher risk for having hypersensitivity reactions to parenteral iron therapy. Patients who have neurologic symptoms upon diagnosis of vitamin B_{12} deficiency should strongly be considered for parenteral B_{12} supplementation. If ESAs are used to treat AI, iron status should be closely monitored to ensure efficacy of these agents as functional iron deficiency can develop.

EVALUATION OF THERAPEUTIC OUTCOMES

For IDA, a positive response to a trial of oral iron therapy is characterized by a modest reticulocytosis in days, with an increase in Hb starting after about 2 weeks with continued rapid rise in Hb. As the Hb level approaches normal, the rate of increase slows progressively. Hb should reach a normal level after about 2 months of therapy and often sooner.[9] If the patient does not develop reticulocytosis, reevaluation of the diagnosis or iron replacement therapy is necessary. Iron therapy should continue for a period sufficient for complete restoration of iron stores. Serum ferritin concentrations should return to the normal range prior to discontinuation of iron. The time interval required to accomplish this goal varies, although at least 6 to 12 months of therapy usually is warranted.

When large amounts of parenteral iron are administered, by either total dose infusion or multiple intramuscular or IV doses, the patient's iron status should be closely monitored. Patients receiving regular IV iron should be monitored for clinical or laboratory evidence of iron toxicity or overload. Iron overload may be indicated by abnormal hepatic function tests, serum ferritin greater than 800 ng/mL (greater than 800 mcg/L [1800 pmol/L]), or transferrin saturation greater than 50%. Serum ferritin and transferrin saturation should be measured in the first week after larger IV iron doses. Hb and Hct should be measured weekly, and serum iron and ferritin levels should be measured at least monthly.

In the treatment of vitamin B_{12} deficiency anemia, most patients respond rapidly to vitamin B_{12} therapy. The typical patient will experience an improvement in strength and well-being within a few days of treatment initiation. Reticulocytosis is evident in 3 to 5 days. Hb begins to rise after the first week and should normalize in 1-2 months. CBC count and serum cobalamin levels usually are drawn one to 2 months after initiation of therapy and 3 to 6 months thereafter for surveillance monitoring. Homocysteine and MMA levels can be repeated 2-3 months after initiation of replacement therapy to evaluate for normalization of levels, although levels begin to decrease in 1-2 weeks. Neuropsychiatric signs and symptoms can be reversible if treated early. If permanent neurologic damage has resulted, progression should cease with replacement therapy. Slow response to therapy or failure to observe normalization of laboratory results may suggest the presence of an additional abnormality such as iron deficiency, thalassemia trait, infection, malignancy, nonadherence, or misdiagnosis.

In folic acid deficiency anemia, symptomatic improvement, as evidenced by increased alertness and appetite, often occurs early during the course of treatment. Reticulocytosis begins in the first week. Hct begins to rise within 2 weeks and should reach normal levels within 2 months. MCV initially increases because of an increase in reticulocytes but gradually decreases to normal.

One of the earliest responses with ESA use is an increase in blood reticulocyte count, which usually occurs in the first few days. Baseline iron status should be checked before and during treatment, as many patients receiving ESAs require supplemental iron therapy. The optimal form and schedule of iron supplementation are not known. Hb levels should be monitored twice a week until stabilized. Hb should also be monitored twice weekly for 2 to 6 weeks after a dose adjustment.[46] A fall in Hb during ESA therapy may indicate a need for iron supplementation or signal occult blood loss. Baseline and periodic monitoring of iron, TIBC, transferrin saturation, or ferritin levels may be useful in optimizing iron repletion and limiting the need for ESAs. Patients who do not respond to 8 weeks of optimal dosage should not continue taking ESAs. Target Hb levels should be 11 to 12 g/dL (110-120 g/L; 6.83-7.45 mmol/L). Cost is an issue with ESA therapy; therefore, drug cost must be weighed against the effects on transfusions and hospitalizations.

Responses and monitoring of treatment are similar in the elderly as described for the general adult population described earlier in the chapter. If the reticulocyte count rises but the anemia does not improve, inadequate absorption of iron or continued blood loss should be suspected. As with any form of anemia, symptomatic improvement should be evident shortly after starting therapy and Hb/Hct should begin to rise within a few weeks of initiating therapy. A key component of symptom assessment among older adults is the functional domain. Patients should be asked about changes in self-care abilities, mobility, and stamina.

Therapeutic outcomes are assessed in children by monitoring Hb, Hct, and RBC indices 4 to 8 weeks after initiation of iron therapy. For premature infants, Hb or Hct should be monitored weekly.

Chapter 101: Coagulation Disorders

Heidi Trinkman; Donald Beam; Tracy Hagemann

INTRODUCTION

Key Concepts

- 1 Hemophilia is an inherited bleeding disorder resulting from a congenital deficiency in factor VIII or IX.
- 2 The goal of therapy for hemophilia is to prevent bleeding episodes, and as a result their long-term complications, and to arrest bleeding if it occurs.
- 3 Recombinant factor concentrates usually are first-line treatment of hemophilia as they have the lowest risk of infection.
- 4 Inhibitor formation is the most significant treatment complication in hemophilia. It is associated with significant morbidity and decreased quality of life.
- 5 Recombinant factor VIIa is effective for the treatment of acute bleeds in patients with hemophilia A or B that has developed inhibitors.
- 6 The goal of therapy for von Willebrand disease (vWD) is to increase von Willebrand factor (vWF) and factor VIII levels to prevent bleeding during surgery or arrest bleeding when it occurs.
- 7 Factor VIII concentrates that contain vWF are the agents of choice for treatment of type 3 vWD and some type 2 von Willebrand disease, and for serious bleeding in type 1 von Willebrand disease.
- 8 Desmopressin acetate often is effective for treatment of type 1 vWD. It also may be effective for treatment of some forms of type 2 vWD in addition to mild to moderate hemophilia A.

The coagulation system is intricately balanced and designed to stop bleeding at the site of vascular injury through complex interactions between the vascular endothelium, platelets, procoagulant

proteins, anticoagulant proteins, and fibrinolytic proteins. Hemostasis stops bleeding at the site of vascular injury through the formation of an impermeable platelet and fibrin plug. Three key mechanisms facilitate hemostasis including vascular constriction, primary platelet plug formation (primary hemostasis), and clot propagation through fibrin formation (secondary hemostasis). Derangements in this system can lead to either bleeding or thrombosis. Bleeding disorders are the result of a coagulation factor defect, a quantitative or qualitative platelet defect or enhanced fibrinolytic activity.

COAGULATION FACTORS

Secondary hemostasis facilitates propagation and stabilization of the initial platelet plug formed in primary hemostasis through the formation of fibrin on the activated platelet surface. This step is initiated via the tissue factor pathway and is vital for adequate hemostasis. Coagulation factors circulate as inactive precursors (zymogens). Activation of these coagulation proteins leads to a cascading series of proteolytic reactions (Fig. 19-2). At each step, a clotting factor undergoes limited proteolysis and becomes an active protease (designated by a lowercase "a," as in Xa).

The coagulation factors can be divided into three groups on the basis of biochemical properties: vitamin K-dependent factors (II, VII, IX, and X), contact activation factors (XI and XII, prekallikrein, and high-molecular-weight kininogen), and thrombin-sensitive factors (V, VIII, XIII, and fibrinogen). Biologic half-life and blood product source varies by coagulation factor (**Table 101-1**).

TABLE 101-1 Blood Coagulation Factors

Factor *a*	Synonym	Biologic Half-life (h)	Blood Product Source
I	Fibrinogen	100-150	Cryoprecipitate (200-300 mg/bag)
II	Prothrombin	50-80	FFP, PCC
V	Proaccelerin	12-36	FFP
VII	Proconvertin	4-6	Recombinant VIIa, FFP, PCC
VIII	Antihemophilic factor	12-15	FFP, factor concentrates, cryoprecipitate
IX	Christmas factor	18-30	FFP, PCC, factor concentrates
X	Stuart-Power factor	25-60	FFP, PCC
XI	Plasma thromboplastin antecedent	40-80	FFP
XII	Hageman factor	50-70	Not associated with bleeding diathesis
XIII	Fibrin-stabilizing factor	150	FFP, cryoprecipitate, factor concentrate
VWF	von Willebrand factor	8-12	FFP, cryoprecipitate, factor concentrate

FFP, fresh-frozen plasma; PCC, prothrombin complex concentrate.

[a]Coagulation factors are numbered with roman numerals in order of their discovery. The most common synonyms are listed. Factor III (tissue factor) and factor IV (calcium ions) have been omitted. There is no factor VI.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The diagnosis of coagulation disorders can be established from a detailed clinical history, physical examination, and laboratory test results. The clinical history should ascertain if there is a family history of bleeding or known bleeding disorders. Laboratory testing can distinguish bleeding disorders caused by defects in the coagulation pathways (Fig. 19-4), fibrinolytic pathways, or alterations in the number or function of platelets. **Table 101-2** describes common coagulation tests.

TABLE 101-2 Laboratory Procedures

Procedure	Identifies	Coagulation Cause of Abnormal Value	Clinical Manifestations
Prothrombin time (PT)	Factors I, II, V, VII, X	Newborn Vitamin K deficiency Inherited factor deficiencies[a] Warfarin therapy Liver disease Lupus anticoagulant (rare) Afibrinogenemia Dysfibrinogenemia	Bleeding following surgery, trauma, etc. Easy bruising
Activated partial thromboplastin time (aPTT)	Factors I, II, V, VIII, IX, X	Inherited factor deficiencies[a] Lupus anticoagulant Heparin therapy Liver disease Afibrinogenemia Dysfibrinogenemia	Joint and muscle bleeding Bleeding after surgery, trauma, etc.
	HMWK, prekallikrein		No bleeding manifestations

Procedure	Identifies	Coagulation Cause of Abnormal Value	Clinical Manifestations
	Factor XII		Increased incidence of thrombotic disease possible with severe factor XII deficiency
	Factor XI		Variable bleeding tendency Bleeding following surgery, trauma, etc.
Thrombin time (TT)	Fibrinogen	Afibrinogenemia	Lifelong hemorrhagic disease
	Inhibitors of fibrin aggregation	Dysfibrinogenemia Heparin therapy	Variable clinical symptoms from asymptomatic to either a bleeding diathesis or prothrombotic
Platelet count	Thrombocytopenia	Quantitative platelet disorder, type 2B von Willebrand disease, immune thrombocytopenia, other cause of thrombocytopenia	Mucocutaneous bleeding
		Qualitative platelet defects, von Willebrand disease, antiplatelet therapy	
Platelet function analyzer	Platelet function	Also prolonged in anemia and thrombocytopenia **Insensitive to mild platelet defects and has fallen out of favor as a screening test*	Mucocutaneous bleeding
Platelet aggregation	Gold standard to assess platelet function	Qualitative platelet defects, antiplatelet medications	Mucocutaneous bleeding
Euglobulin clot lysis time (ECLT)	Fibrinolytic defect	A decreased ECLT indicates hyperfibrinolysis, which indicates an abnormality in the fibrinolytic pathway including: plasminogen activator inhibitor 1 deficiency, α_2-plasminogen inhibitor deficiency	Bleeding after trauma or surgical procedures especially in oral and urogenital areas
		Hypofibrinogenemia	

HMWK, high-molecular-weight kininogen.

[a]Bleeding manifestations depend on factor levels.

HEMOPHILIA

1 Hemophilia is a bleeding disorder that results from a congenital deficiency in a plasma coagulation protein. Hemophilia A (classic hemophilia) is caused by a deficiency of factor VIII, while hemophilia B (Christmas disease) is caused by a deficiency of factor IX. Hemophilia affects about 400,000 males worldwide.[1,2] The incidence of hemophilia A is about 1 in 5,000 male births and hemophilia B occurring in 1 in 30,000 male births.[2] Hemophilia A constitutes 80% to 85% of all patients with hemophilia with the other 15% to 20% being hemophilia B.[1] There are no significant racial differences in the incidence of hemophilia.

About one-third of patients with hemophilia have a negative family history, presumably representing a spontaneous mutation.[1] Both hemophilia A and hemophilia B are recessive X-linked diseases, which mean that the defective gene is located on the X chromosome. The disease primarily affects only males while females are carriers. Since affected males have the abnormal allele on their X chromosome and no matching allele on their Y chromosome, their sons would be normal (assuming the mother is not a carrier) and their daughters would be obligatory carriers. Female carriers have one normal allele and therefore do not usually have a bleeding tendency, although female carriers have lower factor VIII levels than females who are not carriers.[3] Sons of a female carrier and a normal male have a 50% chance of having hemophilia and daughters have a 50% chance of being carriers. Thus, there is a "skipped generation" mode of inheritance in which the female carriers do not express the disease but can pass it on to the next male generation. Hemophilia has been observed in a small number of females. It can occur if both factor VIII and IX genes are defective or if a female patient has only one X chromosome as in Turner syndrome.[4]

CLINICAL PRESENTATION Hemophilia Signs and Symptoms

- Ecchymoses (palpable/raised)
- Hemarthroses (especially knee, ankle, and elbow)
- Joint pain
- Joint swelling and erythema
- Decreased range of motion
- Muscle hemorrhage
- Swelling at the site of muscle bleeding
- Pain with motion of affected muscle

- Signs of nerve compression
- Significant anemia from an iliopsoas or thigh bleed
- Oral bleeding with dental extractions or trauma
- Hematuria
- Intracranial hemorrhage (spontaneous or following trauma)
- Excessive bleeding with surgery

Laboratory Testing

- Prolonged activated partial thromboplastin time (aPTT)
- Decreased factor VIII or factor IX level
- Normal prothrombin time (PT)
- Normal platelet count
- Normal von Willebrand factor antigen and activity
- Normal bleeding time

In 1984, researchers isolated and cloned the human factor VIII gene. It is a large gene, consisting of 186 kilobases (kb).[5] More than 2,000 unique mutations in the factor VIII gene, including point mutations, deletions, and insertions, have been reported.[6] Deletions and nonsense mutations are often associated with the more severe forms of factor VIII deficiency because functional factor VIII is not produced. In 1993, researchers identified an inversion in the factor VIII gene at intron 22 that accounts for almost 50% of severe hemophilia A gene abnormalities.[7] That discovery has greatly simplified carrier detection and prenatal diagnosis in families with this gene mutation.

The factor IX gene, cloned and sequenced in 1982, consists of only 34 kb and is significantly smaller than the factor VIII gene.[5] Unlike the factor VIII gene in patients with severe hemophilia A, the factor IX gene in patients with hemophilia B has no predominant mutation. Direct gene mutation analysis is simpler in hemophilia B because of the smaller gene size, and to date more than 1,000 different mutations have been reported.[8] Most of these mutations are single base-pair substitutions. About 3% of factor IX gene mutations are deletions or complex rearrangements, and the presence of these mutations is associated with a severe phenotype.[7]

Hemophilia B Leyden is a rare variant in which factor IX levels initially are low but rise at puberty.[7] The mechanism of this disorder is controversial. Some propose that the binding of the androgen receptor and other transcription factors are responsible. Other molecular mechanisms for age-related gene regulation have been recently discovered and implicated in factor IX Leyden.[9] Identification of this genotype is clinically important because it confers a better prognosis.

Clinical Manifestations

The characteristic bleeding manifestations of hemophilia include palpable ecchymosis, bleeding into joint spaces (hemarthroses), muscle hemorrhages, and excessive bleeding after surgery or trauma. The severity of clinical bleeding generally correlates with the degree of deficiency of either factor VIII or factor IX. Factor VIII and factor IX activity levels are measured in units per milliliter, with 1 unit/mL representing 100% of the factor found in 1 mL of normal plasma.[10] Normal plasma levels range from 0.5 to 1.5 units/mL. Patients with less than 0.01 units/mL (1%) of either factor are classified as having severe hemophilia, those with between 0.01 and 0.05 units/mL (1%-5%) are moderate, and those with 0.05 units/mL and 0.4 units/mL (5%-40%) have mild hemophilia (**Table 101-3**).

TABLE 101-3 Laboratory and Clinical Manifestations of Hemophilia

	Severe (<0.01 units/mL)	**Moderate (0.01-0.05 units/mL)**	**Mild (>0.05 units/mL)**
Age at diagnosis	≤1 year	1-2 years	2 years to adult
Neonatal symptoms			
PCB	Usually	Usually	Rarely
ICH	Occasionally	Uncommonly	Rarely
Muscle/joint hemorrhage	Spontaneous	Minor trauma	Minor to major trauma
CNS hemorrhage	High risk	Moderate risk	Uncommon
Postsurgical hemorrhage (without prophylaxis)	Frank bleeding, severe	Wound bleeding, common	Wound bleeding
Oral hemorrhage following trauma, tooth extraction	Usually	Common	Common

CNS, central nervous system; ICH, intracranial hemorrhage; PCB, postcircumcisional bleeding.

Normal range of factor VIII/IX activity level is 0.5-1.5 units/mL (50%-150%). A value of 1 unit/mL corresponds to 100% of the factor found in 1 mL of normal plasma.

Patients with severe disease experience frequent spontaneous hemorrhages, while those with moderate disease have excessive bleeding following mild trauma and rarely experience spontaneous hemarthroses. Patients with mild hemophilia may have few symptoms that their condition can be undetected for many years and they usually have excessive bleeding only after significant trauma or surgery. Disease severity does not always correlate with disease manifestations. Those with severe disease (<1% factor activity) may occasionally not display a severe phenotype, while some with milder forms of the disease may have more severe bleeding. Prolonged bleeding after circumcision is a common presenting sign. Most patients will have some manifestation of the disease sometime after their first year of life, when they begin to walk and increase their risk of bleeding due to falling.[1,7]

Diagnosis

The diagnosis of hemophilia should be considered in any male with unusual bleeding. A family history of bleeding is helpful in the diagnosis but is absent in up to 50% of patients with about one-third representing spontaneous mutations and the remaining secondary to an unrecognized family history.[5] Brothers of patients with hemophilia should be screened; sisters should consider undergoing carrier testing. Laboratory testing in patients with hemophilia will usually reveal an isolated prolonged partial thromboplastin time (PTT) and they will have a decreased factor VIII or factor IX level.

Patients with severe hemophilia A should be tested for the common factor VIII gene inversions. In patients with severe hemophilia A that lack an inversion mutation or in patients with moderate or mild hemophilia A, the gene can be sequenced to determine the exact mutation if needed. The exact mutation can determine carrier status but is not done routinely in everyone since it is very costly and does not change therapy. Techniques to determine the genetic mutation in patients with hemophilia B are similar, but no predominant mutation like the factor VIII inversion has been found. The smaller size of the factor IX gene facilitates direct DNA mutational analysis.[7]

Hemophilia can be diagnosed prenatally, if desired, by chorionic villus sampling in gestational weeks 9 to 14 or by amniocentesis after 15 to 17 weeks of gestation.[1,11] These are invasive procedures with a 0.5% to 1% chance for pregnancy loss so it is not routinely done.[11] A new noninvasive method uses cell-free fetal DNA in maternal circulation to determine the sex of the fetus; more invasive testing is required for a male fetus.[11] This method was used to successfully identify hemophilia mutations in 12 subjects,[12] but is still experimental and requires further validation.

TREATMENT

The comprehensive care of hemophilia requires an interprofessional team approach. The patient is best managed in specialized centers with trained personnel and appropriate laboratory, radiologic and pharmaceutical services.[1] The healthcare team includes hematologists, orthopedic surgeons, nurses, physical therapists, dentists, genetic counselors, psychologists, pharmacists, case managers, and social workers who have experience in caring for patients with bleeding disorders. The goal for comprehensive hemophilia care is to prevent bleeding episodes and their long-term sequelae so that patients with hemophilia can live full, active, and productive lives.

2 IV factor replacement therapy for the treatment or prevention of bleeding is the mainstay of treatment for hemophilia. Parents of children with hemophilia usually learn how to infuse factor concentrate to facilitate home treatment peripherally or via central venous access device. Older children and adult patients learn self-administration. Home healthcare nursing support may be helpful, particularly for the youngest patients in whom venous access may be difficult. In the setting of poor venous access, venous access devices may be indicated. Administration of factor at home is more convenient for families and allows for earlier treatment of acute bleeding episodes. However, serious bleeding episodes always require evaluation by medical personnel.

Patients with hemophilia should receive routine immunizations, including immunization against hepatitis B. Hepatitis A vaccine is also recommended for patients with hemophilia because of the risk

(albeit small) of transmitting the causative agent through factor concentrates.[1,13] Administration of vaccines is preferred subcutaneously in patients with severe disease.[1] If intramuscular administration is required, use of a small-gauge needle with cold compresses and pressure to the site can prevent excessive bleeding.

A few special considerations apply to the perinatal care of male infants of hemophilia carriers. Intracranial or extracranial hemorrhage has been estimated to occur in 1% to 2% of newborns with hemophilia.[7] Vacuum extraction and forceps delivery increase the risk of cranial bleeding. Elective cesarean section has not been shown to prevent intracranial bleeding. The optimal mode of delivery or the use of prophylactic factor replacement in male infants of hemophilia carriers is controversial.[1] Circumcision should be postponed until a diagnosis of hemophilia is excluded. Factor levels can be assayed from cord blood samples or from peripheral venipuncture. Arterial puncture should be avoided because of the risk of hematoma formation. If an infant has hemophilia, many clinicians recommend a screening head ultrasound to rule out an intracranial hemorrhage prior to discharge from the nursery.

History of Hemophilia Treatment

Therapy for hemophilia has undergone dramatic advances over the past few decades. Fifty years ago, administration of fresh-frozen plasma was the only available treatment. The introduction of cryoprecipitate in the early 1960s allowed more specific therapy for hemophilia A.[14] Intermediate-purity factor VIII and IX plasma-derived concentrates became available in the 1970s.[14] Plasma-derived factor concentrates are made from the donations of thousands of people. Contamination of plasma pools with hepatitis B, hepatitis C, and the human immunodeficiency virus (HIV) during the late 1970s and early 1980s resulted in transmission to a large portion of patients with hemophilia. Since the mid-1980s, plasma-derived concentrates have been manufactured with a variety of virus-inactivating techniques, including dry heat, pasteurization, and treatment with chemicals (eg, solvent detergent mixtures).[5] Since 1986, no transmission of HIV through factor concentrates to patients with hemophilia in the United States has been reported.[5] Protein purification techniques, introduced in the 1990s, led to the production of high-purity plasma-derived concentrates with increased amounts of factor VIII or factor IX relative to the product's total protein content. Recombinant factor VIII and then factor IX also became available in the 1990s.[14] Significant improvements have been made with recombinant products in limiting the risk of infectious transmission from albumin used to stabilize some of the products. Like plasma-derived products, these products use viral inactivation steps. With each subsequent generation of recombinant factor VIII products, the use of human proteins has been reduced.[14]

More recently, several novel long-acting factor VIII or IX products have been developed. Different methods have been utilized to prolong the half-life of either factor VIII or IX including pegylation, polysialic acid, albumin fusion, and Fc fusion.[15,16,17] Two of these improved factor products were recently approved by FDA; both attach the factor to IgG1 which then binds to the neonatal Fc receptor (FcRn) present in the acidified endosomes of the endothelial cells. This binding protects the factor fusion product from targeted lysosomal degradation and facilitates recycling of the FcRn

ligands at the endothelial surface resulting in a prolonged systemic half-life of the factor.[18,19] Currently these products are only approved for routine prophylaxis and their role in acute bleeds or surgical management of hemophilia patients has yet to be defined. Clinical trials for factor VIII and factor IX with improved pharmacokinetic properties are ongoing.

Hemophilia A

Table 101-4 summarizes most of the factor VIII products currently available in the United States. Most patients are treated with high-purity products, which generally have the lowest risk of transmitting infectious disease and are therefore recommended as first line agents.[1] Recombinant products, when available, are generally used rather than plasma-derived products.

TABLE 101-4 Factor Concentrates

Brand Name	Product Type	Viral Inactivation or Exclusion Method	Other Contents
Factor VIII Concentrates			
Alphanate AHF/VWF complex	Plasma	Solvent detergent, dry heat	Albumin, heparin, vWF
Hemofil M AHF	Plasma	Solvent detergent, monoclonal antibody, ion-exchange chromatography	Albumin
Humate-P AHF/VWF complex	Plasma	Pasteurization	Albumin, vWF
Koāte-DVI	Plasma	Solvent detergent, dry heat, gel permeation chromatography	Albumin
Monarc-M	Plasma	Solvent detergent, monoclonal antibody	Albumin
Monoclate P	Plasma	Pasteurization, monoclonal antibody	Albumin
Wilate VWF/FVIII Complex	Plasma	Solvent detergent, dry heat	Sodium citrate, sucrose, vWF
Advate	Recombinant	Solvent detergent, column chromatography, monoclonal antibody	Trehalose
Eloctate B domain deleted, Fc Fusion	Recombinant	Solvent detergent, chromatography, nanofiltration	Sucrose, IgG_1
Helixate FS	Recombinant	Solvent detergent, ion-exchange chromatography, monoclonal antibody	Human plasma protein solution (fermentation only); sucrose
Kogenate FS	Recombinant	Solvent detergent, ion-exchange chromatography, monoclonal antibody	Human plasma protein solution (fermentation only); sucrose
Novoeight B domain deleted	Recombinant	Solvent detergent, chromatography, immunoaffinity column, monoclonal antibody, nanofiltration	Sucrose, Polysorbate 80

Brand Name	Product Type	Viral Inactivation or Exclusion Method	Other Contents
Nuwiq Bdomain deleted	Recombinant	Solvent detergent, nanofiltration	Sucrose, sodium citrate, L-arginine hydrochloride
Recombinate	Recombinant	Immunoaffinity, chromatography, monoclonal antibody	Albumin
ReFacto B domain deleted	Recombinant	Chromatography	Albumin (fermentation only); sucrose
Xyntha B domain deleted	Recombinant	Chromatography, solvent detergent, nanofiltration	Sucrose
Factor IX Concentrates			
AlphaNine SD	Plasma	Solvent detergent, nanofiltration	Heparin
Mononine	Plasma	Sodium thiocyanate, dual ultrafiltration	Heparin, mannitol
Alprolix Fc Fusion	Recombinant	Nanofiltration, chromatography	Sucrose, mannitol, IgG_1
BeneFix	Recombinant	Chromatography, nanofiltration	Sucrose, Polysorbate 80
Rixubis	Recombinant	Chromatography, solvent detergent, nanofiltration	Sucrose, mannitol
aPCC			
Feiba VH Immuno	Plasma	Vapor heat	IIa, VIIa, VIIIa, IXa, Xa
PCC			
Bebulin VH	Plasma	Vapor heat	Heparin, II, IX, X
Profilnine S/D	Plasma	Solvent detergent	II, IX, X
Other			
Corifact	Plasma	Heat, precipitation/adsorption, ion exchange chromatography	XIII, albumin
NovoSeven	Recombinant	Solvent detergent	VII

aPCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate; vWF, von Willebrand factor.

Recombinant Factor VIII

3 Recombinant factor VIII is produced with recombinant DNA technology and is derived from cultured Chinese hamster ovary cells or baby hamster kidney cells transfected with the human factor VIII gene.[5] Since these products are not derived from blood donations, the risk of transmitting infections through administration of recombinant factor VIII is low and recombinant products are generally favored over plasma-derived products. A very small risk of viral infection of the cell lines used to produce the clotting factor still remains. Furthermore, human or animal proteins are used in the production process of some recombinant products.[14] Therefore, these products have a

theoretical risk of transmitting infection, although hepatitis and HIV infection have never been reported with their use.[5] First-generation recombinant factor VIII products contain human albumin as a stabilizing protein.[5] Second-generation recombinant factor VIII products add sugar instead of human albumin as a stabilizer, but human albumin is used in the culture process. One second-generation product (ReFacto®) and one third-generation product (Xynitha®) delete the B domain of the factor VIII gene, yielding a smaller protein product.[5,20] This B domain does not appear to be necessary for coagulation function. Third-generation recombinant factor VIII products do not contain human protein either in the culture or in the stabilization processes.[14]

Plasma-Derived Factor VIII Products

Clinical trials have demonstrated that recombinant factor VIII products are comparable in effectiveness to plasma-derived products.[5] Several different plasma-derived factor VIII products are available (Table 101-4). These products are derived from the pooled plasma of thousands of donors and therefore have the potential to transmit infection. Donor screening, testing of plasma pools for evidence of infection, viral reduction through purification steps, and viral inactivation procedures (eg, dry heat, pasteurization, and solvent detergent treatment) have resulted in a safer product. No cases of HIV transmission from factor concentrates have been reported since 1986.[5] However, isolated cases of hepatitis C infection with use of plasma-derived products have been reported.[5] Additionally, outbreaks of hepatitis A viral infections associated with plasma-derived products have been reported, likely because solvent detergent treatment does not inactivate this non-enveloped virus. Finally, possible infection with as yet unidentified viruses not inactivated by currently used methods remains a concern. In addition, Prion disease may be present in plasma-derived factor products.[21]

Factor VIII concentrates can be classified according to their level of purity, which refers to the specific activity of factor VIII in the product. Cryoprecipitate is a low-purity product that also contains vWF, fibrinogen, and factor XIII. Current American Association of Blood Banks standards call for a minimum of 80 international units of factor VIII per cryoprecipitate pack.[5] This product is no longer considered a primary treatment of factor VIII deficiency in countries where factor VIII concentrates are available because cryoprecipitate does not undergo a viral inactivation process. Intermediate-purity products have a specific factor VIII activity of 5 units/mg of protein and high-purity products have up to 2,000 units/mg of protein.[5] Ultrahigh-purity plasma-derived products are prepared with monoclonal antibody purification steps and have a specific activity of 3,000 units/mg of protein prior to addition of albumin as a stabilizer.

Factor VIII Concentrate Replacement

Appropriate dosing of factor VIII concentrate depends on the half-life of the infused factor, the patient's body weight, and the location and severity of the bleed. The presence or absence of an inhibitory antibody to factor VIII and the titer of this antibody also influence treatment. Recovery studies, which measure the immediate post-infusion factor level, and survival studies, which assess the half-life of the factor, can establish patient-specific pharmacokinetics. The location and magnitude of the bleeding episode determine the percent correction to target as well as the duration

of treatment.[7] Serious or life-threatening bleeding requires peak factor levels of greater than 0.75 to 1 units/mL (75%-100%); less severe bleeding may be treated with a goal of 0.3 to 0.5 units/mL (30%-50%) peak plasma levels. **Table 101-5** provides general guidelines for the management of bleeding in different locations.

TABLE 101-5 Guidelines for Factor Replacement Therapy for Hemorrhage in Hemophilia A and B

Site of Hemorrhage	Desired Hemostatic Factor Level (% of Normal)	Comments
Joint	50%-70%, 2-3 days	Rest/immobilization/physical therapy rehabilitation following bleed; several doses may be necessary to prevent or treat target joint
Muscle	30%-50% for most sites	Risk of significant blood loss with a thigh or iliopsoas bleed; bed rest for iliopsoas or thigh bleeding
	70%-100% for thigh, iliopsoas, or nerve compression	
Oral mucosa	30%-50%	May try antifibrinolytic or topical thrombin prior to factor replacement for minor bleeding; higher factor levels are needed for tongue swelling or risk of airway compromise; antifibrinolytic therapy should be used following factor replacement
GI	Initially 100%, then 40%-60%	Endoscopy is highly recommended; antifibrinolytic therapy may be useful. Continue until healing occurs
Hematuria	30%-50% if no trauma	If no pain or trauma, consider bed rest and fluids for 24 hours; factor should be given if hematuria persists; evaluate if hematuria persists; if trauma to abdomen or back, perform imaging and give aggressive factor replacement
	70%-100% if traumatic	
CNS	Initially 100%, then 50%-100% for 10-21 days	Lumbar puncture requires prophylactic factor coverage
Trauma or surgery	Initially 100%, then 50%-100% until wound healing complete	Perioperative and postoperative management plan must be in place preoperatively; evaluation for inhibitors is crucial prior to elective surgery

aPCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate.

Factor VIII is a large molecule that remains in the intravascular space. Therefore, the plasma volume (about 50 mL/kg) can be used to estimate the volume of distribution. In general, each unit of factor VIII concentrate infused per kilogram of actual body weight results in a 2% rise in plasma factor VIII

levels.[7] The following equation can be used to calculate an initial dose of factor VIII:

$$\text{Factor VIII (units)} = (\text{Desired level} - \text{Baseline level}) \times 0.5 \times (\text{Weight [in kilograms]})$$

The baseline level usually is omitted from the equation when it is negligible compared to the desired level. The half-life of factor VIII ranges from 8 to 15 hours. It is generally necessary to administer 50% of the initial dose about every 12 hours to sustain the desired level of factor VIII. A single treatment may be adequate for minor bleeding such as oral bleeding or slight muscle hemorrhages. However, because of the potential for long-term joint damage with hemarthroses, 2 or 3 days of treatment is often recommended for these bleeds. Serious bleeding episodes may require maintenance of 70% to 100% factor activity for 1 week or longer. As previously mentioned, factor VIII dosing depends on several variables, and each case must be considered individually. Individualized pharmacokinetics may help guide treatment, particularly for serious bleeding episodes.

Alternatively, factor VIII can be administered as a continuous infusion when prolonged treatment is required (eg, in the perioperative period or for serious bleeding episodes). Infusion rates ranging from 2 to 4 units/kg/h usually are given in fixed-dose continuous infusion protocols, with the aim of maintaining a steady-state level of 60% to 100%.[22] Administration of factor concentrate via continuous infusion may reduce factor requirements by 20% to 50% because unnecessarily high peaks of factor VIII that occur with bolus injections are avoided. A gradual decrease in factor VIII clearance during the first 5 to 6 days of treatment contributes to the lower factor concentrate requirements. Daily monitoring of factor level can help determine the appropriate rate of infusion.

Administration of factor VIII concentrate via continuous infusion has been shown to be safe and effective, and it may be more convenient than bolus therapy for hospitalized patients.[23] Concerns about the stability of the formulations appear to be unwarranted, as most high-purity factor VIII concentrates have been shown to remain stable for at least 7 days after reconstitution.[23] However, exposure of factor VIII to light for 10 hours after reconstitution can decrease activity by 30%.[23] Therefore, it would be prudent to shield the container with foil wrap or an appropriate bag.

Other Pharmacologic Therapy

Treatment with desmopressin acetate often is adequate for minor bleeding episodes in patients with mild hemophilia A. A synthetic analog of the antidiuretic hormone vasopressin, desmopressin causes release of vWF and factor VIII from endogenous endothelial storage sites. It appears to be most effective in patients with higher baseline factor VIII levels (0.1-0.15 units/mL).[24] The recommended dose of desmopressin is 0.3 mcg/kg diluted in 50 mL of normal saline and infused IV over 15 to 30 minutes.[24] Patients with mild or moderate hemophilia A should undergo a desmopressin trial to determine their response to this medication. At least a twofold rise in factor VIII to a minimal level of 0.3 units/mL within 60 minutes is considered an adequate response.[1,22] Infusion of desmopressin can be repeated daily for up to 2 to 3 days. Tachyphylaxis, an attenuated response with repeated dosing, may develop after that time due to the depletion of factor stores. The factor increase after the second dose of desmopressin is about 30% lower than after the initial dose.[24] Factor concentrate therapy

may be necessary if the patient requires additional treatment. Factor levels should be measured to ensure that an adequate response has been achieved. Treatment with desmopressin will not result in hemostasis in patients who have severe hemophilia and those who are only marginally responsive. Desmopressin should not be used as primary therapy for life-threatening bleeding episodes such as intracranial hemorrhage or for major surgical procedures.[1]

Desmopressin can be administered intranasally via a concentrated nasal spray.[24] It elicits a slower and less marked response, with a peak effect in 60 to 90 minutes after administration, which is somewhat longer than with IV administration.[22,24] The dosage is one spray (150 mcg) in one nostril for patients who weigh less than 50 kg and two sprays (300 mcg) (one in each nostril) for those who weigh more than 50 kg.[22] The nasal spray may serve as an alternative to the IV formulation, especially in patients with mild bleeding episodes. Few adverse effects are associated with desmopressin. The most commonly observed side effect is facial flushing.[24] Less frequently reported side effects include mild headaches, increased heart rate, and decreased blood pressure. Desmopressin has the potential to cause water retention because of its antidiuretic effects, which may lead to severe hyponatremia. This may be a particular problem in children younger than 2 years and therefore should be used with caution in this age group.[22] Fluid restriction for 24 hours after the desmopressin dose and monitoring of urine output are recommended with desmopressin administration.[22]

Antifibrinolytic therapy inhibits clot lysis and therefore is a useful adjunctive therapy for the treatment of hemophilia, primarily with mucocutaneous bleeding. Antifibrinolytic agents are particularly beneficial for treatment of oral bleeding because of a high concentration of fibrinolytic enzymes in saliva. Antifibrinolytic therapy can also be helpful as adjuvant therapy in GI bleeding, epistaxis and menorrhagia. Antifibrinolytic therapy should be used with caution in patients with urinary bleeding, due to the risk of obstruction and subsequent renal toxicity. The two currently available antifibrinolytics include aminocaproic acid and tranexamic acid. Aminocaproic acid is given at a dosage of 100 mg/kg (maximum 6 g) every 6 hours and can be administered orally or IV.[5] The dosage of tranexamic acid is 25 mg/kg (maximum 1.5 g) orally every 6 to 8 hours.[5]

Hemophilia B

Therapeutic options for hemophilia B have improved greatly over the past several years, first with the development of monoclonal antibody-purified plasma-derived products and then with the licensure of recombinant factor IX. Products currently available in the United States for treatment of hemophilia B are listed in Table 101-4.

Recombinant Factor IX

Recombinant factor IX was not available until 1998, which is 6 years after the first recombinant factor VIII product.[25] Recombinant factor IX is produced in Chinese hamster ovary cells transfected with the factor IX gene. Since blood and plasma products are not used to produce recombinant factor IX or to stabilize the final product, recombinant factor IX has an excellent viral safety profile.[5,25] Clinical trials have shown the product to be safe and efficacious in the treatment of acute bleeding episodes and in

the management of bleeding associated with surgical procedures.[5,25] Although the half-life of recombinant factor IX is similar to that of the plasma-derived products, recovery is about 30% lower.[25] As a result, doses of recombinant factor IX concentrate must be higher than those of plasma-derived products to achieve equivalent plasma levels. Because individual pharmacokinetics may vary, recovery and survival studies should be performed to determine optimal treatment.[5] Recombinant factor IX is considered the treatment of choice for hemophilia B.[1]

Plasma-Derived Factor IX Products

High-purity factor IX plasma concentrates have been available in the United States since the early 1990s.[5,25] These products are derived from plasma through biochemical purification and monoclonal immunoaffinity techniques. Other viral inactivation measures, such as solvent detergent or chemical treatment, are also used. High-purity factor IX concentrates have excellent efficacy in the treatment of bleeding episodes and in the control of bleeding associated with surgical procedures.[25] Their viral safety profile has been reported to be excellent and the risk of thromboembolic complications is low.[25]

Before the high-purity products were approved for use, hemophilia B patients were treated with factor IX concentrates that also contained other vitamin K-dependent proteins (factors II, VII, and X), known as prothrombin complex concentrates (PCCs). These products contain small amounts of activated factors generated during processing, and their use has been associated with thrombotic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction, and disseminated intravascular coagulation.[5,25] The risk of such complications is highest in patients who are receiving high or repeated doses of PCCs, in those who have hepatic disease (the liver produces antithrombotic factors and removes the activated factors from circulation), in neonates, and in patients who have experienced crush injuries or who are undergoing major surgery.[5,25] Concomitant use of PCCs and antifibrinolytics should be avoided because of the risk for thrombosis. Because of the lower purity of PCCs and their thrombogenic potential, these products are not first-line treatment for hemophilia B.

Factor IX Concentrate Replacement

Factor IX is a relatively small protein. Unlike factor VIII, it is not limited to the intravascular space; it also passes into the extravascular compartment.[25] Therefore, it has a volume of distribution that is about twice that of factor VIII. For plasma-derived factor IX concentrates, each unit of factor IX infused per kilogram of actual body weight results in about a 1% rise in the plasma level of factor IX (range, 0.67%-1.28%).[5] The following equation can be used to calculate the initial dose:

$$\text{Plasma-derived factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times (\text{Weight [in kilograms]})$$

As with the factor VIII dose calculation, the baseline level term can be omitted from the formula if it is negligible compared to the desired level. Because recovery of recombinant factor IX is lower than that of the plasma-derived products, the following adjustment is made:

Pediatric dosing:

$$\text{Recombinant factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times 1.4 \times (\text{Weight [in kilograms]})$$

Adult dosing:

$$\text{Recombinant factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times 1.2 \times (\text{Weight [in kilograms]})$$

A recovery study to determine optimal dosing is recommended for patients who receive recombinant factor IX because of the wide interpatient variability in pharmacokinetics. Because the half-life of factor IX is about 24 hours, dosing can be less frequent than with factor VIII. Table 101-5 provides general guidelines for dosing factor IX based on the site and severity of the bleeding episode.

Prophylaxis Versus On Demand Therapy

One approach to treating hemophilia patients is to administer the necessary factor only for acute bleeding episodes; this is referred to as *on demand therapy*. However, recurrent joint bleeding can damage the joint and lead to the development of severe physical disability. It is therefore advisable to prevent bleeding episodes and avoid the resultant damage. This is the rationale for the second approach to treatment known as *prophylactic factor replacement therapy*. The goal of this approach is to maintain a patient's minimum factor level at or above 0.01 units/mL (1%) with regular infusions of factor products. In developed countries, prophylaxis for patients with severe hemophilia is considered standard of care. It is also recommended by the World Health Organization and the World Federation of Hemophilia.[6] Prophylaxis is sometimes required in patients with moderate hemophilia and is rarely used in patients with mild hemophilia.

Prophylactic replacement therapy converts severe hemophilia into a milder form of the disease. The rationale for this approach is that patients with moderate hemophilia rarely experience spontaneous hemarthroses, and they have a much lower risk of chronic arthropathy. Recent pediatric clinical trials have demonstrated the efficacy of prophylaxis in pediatric patients.[26] The first pediatric randomized clinical trial comparing prophylaxis to enhanced episodic treatment in boys (age less than 30 months) with severe hemophilia demonstrated that prophylaxis prevented joint damage and decreased the frequency of joint and other hemorrhages.[27] More recently, a European randomized clinical trial of prophylaxis in pediatric patients with hemophilia A confirmed the efficacy of prophylaxis in preventing bleeds and arthropathy.[26] The efficacy of prophylaxis in adult patients with hemophilia is still unclear.

The dosing for prophylactic regimens varies considerably and no one regimen has been proven to be superior.[27] A common regimen for patients with hemophilia A is 20 to 40 units/kg of factor VIII given every other day or three times per week.[28] For hemophilia B, the usual dosage ranges between 25 and 60 units/kg of factor IX given twice weekly because of the intrinsically longer half-life of factor IX.[25] The recent introduction of longer lasting factor products has made prophylaxis a more feasible approach. Patients with hemophilia A can now be dosed with the Fc fusion product at a dose of 25 to

65 units/kg at 3 to 5 day intervals depending on their individual response.[28] Similarly, patients with hemophilia B can be dosed with the corresponding Fc fusion protein product either 50 units/kg once weekly or 100 units/kg every 10 days.[28]

Controversy exists regarding the ideal timing for the initiation of prophylaxis. Primary prophylaxis is regular replacement therapy started at a young age (usually before age 2 years), prior to the onset of joint bleeding.[27] Secondary prophylaxis begins after significant joint bleeding has already occurred.[27] In 2001, the Medical and Scientific Advisory Council of the National Hemophilia Foundation of the United States recommended primary prophylaxis beginning at age 1 to 2 years for children with severe hemophilia. Prophylaxis regimens are best administered in the morning to protect the patient during daily activities.[1]

Clinical Controversy...

Despite the evidence based support for prophylaxis in children, controversy still exists over its benefit in adults. Appropriate time to initiate prophylaxis in children, and appropriate dosing for prophylaxis has still yet to be clearly defined.

Prophylaxis therapy comes with its own set of challenges. In addition to the paucity of evidence regarding dosing and initiation, a prohibitive challenge is the high cost of this approach. The cost to treat a patient with hemophilia A in the United States has been estimated to be about $300,000 per year.[29] Other issues to consider are the inconvenience to families and possible difficulties with adherence. Central venous lines may be necessary for frequent administration of factor concentrates, particularly in children younger than 2 years, who are at the age targeted for initiation of primary prophylaxis regimens. Potential complications of central venous access include surgical risks, infection, and catheter-related deep-vein thrombosis. Finally, routine use of primary prophylaxis may initially overtreat some patients with severe hemophilia who do not have a severe clinical phenotype. For these reasons, the use of primary prophylaxis has not been widely adopted in the United States. Many institutions continue to use some form of secondary prophylaxis, in which prophylaxis is started after a pattern of bleeding has been established.

Treatment of Inhibitors in Hemophilia

Neutralizing antibodies to factors VIII and IX, known as *inhibitors*, develop in a subset of patients with hemophilia. 4 The development of an inhibitor is the most serious complication of factor replacement therapy and is associated with considerable morbidity and a decreased quality of life. The incidence of new factor VIII inhibitors in patients with severe factor VIII deficiency is about 30%.[2,32] Inhibitors are less common in patients with mild or moderate hemophilia occurring in about 5% to 10% of patients.[1] The risk of developing inhibitors in patients with hemophilia B is much lower, occurring in only 3% of patients.[2,5]

Most inhibitors develop in childhood, after relatively few exposure days (median 10-15 days).[30] Patients with severe hemophilia are much more likely to develop inhibitors than those with milder forms of the disease.[30] It is possible that the low levels of factor produced in patients with mild or

moderate hemophilia induce immune tolerance in these individuals. In contrast, factor levels are undetectable in patients with severe hemophilia, so infused factor VIII is regarded as a foreign protein, which may provoke an antibody response. The rate of inhibitor formation varies even among patients with identical mutations, which suggests that host factors modify the risk. The development of an inhibitor is the result of a complex interaction between a patient's immune system and genetic and environmental risk factors.

An inhibitor is a polyclonal high-affinity immunoglobulin G (IgG) directed against the factor VIII or IX protein.[31] Inhibitors interfere with infused factor concentrate, rendering them ineffective. The presence of an inhibitor is suspected when a decreased clinical response to factor replacement is observed or it may be discovered incidentally on routine laboratory screening. Inhibitors are measured with the Bethesda assay, and titers are reported in Bethesda units (BUs). One BU is the amount of inhibitor needed to inactivate half of the factor VIII or factor IX in a mixture of inhibitor-containing plasma and pooled normal plasma.[5] Patients with inhibitors to factor VIII or factor IX are divided into two groups: low responders, who have low levels of inhibitors (<5 BU/mL) and generally have little or no rise in antibody titers after exposure to the factor; and high responders (>5 BU/mL), who have higher inhibitor levels and develop an increase in antibody titer after exposure (anamnestic response).[2]

Clinical Controversy…

The risk of inhibitor formation has been reported to be higher in recombinant products as compared with plasma-derived products. However, it is difficult to compare the cumulative incidence from different studies because of differences in patient population (eg, heterogeneity in risk factors for inhibitor formation), study methodology, frequency of inhibitor testing, and length of follow-up. The results of several reviews have been contradictory. To address this very important clinical question, a prospective international randomized clinical trial (SIPPET—Survey of Inhibitors in Plasma Product Exposed Toddlers) is currently comparing inhibitor incidence in previously untreated patients exposed to either plasma or recombinant factor products.

Therapy for patients with inhibitors involves treatment of acute bleeding episodes and treatment directed at eradicating the inhibitor. The inhibitor titer, the site and magnitude of bleeding, and the patient's past response to bypassing therapy determine the approach to the treatment of acute bleeding. For patients with a low inhibitor titer, administration of high doses of the specific factor often can control bleeding episodes. Two to three times the usual replacement dose and more frequent dosing intervals are often necessary to overcome the antibody. Factor-level monitoring and clinical assessments help to evaluate the adequacy of treatment. Additional supportive measures, such as immobilization and administration of antifibrinolytic agents, should be used, where appropriate.

In the presence of a high-titer inhibitor, it is impossible to administer enough factor VIII or factor IX to neutralize the antibody and achieve a hemostatic plasma level. Therefore, the treatment of bleeding episodes consists of agents that bypass the factor to which the antibody is directed. These bypassing agents include PCCs, activated prothrombin complex concentrates (aPCCs), and recombinant factor VIIa. PCCs contain the vitamin K-dependent factors II, VII, IX, and X. Small

quantities of activated factors are present in these products. Activated PCCs contain greater quantities of the activated factors primarily factor X and prothrombin. The only available aPCC product in the United States is FEIBA® (Factor Eight Inhibitor Bypassing Agent). The recommended dosage is 50 to 100 units/kg administered every 8 to 12 hours, depending on the severity of the bleeding episode and the maximum dose should not exceed 200 units/kg/day.[28] Activated PCCs appear to be more effective than PCCs and are preferred in patients with inhibitors. As previously mentioned, there is a risk of serious thrombotic complications, including pulmonary emboli, deep-vein thrombosis, and myocardial infarction associated with use of PCCs and aPCCs.[28] Other minor side effects include dizziness, nausea, hives, flushing, and headaches. Patients with factor IX inhibitors occasionally develop severe allergic reactions in response to infusion of factor IX-containing products, so these patients should be monitored closely.[25]

5 Recombinant factor VIIa is effective for the treatment of acute bleeds in patients with hemophilia A or B who have developed inhibitors. Recombinant factor VIIa is a bypassing agent which is thought to be hemostatically active only at the site of tissue injury where the tissue factor is present. Recombinant factor VIIa is not a plasma-derived product, so both viral transmission and anamnestic responses to factor VIII or factor IX are unlikely. The initial recommended dose for bleeding episodes is 90 mcg/kg.[28] However, depending on a patient's response, higher doses up to 300 mcg/kg can be used. A drawback is the product's short half-life, which necessitates initial dosing every 2 hours. Continuous infusion of recombinant factor VIIa, which may be more convenient and cost-effective, has been reported.[33] Patients treated with bypassing agents must be monitored clinically because no laboratory test directly measures the effectiveness of treatment.

Both recombinant factor VIIa and aPCCs have been demonstrated to be effective in the treatment of bleeding for patients with inhibitors. In determining which bypassing product to use in an individual patient, the clinician must consider multiple factors. In a patient with a newly diagnosed inhibitor, it is prudent to use recombinant factor VIIa because aPCCs contain a small amount of factor VIII or IX and have been shown to increase the inhibitor titer. It is also important to consider an individual's response to specific bypassing agents because of the significant variability in response between individuals. In some patients, bleeding can be unresponsive to monotherapy and may require alternating products.[34] Due to the risk of developing thrombosis or disseminated intravascular coagulation from alternating bypassing agents, this therapy should be used with caution and only in an inpatient setting.[35]

In the past, plasma derived porcine factor VIII was an alternative therapeutic option for patients who have hemophilia A and inhibitors. It was removed from the market secondary to contamination with porcine parvovirus. The rationale for its use is that porcine factor VIII is enough like human factor VIII to participate in the coagulation cascade, yet most factor VIII inhibitors have absent or only weak neutralizing activity against nonhuman factor VIII making this an effective agent to treat an acute bleed. Unfortunately, cross-reactivity with porcine factor VIII does occur, and a high titer of antibody against porcine factor VIII can develop and hypersensitivity to porcine proteins can occur. Recently a recombinant porcine factor VIII has been approved (Obizur®), but only for treatment of acute bleeds in patients with acquired hemophilia A.[28]

The current hemostatic therapies for patients with an inhibitor have limited effectiveness leading to significant morbidity and a decreased quality of life. The ideal therapy for patients with an inhibitor is total eradication so that optimal hemostatic treatment with either factor VIII or IX is possible. At this time, the only proven method for inhibitor eradication is immune tolerance induction (ITI), which involves the regular infusion of factor VIII to induce antigen-specific tolerance. This approach is not recommended for patients with hemophilia B who have developed inhibitors due to the risk of hypersensitivity reactions and anaphylaxis associated with factor IX administration in this group.

Multiple immune tolerance registries were established to help determine patient- and treatment-related factors associated with immune tolerance outcome.[36,37] Across these registries, a patient's peak historical factor VIII inhibitor titer (<200 BU) and the inhibitor titer at the time of ITI induction (<10 BU) were associated with successful immune tolerance. The overall ITI success rate from these registries ranges from 51% to 79%;[36,37] the variability is likely related to a lack of standardization in study methodologies, treatment protocols, and eradication definitions.

The relationship between factor VIII dose and ITI success rate is not clear. A variety of different dosing regimens, ranging from 25 units/kg every other day to more than 200 units/kg every day, have been used. The International Immune Tolerance Registry demonstrated improved ITI success with high doses (200 IU/kg), while the North American and Spanish Immune Tolerance Registries showed improved success with lower dosing strategies.[37] The International Immune Tolerance Study is a multicenter randomized clinical trial that compared high-dose (200 units/kg/day) to low-dose (50 units/kg three times/wk) regimens in patients with severe hemophilia A and high titer inhibitors (>5 BU).[7,38] This study was stopped early due to an increased risk of bleeding events in the low-dose arm. At the stopping point, the proportion of ITI success was not significantly different between the two arms, but the time to achieve ITI success was shorter in the high-dose arm. Because the study was stopped early, it lacked statistical power to demonstrate therapeutic equivalence below the 30% boundary of equivalence. It appears that a high-dose strategy achieves tolerance at a faster rate, which explains the lower bleeding rate.

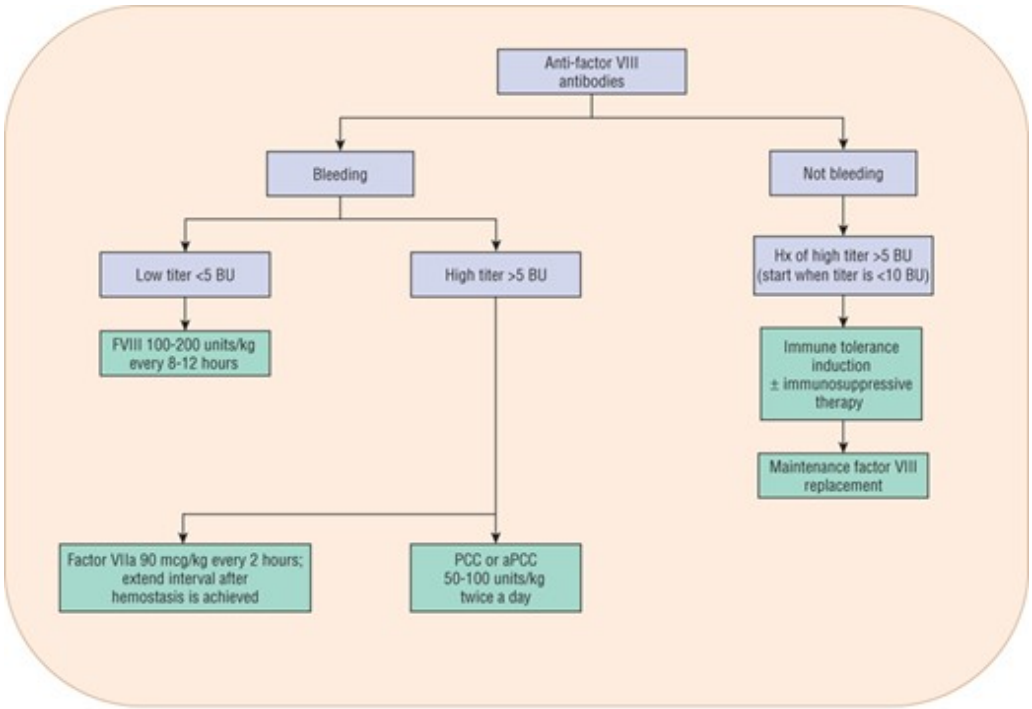
Some studies report better success rates for ITI in patients receiving plasma-derived factor products containing vWF, which may be related to the role of vWF in factor VIII function, stabilization, and immunogenicity.[39,40] vWF binding to the C2 domain of factor VIII, a common site for inhibitor formation, may result in epitope masking and decreased inhibitor activity.[40] The use of vWF-containing products may also extend the plasma half-life of factor VIII during ITI, thus increasing antigen presentation and possibly contributing to its overall success.[39]

Although not commonly used in ITI protocols, immune modulation has been reported as a method to improve tolerance success. Agents, such as cyclophosphamide and intravenous immune globulin, have been used in an effort to reduce inhibitor titers and make ITI more successful.[7] Another immune modulating agent, rituximab, an anti-CD20 monoclonal antibody that inhibits B-cells and interferes with IgG production, has been used with some success. In a phase II trial of rituximab in patients with high titer inhibitors, only 3 out of 16 subjects (18.8%) had a major response (decline in the inhibitor to <5 BU without an increase in the inhibitor titer after rechallenge to factor VIII).[41] When used as a single agent in previously treated patients with inhibitors, rituximab had a modest effect, but further

studies are needed to determine the activity of rituximab combined with ITI. **Figure 101-1** summarizes the therapeutic options in the management of hemophilia A patients with inhibitors.

FIGURE 101-1

Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. (aPCC, activated prothrombin complex concentrate; BU, Bethesda unit; PCC, prothrombin complex concentrate.)



Gene Therapy in Hemophilia

Hemophilia is an excellent candidate for gene therapy because tight control of gene expression is not required. Even low levels of factor expression can reduce bleeding episodes in patients with severe hemophilia, which is similar to the rationale for prophylactic factor replacement. The goal of gene therapy would be to achieve a sustainable factor activity level of over 5%, which is sufficient to convert patients with severe disease to a much milder phenotype.[42] If a treatment strategy could produce consistent factor activity levels of around 50%, it would be considered curative.[42] Gene therapy for the treatment of hemophilia remains in the early clinical stages. Advances are most apparent in hemophilia B, which has been attributed to the smaller size (about 1.4 kb) of its complementary DNA (cDNA).[42] Recently, a landmark clinical trial reported the results of a single peripheral venous infusion of an adenovirus associated factor IX transgene vector under the control of a liver-restricted promoter in six patients with severe hemophilia B.[43] All of the study subjects demonstrated long-term (over 2 years) expression of the factor IX transgene with therapeutic levels of factor IX (plateau factor IX levels from 1% to 6%).[43,44] At this time, gene therapy for factor VIII deficiency has not progressed as far due to the considerably larger size of its cDNA (about 9 kb).[42]

Potential benefits to gene therapy include patient convenience, viral safety, and decreased cost. Possible drawbacks to gene therapy include a risk of inhibitor formation, tumorigenesis related to possible integration of the viral vector, possible germ-line transmission of the viral vector, and concerns about long-term gene expression.

Pain Management in Hemophilia

Pain, both acute and chronic, can be a common occurrence in patients with hemophilia. The most likely cause of acute pain is bleeding, and treatment should include factor replacement to stop the bleeding, and RICE (Rest, Ice, Compression, and Elevation).[7,45] Acetaminophen can be used for mild pain, although narcotic analgesia may be required for more severe pain. Nonsteroidal anti-inflammatory drugs impair platelet function and may increase bleeding and should not be used during acute bleeding episodes. Cyclooxygenase-2 inhibitors have less antiplatelet activity and are an option for acute and chronic pain management.[1,45]

Chronic pain in patients with hemophilia is typically secondary to hemophilic arthropathy. Hemophilic arthropathy is the direct result of recurrent hemarthrosis. Persistent blood in the joint leads to inflammation, synovial hypertrophy and inflammation, cartilage destruction, and finally bony erosion. Cyclooxygenase-2 inhibitors can also be helpful in managing chronic pain. Surgical interventions may help to alleviate chronic pain. Synovectomy (removal of the hypertrophied synovium) can reduce chronic pain from recurrent bleeding. Patients with more advanced joint disease could benefit from joint replacement.

Surgery in Hemophilia

In patients with severe hemophilia, the dose of replacement factor required in the perioperative period will depend on the surgery, the inhibitor status, and the patient's previous response to factor products. Ideally, the patient's factor activity level should be maintained in the range of 50% to 100% depending on clinical status and type of procedure. Intermittent dosing or continuous infusion factor replacement may accomplish this goal.[1,33,46] Before surgery, factor concentrate is usually infused to obtain a plasma level of 1 unit/mL (100%). Replacement therapy is continued to maintain plasma levels greater than 0.5 units/mL (50%) for 5 to 7 days or longer, depending on the type of surgery and the patient's clinical response. Preoperative evaluation for elective procedures should include measurement of an inhibitor titer no longer than 2 weeks prior to procedure and assessment of the recovery and half-life of infused factor in the patient.[1] For those patients with inhibitors undergoing surgical procedures, there is evidence to support the use of both activated factor VII and aPCCs.[1,33]

Personalized Pharmacotherapy

The newest approach in hemophilia treatment is "personalized" prophylaxis.[47] Traditionally, standard prophylaxis is prescribed based on a weight-based calculation to increase a patient's trough factor level to greater than 0.01 units/mL (1%). Although this approach is successful for many patients, some may still experience breakthrough bleeding, which suggests that prophylactic dosing and timing may need to be personalized to prevent bleeding. Many factors can contribute to

breakthrough bleeding including the patient's activity level, individual pharmacokinetics, the presence of a target joint, synovial hypertrophy, and the degree of hemophilic arthropathy present.[47] The prophylaxis regimen should take into account these factors and be adjusted accordingly.

Since inhibitor formation is the most significant treatment complication in hemophilia, targeted pharmacotherapy is being evaluated to decrease a patient's risk of inhibitor formation. For example, researchers are working to identify immunodominant epitopes in factor VIII that could lead to the development of new therapeutic factor VIII products for high-risk individuals.[48]

Evaluation of Therapeutic Outcomes

The main goal in the treatment of hemophilia is to control and prevent bleeding episodes and their long-term sequelae such as chronic arthropathies. Pharmacologic and nonpharmacologic interventions should be aimed at achieving this goal. Treatment response can be monitored through clinical parameters such as cessation of bleeding and resolution of symptoms. Monitoring plasma factor levels also may be helpful, particularly for severe bleeding episodes. Home therapy for administration of factor concentrates is common among patients with hemophilia because this approach can lead to earlier treatment and more independence for the patient. Diaries in which the patient documents symptoms, the dose of factor replacement, adjuvant therapies used, and treatment response can help the caregiver to evaluate the success of home therapy. Monitoring the number and type of bleeding episodes and trough plasma factor levels makes it possible to evaluate the adequacy of prophylactic regimens. Physical examination with evaluation of joint range of motion and radiographic imaging of target joints indicates the long-term success of preventing and treating arthropathies.

Clinicians should check for the development of inhibitors, especially in patients with severe disease and exposure to factor concentrates, at least yearly and with any suspicion of poor treatment response. The development of inhibitors challenges the management and control of bleeding episodes. A full understanding of the clinical situation and the titer of the inhibitor are mandatory to address all treatment options for each patient. Because no laboratory test measures the effectiveness of bypassing therapy in patients with inhibitors, close clinical monitoring for worsening or resolution of symptoms is essential for optimizing the outcome.

VON WILLEBRAND DISEASE

von Willebrand disease (vWD) is the most common congenital bleeding disorder in the United States and in the world, with a prevalence of 1% to 2%.[49,50] vWD refers to a family of disorders caused by a quantitative and/or qualitative defect of vWF, a glycoprotein that plays a role in both platelet aggregation and coagulation (**Table 101-6**). vWF mediates platelet adhesion to injured blood vessel sites and promotes platelet aggregation. It binds factor VIII and protects it from degradation by plasma proteases, thus prolonging its half-life. Unlike hemophilia, vWD has an autosomal inheritance pattern, resulting in an equal frequency of disease in males and females.

TABLE 101-6 von Willebrand Disease

von Willebrand factor (vWF)

Large multimeric glycoprotein that is necessary for normal platelet adhesion, normal bleeding time, and stabilization of factor VIII

von Willebrand factor antigen (vWF:Ag)

Antigenic determinant(s) on vWF measured by immunoassays; usually low in types 1 and 2; virtually absent in type 3

Ristocetin cofactor activity (RCo)

Functional assay of vWF activity based on platelet aggregation with ristocetin. Reduced by the same degree as vWF:Ag in types 1 and 3, but to a greater extent in type 2 disease (except 2B)

The gene for vWF is located on chromosome 12 and is 178 kb in length.[49,53] Transcription and translation produce a large primary product that subsequently undergoes complex modifications, resulting in vWF multimers of various sizes with molecular weights ranging from 500 to 20,000 kDa.[51,52] vWF is synthesized in endothelial cells, where it is either stored in Weibel–Palade bodies or secreted constitutively. It is also synthesized in megakaryocytes and stored in α-granules, from which it is released following platelet activation.[53,54]

von Willebrand factor is important for both primary and secondary hemostases. In response to vascular injury, it promotes platelet adhesion by interacting with the glycoprotein Ib receptor on platelets.[53] It can facilitate platelet aggregation by binding to the platelet glycoprotein IIb/IIIa receptor, although fibrinogen is the main ligand for this receptor.[55] The highest-molecular-weight vWF multimers appear to be the most important in platelet adhesion because their large surface area contains numerous binding sites for various ligands and receptors. vWF is also the carrier molecule for circulating factor VIII, protecting it from premature degradation and removal.[53,54] A deficiency of vWF reduces the half-life of factor VIII and decreases plasma factor VIII levels. Therefore, vWF plays a dual role in hemostasis, affecting both platelet function and coagulation.

CLINICAL PRESENTATION von Willebrand Disease Signs and Symptoms

- Clinical manifestations are variable; some patients are asymptomatic
- Mucocutaneous bleeding: epistaxis, gingival bleeding with minor manipulation, menorrhagia
- Easy bruising
- Postoperative bleeding

Classification of von Willebrand Disease

von Willebrand Disease consists of a heterogeneous group of disorders that can be classified into three major subtypes. The National Institutes of Health has developed a classification scheme that

characterizes vWD according to both the quantity of the von Willebrand clotting factors and their functionality (**Table 101-7**). Types 1 and 3 are associated with quantitative defects in vWF; type 2 mutations refer to functional abnormalities in vWF.[50,53] It is important to determine disease subtype because it influences treatment.

TABLE 101-7 von Willebrand Disease Classification and Laboratory Values (Modified from Nichols 2009)

Condition	Description	vWF-RCo (IU/dL)[1]	vWF-Ag (IU/dL)[1]	FVIII	vWF-RCo/vWF-Ag Ratio
Definite Type 1	Partial quantitative vWF deficiency	<30	<30	↓ or Normal	>0.5-0.7
"Probable type 1"		30-50	30-50	Normal	>0.5-0.7
Type 2A	↓ vWF-dependent platelet adhesion with selective deficiency of high-MW vWF multimer	<30	<30-200	↓ or Normal	<0.5-0.7
Type 2B	↑ vWF affinity for platelet GP 1b; + ↓ platelet numbers	<30	<30-200	↓ or Normal	Usually <0.5-0.7
Type 2M	↓ vWF-dependent platelet adhesion without selective deficiency of high MW vWF multimers	<30	<30-200	↓ or Normal	<0.5-0.7
Type 2N	Markedly ↓ vWF binding affinity for FVIII	30-200	30-200	↓↓	>0.5-0.7
Type 3	Virtually complete deficiency of vWF	<3	<3	↓↓↓ (<10 IU/dL)	Not applicable
Normal		50-200	50-200	Normal	>0.5-0.7

vWF, von Willebrand factor; RCo, ristocetin cofactor.

To calculate levels of vWF-RCo and vWF-Ag in units of IU/mL multiply the corresponding value expressed in IU/dL by 0.010.

Modified from Nichols WL, Rick ME, Ortel TL. Clinical and laboratory diagnosis of von Willebrand disease: A synopsis of the 2008 NHLBI/NIH guidelines. Am J Hematol 2009;84:366-370.

Type 1 vWD is the most common type, accounting for 70% to 80% of cases.[50,56] It is characterized by a mild-to-moderate quantitative reduction in the level of vWF (although its multimeric structure is normal) and a similar reduction in the level of factor VIII. It usually is inherited in an autosomal-dominant fashion with variable penetrance and expression.[53] Bleeding symptoms often are very mild to moderate.[53] Patients with vWD can experience mucocutaneous bleeding such as nosebleeds, bruising, gastrointestinal, or menstrual bleeding. Subjects may be at risk of bleeding following

surgery, traumatic injury, or childbirth.[53]

Type 2 vWD, diagnosed in 20% to 30% of affected patients, is characterized by a qualitative abnormality of vWF.[50] Bleeding manifestations may be more severe than with type 1 disease. Inheritance most often is autosomal dominant but may be recessive.[53] Type 2 vWD can be subdivided into four variants. Type 2A is the most frequent subtype and is characterized by a reduced vWF–platelet interaction and an absence of high- and intermediate-molecular-weight factor multimers. Type 2B is a less common variant characterized by an abnormal vWF that has an increased affinity for the platelet glycoprotein Ib receptor. This subtype is associated with thrombocytopenia, which is usually mild. In addition, high-molecular-weight forms of vWF are usually absent. A platelet-type pseudo-vWD has been characterized in which vWF is normal but a defect in the platelet glycoprotein Ib receptor causes an increased affinity for normal vWF.[53] As a result, platelet-type pseudo-vWD is phenotypically similar to type 2B disease but should be distinguished from it because the treatment is different. Type 2M arises from a qualitative defect in vWF that impairs its binding to platelets; it is similar to type 2A, except there is no measurable reduction in the high-molecular-weight multimers.[53] Finally, type 2N vWD (Normandy) is a rare form of the disease in which vWF has a markedly reduced affinity for factor VIII. This subtype leads to a moderate-to-severe reduction of factor VIII plasma levels with normal vWF levels.[53]

Type 3 vWD refers to a severe quantitative variant of the disease in which vWF is nearly undetectable and factor VIII levels are very low (<20 IU/dL [<0.2 IU/mL]). It is often inherited in an autosomal recessive fashion.[56] Type 3 vWD is rare and accounts for 1% to 3% of all cases.[50] The clinical phenotype is severe, reflecting major deficits in primary hemostasis and coagulation.

Acquired vWD is a rare bleeding disorder that is similar to the congenital form of the disease. It has been reported primarily in association with autoimmune disorders, such as systemic lupus erythematosus, lymphoproliferative disorders, myeloproliferative disorders, hypothyroidism, and certain neoplastic diseases such as Wilms' tumor and lymphoma. It has been reported in situations of high shear stress such as aortic stenosis.[57] Certain medications have been associated with acquired vWD, including valproic acid, griseofulvin, hydroxyethyl starch, and ciprofloxacin.[57] Bleeding manifestations vary from mild to severe, and the condition often resolves with treatment of the underlying disease. Various mechanisms have been proposed, including autoantibodies to vWF resulting in rapid removal from the plasma, adsorption to tumor cells or activated platelets, increased proteolysis, or mechanical destruction.[57]

Diagnosis

When a patient has a lifelong history of mucocutaneous bleeding and a family history of abnormal bleeding, vWD should be suspected. For a review of clinical questions to ask the patient, refer to the National Heart, Lung, and Blood Institute guidelines (**Table 101-8**).[58]

TABLE 101-8 Questions to Ask Patients

1. Have you or a blood relative ever needed medical attention for a bleeding problem or been

told you have a bleeding disorder or problem?

   - During or after surgery?
   - With dental procedures or extractions?
   - During childbirth or for heavy menses?
   - Ever had bruises with lungs?

2. Do you have or have you ever had:
   - Liver or kidney disease?
   - A blood or bone marrow disorder?
   - A high or low platelet count?
3. Do you take aspirin, NSAIDs, clopidogrel, warfarin, heparin?

If yes to any of the above questions, ask additional questions:

1. Do you have a blood relative who has a bleeding disorder, such as von Willebrand disease or hemophilia?
2. Have you ever had prolonged bleeding from trivial wounds, lasting more than 15 minutes or recurring spontaneously during the 7 days after the wound?
3. Have you ever had heavy, prolonged, or recurrent bleeding after surgical procedures, such as tonsillectomy?
4. Have you ever had bruising, with minimal or no apparent trauma, especially if you could feel a lump under the bruise?
5. Have you ever had a spontaneous nosebleed that required more than 10 minutes to stop or needed medical attention?
6. Have you ever had heavy, prolonged, or recurrent bleeding after dental extractions that required medical attention?
7. Have you ever had blood in your stool, unexplained by a specific anatomic lesion (such as an ulcer in the stomach or polyp in the colon) that required medical attention?
8. Have you ever had anemia requiring treatment or received a blood transfusion?
9. For women, have you ever had heavy menses, characterized by the presence of clots greater than an inch in diameter and/or changing a pad or tampon more than hourly or resulting in anemia or low iron level?

NSAID, non-steroidal antiinflammatory drug.

Adapted from Nichols WL, Rick ME, Otel TL, et al. Clinical and laboratory diagnosis of von Willebrand disease: a synopsis of the 2008 NHLBI/NIH guidelines. Am J Hematol 2009;84:366-370.

Several different laboratory tests are helpful in the diagnosis of this hemostatic abnormality. Initial screening tests include determinations of PT, activated partial thromboplastin time (aPTT), and platelet count. PT is normal, while aPTT may be normal or prolonged in relation to the reduction in plasma factor VIII levels. A normal aPTT does not rule out vWD; specific laboratory assessment of the vWF is required. The platelet count usually is normal, although thrombocytopenia is common in type 2B and platelet-type pseudo-vWD. The platelet function analysis (PFA-100), or the less commonly used bleeding time, may be prolonged but can be normal in patients with milder forms of the disease.[53,59]

Specific laboratory tests for the diagnosis of vWD include measurement of vWF antigen (vWF:Ag) level, factor VIII assay, determination of vWF ristocetin cofactor (vWF:RCo) activity, and vWF multimer analysis (see Table 101-6). Unfortunately, these levels vary considerably and often indeterminate or unreliable results can lead to confusion in the diagnosis. For example, the cutoff normal values for vWF:Ag, vWF:RCo, and other specialized tests vary between laboratories. This coupled with the natural variation of plasma concentrations of vWF can make interpretation of these results complicated.[53] Plasma concentrations of vWF have been shown to increase with age, stress, cigarette smoking, exercise, pregnancy starting in the second trimester, infection, and with the use of certain medications such as corticosteroids, high-dose estrogen birth control pills, and desmopressin. Repeated test measurements may be necessary due to this physiologic variability.[53]

Electroimmunoassay, immunoradiometric assay or enzyme-linked immunosorbent assay (ELISA) can be used to quantify vWF:Ag.[53] vWF:Ag levels are known to vary with different ABO blood types. Individuals with type O blood exhibit up to a 25% decrease in vWF levels when compared to those with type A due to increased plasma protein clearance.[53] The vWF:Ag level is usually low in types 1 and 2 vWD and virtually absent in type 3 disease. Factor VIII levels are normal or mildly decreased in patients with type 1 or 2 disease and very low (<10%) in those with type 3 disease.[53] Ristocetin, an antibiotic that causes platelet aggregation in the presence of functional vWF, is used to measure vWF activity. The assay is performed by mixing platelet-free patient plasma, normal formalin-fixed platelets, and ristocetin and then quantitating the extent of platelet agglutination.[52] Ristocetin cofactor activity usually is reduced in parallel to vWF:Ag levels in types 1 and 3 disease and decreased to a greater extent than vWF:Ag in type 2 disease (except type 2B).[53] Low-dose ristocetin-induced platelet agglutination (LD-RIPA) is useful for further distinguishing type 2B disease, as a low concentration of ristocetin induces excessive aggregation in type 2B disease (see Table 101-7).[53]

von Willebrand factor, secreted as high molecular weight multimers, is cleaved in plasma to increasingly small protein fragments. The distribution of these multimer sizes can be helpful in determining the type of vWD. All multimer sizes are present in type 1 disease, whereas reduced levels of intermediate- and high-molecular-weight multimers are characteristic of type 2 disease. Type 3 patients lack all types of vWF multimers. Molecular genetic testing for vWD is now a feasible option

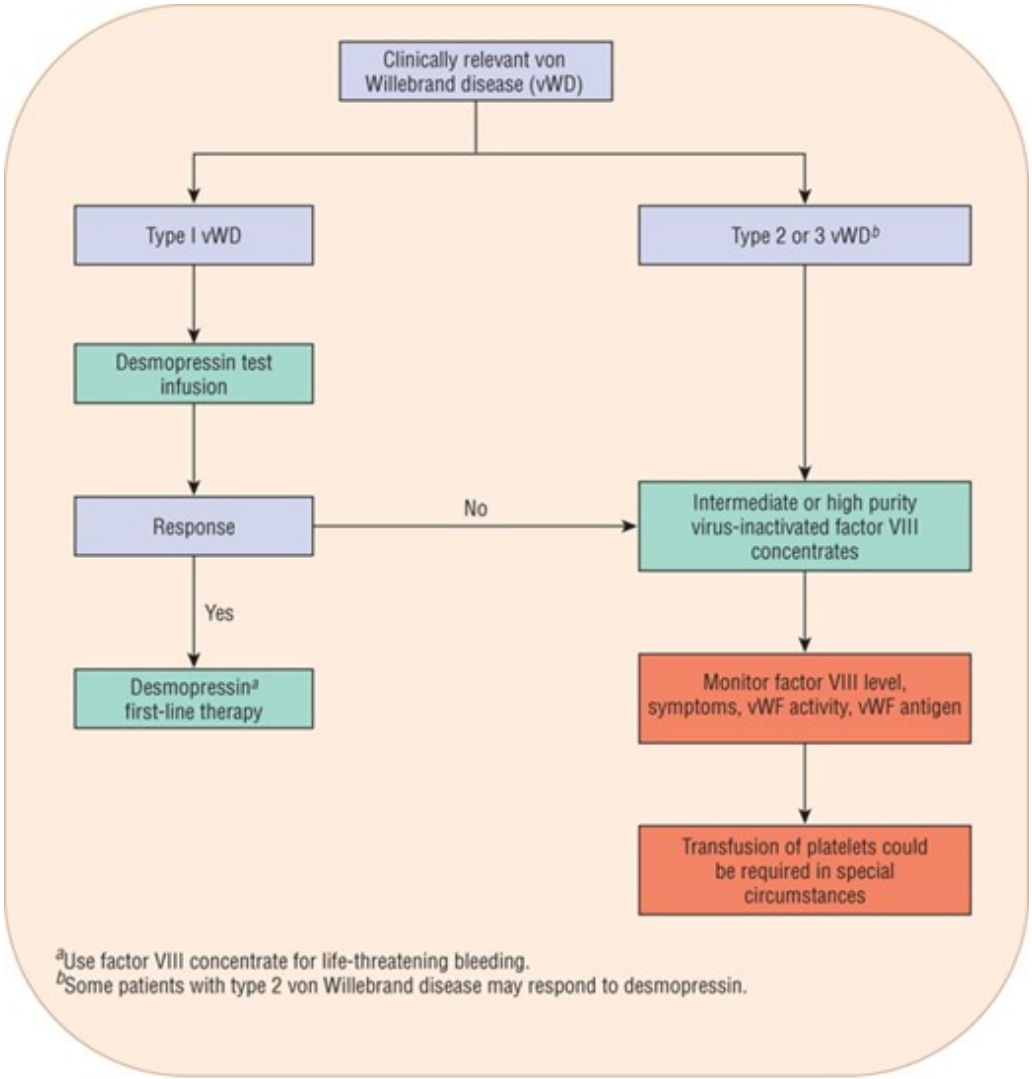
in some instances. Genetic testing may be used to clarify diagnostic uncertainty that may remain after coagulation testing and clinical evaluation.[53]

TREATMENT

6 The specific type of vWD and the location and severity of bleeding determine the approach to treatment. The comprehensive care of patients with vWD requires a team approach. The desired outcome is to prevent bleeding episodes and their short-term and long-term consequences so that patients with vWD can live active and productive lives. Local measures, including pressure, ice, and topical thrombin, often can control superficial bleeding. Systemic treatment is used for bleeding that cannot be controlled in this manner and for prevention of bleeding with surgery. The goal of systemic therapy is to correct platelet adhesion and coagulation defects by stimulating the release of endogenous vWF or by administering products that contain vWF and factor VIII.[60] General guidelines for treatment of vWD are shown in **Fig. 101-2**.

FIGURE 101-2

Guidelines for treatment of von Willebrand disease.



Replacement Therapy

7 The treatment of choice for patients with types 2B, 2M, and 3 vWD and for patients with type 1 or 2A vWD who are unresponsive to desmopressin (which is discussed in the next section) is replacement therapy with plasma-derived vWF-containing products.[56] Several virus-inactivated, intermediate- or high-purity plasma derived factor VIII concentrates contain sufficient amounts of functional vWF for treatment in this patient population (see Table 101-4). Ultrahigh-purity (monoclonal antibody-derived) plasma-derived products contain only negligible amounts of vWF and recombinant factor VIII products contain no vWF and are inadequate for treatment of vWD. Developing improved factor replacement products is an active area of research at this time. A recent prospective first-in-human clinical trial of a combination of recombinant vWF and recombinant factor VIII in a fixed ratio was completed. The study showed the combination product to be safe and well tolerated with only minor and transient adverse effects similar to those seen in patients receiving plasma derived products. The pharmacokinetics of the recombinant combination were also comparable to the plasma derived vWF with the added benefit of enhanced factor VIII stabilization,

resulting in no additional factor VIII product required for adequate hemostasis.[62]

Cryoprecipitate contains about 80 to 100 units of vWF per unit (5 to 10 times more vWF and factor VIII than fresh-frozen plasma), and historically it was the mainstay of therapy for vWD. However, because cryoprecipitate is not virally inactivated, it should not be used as first-line treatment. General guidelines for the dosing of replacement therapy in patients with vWD unresponsive to desmopressin are provided in **Table 101-9**. The vWD guidelines are also available at the National Heart, Lung and Blood Institute Web site (*http://www.nhlbi.nih.gov/guidelines/vwd/index.htm*). In addition, a consensus guideline for the treatment of vWD and other bleeding disorders in women was published in 2009.[61]

TABLE 101-9 Replacement Therapy in von Willebrand Disease[a]

Condition	Therapy
Major surgery	Maintain factor VIII level ≥50% for 1 week
	Prolonged treatment in type 3 patients (>7 days)
Minor surgery	Maintain factor VIII level ≥50% for 1-3 days
	Maintain factor VIII level >20%-30% for an additional 4-7 days
Dental extraction	Single infusion to achieve factor VIII level >50%
	Desmopressin prior to procedure for type I
Spontaneous or posttraumatic bleeding	Usually single infusion of 20-40 units/kg

[a]The yield of factor VIII after first infusion is similar to that observed in hemophilia A (about 2% increment over baseline amount for every 1 unit/kg of factor VIII infused).

Other Pharmacologic Therapy

Desmopressin stimulates the endothelial cell release of vWF and factor VIII. It is temporarily effective for patients with vWD who have adequate endogenous stores of functional vWF, which includes most patients with type 1 disease and some patients with type 2A disease. Conversely, desmopressin is not appropriate for patients with type 3 disease, who lack stores of vWF. Desmopressin usually is not recommended for treatment of type 2B disease because the release of additional abnormal vWF may exacerbate thrombocytopenia, but it has been reported to be beneficial in some patients with type 2B disease.[59] If desmopressin is used for treatment of type 2B disease, close monitoring is necessary.

Clinical Controversy...

The use of desmopressin in treating acute bleeds in patients with type 2B vWD is controversial. There is some evidence that it may put patients at risk of severe thrombocytopenia.

The dose of desmopressin used for treatment of vWD is identical to that used for treatment of mild factor VIII deficiency, 0.3 mcg/kg given IV over 15 to 30 minutes.[28] Patients with vWD generally have

a better response to desmopressin than those with hemophilia, with an average threefold to fivefold increase in vWF and factor VIII levels.[59] These levels remain elevated for about 6 to 8 hours. The response to desmopressin in a given patient usually is consistent, and a desmopressin trial should determine if the medication likely will be effective for the individual. Desmopressin is preferable to use of plasma-derived products for patients who have an adequate response because desmopressin does not carry a risk of viral transmission. An added benefit is the substantially lower cost of desmopressin compared to the plasma-derived products. (For a discussion of the side effects of desmopressin, see Treatment of Hemophilia A discussed earlier.)

Desmopressin can be administered every 12 to 24 hours, but the response diminishes with repeated treatment. After three to four doses, desmopressin often is no longer effective and alternative replacement therapy may be necessary if prolonged treatment is required. Laboratory monitoring, including vWF:Ag measurements, factor VIII assays, vWF:activity assessments, and clinical examinations, will determine the adequacy of treatment.[59] Intranasal administration of desmopressin, at the same dosage as that used for mild factor VIII deficiency, can be useful for treatment of mild bleeding episodes. One or two doses administered at the start of menses may be helpful in controlling menorrhagia. Oral contraceptives may also be very effective in controlling this symptom. Antifibrinolytic agents, such as aminocaproic acid and tranexamic acid, may be of special value in bleeds associated with tissues rich in plasminogen activators, such as the mouth, especially with tooth extractions.[59] These agents can also be used in the management of epistaxis, GI bleeding, and menorrhagia. However, these agents should be avoided in urinary tract bleeding because of the risk of thrombosis and obstruction.

In acquired vWD, low levels of plasma vWF are the result of accelerated removal of protein from plasma through the action of different pathogenic mechanisms. Acquired vWD may be associated with monoclonal gammopathy, lymphoproliferative or myeloproliferative syndromes, or cardiovascular disease. The treatment of the underlying lymphoproliferative disease with rituximab, a monoclonal antibody against CD20 on lymphocytes, has been reported to be relatively ineffective in the management of acquired vWD.[57] IV immune globulin remains a therapeutic option in acquired vWD, along with vWF concentrate and/or desmopressin.

Gene Therapy

Patients with the most severe bleeding phenotypes of vWD (type 3 and some severe cases of types 1 and 2) may be the most likely candidates for gene therapy, which offers the potential of a long-term, if not lifelong, correction of vWF deficiency. Studies placing vWF cDNA into a lentiviral vector are currently ongoing.[51] Preclinical trials are being conducted to test the feasibility of gene transfer in the management of vWD.

Personalized Pharmacotherapy

Current treatment of individual patients with vWD is personalized. Although the general goal of systemic therapy is to correct platelet adhesion and coagulation defects by stimulating the release of vWF or administering products that contain vWF, each patient's bleeding risk factors must be taken

into consideration, and therapy tailored to the individual. The proposed regimen should take into account these risk factors and the most appropriate individualized therapy should be provided.

Evaluation of Therapeutic Outcomes

Since the main goal in the treatment of vWD is to prevent or control bleeding and the consequences of such bleeding, bleeding episodes can be monitored via clinical and laboratory parameters. Monitoring the number and types of bleeding episodes and measurement of plasma concentrations of vWF and factor VIII make it possible to evaluate the effectiveness of specific prophylactic and treatment regimens. As with hemophilia patients, assessment of patients' activities of daily living gives clinicians a better appreciation of the success of the treatment plan.

OTHER CONGENITAL FACTOR DEFICIENCIES

Rare bleeding disorders constitute 3% to 5% of all inherited coagulation factor deficiencies.[63] These rare bleeding disorders include congenital deficiencies in fibrinogen, in factors II, V, VII, X, XI, and XIII, and in combinations of factor deficiencies. Contact factor abnormalities, including deficiencies in factor XII, high-molecular-weight kininogen, and prekallikrein, prolong the aPTT but do not lead to any bleeding diathesis. Identification of these disorders is important so that inappropriate treatment is not given. The only contact factor deficiency associated with bleeding symptoms is factor XI deficiency. Also known as hemophilia C, this deficiency is particularly common in people of Ashkenazi Jewish descent.[61] Bleeding manifestations are variable. Bleeding usually does not occur spontaneously, but excessive bleeding may occur after trauma or surgery. Most other deficiencies are inherited as autosomal recessive disorders and are rare. Some patients with abnormal molecules, such as a dysfibrinogenemia, may have an increased tendency to develop thromboembolic disease. Most of these deficiencies are treated with fresh-frozen plasma. Newer specific concentrates are becoming available. For example, a factor XIII plasma-derived concentrate is available, and recombinant factor VIIa is approved for use in patients with congenital VII deficiency. Cryoprecipitate, which is rich in fibrinogen, or fibrinogen concentrates (RiaSTAP®), can be used to treat patients with fibrinogen deficiency or dysfunctional fibrinogen (dysfibrinogenemia).

COMPLICATIONS OF REPLACEMENT THERAPY

As discussed previously, transmission of bloodborne infectious diseases is always a concern when blood and blood-derived products are used. Most patients with hemophilia who received plasma-derived products were infected with hepatitis viruses and HIV during the 1980s prompting the development of viral inactivation methods for use during the manufacturing of factor concentrates.[28] All currently available plasma-derived factor concentrates come from screened donors and undergo viral inactivation procedures in an effort to reduce the risk of viral transmission. Heat treatment, which includes dry and wet heat, is one method of viral inactivation. Wet heat is applied while the concentrate is in suspension or in solution (pasteurization) and appears to be more effective than dry heat. Other methods of viral inactivation include chemical (solvent detergent) and affinity chromatography with monoclonal antibodies. Solvent detergent treatment inactivates lipid-coated

viruses, such as HIV and hepatitis B and C, but it is not effective against parvovirus B19, transfusion transmitted virus, hepatitis A, or prions.[5] Parvovirus B19 has been found in both plasma-derived and recombinant factor VIII concentrates (due to the use of albumin as a stabilizer in some recombinant products).[5,14] Parvovirus B19 may be particularly important for patients with hemophilia and HIV infection because it can cause chronic anemia in patients with immune deficiency. Prions are not inactivated by either solvent detergent treatment or by heat, so there is a risk of transmission.[7]

Other complications associated with factor administration include allergic reactions, fever, chills, urticaria, and nausea. PCCs and aPCCs also have the potential to cause thromboembolic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction and DIC, likely related to the presence of activated factors.[28] Antifibrinolytic agents should not be given to patients receiving PCCs or aPCCs to avoid thrombotic complications.

Porcine factor VIII, used in the treatment of patients with inhibitors to factor VIII, is not known to transmit human viruses. However, allergic-type reactions (eg, fever, chills, skin rashes, nausea, and headaches) have been reported.[28] Patients who experience these reactions can be treated with steroids and/or diphenhydramine. Thrombocytopenia is another potential complication of porcine factor VIII use.[28]

CONCLUSION

Coagulation disorders, such as hemophilia and vWD, affect a small subset of the overall population, but their treatment can be costly and complicated, requiring knowledgeable healthcare professionals and an interprofessional team approach for optimal outcomes to be achieved. Exciting progress is being made in the development of new strategies for treating these types of disorders. The development of new factor products with improved pharmacokinetic properties as well as the advances in gene therapy may soon redefine the therapeutic landscape for these patients and improve their overall experience.

Chapter 102: Sickle Cell Disease

C. Y. Jennifer Chan; Melissa Frei-Jones

INTRODUCTION

KEY CONCEPTS

- 1 Sickle cell disease is an inherited disorder caused by a defect in the gene for β-globin, a component of hemoglobin, and is called a qualitative hemoglobinopathy. Patients can have one defective gene (sickle cell trait) or two defective genes (sickle cell disease).
- 2 Although sickle cell disease usually occurs in persons of African ancestry, other ethnic groups can be affected. Multiple mutation variants are responsible for differences in clinical manifestations.
- 3 Sickle cell disease involves multiple organ systems. Usual clinical signs and symptoms include anemia, pain, splenomegaly, and pulmonary symptoms. Sickle cell disease is identified through routine newborn screening programs available in all 50 states. Early diagnosis allows early preventive and comprehensive care.
- 4 Patients with sickle cell disease are at risk for infection. Prophylaxis against pneumococcal infection reduces death during childhood in children with sickle cell anemia or hemoglobin SS.
- 5 Hydroxyurea decreases the incidence of painful episodes, but patients treated with hydroxyurea should be carefully monitored.
- 6 Neurologic complications caused by vasoocclusion can lead to stroke. Screening with transcranial Doppler ultrasound to identify children at risk accompanied by chronic transfusion therapy programs can decrease the risk of overt and silent stroke in children with sickle cell disease.
- 7 Patients with fever greater than 38.5°C (101.3°F) should be evaluated, and appropriate antibiotics administered immediately, including coverage for encapsulated organisms, especially pneumococcal organisms.

- 8 Pain episodes can often be managed at home. Hospitalized patients require parenteral analgesics. Analgesic options include opioids, nonsteroidal anti-inflammatory agents, and acetaminophen. The patient characteristics and the severity of the pain should determine the choice of agent and regimen.

- 9 Patients with sickle cell disease should be followed regularly for healthcare maintenance issues and monitored for changes in organ function.

1 Sickle cell syndromes, which can be divided into sickle cell trait (SCT) and sickle cell disease (SCD), are a group of hereditary conditions characterized by the presence of sickle cell hemoglobin (HbS) in red blood cells. SCT is the heterozygous inheritance of one normal β-globin gene producing HbA and one sickle gene, producing HbS (HbAS). Individuals with SCT are asymptomatic. SCD can be of homozygous or compounded heterozygous inheritance. Homozygous HbS (HbSS) has historically been referred to as sickle cell anemia (SCA) which now also includes HbSβ^0-thal due to similarities in clinical severity. The heterozygous inheritance of HbS with another qualitative or quantitative β-globin mutation results in sickle cell hemoglobin C (HbSC), sickle cell β-thalassemia (HbSβ^+-thal and HbSβ^0-thal), and some other rare phenotypes.[1,2]

Over the years, progress has been made in understanding the relationship between clinical severity and genotype, as well as the natural history of common morbidities associated with SCD. Ongoing research focuses on pharmacotherapies to treat SCD and prevent organ damage. Recent advances in the care of SCD patients have increased life expectancy. Therefore, the transition from pediatric to adult medical care has become a focus to further improve survival and quality of life.[1,2,3,4,5,6,7]

SCD is a chronic illness with significant psychosocial consequences for patients, caregivers and society. Frequent hospitalizations can interrupt schooling and result in employment difficulties.[8,9,10] Acute complications of the disease can be unpredictable, rapidly progressive, and life threatening. Later in life, chronic organ damage and cognitive or emotional impairment can develop.[1,2,7] Because of the complexity and gravity of the illness, it is essential that comprehensive care is available to all patients and that all providers involved have a good understanding of the disease and its management.[1,2,8,11]

EPIDEMIOLOGY

2 SCD affects millions of people worldwide and is most common in people with African heritage.[1,12] The most common SCD genotype is HbSS (~60%-65%), followed by HbSC (~25%-30%), HbSβ^+-thal and HbSβ^0-thal (~5%-10%). Other variants account for less than 1% of patients.[1,2] The disease is common among those with ancestors from sub-Saharan Africa, India, Saudi Arabia, and Mediterranean countries.[2,13] In the United States, about 100,000 Americans have SCD with a prevalence of 1 in 2,500 newborns, 1 in 365 African Americans and 1 in 36,000 Hispanic births.[1,14,15] About 2 million Americans have SCT with a prevalence rate of 1 in 13 African Americans and 1 in 100 Hispanics.[15,16]

About 275,000 babies are born with SCD every year with 85% of births in Africa.[2,12] The prevalence of SCD in the region is determined by the frequencies of SCT. The distribution of SCT reflects the survival advantage in regions where malaria is endemic as the gene mutation offers partial protection against serious malarial infection. Red blood cells (RBCs) carrying the abnormal sickle hemoglobin prevent the normal growth and development of *Plasmodium falciparum* within RBCs. Individuals with SCT are more likely to survive acute malarial illness whereas individuals with SCD-HbSS often present with more severe disease. The incidence of the sickle gene in a population correlates with the historical incidence of malaria and SCT results in partial resistance to the disease.[1,2,12,17]

The prevalence of SCD is highest in sub-Saharan Africa. Other areas where the sickle mutation can be found include the Arabian Peninsula, the Indian subcontinent, and the Mediterranean region. Genetic analysis shows that the mutation found in Arabic patients is different from the mutation in those of African descent. SCD gene variants associated with different geographic locations may be responsible for variations in clinical manifestations.[3,5,13]

ETIOLOGY

Normal hemoglobin (hemoglobin A [HbA]) is composed of two α chains and two β chains (α_2 β_2). The biochemical defect that leads to the development of HbS involves the substitution of valine for glutamic acid as the sixth amino acid in the β-polypeptide chain. Another abnormal hemoglobin, hemoglobin C (HbC), is produced by the substitution of lysine for glutamic acid as the sixth amino acid in the β-chain. Structurally, the α chains of HbS, HbA, and HbC are identical. Therefore, it is the chemical differences in the β-chain that account for sickling and its related sequelae.[1,2,3,7]

Homozygous HbSS is the most common form of SCD and occurs when an individual inherits both maternal and paternal β-globin alleles that code for HbS. **Figures 102-1,102-2,102-3,102-4** show the probability of inheritance with each pregnancy for the offspring of parents with HbA, SCT, and HbSS. If both parents are carriers, the offspring will have a 25% risk of inheriting SCD and a 50% risk of SCT (see Fig. 102-1). β-Thalassemia is a quantitative hemoglobinopathy resulting from a genetic defect in β-globin production. β-Thalassemia can be co-inherited with HbS and may vary from no β-globin production (β^0) to some β-globin production (β^+). Individuals with HbSS and HbSβ^0-thal have a more severe course than those with HbSC and HbSβ^+-thal and are now both referred to as SCA.[2,7,13]

FIGURE 102-1

Sickle cell gene inheritance scheme for both parents with sickle cell trait (SCT). Possibilities with each pregnancy: 25% normal (AA); 50% SCT (AS); 25% sickle cell anemia (SS). (A, normal hemoglobin; S, sickle cell hemoglobin)

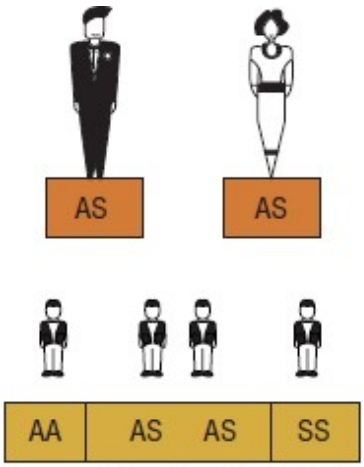

FIGURE 102-2

Sickle cell gene inheritance scheme for one parent with sickle cell trait (SCT) and one parent with no sickle cell gene. Possibilities with each pregnancy: 50% normal (AA); 50% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin)

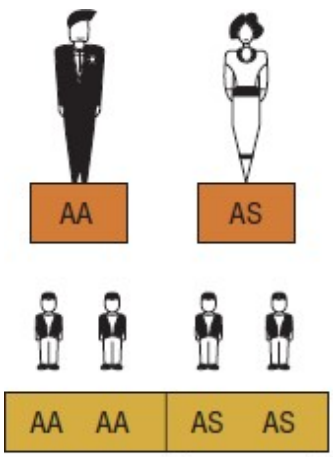

FIGURE 102-3

Sickle cell gene inheritance scheme for one parent with sickle cell trait (SCT) and one parent with sickle cell anemia (SCA). Possibilities with each pregnancy: 50% SCA (SS); 50% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin)

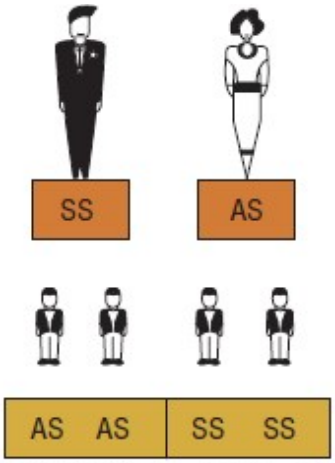

FIGURE 102-4

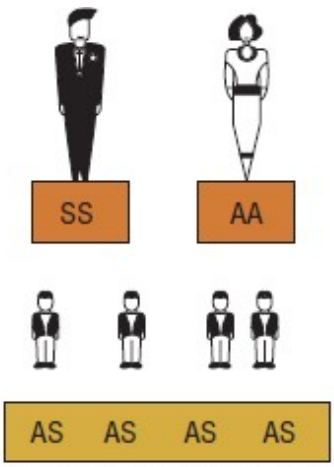
Sickle cell inheritance scheme for one parent without sickle cell gene and one parent with sickle cell anemia (SCA). Possibilities with each pregnancy: 100% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin)



Several haplotypes characterize the sickle gene, resulting in different clinical and hematologic courses. The three most common haplotypes in the United States are the Bantu haplotype, characterized by severe disease; the Senegal haplotype, characterized by mild disease; and the Benin haplotype, characterized by a course intermediate to that of the other two haplotypes. Although there are a number of other haplotypes seen around the world, the major types outside of the United States include Saudi Arabian and Cameroon, both with milder courses of illness.[2,3,5,7]

PATHOPHYSIOLOGY

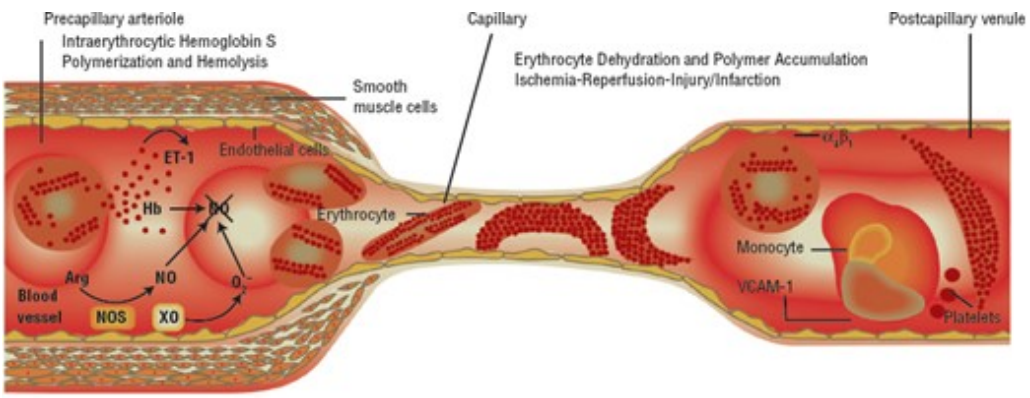
Normal adult RBCs contain predominantly HbA (96%-98%). Other forms of hemoglobin are HbA_2

(2%-3%) and fetal hemoglobin (<1%). Normal RBCs are biconcave shape and able to deform to squeeze through capillaries.[1,2,3,18] Fetal hemoglobin (HbF) is present predominantly in fetal RBCs and is a tetramer of two α-globin chains and two γ-globin chains ($\alpha_2\gamma_2$). Prior to birth, HbF is the predominant hemoglobin type. At around 32 weeks gestation, a switch from the production of γ chains to β chains occurs and consequently, an increase in HbA production is seen. Increased HbF production is seen under severe erythroid stress, such as anemia, post-hematopoietic stem cell transplantation, or chemotherapy or in the hereditary condition, hereditary persistence of fetal hemoglobin (HPFH) where a mutation in the β-globin gene cluster results in continued HbF production after birth. HPFH is a benign, asymptomatic condition.[3,5,19]

In the pathogenesis of SCD, the following are responsible for the various clinical manifestations: impaired circulation, destruction of RBCs, stasis of blood flow and ongoing inflammatory responses. These changes result directly from two major disturbances involving RBCs: abnormal hemoglobin polymerization and membrane damage (**Fig. 102-5**).

FIGURE 102-5

Pathophysiology of sickle cell disease. (Arg, arginine; ET-1, endothelin-1; Hb, hemoglobin; NO, nitric oxide; NOS, nitrous oxide synthase; VCAM-1, vascular cell adhesion molecule 1; XO, xanthine oxidase.) *(From Kato GJ, Gladwin MT. Sickle cell disease. In: Hall JB, Schmidt GA, Wood LDH. Principles of Critical Care, 3rd ed. New York: McGraw-Hill, 2005:1658.)*



The solubilities of HbS and HbA are the same under conditions of normal oxygenation. Because of increased hydrophobicity as a result of the valine substitution, solubility of deoxygenated HbS is reduced. Saturation of deoxy-HbS leads to intermolecular binding and formation of thin bundles of fibers, which initially are unstable. However, the increased binding of deoxy-HbS eventually results in cross-linked fibers and stable polymers. This process is influenced by mean corpuscular hemoglobin concentration (MCHC), temperature, intracellular pH, and the circulating amount of HbS. Polymerization allows deoxygenated hemoglobin molecules to exist as a semisolid gel that protrudes into the cell membrane, leading to distortion of RBCs (sickle shaped) and loss of deformability. The

presence of sickled RBCs increases blood viscosity and encourages sludging in the capillaries and postcapillary venules. Such obstructive events lead to local tissue hypoxia, which tends to accentuate the pathologic process.[1,2,6]

When reoxygenated, polymers within the RBCs are lost and the RBCs eventually return to normal shape. This process contributes to the vasoocclusive manifestation in that HbS-containing RBCs are able to enter the microvasculature when oxygenated, but sickle when deoxygenated. The cycle of sickling and unsickling results in damage to the cell membrane, loss of membrane flexibility, and rearrangement of surface phospholipids. Membrane damage also alters ion transport, resulting in potassium and water loss, which can lead to a dehydrated state enhancing the formation of sickled forms. After continual repetitions of the process, the RBC membrane develops into rigid irreversibly sickled cells (ISC). Unlike the reversible sickled cells (RSC), which have normal morphology when oxygenated, ISCs are elongated cells and remain sickled when oxygenated. More rigid membranes of HbS-containing RBCs retard flow, particularly through the microcirculation. In addition, sickled RBCs tend to adhere to vascular endothelial cells, which further increase polymerization and obstruction.[1,2,6]

Intermolecular binding and polymer formation are reduced by HbF and to a lesser degree by HbA_2. RBCs that contain HbF sickle less readily than cells without. ISCs, not surprisingly, have a low HbF level. Increased levels of HbF, as in the case of the Saudi Arabian genotype, result in a more benign form of SCD. The amount of HbF and HbA_2 in relation to HbS influences the clinical manifestations and accounts for some of the variability in severity among SCD genotypes.[2,3,5]

Intravascular destruction of sickle cells can occur at an accelerated rate. The stresses of circulation and repetitive sickle–unsickle cycles lead to cell fragmentation. Damage to the cell membrane promotes cell recognition by macrophages. Rigid ISCs are easily trapped, resulting in short circulatory survival and chronic hemolysis. The typical sickled cell survives for about 10 to 20 days, while the life span of a normal RBC is 120 days.[7] Anemia triggers the release of immature RBCs (reticulocytes) from the bone marrow prematurely. Surface adhesion proteins that maintain the reticulocytes inside the marrow adhere to the endothelium in postcapillary venules further blocking the mature HbS-containing RBCs leading to complete occlusion of microvessels.[6,7]

In addition to sickling, other factors contribute to the clinical manifestations associated with SCD. Sickled cells also interact with leukocytes, endothelial cells, and platelets to form an occlusive clot. Hemolysis releases free hemoglobin resulting in generation of reactive oxygen species, nitric oxide (NO) depletion, and vascular inflammation. Chronic NO depletion contributes to vasoconstriction, activation of platelet, and adhesion molecules such as vascular cell adhesion molecule 1 (VCAM-1) and production of potent vasoconstrictor and endothelin 1 (ET-1).[2,20]

Obstruction of blood flow to the spleen by sickle cells can result in functional asplenia, defined as the loss of splenic function with an intact spleen. These patients can also have deficient opsonization. Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly pneumococcal bacteria. Coagulation abnormalities in SCD can be the result of continuous activation of the hemostatic system or disorganization of the membrane layer.[2,6,7,20]

CLINICAL PRESENTATION

SCD is usually identified on routine newborn screening programs in the United States. Since 2006, universal newborn screening for SCD is performed in all 50 states. The sensitivity and specificity of screening methods such as isoelectric focusing high-performance liquid chromatography and hemoglobin electrophoresis approaches 100%. For infants with a positive screening result, a second test should be performed before 2 months of age to confirm the diagnosis. More than 98% newborns in the United States are screened for SCD to identify the disease. Despite universal screening, some infants with SCD escape identification at birth because of extreme prematurity, prior blood transfusion, or inability to contact family.[2,19,21]

SCD involves multiple organ systems, and its clinical manifestations vary greatly between genotypes (**Table 102-1**).[1,2,13,22] Persons with SCT are usually asymptomatic and SCT is not considered a disease. However, under certain extreme situations where hemoglobin oxygenation is altered, RBC sickling can occur. Sickling of RBCs in the renal medulla, an area with low-oxygen tension, can result in the inability to concentrate urine. Individuals with such impairment can be at risk of dehydration. Microscopic hematuria has been observed, and gross hematuria can occur after heavy exercise. Other reported complications associated with SCT are venous thromboembolism, particularly pulmonary embolism, renal medullary carcinoma and chronic kidney disease.[14,17] Individuals with SCT should be cautious when participating in exercise under extreme conditions, such as athletic or military training. The US Sudden Death in Athletes Registry reported that 0.9% of 2,462 deaths occurred in athletes with SCT. The events in those 23 athletes with SCT were sudden cardiovascular collapse followed by several minutes of gradually worsening symptoms including dyspnea, fatigue and weakness during or after vigorous physical activity.[23] Preventive strategies such as gradual conditioning, adequate rest and hydration are recommended to minimize risk of sudden death in personnel undergoing athletic or military training.[17,23]

TABLE 102-1 Clinical Features of Sickle Cell Trait and Common Types of Sickle Cell Disease

Type	Clinical Features
Sickle cell trait (SCT)	Rare painless hematuria; normal Hb level; heavy exercise under extreme conditions can provoke gross hematuria and complications (normal Hb)
Sickle cell anemia (SCA- HbSS)	Pain episodes, microvascular disruption of organs (spleen, liver, bone marrow, kidney, brain, and lung), gallstones, priapism, leg ulcers; anemia (Hb 6-9 g/dL [60-90 g/L; 3.72-5.59 mmol/L])
Sickle cell hemoglobin C (HbSC)	Painless hematuria and rare aseptic necrosis of bone; pain episodes are less common and occur later in life; other complications are ocular disease and pregnancy-related problems; mild anemia (Hb 9-14 g/dL [90-140 g/L; 5.59-8.69 mmol/L])
Sickle cell β^+-thalassemia (HbSβ^+-thal)	Rare pain; milder severity than HbSS because production of some HbA; Hb 9-12 g/dL (90-120 g/L; 5.59-7.45 mmol/L) with microcytosis

Type	Clinical Features
Sickle cell β^0-thalassemia (HbSβ^0-thal)	No HbA production; severity similar to SCA; Hb 7-9 g/dL (70-90 g/L; 4.34-5.59 mmol/L) with microcytosis

Hb, hemoglobin; HbA, hemoglobin A.

From McCavit,[1] Quinn,[2] Apanah,[13] Steinberg,[14] National Institutes of Health.[22]

The cardinal features of SCD are hemolytic anemia and vaso-occlusion. In individuals with HbSS, anemia usually develops from 4 to 6 months after birth. The delay is due to the presence of HbF in fetal RBCs. HbF production is gradually replaced by HbS, leading to the clinical manifestations of the disease, such as pain and swelling of the hands and feet, commonly referred to as *hand-and-foot syndrome* or *dactylitis* in infants.[1,2]

The common clinical signs and symptoms associated with HbSS include chronic anemia and pallor; fever; arthralgia; scleral icterus; abdominal pain; weakness; anorexia; fatigue; enlargement of the liver, spleen, and heart; and hematuria. Laboratory findings include low hemoglobin level around 6 to 9 g/dL (60-90 g/L; 3.72-5.59 mmol/L), elevated reticulocytes of 10% to 25%, and elevated platelet and white blood cell (WBC) counts. Mean corpuscular volume (MCV) is normal. The peripheral blood smear demonstrates sickled red cell forms.[1,2,14]

Individuals with HbSC disease present with less severe symptoms than that of HbSS and can be characterized primarily by mild anemia (hemoglobin levels of 9-14 g/dL [90-140 g/L; 5.59-8.69 mmol/L] and reticulocytes of 5%-10%), infrequent episodes of pain, persistence of splenomegaly into adult life, and excessive target cells in the peripheral blood smear. In individuals with heterozygous HbS-β-thalassemia syndrome, severity of disease depends on the thalassemia gene involved.[1,2]

Predictors for severe disease in children have not been established. Dactylitis before 1 year of age, average hemoglobin less than 7 g/dL (70 g/L; 4.34 mmol/L) in the second year of life, and leukocytosis in the absence of infection are markers of disease severity previously described but not validated in a subsequent study.[24] The Cooperative Study of Sickle Cell Disease recently reported that reticulocytosis is associated with increased risk of death and stroke in infants.[25] Early acute chest syndrome during the first 3 years of life is a predictor for recurrent episodes throughout childhood. Children with concomitant SCD and asthma have increased frequencies of acute chest syndrome and pain episodes and increased mortality.[26] Factors associated with decreased survival in adults with SCD include frequency of sickle cell pain, elevated WBC, cerebrovascular events, renal failure, proteinuria and pulmonary hypertension.[26,27] With improved survival for SCD, chronic manifestations of the disease contribute to the increased morbidity later in life.

COMPLICATIONS

Acute Complications

Functional asplenia and failure to make antibodies against encapsulated organisms contribute to the high risk of overwhelming sepsis in individuals with SCD. Penicillin prophylaxis and vaccination have significantly reduced the overall risk of *Streptococcus pneumonia* bacteremia, but nonvaccine serotypes of *Streptococcus pneumonia* has been reported.[2] Children with SCD remain at a greater risk of invasive pneumococcal infections when compared to those with other underlying diseases or healthy children.[28] This is not specific to SCD but to the presence of vascular device and is not due to asplenia. Would like to rephrase and move.[29] Other encapsulated organisms are *Haemophilus influenzae, Neisseria meningitidis,* and *Salmonella*, with the latter known to cause osteomyelitis and pneumonia in SCD. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* should be considered in older children with infiltrates on chest radiograph. Viral infections (eg, influenza and parvovirus B19) can result in severe morbidity.[1,2] In children with SCD admitted for bacteremia, coagulase-negative *Staphylococcus* was associated with central venous access;[29] and should be considered for those with central line placed for chronic transfusion. In adults, overt pneumococcal bacteremia is less common and pathogens such as *Staphylococcus aureus* and gram-negative organisms are associated with immunosuppression, indwelling catheter and bone and joint infections.[30]

All SCD patients with fever greater than 38.5°C (101.3°F) must be evaluated to determine the risk of infection or sepsis; and those with temperature 39.5°C (103.1°F) and appear ill should be hospitalized. Evaluation should include physical examination, complete blood count with reticulocyte count, blood culture, chest radiograph, urinalysis, and urine culture. Lumbar puncture may be needed, especially in young and toxic-appearing children. Fever in a patient with SCD should be considered a medical emergency with rapid administration of intravenous antibiotics due to risk of overwhelming sepsis.[1,22]

Children with SCD may experience a severe complication due to infection that results in impaired production of RBCs. An aplastic crisis is characterized by a decrease in the reticulocyte count and the rapid development of severe anemia (**Table 102-2**). The bone marrow becomes hypoplastic and is most often associated with a viral infection, particularly parvovirus B19.[1,2,14]

TABLE 102-2 Acute Sickle Cell Complications

Vasoocclusive pain episodes[a]
Clinical features: Acute painful infarction without changes in Hb; almost all patients with SCA will have episodes of acute pain. Recurrent acute pain results in bone, joint, and organ damage and chronic pain. Vasoocclusive episodes most commonly involve the bones, liver, spleen, brain, lungs, and penis. Acute long bone pains can be accompanied by signs of inflammation, making it difficult to differentiate from osteomyelitis. Abdominal involvement can resemble a surgical abdomen. Precipitating factors include infection, extreme weather conditions, dehydration, and stresses.
Signs and symptoms: Deep throbbing pain; local tenderness, erythema, and swelling can be seen. Fever and leukocytosis are common. Dactylitis usually occurs in young infants. Jaundice and increased transaminases can be present if liver is involved.

Evaluation: Frequent physical examination, CBC, reticulocyte count, and urinalysis. Based on symptomatology, the following may be needed: needle aspiration to rule out osteomyelitis, abdominal studies (radiograph, computed tomography scan, etc.), liver function tests, bilirubin, culture, and chest radiograph.

Aplastic crisis[b]

Clinical features: Acute decrease in Hb with decreased reticulocyte count (usually <1%); transient suppression of RBC production in response to bacterial or viral infection, most common being parvovirus B19.

Signs and symptoms: Headache, fatigue, dyspnea, pallor, and tachycardia; can also present with fever, upper respiratory or gastrointestinal infection symptoms.

Evaluation: CBC, reticulocyte count, radiograph, cultures (blood, urine, and throat), evaluation of viral infection (eg, parvovirus titers).

Acute splenic sequestration[c]

Clinical features: Acute exacerbation of anemia due to sequestration of large blood volume by the spleen. More commonly seen in patients with functioning spleens (eg, infants with HbSS and older children and rarely adults with HbSC disease); onset often is associated with viral or bacterial infections; recurrences are common and can be fatal.

Signs and symptoms: Sudden onset of fatigue, dyspnea, and distended abdomen; rapid decrease in Hb and Hct with elevated reticulocyte count, abdominal pain, splenomegaly, vomiting, hypotension, and shock.

Evaluation: Close monitoring of vital signs, spleen size, and oxygen saturation, CBC, reticulocyte count, and cultures.

CBC, complete blood count; Hb, hemoglobin; HbSC, sickle cell hemoglobin C; HbSS, Homozygous; Hct, hematocrit; RBC, red blood cell.

Neurologic

Neurologic abnormalities and cognitive deficits are well documented in patients with SCD. Vasoocclusive processes can lead to cerebrovascular occlusion that manifests as signs and symptoms of overt stroke, such as headache, paralysis, aphasia, visual disturbances, facial droop and convulsions. The risk of stroke is highest for HbSS and lowest for HbSβ^+-thal. The incidence of cerebral infarct in HbSS is 11% by age 20 years and 24% by age 45 years with a recurrence rate as high as 70% in 3 years. The highest risk occurs during the first decades, in particular ages 2 to 5. The

risk is lowest before age 2 secondary to the protective effect of HbF. Ischemic strokes occur in 54% of cerebrovascular accidents with the highest risk before age 10 years and after 30 years of age; whereas hemorrhagic strokes are more common when patients are in their 20s and is associated with poor outcome.[1,2,7,31,32]

In addition to neurologic examination, evaluation of acute events include computed tomography (CT) scan and magnetic resonance imaging (MRI). Asymptomatic or silent infarcts are detected by screening MRI; and transcranial Doppler ultrasound (TCD) is important in primary stroke prevention and is used. In addition, electroencephalography (EEG) can be used if there is a history of seizure.[1,2,22]

About 10% to 30% of SCD who have HbSS with no prior history of stroke have been found to have changes on MRI of the brain consistent with infarction or ischemia. Silent cerebral infarcts can be associated with increased risk of stroke, decreased neurocognitive functions, behavioral changes and poor academic performances. Ongoing intermittent cerebral ischemia episodes have been found in asymptomatic children without concurrent illness.[33] Finally, lower intelligence, visual-motor impairments and neuropsychological dysfunctions have been reported in patients not affected by acute or silent strokes and are associated with severity of anemia.[1,2,31,33]

Acute Chest Syndrome

Acute chest syndrome (ACS) is the second most common cause of hospitalization and responsible for about 25% of deaths among individuals with SCD. ACS is defined as a new pulmonary infiltrate associated with one or more of the following: cough, dyspnea, tachypnea, chest pain, fever, wheezing, and new-onset hypoxia. As many as one-half of individuals with SCD experience at least one episode of ACS.[2,18,34]

Risk factors for ACS and recurrence include young age (peak incidence between age 2 and 4 years), lower HbF, higher leukocytes, history of asthma or bronchial hyper-responsiveness, and smoke exposure. Genotype and haplotype also influence the occurrence. Patients with HbSS and HbSβ^0-thal have higher incidence than those with HbSC and HbSβ^+-thal. The prevalence is higher with African haplotypes than that of Saudi Arabia.[1,18,26]

The primary etiology for ACS is pulmonary vascular occlusion. Infections, fat emboli released from bone marrow or direct adhesion of RBCs to the pulmonary vasculature lead to the inflammation and injury of the lung. The most common cause of ACS is infection. Viral causes are more common in children than adults. Bacteria that cause community acquired pneumonias can be the pathogens, which include *Mycoplasma pneumonia, Chlamydia pneumoniae,* and *Streptococcus pneumoniae*.[2,18,34]

ACS is more common in children but more severe in adults. Hypoxia is a predictor for severity and outcome. In addition to physical examinations, evaluations may include complete blood count and chest radiographs. In severe cases, CT scan, perfusion scintigraphy, transthoracic echocardiography and bronchoscopy may also be considered to exclude other etiologies. Pulmonary changes often involve the lower lobes of the lungs and may cause pleural effusions. Bilateral infiltrates or multiple

lobe involvement may be an indication of poor prognosis.[2,18,26] Pulmonary manifestations must be recognized early and managed aggressively as ACS can rapidly progress to pulmonary failure and death.[26]

Priapism

Stasis and sickling of RBCs within the sinusoids of the corpora cavernosa is the primary mechanism of priapism, a sustained painful erection. In recent years, a better understanding of pathophysiology of priapism has identified other mechanisms at molecular level, such as abnormal NO signaling as result of chronic NO depletion. Stuttering priapism is repeated intermittent attacks up to several hours before remission; ischemic priapism is a persistent painful erection greater than 4 hours and should be considered as an emergency. Thirty percent to 45% of males with SCD will present with at least one episode of priapism during their lifetime and the first episodes often occur during childhood. Impotence has been reported after repeated episodes and is directly related to the duration prior to treatment.[1,35,36]

Sickle Cell Pain

Acute episodes of pain are the most common symptoms and reason for seeking treatment in SCD. Sickle cell pain may be caused by bone or muscle infarction due to vasoocclusion (see Table 102-2). Although fever, infections, dehydration, hypoxia, acidosis, and sudden temperature alterations can precipitate pain, multiple factors often contribute to its development.[2,37,38] The back, chest and extremities are the most common locations of pain but pain can occur in any location such as abdomen or head and lead to confusion with other acute complications such as stroke.[1,22]

Individuals with HbSS experience more frequent episodes of pain than those with HbSC or other variants. Risk factors associated with painful episodes include older age, iron overload, higher Hb and lower HbF.[1,2,14,38] Biomarkers for severity of pain during vasoocclusion episodes include elevated C-reactive protein and lactate dehydrogenase (LDH).[4] Dactylitis (hand-and-foot syndrome) is a subtype of sickle cell pain, occurring in infancy and early childhood and is characterized by redness and swelling of the dorsal aspects of the hands, feet, fingers, and toes. The episodes are painful but usually do not result in permanent damage.[1,2]

Splenic Sequestration

Splenic sequestration is the sudden massive enlargement of the spleen resulting from the sequestration of sickled RBCs in the splenic parenchyma (see Table 102-2). Hematocrit and hemoglobin concentrations dramatically fall, with reticulocytosis and no evidence of marrow failure or accelerated hemolysis. The trapping of the sickled RBCs by the spleen also leads to a decrease in circulating blood volume, which can result in hypotension and shock. The condition is most often seen in infants and children because their spleens are intact, and can cause sudden death in young children. Splenic enlargement may also be acutely painful due to rapid capsular expansion. Over time, repeated splenic infarctions lead to autosplenectomy and the spleen can no longer become engorged. Sequestration usually occurs between one to 4 years of age and is uncommon beyond 5

year for children with HbSS and HbSβ^0-thal because autoinfarction usually is completed by then. For HbSC and HbSβ^+-thal, autoinfarction is delayed and sequestration can occur even during adulthood.[1,2,22,39]

Chronic Complications

Pulmonary

Over 90% of children survive into adulthood, increasing the contribution of pulmonary manifestations to the morbidity and mortality of SCD. Physical exam and history should be performed to identify signs and symptoms of respiratory conditions such as asthma, restrictive lung disease and chronic obstructive pulmonary disease. Pulmonary function testing is recommended to determine the cause in symptomatic patients but not as a routine screening tool.

Pulmonary hypertension, defined as a resting mean pulmonary arterial pressure (PAP) 25 mmHg or greater by right heart catheterization, is associated with increased morbidity and mortality in SCD. Symptoms of pulmonary hypertension include shortness of breath during normal activities, fatigue, syncope, and peripheral edema. A less invasive test, tricuspid regurgitant jet velocity by Doppler echocardiography, is frequently performed initially to estimate PAP. Serum NT-pro-BNP measurement is an alternative test that can be used in patients with normal renal function when Doppler echocardiography is not an option. The American Thoracic Society recommends assessment of mortality risk using noninvasive (indirect) or invasive direct measurement to guide management of pulmonary hypertension (**Table 102-3**).[22,26,40,41]

TABLE 102-3 Risk Stratification and Management Recommendation for Pulmonary Hypertension

	Recommendations	Strength	Evidence Quality
Increased risk for mortality[a]	Hydroxyurea	Strong	Moderate
Increased risk for mortality, unresponsive or not candidates for hydroxyurea	Chronic transfusion therapy	Weak	Low
RHC-confirmed PH, venous thromboembolism, no risk factors for hemorrhage	Indefinite anticoagulant therapy	Weak	Low
Elevated TRV alone Elevated NT-pro-BNP alone	No PAH therapy[b]	Strong	Moderate
RHC-confirmed marked elevation of pulmonary vascular resistance, normal pulmonary artery wedge pressure, presence of related symptoms	• A trial of prostacyclin agonist or endothelin receptor antagonist • Phosphodiesterase-5 inhibitor should not be used as first-line therapy	Weak Moderate	Very low Moderate

[a]Increased risk for mortality: (1) Tricuspid regurgitant jet velocity (TRV) greater than or equal to 2.5 m/s, (2) an N-terminal pro-brain natriuretic peptide (NT-pro-BNP) level greater than or equal to 16 pg/mL (ng/L; 1.9 pmol/L) or (3) right heart catheterization (RHC)-confirmed pulmonary hypertension (PH).

[b]PAH therapy: (1) prostacyclin agonist (epoprostenol, treprostinil, iloprost), (2) soluble guanylate cyclase stimulator (riociguat), (3) endothelin receptor antagonist (bosentan, macitentan, ambrisentan), (4) phosphodiesterase-5 inhibitor (sildenafil, vardenafil, tadalafil).

Klings, Machado and Barst[40] and Abman, Hansmann and Archer.[41]

The prevalence of asthma in children with SCD is similar to that of general population. Symptoms of asthma exacerbation can overlap with ACS making it difficult to differentiate the two. Asthma and wheezing in individuals with SCD have been associated with ACS and vasoocclusive pain episodes and increased mortality. Early screening for asthma and other signs of respiratory conditions has been recommended.[1,22] In general, the national asthma education and prevention program asthma management guideline should be utilized in the management of asthma in children with SCD. Inhaled corticosteroids are first line for persistent symptoms.[42]

Skeletal and Skin Diseases

Bone diseases are common in SCD and vitamin D level has been suggested to be the biomarker.[4] Osteonecrosis, particularly of the femoral or humeral heads, causes permanent damage and disability.[14,22,43,44] Low bone mineral density can occur early with a prevalence of over 70% reported in adults with SCD.[43] Osteopenia and osteoporosis associated with low bone formation has been reported in both males and females with SCD.[43,44] Children with SCD also have an increased incidence of osteomyelitis; the organism most often responsible is *Salmonella*.[30,44] In addition to necrosis of joints, chronic leg ulcers most commonly seen in the medial and lateral malleolus (ankles) can become a difficult and painful problem for adult. Ulcers are often seen after trauma or infection and are usually slow to heal.[22]

Ocular Manifestations

Ocular problems seen in patients with SCD include transient monocular blindness, visual field defects from retinal hemorrhage, retinal detachment, vitreous hemorrhage, venous microaneurysms, and neovascularization. The incidence of proliferative sickle retinopathy and vitreous hemorrhage is up to 50%. Vasoocclusion in the eye can occur as early as 20 months of age, and clinically detectable retinal diseases usually occur during adolescence and early adulthood. Despite the less systemic manifestations, individuals with HbSC develop serious retinal complications more often and earlier than those with HbSS. Annual retinal examination is recommended for patients with SCD to prevent blindness from retinopathy and other complications.[22,45]

Hepatobiliary Diseases

Cholelithiasis is a common complication of SCD resulting from chronic hemolysis and increased bilirubin production, and leading to biliary sludge and/or stone formation. The risk of gallstones increases with age: 12% for age 2 to 4 years, 43% by age 15 to 18 years and 70% to 75% in adults. Cholecystitis, exemplified by pain in the right upper quadrant, can be confused with an acute sickle pain episode in the abdomen. Mild baseline hepatomegaly and elevation of lever function tests are found in individuals with SCD. Cirrhosis occurred in 18% of young adults with SCD. Causes for development of chronic hepatic disease include repeated occlusion in the liver, iron overload, and hepatitis.[22,46]

Cardiac Diseases

Cardiovascular complications associated with anemia, including cardiac enlargement and various murmurs, can occur in patients with SCD. Patients experience various degrees of exertional dyspnea, tachycardia, and palpitation because of the decreased oxygen-carrying capacity of the blood. Left ventricular diastolic dysfunction has been reported in 18% of adults with SCD and is associated with increased mortality, especially in patients with pulmonary hypertension. Left ventricular stiffness and left ventricular hypertrophy have been reported, and the progression is speculated to lead to diastolic dysfunction later in life. Acute myocardial infarction in adults with SCD may be under-recognized due to the high incidence of sickle cell acute chest pain.[7,47,48]

Renal Diseases

Renal dysfunction in SCD begins during infancy as evidenced by glomerular hyperfiltration. Other manifestations include inability to concentrate urine, hematuria, tubular acidosis, papillary necrosis, glomerulonephritis, microalbuminuria, and proteinuria. Enuresis, as a result of increased urine production, occurs in 42% of children ages 6 to 8 and 9% in young adults age 18 to 20. Microalbuminuria is typically the first sign of chronic kidney disease, which has been associated with increased mortality.[22,49,50]

Growth and Development

Delayed growth and sexual maturation are common in patients with SCD. Despite normal birth weight and length, growth retardation occurs between 6 months and 4 years with height, weight and bone mass index being affected. The poor growth cannot be explained by nutritional factors alone. Alternations in growth factors as well as increased metabolic rate are factors contributing to the growth failure. Pubertal delay by 1 to 2 years is common in adolescents with SCD and fertility problems have been reported in both men and women with SCD.[14,51,52,53]

Psychiatric

Depression and anxiety are more common in children and adults with SCD than in the general population and have a significant impact on quality of life.[54,55] Depression is associated with pain episodes in children with SCD. In addition, depression is associated with social support for parents as well as individuals with SCD.[54] DSM-IV psychiatric diagnoses in adolescents with SCD include

attention-deficit-hyperactivity, oppositional defiant, conduct, major depressive and anxiety disorders.[56]

Pregnancy

Pregnancy introduces an increased risk for the mother with SCD and for the fetus. Some women experience increased pain episodes during pregnancy and the anemia of SCD can lead to intrauterine growth retardation. Preterm labor and premature delivery are common in mothers with SCD, and the risk of spontaneous abortion is increased. The incidence of cesarean delivery and pregnancy-related complications are higher when compared to mothers who do not have SCD.[22,57,58]

TREATMENT

Desired Outcomes

The goal of treatment is to reduce hospitalizations, complications, and mortality. Treatment for SCD involves the use of general measures to meet the unique demands for increased erythropoiesis. Additional interventions can be aimed at preventing or treating complications of the disease. When an acute complication occurs, the type and severity of the episode determines the appropriate therapeutic plan.

With availability of public health programs and comprehensive care, most children in developed countries survive through childhood.[2,14] The median survival rate is estimated to be 42 years for males and 48 years for females for HbSS, and 60 years for males and 68 years for females for HbSC.[12,59] With increased life expectancy, outcome evaluation for management of SCD therefore should include assessment of health-related quality of care in both adults and children.

Patients with SCD require lifelong multidisciplinary care. All patients with SCD should receive regularly scheduled comprehensive medical evaluations. Because of the complexity of the disease, a multidisciplinary team is needed to provide high quality medical care, education, counseling, and psychosocial support. Appropriate comprehensive care can have a positive impact on both longevity and quality of life. This care includes the use of evidence based treatment combining general symptomatic supportive care, preventative medical therapies and specific disease modifying therapies aimed at altering hematologic capacity and function.

Routine Health Maintenance

SCD is a complex chronic disease involving multiple organs. In addition to the preventive care recommended for the general population, individuals with SCD also need health maintenance and screenings that are focused on minimizing complications from the disease (**Table 102-4**).

TABLE 102-4 Health Maintenance

Invasive Pneumococcal Infection Prevention[a]

1. Oral penicillin until age 5 for children with HbSS

a. Discontinue penicillin prophylaxis at age 5 unless have had splenectomy or invasive pneumococcal infection

2. Consider no penicillin prophylaxis for children with HbSC disease and HbS—thal unless they have had a splenectomy

Immunization[b]

1. All individuals should receive immunization according to The Advisory Committee on Immunization Practices

2. Pneumococcal Vaccine

a. All infants should receive complete series of PCV13.

b. All children should receive PPSV23 at age 2 years and second dose at age 5 years.

c. Children age 6-18 years with functional or anatomic asplenia should receive 1 dose of PCV13.

d. Adults (age ≥ 19 years) with functional or anatomic asplenia.

i. Not previously received PCV13 or PPSV23

1. One dose PCV13; followed by PPSV23 at least 8 weeks later

ii. Previously received PPSV23

1. One dose PCV13 at least 1 year after last PPSV23

iii. For individual age 19-64 years, a second dose of PPSV23 should be 5 years after first dose and no sooner than 8 weeks after PCV13

3. Haemophilus Influenza (Hib) Vaccine

a. Children age greater than 5 years who have not previously received Hib vaccine should receive one dose

4. Meningococcal Vaccine (indicated for persons have functional or anatomic asplenia)

a. 4-dose primary series to be administered with Hib-MenCY-TT (2, 4, 6, and 12-15 months) or MenACWY-CRM (2, 4, 6, and 12 months)

b. Booster dose to be administered with MenACWY-CRM or MenACWY-D

i. Primary series completed prior to age 7: booster dose 3 years after primary series and repeat every 5 years thereafter

ii. Primary series completed age 7 or older: booster dose 5 years after primary series

and repeat every 5 years thereafter

c. Unvaccinated children 7-23 months: 2 doses of MenACWY-CRM with second dose at least 12 weeks after the first dose AND after first birthday

d. Unvaccinated children age 2 years or older and adults: 2 doses of MenACWY-CRM or MenACWY-D 8-12 weeks apart

    i. MenACWY-D to be given at least 4 weeks after completion of all PCV13 doses

e. Adults previously vaccinated should receive MenACWY-CRM or MenACWY-D every 5 years

5. Influenza vaccine annually for age ≥ 6 months

Renal[c]

1. Screen for proteinuria by age 10 and annually if negative
2. Initiate ACE inhibitor for adults with microalbuminuria or proteinuria without apparent cause

Pulmonary Hypertension (PH)[d]

1. Noninvasive tests (Doppler echocardiography or alternatively, serum NT-pro-BNP measurement) can be used to assess mortality risk
2. Echocardiogram to screen for PH and associated cardiac problems by age 8 for those with frequent cardiorespiratory symptoms
3. The optimal frequency for Doppler echocardiography is unknown but every 1-3 years seems to be reasonable
4. Children with evidence of PH by echocardiogram should be further evaluated: pulmonary function test, polysomnography, oxygenation assessment and thromboembolic disease
5. Cardiac catheterization should be performed before initiation of PAH-specific therapy

Ophthalmological Evaluation[c]

1. Eye examination begins at age 10 and rescreen at 1-2 year intervals

Stroke Prevention[c]

1. Children with SCA: transcranial Doppler (TCD) annually beginning at age 2 until at least age 16
2. Chronic transfusion therapy for stroke prevention in children with elevated (>200 cm/s) TCD results

PCV13, 13-valent conjugate pneumococcal vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine; ACE Inhibitor, angiotensin converting enzyme inhibitor; NT-pro-BNP, N-terminal pro-brain natriuretic peptide; PAH, pulmonary artery hypertension; PH, pulmonary hypertension.

Immunizations

Administration of routine immunizations is crucial preventive care in managing SCD. Children 6 months and older and adults with SCD should receive influenza vaccine annually. The most updated immunization and catch-up schedules are provided by the Centers for Disease Control and Prevention (http://www.cdc.gov/vaccines/schedules.)

Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly *S. pneumoniae*. Prior to the routine use of penicillin prophylaxis and the development of pneumococcal vaccines, invasive pneumococcal disease was 20- to 100-fold more common in children with SCD than in healthy children. Reduced mortality has been associated with the introduction of pneumococcal vaccines.[2,30]

Two different pneumococcal vaccines are available. The 13-valent pneumococcal conjugate vaccine (PCV13; Prevnar®) induces good antibody responses in infants and children less than 2 years of age. Immunization with the PCV13 is recommended for all children, regardless of SCD status, younger than 24 months of age. Infants should receive the first dose after 6 weeks of age. Two additional doses should be given at 2-month intervals, followed by a fourth dose at age 12 to 15 months. One dose of PCV13 should be given to children age 6 to 18 years and adults with functional or anatomic asplenia (see Table 102-4). The 23-valent pneumococcal polysaccharide vaccine (PPSV23; Pneumovax®23) is recommended for all children with functional or acquired asplenia but must be given after 2 years of age because of poor antibody response. To cover different serotypes, PPSV23 should be given starting at 2 years of age, and be administered 2 months after the last dose of the PCV13. A booster dose of PPSV23 is recommended 5 years after the first dose.[22,60,61]

The risk of meningococcal disease is also higher in SCD and vaccination is recommended for individuals with functional or acquired asplenia. Three different meningococcal vaccines are available: Meningococcal groups C and Y and *Haemophilus* b tetanus toxoid conjugate vaccine (Hib-MenCY-TT), and quadrivalent (serogroups A, C, Y, and W-135) meningococcal conjugate vaccines, MenACWY-CRM and MenACWY-D. Infants with functional asplenia should receive 4-dose series with Hib-MenCY-TT at 2, 4, 6, and 12 through 15 months or MenACWY-CRM at 2, 4, 6, and 12 months. If the first dose of Hib-MenCY-TT is given at or after 12 months of age, 2 doses should be given at least 8 weeks apart. Children over 2 years and adults with functional or acquired asplenia

should receive a primary immunization series with two doses of the quadrivalent vaccine given 8 weeks apart. MenACWY-D should be given at age 2 years or older and at least 4 weeks after completion of all PCV13. A booster is recommended every 5 years for individuals with SCD.[22,62,63]

Penicillin

4 Penicillin prophylaxis until at least 5 years of age is recommended in children with SCD HbSS or HbSβ^0-thal, even if they have received PCV13 or PPSV23 immunization, as prophylaxis against invasive pneumococcal infections. An effective regimen that reduces the risk of pneumococcal infections by 84% is penicillin V potassium at a dosage of 125 mg orally twice daily until the age of 3 years, followed by 250 mg twice daily until the age of 5 years. Individuals who are allergic to penicillin can be given erythromycin 20 mg/kg per day. Penicillin prophylaxis is not routinely given in older children, based on a study demonstrating no benefit over placebo beyond the age of 5 years. However, continuation of oral pneumococcal prophylaxis should be considered on a case-by-case basis, and is recommended for anyone with a history of invasive pneumococcal infection or surgical splenectomy.[22,24]

Clinical Controversy…

The need for routine penicillin prophylaxis in HbSC and HbSβ^+-thal patients is controversial because these patients have less severe disease. The original trial showing decreased morbidity from invasive infection included children with HbSS or SCA. But some clinicians recommend that children with any genotype should start penicillin prophylaxis as severe and fatal pneumococcal infections can occur with HbSC and HbSβ^+-thal.

Fetal Hemoglobin Inducers

HbF reduces polymer formation of HbS due to its high-oxygen affinity. Increased HbF levels significantly correlate with decreased RBC sickling and RBC adhesion and observational studies show a relationship between HbF concentration and severity of SCD. Individuals with SCD and low HbF levels experience more frequent pain and higher mortality. HbF levels of 20% or greater reduce the risk of acute sickle cell complications. Based on these observations, HbF induction has become a treatment modality for patients with SCD.

Hydroxyurea

Hydroxyurea (HU), a chemotherapeutic agent, stimulates HbF production and increases the number of HbF-containing reticulocytes and intracellular HbF. The antineoplastic activity of HU is related to inhibition of DNA synthesis by blocking the conversion of ribonucleoside to deoxyribonucleotides. The exact mechanism of HbF production is unknown, but is postulated that the cytotoxic effect in the bone marrow stimulates stress erythropoiesis and triggers rapid erythroid regeneration and shifts erythrocyte hemoglobin production to HbF. In addition, HU increases NO levels, reduces neutrophils and monocytes, has antioxidant properties, alters the RBC membrane, increases RBC deformability by increasing intracellular water content, and decreases RBC adhesion to the endothelium.[1,22,24]

HU can decrease the frequency of acute sickle cell pain and is FDA approved for adults with SCD based on the results of the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH Trial), a double-blind, placebo-controlled randomized controlled trial. In that study, HU significantly reduced the frequency of painful episodes, risk of ACS, need for blood transfusions, and number of hospitalizations. The incidence of death, stroke, and hepatic sequestration in the HU and placebo groups was not significantly different during the evaluation period. However, a follow-up study showed a 40% reduction in mortality with HU over a 9-year period. The original 299 patients from the MSH study were followed for 17.5 years and the results suggest improved survival with the long-term use of HU.[2,7,64,65]

Studies in pediatric patients have demonstrated similar results to the MSH Trial with no adverse effects on growth and development. In addition, some patients treated with HU therapy had possible recovery or preservation of splenic and brain functions, including cognitive performances. The Transcranial Doppler with Transfusions Converting to Hydroxyurea study (TWiTCH) closed early after interim analysis found that HU was not inferior to chronic blood transfusions to prevent primary stroke. However, the Stroke with Transfusions Changing to Hydroxyurea (SWiTCH) trial also closed early when the interim analysis showed that HU was inferior to chronic transfusions to prevent recurrent stroke. Therefore, chronic transfusions with iron chelation remain the best therapy to prevent stroke.[2,7,24] Initiating HU early and prior to development of complications may be beneficial. The Pediatric HU Phase III Clinical Trial (BABY HUG) evaluated HU therapy in young children ages 9 to 18 months.[66] Infants were randomized between HU and a placebo; the primary endpoints were splenic and renal function. Investigators found no significant difference in the primary endpoints but did find fewer episodes of pain and dactylitis with no significant toxicities. HU reduced the risk of painful events, ACS, renal enlargement, hospitalizations, and transfusions. In addition, improved urine concentration ability as demonstrated by higher urine osmolality was reported.[66,67,68] In a retrospective study of children aged 3 to 18 years with SCD, significant reduction in mortality, fewer hospitalizations and emergency visits and shorter admissions were reported.[69]

The most common adverse effect of HU is bone marrow suppression, resulting in neutropenia, thrombocytopenia, anemia, and decreased reticulocyte count. These hematologic adverse effects usually recover within 2 weeks of therapy discontinuation. Other side effects include dry skin and hyperpigmentation of skin or nails.[2,67,68,70] Long-term adverse effects of HU therapy in patients with SCD are not fully known although no serious adverse effects were reported in the long term (17.5 years) follow-up study of the MSH trial.[65] Studies in children have not demonstrated delays in growth or puberty, increased risk of infections or genotoxicity.[70,71] Myelodysplasia, acute leukemia, and chronic opportunistic infection associated with T-lymphocyte abnormalities have been reported in other patient populations treated with higher doses of HU. Reproductive toxicity is also a concern. High-dose HU has been shown to be teratogenic in animals, but normal pregnancies have been reported in women with SCD who received HU during pregnancy.[53]

Although HU is only FDA approved for adults with SCD, the National Institutes of Health (NIH) has supported its use in children and adolescents (**Table 102-5**).[22] Clinical indications for HU include frequent painful episodes, severe symptomatic anemia, a history of ACS, or other severe

vasoocclusive complications. The starting dose for adult is 15 mg/kg per day rounded to the nearest 500 mg as a single daily dose (**Fig. 102-6**). A lower dose of 5 to 10 mg/kg per day is used for patients with chronic disease. The Baby HUG study found that children can be safely started at 20 mg/kg. Dosage can be increased by 5 mg/kg up to a maximum of 35 mg/kg in 8 week intervals if the patient does not demonstrate significant adverse effects and blood counts are stable. HU dosage should be individualized based on response and toxicity. In general, 3 to 6 months of therapy are required before improvement is observed. Medication adherence can be an issue. Since the MCV generally increases as the level of HbF increases, monitoring MCV is an inexpensive and convenient method to monitor response and adherence.[2,22,66,72]

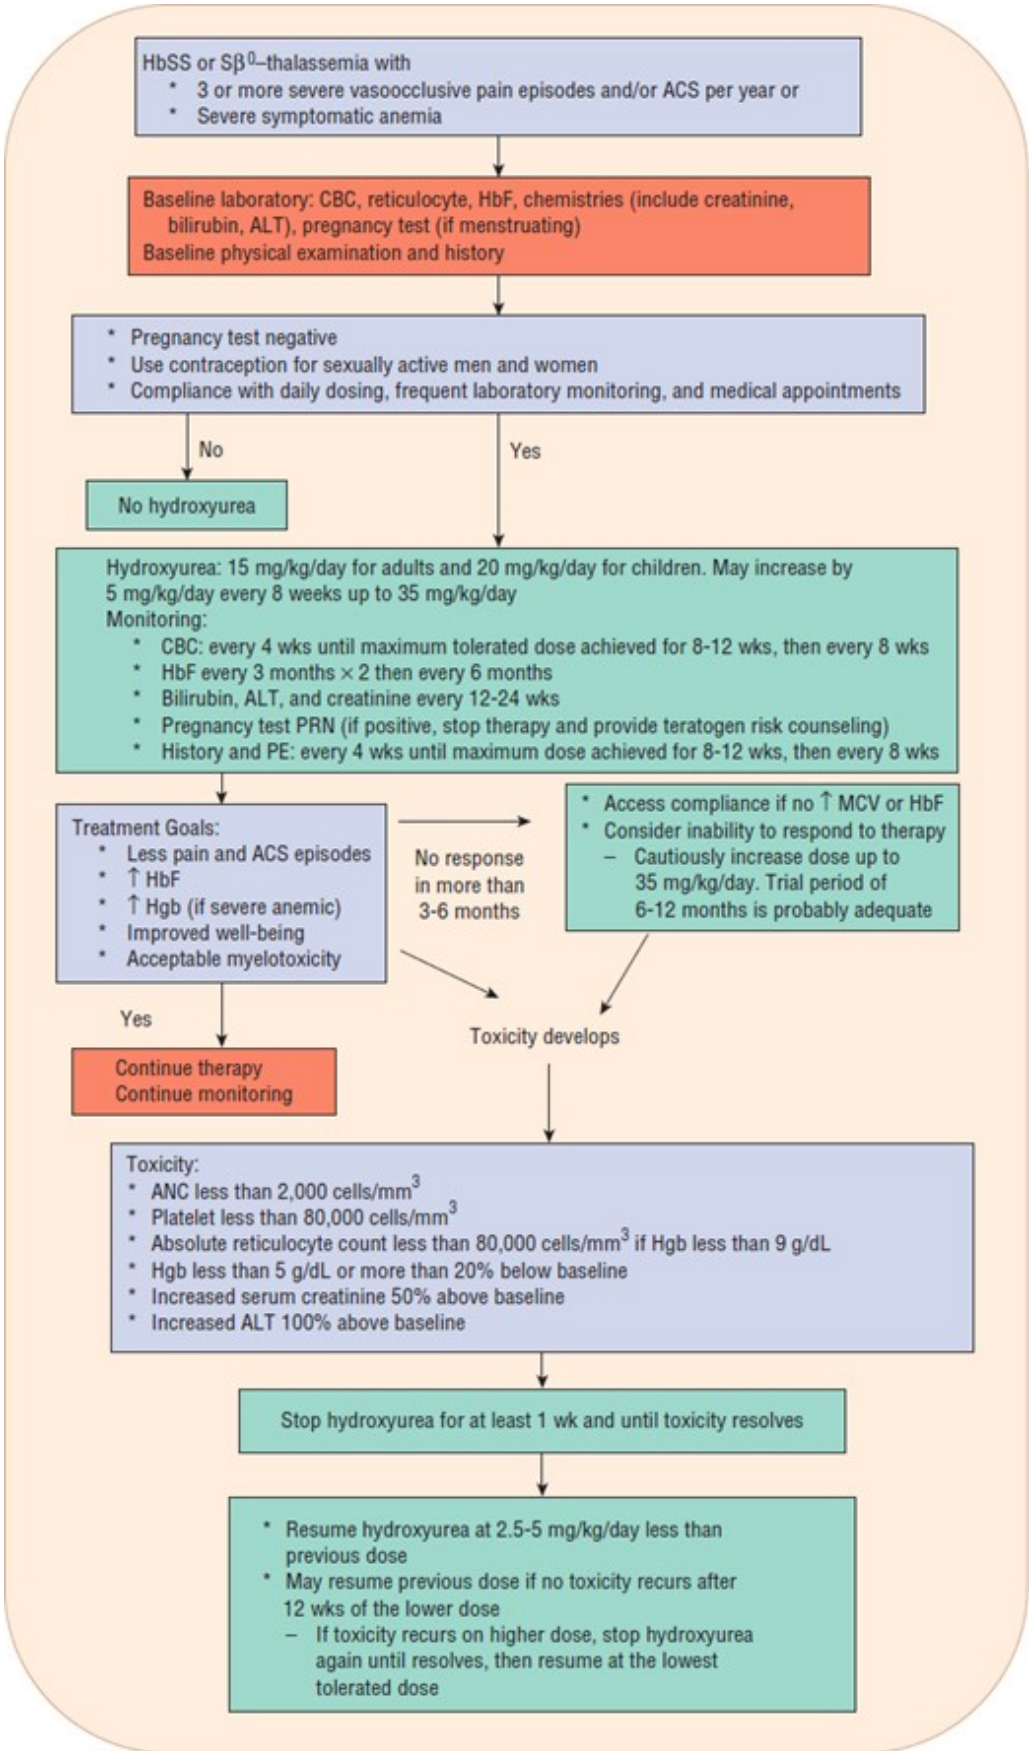
TABLE 102-5 Recommendations on Hydroxyurea Therapy

	Recommendation	Strength	Evidence Quality
Adults with HbSS or Sβ^0-thalassemia			
1. Three or more sickle cell associated moderate to severe pain crises per year	Treat with hydroxyurea	Strong	High
2. Sickle cell associated pain that interferes with daily activities and quality of life		Strong	Moderate
3. History of severe and/or recurrent ACS		Strong	Moderate
4. Severe symptomatic chronic anemia that interferes with daily activities or quality of life		Strong	Moderate
Infants 9 months of age and older, children, and adolescents with HbSS or Sβ^0-thalassemia regardless clinical severity	Offer hydroxyurea	Strong	High (age 9-42 months); Moderate (>42 months)
Chronic kidney disease and taking erythropoietin	Hydroxyurea can be added	Weak	Low
HbSC or HbSβ^+-thalassemia with recurrent sickle cell associated pain that interferes with daily activities or quality of life	Consider hydroxyurea	Moderate	Low
History of stroke and unable to implement chronic transfusion	Initiate hydroxyurea	Moderate	Low

From National Institutes of Health,[22] Wong, Brandow and Lim.[64]

FIGURE 102-6

Hydroxyurea use in sickle cell disease. (ACS, acute chest syndrome; ALT, alanine aminotransferase; ANC, absolute neutrophil count; CBC, complete blood cell count; Hb, hemoglobin; HbF, fetal hemoglobin; HbSS, homozygous sickle cell hemoglobin; HbSSβ^0, sickle cell β^0-thalassemia; MCV, mean corpuscular volume; PE, physical examination; PRN, as needed; RBC, red blood cell) *(From McCavit[1], National Institute of Health[22] and Wong, Brandow, and Lim[64].)*



5 Patients receiving HU should be closely monitored for toxicity. Blood counts should be checked every 4 weeks during dose titration and every 8 weeks thereafter. Treatment should be interrupted if hematologic indices fall below the following values: absolute neutrophil count, 2,000 cells/mm^3 (2 × 10^9/L); platelet count, 80,000 cells/mm^3 (80 × 10^9/L); hemoglobin, 5 g/dL (50 g/L; 3.1 mmol/L); or reticulocytes, 80,000 cells/mm^3 (80 × 10^9/L) if the hemoglobin concentration is less than 9 g/dL (90 g/L; 5.59 mmol/L). Other laboratory abnormalities warranting temporary discontinuation of therapy are a 50% increase in serum creatinine and a 100% increase in transaminases. After recovery has occurred, treatment should be resumed at a dose that is 5 mg/kg per day lower than the dose associated with toxicity. If no toxicity occurs after 12 weeks with the lower dose, the dose can be increased by 2.5 to 5 mg/kg per day. If the increased dose produces hematologic toxicity, the patient should be maintained at the last tolerated dose with no further escalation except for normal growth or weight gain.[22,64,72]

Chronic Transfusion Therapy

RBC transfusions play an important role in the management of SCD. In acute illness, transfusions can be life saving and the guidelines for acute transfusion are discussed in a later section. Chronic transfusion programs can prevent serious complications of SCD. The primary indication for chronic transfusion is primary and secondary stroke prevention and amelioration of organ damage.[1,2,73] Blood transfusions can be administered as a simple transfusion, a manual exchange or an automated exchange called erythrocytapheresis. Exchange transfusion frequently requires permanent venous access and is associated with higher cost but has the advantage of increasing normal (donor) HbA, limiting volume, minimizing hyperviscosity and transfusional iron overload.[22]

6 In children with an overt stroke, chronic transfusions are used as secondary stroke prevention and reduce stroke recurrence from about 50% to about 10% over 3 years. An initial stroke in SCD can be devastating and transfusions can be given for primary stroke prevention. Prophylactic transfusions significantly reduced the incidence of first stroke over a 2-year period in children 2 to 16 years of age who were at an increased risk for stroke based on TCD. The risk of stroke was reduced from 16% in patients receiving usual care to 2% in those who received prophylactic transfusions.[1,4,73] Chronic transfusions should be considered in selected children and adults with previous stroke or children with abnormal TCD measurements.[22] Chronic transfusions have also been used in patients with severe or recurrent ACS, debilitating pain, splenic sequestration, recurrent priapism, chronic organ failure, intractable leg ulcers, severe chronic anemia with cardiac failure, and complicated pregnancies, although data supporting the efficacy of chronic transfusion in these situations are limited.[1,74]

The goal of transfusions is to achieve and maintain an HbS concentration of less than 30% of total hemoglobin in the primary and secondary prevention of neurologic complications. Transfusions are usually given every 3 to 4 weeks, but the frequency of transfusion is adjusted to maintain the desired HbS levels. The risk of recurrent stroke decreases after 2 years of transfusion therapy and, in the absence of recurrent stroke, many clinicians will liberalize the HbS goal to less than 50%.[2,14] The optimal duration of primary prophylactic transfusion therapy in children with abnormal TCD is not

clear, but discontinuation of transfusions has been associated with a 50% stroke recurrence rate within 12 months and abnormal blood flow velocity on TCD in children with SCD. The results of the TWiTCH trial suggest that some patients can safely transition to HU therapy after normalization of TCD and no evidence of cerebral vasculopathy with at least a 6-month overlap in transfusions and HU therapy. For secondary stroke prevention, transfusions should be continued indefinitely.[2,14,73] A pilot study suggested that HU could be started prior to discontinuation of transfusion for secondary stroke prevention with at least a 6-month overlap with transfusions. However, the phase III trial of switching HU for transfusion in secondary stroke prevention, the SWiTCH trial, was closed early due to an increased risk of recurrent strokes in the HU arm when compared to the transfusions arm.[14,31] The NIH recommends HU for prevention of recurrent stroke only if implementation of a transfusion program is not possible.[22]

Although the benefits of transfusion therapy are clear in some clinical situations, its role in other situations such as an acute pain episode remains controversial.[22] The risks of transfusion therapy must be weighed against possible benefits. The risks associated with transfusion therapy include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and nonhemolytic transfusion reactions. The use of leukocyte-reduced RBC transfusions in chronically transfused patients can reduce the risk of nonhemolytic transfusion reactions and viral transmission.[2,14] Transfusion-related infections also remain a concern. All patients should be immunized with hepatitis A and B vaccines. Other viruses that can be transmitted through blood products are parvovirus B19, hepatitis,[74] and cytomegalovirus. The risk of contracting human immunodeficiency virus from blood transfusions, although still of concern, has decreased with routine blood screening.[2,30]

Alloimmunization or alloantibody formation occurs in 19% to 37% of SCD patients who receive RBC transfusions and results from antigen differences on the red cell surface between the primarily Caucasian donor pool and recipients with SCD. Alloimmunization can make it difficult to find cross-matched blood and cause delayed hemolytic transfusion reactions. To prevent alloimmunization, patients receiving chronic transfusions should receive the best cross-matched blood including extended typing of other red cell antigens especially C, E, and Kell or full RBC phenotyping.[22,73,74]

The development of alloimmunization can be life threatening for individuals with SCD. Delayed hemolytic transfusion reactions (DHTR) usually occur within 7 to 10 days after transfusion but can occur as early as 2 days or as late as 20 days after transfusion. During a DHTR, patients develop symptoms consistent with hemolysis such as worsening pain, especially abdominal pain, severe anemia due to hemolysis of the transfused unit and reticulocytopenia, further aggravating the anemia. Subsequent transfusions can further worsen the clinical situation because of the presence of multiple antibodies making cross-matching difficult. Life-threatening events can be treated with steroids and intravenous immunoglobulin. Recombinant erythropoietin has been used in patients with reticulocytopenia.[73] Recovery, as evidenced by reticulocytosis with a gradual increase in the hemoglobin level, may occur only after further transfusions are withheld. Although some patients tolerate further transfusions after recovery, especially if the donor unit is negative for the offending alloantibody, others cannot avoid recurrent transfusions and may experience another hemolytic transfusion reaction. Rituximab has been used in two patients to prevent recurrent DHTR. It is

generally preferable to prevent the development of DHTR by performing RBC phenotyping and, at a minimum, transfusing individuals with blood that is C, E, and Kell negative.[2,22,74]

Transfusional iron overload is another complication of RBC transfusions, and patients should be counseled to avoid excess dietary iron.[73,74] Abnormal liver biopsy results showing mild to moderate inflammation or fibrosis have been reported. Iron overload assessments include liver function test annually or semiannually and serum ferritin. Iron overload can be confirmed by liver biopsy or less invasively by MRI.[22,75] Three chelating agents are available. Deferoxamine has been used as a chelating agent for decades but must be administered by subcutaneous or intravenous infusion. Oral chelation agents, deferasirox and deferiprone have been shown to be equally effective as deferoxamine with demonstrated acceptable safety profile in long-term studies up to 5 years.[7,75,76,77] Deferasirox is given once daily (20-30 mg/kg) and the most common side effects are transient skin rash and gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal pain. Deferiprone has good oral bioavailability but a short half-life. The usual dose for deferiprone is 75 to 100 mg/kg per day in three divided dose. Similar to deferasirox, the common adverse effects for deferiprone are rashes and gastrointestinal symptoms but the most concerning side effects are neutropenia and agranulocytosis.[75,76,77]

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation (HSCT) is currently the only therapy that can cure patients with SCD. The overall survival rate and disease-free survival rate for children and young adults with sibling matched donors, has been reported at 95% to 98% and 87% to 92%, respectively.[78,79] The reported incidences of acute and chronic GVHD ranged from 5% to 17% and 0% to 3%, respectively. Other complications included seizures, marrow rejection, and sepsis. Improved growth, stabilization or improvement of CNS abnormalities and recovery of splenic dysfunction were observed in posttransplant SCD patients, but gonadal failure and delayed sexual development in females requiring hormonal replacement have been reported.[80]

The optimal candidates for unrelated matched allogeneic HSCT are SCD patients who are younger than 16 years of age, have a severe form of SCD and complications such as refractory pain, stroke, or recurrent ACS. Because allogeneic HSCT performed in young children before organ damage and alloimmunization occur is associated with increased success, counseling and screening for sibling matched donors during the first year of life is now recommended. The risks associated with allogeneic HSCT must be carefully considered, as the transplant-related mortality rate is about 5% to 10%, and graft rejection is about 10%. Other risks associated with allogeneic HSCT include secondary malignancies. Neurologic events, such as intracranial hemorrhage and seizures during transplant, were seen more frequently in patients with a history of stroke.[81,82,83]

Unfortunately, many children who are eligible for HSCT do not have an HLA-matched sibling donor and unrelated HLA-matched transplants are associated with higher transplant-related mortality. Umbilical cord blood is another potential donor source with some advantages over marrow donors including a lower incidence of severe GVHD and a larger donor pool from which to select donors, but such advantages are offset by longer time to engraftment and a higher rate of graft rejection.[80,82]

Use of nonmyeloablative allogeneic HSCT in adults and pediatric patients reported mixed donor-recipient chimerism and reversal of SCD in several clinical trials and has the advantage of less acute toxicity.[78,79,80]

Clinical Controversy...

Consideration of HSCT before disease complications develop rather than waiting for severe problems to manifest has been advocated for asymptomatic individuals with HLA-identical sibling.

Treatment of Complications

Parents and older children should be educated on the signs and symptoms of complications and conditions that require urgent evaluation. During acute illness, patients should be evaluated promptly because deterioration can occur rapidly. Fluid balance should be maintained because dehydration and fluid overload can worsen complications associated with SCD. Oxygen saturation by pulse oximetry should be maintained at least 92% or at baseline. New or increasing supplemental oxygen requirements should be investigated.

Episodic Transfusions for Acute Complications

Indications for acute blood transfusions include (1) acute exacerbation of baseline anemia, such as aplastic crisis if the anemia is severe, hepatic or splenic sequestration, or severe hemolysis; (2) ACS, stroke, intrahepatic cholestasis, or acute multisystem organ failure; and (3) preparation for procedures that require the use of general anesthesia.[22] Patients in whom chronic transfusions can be useful include primary or secondary stroke prevention, patients with complicated obstetric problems, refractory leg ulcers, or refractory and protracted painful episodes. Acute transfusion is not indicated for priapism, uncomplicated pain or asymptomatic anemia. Simple transfusion or partial exchange transfusion can be used though red cell exchange has been shown to have superior outcomes when compared to simple transfusion in overt stroke. If simple transfusion is used, volume overload leading to congestive heart failure can occur if anemia is corrected too rapidly in patients with severe anemia. In addition, increases in hemoglobin levels to greater than 10 g/dL (100 g/L; 6.21 mmol/L) can cause hyperviscosity and should be avoided.[14,22]

Infection and Fever

Patients with SCD should be evaluated as soon as possible for any fever greater than 38.5°C (101.3°F). Criteria for hospitalization include an infant younger than 1 year, history of previous bacteremia or sepsis, temperature greater than 39.5°C (103.1°F), WBC greater than 30,000 cells/mm^3 (30 × 10^9/L) or less than 5,000 cells/mm^3 (5 × 10^9/L) and/or platelets less than 100,000 cells/mm^3 (100 × 10^9/L), and evidence of other acute complications or toxic appearance. Outpatient management can be considered in older nontoxic children with reliable family caregivers. Antibiotic choice should provide adequate coverage for encapsulated organisms.[2,22,30]

7 Ceftriaxone should be used for outpatient management because it provides coverage for 24

hours. If admitted, cefotaxime can also be used. For patients with cephalosporin allergy, clindamycin can be used. Vancomycin should be considered for acutely ill children or if *Staphylococcus* is suspected. A macrolide antibiotic should be added if *Mycoplasma pneumoniae* is suspected such as in ACS. Penicillin prophylaxis should be discontinued while the patient is receiving broad-spectrum antibiotics. Acetaminophen or ibuprofen can be used for fever control. Increased fluid requirements may be present because of poor oral intake and/or increased insensible losses contributing to dehydration.[1,30]

Cerebrovascular Accidents

Patients with acute neurologic events must be hospitalized and monitored closely. Physical and neurologic examination should be performed every 2 hours. Acute treatment for children should include exchange transfusion to maintain hemoglobin at about 10 g/dL (100 g/L; 6.21 mmol/L) and HbS less than 30%, anticonvulsants for patients with a seizure history, and therapy for increased intracranial pressure if needed. Chronic transfusion therapy should be initiated for children with ischemic stroke as discussed earlier. In adults presenting with ischemic stroke related to atherosclerotic disease and not occlusion by sickled red cells, thrombolytic therapy should be considered if it is less than 3 hours since the onset of symptoms.[1,2,32]

Acute Chest Syndrome

Patients with ACS should use incentive spirometry frequently (eg, at least every 2 hours while awake) to reduce atelectasis development. In addition, proper management of pain is important. The goal is to provide relief while avoiding analgesic-induced hypoventilation. Appropriate fluid therapy is important as overhydration can cause pulmonary edema and exacerbate respiratory distress. Early use of broad-spectrum antibiotics, including a macrolide or quinolone in adults, is also recommended. Studies indicate that infection is the most common cause of ACS and can involve gram-positive, gram-negative, or atypical bacteria. Oxygen therapy is indicated for all patients who are hypoxic or in acute distress. In a patient with a history of reactive airway disease, asthma or wheezing on examination, a trial of bronchodilators is appropriate. Transfusions are indicated for severe ACS with worsening hypoxia and increased work of breathing.[1,14,18]

Steroids can decrease inflammation and endothelial cell adhesion. Glucocorticoids can decrease the duration of hospitalization and need for transfusions and other supportive care but can also increase the readmission rate for other sickle cell-related complications. Another potential therapy is the use of NO, which relaxes and dilates blood vessels. Its hematologic effects include inhibition of platelet aggregation and reduction in the polymerization tendency of HbS. Marked improvement of pulmonary status and cardiac output were reported in case reports of patients with ACS.[1,14,34]

Priapism

Stuttering priapism, episodes that last a few minutes to 2 hours, may resolve spontaneously with exercise, warm bath and oral analgesics. Prolonged episodes lasting more than 2 to 3 hours require prompt medical attention. The initial goals of treatment are to provide appropriate analgesic therapy,

reduce anxiety, produce detumescence, and preserve testicular function and fertility. Treatment given within 4 to 6 hours can usually reduce erection. Aggressive hydration and adequate pain control should be initiated. Use of ice packs is not recommended. Heat (hot water bottles, hot packs, or sitz baths) can provide comfort without precipitating pain crisis. Although transfusions have been given to these patients, transfusions are not recommended for this use because they have not been shown to be efficacious and are associated with severe neurologic sequelae.[1,24]

Clinicians have used both vasoconstrictors and vasodilators in the treatment of priapism. Vasoconstrictors, such as diluted phenylephrine (10 mcg/mL) or epinephrine (1:1,000,000), are thought to work by forcing blood out of the corpus cavernosum into the venous return. In one uncontrolled open-label study, aspiration followed by intrapenile irrigation with a 1:1,000,000 solution of epinephrine was effective and well tolerated with 37 of 39 episodes experiencing resolution. Detumescence can be achieved more rapidly using penile irrigation than simple transfusion but the procedure should be performed by an urologist with experience in the treatment of priapism.[36,84]

Vasodilators, such as terbutaline and hydralazine, relax the smooth muscle of the vasculature. This relaxation allows oxygenated arterial blood to enter the corpus cavernosum, which displaces or washes out the damaged sickle cells that are stagnant in the corpus cavernosum. Terbutaline has been used to treat priapism, but it has not been formally studied in patients with SCD.[36,84] In one case report, a single oral sildenafil dose at onset of priapism aborted episodes. However, long-term studies of sildenafil have shown an increase in the frequency of pain episodes.[84,85] Surgical interventions used in severe refractory priapism have included a variety of shunt procedures. These surgical procedures have been successful in some cases, but they have a high failure rate and potential serious complications, which include impotence, skin sloughing, cellulitis, and urethral fistulas.[36,84]

Modalities to prevent priapism are limited and not well studied. Pseudoephedrine (30 or 60 mg/day given orally at bedtime) and leuprolide, a gonadotropin-releasing hormone, have been used to decrease the number of recurrent episodes of priapism. HU therapy can also be used, but the effect of HU on risk of priapism has not been formally investigated. Finally, antiandrogens (bicalutamide and finasteride) have been used in SCD for treatment of recurrent or refractory priapism without major side effects.[84] The role of chronic transfusion in preventing priapism remains unclear and transfusion is not recommended for long-term management.[22,84]

Clinical Controversy…

Some clinicians transfuse patients to maintain an HbS level less than 30% to prevent recurrent priapism. Duration of such regimens should be limited to 6 to 12 months. Clinical practice guidelines do not recommend chronic transfusion to prevent recurrent priapism.

Aplastic Crisis

Treatment of aplastic crisis is primarily supportive, and most patients recover spontaneously within 5

to 10 days. The only treatment may be blood transfusion if the anemia is severe or symptomatic. The reticulocyte count is used to detect the suppression of red cell production and the need for transfusion. The most common cause, parvovirus B19, is contagious and infected patients should be placed in isolation. In addition, contact with pregnant healthcare providers should be avoided because parvovirus infection during the midtrimester of pregnancy can result in hydrops fetalis and stillbirth.[1,2,30]

Splenic Sequestration

Splenic sequestration is a major cause of mortality in young children with SCD. The sequestration of RBCs in the spleen can result in a rapid drop of hemoglobin, leading to hypovolemia, shock, and death. Immediate treatment with fluid resuscitation and blood transfusions is indicated to correct hypovolemia. Broad-spectrum antibiotic therapy, which includes coverage for *S. pneumoniae* and *H. influenzae*, can also be beneficial if the patient is febrile as infection can precipitate sequestration.[14,22]

Recurrent episodes occur in about half of patients and are associated with increased mortality. Options for management of recurrence include observation and splenectomy.[22] Increased risk of invasive infection after splenectomy is a concern in very young children, but most experts agree individuals with HbSS develop splenic dysfunction as early as 6 months of age and have acquired asplenia by 5 years of age and by 10 to 12 years for those with HbSC. Splenectomy is probably indicated, even after a single sequestration crisis, if that sequestration was life threatening. Splenectomy should be considered after repetitive episodes, even if they are less serious. For children younger than 2 years of age, chronic blood transfusions are recommended by some experts to prevent sequestration and delay splenectomy until the age of 2 years, when the risk of postsplenectomy septicemia is lower and pneumococcal vaccination has been completed. Finally, splenectomy should also be considered for patients with chronic hypersplenism.[1,2,22,39]

Acute Sickle Cell Pain

Hydration and analgesia are the mainstays of treatment for vasoocclusive (painful) episodes (**Table 102-6**). Patients with mild pain crisis can be treated as outpatients with rest, increased fluid intake, warm compresses, and oral analgesics. Hospitalization is necessary for moderate-to-severe pain or when oral analgesics fail to relieve pain. A pain episode may be precipitated by several risk factors including infection. In the setting of pain and fever, an infectious etiology should be evaluated, and appropriate empiric therapy should be initiated in patients. In patients with severe symptomatic anemia, transfusions may be indicated. Fluid replacement given intravenously or orally to correct or prevent hydration at 1 to 1.5 times the maintenance requirement is recommended. Close monitoring of fluid status is essential as aggressive hydration, particularly with sodium-containing fluids, can lead to volume overload, ACS, and heart failure.[1,22,24]

TABLE 102-6 Management of Acute Pain of Sickle Cell Disease

Principles

1. Treat underlying precipitating factors
2. Avoid delays in analgesia administration
    a. Initiate analgesic within 30 minutes of triage or 60 minutes of registration
3. Use pain scale to assess severity
4. Choice of initial analgesic should be based on previous pain pattern, history of response, current status, and other medical conditions
5. Schedule pain medication; avoid as-needed dosing
6. Provide rescue dose for breakthrough pain
7. If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics
8. Frequently assess to evaluate pain severity and side effects; titrate dose as needed
9. Treating adverse effects of opioids is part of pain management
10. Consider nonpharmacologic intervention (eg, relaxation techniques, guided imagery, deep breathing)
11. Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a product with a rapid onset is also needed for breakthrough pain

Analgesic regimens

Mild-to-moderate pain: nonopioid ± weak opioid

Moderate-to-severe pain: weak opioid or low dose of a strong opioid ± nonopioid

Severe pain: strong opioid + nonopioid

Other adjunct therapy

Hydration, heating pads, relaxation, and distraction

Laxatives for constipation

Antihistamine for itching

Antiemetics for nausea or vomiting

From Zempsky,[86] Jerrell, Tripathi and Stallworth,[87] and Wright and Ahmedzai.[88]

The frequency and severity of acute pain episodes associated with SCD are variable. Pain should be assessed and analgesic therapy should be tailored for each patient and each individual episode. Several verbal and nonverbal pain assessment tools are available and should be used to measure the

intensity of pain. Unfortunately, they have not been validated for sickle cell pain. However, pain scales validated for use in children, such as the Wong-Baker FACES scale should be used in pediatric patients with SCD pain. The healthcare provider should choose one tool appropriate for age and use it routinely to assess pain. Other useful information to guide choice of analgesics should include previous effective agents and their dosages, response to therapy and previous clinical course, and duration of pain episodes.[86,87,88]

8 Aggressive therapy that relieves pain and enables the patient to attain maximum functional ability should be initiated in patients with acute pain. Mild-to-moderate pain should be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen, unless there are contraindications to their use. Ketorolac may be useful for patients requiring intravenous therapy. Because of increased risk of gastrointestinal bleeding, it is recommended to limit the duration of therapy to 5 days or less. Ketorolac has also been associated with acute nonreversible kidney failure in a patient with SCD and should be used with caution and renal function monitored appropriately. When acetaminophen is used, it is important to monitor the total dose of acetaminophen administered in patients who may also be receiving the agent for fever or another acetaminophen-containing product for pain. If mild-to-moderate pain persists, an opioid should be added.[14,22,86,87]

Severe pain should be treated aggressively until the pain is tolerable. Commonly used opioids include morphine, hydromorphone, fentanyl, and methadone. The weak opioids, codeine, and hydrocodone, are used to manage mild-to-moderate pain usually in the outpatient setting. Meperidine has no advantages as an analgesic and many disadvantages. Meperidine toxicity is caused by accumulation of the metabolite normeperidine which can cause central nervous system side effects, ranging from dysphoria to seizures. Effective combination therapy, such as an NSAID and an opioid, can enhance analgesic efficacy while decreasing side effects.

Both prior history and current assessment should be considered in the management of acute sickle cell pain. For patients whose typical pain improves in a short time, preparations with a short duration of action are appropriate. For patients whose pain requires many days to resolve, sustained-release preparations combined with a short-acting product for breakthrough pain are more appropriate. If the patient has been on long-term opioid therapy at home, tolerance can develop. In these cases, the acute pain can be treated with an opioid of different potency or a larger dose of the same medication. Intravenous administration provides a rapid onset of action and therefore is preferred for severe pain. Intramuscular injections should be avoided. Children may actually deny pain due to fear of injections. Analgesics should be titrated to pain relief. In patients with continuous pain, the analgesic should be given as a scheduled dose or continuous infusion. Continuous infusion has the advantage of less fluctuation of blood levels between dosing intervals. As needed dosing is only indicated for breakthrough pain. Patient-controlled analgesia (PCA) is commonly prescribed for severe pain episodes. When used properly, PCA allows patients to have control over pain therapy and minimizes the lag time between perception of pain and administration of analgesics. Studies have shown PCA use reduced cumulative dosage required for pain control. The transdermal fentanyl patch has also been used successfully, but its role in sickle cell acute pain crisis is unclear because of its slow onset of onset of pain relief (12-16 hours) and fixed dosage form, which makes it difficult to titrate the dose. Other alternative pain management techniques such as physical therapy, massage,

biofeedback, and relaxation therapy can be helpful as adjunct therapy.[86,87,88]

Suboptimal pain relief has been reported in both emergency room and hospitalized patients. The most common cause of suboptimal pain control in children and adults with SCD is the suspicion of addiction.[22] This obstacle is especially common in adolescents. In one study, 53% of emergency physicians believed that 20% of SCD patients are psychologically addicted to opioid analgesics. Another barrier to effective pain control is the difference in perception between patients, family, and healthcare providers. Patients with SCD have been reported to experience pain over 50% of days, and they develop coping strategies including flat affect. Patients who have inadequate pain control can exhibit anxiety and drug-seeking behavior for fear of pain. Tolerance to opioids may also be misinterpreted as drug addiction by healthcare providers and families. Aggressive pain control, frequent monitoring of pain during episodes, and tapering medication according to response are factors that minimize physical dependence. The use of a protocol has been shown to result in optimal management of pain control in SCD.[24,86,87,88,89]

With better understanding of NO and inflammation on vasculopathy, therapy targeting blood rheology, endothelium adhesion or inflammation have been explored as adjunct therapy. Inhaled NO has been studied as therapy to abort pain at onset of episodes. Significant reduction of pain scores in adult patients received inhaled NO in the emergency room. However, no differences in duration of episodes, hospital stay, or opioid use when given to hospitalized adult and pediatric patients were observed.[90,91] In a randomized controlled trial in children hospitalized for painful episodes, arginine, the precursor for NO, reduced total opioid use by more than 50%. Length of hospital stay was not reduced significantly but the pain scores were significantly lower at discharge when compared to placebo.[92] Systemic corticosteroids, methylprednisolone and dexamethasone have also been evaluated as an adjunct therapy for pain control. Shorter duration of analgesic therapy and duration of hospitalization were reported but increased risk of readmission was also reported.[93]

Chronic Sickle Cell Pain

As the number of adults living with SCD increases due to improved survival, the prevalence of disease morbidities including chronic pain also increases. Most of the published research has focused on the prevention of pain and the management of acute pain episodes. The mechanisms of chronic pain development in SCD are poorly understood and no systematic studies have evaluated risk factors for chronic pain development. Central sensitization and peripheral neural sensitization have been hypothesized to play a role in the development of chronic SCD pain.[37,38,94] Currently, there are no published reports of other medications such as selective serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors and anticonvulsants commonly used to treat chronic pain in patients with SCD. Treatment of chronic pain in SCD requires a multidisciplinary approach and most physicians with expertise in treating SCD recommend following established guidelines for chronic pain.[95]

PERSONALIZED PHARMACOTHERAPY

The mainstay of treatment in SCD involves medical therapy both for supportive care and disease modification. Classically, pharmacotherapy is individualized by weight-based dosing. However, new research is evaluating approaches to further personalize therapy. For example, many adults with SCD have abnormal renal function due to intrarenal sickling. HU, the most important disease modifying medication, is renally excreted with urinary recovery of 40% of the administered dose in adults with SCD. A lower initial dose of 5 to 10 mg/kg per day is recommended for individuals with creatinine clearance of less than 60 mL/min (1 mL/s).[22] Pharmacokinetic differences between adult and pediatric patients were not reported in initial studies. As a result, investigators designed a prospective clinical trial, the Hydroxyurea Study of Long-Term Effects (HUSTLE, NCT00305175), to evaluate interpatient variability among children taking HU. For the first-dose pharmacokinetic studies, 51 of 87 patients showed a "fast" absorption profile with an earlier and higher maximum concentration after a single dose of 20 mg/kg. Although several parameters were associated with maximum tolerated dose (MTD) and HbF at MTD, the investigators concluded that standardized dose titration to myelosuppression remains the best option.[96]

Adults and children with SCD require the use of acute and chronic pain medications including opioids to control painful episodes. Some patients have clinically demonstrated inadequate relief to analgesic dosing with codeine. Children who failed oral therapy with codeine were found to carry a polymorphism in the *CYP2D6* gene resulting in a poor metabolizer phenotype. The CYP2D6 isoenzyme mediates the metabolism of codeine to morphine. These results have led to early discontinuation of codeine analgesics in children with SCD if no response is seen after their first dose and use of alternative oral analgesics for the treatment of pain at home. Often in treating individuals with SCD, analgesia is not obtained even with very high intravenous opioid doses. A recent review highlighted several enzymes that play a role in morphine metabolism that may be altered in patients with SCD including UGT2B7, a morphine-metabolizing enzyme; OPRM1, a mu opioid receptor or ABCB1, a transporter protein at the blood brain barrier. However, further investigation is needed and genetic testing has not been used to guide morphine dosing.[97,98]

The concept of individualized therapy in SCD is being tested with the identification of single nucleotide polymorphisms (SNPs) associated with severity of disease and HbF responses to HU therapy. Increases in HbF with HU appeared to be related to baseline levels suggesting that genomic profiles may contribute to the differences. Genome-wide association studies have identified several loci in HbF expression. BCL11A is a transcription factor that regulates hemoglobin switching and could account for the variability of HbF levels between individuals with high and low HbF. Different biomarkers have been studied in SCD to identify complications and phenotypic variability. The potential use of biomarkers and genome-based modification of phenotype in SCD may allow a personalized therapeutic approach in the future.[97]

EVALUATION OF THERAPEUTIC OUTCOMES

9 SCD is a complex disorder that requires multidisciplinary comprehensive care. All patients should receive regular medical evaluation to provide preventive care, establish baseline symptoms and laboratory values, monitor changes, and provide education appropriate for age. For infants younger

than 1-year-old, medical evaluations every 2 to 4 months are recommended. Beyond 2 years of age, evaluation can be extended to every 6 to 12 months with modifications depending on severity of the illness.

Routine laboratory evaluation including complete blood cell counts and reticulocyte counts every 3 to 6 months up to 2 years of age, then every 6 to 12 months; HbF level should be screened annually until 2 years of age. Evaluation of renal, hepatobiliary, and pulmonary function should be done annually. TCD screening is recommended to start at age 2 years and performed annually for children with HbSS and HbSβ. Ophthalmologic examination to screen for retinopathy is recommended at around age 10 to 12 years for those with HbSC and 14 years for HbSS. In patients with recurrent ACS, pulmonary function tests should be done to establish baseline values and identify declines in lung function as well as an evaluation by pulmonology to screen for lower airway hyper-responsiveness.

It is essential that immunizations and prophylactic antibiotics be given. When infections do occur, appropriate antibiotic therapy should be initiated, and the patient should be monitored for laboratory and clinical improvement. The efficacy of HU can be measured as a decrease in the number, severity, and duration of sickle cell pain episodes. HbF concentrations or MCV values can also provide some indication of the patient's response to therapy. When painful episodes do occur, the effectiveness of analgesics can be measured by subjective assessments made by the patient, and healthcare practitioners. The success of poststroke blood transfusions can be measured by clinical progression or the occurrence of subsequent strokes. Finally, indicators can be used for measurements of quality of care for children with SCD.

ABBREVIATIONS

ACS	acute chest syndrome
CT	computed tomography
ET-1	endothelin 1
GVHD	graft-versus-host disease
HbA	hemoglobin A
HbAS	one normal (hemoglobin A) and one sickle cell hemoglobin (hemoglobin S) gene
HbC	hemoglobin C
HbF	fetal hemoglobin
HbS	sickle cell hemoglobin
HbSβ^+-thal	hemoglobin sickle cell β^+-thalassemia
HbSβ^0-thal	hemoglobin sickle cell β^0-thalassemia
HbSC	sickle cell hemoglobin C
HbSS	homozygous sickle cell hemoglobin (hemoglobin S)
HLA	human leukocyte antigen
HPFH	hereditary persistence of fetal hemoglobin
HSCT	hematopoietic stem cell transplantation
HU	hydroxyurea

ISC	irreversibly sickled cell
MCHC	mean corpuscular hemoglobin concentration
MCV	mean corpuscular volume
MRI	magnetic resonance imaging
MSH	Multicenter Study of Hydroxyurea in Sickle Cell Anemia
MTD	maximum tolerated dose
NIH	National Institutes of Health
NO	nitric oxide
NSAID	nonsteroidal anti-inflammatory drug
NT-pro-BNP	N-terminal pro-brain natriuretic peptide
PAH	pulmonary artery hypertension
PAP	pulmonary arterial pressure
PCA	patient-controlled analgesia
PCV7	7-valent pneumococcal conjugate vaccine
PCV13	13-valent pneumococcal conjugate vaccine
PPSV23	23-valent pneumococcal polysaccharide vaccine
RBC	red blood cell
SCA	sickle cell anemia
SCD	sickle cell disease
SCT	sickle cell trait
TCD	transcranial Doppler ultrasound
VCAM-1	vascular cell adhesion molecule 1
WBC	white blood cell

Chapter e103: Drug-Induced Hematologic Disorders

FIGURE e103-1

Elisa M. Greene; Tracy M. Hagemann

INTRODUCTION

KEY CONCEPTS

- 1 The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.
- 2 Drug-induced hematologic disorders are generally rare adverse effects associated with drug therapy.
- 3 The incidence of rare adverse drug reactions (ADRs) is usually established by postmarketing surveillance and reporting.
- 4 Rechallenging a patient with an agent suspected of inducing a blood disorder is not generally recommended.
- 5 Drug-induced hematologic disorders can occur by two mechanisms: direct drug or metabolite toxicity or an immune reaction.
- 6 The primary treatment of drug-induced hematologic disorders is removal of the drug in question and symptomatic support of the patient.

1 Hematologic disorders have long been a potential risk of modern pharmacotherapy. Granulocytopenia (agranulocytosis) was reported in association with one of medicine's early therapeutic agents, sulfanilamide, in 1938.[1] Some agents cause predictable hematologic disease (eg, antineoplastics), but others induce idiosyncratic reactions not directly related to the drugs'

pharmacology. The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.

2 The incidence of idiosyncratic drug-induced hematologic disorders varies depending on the condition and the associated drug. Few epidemiologic studies have evaluated the actual incidence of these adverse reactions, but these reactions appear to be rare. Women are generally more susceptible than men to the hematologic effects of drugs. The incidence varies based on geography, which suggests that genetic differences may be important determinants of susceptibility. Drug-induced thrombocytopenia is the most common drug-induced hematologic disorder, with reports suggesting that between 0.1% and 5% of patients who receive heparin develop heparin-induced thrombocytopenia (HIT).[2,3] The Berlin Case-Control Surveillance Study was conducted from 2000 to 2009 to assess the incidence and risks of drug-induced hematologic disorders and found that almost 30% of all cases of blood dyscrasias were "possibly" attributable to drug therapy.[4]

Although drug-induced hematologic disorders are less common than other types of adverse reactions, they are associated with significant morbidity and mortality. Aplastic anemia is the leading cause of death followed by thrombocytopenia, agranulocytosis, and hemolytic anemia.[5] Similar to most other adverse drug reactions (ADRs), drug-induced hematologic disorders are more common in elderly adults than in the young; the risk of death also appears to be greater with increasing age.

3 The MedWatch program supported by the Food and Drug Administration[6] is the most common avenue for postmarketing surveillance to establish the incidence of ADRs. Many facilities have similar drug-reporting programs to follow ADR trends and to determine whether an association between a drug and an ADR is causal or coincidental. These programs enable practitioners to confirm that an adverse event is the result of drug therapy rather than one of many other potential causes; general guidelines are readily available.[7,8]

4 Because drug-induced blood disorders are potentially dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis is not recommended. In vitro studies with the offending agent and cells or plasma from the patient's blood can be performed to determine causality.[9] These methods are often expensive, however, and require facilities and expertise that are not generally available. Laboratory confirmation of drug causation is not always necessary to warrant interruption or discontinuation of therapy. Therefore, it is extremely important that practitioners be able to clinically evaluate suspect drugs quickly and to interrupt therapy when necessary.

Through the use of surveillance programs, lists of drugs that may be associated with adverse events have been published. These lists include a large number of commonly used drugs. Although these lists may help clinicians identify specific drug causes of adverse events, the large number of agents implicated may make this a difficult process. The absence of a drug from such a list should not discourage the investigation and reporting of a suspected agent associated with an adverse event. It is imperative that clinicians use a rational approach to determine causality and identify the agents associated with a reaction. The clinician should focus on the issue, perform a rigorous investigation, develop appropriate criteria, use objective criteria to grade the response, and complete a quantitative summary. A complete, thorough, and detailed drug and exposure history must be obtained from the

patient in order to best determine any potential for drug causation.

A common tool used to rate the likelihood of causality in ADR investigations is an ADR probability scale (algorithm). One such scale was developed and tested by Naranjo and colleagues.[10] This tool provides a series of scored questions that leads an investigator to the likelihood that an ADR was caused by the suspected medication. Depending on the aggregate score, the causality is rated as *doubtful, possible, probable,* or *definite*. The scale gives the most weight to the temporal relationship of the reaction with relation to administration of the drug, observations after a rechallenge of the suspected medication, and alternate explanations for the ADR. As mentioned earlier, it is often unethical to rechallenge patients who experience severe hematologic toxicities. Thus, without a rechallenge, it is difficult to achieve a causality rating of *definite* with such an algorithm.

In determining the likelihood that an observed reaction is caused by a particular medication, clinicians should review the medical literature for past reports supporting the observation. Greater weight should be assigned to prospective study designs such as clinical trials or cohort studies than to case reports or expert opinion.

Evaluating drug-induced hematologic disorders requires a basic understanding of hematopoiesis (see Chapter e86). The pluripotent hematopoietic stem cells in the bone marrow self-reproduce in order to maintain the blood. These cells further differentiate to intermediate precursor cells, which are also called progenitor cells or colony-forming cells. Committed to a particular cell line, these intermediate stem cells differentiate into colonies of each type of blood cell in response to specific colony-stimulating factors. Drug-induced hematologic disorders can affect any cell line, including white blood cells (WBCs), red blood cells (RBCs), and platelets. When a drug causes decreases in all three cell lines accompanied by a hypoplastic bone marrow, the result is drug-induced aplastic anemia. The decrease in WBC count alone by a medication is drug-induced agranulocytosis. Drugs can affect RBCs by causing a number of different drug-induced anemias, including immune hemolytic anemia, oxidative hemolytic anemia, or megaloblastic anemia. For a more detailed review of anemias, see Chapter 100. A drug-induced decrease in platelet count is drug-induced thrombocytopenia.

DRUG-INDUCED APLASTIC ANEMIA

Aplastic anemia is a rare, serious disease of unclear etiology in which pancytopenia (anemia, neutropenia, and thrombocytopenia),[11] hypocellular bone marrow and no gross evidence of increased peripheral blood cell destruction occurs.[12] Bone marrow examination shows an absence or marked reduction of hematopoietic stem cells and an increase in fat cells.

The reported incidence is two per million in Europe and North America, and four to six per million in pointing to a relationship between environment and risk.[13,14] It has been estimated that 50% of aplastic anemia cases are acquired in nature, but a definitive causative agent cannot be identified in most cases.[15,16] Men and women are affected equally, but there is a bimodal risk distribution when it comes to age, with peak incidences in those ages 10 to 25 years and again in those older than 60 years of age.[17]

Diagnosis and Classification

The diagnosis of aplastic anemia requires the presence of two of the following criteria: a WBC count of 3,500 cells/mm^3 (3.5 × 10^9/L) or less, a platelet count of 55,000 cells/mm^3 (55 × 10^9/L) or less, or a hemoglobin value of 10 g/dL (100 g/L; 6.21 mmol/L) or less with a reticulocyte count of 30,000 cells/mm^3 (30 × 10^9/L) or less.[18] Depending on the blood counts, aplastic anemia can be categorized as moderate, severe, and very severe aplastic anemia[19,20,21]:

1. Moderate aplastic anemia (MAA): Two of the following three criteria—neutrophils less than 1,500 cells/mm^3 (1.5 × 10^9/L), platelets less than 50,000 cells/mm^3 (50 × 10^9/L), hemoglobin less than 10 g/dL (100 g/L; 6.21 mmol/L)

2. Severe aplastic anemia (SAA): Two of the following three criteria—neutrophils less than 500 cells/mm^3 (0.5 × 10^9/L), platelets less than 20,000 cells/mm^3 (20 × 10^9/L), reticulocytes less than 1%

3. Very severe aplastic anemia (VSAA): SAA with a neutrophil count less than 200 cells/mm^3 (0.2 × 10^9/L)

The diagnosis of aplastic anemia requires a bone marrow aspirate and biopsy to exclude other causes of pancytopenia.[22] The patient must not have had previous exposure to cytotoxic chemotherapy or intensive radiation.

Mechanism

Aplastic anemia can be divided into two broad categories, inherited and acquired. Inherited aplastic anemias, such as Fanconi's and Blackfan Diamond, result in bone marrow failure, fatty infiltration of the marrow, and loss of circulating blood cells. Acquired aplastic anemia is the focus of this section because it is the type of aplastic anemia that results from drugs, radiation, viruses, or chemical exposure, and it accounts for most cases of aplastic anemia. Acquired, drug-induced aplastic anemia is an idiosyncratic reaction, with unpredictable severity and time to recovery.

5 Three major mechanisms of acquired aplastic anemia have been identified: direct toxicity, metabolite-driven toxicity, and immune-mediated mechanisms.[20] Idiosyncratic drug-induced aplastic anemia secondary to direct toxicity can be characterized by dose independence, a latent period before the onset of anemia, and continued marrow injury after drug discontinuation.[23] When intermediate metabolites of drugs bind to proteins and DNA on hematopoietic cells, bone marrow failure can occur. Genetic variation leads to variability in the presence of these reactive metabolites and explains the idiosyncratic nature of these drug reactions. The most common cause of drug-induced aplastic anemia is the development of an immune reaction. It is proposed that exposure to an inciting antigen (drug) activates cells and cytokines of the immune system, leading to the death of stem cells.[20] The immune mechanism of aplastic anemia explains the responsiveness of the disease to immunosuppressive therapy.[20]

Genetic predisposition can also influence the development of drug-induced aplastic anemia.[24,25] Pharmacogenetic research to identify patients who may be slow or normal metabolizers of drugs can increase the clinician's ability to predict the development of aplastic anemia. Initial observational studies have not demonstrated a significant difference between control participants and cases, but continued research may establish the role of altered metabolism in patients with aplastic anemia.[26]

Causative Agents

Cytotoxic chemotherapy and radiation therapy are known to induce varying degrees of bone marrow suppression or failure. The antineoplastic agents exemplify the dose-dependent mechanism for the development of aplastic anemia. Many of these agents have the ability to suppress one or more cell lines in a reversible manner. The degree of suppression and the cell line involved depend on the nature of the particular drug and its potential for inhibiting marrow proliferation. Certain chemicals or agents may also induce direct injury to hematopoietic cells.

Chloramphenicol, already known to cause a dose-dependent reaction, is the prototype drug for the idiosyncratic mechanism. The estimated incidence of chloramphenicol-induced aplastic anemia is one case per 20,000 patients treated,[25] but the overall prevalence has declined with decreased use of this agent.[23] The dose-dependent and idiosyncratic reactions seen with chloramphenicol do not appear to be related. Other drugs thought to induce aplastic anemia through toxic metabolites include phenytoin and carbamazepine. Investigators have theorized that metabolites of these medications bind covalently to macromolecules in the cell and then cause cell death either by exerting a direct toxic effect on the stem cell or by causing the death of lymphocytes involved in regulating hematopoiesis.[27]

Treatment

Rapid diagnosis and immediate therapy initiation are imperative because of the high mortality rate associated with severe and very SAA. Treatment should be based on the severity of disease, with the goal of therapy being to improve peripheral blood counts, limit the requirement for transfusions, and minimize the risk for infections.

6 As with all cases of drug-induced hematologic disorders, the first step is to remove the suspected offending agent. Early withdrawal of the drug can allow for reversal of the aplastic anemia. Appropriate supportive care is also essential because the major causes of mortality in patients with aplastic anemia are infections (bacterial and fungal) and bleeding. Patients must receive transfusion support with erythrocytes and platelets, as well as appropriate antimicrobial prophylaxis or treatment during neutropenic periods. Routine use of growth factors such as recombinant human erythropoietin and granulocyte colony-stimulating factor (G-CSF) has not been shown to improve outcome and are not recommended for the management of aplastic anemia except when life threatening infections are present.[11] Current treatment guidelines for aplastic anemia recommend the use of prophylactic antibiotic and antifungal agents when neutrophil counts are below 500 cells/mm^3 (0.5×10^9/L). If patients experience febrile neutropenia, broad-spectrum IV antibiotics should be started immediately. Current guidelines do not recommend the use of prophylaxis for

viruses or *Pneumocystis jiroveci*. For patients who have been heavily transfused, iron chelation therapy with agents such as deferoxamine or deferasirox may be necessary to avoid the serious consequences of iron overload.

TABLE e103-1 Drugs Associated with Aplastic Anemia

Observational study evidence

Carbamazepine

Furosemide

Gold salts

Mebendazole

Methimazole

NSAIDs

Oxyphenbutazone

Penicillamine

Phenobarbital

Phenothiazines

Phenytoin

Propylthiouracil

Sulfonamides

Thiazides

Tocainide

Case report evidence (*probable* or *definite* causality rating)

Acetazolamide

Aspirin

Captopril

Chloramphenicol

Chloroquine

Chlorothiazide

Chlorpromazine

Dapsone

Felbamate

Interferon alfa

Lisinopril

Lithium

Nizatidine

Pentoxifylline

Quinidine

Sulindac

Ticlopidine

MedWatch postmarketing reports 2009-2015

Adalimumab

Aliskirin

Amlodipine

Carvedilol

Dantrolene

Etanercept

Oxcarbazepine

Valsartan

NSAID, nonsteroidal anti-inflammatory drug.

The two major treatment options for patients with drug-induced aplastic anemia are allogeneic hematopoietic stem cell transplantation (HSCT) and immunosuppressive therapy. Factors that determine which therapy would be preferred include age, disease severity, and availability of a human leukocyte antigen– (HLA-) matched donor. For healthy patients younger than the age of 45 years, the treatment of choice is allogeneic HSCT from an HLA-matched sibling donor. This is associated with potential cure and results in a 5-year survival rate of 77% in adults and up to 90% in children.[11,28,29] Unfortunately, most patients do not have a matched sibling donor and so allogeneic HSCT from a HLA-matched unrelated unrelated donor may be considered but is usually reserved for

those who fail prior immunosuppressive therapy. When used in this setting, the 5-year overall survival rate in these patients has improved to over 50%, primarily because of improvements in HLA typing and unrelated donor selection.[30,31] For patients older than the age of 45 years and for those who are not candidates for transplant due to comorbidities or no available match, the preferred first-line therapy is immunosuppressive therapy.[11] Complications of allogeneic HSCT, such as graft-versus-host disease and graft rejection, require all patients to be closely monitored for an extended period of time.

The current standard immunosuppressive regimen for the treatment of acquired aplastic anemia is combination therapy with antithymocyte globulin (ATG) and cyclosporine. This combination has been reported to achieve 5-year survival rates between 75% and 85%, but the response rate in older patients is lower.[32] Although cyclosporine monotherapy has been used to treat MAA, the combination of these agents has been shown to increase response rate, improve failure-free survival, and reduce the number of immunosuppressive courses needed.[33,34] Cyclosporine inhibits interleukin-2 production and release and subsequent activation of resting T cells. Cyclosporine dosing has varied from 4 to 6 mg/kg per day to 10 to 12 mg/kg per day, with the most frequently reported initial dose of 5 mg/kg per day in two divided doses. Cyclosporine doses are titrated to a target blood concentration that can be patient and institution specific but are usually in the range of 150 to 250 mcg/L (125-208 nmol/L) for adult patients. It is recommended that cyclosporine be continued for at least 12 months after response and then tapered slowly, as increased relapse rates have been observed when tapering rapidly.[32] ATG is composed of polyclonal immunoglobulin G (IgG) against human T lymphocytes derived from either horses or rabbits, and has been a standard component of immunosuppressive therapy for aplastic anemia for many years. In one study comparing the horse versus rabbit product, both given in combination with cyclosporine, treatment with the horse-derived ATG product resulted in significantly higher response rates (68% vs 37%) and 3-year overall survival rates (96% vs 76%). Although the mechanism for this difference is not completely understood, the greater depletion of $CD4^+$ cells associated with the rabbit ATG as compared with horse ATG may be associated with adverse outcomes. However, other studies found no difference between formulations.[11,35] Based on these results, treatment with the horse-derived ATG product may be preferred for treatment when available. A clinical trial comparing the two products is currently underway.[11] Because response to immunosuppressive therapy is often delayed (3-4 months), patients require continued supportive care until recovery. Patients should be monitored for adverse effects, including serum sickness, which can occur about 1 week after ATG begins.[32]

Corticosteroids are added to ATG-based immunosuppression because of their ability to reduce adverse reactions associated with ATG administration. In an effort to improve outcomes, several other agents have also been investigated in the treatment of aplastic anemia. The additive benefits of other immunosuppressive agents such as mycophenolate, cyclophosphamide, and sirolimus have been evaluated.[28] However, they have not been shown to be superior to the combination of ATG and cyclosporine, and their place in therapy is not clearly defined. In the case of refractory or relapsed disease, a second cycle or alternative agent, such as alemtuzumab or high dose cyclophosphamide, may be able to achieve a remission rate of 50%.[11]

Clinical Controversy...

Refractory SAA may extend to more than 6 months after initial treatment, but fortunately, half of patients considered nonresponders at 6 months will still see some improvement in their neutrophil counts over time. Nonresponders who continue to be severely neutropenic should be considered for HSCT, but for patients without a histocompatible donor, a second course of immunosuppression with rabbit ATG and cyclosporine, or with alemtuzumab monotherapy may be an option. Failure to respond to ATG, may necessitate eltrombopag, novel immunosuppressants or the use of androgens. Anecdotal evidence from uncontrolled studies suggests that androgens may be beneficial in some patients when administered over three months, but all of these second line therapies require further study to assess their role in the management of drug-induced, refractory SAA.

DRUG-INDUCED AGRANULOCYTOSIS

Agranulocytosis is defined as a reduction in the number of mature myeloid cells in the blood (granulocytes and immature granulocytes [bands]) to a total count of 500 cells/mm^3 (0.5×10^9/L) or less. The incidence ranges from 1.6 to 9.2 cases per million in Europe and 2.4 to 15.4 cases per million in the United States.[36,37,38] Older patients are thought to be at greater risk for drug-induced agranulocytosis, most likely due to increased medication use.[37,39] Drug-induced agranulocytosis also occurs more frequently in women than in men.

Clinical Presentation

Agranulocytosis is a rare reaction that typically presents with fever.[38] Symptoms arise from the increased infection risk associated with the lack of WBCs and include sore throat, fever, malaise, weakness, and chills. Agranulocytosis may develop 19 to 60 days after exposure of the offending drugs but typical time of onset is at least 1 month after drug initiation. Symptoms may appear either immediately or insidiously, depending on the time course of neutropenia development.[40]

Mechanism

5 The cause of drug-induced agranulocytosis is not fully understood, but two mechanisms- direct toxicity and immune-mediated toxicity—have been proposed. Direct toxicity may be due to either the parent drug or a toxic metabolite or byproduct. Agranulocytosis associated with direct toxicity is usually associated with a slower decline in neutrophils, with a more insidious presentation of symptoms.[41,42,43] With immune-mediated mechanisms, agranulocytosis occurs within days to a few weeks after drug exposure, with rapid appearance of symptoms.[43] Within the immune-mediated subset of agranulocytosis, three mechanisms of toxicity have been proposed. The *hapten mechanism* involves the drug or its metabolite binding to the membrane of neutrophils or myeloid precursors. After binding, antibodies are induced that destroy the cell.

In the *immune-complex mechanism*, antibodies form complexes with the causative drug, and the immune complex adheres to the target cell, leading to cell destruction. Finally, in the *autoimmune*

mechanism, the drug triggers the production of autoantibodies that react with neutrophils. In this reaction, the causative drug is not directly involved with the serologic reaction. In all mechanisms, cell destruction occurs via antibody-mediated cell toxicity, complement activation, and phagocytic elimination through the mononuclear phagocytic system.

Causative Agents

A list of medications that have been associated with drug-induced agranulocytosis can be seen in **Table e103-2**. Antipsychotics, antibiotics, and antithyroid medications are commonly implicated.[44] Nearly all classes of drugs have been associated with some incidence of acute neutropenia or agranulocytosis, although the risk is exceedingly small. But the risk may be higher for some drugs. Higher risk agents include antithyroid medications (propylthiouracil and methimazole), ticlopidine, clozapine, sulfasalazine, trimethoprim–sulfamethoxazole,deferapirone, and β-lactam antibiotics. Mechanisms associated with selected agents can be seen in **Table e103-3**.

TABLE e103-2 Drugs Associated with Agranulocytosis

Observational Study Evidence	Case Report Evidence (*Probable* or *Definite* Causality Rating)		Med Watch Post Marketing Reports 2009-2015
β-Lactam antibiotics	Acetaminophen	Levodopa	Amlodipine
Carbamazepine	Acetazolamide	Meprobamate	Aripiprazole
Carbimazole	Ampicillin	Methazolamide	Benazapril
Clomipramine	Captopril	Methyldopa	Bocepravir
Digoxin	Carbenicillin	Metronidazole	Clozapine
Dipyridamole	Cefotaxime	Nafcillin	Defarasirox
Ganciclovir	Cefuroxime	NSAIDs	Fluoxetine
Glyburide	Chloramphenicol	Olanzapine	Haloperidol
Gold salts	Chlorpromazine	Oxacillin	Hydrochlorothiazide
Imipenem–cilastatin	Chlorpropamide	Penicillamine	Iacosamide
Indomethacin	Chlorpheniramine	Penicillin G	Leflunomide
Macrolide antibiotics	Clindamycin	Pentazocine	Levitiracetam
Methimazole	Clozapine	Phenytoin	Memantine
Mirtazapine	Colchicine	Primidone	Molindone
Phenobarbital	Doxepin	Procainamide	Olanzapine
Phenothiazines	Dapsone	Propylthiouracil	Oxcarbazepine
Prednisone	Desipramine	Pyrimethamine	Paliperidone
Propranolol	Ethacrynic acid	Quinidine	Pantoprazole
Spironolactone	Ethosuximide	Quinine	Pimozide
Sulfonamides	Flucytosine	Rifampin	Propafenone
Sulfonylureas	Gentamicin	Streptomycin	Quetiapine
Ticlopidine	Griseofulvin	Terbinafine	Rifabutin

Observational Study Evidence	Case Report Evidence (*Probable* or *Definite* Causality Rating)		Med Watch Post Marketing Reports 2009-2015
Valproic acid	Hydralazine	Ticarcillin	Risperidone
Zidovudine	Hydroxychloroquine	Tocainide	Sulfasalazide
	Imipenem–cilastatin	Tolbutamide	Thiothixene
	Imipramine	Vancomycin	Trandolapril
	Lamotrigine		Ziprasidone

NSAID, nonsteroidal antiinflammatory drug.

TABLE e103-3 Mechanisms of Drug-Induced Agranulocytosis

Direct Toxicity to Myeloid Cells	Hapten Mechanism	Immune Complex Mechanism	Autoimmune Mechanism
Chlorpromazine	Aminopyrine	Quinine	Levisamole
Procainamide	Penicillin	Quinidine	
Clozapine	Gold compounds		
Dapsone			
Sulfonamides			
Carbamazepine			
Phenytoin			
Indomethacin			
Diclofenac			

The mechanism by which antithyroid agents cause agranulocytosis is unknown, but antineutrophil cytoplasmic antibodies have been identified.[45] Agranulocytosis appears to occur more frequently in patients over 40 years of age and within 2 months after the initiation of therapy. Although a possible dose–response relationship has been reported,[46] agranulocytosis has been associated with long-term low doses of propylthiouracil and methimazole treatment.[47]

Ticlopidine produces neutropenia in about 2.4% of patients and agranulocytosis in 0.8%, possibly by inhibiting hematopoietic progenitor stem cells.[48] Agranulocytosis associated with ticlopidine most commonly occurs within 1 to 3 months from the initiation of the drug.

Clozapine is associated with a significantly higher risk of agranulocytosis compared with other antipsychotic medications.[49] Because of the frequency and seriousness of this effect and its reversible nature if detected early in therapy, clozapine is currently only available through a limited distribution program that requires strict monitoring of WBC count.[50]

The phenothiazine class of drugs is known to cause drug-induced agranulocytosis by the immune-complex mechanism. When the bone marrow from a patient with phenothiazine-induced agranulocytosis is examined, it initially appears to have no cellularity (aplastic), but over time, it becomes hyperplastic. It is believed that toxic effects of the phenothiazines are not seen in all

patients taking the medications because most patients have enough bone marrow reserve to overcome the toxic effects.[51] The onset of phenothiazine-induced agranulocytosis is about 2 to 15 weeks after the initiation of therapy, with a peak onset between 3 and 4 weeks.[52,53]

Penicillin derivatives may suppress WBCs by several mechanisms. Although the hapten mechanism is thought to be the cause of penicillin-induced agranulocytosis because of the rapid onset of symptoms and the dose-related phenomenon, a second mechanism could possibly be involved. That mechanism involves an accumulation of drug to toxic concentrations in hypersensitive individuals. Researchers have shown with in vitro cell cultures that penicillin derivatives in high concentrations inhibit the growth of myeloid colony-forming units (CFUs) in patients recovering from drug-induced agranulocytosis.[54]

Treatment

 Removal of the drug is the best treatment option, with blood cell counts usually returning to normal within 2 to 4 weeks. Sargramostim (granulocyte-macrophage colony-stimulating factor [GM-CSF]) and filgrastim (G-CSF) have been shown to shorten the duration of neutropenia, length of antibiotic therapy, and hospital length of stay.[55] Although the use of both agents has been reported in the literature, a commonly reported regimen is G-CSF 300 mcg/day via subcutaneous injection. Most clinicians recommend the use of growth factors in patients with a neutrophil nadir less than 100 cells/mm^3 (0.1 $\times 10^9$/L), regardless of the presence of infection.

The overall mortality rate of agranulocytosis has fallen dramatically over the past 20 years largely because of improvements in infection prophylaxis and supportive care.[36,40] The mortality rate is highest among elderly adults and patients with renal failure, bacteremia, or shock at the time of diagnosis.[55,56] Drug-induced agranulocytosis usually resolves over time with supportive care and management of infection. The time to neutrophil recovery has typically been reported to range from 4 to 24 days.[40] Restarting the drug is not usually recommended. In the case of penicillin-induced agranulocytosis, the patient can often begin taking penicillin again, at a lower dosage, after the neutropenia has resolved without any recurrence of drug-induced agranulocytosis.[57]

DRUG-INDUCED HEMOLYTIC ANEMIA

After their release from the bone marrow, normal RBCs survive for about 120 days before they are removed by phagocytic cells of the spleen and liver. The process of premature RBC destruction is referred to as hemolysis, which can occur because of either defective RBCs or abnormal changes in the intravascular environment. Drugs can promote hemolysis by both processes.

The incidence of drug-induced hemolytic anemia is estimated to be about one in 1 to 2 million individuals, although the exact incidence has been difficult to ascertain because of difficulty in establishing a clear diagnosis and relationship to a specific agent.[58]

Clinical Presentation

The onset of drug-induced hemolytic anemia is variable and depends on the drug and mechanism of the hemolysis. Symptoms of hemolytic anemia can include fatigue, malaise, pallor, and shortness of breath. Patients may present with abdominal pain, lumbar pain, or red urine as a result of the hemolysis.[59]

Diagnosis

The best means to diagnose drug-induced immune hemolytic anemia is with the direct Coombs test (or direct antiglobulin test [DAT]), which identifies foreign immunoglobulins either in the patient's serum or on the RBCs themselves. The direct Coombs test involves combining the patient's RBCs with antiglobulin serum. This serum is created by injecting rabbits with preparations of human complement, crystalizable fragment (of immunoglobulin) (Fc), or immunoglobulins. The rabbits then produce antibodies against human immunoglobulins and complement, which becomes the antiglobulin serum. In a drug-induced process, the patient's RBCs are coated with antibody or complement and the antibodies in the antiglobulin serum attach to the separate RBCs, creating a lattice formation called agglutination.[60] This agglutination is considered positive for the presence of IgG or complement on the cell surfaces.

An indirect Coombs test can identify whether there are antibodies in a patient's serum. This test is performed by combining the patient's serum with normal RBCs and then subjecting them to the direct Coombs test. This process is important in blood bank procedures.

Mechanism

5 The mechanism of drug-induced hemolytic anemia can be divided into two categories, immune or metabolic (ie, oxidative).

Immune

In immune hemolytic anemia, IgG, immunoglobulin M (IgM), or both bind to antigens on the surface of RBCs and initiate their destruction through the complement and mononuclear phagocytic systems.[51] Immunologic mechanisms can be either drug dependent or independent.[61]

Drug-Dependent

The drug-dependent mechanism is most common and involves the formation of antibodies directed against RBCs. In this scenario, antibodies are only present when the drug itself is present.[62]

Four mechanisms have been proposed to explain how drugs can induce immune hemolytic anemia; these are similar to those proposed for drug-induced agranulocytosis.[63]

The first mechanism is the "hapten mechanism" or "drug adsorption" mechanism. Haptens are drugs or molecules that cause an immune response when they bond to a protein in the body. In this mechanism, patients make an antibody against a stable complex of the drug with some soluble

noncellular molecule or protein. When the drug is administered again, an immune complex of drug–antidrug forms and attaches nonspecifically to RBCs, activating complement and leading to cell destruction.[63,64] The anemia usually develops gradually over 7 to 10 days and reverses over a couple of weeks after the offending drug is discontinued. The direct Coombs test result may remain positive for several weeks.

The second mechanism is the immune complex or "innocent bystander" mechanism. In this mechanism, drugs bind to an antibody, usually IgM, to form an immune complex. This immune complex then attaches to the RBC membrane, activating complement and leading to intravascular hemolysis.[63] As soon as complement is activated, the complex can detach and move on to other RBCs. Because of this low affinity, only a small amount of drug is needed to cause the reaction, and the direct Coombs test result is positive for complement only. RBCs are essentially victims, or "innocent bystanders," of the immunologic reaction. This mechanism is associated with acute intravascular hemolysis that can be severe, sometimes leading to hemoglobinuria and renal failure. After clearance of the drug from the circulation, the direct Coombs test result will become negative.

The third mechanism involves the production of true RBC autoantibodies. The mechanism for autoantibody production is poorly understood,[65] although two hypotheses have been proposed.[66] The first suggests that the medication or its metabolites act on the immune system and impair immune tolerance. An alternative hypothesis is that the offending drug may bind to immature RBCs, altering the membrane antigens and inducing autoantibodies. Methyldopa is the prototype drug for this mechanism. About 10% to 20% of patients receiving methyldopa will develop a positive Coombs test, usually within 6 to 12 months of initiating therapy.[67] However, less than 1% of these patients experience hemolysis, and hemolysis can develop from 4 to 6 months to more than 2 years after the start of therapy. After the withdrawal of the drug, results of the Coombs test can remain positive for many months.[68] Because of the autoantibodies produced, methyldopa is often considered to cause autoimmune hemolytic anemia.[68,69] It is not known why only some patients develop autoantibodies and why only some of the patients who have autoantibodies develop hemolytic disease.

The fourth mechanism of drug-induced immune hemolytic anemia is through nonimmunologic protein adsorption (NIPA) to RBC membranes.[63,70] In this "membrane modification mechanism," drugs can change the RBC membrane so that proteins attach to the cell, leading to a positive antiglobulin test result. This phenomenon was originally thought to be important only because of laboratory test interference.

Drug-Independent

Drug-independent mechanisms are also referred to as in vitro reactions. With this mechanism, antibodies are present even in absence of the drug.[65] These are true RBC antibodies and can be the cause of autoimmune hemolytic anemia. The laboratory and clinical findings may be indistinguishable from those found with idiopathic autoimmune hemolytic anemia. It is thought that drugs evoke the formation of these antibodies by having a direct effect on the immune system in a mechanism similar to microbial or viral infections.

Metabolic

Metabolic mechanisms of hemolytic anemia are considered to be oxidative. These most often occur in the presence of a glucose-6-phosphate dehydrogenase deficiency (G6PD deficiency). A G6PD deficiency is a disorder of the hexose monophosphate shunt, which is responsible for producing nicotinamide adenine dinucleotide phosphate hydrogen (NADPH) in RBCs, which in turn keeps glutathione in a reduced state. Reduced glutathione is a substrate for glutathione peroxidase, an enzyme that removes peroxide from RBCs, thus protecting them from oxidative stress.[71] Without reduced glutathione, oxidative drugs can oxidize the sulfhydryl groups of hemoglobin, removing them prematurely from the circulation (ie, causing hemolysis).

Causative Agents

Over 130 drugs have indisputable evidence of causing hemolytic anemia. Since 2008, piperacillin is the most commonly reported agent.[58,61] A list of drugs associated with drug-induced immune hemolytic anemia is provided in **Table e103-4**. Of note, diclofenac, fludarabine, oxaliplatin, and cephalosporins are some of the most frequent offenders.[72] Of these, diclofenac is the most common, but can be especially prone to misdiagnosis.[69] Certain drugs and their responsible mechanisms are listed in **Table e103-5**. For a list of agents associated with drug-induced metabolic hemolytic anemia, refer to **Table e103-6**.

Treatment

The treatment of drug-induced immune hemolytic anemia includes the immediate removal of the offending agent and supportive care. The severity of the reaction depends on the rate of hemolysis.

Immune

Immune hemolytic anemia caused by drugs through the hapten or adsorption and autoimmune mechanisms tends to be slower in onset and mild to moderate in severity. Conversely, hemolysis prompted through the immune complex mechanism (innocent bystander) can have a sudden onset, lead to severe hemolysis, and result in renal failure. In the metabolic mechanism, the degree of hemolysis depends on the severity of the enzyme deficiency and the amount of oxidative stress. However, the dose required for hemolysis to occur is often less than prescribed quantities of the suspected drug.[68,71] Although severe hemolysis is rare, any drug that places oxidative stress on RBCs can cause drug-induced metabolic hemolytic anemia.

Glucocorticoids can be helpful in severe cases, but their use outside of autoimmune hemolytic anemia is not supported by strong evidence.[73] Other agents such as rituximab and IgG treatments have been used, but their role is yet to be clearly defined.[74,75] Patients experiencing hemolytic anemia from cephalosporins should be advised to avoid all agents in the class. Cross-reactivity may occur, and the second episode is likely to be worse than the first.[65]

Metabolic

Removal of the offending drug is the primary treatment for drug-induced metabolic hemolytic anemia. No other therapy is usually necessary because most cases are mild in severity. Patients with known G6PD enzyme deficiencies should be advised to avoid medications capable of inducing the hemolysis.

DRUG-INDUCED MEGALOBLASTIC ANEMIA

In drug-induced megaloblastic anemia, the development of RBC precursors called megaloblasts in the bone marrow is abnormal. Deficiencies in either vitamin B_{12} or folate are responsible for the impaired proliferation and maturation of hematopoietic cells, resulting in cell arrest and subsequent

sequestration.

Diagnosis

Examination of peripheral blood shows an increase in the mean corpuscular hemoglobin concentration. Some patients can have a normal-appearing cell line, and the diagnosis must be made by measurement of vitamin B_{12} and folate concentrations. These megaloblastic changes are caused by the direct or indirect effects of the drug on DNA synthesis. The abnormality can be seen in any portion of the replication process, including DNA assembly, base precursor metabolism, or RNA synthesis.[76]

Causative Agents

Because of their pharmacologic action on DNA replication, the antimetabolite class of chemotherapeutic agents is most frequently associated with drug-induced megaloblastic anemia. Methotrexate, an irreversible inhibitor of dihydrofolate reductase, causes megaloblastic anemia in 3% to 9% of patients.[77] Other drugs, such as cotrimoxazole, phenytoin, and the barbiturates, have also been implicated in megaloblastic anemia. Cotrimoxazole, for example, has been reported to cause drug-induced megaloblastic anemia with both low and high doses,[78,79] particularly in patients with a partial vitamin B_{12} or folate deficiency.[80] Because the drug's affinity for human dihydrofolate reductase is low, patients with adequate stores of these vitamins are at low risk of developing drug-induced megaloblastic anemia. It has been postulated that phenytoin, primidone, and phenobarbital cause drug-induced megaloblastic anemia by either inhibiting folate absorption or by increasing folate catabolism. In both instances, the patient develops a relative deficiency of folate. A list of drugs that have been suggested as causative factors in drug-induced megaloblastic anemia is found in **Table e103-7**.

Vinblastine

Treatment

When drug-induced megaloblastic anemia occurs following chemotherapy, the anemia is considered an accepted side effect of therapy. If drug-induced megaloblastic anemia results from cotrimoxazole, a trial course of folinic acid, 5 to 10 mg up to four times a day, can correct the anemia.[78,79] Folic acid supplementation of 1 mg daily often corrects the drug-induced megaloblastic anemia produced by either phenytoin or phenobarbital, but some clinicians suggest that folic acid supplementation can decrease the effectiveness of these medications.[81]

DRUG-INDUCED THROMBOCYTOPENIA

Thrombocytopenia is usually defined as a platelet count below 100,000 cells/mm^3 (100×10^9/L) or greater than 50% reduction from baseline values.

Epidemiology

The annual incidence of drug-induced thrombocytopenia is about 10 cases per 1,000,000 population (excluding cases associated with heparin).[82,83] Although numerous epidemiologic studies have been reported, none of them have identified patient-specific risk factors that are associated with an increased risk for the development of drug-induced thrombocytopenia.[82]

HIT has garnered much attention. Certain patient populations have a higher risk for developing HIT

than others; patients who have had recent, major surgery are one of the highest risk groups.[84] The next highest risk groups include patients receiving heparin for thrombosis prophylaxis after peripheral vascular surgery, cardiac surgery, and orthopedic surgery.[85] A lower incidence is seen in medical, obstetric, and pediatric patients, especially those receiving low molecular weight heparin (LMWH) instead of unfractionated heparin (UFH).[84] The most recent practice guidelines by the American College of Chest Physicians recommend varying degrees of platelet monitoring based on the relative risk of developing HIT.[86]

Clinical Presentation

Drug-induced thrombocytopenia typically presents 1 to 2 weeks after a new drug is initiated, but may present immediately after a dose when an agent has been used intermittently in the past.[87] Rapid onset may also occur with the GPIIb/IIIa inhibitor class of drugs.[88] Development of thrombocytopenia may be associated with the systemic drug concentration, as is the case with linezolid.[89] This condition may be overlooked or misdiagnosed as idiopathic thrombocytopenia purpura (ITP); clinicians may distinguish between the two by the severity of thrombocytopenia (platelets <20,000 cells/mm^3[<20 $\times 10^9$/L]), timing in relation to medication administration, and the presence of bleeding which almost always accompanies drug-induced thrombocytopenia.[88,90]

Heparin-Induced Thrombocytopenia

HIT causes paradoxical increases in thrombotic rather than bleeding complications.[91] It is caused by the development of antibodies against platelet factor-4 (PF-4) and heparin complexes(**Fig. e103-1**).[91] LMWH binds less well to PF-4 than UFH, and therefore antibody formation is less common. However, antibodies developed by patients receiving UFH react against LMWH; thus, LMWH should not be used in patients with HIT.[84] After the antibodies bind to the complexes, platelet activation and aggregation occur, with subsequent release of more circulating PF-4 to interact with heparin. In addition, procoagulant microparticles are also released that increase the risk of thrombosis.[84]

FIGURE e103-1

Proposed explanation for the presence of both thrombocytopenia and thrombosis in heparin-sensitive patients who are treated with heparin. Injected heparin reacts with PF-4, which is normally present on the surface of endothelial cells (ECs) or released in small quantities from circulating platelets, to form PF-4–heparin complexes (1). Specific IgG antibodies react with these conjugates to form immune complexes (2) that bind to crystallizable fragment (Fc) receptors on circulating platelets. Fc-mediated platelet activation (3) releases PF-4 from *α*-granules in platelets (4). Newly released PF-4 binds to additional heparin, and the antibody forms more immune complexes, establishing a cycle of platelet activation. PF-4 released in excess of the amount that can be neutralized by available heparin binds to heparin-like molecules (glycosaminoglycans) on the surface of ECs to provide targets for antibody binding. This process leads to immune-mediated EC injury (5) and heightens the risk of thrombosis and disseminated intravascular coagulation. *(Used with*

Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic

At least two types of HIT have been identified. The most common, type I, occurs in about 10% to 20% of patients treated with heparin.[84] It is a mild, reversible, nonimmune-mediated reaction that usually occurs within the first 2 days of therapy. The platelet count slowly returns to baseline after an initial decline despite continued heparin therapy. HIT type I is usually an asymptomatic condition and is thought to be related to platelet aggregation.[2] It is not antibody mediated and is not considered clinically significant.[92]

Patients with HIT type II usually present with a low platelet count (eg, below 150,000 cells/mm^3 [150 × 10^9/L]) or a 50% or more decrease in platelet count from the highest platelet count value after initiation of heparin, and thrombosis may be present at diagnosis.[91] The platelet count generally begins to decline 5 to 10 days after the start of heparin therapy. However, this decline can occur within hours of receiving heparin if the patient has recently received heparin (ie, within 100 days).[91] Thrombocytopenia and thrombosis can develop with low-dose heparin, heparin-coated catheters, or even heparin flushes.[91]

The diagnosis of HIT is frequently a clinical one, supported by laboratory testing. Clinicians should use a scoring system, such as the 4T scoring system, to evaluate the probability of HIT.[91] Such a system should evaluate timing and magnitude of platelet drop, thrombosis, and other potential causes of thrombocytopenia.[91] If the scoring system indicates that HIT is likely, the clinician can order laboratory tests to assist in the diagnosis of HIT, including platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods, each with varying sensitivities and specificities.[7] Overall, these tests have a high negative predictive value.[91]

Protamine is an agent often used to neutralize heparin's anticoagulant action. Protamine-induced thrombocytopenia may be confused with HIT, since patients may have exposure to both agents. In protamine-induced thrombocytopenia, antibodies activate platelets similar to those in HIT, but it often occurs after cardiovascular surgery and is associated with earlier onset of thrombocytopenia and thrombosis, compared with the 5 to 10 day delay usually seen with HIT.[93]

Mechanism

5 Drug-induced thrombocytopenia can result from immune-mediated mechanisms or through a nonimmune-mediated mechanism. Nonimmune-mediated mechanisms, such as direct-toxicity-type reactions, are associated with medications that cause bone marrow suppression. This results in suppressed thrombopoiesis and a decreased number of megakaryocytes. This type of reaction is dose-dependent and often takes weeks to manifest.[88] Several mechanisms have been proposed for the development of immune-mediated drug-induced thrombocytopenia. These include hapten-type reactions, drug-dependent antibody mechanism, platelet-specific autoantibody, immune complex-induced thrombocytopenia, and drug-specific autoantibody type reaction. Although several mechanisms of drug-induced thrombocytopenia have been proposed, it is often not possible to determine the mechanism for an individual drug or patient, and more than one mechanism can be responsible for the condition.

Hapten-Type Reactions

In hapten-type reactions, the offending drug binds covalently to certain platelet glycoproteins (GP). Antibodies are generated that bind to these drug-bound GP epitopes. After the binding of antibodies to the platelet surface, lysis occurs through complement activation or through clearance from the circulation by macrophages.[94,95,96] Platelets are destroyed by the autoantibodies.[88] Hapten-mediated immune thrombocytopenia usually occurs at least 7 days after the initiation of the drug, although it can occur much sooner if the exposure is actually a re-exposure to a previously administered drug.

Drug-Dependent Antibody

This mechanism is slightly different from the hapten-type mechanism. In this type of reaction, platelet-reactive antibodies bind platelets when the drug is present. The antibodies may occur naturally, but there is an increased affinity if the drug is present. Reactions typically occur after 5 to 10 days of therapy.[88] It is thought that antibodies exist within the patient's circulation that recognize an epitope on the platelet GP, but this recognition is too weak to result in antibody binding to the platelet surface. However, the drug contains structural elements that are noncovalently complementary to regions of the antibody and the GPs on the platelet surface. This causes an improved fit between the antibody and the platelet surface, with the drug "trapped" in between, resulting in antibody binding of platelet.[94]

Eptifibatide and tirofiban are platelet GPIIb/IIIa receptor antagonists that prevent platelet activation and binding of fibrinogen, thereby inhibiting platelet thrombus formation. Competitive inhibition of fibrinogen bindings causes platelet clearance and activation, so concomitant thrombosis may occur.[88] In clinical trials and postmarketing studies, it was found that about 0.1% to 2% of patients treated with these medications experienced acute profound thrombocytopenia within several hours of their first exposure to the drug.[94,95,97,98] This acute drop in platelets without prior drug exposure suggested initially that this reaction was mediated by a nonimmune mechanism. However, a plausible immune-mediated mechanism has since been proposed. After binding to the GPIIb/IIIa receptor, these medications cause a conformational change in the receptor that allows it to be recognized by naturally occurring antibodies already in the patient's blood (ie, a ligand-induced binding site). In contrast to the two previously discussed immune-mediated mechanisms (hapten-type and drug dependent), the drug is not present within the binding between the antibody and the platelet surface. The drug has been removed from the platelet surface before the antibody binds, but the conformational change in the GPIIb/IIIa receptor remains.[95]

Abciximab, a GPIIb/IIIa receptor antagonist like tirofiban and eptifibatide, is also associated with thrombocytopenia. Abciximab-induced thrombocytopenia appears to occur through a different drug-specific antibody mechanism as opposed to a ligand-induced binding site mechanism with eptifibatide and tirofiban.[94,95,98] Abciximab is a chimeric monoclonal antibody. Therefore, it is not surprising that this molecule may exhibit some immunogenic properties. The murine component binds platelets' surface proteins and attracts antibodies that then destroy the platelet.[88] It has been demonstrated that patients who experience thrombocytopenia after the administration of abciximab

have circulating antibodies that directly recognize the drug.[94,95] Because the drug is bound to platelets, thrombocytopenia results. About 2% of patients experience thrombocytopenia with the first administration and 10% to 12% with subsequent administrations.[97,99] Furthermore, in patients who experience the reaction with the first administration, some experience immediate thrombocytopenia, but a few patients develop delayed thrombocytopenia about one week after drug administration. In patients who experience immediate thrombocytopenia, drug-specific antibodies are naturally occurring and present at the time of drug administration. For those with a delayed response (6-8 days later), drug-specific antibodies are produced during this time, and because abciximab remains bound to platelets for up to 2 weeks, the reaction can still occur.[100] Because all three GPIIb/IIIa receptor antagonists are co-administered with heparin, it is important to distinguish between GPIIb/IIIa receptor antagonist-induced thrombocytopenia and HIT. A heparin-induced platelet aggregation study can help to determine the offending agent. Pseudothrombocytopenia, defined as in vitro platelet aggregation in blood anticoagulated with ethylenediamine tetraacetic acid (EDTA), is clinically insignificant, but it must also be differentiated from thrombocytopenia induced by GPIIb/IIIa receptor antagonists.[101] This type of reaction may also occur with rituximab, and may be complicated by infusion reactions and disseminated intravascular coagulopathy (DIC).[88]

Platelet-Specific Autoantibody

In this type of reaction, a drug, such as gold or procainamide, induces the production of autoantibodies that bind to platelet membranes and cause destruction, but the causative drug does not have to be present for the reaction to occur. These agents bind platelets in the absence of the drug, so can persist after discontinuation of the agent; reports of thrombocytopenia up to 39 months after exposure have been published.[88] In contrast, the drug-dependent antibody reaction requires the presence of the drug to allow antibody binding.

Immune Complex

The final type of immune-mediated thrombocytopenia has been categorized as immune complex-induced thrombocytopenia.[94,95] This describes the mechanism of the most serious type of HIT, type II.HIT type II is less common but more severe than HIT type I and can be associated with more complications. In this type of reaction, heparin binds the platelet and forms an antigenic structure, which is then bound by antibodies. This complex activates the platelets.[91] HIT has been reported to occur in 1 of every 5,000 hospitalized patients and 1% to 3% of patients after cardiac surgery. The risk is higher following major surgery than minor surgical procedures or medical treatment, and is about 10 times higher for those receiving UFH as compared to LMWH.[91]

Causative Agents

In 1998, George et al. from the University of Oklahoma undertook the first attempt at a systematic review of the literature and case reports associated with drug-induced thrombocytopenia.[102] At that time, there were 98 drugs reported to be associated with thrombocytopenia. The Oklahoma group has continued to update this systematic review nearly every 2 years since 1998.[103] In 2009, 317 drugs

had been implicated in 1,301 reports.[87] It has also been reported with foods, such as walnuts, cranberries, milk, and sesame seed.[104] One study found that only about 40% of implicated agents had a positive laboratory test, and only 10% should be considered definite causes.[88] This condition is more common in adults than children, but may be unrecognized in children. Thirty-one medications have been noted as definite or probable causes of thrombocytopenia in children.[90]

The agents most commonly implicated in immune-mediated thrombocytopenia are quinine, quinidine, gold salts, sulfonamide antibiotics, rifampin, GPIIb/IIIa receptor antagonists, vancomycin, and heparin.[88,95] A list of medications (excluding cancer chemotherapeutic agents) associated with drug-induced thrombocytopenia is provided in **Table e103-8**.

TABLE e103-8 Drugs Associated with Thrombocytopenia

Observational study evidence	Low-molecular-weight heparins	Cotrimoxazole
Carbamazepine	Measles, mumps, and rubella vaccine	Dabigatran
Phenobarbital	Meclofenamate	Dalteparin
Phenytoin	Mesalamine	Dantrolene
Valproic acid	Methyldopa	Deferasirox
Case report evidence (*probable*	Minoxidil	Didanosine
or	Morphine	Drotecogin alfa
***definite* causality rating)**	Nalidixic acid	Efalizumab
Abciximab	Naphazoline	Eltrombopag
Acetaminophen	Naproxen	Enoxaparin
Acyclovir	Nitroglycerin	Epirubicin
Albendazole	Octreotide	Epoprostenol
Aminoglutethimide	Oxacillin	Eptifibatide
Aminosalicylic acid	p-Aminosalicylic acid	Ethionamid
Amiodarone	Penicillamine	Filgrastim
Amphotericin B	Pentamidine	Fondaparinux
Ampicillin	Pentoxifylline	Glimepiride
Aspirin	Piperacillin	Heparin

Atorvastatin

Captopril

Chlorothiazide

Chlorpromazine

Chlorpropamide

Cimetidine

Ciprofloxacin

Clarithromycin

Clopidogrel

Danazol

Deferoxamine

Diazepam

Diazoxide

Diclofenac

Diethylstilbestrol

Digoxin

Ethambutol

Felbamate

Fluconazole

Gold salts

Haloperidol

Heparin

Hydrochlorothiazide

Ibuprofen

Inamrinone

Primidone

Procainamide

Pyrazinamide

Quinidine

Quinine

Ranitidine

Recombinant hepatitis B vaccine

Rifampin

Simvastatin

Sirolimus

Sulfasalazine

Sulfonamides

Sulindac

Tamoxifen

Tolmetin

Trimethoprim

Vancomycin

Medwatch post-marketing reports 2009-2015

Acarbose

Adalimumab

Ado-trastuzumab

Alfuzosin

Aliskirin

Amlodipine

Hydrochlorothiazide

Indomethacin

Iloprost

Interferon beta 1a

Leflunomide

Linezolid

Losartan

Montelukast

Morphine

Obinutuzumab

Octreotide

Oxcarbazepine

Palivizumab

Pamidronate

Pemetrexed

Pioglitazone

Pomalidomide

Propylthiouracil

Quinine

Raltegravir

Rivaroxaban

Rosiglitazone

Rosuvastatin

Spironolactone

Sunitinib

Indinavir

Indomethacin

Interferon alfa-2b

Isoniazid

Isotretinoin

Itraconazole

Levamisole

Linezolid

Lithium

Benazapril

Bevacizumab

Bocepravir

Bortezomib

Chlorambucil

Cladribine

Telmisartan

Torsemide

Trepostinil

Ursodiol

Treatment

6 The primary treatment of drug-induced thrombocytopenia is immediate removal of the offending drug and symptomatic treatment of the patient. The use of corticosteroid therapy in the treatment of drug-induced thrombocytopenia is controversial, although some experts recommend it in severe cases.[105] Corticosteroids are sometimes helpful when clinicians are initially trying to distinguish between drug-induced thrombocytopenia and ITP. Clinicians may also consider the use of IVIG, although data is limited.[88] Platelet transfusions may be used if severe bleeding is present.[88]

Clinical Controversy...

Drug-induced thrombocytopenia, in most cases, resolves quickly after removal of the offending agent. In some cases, however, thrombocytopenia can persist for weeks or months, especially in the case of chemotherapy-induced thrombocytopenia or thrombocytopenia caused by immune mechanisms. In this setting, limited options are available to maintain platelets in a safe range while awaiting recovery. Historically, transfusions were used to maintain platelet counts until bone marrow recovery. The emergence of thrombopoietin analogs such as eltrombopag and romiplostim has raised the question of using drug therapy to treat drug-induced thrombocytopenia. Current indications for these agents are limited to ITP, but preliminary data suggest a potential benefit in patients with prolonged drug-induced thrombocytopenia. Currently, this treatment cannot be recommended routinely, but future studies can help to elucidate if there is a role for these agents in the management if drug-induced thrombocytopenia.

In the case of HIT, the main goal of management is to reduce the risk of thrombosis or thrombosis-associated complications in patients who have already developed a clot. All forms of heparin must be discontinued, including heparin flushes, and alternative anticoagulation must begin immediately.[91] Direct thrombin inhibitors are the alternative anticoagulants most commonly used in current practice. Four direct thrombin inhibitors are currently available in the United States: argatroban, bivalirudin,

desirudin and dabigatran, but only argatroban is approved by the Food and Drug Administration for this indication.[91] Argatroban is an IV thrombin inhibitor indicated for the management of HIT. It is preferred for use in renal insufficiency,[106] is metabolized in the liver and can be used in patients with end-stage renal disease. However, dosage adjustment is needed for patients with significant hepatic impairment. It also affects the international normalized ratio, so clinicians should follow labeled dosing protocols when transitioning patients to warfarin.[91,106] Fondaparinux, an anticoagulant pentasaccharide that inhibits factor Xa, has been proposed by some as a potential treatment for HIT because it does not appear to cause in vitro cross-reactivity with HIT antibodies.[107] Little data to support the use of fondaparinux in the treatment of HIT is available, although case series of successful outcomes with both fondaparinux and bivalirudin have been published.[91] The most recent guidelines by the American College of Chest Physicians suggest that fondaparinux is most appropriately used in patients with a history of HIT that presently have a clot with normal renal function. Fondaparinux may also be considered when the patient is not in the intensive care unit due to ease of subcutaneous administration.[91] These agents should also be considered for the treatment of patients who have acute HIT without thrombosis because of the increased risk of thrombosis occurring in these patients. Thrombosis can occur in up to 50% of patients with HIT[108] and is often the precipitating factor that leads the diagnosis. Because the high risk of thrombosis continues for days to weeks after heparin discontinuation and platelet recovery, continued anticoagulation with an alternative agent is essential during this time period.[91] Recovery begins within 1 to 2 days of discontinuation of the offending agent and is complete at one week. Antibodies to that agent may persist for years, so patients should be advised to avoid the drug indefinitely.[87]

Clinical Controversy…

Until recently, few options existed for treatment of heparin-induced thrombocytopenia. However, the approval of the anti-factor Xa agent, argatroban, has provided an effective agent that is frequently used in critically ill patients. Although it has the benefits of a short half-life and lack of renal adjustments, use is limited by its intravenous administration. In vitro data is available to support the use of other novel anticoagulants, such as dabigatran, rivaroxaban, and apixaban. These agents are administered orally, offering a potential advantage for certain patients. However, evidence that they may be used successfully in acute HIT is lacking, in part due to investigator concern about how well they are able to prevent thrombin generation at trough levels. These agents cannot be recommended for use at the present time, but further study is likely to determine their role in treating HIT.

CONCLUSION

Drug-induced hematologic disorders are a dangerous and often under-recognized cause of patient morbidity and health care expenditures. Symptoms and time of presentation of these disorders depend on the cell line affected. However, prompt recognition and removal of suspected offending medications is essential to successful management of all types of drug- induced hematologic disease. Clinicians should remain vigilant for cases of drug-induced aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia in their patients.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ADR	adverse drug reaction
ATG	antithymocyte globulin
CFU	colony-forming unit
DAT	direct antiglobulin test
DIC	disseminated intravascular coagulopathy
Fc	crystalizable fragment (of immunoglobulin)
G6PD	glucose-6-phosphate dehydrogenase
G-CSF	granulocyte colony-stimulating factor
GM-CSF	granulocyte-macrophage colony-stimulating factor
GP	glycoproteins
GPIIb/IIIa	glycoprotein IIb/IIIa
HIT	heparin-induced thrombocytopenia
HLA	human leukocyte antigen
HSCT	hematopoietic stem cell transplantation
IgG	immunoglobulin G
IgM	immunoglobulin M
ITP	idiopathic thrombocytopenic purpura
IVIG	intravenous immunoglobulin
LMWH	low-molecular-weight heparin
MAA	moderate aplastic anemia
NADPH	nicotinamide adenine dinucleotide phosphate hydrogen
NIPA	nonimmunologic protein adsorption
PF-4	platelet factor-4
RBC	red blood cell
SAA	severe aplastic anemia
UFH	unfractionated heparin
WBC	white blood cell
VSAA	very severe aplastic anemia

Chapter e104: Laboratory Tests to Direct Antimicrobial Pharmacotherapy

Michael J. Rybak; Jeffrey R. Aeschlimann; Kerry L. LaPlante

INTRODUCTION

KEY CONCEPTS

- 1 Understanding the difference between normal host flora and typical pathogens will help to determine whether a patient is truly infected or merely colonized.
- 2 Direct examination of tissue and body fluids by Gram stain provides rapid information about the causative pathogen.
- 3 Isolation of the offending organism by culture or rapid diagnostic testing assists in the diagnosis of infection and allows for more definitive directed treatment.
- 4 Development of molecular testing systems (or rapid diagnostic testing) has improved our ability to diagnose infection and determine the antimicrobial susceptibilities for numerous pathogens, including fastidious or slow growing mycobacteria and viruses.
- 5 Although highly standardized, in vitro antimicrobial susceptibility testing has limitations and often cannot truly mimic the conditions found at the site of an infection. This can cause discordance between in vitro susceptibility results and in vivo response to therapy.
- 6 Laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases.
- 7 When used appropriately, rapid automated susceptibility test systems appear to improve therapeutic outcomes of patients with infection, especially when they are linked with other clinical information systems.
- 8 Laboratory tests such as the minimum inhibitory and minimum bactericidal concentration tests, time-kill tests, postantibiotic effect tests, and antimicrobial combination testing are

important for the clinician to understand because they help to determine antimicrobial pharmacodynamic properties.

- Routine monitoring of serum concentrations is currently used for a select few antimicrobials (eg, aminoglycosides and vancomycin) in an attempt to minimize toxicity and maximize efficacy.
- Appropriate timing for the collection of serum samples when measuring antimicrobial serum concentrations is crucial to ensure that proper data are generated on the pharmacokinetics of antimicrobials.
- Monitoring of aminoglycoside serum concentrations and the use of extended-interval doses can help to maximize the probability of therapeutic success and minimize the probability of aminoglycoside-related toxicity for certain infections.
- Vancomycin and aminoglycoside serum concentration monitoring should be routinely done to ensure adequate serum concentrations, minimize toxicity, and avoid the potential for resistance.
- Antimicrobial pharmacodynamics have become a crucial consideration for the selection of both empirical and pathogen-directed therapy in the current era of antimicrobial resistance.
- Optimization of antimicrobial pharmacodynamic parameters such as the ratio of the peak serum concentration to minimum inhibitory concentration (MIC) or the time that the antibiotic serum concentration remains above the MIC and area above the curve over MIC can improve infection treatment outcomes.

Selection of an appropriate antimicrobial therapeutic regimen for a given infection requires knowledge of the infecting pathogen, host characteristics, and the drug's expected activity against the pathogen. The most fundamental aspect of therapy starts with an appropriate diagnosis. A vast array of laboratory tests including rapid diagnostic technology is available to assist in verifying the presence of infection and for monitoring the response to therapy. Although rigorous standardization of these tests is desirable, many of the tests may be difficult to interpret correctly and therefore, often they should be considered complementary to sound clinical judgment. Organism susceptibility to the administered antimicrobials is key to determining the outcome from therapy. Host characteristics, however, such as immune status, infection site location, and body organ function, play a significant role in selecting the most appropriate antimicrobial for a given individual.[1] This chapter reviews the routine laboratory tests that are used to assist in the diagnosis and treatment of infection.

In order to optimize antimicrobial treatment outcomes for patients with infectious diseases, the clinician should always attempt to determine the infecting pathogen(s), consider host characteristics, and select an antimicrobial drug with the best expected activity against the pathogen(s). A vast array of laboratory tests are available to assist the clinician with this crucial but difficult clinical activity. Although rigorous standardization of these tests is desirable, many of the tests may be difficult to interpret correctly and therefore, often they should be considered complementary to sound clinical

judgment. This chapter reviews the wide array of laboratory tests that are routinely used by the clinician for the diagnosis and treatment of infection.

LABORATORY TESTS CONFIRMING THE PRESENCE OF INFECTION

Nonspecific Tests

Many tests can be conducted to determine whether a patient has an infection. Often, no single test can prove that a patient is infected, but when used in combination with other tests and clinical findings, the clinician can reliably make a definitive diagnosis of infection. Because many tests are nonspecific, there are factors other than infection that can cause a test to be reported as positive when no infection exists. Therefore, the importance of careful interpretation and sound clinical judgment cannot be overemphasized.

White Blood Cell Count and Differential

Understanding the role of the white blood cell (WBC) in fighting infection is important in the diagnosis of infection, the selection of drug therapy, and the monitoring of patient progress. The major role of the WBC is to defend the body against invading organisms such as bacteria, viruses, and fungi. The typical normal range of the WBC is 4,500 to 11,000 cells/mm^3 (4.5×10^9-11×10^9/L).[2] This range will vary between laboratories and patients, as it is dependent on patient age, gender, comorbidity status (WBC, especially neutrophils, increase naturally during pregnancy). WBCs usually are elevated in response to infection, but many other noninfectious conditions can increase the WBC, including stress, inflammatory conditions such as rheumatoid arthritis, and leukemia or in response to certain drugs (eg, corticosteroids).

WBCs are divided into two groups: the granulocytes, which have prominent cytoplasmic granules, and the agranulocytes, which lack granules. Polymorphonuclear (PMN) granulocytes are made up of neutrophils, basophils, and eosinophils. The two other classes of WBCs are the monocytes and lymphocytes. Neutrophils are the most common type of WBCs in the blood, comprising approximately 70% of the total WBC count. In response to infection, they leave the bloodstream and enter the tissue to interact with and phagocytize offending pathogens. Mature neutrophils sometimes are referred to as *segs* because of their segmented nucleus, which usually consists of two to five lobes. Immature neutrophils lack this segmented feature and are referred to as bands. During an acute infection, immature neutrophils, such as bands (single-lobed nucleus), are released from the bone marrow into the bloodstream at an increased rate, and the percentage of bands (usually 5%) can increase in relationship to mature cells. The change in the ratio of mature to immature cells is often referred to as a “shift to the left” because of the way the cells were counted by hand with a microscope and charted from immature to mature cells (left to right).

Leukocytosis, an increase in WBCs, is a normal host response to infection. Unfortunately, bacterial infection is a common complication of neutropenia from cancer chemotherapy. Neutropenia occurs when the bone marrow does not produce enough WBCs to fight infection. Patients who are

neutropenic are incapable of increasing their WBCs in response to infection. In fact, susceptibility to infection in these patients is highly dependent on their WBC status. Patients with absolute neutrophil counts of less than 500 cells/mm^3 (0.5×10^9/L) are at high risk for the development of bacterial or fungal infections. The absence of leukocytosis also frequently can occur in the elderly and in severe cases of sepsis.[2,3]

Lymphocytes comprise 15% to 40% of all WBCs and are of central importance to the immune system. Two functional types of lymphocytes are the T cell, which is involved in cell-mediated immunity, and the B cell, which produces antibodies involved in humoral immunity. Lymphocytosis is frequently associated with acute viral infections such as Epstein–Barr virus infection (mononucleosis) and cytomegalovirus (CMV) infection and rarely with unusual bacterial infections (ie, *Brucella* species infections).

T lymphocytes are characterized on the basis of function (ie, T-helper cells, Th1 and Th2) and on the basis of surface protein. Most type 1 and type 2 T cells carry a T4 (CD4) marker that recognizes class II major histocompatibility complex (MHC) antigens, and most cytoxic T cells carry a T8 (CD8) marker that recognizes class I MHC antigens. A severe deficiency of CD4 cells is associated with human immunodeficiency virus (HIV) infection and opportunistic infections.[4] Malignancies also can adversely affect cellular immunity. Patients with Hodgkin's disease and other types of lymphoma exhibit defective cell-mediated immunity that predisposes them to a variety of infections, notably fungal diseases and infections by the Listeria species. Drug treatment with cytotoxic chemotherapy and corticosteroids also can have profound deleterious effects on cell-mediated immunity.[5] Defects in cell-mediated immune function can be demonstrated by a variety of simple laboratory tests, including quantification of lymphocytes on a routine complete blood cell count and skin testing for anergy. A more detailed investigation includes quantitative measurements of $CD4^+$ and $CD8^+$ cells. Monocytosis is correlated less frequently with acute bacterial infection, although its presence has been associated with the response of certain infections (eg, tuberculosis) to chemotherapy.[6] Eosinophilia can result from parasitic infection. **Figure e104-1** describes a number of cell types and their biologic function.

FIGURE e104-1

Various cell types and their biologic functions.

Cell type	Cellular function	
Macrophage/monocyte	Antigen presenting cell Surveillance of foreign antigens	
Neurophils	Defense against bacteria and fungus	
Eosinophils	Defense against parasites Response against allergic reactions	
Basophil	Allergic response	
B lymphocyte	Antibody production Antigen presenting cell	
T lymphocytes	Cellular immunity against virus and tumors Regulation of the immune system	

Other Tests

Some nonspecific laboratory tests are useful to support the diagnosis of infection. The inflammatory process initiated by an infection sets up a complex host response that includes. Activation of the nuclear factor-κB (NF-κB) transcription factors plays an important role in the regulation of the immune system. NF-κB is activated by bacterial and viral antigens, which eventually leads to the production of proinflammatory cytokines and chemokines. The rapid detection of activated NF-κB can be measured by transcription factor enzyme-linked immunoassay (TF-ELISA) during a systemic inflammatory response syndrome (SIRS) and is considered to be crucial for the treatment of patients with septicemia. Acute-phase reactants, such as the erythrocyte sedimentation rate (ESR) and the C-reactive protein (CRP) concentration, are elevated in the presence of an inflammatory process but do not confirm the presence of infection because they are often elevated in noninfectious conditions, such as collagen-vascular diseases and arthritis. However, large elevations in ESR are associated with infections such as endocarditis, osteomyelitis, and intraabdominal infections.[7,8]

Procalcitonin (PCT) is another acute-phase reactant that is released in response to various cytokines. PCT appears to be a more specific marker for bacterial infections than either CRP or ESR. Controlled clinical trials have shown that it can be a valuable tool for the clinician to help assess mortality risks of patients with infections and also can help to determine when to initiate antibacterial therapy in respiratory tract infections.[9]

Changes in endothelial membranes and the presence of a foreign pathogen and its endotoxins cause inflammatory cytokines, such as interleukin (IL) IL-1, IL-6, and IL-8 and tumor necrosis factor-α (TNF-α), to be produced by macrophages or lymphocytes. Fluctuations in cytokine levels occur during the course of an infection, which can be useful in staging and monitoring the response to therapy. Although abnormally high levels of TNF have been associated with a variety of noninfectious causes, spiked elevations in TNF are found in patients with serious infections, such as sepsis. Studies of the relationship of circulating mediators to patient outcome have determined the value of

endotoxin and cytokine measurements in patients with sepsis. Although the combination of elevations in endotoxin and individual cytokines has correlated well with the mortality rate, measurement of IL-6 was by far the best individual cytokine that predicted patient outcome.[7] Understanding the balance between these pro-inflammatory and anti-inflammatory processes likely will lead to interventions that can have a direct impact on the outcome of patients with sepsis.[10]

LABORATORY IDENTIFICATION OF PATHOGENS

Colonization versus Infection

Pathogens are organisms that are capable of damaging host tissues and that elicit specific host responses and symptoms that are consistent with an infectious process. These organisms are transferred from patient to patient, vector to patient (animals, insects, and so on), environment to patient (eg, hospital settings) or are derived from the patient's own flora. Conversely, the human body contains a vast variety of microorganisms that colonize body systems and make up the so-called normal flora. These organisms occur naturally in the tissues of the host and provide some benefits, including defense by occupying space, competing for essential nutrients, stimulating cross-protective antibodies, and suppressing the growth of potentially pathogenic bacteria and fungi (**Table e104-1**).

TABLE e104-1 Examples of Normal Bacterial Flora

	Gram-Positive		Gram-Negative		
	Cocci	***Rods***	***Cocci***	***Rods***	***Other***
Skin	*Staphylococcus* spp. (eg, *S. epidermidis*), *Streptococcus* spp.	*Corynebacterium* spp., *Propionibacterium* spp.		Enteric bacilli (some sites), *Acinetobacter* spp. (Coccobacilli)	
Oropharynx	Streptococci —viridans group Micrococcus	*Corynebacterium* spp.	Neisseria	*Haemophilus* spp.	Spirochetes
GI tract	*Enterococcus* spp., *Peptostreptococcus* spp.	*Lactobacillus, Clostridium*		*Bacteroides* spp., Enteric bacilli (*E. coli, Klebsiella* spp.)	
Genital tract	*Streptococcus* spp., *Staphylococcus* spp.	*Lactobacillus, Corynebacterium* spp.		Enterobacteriacea, *Prevotella* spp., *Candidia* spp.	*Mycoplasma*

Organisms that comprise the normal flora can become pathogenic when host defenses become impaired or if they are translocated to other body sites during trauma. The identification of an organism that is considered to be normal flora in a wound or otherwise sterile body cavity or fluid often becomes a dilemma for the clinician in deciding whether or not a patient is infected and whether or not the patient requires treatment. Such is the case with *Staphylococcus epidermidis* when

it is identified in the blood of a hospitalized patient. *S. epidermidis* is considered normal skin flora and commonly colonizes IV catheters. In these conditions, identification of the organism must be taken in light of the patient circumstances (signs and symptoms, laboratory indices supporting infection) and the probability of the organism being responsible for the infection. Often the simple removal of the catheter can eliminate the organism from the bloodstream, thereby preventing misdiagnosis and unnecessary application of antimicrobials.[11]

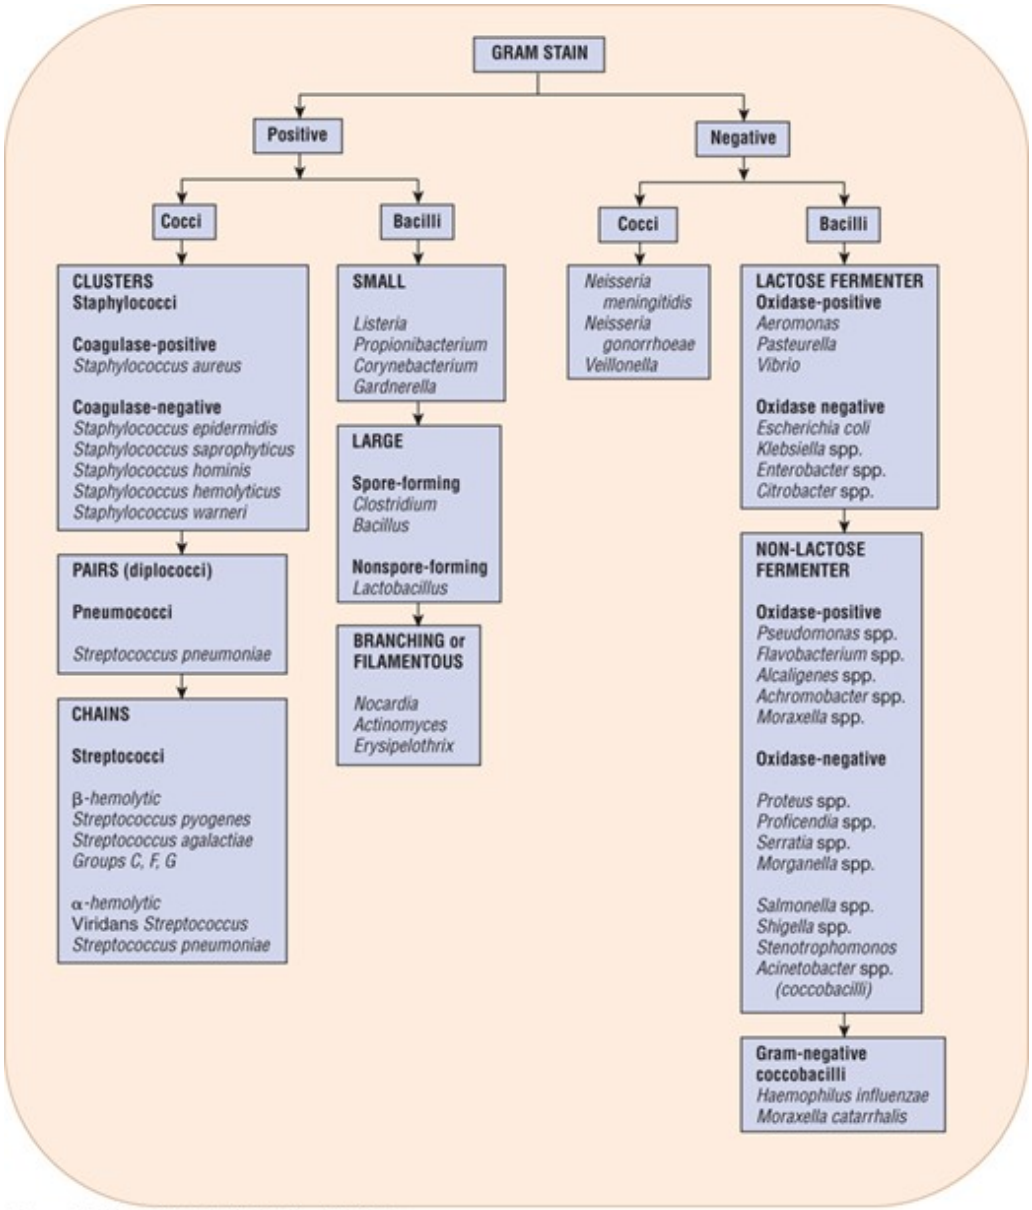
Direct Examination

2 Direct examination of tissue samples or body fluids believed to be infected can provide simple, rapid information to the clinician. Microscopic examination of wet-mount specimen preparations can provide valuable information regarding potential pathogens. Applications of this procedure with or without staining preparations include direct examination of sputum, bronchial aspirates, scrapings of mucosal lesions, and urinary sediment. The Gram stain is one of the first identification tests run on a specimen brought to the laboratory. For this procedure, crystal violet is applied as the primary stain, with iodine added to enhance the staining process and to form a crystal violet–iodine complex. Alcohol decolorization is the next step in the procedure. Gram-negative cells are decolorized by the addition of alcohol, and they take in a red color when counterstained by safranin. Gram-positive cells are not decolorized by alcohol and retain the crystal violet color and appear purple. Gram staining in conjunction with microscopic examination can provide a presumptive diagnosis and some indication of the organism's morphologic characteristics (Gram-positive, Gram-negative, Gram-variable, bacillus, or cocci). This is extremely useful information for the selection of empirical antibiotic therapy.

Gram stains are performed routinely on cerebrospinal fluid (CSF) in cases of suspected meningitis, on urethral smears for venereal diseases, and on abscess or effusion specimens. They are helpful in identifying organisms that may not grow on culture and which otherwise would be missed. Although Gram stains of sputum are performed routinely when respiratory tract infections are suspected, there is controversy regarding the usefulness of this test because the sputum is often contaminated with mixed or normal flora. The predominance of one particular organism, the overall number of organisms present, the amount of PMN granulocyte present, and the presence or absence of a significant amount of squamous epithelial cells (<10 per low-power field) can improve the significance of the sputum Gram stain specimen. **Figure e104-2** lists some common infecting pathogens grouped according to Gram stain and other characteristics.

FIGURE e104-2

Important bacterial pathogens classified according to Gram stain and morphologic characteristic.



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Other staining techniques are used to identify pathogens such as those that are best identified microscopically because of their poor growth characteristics in the laboratory setting. The best examples of these are the Ziehl–Neelsen stain for acid-fast bacilli, which is used for the identification of mycobacteria species, and the India ink, potassium hydroxide (KOH), and Giemsa stains, which are useful for detecting certain fungi.[12]

Cultures

3 Isolation of the etiologic agent by culture is the most definitive method available for the diagnosis and eventual treatment of infection. Although suspicion of a specific pathogen or group of pathogens is helpful to the laboratory for the selection of a specific cultivating medium, the more common procedure for the laboratory is to screen for the presence of any potential pathogen. After receipt of a clinical specimen, the laboratory will inoculate the specimen in a variety of artificial

media. Some culture media are designed to differentiate various organisms on the basis of biochemical characteristics or to select specific organisms on the basis of resistance to certain antimicrobials. Other media are employed commonly for the isolation of more fastidious organisms, such as *Listeria, Legionella, Mycobacterium,* or *Chlamydia*. Cultures for viruses are more difficult to perform and are undertaken primarily by larger institutions or outside laboratories because of the technical expense and time involved in processing samples.

When a culture is obtained, careful attention must be paid to ensuring that specimens are collected and transported appropriately to the laboratory. Every effort should be made to avoid contamination with normal flora and to ensure that the specimen is placed in the appropriate transport medium. Culture specimens should be transported to the laboratory as soon as possible because organisms can perish from prolonged exposure to air or drying. This is especially important for swab specimen preparations. Transport media may not be ideal for all organisms. Specimens that contain fastidious organisms or anaerobes require special transport media and should be forwarded immediately to the laboratory for processing. Finally, the source of the specimen should be clearly recorded and forwarded along with the culture to the laboratory. This process will aid the laboratory in differentiating true pathogens from the expected normal flora, and it will help in the selection of the appropriate culture media. Detection of microorganisms in the bloodstream by standard culturing techniques is difficult because of the inherently low yield of organisms diluted by blood, humoral factors with bactericidal activity, and the potential of antimicrobial pretreatment affecting organism growth. Most blood collection bottles dilute the blood specimen 1:10 with growth medium to neutralize the bactericidal properties of blood and antimicrobials. The addition of a polyanionic anticoagulant abolishes the effect of complement and antiphagocytic activity in the specimen. Some laboratories also add β-lactamase to their blood collection bottles to inactivate antibiotics such as penicillins or cephalosporins.

The initial identity of the organism can be determined by a variety of testing procedures. General schemes differentiate organisms into primary groups, such as Gram-positive and Gram-negative bacteria. This can be accomplished by simple Gram staining, as described previously, by evaluating organism growth patterns on selective media, and by testing for the presence or absence of specific enzymes and chemical characteristics, such as hemolytic and fermentation properties. For example, non-lactose-fermenting Gram-negative bacilli that are oxidase-positive can suggest *Pseudomonas aeruginosa* as opposed to a variety of other potential Gram-negative organisms. This preliminary information, which is readily obtainable from the laboratory, can greatly assist the clinician in choosing the appropriate empirical therapy. Definitive identification of organisms requires more complex testing procedures and devices that can further differentiate the organism on the basis of specific fermentation and biochemical reactive properties.

A method that provides a positive microbiological sample in a few hours, as opposed to days (culture method), is the use of automated culturing systems. One commonly used system is the BACTEC (Becton Dickinson Diagnostic Instruments, Sparks, MD) system, which uses bottles of growth medium containing a fluorescent sensor that monitors culture bottles every 10 minutes for the presence of carbon dioxide (CO_2) as a by-product of microorganism growth. Computers monitoring the system alert laboratory personnel of positive culture results by both audible and visual alarms. Once detected, a battery of testing can be performed rapidly that shortens the reporting time and that

enables clinicians to obtain preliminary information about the organism. Commercially available automated systems can inoculate the test organism into a series of panels containing a variety of test media, sugars, and other reagents. The system can then photometrically determine the results and compare the findings to a library of organism characteristics to produce a definitive identification.[12]

Viral agents can be detected by direct observation of inoculated culture cells for cytopathic effects or by detection of antigens after incubation by immunofluorescent methods. The culture method is most useful for organisms such as CMV or herpes simplex virus because these viral agents are rapidly propagated in culture cells, making them easily detected.[13]

Rapid Diagnostic Technologies

There has been a recent explosion of FDA-approved rapid diagnostic testing methodologies for infectious diseases. In the current era of managed care and antimicrobial stewardship programs the need for rapid diagnostic tests (RDTs) is critical. In addition, RDT is further highlighted by the emergence of multidrug resistant bacteria, and increased pathogenic virulence (ie, toxin production). A major focus of RDT is on pathogens associated with increased morbidity and mortality, which include influenza virus, methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* spp. (VRE), *Clostridium difficile*, extended-spectrum β-lactamase (ESBL)-producing *Klebsiella* spp., and *Mycobacterium tuberculosis*.

The benefit of rapid diagnostic technology is to quickly identify and/or rule out infectious pathogens, streamline antimicrobial therapy, and improve infection control measures such as isolation. Utilization of rapid diagnostic testing significantly reduces the time required to identifying the infecting pathogen, thus improving clinician's ability to more rapidly diagnose and treat infections. Pathogen RDT also prompts de-escalation of antibiotic therapy and if the test is negative, discontinuation of therapy, which decreases the potential for antimicrobial resistance.

The process of RDT often requires the evaluation of a clinical specimen such as blood (ie, serum or plasma), stool, or bodily fluids (ie, as saliva, urine). These specimens are processed in a qualitative or quantitative manner, to provide a result that is available within 15 minutes to a few hours (depending on the technology). This is in contrast to traditional culture methodologies discussed above which may take 4 to 6 days (ie, for *Staphylococcus* in the blood) or up to 6 weeks (ie, mycobacterium).

The most current RDT involves genomic testing methodologies, which include immunologic, molecular technologies, and mass spectrometry.

DIAGNOSIS OF INFECTION USING IMMUNOLOGIC ASSAYS

4 The use of immunologic methods for the diagnosis and monitoring of human host immune response (ie, antibody and antigen detection) to infection has become an indispensable laboratory tool. The primary immunologic methods involve the detection and quantification of antibodies directed against a specific pathogen or its components. These methods have the advantage of a rapid turnaround time and an acceptable level of sensitivity and specificity. Some rapid antigen

detection tests (eg, identification of group A streptococci and the Rapid Influenza diagnostic tests) are simple to use, can be performed conveniently in the physician's office, and often can be used to decide whether antimicrobials should be administered for a suspected infection. Limitations with these tests exist as antigens will still exist even if the pathogen is not longer alive, hence allowing for a false-positive test. In addition, the positive test result indicating the presence of the pathogen does not assist in determining if the patient was infected or simply colonized with the pathogen.

Antibody or antigen detection can be accomplished by a variety of techniques, including immunofluorescence, which has been used routinely for the detection of CMV, respiratory syncytial virus, varicella-zoster virus, *Treponema pallidum* (syphilis), *Borrelia burgdorferi* (Lyme disease), and *Chlamydia trachomatis*. Latex agglutination is useful for detecting meningococcal capsular antigens in CSF of patients suspected of having bacterial meningitis and as an aid in the diagnosis of *Legionella pneumophila*. Enzyme-linked immunosorbent assay (ELISA) is a commonly employed method for detecting HIV, herpes simplex virus, respiratory syncytial virus, pneumococcal serum antibody, *Neisseria gonorrhoeae*, and *Haemophilus pylori*.[13]

Molecular Techniques for the Detection of Microorganisms

Hybridization DNA Probes

4 The traditional and more labor intensive means for gene detection involves the use of separation of the organism DNA into specific fragments (gel electrophoresis), transfer and fixation of the mixture to specialized paper or nylon membranes (Southern or Northern blotting), the mixing of the DNA fragments with the labeled probe (hybridization), and transfer to radiographic or photographic film for processing. These techniques have been used for many years and are fairly standardized methods for the detection of a variety of organisms. However, with increased technology, highly sensitive and specific molecular methods are commonly being used for a more rapid detection and identification of a variety of microorganisms.

The use of hybridization probes is particularly helpful for the detection of pathogenic bacteria, and for slow-growing organisms such as *M. tuberculosis*, *N. gonorrhoeae*, and certain species of fungi such as *Candida* species.

One of the most widely used FDA-approved hybridization probe technology is the peptide nucleic acid fluorescence in situ hybridization (PNA-FISH) assay. This technology uses fluorescent-labeled probes (peptide nucleic acid molecules) to target ribosomal RNA sequences.[14,15] These rRNA sequences are specific to different species of microorganisms.

Peptide nucleic acid molecules contain the same nucleotide bases found in DNA, but they are noncharged, which allows for more specific hybridization to target nucleic acids in ribosomal RNA of bacteria and yeast. With this technology, samples are taken from positive blood culture vials after a Gram stain is performed, and results can be obtained within 90 minutes as opposed to the 1 to 5 days it can take for traditional laboratory methods. When viewed under a fluorescence microscope, different colors make it easy to decipher results in regard to microorganism speciation.[3]

FDA-approved PNA-FISH assays are available for *S. aureus*, coagulase-negative staphylococci, *E. coli*, *P. aeruginosa*, *E. faecalis*, *E. faecium*, *C. albicans*, *C. glabrata*, *C. tropicalis*, and *C. parapsilosis*. Limitations of the PNA-FISH procedure include its sole application to positive blood cultures as well as the requirement of isolation on solid media in order to differentiate organisms.

Nucleic Acid Amplification Methods

Nucleic acid amplification methods are now considered a standard laboratory tool. They have had a tremendous impact on the diagnosis and treatment of infectious diseases. These highly sensitive methods have the capability to detect and quantitate minute amounts of target nucleic acid in a rapid manner. The polymerase chain reaction (PCR) is based on the capability of a DNA polymerase to copy and elongate a targeted strand of DNA. Each cycle doubles the amount of DNA originally present at the start of the cycle, thereby exponentially increasing the overall number of DNA copies. In theory, more than 1 million copies of the original DNA can be generated from as few as 20 cycles. Although this amplification technique is very sensitive and has tremendous application potential, it is not without problems. The powerful amplification procedure can yield false-positive results when samples are contaminated by nucleic acid left over from previously amplified DNA or by dead pathogens that exist in the sample.

Several modifications to the original PCR technology have been made over the years to improve the sensitivity and application potential for PCR, including the use of multiple sets of amplification primers, multiplex PCR, PCR amplification of RNA by converting targeted RNA with reverse transcriptase to complementary DNA templates, and real-time quantitative PCR. The cost–benefit ratio of PCR as compared with traditional microbiologic methods must be evaluated.

Molecular amplification schemes such as PCR have become routine in situations in which rapid turnaround time is essential to improve patient diagnosis and outcome, for example, real-time universal screening for acute HIV infection and routine testing and monitoring of patients receiving treatment for HIV infection, and the isolation and detection of fastidious or slow-growing organisms such as *M. tuberculosis*, *B. burgdorferi*, and *Helicobacter pylori*.[19,20]

Rapid polymerase chain reaction (rPCR) technology has been used with increasing excitement. rPCR is a multistep process that involves the amplification of specific DNA sequences for rapid and specific detection of microorganisms. Contrasted to conventional PCR, both steps of rPCR amplification and detection occur within the same closed system. As a result, rapid PCR methods are less labor-intensive, yield a faster turnaround time, and reduce the likelihood of contamination. Other benefits to this technology include the ability to detect slow-growing or nonfastidious organisms as well as not being limited to only a positive blood culture as the source of specimen.

Probe-based methods require the extraction of DNA or RNA from a clinical specimen (ie, body fluid, tissue, or WBC) or directly from a microorganism culture. The extract is then tested for the presence of pathogen DNA or RNA using a probe that contains a specific oligonucleic acid-based sequence for the organism. For example, a probe with a sequence of ACTGTT would bind to the complementary organism nucleic acid sequence of TGACAA. Because the probe is labeled with a signal-emitting molecule (ie, radiolabeled, colorimetric, or chemoluminescent), a match would be detected.

Mass Spectrometry to Detect Microorganisms

Mass spectrometry is another useful diagnostic device to identify microorganisms and resistance patterns in a more rapid way.[18] The matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) device and library of organisms was a much anticipated system that received de novo approval as a diagnostic device from the United States Food and Drug Administration (FDA) in 2015. This very specific technology measures molecular masses of proteins and other bacteria components using a low bacterial load (approximately 1,000 colony forming unit per mL [10^6 CFU/L]). The sensitivity and specificity of this system is a welcomed addition to the clinical microbiology laboratory, infection control, and Antimicrobial Stewardship programs across the country.

EVALUATION OF ANTIMICROBIAL ACTIVITY AND DETERMINATION OF ANTIMICROBIAL PHARMACODYNAMICS

5 The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases. The integration of this activity 6 with various pharmacokinetic properties of the antimicrobial agent determines the drug's pharmacodynamic characteristics. Antimicrobial pharmacodynamics have become a crucial consideration for the clinician for selecting both empirical and pathogen-directed therapy, formulary decision making, developing antimicrobial streamlining programs, and for IV-to-oral antimicrobial switch protocols.

5 Most antimicrobial susceptibility testing methods that are used in the clinical laboratory are well characterized and have been standardized by the Clinical and Laboratory Standards Institute (CLSI). However, controversies exist about which test methods provide the most useful information, how to best report these results to clinicians, and how to apply them to the treatment of patients. CLSI provides guidelines regarding MIC testing including the acceptable range for MIC results to a given pathogen.[21] Nevertheless, there are many investigations that show that the general antimicrobial susceptibility or resistance profile of an infecting organism correlates with clinical and/or microbiologic responses to therapy.

Most of the standardized and well-accepted test methods evaluate the susceptibility of aerobic, nonfastidious bacteria. However, substantial progress has been made to develop sensitive, specific, reproducible, and clinically useful susceptibility tests for anaerobic bacteria, yeasts, mycobacteria, and viruses. Continued advances in technology should further improve test methods and the rapidity with which the results can be applied to the management of patients. Although these newer systems are often expensive, the increased quality and decreased overall costs of patient care can determine their cost-effectiveness.

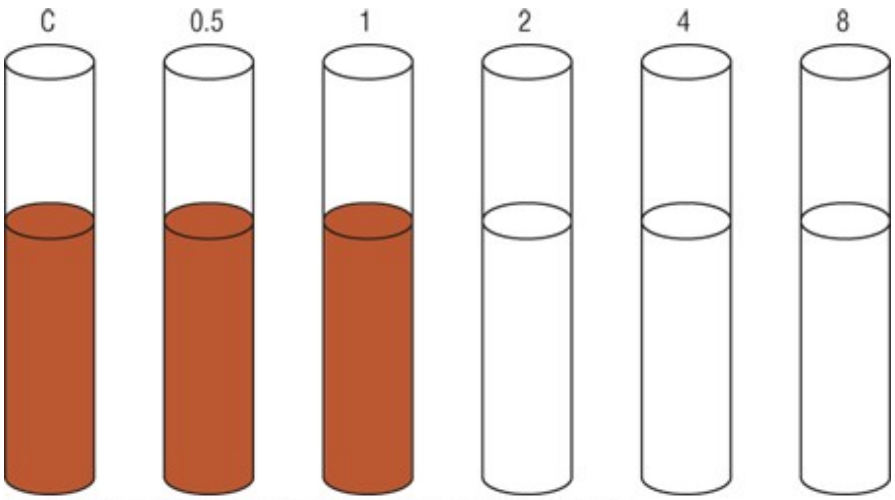
QUANTITATIVE ANTIMICROBIAL SUSCEPTIBILITY TESTING

Minimum Inhibitory Concentrations

5 The *minimum inhibitory concentration* (MIC) is defined as the lowest antimicrobial concentration that prevents visible growth of an organism after approximately 24 hours of incubation in a specified growth medium. The MIC quantitatively determines in vitro antibacterial activity. MICs were traditionally determined through the micro or macro dilution method, which uses liquid growth medium (broth), doubling serial dilutions of antimicrobials in test tubes, and a standard inoculum of bacteria (approximately $10^{5.5\text{-}6}$ colony-forming units [CFU]/mL [$10^{8.5\text{-}9}$ CFU/L]). The organism, broth and antibiotic are incubated at approximately 35°C to 37°C (95°F-98.6°F) for 18 to 24 hours and then examined for visible bacterial growth (**Fig. e104-3**).

FIGURE e104-3

Macrotube minimum inhibitory concentration (MIC) determination. The growth control (*C*), 0.5 mg/L, and 1 mg/L tubes are visibly turbid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/L).



The microdilution MIC test method is currently the most commonly used and automated susceptibility test method in the clinical microbiology laboratory. Automated systems allow efficient preparation of numerous tests but have some limitations (**Fig. e104-4**). These include both limitations in the numbers and various types of antimicrobials to use in the test (especially with premade or premanufactured trays) and a limited ability to detect some forms of antimicrobial resistance (eg, β-lactamases in Gram-negative bacteria).

FIGURE e104-4

Depiction of a 96-well microtiter plate with minimum inhibitory concentration (MIC) assays for antibiotics used commonly against Gram-negative pathogens. The shaded wells indicate visible bacterial growth. The MICs (milligrams per liter) for this organism would be 16 for piperacillin, 4 for aztreonam, 2 for ceftazidime and cefepime, 1 for meropenem, 0.5 for ciprofloxacin and gentamicin, and 0.25 for tobramycin. GC is the growth control (no antibiotic added).

Limitations and Problems with MIC Testing

5 Some of the limitations and problems of MIC testing are academic in nature, whereas others can have important implications for the management of patients with serious infections. For example, because the MIC only represents the concentration of antimicrobial that is needed to inhibit visual growth of the most resistant cells within the tested bacterial population, there can be a small percentage of bacteria present within the large numbers at the site of infection that are more antimicrobial-resistant than the MIC would indicate. Therefore, the bacterial density used to perform the susceptibility testing (eg, $10^{5.5}$ CFU/mL [$10^{8.5}$ CFU/L]) may over represent the antimicrobial's activity at the site of infection. Use of the antimicrobial then could select these more resistant subpopulations, resulting in poor clinical response. This phenomenon can be observed with intermediate vancomycin resistance in *S. aureus*, as well as in strains of Gram-negative bacteria such as the *Enterobacteriaceae* species that produce both plasmid-borne and chromosomal *β*-lactamases.[22]

Many other factors also can influence the in vitro MIC value obtained and its subsequent application to the in vivo situation. The bacterial growth medium used and cation content can affect the activity of many drugs significantly. MIC values of antibiotics that are highly bound to plasma proteins are significantly higher when the test medium contains human serum. As testing of these drugs in a serum-supplemented medium has not gained widespread acceptance, their in vivo activity can be overestimated by in vitro MIC test results. Fortunately, the standardized guidelines for testing and quality assurance procedures proposed by the CLSI attempt to minimize the impact of these problems and are followed by most clinical and research laboratories.[21] However, when a patient infected with an apparently susceptible organism fails therapy, it is important for the clinician to consider these potential confounding factors as possibly being related to the observed failure. In such situations, consideration of antimicrobial pharmacokinetics and pharmacodynamics also often

can help to better predict therapeutic response as compared with organism susceptibility alone.

Clinical Controversy…

Some clinicians believe that the susceptibility for all antimicrobials tested should be reported to allow for the most appropriate antimicrobial selection for the patient. However, others believe that only selective antimicrobial susceptibility should be reported to avoid overprescribing of more costly broad-spectrum antimicrobials.

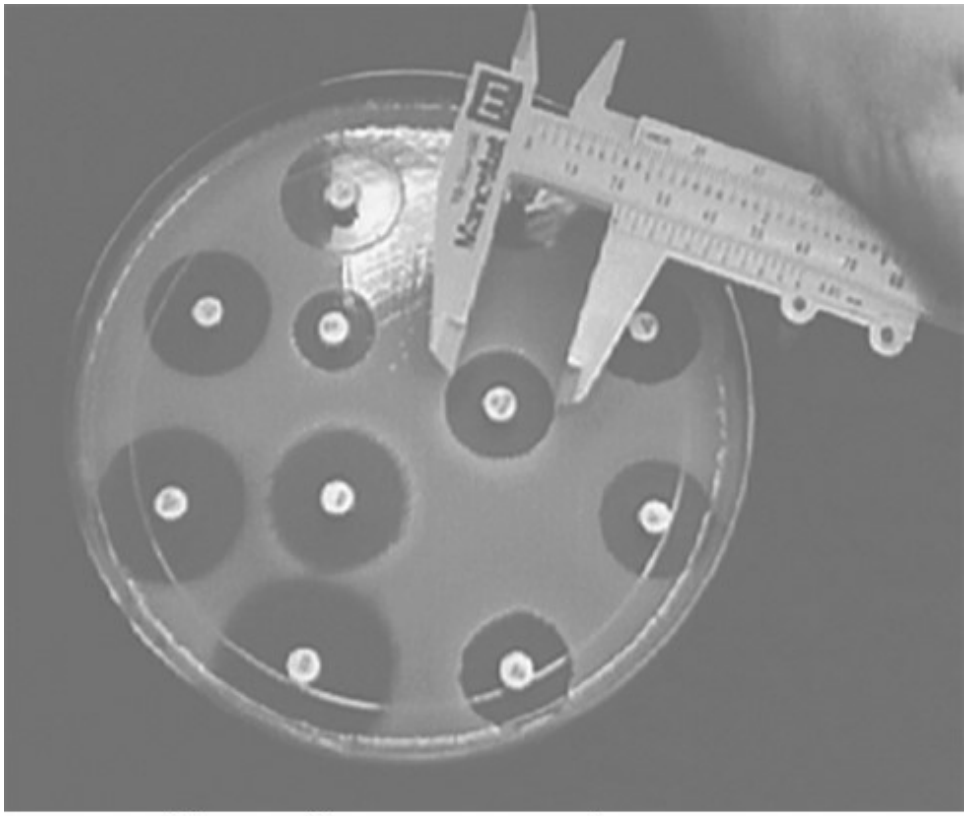
QUALITATIVE ANTIMICROBIAL SUSCEPTIBILITY TEST METHODS

Disk Diffusion Assay

The disk diffusion assay method for susceptibility testing (Kirby–Bauer method) was developed in the 1960s by Bauer and coworkers as a way to reduce the labor needed for tube dilution susceptibility testing.[23] It still is used in many clinical microbiology laboratories owing to its high degree of standardization, reliability, flexibility, low cost, and simplicity of test interpretation. Up to 12 user-selected antibiotic-impregnated paper disks are placed on an agar plate previously streaked with a standard suspension of bacteria (1-2 × 10^8 CFU/mL [1-2 × 10^{11} CFU/L]). The drug contained in the disk diffuses in a concentration gradient out into the agar. The plate is incubated (18-24 hours at 35°C), and visual bacterial growth occurs only in areas in which the drug concentrations are below those required for growth inhibition. The diameters of the zones of inhibition are measured via calipers or automated scanners and are compared with standard zone size ranges that determine susceptibility, intermediate susceptibility, or resistance to the antimicrobials that were tested (**Fig. e104-5**). Although factors such as agar composition, incubation temperature, bacterial inoculum, and antibiotic paper disk composition can influence results, the standards for testing conditions and interpretive zone sizes are well defined by the CLSI.

FIGURE e104-5

Disk diffusion susceptibility test. Antibiotic-impregnated disks are placed on the surface of a plate previously inoculated with the test organism. The plate is incubated for 18 hours, and the subsequent zones of inhibition are measured. The zone size correlates with the sensitivity of the organism. The larger the zone, the more sensitive is the organism to the specific antibiotic. On the basis of predetermined zone breakpoints, organisms can be classified as susceptible, resistant, or intermediately susceptible to the antibiotic. *(Photograph courtesy of the Anti-Infective Research Laboratory, Wayne State University, Detroit, MI.)*



Qualitative Versus Quantitative Susceptibility Testing of Microorganisms

Quantitative MIC data often are reported to the clinician qualitatively by deeming an organism "susceptible" reported as ("S"), "intermediate or indeterminate" reported as ("I"), or "resistant" reported as ("R") to a given antimicrobial agent. Many factors are considered to determine these qualitative susceptibility classifications (also referred to as "breakpoints" for the antibiotic). These include pharmacokinetic properties, the distribution of MICs for the organisms, and the clinical and bacteriologic responses observed for the antimicrobial against strains of bacteria with various MIC values. This simplification makes the susceptibility data easily interpretable by noninfectious disease clinicians. Pathogens classified as susceptible to an antibiotic are those that fall below a breakpoint MIC, which take in account clinically achievable serum concentrations in a patient (within appropriate safety profiles) and killing activity of the antimicrobial agent. Conversely, resistant organisms are bacteria with significantly higher MICs that, when treated with the antimicrobial, will result in a less-than-optimal clinical response, even at the highest doses. The indeterminate classification exists when the number of strains with MICs in the given range is too small to derive robust conclusions on susceptibility or resistance to the antimicrobial. Responses to therapy for organisms that are moderately susceptible/intermediately susceptible/indeterminate can be variable. These organisms may respond to treatment with maximal doses of the antimicrobial or can respond when the drug is known to be concentrated at the site of infection (eg, urinary tract infections treated by drugs excreted by the kidneys).

There are concerns that the "user friendly" susceptible/resistant classification system can oversimplify

the decision-making process for treating infections. For example, a critically ill patient may not respond to the antimicrobial therapy of a susceptible organism at the usual doses. If serum concentrations or concentrations at the site of infection could be assayed (not practically done), one might discover suboptimal concentrations as a result of inadequate tissue perfusion. Likewise, a patient with severe vascular insufficiency and a diabetic foot infection may fail a course of therapy with normal doses of an antimicrobial and a susceptible organism because of inadequate drug penetration. Additionally, different outcomes can be achieved for "susceptible" organisms with different MIC values[24] and substantial (although not clinically acceptable) clinical and/or microbiologic cure rates can occur for infections that are caused by resistant organisms.[25] These reports emphasize that in vitro susceptibility does not correlate unequivocally with clinical success and that resistant organisms do not always equate with impending clinical failure.

Similarities in the spectrum of activity for classes of antibiotics have led to the concept of *class testing*. Thus cephalothin susceptibility results are extrapolated to other first-generation cephalosporins, such as cephalexin or cefazolin. Likewise, susceptibility to an antibiotic that typically has minimal activity usually ensures that other more potent agents in its class will have activity as well. However, many Gram-negative organisms have now developed ESBLs that often have different activity against members of the same drug class. These developments significantly limit the utility of class testing to reduce susceptibility testing workload.

OTHER SUSCEPTIBILITY TESTS

Epsilometer Test

7 The Epsilometer test (Etest; AB bioMérieux, Nouvelle, France) combines the benefits of quantitative MIC test methods with the ease of agar diffusion testing. The Etest is a plastic strip impregnated with a known, prefixed concentration gradient of antibiotic that is placed on an agar plate streaked with a suspension of known bacterial inoculum. The drug instantly diffuses from the plastic strip to form an effective concentration gradient within the agar. After overnight incubation, elliptical zones of inhibition are formed; the point where the bottom of the ellipse crosses the plastic strip is correlated with an MIC value printed on the strip (**Fig. e104-6**). A similar product (M.I.C. Evaluator; Oxoid Limited, Hampshire, U.K.) is also available. Many investigators have analyzed the Etest's correlation with standard susceptibility methods and assessed its potential clinical use. In general, values obtained with Etest methods are comparable with or even more consistent and accurate than standard methods. In fact, the Etest method is the recommended method for susceptibility testing of *Streptococcus pneumoniae*. However, the widespread clinical use of the Etest has been limited primarily by the excessive costs of the test strips (nearly 10 times more costly than antibiotic-impregnated disks) in relation to the benefits that may be gained from their use.

AUTOMATED ANTIMICROBIAL SUSCEPTIBILITY TESTING

7 Various degrees of automation have been applied to susceptibility testing. Early advances included automated preparation of microtiter trays, instrument-assisted readers, and computer-assisted result databases. Rapid automated susceptibility tests became available in the 1980s, and their use has increased substantially in the three subsequent decades. These systems often incorporate microprocessors, robotics, and microcomputers to rapidly identify organisms and produce susceptibility test results in as few as 3 hours.

There are three rapid automated susceptibility test systems in common use in clinical microbiology laboratories. The Vitek system (bioMerieux, Durham, NC) uses small plastic reagent "cards" that contain 64 microwells for the testing of various antimicrobials or indicator chemicals. Bacterial test suspensions enter the wells by capillary diffusion, and growth is monitored automatically via photometric assessment of turbidity every hour for up to 15 hours. When the growth control reaches a specified turbidity level, growth curves for all wells are calculated and compared with the growth

control curve for slope normalization. Computerized linear regression and the use of best-fit line coefficients produce an algorithm-derived MIC. The clinical laboratory can control the result output that is generated (qualitative susceptibility, quantitative susceptibility, or both).

The Microscan WalkAway system (Beckman Coulter, Brea, CA) is a rapid test system that uses fluorogenic substrate hydrolysis as an indicator of bacterial growth. This system uses standard micro-dilution test trays and a computer-controlled incubator and reader unit that can perform robotic manipulations, such as reagent addition and tray rotation, to allow for spectrophotometric or fluorometric growth assessments. As with the Vitek system, growth curves are generated, and algorithms applied for the determination of MICs; output is via computer or video display.

The final system is the BD Phoenix Automated Microbiology System (BD Diagnostics, Sparks, MD). This system utilizes an oxidation–reduction detector and a turbidometric growth detection system to determine antibiotic resistance/susceptibility. Output of data is similar to the other two automated systems previously described.

7 The results obtained from all of these three systems generally are comparable. However, there have been documented differences in the ability of these systems to accurately detect emerging resistance mechanisms such as vancomycin resistance in Staphylococci and carbapenem resistance in Gram-negative pathogens.[26,27] Importantly, all of the systems contain information management software that allow for the storage and rapid retrieval of historical susceptibility data. They can produce chartable patient data reports, antibiograms (summaries of overall resistance for organisms causing infections in a given hospital), and epidemiologic reports. These systems also can be interfaced with other clinical information systems, such as the pharmacy, infection control, or other laboratory data systems, which can help to improve clinical outcomes.[28]

ADVANCES IN SUSCEPTIBILITY TESTING FOR MYCOBACTERIA, FUNGI, AND VIRUSES

Impressive advances have been made in the last decade in the areas of mycobacterial, fungal, and viral susceptibility testing. The use of radiometric techniques, such as the BACTEC TB460 system (Becton Dickinson Biosciences, Sparks, MD), has revolutionized the analysis of antimicrobial susceptibility for *M. tuberculosis* and other slow-growing mycobacteria.[29] Radiometric susceptibility testing involves the incubation of *M. tuberculosis* in liquid medium containing carbon-14 (^{14}C)-labeled growth substrate. As organisms grow, respiration causes the release of ^{14}C, which is then detected. The growth indices for antimicrobial-containing bottles are compared with those of a control bottle with the calculation of an MIC. Use of this method, when coupled with the rapid processing of samples, can reduce the time to susceptibility result generation to approximately 1 week. A newer mycobacterial susceptibility testing method (the BACTEC Mycobacteria Growth Indicator Tube [MGIT 960]; Becton Dickinson Diagnostic Instruments, Sparks, MD) that is fully automated and that employs detection of fluorescence related to growth also has been developed. It produces results in a similar time frame and with similar reliability as the radiometric method.[30] Primary advantages of this system are its automation, the elimination of radioactivity, and the

elimination of needle use. Although the slower agar proportion susceptibility method (generating results in approximately 1 month) is still considered the reference standard for mycobacterial susceptibility testing by the CLSI, the group now recommends the use of a rapid susceptibility testing method to ensure that the Centers for Disease Control and Prevention (CDC) guidelines for reporting susceptibility results for *M. tuberculosis* infections within 28 days of specimen receipt in the laboratory can be met. In the future, the use of molecular probes for mycobacterial resistance genes most likely will become a more important component of mycobacterial susceptibility determinations, especially in light of the increasing problems with antimicrobial resistance.[31,32]

DETECTION OF RESISTANCE FACTORS

There are a number of methods in use that directly detect the production of antimicrobial resistance in pathogens. *β*-Lactamase production can be detected rapidly and easily in the clinical laboratory with the use of nitrocefin disks. Nitrocefin is a chromogenic cephalosporin derivative that changes color on hydrolysis by *β*-lactamase. Colonies from a growing bacterial culture can be touched to a disk, with *β*-lactamase production noted within a few minutes. Although rapid and reliable, this method is limited to the assessment of strains of staphylococci, enterococci, *H. influenzae, Moraxella catarrhalis*, and *N. gonorrhoeae*. The nitrocefin disk cannot detect *β*-lactam resistance caused by altered penicillin-binding proteins or by some of the newer ESBLs.

PCR has now become a standard method to quantify the replication of the HIV and hepatitis viruses in infected patients (the *viral load*, described as copies per milliliter). Similar methods are used to determine the presence of genetic mutations in the HIV that are associated with increased resistance to one or more of the many antiretroviral medications available for clinical use. The use of these genotyping methods as an aid to select an optimized antiretroviral regimen has been correlated with an improved clinical response to therapy, as well as with a more potent reduction in the viral load.[34]

The detection of methicillin-resistance in *Staphylococcus* (MRSA) is crucial to ensure appropriate therapy. Methicillin resistance is the result of the *mecA* gene, which encodes for an altered penicillin-binding protein (penicillin-binding protein 2a) that has a low binding affinity for *β*-lactams. It is particularly difficult to detect this resistance, although, because of the heterogeneous expression of the phenotype—it is common for only 1 in $10^{4\text{-}6}$ tested bacterial cells to express methicillin resistance (even though all cells may have the genetic ability to do so). Screening via oxacillin disks or by oxacillin-containing agar (6 mcg/mL [mg/L]) was once considered the gold standard for resistance detection prior to the development of PCR and DNA probes that were specific for *mecA*. The *mecA* PCR test is available for clinical use, is 99% sensitive and specific, and allows for the rapid (within 6 hours) determination of the presence of methicillin resistance. Although the *mecA* PCR test has been available for many years, many laboratories do not use it commonly because of its high cost relative to other screening methods with acceptable sensitivity/specificity. For example, the presence of MRSA in a nasal swab or a blood culture sample can now be determined directly and rapidly within 24 hours using chromogenic technology (CHROMagar MRSA). This technology uses chromogenic substrates and a cephalosporin; MRSA strains will grow in the presence of cephalosporins such as cefoxitin and will produce mauve-colored colonies resulting from hydrolysis of the chromogenic substrates. The sensitivity and specificity for this test is as high as 97% and 99%, respectively.[35,36]

The detection of decreased vancomycin susceptibility in Gram-positive organisms has become more important with the increased prevalence of both VRE and vancomycin-intermediate-resistant and vancomycin-resistant *S. aureus* (VISA and VRSA). It is important to note that most of the MIC testing methods currently used in the clinical microbiology laboratory do appear to reliably detect these VISA and VRSA strains.[26] The vancomycin agar screening method (Brain-Heart Infusion agar containing 6 mg/L of vancomycin) is an inexpensive and reliable way to detect vancomycin resistance in Enterococci. With this test, the growth of any colonies from a sample of the test organism (10^5-10^6 CFU) after 24 hours of incubation would indicate the presence of VRE. Although this screening method appears to work well for VRE, it appears to be less reliable for detecting VISA or VRSA strains when compared to the CLSI broth microdilution reference method.[26] However, simply reducing the vancomycin concentration in the agar from 6 mg/L to 3-4 mg/L results in improved sensitivity and specificity (both greater than 90%) for detecting these VISA strains.[37]

SPECIAL IN VITRO TESTS OF ANTIMICROBIAL ACTIVITY

Minimum Bactericidal Concentration

7 In certain infections (eg, Gram-positive bacterial meningitis and endocarditis), the bactericidal (killing) activity may be more predictive of a favorable infection outcome than the MIC.[38] The minimum bactericidal concentration (MBC) can be performed in conjunction with the broth microtiter MIC test by taking aliquots of broth from microtiter wells that demonstrate no visible growth and plating the samples onto antibiotic-free agar plates for subsequent incubation. The MBC is defined as the lowest concentration of drug that kills 99.9% of the total initially viable cells (representing a 3 $\log_{10}$ CFU/mL [6 $\log_{10}$ CFU/L] or greater reduction in the starting inoculum).

For certain antibiotic classes such as the aminoglycosides and the quinolones, the MIC often approximates the MBC. However, for β-lactam antibiotics and glycopeptides, the MBC can exceed the MIC substantially, resulting in an overestimation of in vivo bactericidal activity. When the MBC exceeds the MIC by 32-fold or more, an organism is said to be *tolerant* to the antimicrobial's killing activity. Although the phenomenon of tolerance has been documented for β-lactams and glycopeptides against certain staphylococci, streptococci, and enterococci, its impact on the outcome of infections caused by organisms other than those just mentioned appears to be limited.

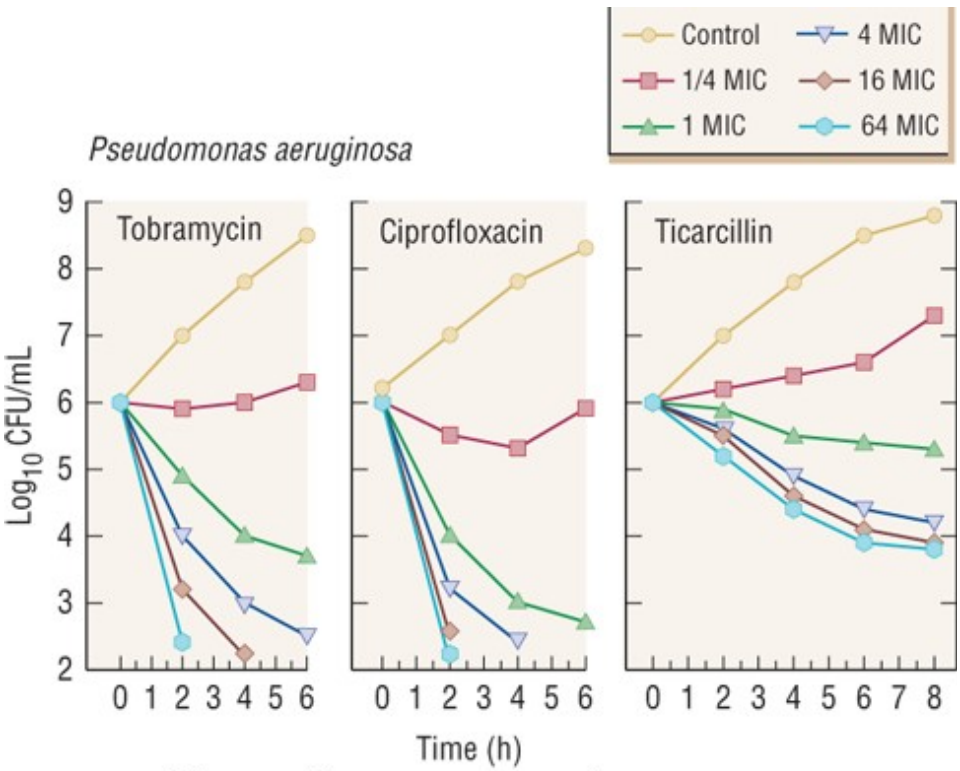
Timed-Kill Curve Tests

Timed-kill curve tests are not performed routinely in the clinical laboratory but can provide important additional data on the effects of an antimicrobial on bacteria. For timed-kill curve tests, a standard inoculum of bacteria (10^6 CFU/mL [10^9 CFU/L]) is placed in a test tube containing liquid growth medium with or without desired test concentrations of antimicrobial. Samples are removed periodically to determine the number of living cells at the given time points. The viable cell counts are plotted versus time to construct the timed-kill profile of the antimicrobial. The tested concentration of antimicrobial is considered to be bactericidal if it causes at least a 3 $\log_{10}$ CFU/mL (6 $\log_{10}$ CFU/L) reduction in viable inoculum. Comparisons of the relative rates of bacterial killing also

can be performed in timed-kill curve experiments. Additionally, the presence of concentration-dependent killing activity (where killing increases with increasing drug concentrations above the MIC) versus concentration-independent killing activity can be determined from a timed-kill curve experiment. An example of results from a timed-kill curve experiment is depicted in **Fig. e104-7**. These data can help to predict the best way to administer an antimicrobial to maximize activity. For example, lower-dose, more frequent (or continuous) infusions would be preferable for concentration-independent antibiotics, while higher-dose intermittent administrations would maximize activity for concentration-dependent antibiotics.

FIGURE e104-7

Killing curve depicting the effect of concentration on antibiotic bactericidal activity. (CFU, colony-forming unit; MIC, minimum inhibitory concentration [0.25-64 times the MIC; the organism tested was *P. aeruginosa* ATCC 27853]). *(Data from Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: A review. Scand J Infect Dis Suppl 1991;74:63-70.)*



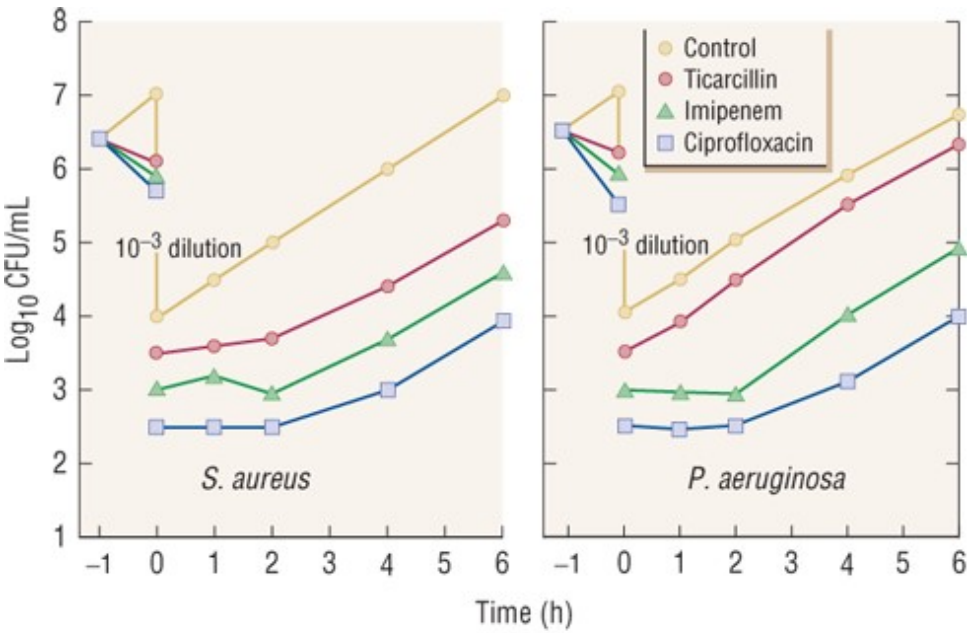
Postantibiotic Effect

The *postantibiotic effect* (PAE) is defined as the persistent suppression of an organism's growth after a brief exposure to an antibiotic.[39] A PAE experiment is performed by exposing a fixed inoculum of organism to a set concentration of antibiotic (typically some multiple of the MIC) (**Fig. e104-8**). The antibiotic is then removed either by inactivation (eg, inactivation by a β-lactamase or binding the antibiotic to a resin), dilution or by filtration/centrifugation of the mixture. The cells are resuspended

in antibiotic-free growth medium, and samples are removed frequently (every 0.5-2 hours) to determine resumption of normal growth. The PAE is quantified as the difference in time that it takes the organism exposed to the antibiotic to demonstrate a 10-fold increase in viable cells per milliliter as compared with a separate culture of organism not subjected to the antibiotic. A PAE equal to or greater than 1 hour has been demonstrated for most antibiotics against Gram-positive bacteria (*β*-lactams, vancomycin, daptomycin, linezolid, and telavancin). As a general rule, antibiotics that inhibit DNA or protein synthesis (eg, quinolones and aminoglycosides) demonstrate significant PAEs against Gram-negative organisms. An exception to this rule are the carbapenem cell wall synthesis inhibitors (eg, doripenem, ertapenem, imipenem, and meropenem), which demonstrate PAEs against selected strains of Gram-negative organisms such as *P. aeruginosa*. The primary clinical application of the PAE is to allow for less frequent administration of antimicrobials while still maintaining adequate antibacterial activity (eg, extended-interval aminoglycoside administration).[39]

FIGURE e104-8

Postantibiotic effect (PAE). In this experiment, fixed inocula of *Staphylococcus aureus* and *Pseudomonas aeruginosa* are exposed to ticarcillin, imipenem, and ciprofloxacin at a set concentration of four times the MIC. The organism and the antibiotic are then diluted 1,000-fold to a point where the antibiotic concentration is far below the MIC of the organism. Growth suppression of *S. aureus* following exposure to the three drugs (PAE) occurs for approximately 2 hours. Growth suppression of *P. aeruginosa*, however, is only demonstrated for imipenem and ciprofloxacin. The *β*-lactam ticarcillin has no effect on the growth of *P. aeruginosa*. (CFU, colony-forming unit; MIC, minimum inhibitory concentration.) *(Data from Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: A review. Scand J Infect Dis Suppl 1991;74:63-70.)*



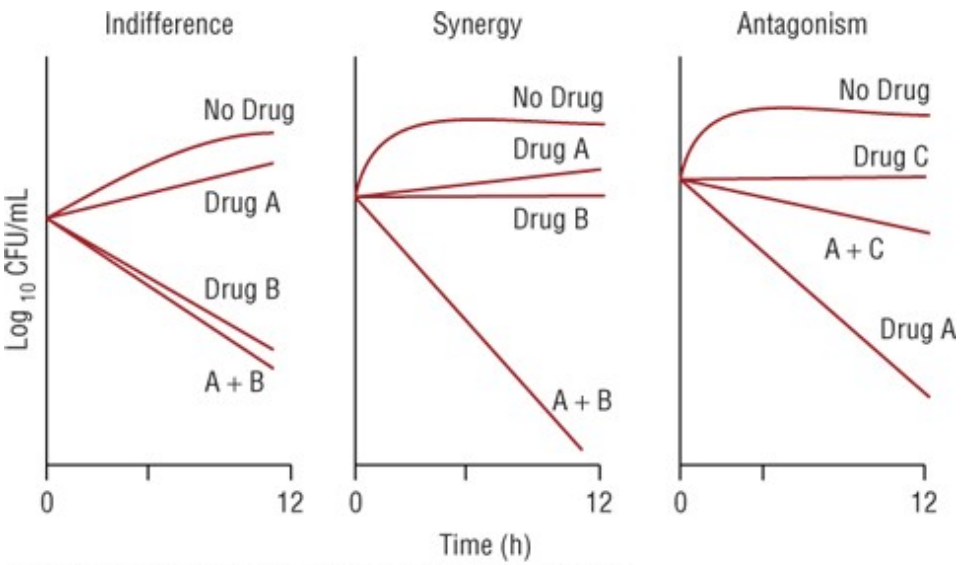
Antimicrobial Combination Effect Test

Antimicrobial combination therapy is used frequently to treat serious infections. Combination therapy can be used prior to knowing the pathogen or antibiotic susceptibility for the treatment of infections in neutropenic patients and in patients with enterococcal endocarditis or bacteremia, sepsis, or pneumonia caused by *P. aeruginosa*. In these cases, it is important to know whether the combination will have beneficial (or detrimental) effects on the overall antibacterial activity of the regimen. For example, the combination can result in activity that is significantly greater than the sum of activity of either agent alone (ie, synergy). Conversely, the combination can result in activity that is worse than either agent alone (ie, antagonism). Combination activity that is neither synergistic nor antagonistic is said to be *indifferent* or *additive*.[40]

More laborious methods are used to determine the expected effects of combination antibiotic therapy. For the most part, both methods are not used commonly in the clinical microbiology laboratory owing to the substantial labor involved with these tests and the lack of strong correlation with clinical outcome in the majority of infections. The first method is the microtiter fractional inhibitory concentration (FIC, or "checkerboard" method). This method has fallen out of favor in the last several decades do to increased specificity of the time-kill assays. The time-kill assays determine the effects of antibiotic combinations. Two antibiotics are added to the same test tube at fixed concentration fractions of the MIC for each drug, and killing is quantified. With this method, synergism is defined as a 100-fold decrease in viable organisms at 24 hours for the combination as compared with the most potent antibiotic tested alone. Antagonism is defined as a 100-fold or greater increase in viable organism count (**Fig. e104-9**).[40] It is important to note that although antagonism has been demonstrated for several combinations in vitro (eg, penicillin plus tetracycline, chloramphenicol and an aminoglycoside, fluoroquinolones and rifampin), antagonism in vivo has been demonstrated only infrequently.

FIGURE e104-9

Timed-kill curve illustrating indifference, synergy, and antagonism. (CFU, colony-forming unit.)



Although the methods for testing the effects of antimicrobial combinations are well described, the results from these tests have not been adequately studied in the context of many infection outcomes. There is little debate that the combination of a β-lactam antibiotic and an aminoglycoside is required for successful treatment of enterococcal endocarditis. For enterococci, susceptibility to high concentrations of aminoglycosides (eg, gentamicin, 500 mg/mL [g/L]) is evaluated in the clinical laboratory because it correlates closely with synergy when the drug is combined with β-lactam antibiotics. In recent years, double-β lactam therapy such as ampicillin and ceftriaxone has been shown to be effective.

The concept of combination therapy is not universally accepted for the treatment of other infections. There is ongoing debate as to whether the combination of a broad-spectrum β-lactam and an aminoglycoside is needed (vs the β-lactam alone) for the therapy of such infections as Gram-negative bloodstream infections or infections in neutropenic patients. In individual studies, combination therapy has resulted in improved outcomes in patients with severe illness and in patients with *P. aeruginosa* bloodstream infections, but pooled meta-analyses have disputed these results.[41]

LABORATORY MONITORING OF ANTIMICROBIAL THERAPY

9 Monitoring serum concentrations is the most common method used to attempt to maximize efficacy and minimize toxicity of antimicrobials. Because most antimicrobials are well tolerated at their usual doses, only a select few agents (eg, aminoglycosides and vancomycin) are monitored routinely in the current clinical environment. Direct and indirect methods can be used to quantify the concentration of antimicrobial in an experimental sample, including radioimmunoassay, high-pressure liquid chromatography, and microbiologic assay, and fluorescence-polarization immunoassay (FPIA).

TIMING OF COLLECTION OF SERUM SAMPLES

9 Peak and/or trough concentrations are monitored routinely for only a select few antimicrobials (eg, aminoglycosides and vancomycin) during the contemporary management of infections. It is crucial for the healthcare team to ensure that antimicrobial administration time and serum sample time(s) are meticulously recorded because even small errors in recording these values (eg, 1 hour) can have a substantial impact on the calculation of the pharmacokinetics for antibiotics such as the aminoglycosides, which have relatively short elimination half-lives.

10 Samples ideally should be obtained after steady state is achieved (usually defined as the passage of at least three to four anticipated half-lives), but in certain situations, this may not be possible (eg, critically ill patients with fluctuations in drug elimination owing to fluctuating hemodynamics, kidney function, and/or liver function). Generally, the timing of the peak serum sample collection is usually more critical than the trough concentration because adequate time must elapse to allow for completion of the distribution phase and to avoid underestimating the drug's volume of distribution.

Monitoring of Specific Agents

Aminoglycosides

The aminoglycosides (ie, amikacin, gentamicin, and tobramycin) and vancomycin remain the most common agents for which serum concentrations are monitored. There are many studies that have linked serum aminoglycoside concentrations with clinical response and with the occurrence of nephrotoxicity. One of the classic investigations into the relationship between serum aminoglycoside activity and clinical outcome revealed that peak serum concentrations of at least 5 mcg/mL (mg/L; ~11 µmol/L) for gentamicin and tobramycin and at least 20 mcg/mL (mg/L; 34 µmol/L) for amikacin were associated with a lower prevalence of clinical failure rates during the treatment of Gram-negative bacteremia.[42] Although earlier studies suggested that trough concentrations exceeding 2 to 4 mcg/mL (mg/L; ~4-8 µmol/L) for gentamicin and tobramycin and 10 mcg/mL (mg/L; 17 µmol/L) for amikacin predisposed patients to nephrotoxicity, other investigations indicated that the development of aminoglycoside-related ototoxicity and nephrotoxicity is more complex and also is associated with the total exposure to the aminoglycoside (as measured by the area under the curve [AUC]) and/or the total duration of aminoglycoside therapy.[43] The specific recommended serum peak and trough concentrations for the various aminoglycosides are described in **Table e104-2**.

TABLE e104-2 Suggested Therapeutic Serum Concentrations for Selected Antimicrobial Agents

Drug	Sample	Target Concentrations (mg/L [µmol/L])	Comments
Gentamicin, tobramycin (traditional dosage regimens)	Peak (1 hour after start of 15- to 45-minute infusion)	<5 (<11 µmol/L)	Urinary tract infections
		>5 (>11 µmol/L)	Bacteremia
		>6 (>13 µmol/L)	Bacterial pneumonia
		>12 (>25 µmol/L)	Endocarditis caused by *Pseudomonas aeruginosa*
	Trough	<2-3 (<4-6 µmol/L)	High trough concentrations are most likely a result of and not a cause of nephrotoxicity
Amikacin	Peak	>15 (>26 µmol/L)	Urinary tract infections
		>20 (>34 µmol/L)	Bacteremia
		>24 (>41 µmol/L)	Bacterial pneumonia, other serious infections
	Trough	>9-10 (>15-17 µmol/L)	See comments regarding trough gentamicin/tobramycin concentrations

Drug	Sample	Target Concentrations (mg/L [µmol/L])	Comments
Single daily dosage regimens[49]			
Gentamicin	8-hour postdose (*mid-dose*)	1.5-6 (3-13 µmol/L)	Concentrations above this range associated with nephrotoxicity in one study with netilmicin
Netilmicin			
Tobramycin			
Vancomycin	Trough	15-20 (10-14 µmol/L)	A higher trough range is suggested due to low lung penetration, potential for resistance, and better outcomes for patients with bacteremia

Data from references 45 and 48.

Newer regimens of high dose once-daily or extended-interval aminoglycoside administration have gained widespread acceptance for use in the clinical setting. These regimens exploit the pharmacodynamic properties of these agents (ie, concentration-dependent bacterial killing and a substantial PAE) to maximize activity while also attempting to minimize drug nephrotoxicity by reducing the total aminoglycoside exposure time for the patient's kidneys. The doses employed for extended-interval treatment typically range from 5 to 7 mg/kg of lean body weight (administered every 24-48 hours), with the dose and/or interval adjusted based on renal function or observed mid-dose serum concentrations.[44] Many prospective studies have been performed to evaluate the safety and efficacy of once-daily aminoglycoside dosing, and most have revealed similar rates of efficacy and toxicity, or trends toward improved efficacy and reduced toxicity for once-daily dosage regimens as compared with traditional (thrice daily) regimens.

Clinical Controversy…

Some clinicians believe that there is sufficient clinical data to support widespread use of once-daily aminoglycoside dosing without determination of individual patient pharmacokinetics. However, there are some clinicians who believe that the data are incomplete and that patients should receive individualized pharmacokinetic assessments and dosage adjustments.

Traditional methods of aminoglycoside serum concentration monitoring (evaluating peak and trough serum concentrations) cannot be applied to extended-interval dosing because the serum concentrations 24 hours after a dose ideally should be undetectable. A midinterval serum sample can be taken approximately 6 to 12 hours after the dose to allow for use of first-order pharmacokinetic equations or nomograms for interval adjustments.[44]

Vancomycin

Although IV vancomycin has been associated with oto- and nephrotoxicity in humans, most of these reports occurred with older, impure formulations of the drug, with extremely high concentrations uncommon with contemporary dosing regimens, or when vancomycin was combined with known nephrotoxic agents. Although serum peak and trough concentrations were previously recommended for monitoring vancomycin therapy, at present, the trough concentration is routinely monitored since vancomycin does not demonstrate concentration-dependent killing. Initially, trough concentrations of 5 to 10 mg/L (3.5-7 µmol/L) appeared sufficient, but more recently, higher vancomycin trough concentrations of 15 to 20 mg/L (10-14 µmol/L) have been recommended for more serious infections such as bloodstream infections, pneumonia, endocarditis, meningitis caused by *S. aureus* because of a number of factors including: (a) its poor penetration into tissue such as the lung, (b) the association of the emergence of vancomycin-nonsusceptible strains in patients who had trough serum concentrations maintained below 10 mg/L (7 µmol/L), and (c) and the trend of higher vancomycin MICs and/or MBCs for most strains of staphylococci. 12 The area under the concentration–time curve to MIC ratio (AUC/MIC) is the parameter that best predicts efficacy as demonstrated by both animal and human data.[45] Clinical studies suggest that achieving a free-fraction (unbound) area-under-the-curve to MIC ratio (fAUC/MIC) of greater than or equal to 211 or AUC/MIC (total) of greater than 400 improved outcomes of patients with *S. aureus* bacteremia and/or endocarditis. It should be noted however, that higher concentrations of vancomycin (troughs greater than or equal to 20 mg/L [14 µmol/L] and AUC/MICs exceeding 700) .[46,47,48,49,50,51]

Clinical Controversy…

Some clinicians believe that vancomycin should no longer be considered as the drug of first-choice for treatment of serious staphylococcal infections—even when it is administered to target the new, higher trough range of 15 to 20 mg/L (10-14 µmol/L). The desired target attainment of an AUC/MIC of ≥400 may not be achieved with conventional doses of vancomycin with *S. aureus* exhibiting a vancomycin MIC of ≥2 mg/L.

USING PHARMACODYNAMICS TO IMPROVE ANTIMICROBIAL THERAPY

13 14 Antimicrobial regimens should be selected and/or designed to maximize the probability that bacterial killing is optimized and that the probability of resistance is minimized. For example, the activity of antimicrobials such as the fluoroquinolones and the aminoglycosides can be maximized if the ratio of the peak serum concentration to the organism MIC (peak-to-MIC ratio) is greater than or equal to 10.[49] Similarly, the probability of clinical and/or microbiologic infection cure can be maximized if a fluoroquinolone is chosen that achieves an AUC-to-MIC ratio of 100 to 125 or greater for Gram-negative bacteria (eg, *P. aeruginosa*) and 30 to 40 or greater for Gram-positive bacteria (eg, *S. pneumoniae*) (**Fig. e104-10**).

FIGURE e104-10

Illustration of the concept of peak concentration to the minimum inhibitory concentration (MIC) ratio

for aminoglycosides. The MIC for the given organism to gentamicin is 2 mg/L, whereas the tobramycin MIC is 0.5 mg/L. Administration of gentamicin would result in a suboptimal peak:MIC ratio (<10), which could increase the chances for development of resistance or an inadequate response. Administration of tobramycin would result in a peak:MIC ratio of 12, which should improve efficacy. Note that modification of the gentamicin regimen to produce peak serum concentrations of 20 mg/L (42 µmol/L) or more (as commonly done with once-daily administration) also would result in a peak:MIC ratio of ≥10.

To date, most of the data on optimization of antimicrobial pharmacodynamics have been generated in in vitro models of infection, in animal models of infection, within the context of controlled clinical trials, or through mathematical modeling of small data sets. However, research continues to emerge on the best ways to apply these valuable data to the everyday management of patients in the clinical setting. The recognition of the importance of antimicrobial pharmacodynamics already has resulted in such therapeutic innovations such as (a) the expansion of serum concentration monitoring for select antimicrobials (eg, antiretroviral agents, antifungal agents), (b) suggested revisions of breakpoint values that define antimicrobial susceptibility and/or resistance, (c) development of nomograms or computer programs that can suggest optimal drugs and doses for a given infection, (d) novel administration methods such as prolonged infusion times for antibiotics such as β-lactams with time-dependent activity, and (e) the development of newer antimicrobial agents with minimized risks of suboptimal pharmacodynamics. These developments present exciting opportunities for healthcare providers to improve the outcomes of patients with infections in a variety of different healthcare settings.

Chapter 105: Antimicrobial Regimen Selection

Grace C. Lee; David S. Burgess

INTRODUCTION

KEY CONCEPTS

- 1 Every attempt should be made to obtain specimens for culture and sensitivity testing prior to initiating antibiotics.
- 2 Empirical antibiotic therapy should be based on knowledge of likely pathogens for the site of infection, information from patient history (eg, recent hospitalizations, work-related exposure, travel, and pets), and local susceptibility.
- 3 Patients with delayed dermatologic reactions (ie, rash) to penicillin generally can receive cephalosporins. Patients with type I hypersensitivity reactions (ie, anaphylaxis) to penicillins should not receive cephalosporins. Alternatives to the cephalosporins include aztreonam, quinolones, sulfonamide antibiotics, or vancomycin based on type of coverage indicated.
- 4 Creatinine clearance should be estimated for every patient who is to receive antibiotics and the antibiotic dose interval adjusted accordingly. Hepatic function should be considered for drugs eliminated through the hepatobiliary system, such as clindamycin, erythromycin, and metronidazole.
- 5 All concomitant drugs and nutritional supplements should be reviewed when an antibiotic is added to a patient's therapy to ensure drug–drug interactions will be avoided.
- 6 Combination antibiotic therapy may be indicated for polymicrobial infections (eg, intra-abdominal and gynecologic infections), to produce synergistic killing (such as β-lactam plus aminoglycoside vs *Pseudomonas aeruginosa*), or to prevent the emergence of resistance.
- 7 All patients receiving antibiotics should be monitored for resolution of infectious signs and symptoms (eg, decreasing temperature and white blood cell count) and adverse drug events.
- 8 Antibiotics with the narrowest effective spectrum of activity are preferred. Antibiotic route

of administration should be evaluated daily, and conversion from IV to oral therapy should be attempted as signs of infection improve for patients with functioning GI tracts (general exceptions are endocarditis and CNS infections).

- 9 Patients not responding to an appropriate antibiotic treatment in 2 to 3 days should be reevaluated to ensure (a) the correct diagnosis, (b) that therapeutic drug concentrations are being achieved, (c) that the patient is not immunosuppressed, (d) that the patient does not have an isolated infection (ie, abscess and foreign body), or (e) that resistance has not developed.

- 10 The main goals of antimicrobial stewardship programs (ASPs) are to optimize antimicrobial selection, dosing, duration, and route of administration while minimizing adverse drug events and the emergence of antimicrobial resistance.

Antimicrobials are among the most widely used classes of drugs. In the United States, expenditures for antimicrobial agents exceed $10 billion annually. Approximately 20% to 40% of hospitalized patients receive antibiotics. The use of antibiotics is the main driver in creating selective pressure for the emergence of antimicrobial resistant pathogens; nevertheless, antibiotic overuse remains common. Selecting appropriate antimicrobial agent(s) to treat an infection has proven to be a challenging task.[1,2] Although the choice of a single agent or a combination of agents should be individualized for each patient, certain general principles of therapy should guide the selection of specific drugs (**Table 105-1**).

Laboratory tests

Assessment of therapeutic failure

The initial selection of antimicrobial therapy is nearly always empirical, which is prior to documentation and identification of the offending organism. Infectious diseases generally are acute, and a delay in antimicrobial therapy can result in serious morbidity or even mortality. Thus, empirical antimicrobial therapy selection should be based on information gathered from the patient's history and physical examination and results of Gram stains or of rapidly performed tests on specimens from the infected site. This information, combined with knowledge of the most likely offending organism(s) and an institution's local susceptibility patterns, should result in a rational selection of antibiotics to treat the patient. This chapter introduces a systematic approach to the selection of antimicrobial therapeutic regimens.

CONFIRMING THE PRESENCE OF INFECTION

An infectious disease diagnosis is determined by assessing the presence of signs and symptoms of an infection, determining the site of infection, and establishing a microbiological diagnosis, when possible.

Fever

The presence of a temperature greater than the expected 37°C (98.6°F) "normal" body temperature is considered a hallmark of infectious diseases. Body temperature is controlled by the hypothalamus. In addition, the circadian rhythm, a built-in temperature cycle, is also operational. The daily temperature rhythm can vary for each individual. In a healthy person, the internal thermostat is set between the morning low temperature and the afternoon peak as controlled by the circadian rhythm. During fever, the hypothalamus is reset at a higher temperature level.

Fever is defined as a controlled elevation of body temperature above the normal range. The average normal body temperature range taken orally is 36.7°C to 37°C (98°F-98.6°F). Body temperatures obtained rectally generally are 0.6°C (1°F) higher and axillary temperatures are 0.6°C (1°F) lower than oral temperatures, respectively. Skin temperatures are also less than the oral temperature but can vary depending on the specific measurement method.

Fever can be a manifestation of disease states other than infection. Collagen vascular (autoimmune) disorders and several malignancies can have fever as a manifestation. Fever of unknown or undetermined origin is a diagnostic dilemma and is reviewed extensively elsewhere.[3]

Many drugs have been identified as causes of fever. *Drug-induced fever* is defined as persistent fever in the absence of infection or other underlying condition. The fever must coincide temporally with

the administration of the offending agent and disappear promptly on its withdrawal, after which the temperature remains normal. Possible mechanisms of drug-induced fever are either a hypersensitivity reaction or development of antigen–antibody complexes that result in the stimulation of macrophages and the release of interleukin 1 (IL-1). While fever is not a common drug effect (accounting for no more than 5% of all drug reactions), it should be suspected when obvious reasons for fever are not present. Almost any medication can produce fever, but β-lactam antibiotics, anticonvulsants, allopurinol, hydralazine, nitrofurantoin, sulfonamides, phenothiazines, and methyldopa appear to be responsible more often than others.

Noninfectious etiologies of fever can be referred to as "false-positives." Although these certainly can confuse the clinician, even more troublesome are false-negatives: the absence of fever in a patient with signs and symptoms consistent with an infectious disease. Careful questioning of the patient or family is vital to assess the ingestion of any medication that can mask fever (eg, aspirin, acetaminophen, nonsteroidal anti-inflammatory agents, and corticosteroids). The use of antipyretics should be discouraged during the treatment of infection unless absolutely necessary because they can mask a poor therapeutic response. Moreover, elevated body temperature, unless very high (greater than 40.5°C [greater than 105°F]), is not harmful and may be beneficial.

Signs and Symptoms

White Blood Cell Count

Most infections result in elevated white blood cell (WBC) counts (leukocytosis) because of the increased production and mobilization of granulocytes (neutrophils, basophils, and eosinophils), lymphocytes, or both to ingest and destroy invading microbes. The generally accepted range of normal values for WBC counts is between 4,000 and 10,000 cells/mm^3 (4×10^9 and 10×10^9/L). Values above or below this range hold important prognostic and diagnostic value.

Bacterial infections are associated with elevated granulocyte counts, often with immature forms (band neutrophils) seen in peripheral blood smears. Mature neutrophils are also referred to as *segmented neutrophils* or *polymorphonuclear* (PMN) *leukocytes*. The presence of immature forms (left shift) is an indication of an increased bone marrow response to the infection. With infection, peripheral WBC counts can be very high, but they are rarely higher than 30,000 to 40,000 cells/mm^3 (30×10^9/L-40×10^9/L). Because leukocytosis indicates the normal host response to infection, low leukocyte counts after the onset of infection indicate an abnormal response and generally are associated with a poor prognosis.

The most common granulocyte defect is neutropenia, a decrease in absolute numbers of circulating neutrophils. A thorough description of the consequences of neutropenia is given in Chapter e99. Lymphocytosis, even with normal or slightly elevated total WBC counts, generally is associated with tuberculosis and viral or fungal infections. Increases in monocytes can be associated with tuberculosis or lymphoma, and increases in eosinophils can be associated with allergic reactions to drugs or infections caused by metazoa. Many types of infections can be accompanied by a completely normal WBC count and differential.

Local Signs

The classic signs of pain and inflammation can manifest as swelling, erythema, tenderness, and purulent drainage. Unfortunately, these are only visible if the infection is superficial or in a bone or joint. The manifestations of inflammation in deep-seated infections (eg, meningitis, pneumonia, endocarditis, and urinary tract infection) must be ascertained by examining tissues or fluids. For example, the presence of neutrophils in spinal fluid, lung secretions (sputum), or urine is highly suggestive of a bacterial infection.

Symptoms referable to an organ system must be sought out carefully because not only do they help in establishing the presence of infection, but they also aid in narrowing the list of potential pathogens. For example, a febrile patient with complaints of flank pain and dysuria can well have pyelonephritis. In this situation, enteric Gram-negative bacilli, especially *Escherichia coli*, are the predominant pathogens. If a febrile patient has no symptoms suggestive of an organ system but only constitutional complaints, the list of possible infectious diseases is lengthy.[3] A febrile individual with cough and sputum production probably has a pulmonary infection. What is not so evident, however, is the etiologic organism in this situation, because it can be caused by bacteria, mycobacteria, viruses, *Chlamydia*, or mycoplasmas.[4] In this situation, attention to the patient's history and background disease states is important. Even more important is a careful examination of the infected material (in this case sputum) to ascertain the identity of the pathogen.

IDENTIFICATION OF THE PATHOGEN

Microbiological Studies

1 Identification and antimicrobial susceptibility of a suspected pathogen are the most important factors in determining the choice of antimicrobial therapy. Generally, infected body materials must be sampled, if at all possible or practical, before or concurrently with institution of any antimicrobial therapy for two reasons. First, a Gram stain of the material might reveal bacteria, or an acid-fast stain might detect mycobacteria or actinomycetes. Second, the premature use of antimicrobials can suppress the growth of pathogens which might result in false-negative cultures results or alterations in the cellular and chemical composition of infected fluids. This is particularly true in patients with vertebral osteomyelitis, urinary tract infections, subacute endocarditis, meningitis, and septic arthritis.[5,6,7,8,9]

Blood cultures usually should be performed in the acutely ill febrile patient. Blood culture collection should coincide with sharp elevations in temperature, suggesting the possibility of microorganisms or microbial antigens in the bloodstream. Ideally, blood should be obtained from peripheral sites as two sets (one set consists of an aerobic bottle and one set an anaerobic bottle) from two different sites approximately 1 hour apart. In selected infections, bacteremia is qualitatively continuous (eg, endocarditis), so cultures can be obtained at any time.[9]

In addition to the infected materials produced by the patient (eg, blood, sputum, urine, stool, and wound or sinus drainage), other less accessible fluids or tissues must be obtained if they are

suspected to be the infected site (eg, spinal fluid in meningitis and joint fluid in arthritis). Abscesses and cellulitic areas also should be aspirated.

When a pathogenic microorganism is identified, the next step for the majority of clinical microbiological laboratories is antimicrobial susceptibility testing which measures the ability of a select organism to grow in the presence of an antimicrobial agent. These methods are described in detail in Chapter e25. Once a microorganism is identified and its susceptibilities are known, specific definitive antimicrobial therapy should be promptly administered.

Over the last decade, there has been an explosion in the development of rapid diagnostic methods that provide simultaneous organism identification and resistance marker detection. These methods include nonamplified probe technologies (peptide nucleic-acid-fluorescence in situ hybridization), proteomics, and nucleic acid amplification methods combined with microarray technologies. These tests can significantly reduce time to organism identification; thereby, can reduce time to effective antimicrobial therapy, overall antimicrobial use, and health outcomes among patients with infectious diseases.[10,11,12]

Interpreting Results

After a positive Gram stain, culture results, or both are obtained, the clinician must be cautious in determining whether the organism recovered is a true pathogen, a contaminant, or a part of the normal flora (see Chapter e25). The latter consideration is especially problematic with cultures obtained from the skin, oropharynx, nose, ears, eyes, throat, and perineum. These surfaces are heavily colonized with a wide variety of bacteria, some of which can be pathogenic in certain settings. For example, coagulase-negative staphylococci are found in cultures of all the aforementioned sites, yet are seldom regarded as pathogens unless recovered from blood, venous access catheters, or prosthetic devices.

Importantly, cultures of specimens from purportedly infected sites that are obtained by sampling from or through one of these contaminated areas might contain significant numbers of the normal flora. For urine cultures, the urinalysis should be used in combination with culture results to assess the presence of WBCs, nitrite, and leukocyte esterase to help confirm infection and rule out colonization.[13]

Particularly problematic are expectorated sputum specimens that must be evaluated carefully by determination of the presence of squamous epithelial cells and leukocytes.[4] A predominance of epithelial cells in sputum specimens reduces the likelihood that recovered bacteria are pathogenic, especially when multiple types of organisms are seen on Gram stain. In contrast, the discovery of leukocytes in large numbers with one predominant type of organism is a more reliable indicator of a valid collection. In general, however, sputum evaluation has poor sensitivity and specificity as a diagnostic test.

Gram-staining techniques, culture methods, and serologic identification, as well as susceptibility testing, are discussed in detail in Chapter e25. Emphasis must be placed on the proper collection and handling of specimens and careful assessment of Gram stain or other test results in guiding the

clinician toward appropriate selection of initial antimicrobial therapy.[14]

SELECTION OF PRESUMPTIVE THERAPY

2 In many instances, empiric therapy must be instituted before microbiological results are available. To select rational antimicrobial therapy for a given clinical situation, a variety of factors must be considered. These include the severity and acuity of the disease, local epidemiology and antibiogram, patient history, host factors, factors related to the drugs used, and the necessity for using multiple agents. In addition, there are generally accepted drugs of choice for the treatment of most pathogens (see **Appendix 105-1**).

Antibiogram

Drugs of choice are compiled from a variety of sources and are intended as guidelines rather than as specific rules for antimicrobial use. These choices are influenced by local antimicrobial susceptibility data rather than information published by other institutions or national compilations. Each institution should publish an annual summary of antibiotic susceptibilities (antibiogram) for organisms cultured from patients. Antibiograms contain both the number of nonduplicate isolates for common species and the percentage susceptible to the antibiotics tested. To further guide empirical antibiotic therapy, some hospitals publish unit-specific antibiograms in unique patient care areas, such as intensive care units or burn units.

Susceptibility of bacteria can differ substantially among hospitals within a community. For example, the prevalence of hospital-acquired methicillin-resistant *Staphylococcus aureus* (HA-MRSA) in some centers is quite high, whereas in other centers the problem might be nonexistent. This particular situation will influence the selection of therapy for possible *S. aureus* infection, where the clinician must choose either a β-lactam or vancomycin. The problem of differing susceptibilities is not limited only to Gram-positive bacteria but also is evident in Gram-negative organisms, and all drug classes are affected.

Patient History

Empirical therapy is directed at organisms that are known to cause the infection in question. These organisms are discussed for different sites of infection in Chapters 83 to e103. To define the most likely infecting organisms, a careful history and physical examination must be performed. The place where the infection was acquired should be determined, for example, the home (community acquired), nursing home environment, or hospital acquired (nosocomial). Nursing home patients can be exposed to potentially more resistant organisms because they are often surrounded by ill patients who are receiving antibiotics. Important considerations when selecting empiric antimicrobial therapy include: 1) prior knowledge of colonization or infections, 2) previous antimicrobial use, 3) the site of infection and the organisms most likely pathogens, and 4) local antibiogram and resistance patterns for important pathogens. Other questions to ask infected patients regarding the history of present illness include: 1) Are any other people sick at home, especially children? 2) Are any unusual pets kept in the home? 3) Where are you employed (ie, are you exposed to contaminated meat or infectious

biohazards)? and 4) Has there been any recent travel (ie, to endemic areas of fungal infections or developing countries)?

Host Factors

Several host factors should be considered when evaluating a patient for antimicrobial therapy. The most important factors are drug allergies, age, pregnancy, genetic or metabolic abnormalities, renal and hepatic function, site of infection, concomitant drug therapy, and underlying disease states.

Allergy

3 Allergy to an antimicrobial agent generally precludes its use. Careful assessment of allergy histories must be performed because many patients confuse common adverse drug effects (ie, GI disturbance) with true allergic reactions.[15,16,17] Among the most commonly cited antimicrobial allergies are those to penicillin, penicillin-related compounds, or both. In the absence of complete penicillin skin testing capabilities, a rule of thumb for giving cephalosporins to patients allergic to penicillin is to avoid giving them to patients who give a good history for immediate or accelerated reactions (eg, anaphylaxis, laryngospasm) and to give them under close supervision in patients with a history of delayed reactions, such as a rash.[18] If a Gram-negative infection is suspected or documented, therapy with a monobactam may be appropriate because cross-reactivity with other β-lactams is nonexistent.

Age

The patient's age is an important factor both in trying to identify the likely etiologic agent and in assessing the patient's ability to eliminate the drug(s) to be used. The best example of an age determinant of organisms is in bacterial meningitis, where the pathogens differ as the patient grows from the neonatal period through infancy and childhood into adulthood.[5,19]

For neonates, hepatic and liver functions are not well developed. Therefore, bilirubin excretion is decreased resulting in increased concentration of unconjugated bilirubin that can cause kernicterus. Neonates (especially when premature) can develop kernicterus when given sulfonamides. This results from displacement of bilirubin from serum albumin. In addition, neonates have more body water content that results in a larger volume of distribution leading to adjustments in antibiotic dosing regimens. Additional special drug considerations for pediatric patients include low frequency of adverse effects and compliance-enhancing features (eg, absorption not affected by food, once- to twice-daily dosing, and good taste).[7,20,21]

The major physiologic change in persons older than 65 years of age is a decline in the number of functioning nephrons that, in turn, results in decreased renal function.[22] This is usually manifested by an increased incidence of side effects caused by antimicrobials that are eliminated renally. For example, renal toxicity caused by aminoglycosides may be apparent much sooner during therapy in older adults than in younger patients.

Pregnancy

During pregnancy, not only is the fetus at risk for drug teratogenicity, but the pharmacokinetic disposition of certain drugs can be altered.[23] Penicillins, cephalosporins, and aminoglycosides are cleared from the peripheral circulation more rapidly during pregnancy. This is probably a result of marked increases in intravascular volume, glomerular filtration rate, and hepatic and metabolic activities. The net result is that maternal serum antimicrobial concentrations can be as much as 50% lower during this period than in the nonpregnant state. Increased dosages of certain compounds might be necessary to achieve therapeutic levels during late pregnancy.[24]

Metabolic or Genetic Variation

Inherited or acquired metabolic abnormalities will influence the therapy of infectious diseases in a variety of ways. For example, patients with impaired peripheral vascular flow may not absorb drugs given by intramuscular injection. In addition, certain metabolic states can predispose patients to enhanced drug toxicity. For instance, patients who are phenotypically slow acetylators of isoniazid are at greater risk for peripheral neuropathy.[25] Patients with severe deficiency of glucose-6-phosphate dehydrogenase can develop significant hemolysis when exposed to such drugs as sulfonamides, nitrofurantoin, nalidixic acid, antimalarials, and dapsone. Although mild deficiencies are found in African Americans, the more severe forms of the disease generally are confined to persons of eastern Mediterranean origin. Another example is the antiretroviral drug abacavir, which is associated with a severe hypersensitivity reaction, consisting of fever, rash, abdominal pain, and respiratory distress. This risk has been associated with the presence of a human leukocyte antigen allele HLA-B*5701. Routine screening for the presence of this allele before initiating treatment with abacavir is a recommendation in the current HIV treatment guidelines. Furthermore, the hepatic cytochrome P450 system is a major pathway for a large number of antimicrobials. While differential host expressions of these enzymes occur, insufficient clinical data are currently available to recommend routine screening for antimicrobial therapy.

Organ Dysfunction

4 Patients with diminished renal or hepatic function or both will accumulate certain drugs unless the dosage is adjusted. It is common for patents requiring antimicrobial therapy to have some degree of renal impairment. Because many of the commonly used antimicrobials are primarily cleared by the kidneys, it is imperative to adjust the dosing regimen or therapy.[26,27] Recommendations for dosing antibiotics in patients with liver dysfunction are not as formalized as guidelines for patients with renal dysfunction. Antibiotics that should be adjusted in severe liver disease include clindamycin, erythromycin, metronidazole, and rifampin. Significant accumulation can occur when both liver dysfunction and renal dysfunction are present for the following drugs: cefotaxime, nafcillin, piperacillin, and sulfamethoxazole.[28]

Concomitant Drugs

5 Any concomitant therapy that the patient is receiving can influence the drug selection, dose, and monitoring. For instance, administration of isoniazid to a patient who is also receiving phenytoin can result in phenytoin toxicity secondary to inhibition of phenytoin metabolism by isoniazid. Furthermore, drugs that possess similar adverse effect profiles can increase the risk for effects (ie, two drugs that cause nephrotoxicity or neutropenia). A detailed review of drug interactions is beyond the scope of this chapter, but an excellent textbook on this subject is available.[29] Lists of potentially severe drug–drug interactions are provided in **Table 105-2**.

TABLE 105-2 Major Drug Interactions with Antimicrobials

Antimicrobial	Other Agent(s)	Mechanism of Action/Effect	Clinical Management
	Neuromuscular blocking agents	Additive adverse effects	Avoid
Aminoglycosides	Nephrotoxins (N) or ototoxins (O) (eg, amphotericin B [N], cisplatin [N/O], cyclosporine [N], furosemide [O], NSAIDs [N], radiocontrast [N], vancomycin [N])	Additive adverse effects	Monitor aminoglycoside SDC and renal function
Amphotericin B	Nephrotoxins (eg, aminoglycosides, cidofovir, cyclosporine, foscarnet, pentamidine)	Additive adverse effects	Monitor renal function
Azoles	See Chapter 98		
Chloramphenicol	Phenytoin, tolbutamide, ethanol	Decreased metabolism of other agents	Monitor phenytoin SDC, blood glucose
Foscarnet	Pentamidine IV	Increased risk of severe nephrotoxicity/hypocalcemia	Monitor renal function/serum calcium
Isoniazid	Carbamazepine, phenytoin	Decreased metabolism of other agents (nausea, vomiting, nystagmus, ataxia)	Monitor drug SDC
Macrolides/azalides	Digoxin	Decreased digoxin bioavailability and metabolism	Monitor digoxin SDC; avoid if possible
	Theophylline	Decreased metabolism of theophylline	Monitor theophylline SDC
Metronidazole	Ethanol (drugs containing ethanol)	Disulfiram-like reaction	Avoid

Antimicrobial	Other Agent(s)	Mechanism of Action/Effect	Clinical Management
Penicillins and cephalosporins	Probenecid, aspirin	Blocked excretion of β-lactams	Use if prolonged high concentration of β-lactam desirable
Ciprofloxacin/norfloxacin	Theophylline	Decreased metabolism of theophylline	Monitor theophylline
	Classes Ia and III antiarrhythmics	Increased Q-T interval	Avoid
Quinolones	Multivalent cations (antacids, iron, sucralfate, zinc, vitamins, dairy, citric acid), didanosine	Decreased absorption of quinolone	Separate by 2 hours
Rifampin	Azoles, cyclosporine, methadone propranolol, PIs, oral contraceptives, tacrolimus, warfarin	Increased metabolism of other agent	Avoid if possible
Sulfonamides	Sulfonylureas, phenytoin, warfarin	Decreased metabolism of other agent	Monitor blood glucose, SDC, PT
Tetracyclines	Antacids, iron, calcium, sucralfate	Decreased absorption of tetracycline	Separate by 2 hours
	Digoxin	Decreased digoxin bioavailability	Monitor digoxin SDC; avoid if possible

PI, protease inhibitor; PT, prothrombin time; SDC, serum drug concentrations.

Azalides: azithromycin; azoles: fluconazole, itraconazole, ketoconazole, and voriconazole; macrolides: erythromycin and clarithromycin; protease inhibitors: amprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, and saquinavir; quinolones: ciprofloxacin, gemifloxacin, levofloxacin, and moxifloxacin.

Concomitant Disease States

Concomitant disease states can influence the selection of therapy. Certain diseases will predispose patients to a particular infectious disease or will alter the type of infecting organism. For example, patients with diabetes mellitus and the resulting peripheral vascular disease often develop infections of the lower extremity soft tissue. Moreover, the alterations in peripheral blood flow associated with the disease and perhaps altered immunity make such infections more difficult to treat than in

nondiabetics. Patients with chronic lung disease or cystic fibrosis develop frequent pulmonary infections that can be caused by somewhat different microorganisms than are found in otherwise normal hosts.

Patients with immunosuppressive diseases, such as malignancies or acquired immunologic deficiencies, are highly predisposed to infections, and the types of causative or pathogenic organisms can be vastly different from what would be expected (see Chapter e99). For instance, patients undergoing chemotherapy for acute forms of leukemia often are profoundly granulocytopenic and are predisposed to infections caused by bacteria and fungi.[30] Patients with the acquired immunodeficiency syndrome (AIDS) often become infected with an enormous variety of organisms (see Chapter e103).

Many factors predisposing to infection are related to disruption of the host's integumentary barriers. For example, trauma, burns, and iatrogenic wounds induced in surgery can lead to a substantial risk of infection depending on the severity and location of the injury or disruption. For a complete discussion of the various risks involved in surgical procedures, see Chapter 100.

Drug Factors

Pharmacokinetic and Pharmacodynamic Considerations

Integration of both pharmacokinetic and pharmacodynamic properties of an agent is important when choosing antimicrobial therapy to ensure efficacy and to prevent resistance.[31] Early researchers relied solely on pharmacokinetic properties such as the area under the (drug concentration) curve (AUC), maximum observed concentration (peak), and drug half-life to optimize therapy. Pharmacodynamics is the study of the relationship between drug concentration and the effects on the microorganism. There is an important relationship between both pharmacokinetic and microbiologic parameters that has resulted in measurements such as AUC:minimal inhibitory concentration (MIC) ratio, peak:MIC ratio, and time (*T*) the concentration is above MIC (*T* > MIC).[32,33,34,35]

Aminoglycosides exhibit concentration-dependent bactericidal effects. An example of the integration of pharmacokinetics and microbiologic activity is the use of high-dose, once-daily aminoglycosides. For these regimens, the drug is given as a single large daily dose to maximize the peak:MIC ratio. Aminoglycosides also possess a postantibiotic effect (persistent suppression of organism growth after concentrations decrease below the MIC) that appears to contribute to the success of high-dose, once-daily administration. Fluoroquinolones exhibit concentration-dependent killing activity, but optimal killing appears to be characterized by the AUC:MIC ratio.

β-Lactams display time-dependent bactericidal effects. Killing activity is enhanced only marginally if drug concentration exceeds the MIC. Therefore, the important pharmacodynamic relationship for these antimicrobials is the duration that drug concentrations exceed the MIC (*T* > MIC). Effective dosing regimens require serum drug concentrations to exceed the MIC for at least 40% to 50% of the dosing interval. Frequent small doses, continuous infusion, or prolonged infusion of *β*-lactams appears to be correlated with positive outcomes.

A detailed discussion on antimicrobial pharmacokinetics–pharmacodynamics is beyond the scope of this chapter. However, excellent sources of information on this topic are available.[31,32,35]

Tissue Penetration

The importance of tissue penetration varies with site of infection. Some of the difficulties in interpreting data include a lack of correlation with clinical outcomes and poor understanding of whether the antimicrobial agents are present in a biologically active form. An example of the former problem is the recognized efficacy of drugs with low biliary fluid concentrations in the treatment of cholecystitis, cholangitis, or both and the absence of the enhanced efficacy of drugs whose primary route of elimination is biliary excretion of active drug. An example of the latter difficulty is with penetration to deep infections, such as abscesses, where various factors such as acid pH, WBC products, and various enzymes can inactivate even high concentrations of certain drugs.

The CNS is one body site where antimicrobial penetration is relatively well defined, and correlations with clinical outcomes are established.[5,36] CSF concentrations of antimicrobial agents necessary to cure bacterial meningitis have been defined, and drugs that do not reach significant concentrations in the CSF should be either avoided or instilled directly, if feasible.

Caution must be exercised when selecting an antimicrobial agent for clinical use on the basis of tissue or fluid penetration. Body fluids where drug concentration data are clinically relevant include CSF, urine, synovial fluid, and peritoneal fluid. Apart from these areas, more attention should be paid to clinical efficacy, antimicrobial spectrum, toxicity, and cost than to comparative data on penetration into a given body site.

The proper route of administration for an antimicrobial depends on the site of infection. Parenteral therapy is warranted when patients are being treated for febrile neutropenia or deep-seated infections such as meningitis, endocarditis, and osteomyelitis. Severe pneumonia often is treated initially with IV antibiotics and switched to oral therapy as clinical improvement is evident.[4,37,38] Patients treated in the ambulatory setting for upper respiratory tract infections (eg, pharyngitis, bronchitis, sinusitis, and otitis media), lower respiratory tract infections, skin and soft-tissue infections, uncomplicated urinary tract infections, and selected sexually transmitted diseases can usually receive oral therapy.

Drug Toxicity

It is incumbent on health professionals to avoid toxic drugs whenever possible. Antibiotics associated with CNS toxicities, usually when not dose-adjusted for renal function, include penicillins, cephalosporins, quinolones, and imipenem. Hematologic toxicities generally are manifested with prolonged use of nafcillin (neutropenia), piperacillin (platelet dysfunction), cefotetan (hypoprothrombinemia), chloramphenicol (bone marrow suppression, both idiosyncratic and dose-related toxicity), and trimethoprim (megaloblastic anemia). Reversible nephrotoxicity classically is associated with aminoglycosides and vancomycin. Irreversible ototoxicity can occur with aminoglycosides. In the outpatient setting, patients must be counseled regarding photosensitivity

with azithromycin, quinolones, tetracyclines, pyrazinamide, sulfamethoxazole, and trimethoprim. Lastly, all antibiotics have been implicated in causing diarrhea and colitis secondary to *Clostridium difficile* (see Chapter 91).[39] List of potential antibiotic adverse drug reactions is provided in **Table 105-3**.

TABLE 105-3 Antimicrobial Adverse Drug Reactions

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
Penicillins	Hypersensitivity reactions and rash, drug fever, diarrhea, emesis, abdominal pain, hepatitis, interstitial nephritis, leukopenia, thrombocytopenia, Coomb's positive-hemolytic anemia, *C. difficile* colitis, electrolyte abnormalities, seizures	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria). During prolonged therapy and/or high-dose regimens, periodically monitor renal function, hepatic function, and CBC	Most serious reaction is immediate IgE-mediated anaphylaxis. Incidence is 0.05%, but 5%-10% can be fatal
Cephalosporins	Hypersensitivity reactions and rash, drug fever, diarrhea, interstitial nephritis, Coomb's positive-hemolytic anemia, leukopenia, thrombocytopenia, coagulopathy, hepatitis, *C. difficile* colitis	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria) and rash, renal function, hepatic function, and CBC	Patients with a history of IgE-mediated allergic reactions to penicillins should not receive a cephalosporin
Carbapenems	Hypersensitivity reactions and rash, headache, nausea, diarrhea, seizures, drug fever, eosinophilia, thrombocytopenia, hepatitis, *C. difficile* colitis	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria) and rash, renal function, hepatic function, and CBC	Skin test cross-sensitivity with penicillin reported to be up to 50%, but clinically significant cross-sensitivity reactions in penicillin-allergic patients reported to be as low as 1% Highest incidence of seizures with use of imipenem–cilastatin. More frequent in patients who are elderly, have history of seizure disorders

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
			and renal dysfunction
Monobactams	Rash, diarrhea, nausea, hepatitis, thrombocytopenia, *C. difficile* colitis	Monitor renal and hepatic function	May be used in patients with allergy to penicillins/cephalosporins
Aminoglycosides	Tubular necrosis and renal failure, vestibular and cochlear toxicity, neuromuscular blockade, vertigo, anemia, hypersensitivity	Monitor renal function, SDC, serum calcium, magnesium, sodium. Monitor for nausea, vomiting, nystagmus, and vertigo	Nephrotoxicity can be reversible. More frequent in patients with the following risk factors: elderly, history of renal dysfunction, concomitant administration of nephrotoxic drug (ie, cyclosporine, amphotericin B, radiocontrast, vancomycin), and duration of therapy Ototoxicities can be irreversible
Glycopeptides	Red man syndrome, phlebitis, renal dysfunction, neutropenia, leukopenia, eosinophilia, thrombocytopenia, drug fever	Monitor renal function, CBC, and SDC	Red man syndrome is associated with rapid infusion and nonspecific histamine release. May be prevented by prolonging infusions to over at least 60 minutes and pretreatment with antihistamines
Lipopeptides (daptomycin)	Hepatotoxicity, CPK elevation with or without myopathy, diarrhea, eosinophilic pneumonia, *C. difficile* colitis	Monitor LFTs, development of muscle pain/weakness, or neuropathy Obtain serum CPK levels at baseline and weekly (or more frequently in patients with prior or concomitant statin, renal dysfunction, or patients with elevations in CPK)	CPK elevation is dose-dependent. Obtain baseline and weekly CPK levels. Discontinue daptomycin if CPK exceeds 10 times normal level or if patient develops myopathy and CPK >1,000 international units/L (>16.7 µkat/L). Consider stopping statin therapy during treatment with daptomycin

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
Oxazolidinones	Myelosuppression (thrombocytopenia, leukopenia, and anemia), peripheral neuropathy, optic neuropathy, blindness, lactic acidosis, diarrhea, nausea, serotonin syndrome, interstitial nephritis	Monitor for signs and symptoms of serotonin syndrome particularly in patients with prior or concomitant serotonergic agents, CBC with differential. For prolonged therapy, perform visual function tests, monitor visual acuity and visual field defect	Myelosuppression is reversible and associated with treatment duration >2 weeks
Tetracyclines	GI upset, nausea, vomiting, diarrhea, hepatotoxicity, esophageal ulcerations, photosensitivity, azotemia, visual disturbances, vertigo, hyperpigmentation, deposition on teeth, hemolytic anemia, pseudotumor cerebri, pancreatitis, *C. difficile* colitis	Monitor CBC with differential, LFTs, and renal function	Doxycycline preferred in patients with renal dysfunction Vestibular symptoms more frequent in women than in men Avoid use during pregnancy and in children
Chloramphenicol	Myelosuppression, aplastic anemia, "gray baby syndrome," optic neuritis, peripheral neuropathy, digital paresthesias, GI upset, *C. difficile* colitis, hypersensitivity	Obtain baseline CBC with differential and every 2 days during therapy. Monitor SDC (particularly in children and in patients with hepatic or renal insufficiency), liver and renal function	Bone marrow suppression associated with doses >4 g/day. Serum levels >50 mcg/mL (mg/L; 155 µmol/L) are associated with increased risk for "gray baby syndrome"
Rifamycines	Discoloration of urine, tears, contact lens, sweat, hepatotoxicity, GI upset, flu-like syndrome, hypersensitivity, thrombocytopenia,	Monitor LFTs, bilirubin, renal function, CBC at baseline; continue to monitor every 2-4 weeks in patients with	Increased potential for hepatitis with concomitant hepatotoxic drugs (ie, TB drugs)

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
	leukopenia, drug fever, interstitial nephritis, thrombocytopenia	hepatic impairment or receiving concomitant hepatotoxic drugs	
Macrolides/azalide	GI intolerance, diarrhea, prolonged QTc, cholestatic hepatitis, reversible ototoxicity, torsade de pointes, rash, hypothermia, exacerbation of myasthenia gravis	Monitor LFTs and ECG in high-risk patients	
Clindamycin	Diarrhea, *C. difficile* colitis, nausea, vomiting, generalized rash, hypersensitivity	For prolonged therapy, monitor liver and renal function	
Fluoroquinolones	GI intolerance, headache, malaise, insomnia, dizziness, photosensitivity, QTc prolongation, tendon rupture, peripheral neuropathy, crystalluria, seizure, interstitial nephritis, Stevens-Johnson syndrome, allergic pneumonitis, *C. difficile* colitis	Monitor renal function, encephalopathic changes (eg, confusion, hallucinations, and tremor)	Tendon rupture more frequently seen in the elderly and kidney, heart, and lung transplant recipients, and with concurrent use of corticosteroids
Polymyxins	Nephrotoxicity, neurotoxicity (paresthesia, vertigo, ataxia, blurred vision, slurred speech), neuromuscular blockade, bronchospasm (administered via inhalation)	Obtain baseline renal function tests and regularly during therapy. Monitor for signs of neuromuscular blockade (eg, respiratory depression, apnea, muscle weakness)	Nephrotoxicity is dose-dependent
Sulfonamides and trimethoprim	GI intolerance, rash, hyperkalemia, bone marrow suppression (anemia with folate deficiency,	Monitor for hypersensitivity reactions and rash, CBC, renal and hepatic function,	HIV-infected patients are at increased risk for developing adverse drug reactions Methemoglobinemia due to severe G6PD deficiency

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
	thrombocytopenia, and leukopenia), serum sickness, hepatitis, photosensitivity, crystalluria with azotemia, urolithiasis, methemoglobinemia, Stevens-Johnson syndrome, toxic epidermal necrolysis, aseptic meningitis, pancreatitis, interstitial nephritis, Sweet syndrome, neurologic toxicity	serum potassium, serum glucose	
Metronidazole	GI intolerance, headache, metallic taste, dark urine, peripheral neuropathy, disulfiram reactions with alcohol, insomnia, stomatitis, aseptic meningitis, dysarthria	Monitor hepatic function, mental/neurologic status	Peripheral neuropathy is reversible and associated with prolonged treatment

CBC, complete blood count; CPK, creatine phosphokinase; LFT, liver function test; SDC, serum drug concentrations; TB, tuberculosis.

Aside from consideration of drug toxicity, some antimicrobial use requires more intensive risk–benefit analysis. An example of this is the decision to use isoniazid prophylactically to prevent tuberculosis. Because the hepatotoxicity of isoniazid increases in frequency with age, older persons (greater than 45 years of age) who are candidates for isoniazid prophylaxis (positive skin test) must have additional risk factors for tuberculosis to balance the potential toxic effects. These include evidence of recent skin test conversion, immunosuppression, or previous gastrectomy. Older patients without additional risk factors are more likely to suffer toxicity from isoniazid than derive benefit from its use.

Combination Antimicrobial Therapy

6 In selecting a drug regimen for a given patient, consideration must be given to the necessity of using more than one drug. Inappropriate or inadequate antimicrobial therapy has been associated with increased morbidity and mortality.[40] Combinations of antimicrobials generally are used to broaden the spectrum of coverage for empirical therapy, achieve synergistic activity against the infecting organism, and prevent the emergence of resistance.

Broadening the Spectrum of Coverage

Increasing the coverage of antimicrobial therapy generally is necessary in two scenarios. First is in mixed infections where multiple organisms are likely to be present. This is the case in intra-abdominal and female pelvic infections, in which a variety of aerobic and anaerobic bacteria can produce disease.[41] Traditionally, a combination of a drug active against aerobic Gram-negative bacilli (such as an aminoglycoside) and a drug active against anaerobic bacteria (such as metronidazole or clindamycin) is selected. Newer compounds, which possess good activity against both of these types of organisms, such as the β-lactam/β-lactamase inhibitor combinations, carbapenems, or glycylcyclines, might be adequate to replace the combination and thereby reduce the cost of therapy. The second scenario is for critically ill patients with presumed health care-associated infections in which an increased spectrum of activity is desirable.[37] Health care-associated infections are frequently caused by multi-drug resistant pathogens; combination therapy is used in this setting to ensure that at least one of the antimicrobials will be active against the pathogen(s).

Synergism

The achievement of synergistic antimicrobial activity is advantageous for infections caused by enteric Gram-negative bacilli in immunosuppressed patients. Laboratory tests to identify synergy between antibiotic combinations are described in Chapter 24. Traditionally, combinations of aminoglycosides and β-lactams have been used because these drugs together generally act synergistically against a wide variety of bacteria. However, the data supporting superior efficacy of synergistic over nonsynergistic combinations are weak. At best, synergistic combinations appear to produce better results in infections caused by *Pseudomonas aeruginosa* and *Enterococcus* species.[33,42,43,44]

The most obvious example of the use of synergy is the treatment of enterococcal endocarditis. The causative organism is usually only inhibited by penicillins, but it is killed rapidly by the addition of streptomycin or gentamicin to a penicillin. The need for bactericidal activity in the treatment of endocarditis underscores the need for these synergistic combinations.[9,45]

Preventing Resistance

The use of antimicrobial combinations to prevent the emergence of resistance is applied widely but not often realized. The only circumstance where this has been clearly effective is in the treatment of tuberculosis. The prevalence of resistance to a first-line drug such as isoniazid or rifampin in a population of organisms may be as high as 1 in 10^6 to 10^8. Because the bacterial load in a patient with active tuberculosis often exceeds this, two drugs are given to reduce the likelihood of encountering resistance to less than 1 in 10. There is ample evidence from in vitro data and experimental bacterial infections that combinations of drugs with different mechanisms are effective in the prevention of the emergence of resistance. Data from clinical trials, however, either are conflicting or do not convincingly support this concept.[42]

Clinical Controversy...

Rapid initiation of appropriate antibiotic therapy is associated with improved outcomes among patients with infections. Therefore, there is a great need for reliable methods to rapidly screen patient risk factors for infections due to multi-drug resistant pathogens. However, prediction tools or criteria definitions may lack sensitivity and or specificity, and may lead to inadequate therapy or to overuse of broad-spectrum antibiotic therapy. For example, there have been numerous studies evaluating the utility of the healthcare-associated pneumonia (HCAP) criteria in guiding empiric broad-spectrum therapy. Despite evidence of high sensitivity in identifying potential multi-drug resistant pathogens, other studies have demonstrated that HCAP criteria have low specificity for identifying specific organisms, such as MRSA or Pseudomonas, and may lead to overuse of antibiotics. Currently, whether the HCAP criteria appropriately guide broad-spectrum empiric therapy remains a debate.

Disadvantages of Combination Therapy

Although there are potentially beneficial effects from combining drugs, there also are potential disadvantages, including increased cost, greater risk of drug toxicity such as nephrotoxicity with aminoglycosides, amphotericin, and possibly vancomycin, and superinfection with even more resistant bacteria.[42,44,46]

The combination of two or more antibiotics can result in antagonistic effects. For example, the effect of antagonism may be evident when one drug induces β-lactamase production and another drug is β-lactamase unstable. Cefoxitin and imipenem are examples of drugs capable of inducing β-lactamases and may result in more rapid inactivation of penicillins when used together.

MONITORING THERAPEUTIC RESPONSE

7 After antimicrobial therapy has been instituted, the patient must be monitored carefully for a therapeutic response. Culture and sensitivity reports from specimens sent to the microbiology laboratory must be reviewed and the therapy changed accordingly. Use of agents with the narrowest spectrum of activity against identified pathogens is recommended. If anaerobes are suspected, even if they are not identified, anti-anaerobic therapy should be continued.

Patient monitoring should include many of the same parameters used to diagnose the infection. The WBC count and temperature should start to normalize. Physical complaints from the patient also should diminish (ie, decreased pain, shortness of breath, cough, or sputum production). Appetite should improve. However, radiologic improvement can lag behind clinical improvement.

Determinations of serum (or other fluid) levels of antimicrobials can be useful in ensuring outcome, preventing toxicity, or both. There are only a few antimicrobials that require serum concentration monitoring and then only in selected situations. These include the aminoglycosides, vancomycin, flucytosine, and chloramphenicol. Achievement of adequate aminoglycoside concentrations within the first few days of therapy of Gram-negative infection has been correlated with better therapeutic outcome.[47]

Changes in the volume of distribution can have a significant impact on the efficacy, safety, or both of

therapy. An unexpectedly low volume of distribution (such as in the dehydrated patient) will result in higher, potentially toxic drug concentrations, whereas a larger-than-expected volume of distribution (such as in patients with edema or ascites) will result in low, potentially subtherapeutic concentrations. The most effective methods use measured serum concentrations of the drugs rather than estimations from renal function tests to assess true drug clearance from the body.

8 As patients improve clinically, the route of administration should be reevaluated. Streamlining therapy from parenteral to oral (switch therapy) has become an accepted practice for many infections.[5] Criteria that should be present to justify a switch to oral therapy include (a) overall clinical improvement, (b) lack of fever for 8 to 24 hours, (c) decreased WBC count, and (d) a functioning GI tract. Drugs that exhibit excellent oral bioavailability when compared with IV formulations include ciprofloxacin, clindamycin, doxycycline, levofloxacin, metronidazole, moxifloxacin, linezolid, and trimethoprim–sulfamethoxazole.

FAILURE OF ANTIMICROBIAL THERAPY

9 A variety of factors may be responsible for an apparent lack of response to therapy. Patients who fail to respond over 2 to 3 days require a thorough reevaluation. It is possible that the disease is not infectious or is nonbacterial in origin, or there is an undetected pathogen in a polymicrobial infection. Other factors include those directly related to drug selection, the host, or the pathogen. Laboratory error in identification, susceptibility testing, or both (presence of inoculum effect or resistant subpopulations) is a rare cause of antimicrobial failure.

Failures Caused by Drug Selection

Factors related directly to the drug selection include an inappropriate drug selection, dosage, or route of administration. Malabsorption of a drug product because of GI disease (such as a short-bowel syndrome) or a drug interaction (such as complexation of fluoroquinolones with multivalent cations resulting in reduced absorption) can lead to potentially subtherapeutic serum concentrations. Accelerated drug elimination is also possible. This can occur in patients with cystic fibrosis or during pregnancy, when more rapid clearance or larger volumes of distribution can result in low serum concentrations, particularly for aminoglycosides. A common cause of failure of therapy is poor penetration into the site of infection. This is especially true for sites such as the CNS, eye, and prostate gland. Drug failure also can result from drugs that are highly protein bound or that are chemically inactivated at the site of infection.

Failures Caused by Host Factors

Host defenses must be considered when evaluating a patient who is not responding to antimicrobial therapy. Patients who are immunosuppressed (eg, granulocytopenia from chemotherapy or AIDS) may respond poorly to therapy because their defenses are inadequate to eradicate the infection despite seemingly adequate drug regimens. A good example is the poor response of infection in granulocytopenic patients that is seen when their WBC counts remain low during therapy. This

contrasts with a much better response when granulocyte counts increase during therapy.

Other host factors are related to the need for surgical drainage of abscesses or removal of foreign bodies, necrotic tissue, or both. If these situations are not corrected, they result in persistent infection and, occasionally, bacteremia despite adequate antimicrobial therapy.

Failures Caused by Microorganisms

There are two types of resistance, intrinsic and acquired resistance. Intrinsic resistance is when the antimicrobial agent never had activity against the bacterial species. For example, Gram-negative bacteria are naturally resistant to vancomycin because the drug cannot penetrate the outer membrane of Gram-negative bacteria. Acquired resistance is when the antimicrobial agent was originally active against the bacterial species but the genetic makeup of the bacteria has changed so the drug can no longer be effective.[48]

The strategies used by bacteria to develop acquired resistance are primarily classified into four general mechanisms of resistance: (a) alteration in the target site, (b) change in membrane permeability, (c) efflux pump, and (d) drug inactivation. Bacteria can use one or more of these mechanisms against a specific antibiotic class. Furthermore, a single mechanism of resistance can result in resistance to multiple related or unrelated classes of antibiotics.

Drug inactivation through either β-lactamases or aminoglycoside-modifying enzymes is the predominant mechanism of resistance. For example, β-lactamases can be either plasmid or chromosomally mediated. In addition, the expression of β-lactamases can be induced or constitutive. There are now multiple types and classes of β-lactamases identified, which is beyond the scope of this chapter. However, there are several outstanding papers discussing all of the different types of β-lactamases.[49,50,51]

The increase in resistance among bacteria is believed to be a result of continued overuse of antimicrobials in the community, as well as in hospitals, and the increasing prevalence of immunosuppressed patients receiving long-term suppressive antimicrobials for the prevention of infections. These resistance patterns are regionally variable, and susceptibility patterns in the community (or hospital) should be monitored closely to promote rational antimicrobial selection.[48]

Enterococci have been isolated with multiple resistance patterns. They may be resistant to β-lactams (by virtue of β-lactamase production, altered penicillin-binding proteins [PBPs], or both), vancomycin (via alterations in peptidoglycan synthesis), and high levels of aminoglycosides (via enzymatic degradation). Pneumococci resistant to penicillins, certain cephalosporins, and macrolides are increasingly common. These organisms generally are susceptible to vancomycin, the new fluoroquinolones, and cefotaxime or ceftriaxone. However, antimicrobial agents such as linezolid, daptomycin, telavancin, and tigecycline have been targeted at resistant Gram-positive bacteria.

Treatment of an infection caused by *Enterobacter*, *Citrobacter*, *Serratia*, or *P. aeruginosa* with a third-generation cephalosporin or aztreonam may produce an initial clinical response by eradicating all the susceptible bacteria in the population. Within a few days, however, the highly resistant

subpopulations have a selective advantage and can overgrow the infection site to produce a relapse. These bacteria usually retain susceptibility to aminoglycosides, carbapenems, and fluoroquinolones but are resistant to all other β-lactams. Host defenses are extremely important in this scenario. Debilitated patients with pulmonary infections, abscesses, or osteomyelitis are at high risk for drug failure. In these situations, a combination regimen to prevent the emergence of resistance or the use of carbapenem or a fluoroquinolone may be warranted for empirical therapy.

ANTIMICROBIAL STEWARDSHIP

The importance of the selection and continuation of appropriate antimicrobial therapy in acute care hospitals are part of a wide movement that is referred to as 'antimicrobial stewardship'. Antimicrobial stewardship programs are aimed at "optimizing antimicrobial selection, dosing, route, and duration of therapy to maximize clinical cure or prevention of infection while limiting the unintended consequences, such as the emergence of resistance, adverse drug events, and cost." Many institutions have developed an antibiotic stewardship program. The team is generally a multidisciplinary group including representation from microbiology, infection control, administration, information technology, pharmacy including infectious disease-trained clinical pharmacists, and physicians from several disciplines, including infectious disease. Components of antimicrobial stewardship activities include formulary restriction, prospective audit and feedback of antimicrobial prescriptions to clinicians, education, use of clinical order sets and guidelines, de-escalation of therapy, and intravenous to oral antimicrobial conversion.[52,53]

Antibiotic Formulary

One of the main roles of an antimicrobial stewardship team is to decide which antibiotics to include on their formularies. The decision to have a formulary remains controversial; however, restricting choices does encourage familiarity with a core of antibiotics for residents and attending physicians. Open formularies allow the empirical use of any commercially available antibiotics, with recommended guidelines for changes when culture and sensitivity results are finalized. The implementation of the guidelines and restrictions requires the cooperation of the entire medical staff. Education is vital to the success of the antibiotic formulary.

Keeping Current

Attention must be paid to the literature on antimicrobials to assist in the selection of therapy. Evidence-based practice guidelines from the Infectious Diseases Society of America can aid clinicians to direct appropriate therapy for specific infectious disease syndromes. In addition, the results from prospective, controlled, randomized clinical trials should be evaluated whenever possible when considering appropriate antimicrobial therapy. Results from prelicensing open trials offer only limited information that can be useful in this regard because patients in these trials generally are not seriously ill and are not infected with multiple resistant bacteria. Other confounding factors found in most clinical situations are excluded by virtue of the study design. Therefore, comparative data in more seriously ill patients are essential for the appropriate application of new agents.

Postmarketing trials are also important because results can demonstrate superiority of one regimen over another, in efficacy, safety, or cost-effectiveness. Appropriate antimicrobial therapy can change as new organisms are discovered, susceptibility patterns change, new drugs become available, and new clinical trial results are published. Classical thinking in the treatment of infectious diseases will continue to change and evolve to maintain antimicrobial efficacy. Optimal use of modern antimicrobials is just beginning to be defined.

ABBREVIATIONS

APPENDIX 105-1: DRUGS OF CHOICE, FIRST CHOICE, *ALTERNATIVE(S)*

Gram-Positive Cocci

Enterococcus faecalis (generally not as resistant to antibiotics as *Enterococcus faecium*)

- Serious infection (endocarditis, meningitis, pyelonephritis with bacteremia)
  - Ampicillin (or penicillin G) + (gentamicin or streptomycin)
  - Vancomycin + (gentamicin or streptomycin), daptomycin, linezolid, tedizolid, telavancin, tigecycline[a]
- Urinary tract infection
  - Ampicillin, amoxicillin
  - *Fosfomycin* or *nitrofurantoin*

E. faecium (generally more resistant to antibiotics than *E. faecalis*)

- Recommend consultation with infectious disease specialist
  - Linezolid, quinupristin/dalfopristin, daptomycin, tigecycline[a]

Staphylococcus aureus/Staphylococcus epidermidis

- Methicillin (oxacillin)-sensitive
  - Nafcillin or oxacillin
  - *FGC,[b,c] trimethoprim–sulfamethoxazole, clindamycin, BL/BLI[d]*
- Hospital-acquired methicillin (oxacillin)–resistant
  - Vancomycin ± (gentamicin or rifampin)
  - *Ceftaroline, daptomycin, linezolid, telavancin, tigecycline,[a] trimethoprim–sulfamethoxazole, quinupristin–dalfopristin*
- Community-acquired methicillin (oxacillin)–resistant

- Clindamycin, trimethoprim–sulfamethoxazole, doxycycline[a]
- *Ceftaroline, dalbavancin, daptomycin, linezolid, oritivancin, tedizolid, telavancin, tigecycline,*[a] or *vancomycin*

Streptococcus (groups A, B, C, G, and *Streptococcus bovis*)

- Penicillin G or V or ampicillin
- *FGC,*[b,c] *erythromycin, azithromycin, clarithromycin*

Streptococcus pneumoniae

- Penicillin-sensitive (minimal inhibitory concentration [MIC] <0.1 mcg/mL [mg/L])
  - Penicillin G or V or ampicillin
  - *FGC,*[b,c] *doxycycline,*[a] *azithromycin, clarithromycin, erythromycin*
- Penicillin intermediate (MIC 0.1-1 mcg/mL [mg/L])
  - High-dose penicillin (12 million units/day for adults) or ceftriaxone[c] or cefotaxime[c]
  - *Levofloxacin,*[a] *moxifloxacin,*[a] *gemifloxacin,*[a] *or vancomycin*
- Penicillin-resistant (MIC ≥1.0 mcg/mL [mg/L])
  - Recommend consultation with infectious disease specialist.
    - – *Vancomycin* ± *rifampin*
    - – *Per sensitivities: ceftaroline, cefotaxime, ceftriaxone,*[c] *levofloxacin,*[a] *moxifloxacin,*[a] *or gemifloxacin*[a]

Streptococcus, viridans group

- Penicillin G ± gentamicin[e]
- *Cefotaxime,*[c] *ceftriaxone,*[c] *erythromycin, azithromycin, clarithromycin*, or *vancomycin* ± *gentamicin*

GRAM-NEGATIVE COCCI

Moraxella (Branhamella) catarrhalis

- Amoxicillin–clavulanate, ampicillin–sulbactam
- *Trimethoprim–sulfamethoxazole, erythromycin, azithromycin, clarithromycin, doxycycline,*[a] *SGC,*[c]

[f] *cefotaxime,*[c] *ceftriaxone,*[c] or *TGCPO*[c,g]

Neisseria gonorrhoeae (also give concomitant treatment for *Chlamydia trachomatis*)

- Disseminated gonococcal infection
  - Ceftriaxone[c] or cefotaxime[c]
  - *Oral follow up: cefpodoxime,*[c] *ciprofloxacin,*[a] or *levofloxacin*[a]
- Uncomplicated infection
  - Ceftriaxone,[c] cefotaxime,[c] or cefpodoxime[c]
  - *Ciprofloxacin*[a] or *levofloxacin*[a]

Neisseria meningitides

- Penicillin G
- *Cefotaxime*[c] or *ceftriaxone*[c]

GRAM-POSITIVE BACILLI

Clostridium perfringens

- Penicillin G ± clindamycin
- *Metronidazole,*[a] *clindamycin, doxycycline,*[a] *cefazolin,*[c] *carbapenem*[h,i]

Clostridium difficile

- Oral metronidazole[a]
- *Oral vancomycin* or *fidaxomicin*

GRAM-NEGATIVE BACILLI

Acinetobacter spp.

- Doripenem, imipenem, or meropenem ± aminoglycoside[j] (amikacin usually most effective)
- *Ampicillin–sulbactam, polymyxins,*[i] or *tigecycline*[a]

Bacteroides fragilis (and others)

- Metronidazole[a]

- *BL/BLI,[d] clindamycin, cefoxitin,[c] cefotetan,[c] ceftolozane-azobactam, ceftazidime-avibactam*, or *carbapenem[h,i]*

Enterobacter spp.

- Carbapenem[h] or cefepime ± aminoglycoside[j]
- *ceftolozane-tazobactam, ceftazidime-avibactam, ciprofloxacin,[a] levofloxacin,[a] piperacillin–tazobactam, ticarcillin–clavulanate*

Escherichia coli

- Meningitis
  - Cefotaxime,[c] ceftriaxone,[c] meropenem
- Systemic infection
  - Cefotaxime[c] or ceftriaxone[c]
  - *BL/BLI,[d] fluoroquinolone,[a,k] carbapenem[h,i]*
- Urinary tract infection
  - Most oral agents: check sensitivities
  - Ampicillin, amoxicillin–clavulanate, doxycycline,[a] or cephalexin[c]
  - *Aminoglycoside,[j] FGC,[b,c] nitrofurantoin, fluoroquinolone[a,k]*

Gardnerella vaginalis

- Metronidazole[a]
- *Clindamycin*

Haemophilus influenzae

- Meningitis
  - Cefotaxime[c] or ceftriaxone[c]
  - *Meropenem[i]*
- Other infections
  - BL/BLI,[d] or if β-lactamase-negative, ampicillin or amoxicillin

- *Trimethoprim–sulfamethoxazole, cefuroxime,*[c] *azithromycin, clarithromycin*, or *fluoroquinolone*[a,k]

Klebsiella pneumoniae

- BL/BLI,[d] cefotaxime,[c] ceftriaxone,[c] cefepime[c]
- Carbapenem,[h,i] *ceftolozane-tazobactam, ceftazidime-avibactam*, fluoroquinolone[a,k]

Legionella spp.

- Azithromycin, erythromycin ± rifampin, or fluoroquinolone[a,k]
- Trimethoprim–sulfamethoxazole, clarithromycin, or doxycycline[a]

Pasteurella multocida

- Penicillin G, ampicillin, amoxicillin
- *Doxycycline,*[a] *BL/BLI,*[d] *trimethoprim–sulfamethoxazole* or *ceftriaxone*[c]

Proteus mirabilis

- Ampicillin
- *Trimethoprim–sulfamethoxazole*

Proteus (indole-positive) (including *Providencia rettgeri*, *Morganella morganii*, and *Proteus vulgaris*)

- Cefotaxime,[c] ceftriaxone,[c] or fluoroquinolone[a,k]
- *BL/BLI,*[d] *aztreonam,*[l] *aminoglycosides,*[j] *carbapenem,*[h,i] *ceftolozane-tazobactam, ceftazidime-avibactam*

Providencia stuartii

- Amikacin, cefotaxime,[c] ceftriaxone,[c] fluoroquinolone[a,k]
- *Trimethoprim–sulfamethoxazole, aztreonam,*[l] *carbapenem*[h,i]

Pseudomonas aeruginosa

- Urinary tract infection only
  - Aminoglycoside[j]
  - *Ciprofloxacin,*[a] *levofloxacin*[a]

- Systemic infection
    - Cefepime,[c] ceftazidime,[c] doripenem,[i] imipenem,[i] meropenem,[i] piperacillin–tazobactam, or ticarcillin–clavulanate + aminoglycoside[j]
    - *Aztreonam,[l] ceftolozane-tazobactam, ceftazidime-avibactam, ciprofloxacin,[a] levofloxacin,[a] polymyxin*[i]

Salmonella typhi

- Ciprofloxacin,[a] levofloxacin,[c] ceftriaxone,[c] cefotaxime[c]
- *Trimethoprim–sulfamethoxazole*

Serratia marcescens

- Ceftriaxone,[c] cefotaxime,[c] cefepime,[c] ciprofloxacin,[a] levofloxacin[a]
- *Aztreonam,[l] carbapenem,[h,i] piperacillin–tazobactam, ticarcillin–clavulanate*

Stenotrophomonas (Xanthomonas) maltophilia (generally very resistant to all antimicrobials)

- Trimethoprim–sulfamethoxazole.
- *Check sensitivities to ceftazidime,[c] doxycycline,[a] minocycline,[a]* and *ticarcillin–clavulanate*

MISCELLANEOUS MICROORGANISMS

Chlamydia pneumoniae

- Doxycycline[a]
- *Azithromycin, clarithromycin, erythromycin, or fluoroquinolone*[a,k]

C. trachomatis

- Azithromycin or doxycycline[a]
- *Levofloxacin,[a] erythromycin*

Mycoplasma pneumoniae

- Azithromycin, clarithromycin, erythromycin, fluoroquinolone[a,k]
- *Doxycycline*[a]

SPIROCHETES

Treponema pallidum

- Neurosyphilis
    - Penicillin G
    - *Ceftriaxone*[c]
- *Primary* or *secondary*
    - Benzathine, penicillin G
    - *Ceftriaxone*[c] or *doxycycline*[a]

Borrelia burgdorferi (choice depends on stage of disease)

- Ceftriaxone[c] or cefuroxime axetil,[c] doxycycline,[a] amoxicillin
- *High-dose penicillin, cefotaxime*[c]

[a]Not for use in pregnant patients or children.

[b]First-generation cephalosporins—IV: cefazolin; orally: cephalexin, cephradine, or cefadroxil.

[c]Some penicillin-allergic patients may react to cephalosporins.

[d]β-Lactam/β-lactamase inhibitor combination—IV: ampicillin–sulbactam, piperacillin–tazobactam, and ticarcillin–clavulanate; orally: amoxicillin–clavulanate.

[e]Gentamicin should be added if tolerance or moderately susceptible (MIC >0.1 mcg/mL [mg/L]) organisms are encountered; streptomycin is used but can be more toxic.

[f]Second-generation cephalosporins—IV: cefuroxime; orally: cefaclor, cefditoren, cefprozil, cefuroxime axetil, and loracarbef.

[g]Third-generation cephalosporins—orally: cefdinir, cefixime, cefetamet, cefpodoxime proxetil, and ceftibuten.

[h]Carbapenem: doripenem, ertapenem, imipenem/cilastatin, and meropenem.

[i]Reserve for serious infection.

[j]Aminoglycosides: gentamicin, tobramycin, and amikacin; use per sensitivities.

[k]Fluoroquinolones IV/orally: ciprofloxacin, levofloxacin, and moxifloxacin.

[l]Generally reserved for patients with hypersensitivity reactions to penicillin.

Chapter 106: Central Nervous System Infections

Ramy H. Elshaboury; Aileen S. Ahiskali; Jessica S. Holt; John C. Rotschafer

INTRODUCTION

KEY CONCEPTS

- 1 The four most common pathogens of acute bacterial meningitis in the United States are *Streptococcus pneumoniae*, group B *Streptococcus*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b, although routine vaccinations are having a dramatic effect on the incidence and distribution of these pathogens.

- 2 In cases of bacterial meningitis, initial findings can include (a) presenting signs and symptoms: fever, headache, nuchal rigidity (the classic triad), Brudzinski's or Kernig's sign, and altered mental status; and (b) abnormal cerebrospinal fluid (CSF) chemistries: elevated white blood cell (WBC) count (greater than 1,000 cells/mm^3[greater than 1 × 10^2/L]), elevated protein (greater than 50 mg/dL [greater than 500 mg/L]), and decreased glucose levels (less than 45 mg/dL [less than 2.5 mmol/L]).

- 3 Two main microbiologic tests that should be obtained include a gram stain and culture of the CSF. Molecular testing such as polymerase chain reaction (PCR), latex coagglutination, and enzyme immunoassay (EIA) tests can provide for the rapid identification of several causes of meningitis.

- 4 Three primary goals of treatment in meningitis include (a) eradication of infection, (b) amelioration of signs and symptoms, and (c) prevention of the development of neurologic sequelae, such as seizures, deafness, coma, and death.

- 5 When selecting antibiotics, the clinician must consider the antibiotic concentration at the site of infection as well as the spectrum of antibacterial activity. Empirical choices should be based on age, predisposing conditions, vaccination history, and comorbidities. (a) Ceftriaxone or cefotaxime and vancomycin are reasonable initial choices for empirical coverage of community-acquired meningitis in adult patients. (b) *Listeria monocytogenes* is a common pathogen in infants and elderly; therefore, ampicillin with or without gentamicin should be empirically added to antimicrobial regimens.

- 6 Empirical coverage with an appropriate antibiotic should be started as soon as possible when clinical suspicion of meningitis exists. If there is a delay in obtaining a lumbar puncture (even 30-60 minutes), or if the patient is to undergo neuroimaging, the first dose of an antibiotic should not be withheld.

- 7 Antibiotic dosages for the treatment of meningitis should be optimized to ensure adequate CNS therapeutic concentrations.

- 8 The duration of antibiotic treatment for meningitis has not been standardized; however, it is generally based on the causative organism and the individual case, and may range from 7 to 21 days.

- 9 Close contacts and relatives of the index case should be assessed for appropriate chemoprophylaxis and vaccinations, particularly for *N. meningitidis* and *H. influenzae* meningitis.

- 10 Steroid treatment includes dexamethasone of 0.15 mg/kg per dose given four times daily for 4 days in infants and children older than 2 months of age with proven or strongly suspected bacterial meningitis. Steroids should be started prior to the first dose of antibiotics.

Central nervous system (CNS) infections are caused by a variety of pathogens, including bacteria, viruses, fungi, and parasites. Infections are the result of hematogenous spread from a primary infection site, seeding from a parameningeal focus, reactivation from a latent site, trauma, or congenital defects within the CNS. Newer diagnostic techniques have enabled more rapid and definitive diagnoses, thus diminishing the number of unknown “aseptic meningitis” diagnoses and improving targeted therapy. Bacteria resistant to multiple antibiotics present new challenges in the management of CNS infections. This chapter presents the etiology, pathophysiology, therapy, and prophylaxis of these infections, concentrating predominantly on bacterial meningitis.

EPIDEMIOLOGY

Approximately 4,100 cases of acute community-acquired bacterial meningitis, excluding epidemics, occurred annually in the United States between 2003 and 2007, resulting in approximately 500 deaths.[1] Risk factors and mortality rates widely vary depending on the causative microorganism and age group, and as high as 20% (range 12.3%-35.3%) of survivors will experience one or more neurologic disabilities.[2] Neurologic sequelae frequently associated with bacterial meningitis include seizures, sensorineural hearing loss, and hydrocephalus. While risk for the development of neurologic sequelae depends on the infecting organism, pneumococcal meningitis is typically associated with the highest risk.[2,3] Despite the availability of antimicrobial therapy against the most common CNS pathogens, CNS infections continue to pose significant morbidity and mortality.

ETIOLOGY

CNS infections are caused by a variety of microorganisms. Historically, infections were primarily community-acquired; however, an increasing number of cases are now nosocomial.[4] *Haemophilus influenzae* type b (Hib) was the most commonly identified cause of bacterial meningitis until the introduction of the Hib conjugate vaccine in 1990,[5] when *Streptococcus pneumoniae* became the most commonly identified cause.[1,6] Between 2003 and 2007 in the United States, *S. pneumoniae* accounted for 58% of all bacterial meningitis cases, followed by group B *Streptococcus* (18.1%), *Neisseria meningitidis* (13.9%), *H. influenzae* (6.7%), and *L. monocytogenes* (3.4%).[1] Other causative organisms included gram-negative organisms and *Staphylococcus* spp.[4,6]

Following the release of the pneumococcal heptavalent protein-polysaccharide conjugate vaccine (PCV7) in 2000, the rate of invasive pneumococcal disease (IPD), including pneumococcal meningitis, steadily dropped from 24.3 cases per 100,000 people in 1999 to 17.3 cases per 100,000 in 2001 and 13.5 cases per 100,000 in 2007.[7] The largest impact was in children younger than 2 years of age, where a nearly 70% decline in infection rate was reported as a result of implementation in the routine childhood vaccination schedule. This positive effect carried into the adult population with significant reduction in IPD across all age groups, despite stagnant adult vaccination coverage.[8] Further reductions in IPD in the United States and Europe were also noted following the introduction of the 13-valent pneumococcal conjugate vaccine (PCV13) in 2010 for routine childhood vaccination, and later for high-risk and older adults.[9,10] Widespread availability of childhood vaccination against Hib starting in 1980s in the United States has also resulted in a dramatic reduction of invasive infections, including meningitis, in the past 20 to 30 years. Finally, targeted meningococcal vaccination for high-risk infants, adolescents, and adults have similarly impacted the epidemiology and risk of meningococcal meningitis, and further changes are expected following the availability of meningococcal group B vaccines in the United States.[11] As a result of the rapid decline of acute community-acquired bacterial meningitis rates in children, the median age of patients increased from 30.3 years in 1998 to 41.3 years in 2007 in the United States.[1]

Both the Hib and pneumococcal vaccines are of limited availability in low-income and developing countries where cost is often prohibitive. Thus rates of invasive disease, neurologic sequelae, and case fatalities among children and adults continue to be substantially higher than western developed countries.[2]

ANATOMY AND PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM

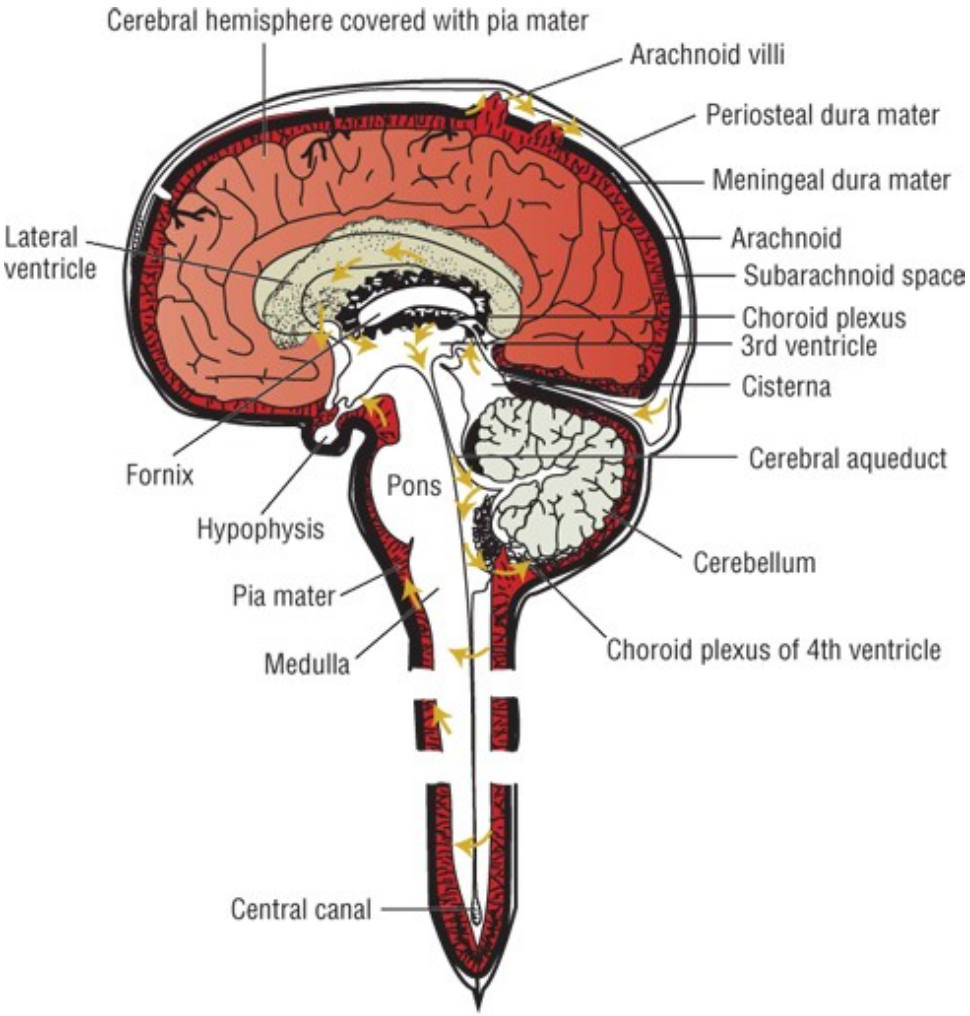
Meninges

The skull and vertebrae protect the CNS from blunt or penetrating trauma (**Fig. 106-1**). The brain is suspended in these structures by cerebrospinal fluid (CSF) and is surrounded by the meninges. The meninges are made up of three separate membranes: dura mater, arachnoid, and pia mater.[12] Dura mater, or pachymeninges, lies directly beneath and is adherent to the skull. The other two membranes are referred to collectively as leptomeninges. Pia mater lies directly over brain tissue.

Arachnoid, the middle layer, lies between the dura mater and the pia mater. The subarachnoid space, located between the arachnoid and the pia mater, is the conduit for CSF. By definition, meningitis refers to inflammation of the subarachnoid space or spinal fluid, whereas encephalitis is an inflammation of the brain tissue itself. Since infectious microorganisms frequently are an underlying cause of these inflammatory processes, the terms meningitis, encephalitis, or meningoencephalitis are frequently used to denote an infectious process.

FIGURE 106-1

Diagram of the central nervous system.



Cerebrospinal Fluid

Approximately 85% of the CSF is produced within the third, fourth, and lateral ventricles by the choroid plexus (Fig. 106-1). CSF volume in the CNS is related to patient age: infants have approximately 40 to 60 mL of CSF, older children have 60 to 100 mL, while adults have 115 to 160 mL. Normally, CSF is produced at the rate of approximately 500 mL/day and flows unidirectionally

downward through the spinal cord. The CSF is removed by the arachnoid villi and vertebral venous plexus located in the spinal cord and does not recommunicate with the point of production.[12]

2 The CSF normally is clear, with a protein content of less than 50 mg/dL (500 mg/L), a glucose concentration of approximately 50% to 60% of the simultaneous peripheral serum glucose concentration, and a pH of approximately 7.4. Also, it typically contains fewer than five WBCs per cubic millimeter (fewer than 5×10^6/L), all of which should be lymphocytes (**Table 106-1**).[13,14,15,16,17] As meninges become inflamed, the constituency of the CSF changes, and these abnormalities can be used diagnostically as markers of CNS infections.

TABLE 106-1 Mean Values of the Components of Normal and Abnormal Cerebrospinal Fluid[13,14,15,16,17]

Type	Normal	Bacterial	Viral	Fungal	Tuberculosis
WBC (cells/mm^3 or 10^6/L)	<5 (<30 in newborns)	1,000-5,000	5-500	100-400	25-500
Differential[a]	Monocytes	Neutrophils	Lymphocytes	Lymphocytes	Variable
Protein (mg/dL)	<50 (<500 mg/L)	Elevated	Mild elevation	Elevated	Elevated
Glucose (mg/dL)	45-80 (2.5-4.4 mmol/L)	Low	Normal	Low	Low
CSF/blood glucose ratio	50%-60%	Decreased	Normal	Decreased	Decreased

[a]Initial cerebrospinal fluid (CSF), while blood cell (WBC) count may reveal a predominance of polymorphonuclear neutrophils (PMNs).

Blood–Brain Barrier/Blood–CSF Barrier

Natural barriers to the exchange of drugs and endogenous compounds among the blood, brain, and CSF are the blood–brain barrier (BBB) and the blood–CSF barrier (BCSFB) (**Fig. 106-2**). The BBB consists of tightly joined capillary endothelial cells. Drug entry into brain tissue is accomplished by direct passage through the capillary endothelial cells and further penetration of the glial cells that envelop the capillary structure.[12] Passage of drugs into the CSF is controlled by the BCSFB. This barrier is created by ependymal cells of the choroid plexus, which function as an active-transport system similar to the renal tubular epithelial cells. The inflammatory process associated with meningitis can also inhibit the active-transport system of the choroid plexus.[18]

FIGURE 106-2

Schematic representation of a blood–cerebrospinal fluid barrier capillary, brain tissue capillary, and normal tissue capillary (*below*).

PATHOPHYSIOLOGY OF THE CNS INFECTION

The development of bacterial meningitis occurs following bacterial invasion of the host and CNS, bacterial multiplication with subsequent inflammation of the CNS; specifically the subarachnoid and the ventricular spaces; pathophysiologic alterations owing to progressive inflammation, and the resulting neuronal damage.[14] The critical first step in the acquisition of acute bacterial meningitis is nasopharyngeal colonization of the host. Immunoglobulins (Igs), such as secretory IgA, are found in high concentrations within nasopharyngeal secretions and work to inhibit bacterial colonization. However, this mucus barrier is deteriorated by IgA proteases secreted by bacteria, which then extend pili allowing adherence to the host cell surface receptors. Bacterial pathogens tightly attach to nasopharyngeal epithelial cells and are then phagocytized into the host's bloodstream. After accessing the patient's bloodstream, bacteria must overcome the host's defense mechanisms. Commonly, CNS bacterial pathogens produce an extensive polysaccharide capsule resistant to neutrophil phagocytosis and complement opsonization. Therefore, *H. influenzae*, *E*scherichia *coli*, and *N. meningitidis* strains lacking polysaccharide capsules are unable to cause meningitis. Capsular polysaccharides activate the alternate complement pathway, which promotes phagocytosis and clearance of infecting pathogens. Patients unable to activate the alternative complement pathway, such as asplenic and sickle cell patients, are predisposed to bacterial infections caused by

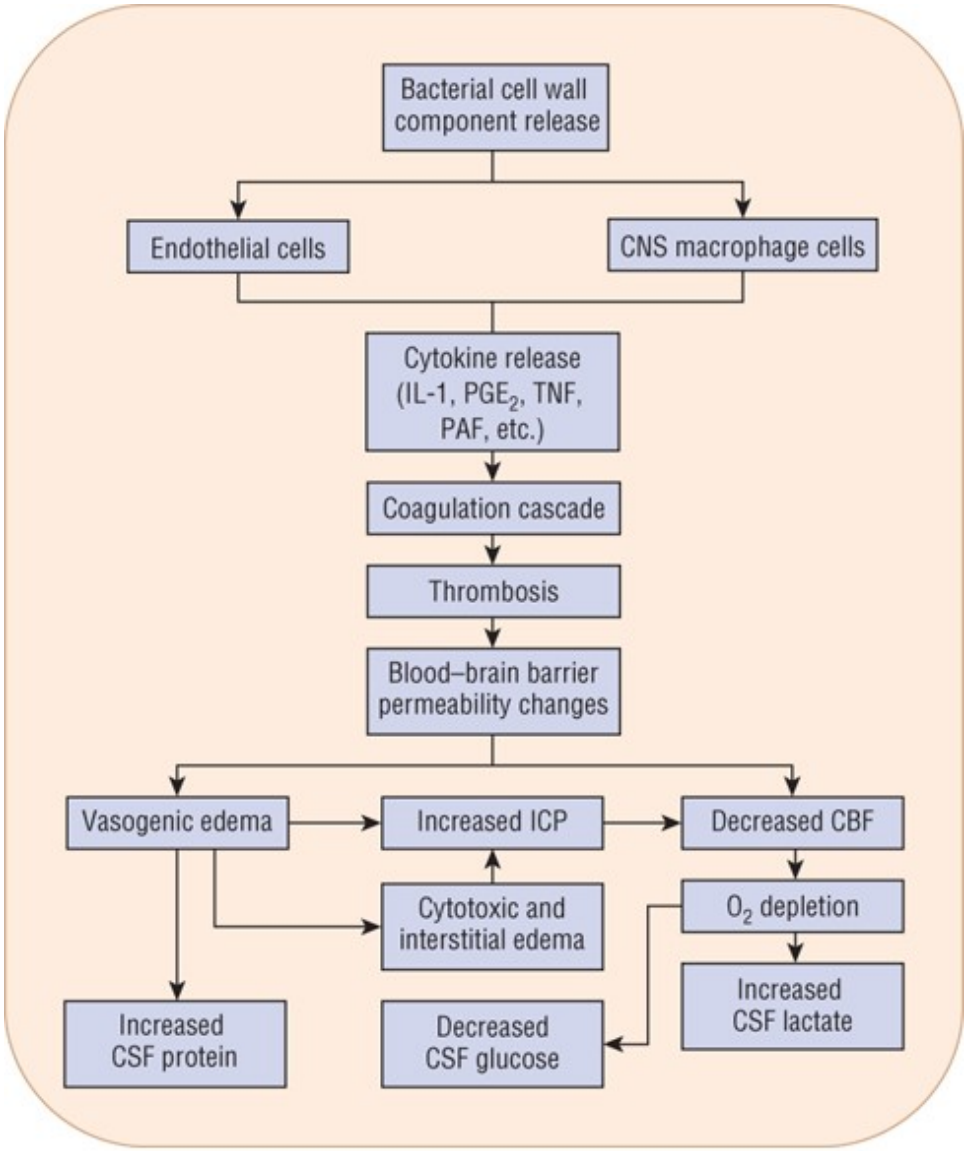
encapsulated microorganisms and therefore are at increased risk for meningitis.[14]

Although the exact site and mechanism of bacterial invasion into the CNS is unknown, studies suggest invasion into the subarachnoid space occurs by continuous exposure of the CNS to large bacterial inoculum. Bacteremia with inoculum densities of at least 10^3 colony-forming units (CFU)/mL [10^6 CFU/L] appears to be essential for subarachnoid space invasion.[19] Although several sites of bacterial invasion have been theorized, the most plausible sites are the choroid plexus and/or the cerebral microvasculature. Host defense mechanisms within the subarachnoid space are inadequate to combat bacterial pathogens; therefore, bacteria replicate freely within the CSF until either overgrowth occurs or an effective antibiotic regimen is administered that terminates the process.

The effects of meningitis, namely, inflammation within the subarachnoid space and the ensuing neurologic damage, are not necessarily a direct result of the pathogens themselves. The neurologic sequelae occur due to the activation of the host's inflammatory pathways, a process induced by the pathogen or its products. Bacterial cell lysis and subsequent death can result in the release of cell-wall components, such as lipopolysaccharide (LPS), lipid A (endotoxin), lipoteichoic acid, teichoic acid, and peptidoglycan, depending on whether the pathogen is gram-positive or gram-negative (**Fig. 106-3**). These cell-wall components cause capillary endothelial cells and CNS macrophages to release cytokines (interleukin-1 [IL-1] and tumor necrosis factor [TNF]) and other inflammatory mediators (IL-6, IL-8, platelet-activating factor [PAF], nitric oxide, arachidonic acid metabolites [eg, prostaglandin and prostacycline], and macrophage-derived proteins). Proteolytic products and toxic oxygen radicals are released from the capillary endothelium, causing an alteration in the permeability of the BBB. PAF activates the coagulation cascade, and arachidonic acid metabolites stimulate vasodilation. These events propagate other sequential events that lead to cerebral edema, elevated intracranial pressure (ICP), CSF pleocytosis, decreased cerebral blood flow, cerebral ischemia, and death.[14,19]

FIGURE 106-3

Hypothetical schema of pathophysiologic events that occur during bacterial meningitis. CBF, cerebral blood flow; CSF, cerebrospinal fluid; ICP, intracranial pressure; IL-1, interleukin-1; PAF, platelet-activating factor; PGE_2, prostaglandin E_2; TNF, tumor necrosis factor.



CLINCAL PRESENTATION AND DIAGNOSIS

Clinical presentation varies with age, and generally, the younger the patient, the more atypical and the less pronounced the clinical picture is. Patients may receive antibiotics in the outpatient setting before a diagnosis of meningitis is made, thus delaying presentation to the hospital. Subsequently, prior antibiotic therapy may cause the gram stain and CSF culture to be negative, but rarely affects CSF protein or glucose.

Signs and Symptoms

2 Classic signs and symptoms include fever, nuchal rigidity, altered mental status (*the classic triad*), chills, vomiting, photophobia, and severe headache; Kernig's and Brudzinski's signs may also be present but are poorly sensitive and frequently absent in children (**Figs. 106-4 and 106-5**).

Additionally, clinical signs and symptoms in young children may include bulging fontanelle, apneas, purpuric rash, irritability, refusal to eat, and convulsions.[20] Ultimately, almost all patients exhibit at least two of these symptoms: fever, nuchal rigidity, headache, and altered mental status.[3] Purpuric and petechial skin lesions may indicate meningococcal involvement, although lesions may also be present with *H. influenzae* meningitis and skin rashes rarely occur with pneumococcal meningitis.[5] Waterhouse–Friderichsen syndrome, a rapid eruption of multiple hemorrhagic lesions associated with a shock-like state, is associated with meningococcal meningitis. *H. influenzae* and meningococcal meningitis both can cause involvement of the joints during the illness. Finally, history of head trauma with or without skull fracture or presence of a chronically draining ear may be associated with pneumococcal involvement.

FIGURE 106-4

(A and B) Brudzinski's neck signs. (B) Hip and knee flexion occurs as a result of flexion of the neck. (C to E) Brudzinski's leg signs. (C) Patient's leg is flexed by examiner (*arrow*). (D) The contralateral leg begins to flex—identical contralateral sign (*arrows*). (E) The contralateral leg now begins to extend spontaneously, resembling a little kick (*arrows*).

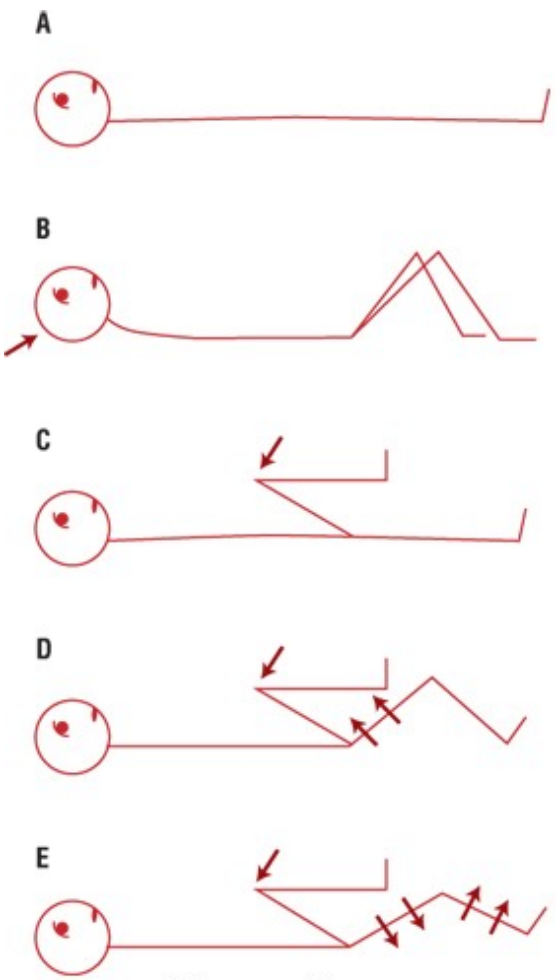


FIGURE 106-5

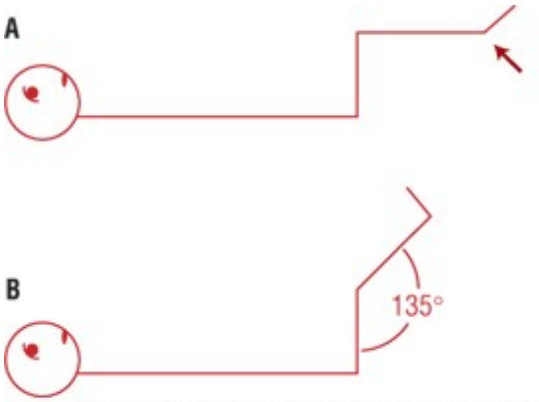
Kernig's sign. (A) Knees are raised to form a 90-degree angle relative to the trunk, and the examiner attempts to extend the knees. (B) Once the knee angle reaches approximately 135 degrees, contracture or extensor spasm occurs.



Bacterial Meningitis Score

Bacterial Meningitis Score is a validated clinical decision tool aimed to identify children older than 2 months with CSF pleocytosis who are at low risk of acute bacterial meningitis.[21,22] This tool incorporates clinical features such as positive CSF gram stain, presence of seizure, serum absolute neutrophil count 10,000 cells/mm^3 or more (10×10^9/L or more), CSF protein 80 mg/dL or more (800 mg/L or more), and CSF neutrophil count 1,000 cells/mm^3 or more (1×10^9/L or more). Treatment is recommended when one or more criteria are present. Certain pediatric patients are excluded including those with purpura, CSF shunt, recent neurosurgery, Lyme disease (LD), and those who received oral or intravenous antibiotics within 72 hours. This scoring tool was validated in several studies showing high accuracy in excluding acute bacterial meningitis. One meta-analysis of eight validation studies between 2002 and 2012 showed the tool to be highly accurate, with combined sensitivity of 99.3%, specificity of 62.1%, and negative predictive value of 99.7%.[22]

Laboratory Tests

Several tubes of CSF are collected via lumbar puncture for chemistry, cytology, microbiology, and hematology tests. Theoretically, the first tube has a higher likelihood of being contaminated with both blood and bacteria during the puncture, although the total volume is more important in practice than the tube cultured. CSF should not be refrigerated or stored on ice. Analysis of CSF chemistries includes measurement of glucose and total protein concentrations. An elevated CSF protein of more than or equal to 50 mg/dL (500 mg/L or more) and a CSF glucose concentration of less than 50% of the simultaneously obtained peripheral value suggest bacterial meningitis (Table 106-1).[13,14,15,16,17] The values for CSF glucose, protein, and WBC found with bacterial meningitis overlap significantly with those with viral, tuberculous, and fungal meningitis (Table

106-1).[13,14,15,16,17] Therefore, CSF WBC counts and CSF glucose and protein concentrations cannot always distinguish the different etiologies of meningitis.

Other Diagnostic Tests

In patients presenting with new-onset seizures, signs of space-occupying lesions, or moderate to severe impairment of consciousness, cranial imaging via magnetic resonance imaging (MRI) or cranial computed tomography (CT) should precede a lumbar puncture[13,15,23,24]. MRI is generally preferred, as it more clearly identifies areas of cerebral edemas. In these instances, the withdrawal of CSF fluid from a lumbar puncture reduces counterpressure that may result in compression of the brain with risk of brain herniation complicating the clinical course. Neuroimaging should not, however, delay initiation of appropriate antibiotic therapy as doing so can result in a poor outcome in this disease.[25,26] Finally, MRI is considered the preferred imaging modality for the diagnosis of encephalitis due to higher specificity and sensitivity than CT.[15]

Blood and other specimens should be cultured according to clinical judgment as meningitis frequently can arise via hematogenous dissemination or can be associated with infections at other sites. 3 Gram stain and culture of the CSF should be performed for suspected meningitis, and gram stain continues to be the most rapid and accurate method for presumptive diagnosis. When performed before antibiotic therapy is initiated, gram stain is both rapid and sensitive and can confirm the diagnosis of bacterial meningitis in 75% to 90% of cases. However, the sensitivity of the gram stain decreases to 40% from 60% in patients who received prior outpatient antibiotic therapy. Procalcitonin (PCT) has emerged as a predictive biomarker for invasive infections, including meningitis, owing to specificity to bacterial infections. Elevation of serum PCT levels was mostly studied in lower respiratory tract and blood stream infections, but some data support its association with bacterial meningitis.[27] Utility of PCT in predicting bacterial meningitis and differentiating bacterial from viral etiologies is controversial, and more studies are needed to confirm the impact of serum PCT monitoring on clinical outcomes.

Polymerase chain reaction (PCR) techniques can be used to diagnose meningitis caused by *N. meningitidis*, *S. pneumoniae*, and Hib. PCR is considered to be highly sensitive and specific, but expense and availability can be limiting. A multiplex PCR system with a meningitis panel is currently under review by the U.S. Food and Drug Administration (FDA) for approval. The panel includes tests for six bacterial, eight viral, and two yeast targets, with a turnaround time of appoximately 1 hour. Latex fixation, latex coagglutination, and enzyme immunoassay (EIA) tests provide for the rapid identification of several bacterial causes of meningitis, including *S. pneumoniae*, *N. meningitidis*, and Hib. Rapid-identification latex tests work by bringing potential capsular antigens of the pathogen causing meningitis in contact with a specific antibody, causing an antigen-antibody reaction. This capsular antigen-antibody reaction can be quickly observed visually without waiting for culture results. The sensitivity and specificity of latex fixation and coagglutination tests can vary with the manufacturer of the antibody, density of the antigen present in the CSF, and pathogen being tested. Latex agglutination is considered most useful for patients who have been previously treated with antimicrobials and whose CSF gram stain and culture remain negative.[15]

Diagnosis of tuberculosis meningitis employs acid-fast stain, culture, and PCR of the CSF. Also, PCR testing of the CSF is the preferred method for diagnosing most viral meningitis/encephalitis infections. Finally, the standard diagnostic tests for fungal meningitis include culture, direct microscopic examination of stained and unstained specimens of CSF, antigen detection of cryptococcal or histoplasmal antigens, and antibody assay of serum and/or CSF.

TREATMENT

Desired Outcome

4 Goals for the treatment of CNS infections should include eradication of infection, amelioration of signs and symptoms, prevention or reduction of morbidity and mortality, initiation of appropriate antimicrobials and supportive care, and prevention of disease through timely introduction of vaccination and chemoprophylaxis. Understanding antibiotic selection and the issues surrounding antibiotic penetration will assist in meeting the goals of treatment.

General Approach to Treatment and Nonpharmacologic and Supportive Therapy

Until a pathogen is identified, prompt empirical antibiotic coverage is often needed. 5 Based on the patient's profile (ie, allergies, age, and concurrent medical conditions), extent of antibiotic CNS penetration,[28] and spectrum of activity; appropriate recommendations can be made, and therapy should last at least 48 to 72 hours or until the diagnosis of bacterial meningitis can be ruled out (**Tables 106-2** and **106-3**).[13,14,15,28] 6 The first dose of antibiotics should not be withheld, even when lumbar puncture is delayed or neuroimaging is being performed, as changes in the CSF after antibiotic administration usually take up to 12 to 24 hours to occur. Continued therapy should be based on the assessment of clinical improvement, culture, and susceptibility testing results. Once a pathogen is identified, antibiotic therapy should be tailored to the specific pathogen (**Tables 106-4** and **106-5**).[13,15,24] Throughout the course of treatment, efficacy parameters such as signs and symptoms, microbiologic findings, and CSF examination should be followed to evaluate the success of meeting the desired outcomes.

TABLE 106-2 Bacterial Meningitis: Most Likely Etiologies and Empirical Therapy by Age Group[13,14,15]

Age	Most Likely Organisms	Empirical Therapy[a]
<1 month	*S. agalactiae* Gram-negative enterics[b] *L. monocytogenes*	Ampicillin + cefotaxime *or* ampicillin + aminoglycoside
1-23 months	*S. pneumoniae* *N. meningitidis*	Vancomycin[c] + 3rd generation cephalosporin (cefotaxime *or* ceftriaxone)

Age	Most Likely Organisms	Empirical Therapy[a]
2-50 years	*H. influenzae* *S. agalactiae* *N. meningitidis* *S. pneumoniae*	Vancomycin[c] + 3rd generation cephalosporin (cefotaxime *or* ceftriaxone)
>50 years	*S. pneumoniae* *N. meningitidis* Gram-negative enterics[b] *L. monocytogenes*	Vancomycin[c] + ampicillin + 3rd generation cephalosporin (cefotaxime *or* ceftriaxone)

[a]All recommendations are A-III.

[b]*E. coli*, *Klebsiella* spp, Enterobacter spp common.

[c]Vancomycin use should be based on local incidence of penicillin-resistant *S. pneumoniae* and until cefotaxime or ceftriaxone minimum inhibitory concentration results are available.

Strength of recommendation: (A) Good evidence to support a recommendation for use; should always be offered. (B) Moderate evidence to support a recommendation for use; should generally be offered.[15]

Quality of evidence: (I) Evidence from 1or more properly randomized, controlled trial. (II) Evidence from 1 or more well-designed clinical trial, without randomization; from cohort or case-controlled analytic studies (preferably from 1 or more center) or from multiple time-series. (III) Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.[15]

TABLE 106-3 Penetration of Antimicrobial Agents into the CSF[a,28]

Therapeutic Levels in CSF With or Without Inflammation	
Acyclovir	Levofloxacin
Chloramphenicol	Linezolid
Ciprofloxacin	Metronidazole
Fluconazole	Moxifloxacin
Flucytosine	Pyrazinamide
Foscarnet	Rifampin
Fosfomycin	Sulfonamides

Ganciclovir	Trimethoprim
Isoniazid	Voriconazole
Therapeutic Levels in CSF With Inflammation of Meninges	
Ampicillin ± sulbactam	Imipenem
Aztreonam	Meropenem
Cefepime	Nafcillin
Cefotaxime	Ofloxacin
Ceftazidime	Penicillin G
Ceftriaxone	Piperacillin/tazobactam[b]
Cefuroxime	Pyrimethamine
Colistin	Quinupristin/dalfopristin
Daptomycin	Ticarcillin ± clavulanic acid[b]
Ethambutol	Vancomycin
Nontherapeutic Levels in CSF With or Without Inflammation	
Aminoglycosides	Cephalosporins (second generation)[d]
Amphotericin B	Doxycycline[e]
β-Lactamase inhibitors[c]	Itraconazole[f]
Cephalosporins (first generation)	

[a]Using recommended CNS dosing and compared to MIC of target pathogens.

[b]May not achieve therapeutic levels against organisms with higher MIC, as in *P. aeruginosa*. Tazobactam does not penetrate BBB.

[c]Includes clavulanic acid, sulbactam, and tazobactam.

[d]Cefuroxime is an exception.

[e]Documented effectiveness for *B. burgdorferi*.

[f]Achieves therapeutic concentrations for *Cryptococcus neoformans* therapy.

TABLE 106-4 Antimicrobial Agents of First Choice and Alternative Choice in the Treatment of Meningitis Caused by Gram-Positive and Gram-Negative Microorganisms[13,15,17]

Organism	Antibiotics of First Choice	Alternative Antibiotics	Recommended Duration of Therapy
Gram-Positive Organisms			
Streptococcus pneumoniae[a]			10-14 days

Organism	Antibiotics of First Choice	Alternative Antibiotics	Recommended Duration of Therapy
Penicillin susceptible MIC ≤ 0.06 mcg/mL (mg/L)	Penicillin G or Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Cefepime (B-II), or Meropenem (B-II)	
Penicillin resistant MIC > 0.06 mcg/mL (mg/L)	Vancomycin[b,c] + Cefotaxime or Ceftriaxone (A-III)	Moxifloxacin (B-II)	
Ceftriaxone resistant MIC > 0.5 mcg/mL (mg/L)	Vancomycin[b,c] + Cefotaxime or Ceftriaxone (A-III)	Moxifloxacin (B-II)	
Staphylococcus aureus			14-21 days
Methicillin susceptible	Nafcillin or Oxacillin (A-III)	Vancomycin (A-III) or Meropenem (B-III)	
Methicillin resistant	Vancomycin[b,c] (A-III)	TMP-SMX or Linezolid (B-III)	
Group B *Streptococcus*	Penicillin G or Ampicillin (A-III) ± Gentamicin[b,c]	Ceftriaxone or Cefotaxime (B-III)	14-21 days
S. epidermidis	Vancomycin[b,c] (A-III)	Linezolid (B-III)	14-21 days[d]
L. monocytogenes	Penicillin G or Ampicillin ± Gentamicin[b,c,e] (A-III)	Trimethoprim-sulfamethoxazole (A-III), Meropenem (B-III)	≥21 days
Gram-Negative Organisms			
Neisseria meningitis			7-10 days
Penicillin susceptible	Penicillin G or Ampicillin (A-III)	Cefotaxime or Ceftriaxone (A-III)	
Penicillin resistant	Cefotaxime or Ceftriaxone (A-III)	Meropenem or Moxifloxacin (A-III)	
Haemophilus influenzae			7-10 days
β-lactamase negative	Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Cefepime (A-III) or	

Organism	Antibiotics of First Choice	Alternative Antibiotics	Recommended Duration of Therapy
		Moxifloxacin (A-III)	
β-lactamase positive	Cefotaxime or Ceftriaxone (A-I)	Cefepime (A-I) or Moxifloxacin (A-III)	
Enterobacteriaceae[f]	Cefotaxime or Ceftriaxone (A-II)	Cefepime (A-III), Moxifloxacin (A-III), Meropenem (A-III) or Aztreonam (A-III)	21 days
Pseudomonas aeruginosa	Cefepime or Ceftazidime (A-II) ± Tobramycin[b,c] (A-III)	Ciprofloxacin (A-III), Meropenem (A-III), Piperacillin plus Tobramycin[a,b] (A-III), Colistin sulfomethate[g] (B-III), Aztreonam (A-III)	21 days

[a]European Guidelines recommend considering the addition of rifampin to vancomycin therapy.

[b]Direct CNS administration maybe considered if failed conventional treatment.

[c]Monitor serum drug levels.

[d]Based on clinical experience; no clear recommendations.

[e]European guidelines recommend adding gentamicin for the first 7 days of treatment.

[f]Includes *E. coli and Klebsiella* spp.

[g]Should be reserved for multidrug-resistant pseudomonal or *Actinetobacter* infections for which all other therapeutic options have been exhausted.

See **Table 106-2** footnotes for rating scale of evidence.

TABLE 106-5 Dosing of Antimicrobial Agents by Age Group Antimicrobial[13,15]

Agent	Infants and Children	Adults	Monitoring/Comments
Antibacterial			
Ampicillin	75 mg/kg every 6 h	2 g every 4 h	
Aztreonam	—	2 g every 6-8 h	Alternative for penicillin allergy
Cefepime	50 mg/kg every 8 h	2 g every 8 h	Consider prolonged infusion
Cefotaxime	75 mg/kg every 6-8 h	2 g every 4-6 h	Preferred in neonates

Agent	Infants and Children	Adults	Monitoring/Comments
Ceftazidime	50 mg/kg every 8 h	2 g every 8 h	
Ceftriaxone	100 mg/kg daily	2 g every 12 h	Avoid in neonates
Ciprofloxacin	10 mg/kg every 8 h	400 mg every 8-12 h	Consider higher doses for *P. aeruginosa* Consider intraventricular doses
Colistin	5 mg/kg/day	5 mg/kg/day	Only for MDR organisms Monitor renal function
Gentamicin	2.5 mg/kg every 8 h	2 mg/kg every 8 h *or* 5-7 mg/kg daily	TDM is recommended Monitor renal function
Levofloxacin	—	750 mg daily	May prolong QTc
Linezolid	10 mg/kg every 8 h	600 mg every 12 h	May cause thrombocytopenia and peripheral neuropathy
Meropenem	40 mg/kg every 8 h	2 g every 8 h	Consider prolonged infusion
Moxifloxacin	—	400 mg daily	May prolong QTc
Oxacillin/Nafcillin	50 mg/kg every 6 h	2 g every 4 h	Nafcillin preferred if renal dysfunction
Penicillin G	0.05 million Units/kg every 4 h	4 million Units every 4 h	
Polymyxin B	—	1.25-1.5 mg/kg every 12 h	Only for MDR organisms No data in pediatric patients
Tobramycin	2.5 mg/kg every 8 h	2.5 mg/kg every 8 h *or* 5-7 mg/kg daily	TDM is recommended Monitor renal function
Trimethoprim-sulfmathoxazole	5 mg/kg every 6-12 h	5 mg/kg every 6-12 h	Dose based on trimethoprim
Vancomycin	15 mg/kg every 6 h	15-20 mg/kg every 8-12 h	TDM is recommended Monitor renal function
Antimycobacterials			
Isoniazid	10-15 mg/kg daily	5 mg/kg daily	Supplemental vitamin B_6 is recommended
Rifampin	10-20 mg/kg daily (max 600 mg daily)	600 mg daily	Many drug-drug interactions
Pyrazinamide	15-30 mg/kg daily	15-30 mg/kg daily	Rarely causes hepatotoxicity

Agent	Infants and Children	Adults	Monitoring/Comments
Ethambutol	15-25 mg/kg daily	15-25 mg/kg daily	May cause neutropenia
Antifungals			
Amphotericin B	1 mg/kg daily	0.7-1 mg/kg daily	Monitor renal function Maintain adequate hydration
Lipid amphotericin B	5 mg/kg once daily	3-5 mg/kg daily	Monitor renal function Maintain adequate hydration
Flucytosine	25 mg/kg every 6 h	25 mg/kg every 6 h	Consider TDM to avoid bone marrow suppression
Fluconazole	6-12 mg/kg daily	800-1,200 mg daily	Monitor liver function
Itraconazole			Consider TDM Suspension form is preferred
Posaconazole	—	400 mg every 12 h	Variable absorption No data in pediatric patients
Voriconazole	7 mg/kg every 12 h	6 mg/kg every 12 h × 2 doses then 4 mg/kg every 12 h	Consider TDM Many drug-drug interactions Monitor liver function
Antivirals			
Acyclovir	10-20 mg/kg every 8 h	10-20 mg/kg every 8 h	Monitor renal function Maintain adequate hydration
Ganciclovir	—	5 mg/kg every 12 h	Monitor renal function
Foscarnet	—	60 mg/kg every 8 h *or* 90 mg/kg every 12 h	Monitor renal function Maintain adequate hydration

TDM, therapeutic drug monitoring.

Supportive care, particularly early in the course of treatment, is critically important. Administration of fluids, electrolytes, antipyretics, and analgesics are indicated for patients presenting with a possible CNS infection. Additionally, venous thromboembolism prophylaxis and ICP monitoring are often needed. Patients may require the administration of osmotic diuretics such as mannitol 25% or hypertonic 3% saline to maintain an ICP of less than 15 mm Hg (less than 2 kPa) and a cerebral perfusion pressure of 60 mm Hg or more (8 kPa or more). Other supportive care measures may include respiratory and circulatory supports, gastrointestinal (GI) care and maintaining normal body temperature. Although supportive care is important initially, appropriate antibiotic therapy (empirical or definitive) should be started as soon as possible.[25,26]

7 Several factors influence the transfer of antibiotic from capillary blood into the CNS. Notably, antibiotic penetration is increased through inflamed meninges due to damage to tight junctions between capillary endothelial cells and reduction of the activity of energy-dependent efflux pumps in the choroid plexus responsible for movement of penicillins and, to a lesser extent, fluoroquinolones and aminoglycosides (Table 106-3).[28] Antibiotics having low molecular weights are passed more easily through biologic barriers than compounds of higher molecular weight. Furthermore, only nonionized antibiotics at physiologic or pathologic pH are capable of diffusion. Highly lipid-soluble compounds penetrate more readily than water-soluble compounds. Antibiotics not extensively bound to plasma proteins provide a larger free fraction of drug capable of passing into the CSF. Passage of large, polar antibiotics into the CSF may be assisted, however, by a carrier transport system. Antibiotic dosages in the treatment of CNS infections must be optimized to ensure adequate penetration to the site of infection.

Problems of CSF penetration were traditionally overcome by direct instillation of antibiotics intrathecally, intracisternally, or intraventricularly. Advantages of direct instillation, however, must be weighed against the risks of invasive CNS procedures and adverse effects. Intrathecal administration of antibiotics is unlikely to produce therapeutic concentrations in the ventricles possibly owing to the unidirectional flow of CSF.[4] Although intraventricular administration from a therapeutic standpoint may be preferred over intrathecal administration, the former requires neurosurgical placement of a subcutaneous reservoir. Intraventricular delivery may be necessary in patients who have shunt infections that are difficult to eradicate or who cannot undergo surgical interventions.[15] Antimicrobial agents often utilized for bacterial meningitis treatment have adequate CSF penetration, which has limited the need for direct CNS instillation. The European Guidelines for meningitis treatment recommend considering the use of intrathecal or intraventricular antibiotics only in patients who fail conventional treatment.[13]

8 Although the length of treatment for bacterial meningitis is generally based on the causative organism, there is no universally accepted standard (Table 106-4).[13,15,17] Meningitis caused by *S. pneumoniae* has been treated successfully with 10 to 14 days of antibiotic therapy, while cases caused by *N. meningitidis* or *H. influenzae* usually can be treated with a 7-day course. In contrast, a longer duration (21 days or more) has been recommended for patients with *L. monocytogenes*, gram-negative or pseudomonal meningitis. Nonetheless, antibiotic treatments for bacterial meningitis should be individualized, and some patients may require enduring courses.

Causative Organisms

Streptococcus pneumoniae (Pneumococcus or Diplococcus)

1 *S. pneumoniae* is the leading cause of meningitis in patients 2 months of age or older, and causes over 50% of all cases of bacterial meningitis in the United States with an overall case-fatality rate of approximately 18%.[1] Despite the decline in rates of pneumococcal meningitis since the introduction of PCV7 vaccination in 2000, case-fatality rate did not significantly change from pre-PCV7 era. Approximately 50% of cases are secondary infections resulting from primary infections of

parameningeal foci, such as the ear or paranasal sinuses. Pneumonia, endocarditis, CSF leak secondary to head trauma, splenectomy, alcoholism, sickle cell disease, and bone-marrow transplantation may predispose the patient to the development of pneumococcal meningitis.

Neurologic complications, such as coma, hearing impairment, and seizures, are common with pneumococcal meningitis. The prognosis of pneumococcal meningitis depends on a variety of factors, including chronic comorbidities, low Glasgow Coma Scale Score, focal neurological deficits on admission, low CSF leukocyte count, pneumonia, bacteremia, and intracranial and systemic complications.[29]

Based on resistance patterns and the fact that sufficient CSF concentrations of penicillin are difficult to achieve with standard intravenous doses, penicillin should not be used as empirical therapy if *S. pneumoniae* is a suspected pathogen. Furthermore, appropriate Clinical Laboratory Standards Institute (CLSI)-approved testing of all CSF isolates for penicillin resistance is recommended. Ceftriaxone and cefotaxime have served as alternatives to penicillin in the treatment of penicillin-resistant pneumococci. Of note, higher cephalosporins minimum inhibitory concentration (MIC) and higher cephalosporin resistance rates were shown in penicillin-resistant isolates.[30] Therapeutic approaches to cephalosporin-resistant pneumococcus include the addition of vancomycin and rifampin. However, only data from animal and experimental trials supporting the use of rifampin are available.[31] Therefore, the combination of vancomycin and ceftriaxone has been suggested as empirical treatment until the results of antimicrobial susceptibility testing are available. Vancomycin should not be used alone even for highly penicillin- and cephalosporin-resistant strains.[13,15] Finally, some pneumococcal strains exhibit tolerance to vancomycin and were linked to increased meningitis mortality.[32,33]

Given the limited therapeutic options for penicillin- and cephalosporin-resistant pneumococcal meningitis, newer agents have been evaluated. Meropenem is approved by the US FDA for the treatment of bacterial meningitis in children aged 3 months and older and has shown similar clinical and microbiologic efficacies to cefotaxime or ceftriaxone. Meropenem is currently recommended as an alternative to a third-generation cephalosporin in penicillin nonsusceptible isolates. Some caution is warranted with the use of imipenem for CNS infections because of the possibility of drug-induced seizures, especially when dosing is not adjusted for declining renal function. Of note, seizures may be caused by meningitis itself or by imipenem, and the cause is often difficult to differentiate. The newer fluoroquinolones (levofloxacin and moxifloxacin) represent another therapeutic option with favorable activity against multidrug-resistant pneumococci and good penetration into the CSF.[31,34]

Intravenous linezolid, daptomycin, and ceftaroline have also emerged as viable therapeutic options for treating multidrug-resistant gram-positive infections. Linezolid in combination with ceftriaxone has been used to treat a limited number of cases of pneumococcal meningitis with outcomes similar to standard treatment.[35] Daptomycin was as effective or better than ceftriaxone plus vancomycin for pneumococcal strains exhibiting penicillin and ceftriaxone resistance, respectively, in a rabbit model.[36] Additionally, daptomycin may reduce the inflammatory response caused by cell-wall components in pneumococcal meningitis compared with ceftriaxone in animal models.[37] Finally, ceftaroline achieved 14% penetration into inflamed meninges and 3% into uninflamed meninges in

an experimental rabbit meningitis model.[38]

Pneumococcal vaccines help in reducing the risk of IPD. Virtually all serotypes of *S. pneumoniae* exhibiting intermediate or complete resistance to penicillin are included in the 23-serotype pneumococcal polysaccharide vaccine (PPV23). Due to low vaccination rates among people 65 years of age and older, the U.S. Centers for Disease Control and Prevention (CDC) issued stronger recommendations for the use of the PPV, calling for vaccination of the following high-risk groups: persons over the age of 65 years; persons aged 2 to 64 years who have a chronic illness, who live in high-risk environments (eg, Alaskan natives and residents of long-term care facilities), and who lack a functioning spleen (eg, sickle cell disease and splenectomy); and immunocompromised persons over the age of 2 years, including those with human immunodeficiency virus (HIV) infection.[39] Additionally, the question of whether or not college students living in dormitories, a possible high-risk environment, should be vaccinated remains debatable.

Use of the heptavalent pneumococcal conjugate vaccine (PCV7), introduced in 2000, significantly reduced the incidence of invasive pneumococcal infections, including sepsis and meningitis.[7,40] In the decade following its introduction, rate of invasive disease caused by non-PCV7 strains increased considerably, especially serotype 19A, leading to the development of a newer vaccine with expanded coverage.[7] In 2010, the FDA approved a PCV13 in replacement of PCV7, leading to a rapid and significant reduction of IPD in children younger than 5 years of age. In the first 3 years after the introduction of PCV13 in the United States, investigators estimated over 30,000 cases of IPD and 3,000 deaths were averted.[9] In 2011, the FDA approved the use of PCV13 in adults 50 years and older as it produced antibody levels that were either comparable to or higher than the levels achieved by PPV23, for the 12 common serotypes included in PCV13. The Advisory Committee on Immunization Practices (ACIP) in 2014 recommended routine use of PCV13 in series with PPV23 for all adults 65 years of age or older.[41] Although the total number of pneumococcal meningitis cases in the United States remained the same with PCV13, the proportion of PCV13 serotypes and antibiotic-resistant strains significantly decreased, mainly serotype 19A.[42] PCV13 is recommended for all healthy infants younger than 2 years of age to be immunized at 2, 4, 6, and 12 to 15 months; all adults of 65 years or older; and high-risk individuals.[39,41,43] High-risk persons include those with cochlear implants, CSF leaks, who lack a functioning spleen, and immunocompromised persons.

Neisseria meningitidis **(Meningococcus)**

1 *N. meningitidis* is a leading cause of bacterial meningitis among children and young adults in the United States and around the world.[1,44] Five of the thirteen serogroups of *N. meningitidis* (A, B, C, Y, and W-135) are primarily responsible for invasive meningococcal disease. Clusters of disease, defined as two or more cases of the same serogroup that are closer in time and space than expected for the population or group under observation, generally are associated with crowding as in schools, dormitories, and military barracks.[45] Other significant risk factors for meningococcal disease include complement deficiency, persons without a functioning spleen, and active smokers.[11] Serogroups B, C, and Y cause the majority of disease in the United States, while serogroup A, although associated with meningococcal outbreaks in Africa and Asia, is a rare cause of disease in the United States.[46] Routine

vaccine recommendations has significantly decreased the prevalence of serogroup C meningococcal disease; however, this led to a surge in serogroup B infections, especially in infants.[47] Overall incidence of meningococcal disease in the United States has been declining since the late 1990s; however, incidence remains highest in infants aged older than 1 year with a second peak in adolescents and young adults 16 to 23 years of age. *N. meningitidis* accounted for 13.9% of all meningitis cases in the United States during 2003 to 2007, with a case-fatality rate of approximately 10%.[1]

Initially, patients are colonized and, at some point, develop bacteremia, which most likely occurs prior to hospital admission. Meningitis occurs after the bacteria seed into the meninges. After the acute phase of meningitis has resolved, there is a unique immune reaction that distinguishes meningococcal meningitis from other bacterial causes. 2 The patient develops a characteristic immunologic reaction of fever, arthritis (usually involving large joints), and pericarditis approximately 10 to 14 days after the onset of disease despite successful treatment. At this time, examination of the synovial fluid may reveal a large number of polymorphonuclear cells, elevated protein concentrations, normal glucose concentrations, and sterile cultures. The reaction may last a week or longer, and no additional antibiotic therapy is required; however, patients may benefit from nonsteroidal anti-inflammatory agents and supportive care.[5,48]

Seizures and coma are uncommon with meningococcal meningitis. Also, patients may develop deafness and transiently impaired ocular movements. Deafness unilaterally or, more commonly, bilaterally may develop early or late in the disease course. Hearing loss secondary to sensory nerve damage (sensorineural hearing) is usually permanent, whereas conductive hearing impairment, such as damage to the tympanic membrane, is often reversible. The presence of petechiae may be the primary clue that the underlying pathogen is *N. meningitidis*. Approximately 60% of adults and up to 90% of pediatric patients with meningococcal meningitis have purpuric lesions, petechiae, or both.[5] Patients may have an obvious or subclinical picture of disseminated intravascular coagulation (DIC), which may progress to infarction of the adrenal glands and renal cortex and cause widespread thrombosis and rapid death.

6 Third-generation cephalosporins (ie, cefotaxime and ceftriaxone) are the recommended empiric treatment for meningococcal meningitis (Table 106-4).[13,15,17] When final culture results are available, penicillin G or ampicillin is recommended for penicillin-susceptible isolates. Meropenem and fluoroquinolones are also suitable alternatives for the treatment of penicillin nonsusceptible meningococci.[13,15]

N. meningitidis is spread by direct person-to-person close contact, including respiratory droplets and pharyngeal secretions. Close contacts of patients contracting meningococcal meningitis are at an increased risk of developing meningitis. Close contacts include daycare center contacts, members of the household, or anyone who has been exposed to respiratory or oral secretions through activities such as coughing, sneezing, or kissing. Secondary cases of meningitis usually develop within the first week following exposure, but may take up to 60 days after contact with the index case.[11] Young children are at the greatest risk of contracting *N. meningitidis*; however, all ages are at risk, especially close contacts exposed via household, daycare, or military contact.

9 Prophylaxis of close contacts should be started only after consultation with the local health department. In general, rifampin, ceftriaxone, ciprofloxacin, or azithromycin are given for prophylaxis. A systematic review of available data suggests an increased rate of rifampin-resistant isolates.[49] Also, cases of ciprofloxacin-resistant isolates were reported in North America. Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to current recommendations from the CDC.[11]

Until recently, only two meningococcal vaccines were available in the United States; but as of 2015, six products became available. Two quadrivalent meningococcal conjugate vaccines are available with antigens to serogroups A, C, W-135, and Y. In 2012, a bivalent conjugate combination vaccine was licensed in the United States, and contains antigens to serogroups C and Y, and *H. influenzae* type b. Until late 2014, serogroup B meningococcal vaccines (MenBs) were unavailable in the United States. Following an outbreak of meningococcal meningitis due to serogroup B on two college campuses in 2013, two MenB vaccines were subsequently granted breakthrough therapy designations for rapid approval. In 2015, ACIP recommended routine administration for persons 10 to 25 years of age identified as being at increased risk due to serogroup B meningococcal disease outbreak or certain medical conditions (complement deficiencies and functional/anatomic asplenia). For full details of vaccination recommendation in various age groups and for those with significant risk factors, readers should refer to current recommendations from the ACIP.

***Haemophilus influenzae* type b**

1 Historically, *H. influenzae* type b was the most common cause of community-acquired bacterial meningitis in children 6 months to 3 years of age. Since the introduction of effective vaccines, the incidence of Hib disease in the Unite States has declined dramatically.[5,50] Widespread vaccination of infants and children has effectively decreased the incidence of bacterial meningitis due to Hib in children between the ages of 1 month and 5 years, resulting in a significant decline in all cases of bacterial meningitis.[1] In children older than 3 years and adults, meningitis caused by Hib may indicate a parameningeal focus of infection, such as middle ear infection, paranasal sinus infection, or CSF leakage. Spread of the organism occurs either through direct spread from infected sinuses, draining of these areas via the veins, or bacteremia originating from the local focus of infection.[51]

6 Third-generation cephalosporins (cefotaxime and ceftriaxone) are the drugs of choice for empirical therapy for *H. influenzae* type b meningitis as they are active against β-lactamase–producing and non–β-lactamase–producing strains.[15] In addition, they are relatively free of toxicity and do not require serum concentration monitoring. Cefepime and fluoroquinolones are suitable alternatives regardless of β-lactamase activity.

9 Prophylaxis is to protect close contacts from the index case by eliminating nasopharyngeal and oropharyngeal carriages of *H. influenzae*. Invasive disease should be reported to the local public health department and the CDC. Prophylaxis of close contacts should be started only after consultation with the local health department. Widespread vaccination has limited the need for chemoprophylaxis. Further discussion of who should receive prophylaxis is beyond the scope of this

chapter; interested readers can refer to the recommendations of the American Academy of Pediatrics.

Vaccination includes a series of doses and usually is begun in children at 2 months of age. In addition to pediatric immunization, the vaccine also should be considered in patients older than 5 years of age with the following underlying conditions: sickle cell disease, asplenia, and immunocompromising diseases. As noted earlier, a bivalent conjugate combination vaccine, MenHibrix®, containing antigens to meningococcal serogroups C and Y, and *H. influenzae* type b became available in 2012. Refer to chapter in this text for further information on vaccine dosing and administration schedules.

Streptococcus agalactiae **(Streptococcus Group B)**

1 Streptococcus group B (GBS) is a leading cause of neonatal meningitis in the United States and around the world.[1,52,53] The causative organism, *Streptococcus agalactiae*, is a gram-positive bacterium with β-hemolytic properties that is often implicated in neonatal sepsis, pneumonia, and meningitis. GI and genitourinary colonization in pregnant women is common, up to 25%.[54] Neonates acquire this infection through vertical transmission while passing through the vaginal canal during birth.

Early-onset infections are those occurring within the first week of life, while late-onset infections occur after the first week of the child's birth. Universal prenatal screening and intrapartum antimicrobial prophylaxis of colonized pregnant women have significantly decreased rate of early onset invasive disease.[55] While rates of GBS meningitis in the United States did not change significantly during 1998 to 2008, including cases in patients less than 2 months of age, most cases during 2002 to 2007 were late-onset infections that are not affected by intrapartum prophylaxis.[1,53] Furthermore, neonatal GBS meningitis survivors carry substantial long-term morbidity and up to 11% die before the age of 3 years.[54]

6 Ampicillin and penicillin G are the recommended agents for the treatment of presumed GBS. Addition of an aminoglycoside should also be considered for confirmed GBS meningitis. GBS continues to be susceptible to ampicillin and penicillin; however, reports of isolates with increased MIC have been published.[55]

Investigations are undergoing to develop vaccines to reduce maternal colonization and prevent fetal transmission of GBS. Clinical trials have shown promising results; however, to date there are no licensed vaccines available for GBS.

Listeria monocytogenes

L. monocytogenes is a gram-positive diphtheroid-like organism. This disease primarily affects neonates, alcoholics, immunocompromised adults, and the elderly; while infections in healthy individuals are rare. *L. monocytogenes* is implicated in approximately 10% of meningitis cases in those older than 65 years of age and carries a case-fatality rate of approximately 18% in the United States.[1]

Transmission usually involves colonization of the patient's GI tract with the organisms, which then

penetrate the gut lumen. Soft cheeses and raw produce are common causes of listeriosis outbreaks. Coleslaw, unpasteurized milk, ready-to-eat foods, and raw beef and poultry have also been identified as sources of this foodborne pathogen.[14] If a sufficient cell-mediated immune response (T-lymphocytes, macrophages) is not produced, bacteremia, meningitis, meningoencephalitis, or cerebritis may develop. Infection of the CNS may be diffuse or localized, possibly involving the cerebral hemispheres, thalamus, and brain stem.

Incidence of *L. monocytogenes* meningitis tends to peak in the summer and early fall. As with gram-negative meningitis, presentation may be subtle and insidious, and clinical suspicion should prompt lumbar puncture. 2 *L. monocytogenes* produces primarily a mononuclear CSF response.[56] One common laboratory error seen with *L. monocytogenes* is a tendency to misidentify the organism on gram stain as a diphtheroid, streptococcus, or a poorly staining gram-negative rod.

Treatment of *L. monocytogenes* meningitis with penicillin G or ampicillin may result in only a bacteriostatic effect and possible persistence of infection. Usually the combination of penicillin G or ampicillin with an aminoglycoside results in a bactericidal effect. 8 Patients should be treated for a minimum of 3 weeks.[15] European Guidelines for meningitis treatment recommend considering combination therapy for the first 7 to 10 days of treatment, with the remaining course of therapy completed with penicillin G or ampicillin alone.[13] Despite in-vitro activity against *L. monocytogenes*, vancomycin was associated with high failure rates. Also, third-generation cephalosporins lack in-vitro activity against *L. monocytogenes*. Trimethoprim-sulfamethoxazole and meropenem may be effective alternatives as adequate CSF penetration is achieved.[13,15]

Gram-Negative Meningitis

Gram-negative bacilli, excluding *H. influenzae*, are an uncommon but increasing cause of nosocomial meningitis in adults.[57] The most common pathogens are *E. coli* and *Pseudomonas* species in adults, while neonates are also at risk for gram-negative meningitis with *E. coli* and *Klebsiella pneumoniae* responsible for 40% to 50% of cases.[58] A 2013 study identified urinary tract infections as the most important independent factor associated with higher risk of gram-negative meningitis in adults.[57] Several additional factors predispose patients to the development of gram-negative meningitis include: congenital defects involving the CNS, accidental cranial trauma, neurosurgery, the use of antimicrobial agents with exclusive gram-positive activity preoperatively in neurosurgery, any form of communication between the skin and subarachnoid space (such as a dermal sinus), diabetes, malignancy, cirrhosis, parameningeal infection, spinal anesthesia, advanced age, immunosuppression, and hospitalization in general.[57]

Elderly debilitated patients are at an increased risk of gram-negative meningitis but typically lack the classic signs and symptoms of the disease. Nuchal rigidity may be difficult to detect secondary to cervical arthritis. Presence of a low-grade fever and changes in mental status without other obvious cause should prompt consideration of meningitis and a lumbar puncture.

Treatment of gram-negative meningitis is complex because of the variety of organisms implicated in

these cases. The treatment of meningitis due to *Pseudomonas aeruginosa* remains a unique problem because antibiotics showing good antibacterial activity, such as antipseudomonal penicillins and aminoglycosides, penetrate the CSF poorly.[28] Furthermore, many isolates of *P. aeruginosa* are resistant to multiple, if not all, commonly used agents, and this trend in resistance is increasing. Initially, cases of *P. aeruginosa* meningitis should be treated with an extended-spectrum β-lactam such as ceftazidime or cefepime, or alternatively aztreonam, ciprofloxacin, or meropenem.[4,15] The addition of an aminoglycoside, usually tobramycin, to one of the aforementioned agents should also be considered. Since aminoglycosides penetrate the CSF poorly, their inclusion is predominant to aid in the treatment of extracerebral infections. If multidrug-resistant *P. aeruginosa* is suspected initially, intraventricular administration of an aminoglycoside should be considered along with intravenous administration. Preservative-free forms of gentamicin and tobramycin are available and should be used for direct administration into the CSF. Since CSF flows unidirectionally with gravity, intraventricular aminoglycoside administration is more likely to produce therapeutic concentrations throughout the CSF than intrathecal administration. While intraventricular administration of aminoglycosides is considered for treatment of *P. aeruginosa* meningitis, this method produced higher mortality in a sample of infants treated for gram-negative bacillary meningitis.[59] Thus intraventricular administration of aminoglycosides to infants is not recommended routinely.

Multidrug-resistant *P. aeruginosa* and *Acinetobacter* infections are of concern to clinicians because of the limited therapeutic options available. This concern has led to the reemergence of the use of older antibiotics, such as colistin and polymyxin B. Colistin can be used, both intravenously and intrathecally, in the treatment of multidrug-resistant *P. aeruginosa* or *Acinetobacter* CNS infections.[60] Furthermore, synergistic activity with the combination of colistin and ceftazidime against multidrug-resistant *P. aeruginosa* was demonstrated in an *in vitro* model.[61] The use of colistin should be reserved for only the most severe cases. New cephalosporin-*β*-lactamase inhibitor combination agents (ceftolozane-tazobactam and ceftazidime-avibactam) have yet to be studied in patients with CNS infections, but may be future alternative therapies for multidrug resistant gram-negative organisms.

Other gram-negative organisms causing meningitis, excluding *P. aeruginosa* and *Acinetobacter* spp., most likely can be treated with a third- or fourth-generation cephalosporin, such as cefotaxime, ceftriaxone, ceftazidime, or cefepime. Ceftazidime, however, may not be the best choice of empirical antibiotic for situations where the offending organism is not known initially because of its lack of reliable gram-positive coverage. Cefotaxime should be used in place of ceftriaxone in the neonatal period because of the potential for the displacement of bilirubin from albumin-binding sites.

Trimethoprim-sulfamethoxazole is useful in the management of the Enterobacteriaceae family and also may be useful in the management of *L. monocytogenes*. One advantage of trimethoprim-sulfamethoxazole is that its penetration into the CSF does not depend on meningeal inflammation.[28] However, trimethoprim-sulfamethoxazole is not bactericidal which limits its routine use for the acute management of CNS infections. Fluoroquinolones exhibit good penetration into the CSF and are effective in animal models of both gram-negative and gram-positive meningitis; however, there are limited data on their efficacy in clinical practice. Ciprofloxacin is recommended as an alternative agent for the treatment of *E. coli*, other Enterobacteriaceae, and *P. aeruginosa*.[15] Cefepime,

meropenem, and aztreonam represent other therapeutic options for the treatment of gram-negative bacterial meningitis.[13,15]

8 CSF cultures may remain positive for several days or more with a regimen that eventually will be curative. Therapeutic efficacy can be monitored through bacterial colony counts every 2 or 3 days, which should decrease progressively over the period of therapy. Therapy for gram-negative meningitis should be continued for a minimum of 21 days from the start of treatment with an effective agent.[13,15]

Clinical Controversy...

Multidrug resistant gram-negative meningitis is an ongoing concern due to the limited number of therapeutic options available. Therapy is often limited to older, and more toxic, antibiotics, such as colistin and polymyxin B. Although new agents with extended spectrum of activity have been developed, they are yet to be studied in patients with CNS infections. Two cephalosporin-β-lactamase inhibitor combination agents (ceftolozane-tazobactam and ceftazidime-avibactam) may be future alternative therapies for multidrug resistant gram-negative organisms, but currently lack data to support their use in clinical settings.

Bacillus anthracis

Bacillus anthracis is a large, endospore-forming, aerobic, gram-positive bacteria capable of producing infection via the cutaneous, pulmonary, or GI routes. Cases of meningitis have been reported following both cutaneous and inhalational infections. According to the CDC, and prior to the bioterrorism-related outbreak in 2001, only a handful of sporadic cases had occurred in the United States in the 20th century, with the last occurrence in 2011. Mortality rates due to uncomplicated cutaneous, GI and inhaled anthrax infections are estimated to be less than 2%, 40% or more, and 45%, respectively, while cases of anthrax meningitis are often fatal.[62]

The major neurologic complication of anthrax infection is fulminant, rapidly fatal hemorrhagic meningoencephalitis. The inhalational form of anthrax seems to be a potent inducer of neurologic symptoms, and death usually occurs within a week for those with neurologic complications.[62] *B. anthracis* typically is susceptible to penicillin, amoxicillin, erythromycin, doxycycline, and ciprofloxacin. The bioterrorism-related strain in 2001 was susceptible to fluoroquinolones, rifampin, tetracycline, vancomycin, imipenem, meropenem, chloramphenicol, clindamycin, and aminoglycoside; but resistant to third-generation cephalosporins and trimethoprim-sulfamethoxazole. Recommendations for the treatment of systemic anthrax with possible or confirmed meningitis call for the use of three active antibacterial agents. Empiric regimens that include high doses of intravenous fluoroquinolones (ciprofloxacin, levofloxacin, or moxifloxacin) along with a carbapenem (meropenem, doripenem, or imipenem) and a protein synthesis inhibitor (eg, linezolid or clindamycin) are recommended. Once penicillin susceptibility is confirmed, the carbapenem can be deescalated to intravenous penicillin G or Ampicillin.[62] Also, adjunctive corticosteroids should be considered for patients with suspected or confirmed anthrax meningitis. Doxycycline is not recommended for the treatment of anthrax meningitis owing to poor CNS penetration, compared to MIC of most bacterial pathogens, but can

be utilized for cases of inhaled or cutaneous anthrax once CNS involvement has been ruled out.[62] Finally, in 2015 the U.S. FDA approved an intravenous anthrax immune globulin for the treatment of inhalation anthrax in adults and pediatric patients along with appropriate antibacterial treatments.

Dexamethasone as an Adjunctive Treatment for Bacterial Meningitis

In addition to antibiotics, dexamethasone is a commonly used adjunctive therapy in the treatment of meningitis. Corticosteroids inhibit the production of TNF and IL-1, both potent proinflammatory cytokines. In clinical trials that measured inflammatory mediators, lower levels of TNF, PAF, or IL-1 were detected in patients treated with dexamethasone.[63,64,65] A series of animal studies, however, suggest adjuvant dexamethasone may aggravate neuronal injury by increasing apoptosis, programmed cell death, in the hippocampus of infant rats with pneumococcal and in rabbits with *E. coli* meningitis.[66] A series of early clinical studies assessing the outcomes of dexamethasone therapy for the initial treatment of bacterial meningitis showed conflicting results.[67] Subsequently, a systematic review in 2004 indicated that treatment with corticosteroids reduced both mortality and neurological sequelae in adults with community-acquired bacterial meningitis.[68] However, large randomized clinical trials showed conflicting results. A fundamental problem with corticosteroid investigations to date is that the majority of patients in the trials had *H. influenzae* meningitis, which has decreased dramatically following the introduction of polysaccharide conjugate vaccines in early 1980s. Additionally, the majority of studies examining dexamethasone use for pneumococcal meningitis were conducted before widespread penicillin-resistant pneumococcus emerged or in parts of the world where penicillin resistance is minimal.

A systematic review of 25 randomized controlled trials involving 4,121 participants showed corticosteroid use in bacterial meningitis was associated with lower rates of severe hearing loss, any hearing loss, and neurological sequelae, but did not reduce overall mortality nor was associated with beneficial effects in low-income countries. Additionally, subgroup analyses showed reduced overall mortality in pneumococcal meningitis and severe hearing loss in children with *H. influenzae* meningitis.[69] While a previous meta-analysis of five randomized, double-blinded, placebo-controlled trials of dexamethasone for bacterial meningitis in patients of all ages showed that adjunctive dexamethasone did not seem to significantly reduce death or neurological disability.[70] Thus, adjunctive corticosteroid use in the management of bacterial meningitis remains controversial.

Most clinical trials on the use of adjunctive dexamethasone in bacterial meningitis have involved children. A retrospective analysis of pediatric patients with pneumococcal meningitis and one unblinded, noncontrolled trial suggested that adjunctive steroids may decrease the neurologic sequelae and mortality associated with *S. pneumoniae* meningitis.[63,71] Also, a meta-analysis in 1997 suggested benefits in *H. influenza* meningitis and, if commenced with or before antibiotics, suggested benefit for pneumococcal meningitis in childhood.[72] Finally, a large multicenter trial did not demonstrate reduction in mortality when adjunctive dexamethasone was used for children with meningococcal or pneumococcal meningitis, but potential benefit in preventing long-term hearing loss was observed.[73]

10 Current recommendations call for the use of adjunctive dexamethasone in infants and children (6 weeks of age and older) with *H. influenza* meningitis.[15] The recommended intravenous dose is 0.15 mg/kg every 6 hours for 2 to 4 days, initiated 10 to 20 minutes prior to or concomitant with, but not after, the first dose of antibiotics. Clinical outcome is unlikely to improve if dexamethasone is given after the first dose of antimicrobial and should therefore be avoided. For infants and children 6 weeks of age and older with pneumococcal meningitis, adjunctive dexamethasone may be considered after weighing the potential benefits and possible risks.[15,74] If adjunctive dexamethasone is used, careful monitoring of signs and symptoms of GI bleeding and hyperglycemia should be employed. Moreover, the use of dexamethasone may interfere with the interpretation of clinical response to treatment, such as resolution of fever.

If pneumococcal meningitis is suspected or proven, it is recommended that adults receive dexamethasone 0.15 mg/kg (up to 10 mg) every 6 hours for 2 to 4 days with the first dose administered 10 to 20 minutes prior to first dose of antibiotics. Similar to the pediatric population, clinical outcome is unlikely to improve if dexamethasone is given after the first dose of antibiotics and should therefore be avoided.[13,15] It is often difficult to ascertain the responsible pathogen on presentation; therefore, some clinicians recommend initiating dexamethasone in all adult patients presenting with community-acquired bacterial meningitis. Dexamethasone is not routinely recommended for patients with acute community-acquired bacterial meningitis due to other bacterial etiologies.[13,15]

Routine use of dexamethasone in meningitis is not without controversy. A potential concern is adjunctive dexamethasone therapy that may reduce the penetration of antibiotics into the CSF by inhibiting or reducing meningeal inflammation. In early experimental models of meningitis, steroids decreased the CSF concentrations of ampicillin, rifampin, vancomycin, and gentamicin.[65,75] Yet, ceftriaxone and vancomycin penetration into CSF was unaffected by concurrent dexamethasone administration in pediatric patients.[76,77] Appropriate concentrations of vancomycin in CSF may be obtained even when adjunctive dexamethasone is used, but the small number of subjects studied limits the generalization of these findings.[78]

Bacterial Brain Abscess

Approximately 1,500 to 2,500 cases of brain abscess occur annually in the United States, with decreasing incidence due to contiguous spread of infection from the oropharynx, middle ear, and paranasal sinuses and increasing incidence due to contiguous spread from cranial trauma or neurosurgical procedures.[79,80] Other sources of infection include hematogenous spread from distant foci of infection, such as endocarditis or intra-abdominal infection. Mortality rates have declined significantly in the past 50 years, with 70% of survivors expected to have no to minimal neurologic sequelae.[81]

2 The clinical presentation varies depending on the number, size, and location of the abscess(es). Headache, mental status changes, focal neurologic deficits, and fever are the most common symptoms of brain abscess, but seizures and nausea and vomiting may also be seen.[81,82] Diagnosis

of brain abscess can be facilitated by CT or MRI, with preference given to MRI due to the ability to better differentiate cerebral tumor, stroke, and abscess. Lumbar puncture is not routinely recommended in patients with brain abscess, while CT-guided aspiration and biopsy can be both diagnostic and therapeutic.[81]

The etiology of brain abscess depends on the initial site of infection. Those arising from spread of infection from oropharynx, middle ear, and paranasal sinuses are commonly caused by streptococci and oral anaerobes (eg, *Actinomyces* spp., *Bacteroides* spp., *Fusobacterium* spp., *Peptostreptococcus*). Staphylococci, aerobic and gram-negative bacilli are commonly involved in postoperative abscesses or those following head trauma. *P. aeruginosa* and *Nocardia* spp. can also cause brain abscesses but are more commonly seen in immunocompromised patients.[81]

6 Because brain abscesses are commonly polymicrobial, empiric antimicrobial therapy should include antibiotics with activity against gram-positive, gram-negative, and anaerobic organisms. For example, the regimen could include vancomycin plus a third- or fourth-generation cephalosporin plus metronidazole, depending on risk factors. A carbapenem (such as meropenem) could replace the cephalosporin and metronidazole. De-escalation of therapy should occur once a causative organism is identified. While no consensus on treatment duration for brain abscesses exists, duration of therapy should be determined for each individual patient and should include consideration of the causative pathogen, size of abscess, use of surgical treatment, and response to therapy. Because seizure is a common complication of brain abscesses, anticonvulsant therapy is recommended for at least 1 year and may be discontinued when an EEG shows no epileptic activity. 10 The benefit of dexamethasone in the treatment of brain abscess is unclear and not routinely recommended, unless signs of cerebral edema are identified.[81]

Cryptococcus neoformans

Cryptococcus spp. are encapsulated soil yeasts acquired by inhalation of spores from the environment leading to CNS infection and less commonly pulmonary disease. The two main pathogenic species are *Cryptococcus neoformans* and *C. gattii*. While cryptococcal infections mainly affect persons with underlying impaired immunity such as HIV-positive (approximately 80%-95% of cases) and HIV-negative immunosuppressed patients, infections in nonimmunosuppressed individuals have been reported in North America.[83] Globally, approximately 958,000 cases of cryptococcal meningitis occur annually, mostly in Sub-Saharan Africa, resulting in an overall 3-months case-fatality rate of over 600,000.[84]

The incubation period in acquired immunodeficiency syndrome (AIDS) patients may be very short, as opposed to a relatively normal host, in whom it may be very long. Symptoms of *C. neoformans* meningitis are insidious and may be present for varying periods, depending on the host involved, before the definitive diagnosis is made. 2 Fever and a history of headaches are the most common symptoms, although altered mentation and evidence of focal neurologic deficits may be present. Examination of the CSF usually reveals mildly elevated WBCs, primarily lymphocytes (Table 106-1). 3 Diagnosis is based on the presence of a positive CSF, blood, sputum, or urine culture for *C.*

neoformans. Organisms may be seen by microscope when stained with India ink and are more likely to be seen in AIDS patients compared with other hosts. An additional rapid test helpful in diagnosis is latex agglutination, which detects the presence of cryptococcal antigens. Latex agglutination is associated with overall sensitivities and specificities of 93% to 100% and 93% to 98%, respectively.[83] A cryptococcal antigen detection test needs to be considered in any patient presenting initially with meningitis. Risk factors predictive of a poor outcome include lethargy at presentation, nonimmunosuppressed patients, high CSF cryptococcal antigen titer, low CSF WBC count, low CD4 cell count, fungemia, and elevated CSF pressure.[85,86,87]

Rapid sterilization of CNS through rapid fungicidal activity is the main approach of induction therapy, which ranges from 2 to 6 weeks, followed by consolidation therapy for 8 weeks.[88] Despite poor penetration into the CSF, amphotericin B has long been the drug of choice for the treatment of acute cryptococcal meningitis due to its rapid fungicidal activity.[85] A landmark clinical trial showed amphotericin B (1 mg/kg/day) combined with flucytosine (100 mg/kg/day) for 2 weeks was more effective than amphotericin alone for 4 weeks or in combination with fluconazole (400 mg twice daily) for 2 weeks in HIV-positive patients.[89] Additionally, this combination was associated with the most rapidly fungicidal activity, when compared with amphotericin alone, in combination with fluconazole or in combination with fluconazole and flucytosine.[90]

Clinical Controversy...

Timing of HAART initiation following acute cryptococcal meningitis in patients with HIV-AIDS remains an area of clinical controversy. Conflicting results from earlier studies prompted a recent prospective trial (COAT Trial) of adult HIV-positive patients with acute cryptococcal meningitis comparing early (1-2 weeks) and late (5 weeks) initiation of HAART following diagnosis. Late HAART initiation was associated with a significant reduction in 26-week mortality. Current HIV and cryptococcal meningitis treatment guidelines recommend a short delay (2-10 weeks) between diagnosis and HAART initiation; however, more definitive recommendations remain an area of clinical debate.

Unfortunately, in the AIDS population, flucytosine is often poorly tolerated, causing bone marrow suppression and GI distress. Careful monitoring of hematologic parameters, therapeutic drug monitoring (TDM) and dose adjustment for patients with renal insufficiency are recommended to avoid flucytosine-associated toxicities. Amphotericin B alone or in combination with high-dose fluconazole may be reasonable alternatives to standard treatment.[91,92] Lipid formulations of amphotericin B at higher doses (3-5 mg/kg/day) can be used for HIV-positive patients with or predisposed to renal dysfunction and are recommended for organ-transplant recipients.[88]

Azole therapy is the most studied alternative regimen for the treatment of *C. neoformans* meningitis in HIV-positive patients. Fluconazole and itraconazole have been studied as monotherapy with mixed results. If used alone or in combination with flucytosine, higher fluconazole doses of 800 to 2,000 mg/day are recommended due to higher success rates.[93] To note, the rate of fluconazole-resistant *C. neoformans* has been increasing in recent years.[94] Itraconazole has limited utility in induction therapy due to limited CSF levels of the active drug. Generally, itraconazole suspension is preferred due to better absorption, and TDM is recommended to ensure optimal drug levels.[88] Voriconazole in

combination with amphotericin B showed similar rate of clearance of cryptococcal CFU in CSF samples compared with standard therapy.[91] Posaconazole has demonstrated clinical activity against cryptococcal and other fungal infections of the CNS in patients with refractory disease or otherwise intolerant to standard antifungal agents. Posaconazole appeared well tolerated at oral doses of 800 mg/day and may be an alternative in the treatment of fungal CNS infection due to *C. neoformans*.[95] More data are needed to determine what role the new azole antifungal agents will play in future treatment of cryptococcal meningitis. Also, widespread TDM of new azole antifungals will be needed to ensure adequate CNS therapeutic concentrations.

HIV-positive persons often require extended maintenance or suppressive therapy, minimum of 12 months, because of high relapse rates following primary therapy (induction and consolidation phases) for *C. neoformans*. A large multicenter, controlled trial compared fluconazole 200 mg/day and amphotericin B 1 mg/kg/wk in the prevention of relapse. Two percent of patients receiving fluconazole versus 18% of patients on amphotericin B relapsed. In addition, the amphotericin B group had significantly more frequent bacterial infections, bacteremia, and drug-related toxicity.[96] Fluconazole was also superior to itraconazole in the prevention of relapse.[97] Current guidelines recommend continuing maintenance therapy until immune reconstitution takes place. Guidelines for the prevention of opportunistic infections in HIV-infected persons are updated frequently and can be found at www.aidsinfo.nih.gov. Readers interested in treatment guidelines for cryptococcal meningitis in HIV-negative immunosuppressed, such as transplant recipients, and nonimmunosuppressed individuals are encouraged to review the Infectious Diseases Society of America Guidelines for the management of cryptococcal disease.[88]

Viral Encephalitis

Encephalitis is defined by the presence of an inflammatory process of the brain in association with clinical evidence of neurologic dysfunction.[24] Patients with metabolic disturbances, organ dysfunction, and noninfectious encephalitis, including postimmunization encephalitis or encephalomyelitis, can have similar clinical presentation to those with infectious encephalitis. Several infectious organisms have been identified to cause encephalitis, with viral etiologies being the most commonly diagnosed.[98,99] Additionally, meningoencephalitis is a term commonly used to describe meningeal inflammation along with encephalitis.

The epidemiology of viral encephalitis in the United States has changed dramatically since the mid-1960s because of the introduction of large-scale polio, rubella, varicella-zoster virus (VZV), and mumps immunization programs. Worldwide, mumps remains a causative agent of viral encephalitis in countries with low vaccination rates. Poliomyelitis, once a significant cause of encephalitis, is now confined to only a few less-developed countries. While a confirmed or probable pathogen is identified in less than 50% of cases, common causes of viral encephalitis and meningoencephalitis in the United States include herpes simplex virus (HSV), West Nile virus (WNV), and the enteroviruses.[98,99] Additionally, viral encephalitis is caused by a variety of other pathogens, such as arboviruses, adenoviruses, influenzae virus A and B, rotavirus, corona virus, cytomegalovirus (CMV), VZV, Epstein-Barr virus, and lymphocytic choriomeningitis. Collectively, about 20,000 encephalitis-

associated hospitalizations are expected per year in the United States, with a case fatality rate of more than 5% and total health-care burden of nearly $2 billion.[56,99]

Viral encephalitis is acquired primarily by hematogenous spread or, alternatively, by neuronal spread of the causative pathogen. After entry into the host, viral replication occurs, resulting in dissemination through the reticuloendothelial system or vasculature. Infection of the capillary endothelial cells and choroid plexus may provide a conduit for CNS infections. Viruses such as polio, HSV, and VZV may also gain access to the CNS by axonal retrograde transmission from peripheral nerve endings. Once a virus gains access to the CNS, the course of infection depends on the virulence of the particular virus and the host immune response. Subsequent neuronal injury is caused by direct cell damage due to viral replication, but inflammatory and immune-mediated responses also contribute to neurological damage.[16,17]

In contrast with purulent meningitis, host response to viral encephalitis is mediated primarily through cytotoxic T-lymphocytes. Increases in concentrations of IL-1, IL-6, and interferon (INF)-α, -β and -γ may occur. While cytokine assays are available for investigational use, they are not used routinely in the clinical diagnosis of viral encephalitis.[16,17] 2 The clinical syndrome associated with viral encephalitis generally is independent of viral etiology and may vary depending on the patient's age. Common signs in adults include headache, mild fever, nuchal rigidity, malaise, drowsiness, nausea, vomiting, and photophobia. Only fever and irritability may be evident in the infant, and acute bacterial meningitis must be ruled out as a cause of fever when no other localized findings are observed in a child. Duration of symptoms generally is 1 to 2 weeks, and specific manifestations outside the meninges can also occur depending on the viral etiology.

Laboratory examination of the CSF usually reveals a pleocytosis with 100 to 1,000 WBC/mm^3 (0.1-1 × 10^9/L), which are primarily lymphocytic; however, 20% to 75% of patients with viral encephalitis may have a predominance of polymorphonuclear cells on initial examination of the CSF. On repeat lumbar puncture, 90% of patients presenting initially with a predominance of neutrophils experience a shift to a predominance of mononuclear cells. Other laboratory findings include normal to mildly elevated protein concentrations and normal or mildly reduced glucose concentrations (see Table 106-1).[16,17]

3 As mentioned earlier, pathogens responsible for viral encephalitis are often not identified. Poor laboratory recovery of viral pathogens and limited treatment options for viral encephalitis made the need for specific identification of pathogens of questionable value. Advances in diagnostic laboratory techniques and the potential for decreased costs associated with longer duration of hospitalization for patients with unconfirmed viral encephalitis have led to a reevaluation of the need for confirmatory pathogen diagnosis. When clinical signs warrant pathogen identification, appropriate laboratory diagnostic techniques, including PCR and serologic testing, should be undertaken. Molecular methods are preferred to conventional laboratory tests, such as viral cultures and brain biopsy, in the diagnosis of viral encephalitis owing to improved sensitivity and specificity, higher yield and rapid results.[23,24]

Supportive and symptomatic treatments of patients with viral encephalitis are of great importance due to limited treatment options for most viral etiologies. Such treatments may include seizure

control, hemodynamic management, venous thromboembolism prevention, ICP management, and secondary bacterial infection prevention. Corticosteroid therapy is generally not recommended in most viral encephalitis cases; however, treatment should be considered for patients with cerebral edema and increased ICP.[23,24]

Although there are numerous pathogenic causes of viral encephalitis, much of the clinical presentation, diagnosis, and treatment are similar. The most commonly isolated viral etiologies are described here. Both HSV type 1 (HSV1) and HSV type 2 (HSV2) are considered the most common treatable causes of viral encephalitis. HSV1 is associated with encephalitis in adults, whereas HSV2 is associated predominantly with encephalitis in newborns.[99,100] Sexually active adults acquire HSV meningitis during or after an attack of genital or rectal HSV, whereas neonates acquire the virus during passage through the vaginal canal of mothers with active HSV infection. HSV PCR testing on CSF specimens should be performed for all patients with presumed encephalitis. Moreover, repeat testing should be considered for patients with an initial negative test after 3 to 7 days.[24] Establishing the correct diagnosis as early as possible is paramount because of high mortality rate without treatment (approaches 70%), and unlike other viral etiologies, specific and effective therapy is available. As a result, empirical therapy of suspected HSV encephalitis, while laboratory results are pending, is necessary. Delaying antiviral therapy has been consistently associated with unfavorable outcomes and increased mortality across several studies. In one retrospective study of 184 patients with HSV encephalitis, administration of intravenous acyclovir within first day of hospital admission was associated with a lower mortality rate (13% vs 31%).[26] Additionally, a clinical decision to treat may need to be made regardless of test results.

Acyclovir is the drug of choice for HSV encephalitis. In adult patients with normal renal function, acyclovir is usually administered as 10 mg/kg intravenously every 8 hours for 2 to 3 weeks.[23,24] Higher doses of acyclovir (20 mg/kg every intravenously every 8 hours) have been used in neonates and are associated with lower mortality rates.[101] HSV resistance to acyclovir has been reported with increasing incidence, particularly in immunocompromised patients with prior or chronic exposures to acyclovir, ranging from 3.5% to 10% in immunocompromised patients.[102] The alternative treatment for acyclovir-resistant HSV is foscarnet. The dose for patients with normal renal function is 40 to 60 mg/kg infused over 1 hour every 8 to 12 hours for 3 weeks, with the higher dose typically reserved for HIV-infected individuals.[23] Ensuring adequate hydration is imperative to decrease risk of acyclovir- and foscarnet-induced nephrotoxicity. In addition, patients receiving foscarnet should be monitored for seizures related to alterations in plasma electrolyte levels. Finally, a recent prospective study examined the utility of long-term antiviral treatment on overall survival with no or mild neuropsychological impairment. Adult patients who completed standard initial HSV encephalitis treatment followed by an additional 3-month course of oral valacyclovir did not show improvements in neuropsychological testing 12 months later compared to placebo.[103]

Because of the recent epidemic in the United States, a separate discussion of the WNV is warranted. Although primarily mosquitoes transmit WNV, transmissions via blood products, organ transplantation, transplacental transfer, and breast milk have been documented. Similar to other arboviruses, the incubation period for WNV ranges from 3 days to 2 weeks. Infection with WNV is asymptomatic in most adults or causes a mild flu-like syndrome characterized by fever, malaise,

myalgia, and lymphadenopathy. Among 41,762 reported cases of WNV in the United States between 1999 and 2014, the overall mortality rate was approximately 4% (9% in patients with neuroinvasive disease).[104] Many patients develop a maculopapular, erythematous rash, which is more common in children than in adults and is uncommon in other forms of viral encephalitis. The other neurologic manifestations include fever, nausea, vomiting, headache, altered mental status, movement disorders, and/or a syndrome much like poliomyelitis.[105] The primary risk factor for this manifestation seems to be advanced age, but alcohol abuse, diabetes, hypertension, immunosuppression, and cardiovascular disease were also identified as potential risk factors for neuroinvasive disease and worse outcomes.[105,106] The poliomyelitis syndrome is characterized by an early prodromic phase of fevers and weakness followed by the sudden onset of flaccid paralysis. CSF examination of WNV encephalitis typically shows pleocytosis and a slightly elevated CSF protein concentration. Several diagnostic methods have been developed for WNV, including a PCR assay and enzyme-linked immunosorbent assay (ELISA) tests. However, serologic tests (ELISA) can cross-react with other flaviviruses causing a false-positive result. Moreover, serum IgM antibodies for WNV can persist for up to 1 year, leading to confusion regarding whether the infection is an acute or previous infection. Ribavirin has shown inhibitory effects on the WNV in neural tissue cultures, but this has not been studied in controlled trials. Finally, DNA vaccines were studied in animals and have shown positive results.[105] Treatment is typically supportive, including treatment for seizures and increased ICP, and in the majority of cases, the disease is self-limiting.[23,24]

CMV has emerged as a major cause of morbidity and mortality in immunocompromised patients, including HIV-infected individuals and transplant recipients on immunosuppressants. CNS infections with CMV are often difficult to treat, with higher failure rates and poor outcomes. Combination therapy with ganciclovir and foscarnet is recommended for induction treatment due to higher failure rates and lack of survival benefits when monotherapy with either agent is utilized.[23,24] In adult patients, ganciclovir 5 mg/kg every 12 hours and foscarnet 60 mg/kg every 8 hours (or 90 mg/kg every 12 hours) for 3 weeks are recommended during the induction phase, followed by maintenance phase with either agent. Other interventions that may improve survival outcomes include the initiation of highly active antiretroviral therapy (HAART) in untreated HIV-infected patients and reduction of immunosuppression intensity in transplant recipients.

HIV encephalitis is a common CNS complication associated with AIDS. Frequently, patients may complain of headache, photophobia, or stiff neck at the time of presumed seroconversion. As the disease progresses neurologic symptoms are frequently reported secondary to other opportunistic infections. Diagnosis of viral encephalitis is difficult because mental status and neurologic examinations are not sensitive enough to detect early changes. Direct evidence of HIV encephalitis can be obtained through CSF culture, p24 antigen testing, or qualitative or quantitative PCR for HIV RNA. Diagnostic workup of other potential copathogens, such as HSV, *Toxoplasma gondii*, *Mycobacterium tuberculosis*, *Aspergillus* spp, and *Cryptococcus*, should also be performed. Refer to chapter on HIV infection for a complete discussion of infectious complications in HIV-positive individuals.

Other Etiologies

Mycobacterium Tuberculosis

M. tuberculosis is the primary cause of tuberculous meningitis and remains the most life-threatening form of extrapulmonary tuberculosis. The incidence of tuberculosis, in general, has decreased to three cases per 100,000 individuals in the United States in 2013.[107]

The CDC recommends an initial regimen of four drugs for empirical treatment of *M. tuberculosis*. This regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol for the first 2 months, generally followed by isoniazid plus rifampin for the remaining duration of therapy.[108] The recommended therapy for HIV-positive individuals is the same as for immunocompetent patients, although rifabutin may be considered in place of other rifamycins in an effort to minimize drug interactions with protease inhibitors and nonnucleoside reverse-transcriptase inhibitors. Therapy in HIV-negative and HIV-positive patients should be individualized based on susceptibility patterns and guidelines from the CDC and the American Thoracic Society, which are updated frequently and available on the Internet (www.cdc.gov/nchstp/tb/pubs/mmwrhtml/maj_guide.htm). Patients with *M. tuberculosis* meningitis should be treated for 9 to 12 months or longer with multiple-drug therapy, and patients with rifampin-resistant strains may receive up to 18 to 24 months of therapy.

***Treponema pallidum* (Neurosyphilis)**

Infection of the CNS by *Treponema pallidum* can occur at any stage of the disease although is most commonly seen in tertiary or latent syphilis many years, even decades, after the initial exposure. According to the CDC, incidence of late latent syphilis, which includes neurosyphilis, can develop in 15% of people who do not receive treatment for syphilis.[109] Patients with neurosyphilis may be asymptomatic, or present with signs and symptoms consistent with acute meningitis. Diagnosis is based on CSF findings, neurologic manifestations, and serologic evidence of exposure.[110] Aqueous penicillin G is recommended for treatment dosed either 3 to 4 million Units every 4 hours or 18 to 24 million units as a continuous infusion for a duration of 10 to 14 days.[109] If CSF pleocytosis is initially present, CSF examination should be repeated every 6 months until the cell count is normal. For further reading on the manifestations and treatment of syphilis we refer you to chapter on sexually transmitted infections in this text.

Toxoplasma gondii

Toxoplasmic encephalitis (TE) is caused by the protozoan *T. gondii*. Approximately 22.5% of the U.S. population 12 years and older have been infected with *T. gondii*. In other parts of the world, up to 95% of populations are infected. The primary routes of transmission are foodborne, animal-to-human (cats serving as the definitive host), mother-to-child (congenital), blood transfusions, and organ transplantation.[111] TE is typically caused by the reactivation of disease in immunocompromised patients, especially those with AIDS, or intrauterine infection in newborns. Clinical manifestations include extrapyramidal signs and symptoms, headache, seizures, confusion, hemiparesis, cranial nerve abnormalities, or fever.[24] In congenital toxoplasmosis, patients may also present with hydrocephalus, intracerebral calcification, microcephaly, convulsions, or chorioretinitis.[24,112] Definitive diagnosis of TE requires a clinical sample via a brain biopsy; therefore, TE is presumptively diagnosed on the basis of

clinical symptoms, positive serology for antitoxoplasma IgG antibodies, and identification of space-occupying lesions on CT, MRI, or other radiologic imaging. In patients with AIDS, MRI typically shows multiple ring-enhancing lesions. *T. gondii* can also be detected by PCR in CSF; however, the sensitivity is low (50%) and the result is usually negative once treatment has started.[24,112,113] First-line treatment for TE in adults consists of pyrimethamine plus sulfadiazine plus leucovorin. Leucovorin is typically added to the treatment regimen to reduce the likelihood of hematologic toxicity associated with pyrimethamine. In patients who are unable to tolerate sulfadiazine, clindamycin may be used as an alternative. Other alternative treatment options include trimethoprim-sulfamethoxazole, atovaquone plus pyrimethamine plus leucovorin, atovaquone plus sulfadiazine, atovaquone monotherapy, or pyrimethamine plus leucovorin plus azithromycin. Treatment recommendations are the same in pediatric patients; however, several of the alternative regimens have not been studied in children.[24,112,113]

Borrelia burgdorferi

LD is caused by the spirochete *Borrelia burgdorferi* and is the most common tick-borne infection in North America and Europe.[114] Lyme neuroborreliosis (LNB) is an infectious disorder of the nervous system caused by *B. burgdorferi* and has been reported in up to 10% to 15% of patients with untreated LD. CNS involvement may include meningitis, myelitis, cerebral vasculitis, or encephalitis. Clinical manifestations include fever, headache, fatigue, photosensitivity, phonosensitivity, confusion, hemiparesis, cranial neuropathy (facial neuropathy being the most common), cerebellar ataxia, ocular flutter, apraxia, opsoclonus-myoclonus syndrome, or Parkinson-like symptoms. Poliomyelitis-like syndromes and acute stroke-like symptoms caused by cerebral vasculitis have been documented in single-case reports but are considered rare. Unlike the European LD, the North American LD is also characterized by a skin rash called erythema migrans.[114,115] Currently there is no international consensus for the diagnosis of LNB. Diagnosis is primarily based on the presence of neurological symptoms without other obvious reasons, CSF analysis (lymphocytic pleocytosis, moderately elevated protein, normal glucose), intrathecal *B. burgdorferi* antibody production, blood and CSF serologic testing (ELISA plus Western blot), and MRI demonstrating areas of inflammation.[24,114,115] PCR testing for detection of *B. burgdorferi* in CSF has a sensitivity of less than 10% to 30% and has an unknown specificity, therefore is not routinely recommended. Parenteral treatment with ceftriaxone once daily is recommended as first-line treatment of LNB. Patients with cranial neuropathy without clinical signs of meningitis may be treated with oral amoxicillin, doxycycline, or cefuroxime axetil. The European Federation of Neurological Societies (EFNS) guidelines also recommend oral doxycycline as a first-line option for patients with symptoms confined to the meninges, cranial nerves, nerve roots, or peripheral nerves based on its CSF penetration, ability to achieve CSF concentrations above the MIC, and several Class III studies showing similar short- and long-term efficacy to various parenteral regimens.[115] Alternative parenteral options to ceftriaxone include cefotaxime or penicillin G. For patients intolerant to β-lactams, doxycycline oral or intravenous is suggested.

EVALUATION OF THERAPEUTIC OUTCOMES

Signs and Symptoms

Because of the potential for rapid deterioration associated with CNS infections, signs and symptoms of fever, headache, meningismus (eg, nuchal rigidity, Brudzinski's or Kernig's sign), vital signs, and signs of cerebral dysfunction should be evaluated every 4 hours for the initial 3 days and then daily thereafter. The Glasgow Coma Scale should be used in severely ill patients. Trends in improvement and resolution rather than single evaluations in time are more important in monitoring the signs and symptoms of meningitis.

Microbiologic Findings

CSF and blood samples for gram-stain, cultures, and sensitivity testing should be taken prior to starting antibiotic therapy. If lumbar puncture is delayed, however, antibiotics should be started. Although the CSF cultures may be negative, antibiotic therapy rarely interferes with the protein and/or glucose concentrations in the CSF. Furthermore, if the laboratory is made aware of the antibiotic therapy, steps can be taken to diminish the effects of the antibiotic during the detection process. Gram stain results can be obtained immediately and can guide empirical antibiotic treatment. Identification of the organism can be made within 24 hours, and sensitivities should be available within 48 hours. Repeat cultures should be performed to help determine if sterilization is achieved. A second tube of blood should be taken to allow for latex agglutination tests of antigens to common meningeal pathogens (*H. influenzae*, *S. pneumoniae*, *N. meningitidis*, *E. coli*, and group B *Streptococcus*) if the gram stain has not been helpful.

CSF Examination

In bacterial meningitis, the CSF WBC count usually is greater than 1,000 cells/mm^3 (1,000 × 10^6/L), the CSF protein concentration is elevated, and the CSF glucose concentration (hypoglycorachia) is often low (45 mg/dL or less [2.5 mmol/L or less] or 50%-60% of a simultaneous blood glucose value). Viral encephalitis, in contrast, results in relatively normal CSF protein and glucose levels and typically does not result in greater than 90% polymorphonuclear neutrophils (PMNs) in the CSF (Table 106-1).

Chapter 107: Lower Respiratory Tract Infections

FIGURE 107-1

Martha G. Blackford; Mark L. Glover; Michael D. Reed

INTRODUCTION

KEY CONCEPTS

- 1 Respiratory infections remain a major cause of morbidity from acute illness in the United States and likely represent the most common reasons why patients seek medical attention.
- 2 The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, whereas microbes less commonly gain access to the lungs via the blood from an extrapulmonary source or by inhalation of infected aerosol particles. The competency of a patient's immune status is an important factor influencing the susceptibility to infection, etiologic cause, and disease severity.
- 3 An appropriate treatment regimen for the patient with uncomplicated lower respiratory tract infection can be established by evaluating the patient history, physical examination, chest radiograph, and properly collected sputum for culture interpreted in light of current knowledge of the most common lung pathogens and their antibiotic susceptibility patterns within the community.
- 4 Acute bronchitis is caused most commonly by respiratory viruses and almost always is self-limiting. Therapy targets associated symptoms, such as lethargy, malaise, or fever and may include fluids for rehydration. Routine use of antibiotics should be avoided and medication to suppress cough is rarely indicated.
- 5 Chronic bronchitis is caused by several interacting factors, including inhalation of noxious agents (most prominent are cigarette smoke and exposure to occupational dusts, fumes, and environmental pollution) and host factors including genetic factors and bacterial (and possibly viral) infections. The hallmark of this disease is a chronic cough, accompanied by excessive

production, and expectoration of sputum with a persistent presence of microorganisms in the patient's sputum.

- 6 Treatment of acute exacerbations of chronic bronchitis includes attempts to mobilize and enhance sputum expectoration (chest physiotherapy, humidification of inspired air), oxygen if needed, aerosolized bronchodilators in select patients with demonstrated benefit, and possibly antibiotics.

- 7 Respiratory syncytial virus is the most common cause of acute bronchiolitis, an infection that mostly affects infants during their first year of life. In the well infant, bronchiolitis usually is a self-limiting viral illness.

- 8 The most prominent pathogen causing community-acquired pneumonia in otherwise healthy adults is *Streptococcus pneumoniae*, whereas the most common pathogens causing hospital-acquired are *Staphylococcus aureus* and gram-negative aerobic bacilli. Anaerobic bacteria are the most common etiologic agents in pneumonia that follow aspiration of gastric or oropharyngeal contents.

- 9 Treatment of community-acquired pneumonia may consist of humidified oxygen for hypoxemia, bronchodilators when bronchospasm is present, rehydration fluids, and chest physiotherapy for marked accumulation of retained respiratory secretions. Antibiotic regimens should be selected based on presumed causative pathogens and pulmonary distribution characteristics and should be adjusted to provide optimal, targeted therapy against pathogens identified by culture (sputum or blood).

- 10 Treatment of hospital-acquired pneumonia requires aggressive therapy with careful consideration of the dominance and susceptibility patterns of the pathogens present within the institution.

1 Respiratory tract infections remain a major cause of morbidity from acute illness in the United States and most likely represent the single most common reason patients seek medical attention. This chapter focuses on bacterial and viral infections involving the lower respiratory tract, which includes the tracheobronchial tree and lung parenchyma.

2 The respiratory tract has an elaborate system of host defenses, including humoral immunity, cellular immunity, and anatomic mechanisms.[1] When functioning properly, respiratory tract host defenses are markedly effective in protecting against pathogen invasion and removing potentially infectious agents from the lungs. For the most part, infections in the lower respiratory tract occur only when these defense mechanisms are impaired, as in cases of dysgammaglobulinemia or compromised ciliary function, such as that caused by the chronic inflammation accompanying cigarette smoking. In addition, local defenses may be overwhelmed when a particularly virulent microorganism or excessive inoculum invades lung parenchyma. The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, which, after achieving sufficiently high concentrations, gain access to the lung via aspiration of oropharyngeal

secretions. Less commonly, microbes enter the lung via the blood from an extrapulmonary source or by inhalation of infected aerosolized particles. The specific type of pulmonary infection caused by an invading microorganism is determined by a variety of host factors, including age, anatomic features of the airway, and specific characteristics of the infecting agent.

The most common infections involving the lower respiratory tract are bronchitis, bronchiolitis, and pneumonia. Bronchitis and bronchiolitis are inflammatory conditions of the large and small airways, respectively, of the tracheobronchial tree. The inflammatory process does not extend to the alveoli. Bronchitis frequently is classified as acute or chronic; acute bronchitis occurs in individuals of all ages, whereas chronic bronchitis primarily affects adults. Bronchiolitis is a disease of infancy.

Lower respiratory tract infections in children and adults most commonly result from either viral or bacterial invasion of lung parenchyma. The diagnosis of viral infections rests primarily on the recognition of a characteristic constellation of clinical signs and symptoms. Because treatment is largely supportive, only occasionally does the diagnosis require laboratory confirmation; this is achieved through serologic tests or identification of the organism by culture or antigen detection in respiratory secretions.[2] Laboratory techniques using polymerase chain reaction (PCR), microarrays, and multiplex ligation-dependent probe amplification, to name a few, have emerged as a means to identify specific pathogens rapidly and accurately.[3]

In contrast, because bacterial pneumonia usually necessitates expedient, effective, and specific antibiotic therapy, its management depends, in large part, on an understanding of the risk factors for acquiring pneumonia, predominant pathogens within the community, and, if necessary, isolation of the etiologic agent by culture from lung tissue or secretions.[4,5,6] The pharynx is colonized with many organisms that can cause pneumonia; therefore, culture of expectorated sputum can be misleading unless the specimen is examined to ensure that it has originated from the lower respiratory tract. The Gram stain provides the easiest method for distinguishing lower from upper respiratory tract secretions; moreover, through determination of the shape and color of the bacteria, the Gram stain frequently narrows the microbiologic differential diagnosis sufficiently to allow accurate initial therapy. Scanned under low-power microscopy, Gram-stained expectorated upper respiratory tract secretions contain many irregularly shaped epithelial cells with little evidence of inflammation and may not reflect the pathogen. In contrast, a lower-tract specimen from a patient with bacterial pneumonia usually contains multiple neutrophils per high-powered field and a single or predominant bacterial species. More aggressive procedures can be performed in an attempt to more accurately identify responsible pathogens including respiratory secretion samples obtained via bronchoscopy or bronchoalveolar lavage (BAL). Culture of specimens confirmed to originate from the lower tract by Gram stain or collection via BAL provides valuable diagnostic information for the majority of patients with bacterial pneumonia. In addition, pneumonia promotes the release of inflammatory mediators and acute-phase proteins, such as C-reactive protein, which is significantly elevated in serum in the presence of respiratory tract infections.[7] Unfortunately with the exception of pathogen identification by culture, elevations in C-reactive protein, changes in sputum color or peripheral white blood count, etc., are not specific for determining viral, bacterial, or fungal etiology. Newer genomic testing may add tremendously in determining the identity of responsible pathogen(s) and then selection of optimal antimicrobial therapy.

3 An appropriate treatment regimen for the patient with an uncomplicated lower respiratory tract infection usually can be established by history, physical examination, chest radiograph, and properly collected sputum cultures interpreted in light of the most common lung pathogens and their antibiotic susceptibility patterns within the community.[2,5] More sophisticated or invasive diagnostic methods (eg, computed tomography, bronchoscopy, and lung biopsy)[2] are reserved for severely ill patients who are unable to expectorate sputum or who are not responding to empirical therapy or for pulmonary infections occurring in immunocompromised patients.

BRONCHITIS

Acute Bronchitis

Epidemiology and Etiology

Acute bronchitis occurs year round, but more commonly during the winter months. Acute bronchitis is responsible for at least 10 million office and urgent care visits annually, underscoring its major financial impact on the healthcare system. Acute bronchitis is characterized by inflammation of the epithelium of the large airways resulting from infection or exposure to irritating environmental triggers (eg, air pollution and cigarette smoke). Acute (viral) infection and or smoking are the most common precipitants of attacks, which usually manifest initially as a persistent cough.

4 Respiratory viruses are the predominant infectious agents associated with acute bronchitis, accounting for 85% to 95% of occurrences. The most common infecting agents include influenza A and B, respiratory syncytial virus (RSV), and parainfluenza virus, whereas the common cold viruses (rhinovirus and coronavirus) and adenovirus are encountered less frequently. Although far less common, bacterial pathogens are involved in a minority of cases and involve pathogens often associated with community-acquired pneumonia (CAP), including *Mycoplasma pneumoniae*, *Streptococcus pneumonia, Haemophilus influenzae, Moraxella catarrhalis*, and less commonly *Chlamydophila pneumoniae* and *Bordetella pertussis*, the agent responsible for whooping cough. Although a primary bacterial etiology for acute bronchitis appears rare, secondary bacterial infection may be involved, particularly in patients with underlying disease(s).[8]

Pathogenesis

4 Since acute bronchitis is primarily a self-limiting illness and rarely a cause of death, few data describing the pathology are available. In general, infection of the trachea and bronchi yields inflammation-induced hyperemic and edematous mucous membranes with an increase in bronchial secretions. Destruction of respiratory epithelium can range from mild to extensive and may affect bronchial mucociliary function. In addition, the increase in desquamated epithelial cells and bronchial secretions, which can become thick and tenacious, further impairs mucociliary activity. The probability of permanent damage to the airways as a result of acute bronchitis remains unclear but appears unlikely. However, epidemiologic evaluations support the belief that recurrent acute respiratory infections may be associated with increased airway hyperreactivity and possibly the pathogenesis of

asthma, chronic obstructive pulmonary disease (COPD), or possibly the asthma-COPD overlap syndrome.[9,10]

Clinical Presentation

Acute bronchitis usually begins as an upper respiratory infection with nonspecific complaints.[8,11] Cough is the hallmark of acute bronchitis and occurs early. The onset of cough may be insidious or abrupt, and the symptoms persist despite resolution of nasal or nasopharyngeal complaints; cough may persist for up to 3 or more weeks. Frequently, the cough initially is nonproductive, but then progresses, yielding mucopurulent sputum. In older children and adults, the sputum is raised and expectorated; in the young child, sputum often is swallowed and can result in gagging and vomiting. Substantial discomfort may result from the coughing. Dyspnea, cyanosis, or signs of airway obstruction are observed rarely unless the patient has underlying pulmonary disease, such as emphysema or COPD. Fever, when present, rarely exceeds 39°C (102.2°F) and appears most commonly with adenovirus, influenza virus, and *M. pneumoniae* infections. The diagnosis typically is made on the basis of a characteristic history and physical examination, and should be differentiated from asthma or bronchiolitis as these latter diseases are usually associated with wheezing, shortness of breath, and hypoxemia. Bacterial cultures of expectorated sputum are of limited use because of the inability to avoid normal nasopharyngeal flora by the sampling technique. Similarly, viral cultures are unnecessary. In the absence of important risk factors, including COPD, congestive heart failure, or immune compromise, throat/sputum cultures have no role in the routine care of patients with acute bronchitis. As newer antigen-based PCR and genetic diagnostic tests for identifying specific pathogens become more routinely available,[12] specific etiologic causes of acute bronchitis will be identified. However, for the vast majority of affected patients, an etiologic diagnosis is unnecessary and will not change the prescribing of routine supportive care for the management of these patients.

TREATMENT

Desired Outcome

In the absence of a complicating bacterial superinfection, acute bronchitis almost always is self-limiting. The goals of therapy are to provide comfort to the patient and, in the unusually severe case, to treat associated dehydration and respiratory compromise.[8]

General Approach to Treatment

4 Treatment of acute bronchitis is symptomatic and supportive in nature. Reassurance and antipyretics frequently are all that are needed. Bedrest for comfort may be instituted as desired. Patients should be encouraged to drink fluids to prevent dehydration and possibly to decrease the viscosity of respiratory secretions. Mist therapy (use of a vaporizer) may promote the thinning and loosening of respiratory secretions.

Pharmacologic Therapy

Mild analgesic–antipyretic therapy often is helpful in relieving the associated lethargy, malaise, and fever. Aspirin or acetaminophen (650 mg/dose in adults [maximum less than 4 g/day] or 10-15 mg/kg/dose in children [maximum 60 mg/kg/day]) administered every 4 to 6 hours or ibuprofen (200-800 mg/dose in adults [maximum 3.2 g/day] or 10 mg/kg/dose in children [maximum 40 mg/kg/day]) should be administered every 6 to 8 hours. Aspirin should be avoided in children less than 19 years of age with a fever-causing illness and acetaminophen or ibuprofen used as the preferred agents because of a possible, but unclear and unproven, association between aspirin use and the possible development of Reye's syndrome.[13]

Use of ibuprofen as an antipyretic has increased. The drug's antipyretic efficacy appears identical to that of aspirin or acetaminophen, although its duration of antipyretic effect may be slightly longer (eg, 3-4 hours for aspirin and acetaminophen vs more than 5-6 hours for ibuprofen). A possible association with acetaminophen use during pregnancy or childhood and the subsequent development of asthma has raised some question as to the viability of routine acetaminophen use during childhood.[14] For these reasons, ibuprofen has become a preferred analgesic and antipyretic by many pediatric practitioners. However, caution should be exercised with the use of ibuprofen in patients younger than 6 months, elderly patients, and individuals with poor renal function. Aspirin, ibuprofen, and other nonsteroidal anti-inflammatory drugs inhibit prostaglandin synthesis and may adversely influence renal function in these predisposed patient populations.

Patients may present with mild-to-moderate wheezing. In otherwise healthy patients, no meaningful benefits have been described with the routine use of oral or aerosolized β_2-receptor agonists[15] and/or oral or aerosolized corticosteroids. Corticosteroids should be avoided in patients with acute bronchitis. A Cochrane review concluded (based on benefit vs potential for adverse effects) there is no evidence to support the use of β_2-receptor agonists in either pediatric or adult patients with acute bronchitis; however, in adults with airflow obstruction, there was a trend toward improvement.[15] Some clinicians, despite no data, may initiate a brief trial (eg, ~5-7 days) of β_2-receptor agonists and even oral or inhaled corticosteroid for patients with a persistent (>14-20 days), troublesome cough. This is rarely if ever necessary in patients with uncomplicated acute bronchitis and should be avoided. Cough may persist for 3+ weeks and airway hyperresponsiveness for 5-6 weeks in as many as 50% of affected patients. In contrast, COPD patients experiencing an acute exacerbation can (will) benefit from a short course of corticosteroid. Studies do not support the use of mucolytic agents in patients with acute bronchitis.

Patients suffering from acute bronchitis frequently medicate themselves with nonprescription cough and cold remedies containing various combinations of antihistamines, sympathomimetics, and antitussives despite the lack of definitive evidence supporting their effectiveness. The tendency of these agents to dehydrate bronchial secretions could aggravate and prolong the recovery process. Although not recommended for routine use, persistent, mild cough, which may be bothersome, can be treated with dextromethorphan; more severe coughs may require intermittent codeine or other similar agents.[16] In severe cases, the cough may be persistent enough to disrupt sleep, and use of a mild sedative-hypnotic, concomitantly with a cough suppressant (eg, codeine), may be desirable. However, antitussives should be used cautiously when the cough is productive. The primary or supplemental use of expectorants is questionable because their clinical effectiveness has not been

well established.

Routine use of antibiotics for treatment of acute bronchitis should be strongly discouraged due to limited benefit.[8,17] In previously healthy patients who exhibit persistent fever or respiratory symptoms for more than 5 to 7 days or for predisposed patients (eg, elderly/frail, COPD, and immune compromised), the possibility of a concurrent bacterial infection should be suspected. When possible, antibiotic therapy should be directed toward anticipated respiratory pathogen(s) (eg, *S. pneumoniae* and *H. influenza*). *M. pneumoniae*, if suspected by history or if confirmed by culture serology or PCR, can be treated with azithromycin. Alternatively and empirically, a fluoroquinolone antibiotic with activity against these suspected pathogens (eg, levofloxacin) can be used, but due to the increasing rate of pathogen resistance to current antimicrobial drugs, the use of antibiotics in patients with acute bronchitis should be reserved for only those patients not responding adequately to supportive care and deemed at risk of associated complications. During known epidemics involving the influenza A virus, amantadine or rimantadine may have been effective in minimizing associated symptoms if administered early in the course of the disease, though treatment with these drugs, the adamantanes, is no longer recommended by the Centers for Disease Control and Prevention due to increasing influenza resistance and associated adverse effects.[18] The neuraminidase inhibitors (eg, zanamivir and oseltamivir) are active against both influenza A and B viral infections and may reduce the severity and duration of the influenza episode if administered promptly during the onset of the viral infection and are the preferred treatment (see Chapter 109).[19] Unfortunately, the incidence of influenza virus resistance to available antiviral drugs is increasing,[20] necessitating reconsideration of how we administer antiviral drugs for prophylaxis and treatment. The concept of antiviral drug combinations has emerged as a successful approach to effectively treat systemic viral infections.[21]

Chronic Bronchitis

Epidemiology and Etiology

Chronic bronchitis, most often a component of COPD, is a clinical diagnosis for a nonspecific, heterogenic disease that primarily affects adults. An in-depth presentation of the spectrum and management of COPD is given in Chapter 27; this section will focus solely on chronic bronchitis. In developed countries, the prevalence of chronic bronchitis is slightly higher in men than in women and possibly more common in Whites. Depending on the definition used for chronic bronchitis, it is estimated that 3.4% to 22% of adults have chronic bronchitis and that 14% to 74% of COPD patients suffer from chronic bronchitis.[22]

5 Chronic bronchitis is defined clinically as the presence of a chronic cough productive of sputum lasting more than 3 consecutive months of the year for 2 consecutive years without an underlying etiology of bronchiectasis or tuberculosis. The disease is a result of several contributing factors; the most prominent include cigarette smoking, exposure to occupational dusts, fumes, and environmental pollution, and host factors (eg, genetic factors and bacterial [and possibly viral] infections). The contribution of each of these factors and of others (either alone or in combination) to chronic bronchitis is unknown.[23] Cigarette smoke is a well-known airway irritant and is a predominant

factor in the etiology of chronic bronchitis. Although previously assumed the most common etiologic cause of chronic bronchitis, more strict prohibition of public smoking, and the resultant decrease in chronic tobacco smokers, particularly in developed countries, underscores the importance of other factors as causes of this chronic disease. Approximately 4% to 22% of patients with chronic bronchitis report never smoking.[22] Additional airway irritants including occupational dust, chemicals, or air pollution, either alone or more likely in combination, are also responsible for the pathogenesis of chronic bronchitis.[22,23] Furthermore, genome-wide association studies have begun to expand our understanding of the molecular pathways that may have clinical relevance in this very heterogeneous disease; see Chapter 27. Lastly, the influence of recurrent respiratory tract infections during childhood or young adult life on the later development of chronic bronchitis remains obscure, but recurrent respiratory infections may predispose individuals to the development of chronic bronchitis. Whether these recurrent respiratory tract infections are a result of unrecognized anatomic abnormalities of the airways or impaired pulmonary defense mechanisms is unclear.

Numerous consensus statements and published authoritative guidelines define chronic bronchitis and emphysema as the two main components of COPD/chronic obstructive lung disease.[24,25,26] The Global Initiative for Chronic Obstruction Lung Disease (GOLD) guidelines document does not distinguish these two diagnoses (eg, emphysema or chronic bronchitis) in the definition of COPD, but it does define COPD as a disease characterized by airflow obstruction that is not fully reversible and progressive. The GOLD guidelines (www.goldcopd.com) provide a COPD classification scoring system according to severity that can be helpful in staging patients for intensity of therapy, acute/chronic therapy, and prognosis. Unfortunately, differences in definitions between authoritative organizations may cause confusion in the assignment of patients in clinical trials and thus in assessment and application of study results to clinical care.

Pathogenesis

Chronic inhalation of an irritating noxious substance compromises the normal secretory and mucociliary function of bronchial mucosa.[27] Bronchial biopsy specimens in bronchitic patients underscore the importance of T-cell derived proinflammatory cytokines (eg, interleukins IL-4, 5, 13, and interferon gamma) in the pathogenesis and propagation of the observed inflammatory changes. In chronic bronchitis, the bronchial wall is thickened, and the number of mucus-secreting goblet cells on the surface epithelium of both larger and smaller bronchi is increased markedly. In contrast, goblet cells generally are absent from the smaller bronchi of normal individuals. In addition to the increased number of goblet cells, hypertrophy of the mucous glands and dilation of the mucous gland ducts are observed. As a result of these changes, chronic bronchitics have substantially more mucus in their peripheral airways, further impairing normal lung defenses. This increased quantity (overproduction and hypersecretion) of tenacious secretions within the bronchial tree frequently causes mucous plugging of the smaller airways. Accompanying these changes are squamous cell metaplasia of the surface epithelium, edema, and increased vascularity of the basement membrane of larger airways and variable chronic inflammatory cell infiltration. In addition, the amounts of several proteases derived from inflammatory cells are increased and due to COPD-induced defective antiproteases lead to continued destruction of connective tissue. Continued progression of this pathology can result in residual scarring of small bronchi and peribronchial fibrosis augmenting

airway obstruction and weakening of bronchial walls.[22]

Clinical Presentation

5 The hallmark of chronic bronchitis is a cough that may range from a mild to a severe and incessant coughing productive of purulent sputum. Coughing may be precipitated by multiple stimuli, including simple, normal conversation. Expectoration of the largest quantity of sputum usually occurs on arising in the morning, although many patients expectorate sputum throughout the day. The expectorated sputum usually is tenacious and can vary in color from white to yellow-green. Patients with chronic bronchitis often expectorate as much as 100 mL/day more than normal. As a result, many patients complain of a frequent bad taste in their mouth and of halitosis. It is important to recognize that sputum color provides no prognostic indication of infection or cause of an infectious disease exacerbation, that is, viral versus bacterial cause. Although sputum color of more green and yellow can be a predictor of potentially pathogenic bacteria this is unreliable clinically.[28] The diagnosis of an acute exacerbation requires consideration of a number of different factors all occurring within a discrete timeframe, (eg, increased/worsening respiratory symptoms including dyspnea, sputum volume and/or clearance, cough, etc). The tracking of the number of acute exacerbations and their consequences (decline in forced expiratory volume in 1 second (FEV1), persistent/worsening of symptoms annually is extremely important for prognostication and defining ongoing treatment strategies. Each acute exacerbation of chronic bronchitis results in continual declines in lung function.

The diagnosis of chronic bronchitis is based primarily on clinical assessment and history. Any patient who reports coughing sputum on most days for at least 3 consecutive months each year for 2 consecutive years presumptively has chronic bronchitis.[22] The diagnosis of chronic bronchitis is made only when the possibilities of bronchiectasis, cardiac failure, cystic fibrosis, and lung carcinoma, amongst others, have been effectively excluded. In an attempt to be more specific in the diagnosis, some investigators have added the criteria of lost wages for 3 or more weeks. In addition, many clinicians attempt to subdivide their patients based on severity of disease to guide therapeutic interventions. Two primary classification proposals are most often used in an attempt to determine the severity of the underlying disease as well as the occurrence/impending occurrence of an acute exacerbation of chronic bronchitis; for disease severity and acute exacerbations the prognostic tools advocated by GOLD are very helpful including classification based on spirometry (“mild” postbronchodilator FEV1 greater than or equal to 80% predicted to “very severe” postbronchodilator FEV1 less than 30% predicted: see Chapter 27); the COPD assessment test (8-item measure of health status), the Clinical COPD Questionnaire (a measure of clinical control) and the Modified Medical Research Council Questionnaire to predict future mortality. The other simple classification system is that proposed by Anthonisen and colleagues in 1987[29] that is still used to categorize patients in many therapeutic clinical trials. The use of patient symptom diaries can also be helpful in compliant patients. The importance of accurate classification for grouping patients of similar disease involvement cannot be overemphasized with respect to assessing publications outlining treatment strategies for these patients. Although gross, these classifications attempt to capture specific phenotypes of chronic bronchitis patients. The typical clinical presentation of chronic bronchitis is listed in **Table 107-1**. Comparison of the trends in changes in a patient’s physical activity, symptoms,

and clinical/physical findings from the patient's "routine" is extremely helpful in determining the presence and severity of an acute exacerbation.

TABLE 107-1 Clinical Presentation of Chronic Bronchitis

Signs and symptoms
Excessive sputum expectoration
Cough
Cyanosis (advanced disease)
Physical examination
Chest auscultation usually reveals inspiratory and expiratory rales, rhonchi, and mild wheezing with an expiratory phase that is frequently prolonged
Hyperresonance on percussion with obliteration of the area of cardiac dullness
Normal vesicular breathing sounds are diminished
Clubbing of digits (advanced disease)
Obesity
Chest radiograph
Increase in anteroposterior diameter of the thoracic cage (barrel chest)
Depressed diaphragm with limited mobility
Laboratory tests
Erythrocytosis (advanced disease), that is, increased hematocrit
Pulmonary function tests
Decreased vital capacity
Prolonged expiratory flow

In more advanced stages of chronic bronchitis, physical findings associated with cor pulmonale, including cardiac enlargement, hepatomegaly, and edema of the lower extremities, are observed. In general, chronic bronchitics tend to maintain at least normal body weight and commonly are obese. Radiographic studies are of limited value in either the diagnosis or follow-up of a patient. The microscopic and laboratory assessments of sputum are used in the overall evaluation of patients with chronic bronchitis. Gram staining of the sputum often reveals a mixture of both gram-positive and gram-negative bacteria, reflecting normal oropharyngeal flora and chronic tracheal colonization (in order of frequency) by nontypable *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*. **Table 107-2** lists the most common bacterial isolates identified from sputum culture for patients experiencing an acute exacerbation of chronic bronchitis. For patients with more severe airflow disease (eg, FEV_1 less than

40% predicted), enteric gram-negative bacilli, *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa* may be significant pathogens during acute exacerbations.

TABLE 107-2 Common Bacterial Pathogens Isolated from Sputum of Patients with Acute Exacerbation of Chronic Bronchitis

Pathogen	Percent of Cultures
H. influenzae[a,b]	45
M. catarrhalis[a]	30
S. pneumoniae[c]	20
E. coli, *Enterobacter* species, *Klebsiella* species, *P. aeruginosa*	5

[a]Often β-lactamase positive.

[b]Vast majority are nontypable strains.

[c]More than 25% of strains may have intermediate or high resistance to penicillin.

TREATMENT

Desired Outcome

The goals of therapy for chronic bronchitis are twofold: to reduce the severity of chronic symptoms and to ameliorate acute exacerbations and achieve prolonged exacerbation-free intervals.

General Approach to Treatment

The approach to treatment of chronic bronchitis is multifactorial.[22] First and foremost, attempts must be made to reduce the patient's exposure to known bronchial irritants (eg, smoking and workplace pollution). A complete occupational and environmental history for determination of exposure to noxious, irritating gases as well as preference toward cigarette smoking must be assessed. Often easier discussed than accomplished, honest, yet reasonable attempts should be made with the patient to reduce or eliminate the number of cigarettes smoked daily and to reduce exposure to secondhand smoke. An organized, coordinated, smoking cessation program, including counseling, possibly hypnotherapy, and the adjunctive use of nicotine substitutes (eg, nicotine gum or patch) or other pharmacotherapy (eg, bupropion and varenicline) may promote the reduction or complete withdrawal from cigarette smoking. Often just as difficult is modification of exposure to irritating substances within the home and workplace.

The importance of pulmonary rehabilitation has been realized in improving the quality of life for patients with chronic respiratory diseases.[30] Pulmonary rehabilitation is broadly defined as an interdisciplinary program individualized for patients with chronic respiratory impairment designed to optimize each patient's physical and social performance and autonomy. A personalized exercise training program including resistance and aerobic exercise are central to these programs. Pulmonary rehabilitation programs relieve dyspnea and fatigue, improve a patient's emotional function, and

enhance their sense of control over their disease and life. These improvements are often moderately large and clinically relevant.[30] The challenge for the future is to determine what components of a comprehensive pulmonary rehabilitation program provide the greatest benefit.

6 Measures to provide chest physiotherapy (eg, pulmonary "toilet") can be instituted.[31] Clearly the cost-effectiveness of chest physiotherapy needs to be better described but their short-term effects have been demonstrated and may be of symptomatic value to many patients experiencing an acute exacerbation of the chronic bronchitis. During acute pulmonary exacerbations of the disease, the patient's ability to mobilize and expectorate sputum may be reduced dramatically. In these instances, attempts at postural drainage techniques, with instruction and or active participation from a respiratory therapist, may assist in promoting clearance of pulmonary secretions. In addition, humidification of inspired air may promote the hydration (liquefaction) of tenacious secretions, allowing for removal that is more productive. Use of aerosolized mucolytic aerosols, such as *N*-acetylcysteine (NAC) and DNAse, is of questionable therapeutic value, particularly considering their propensity to induce bronchospasm (NAC) and their excessive cost. NAC cleaves the disulfide bonds of mucous, decreasing its elastic property that is important for upward mobility and then expectoration. A Cochrane meta-analysis of aerosol mucolytic therapy in subjects with chronic bronchitis or COPD found that treatment with mucolytics was associated with a small reduction in acute exacerbations and did not cause any harm, improve quality of life, or slow the decline of lung function.[32] The clinical benefit may be greater for chronic bronchitics/COPD patients who have frequent or prolonged exacerbations and are unable to utilize inhaled corticosteroids or long-acting β_2-agonists.[32] Although limited data are available, chronic use of oral or aerosolized bronchodilators may be of benefit by increasing mucociliary and cough clearance. For patients with moderate to severe COPD, combination therapy with a long-acting β_2-agonist and inhaled corticosteroid led to decreased exacerbations and rescue medication use, while it also improved quality of life, lung function, and symptom scores compared with long-acting β_2-agonist monotherapy.

Pharmacologic Therapy

Patients should be up to date with vaccinations, particularly pneumococcal and an annual influenza vaccine; however, the clinical utility of vaccination against haemophilus disease is questionable. For patients who consistently demonstrate clinical limitation in airflow, a therapeutic challenge of a short-acting β_2-agonist bronchodilator (eg, as albuterol aerosol) should be considered. Pulmonary function tests should be performed before and after β_2-agonist aerosol administration for more objective determination of a patient's propensity to benefit from supplemental aerosol therapy. Sufficient published experience supports the use of inhalation therapy with a β_2-agonist for patients with chronic bronchitis (COPD) to improve pulmonary function and exercise tolerance and to reduce the sense of breathlessness.[22] Regular use of a long-acting β-receptor agonist aerosol (eg, salmeterol and formoterol) in responsive patients are more effective and probably more convenient than short-acting β_2-receptor agonists.[33] The aerosol route for β_2-receptor agonist and/or corticosteroid administration is favored over systemic formulations for improved patient acceptance and compliance and to minimize the number and magnitude of associated adverse effects. Chronic inhalation of a long-acting β-receptor agonist (LABA) and a poorly absorbed corticosteroid

combination (eg, salmeterol/fluticasone and formoterol/mometasone) has been associated with improved pulmonary function and quality of life.[34] However, chronic use of aerosolized corticosteroid is associated with increased side effects including hoarseness, sore throat, thrush, pneumonia, and osteoporosis. Nevertheless, caution should be exercised in withdrawing inhaled glucocorticoid administration in patients with severe COPD receiving triple inhalation therapy as it may lead to increased frequency of acute exacerbations and a greater decrease in lung function.

Published experience with inhaled anticholinergic drugs, including ipratropium and tiotropium, is increasing and defining an important role in the chronic management of patients with chronic bronchitis and COPD.[35] Numerous studies are now available demonstrating the clinical effectiveness of inhaled long-acting muscarinic antagonists (LAMAs) alone or more frequently when administered in combination with a LABA, in improving lung function and real benefits in symptom control and reductions in the number of acute exacerbations. Triple combination inhalation therapy (eg, LABA + LAMA + an inhaled corticosteroid) is being evaluated in patients with more severe COPD with promising findings.[36] The exact role of triple therapy remains to be defined. Although once prescribed extensively for patients with chronic bronchitis, chronic theophylline therapy is used with decreasing frequency in favor of aerosolized β_2-receptor agonists, LABA, LAMA, etc. Nevertheless, long-acting theophylline remains an effective "add on" therapy for many patients, particularly those with more severe chronic bronchitis/COPD due to the drugs beneficial effects of bronchodilation, improved ciliary function and increased beat frequency, possibly increased mucus hydration, and low cost.[22]

Phosphodiesterase 4 inhibitors (PDE-4), compared with the nonselective phosphodiesterase inhibitor theophylline, only affect phosphodiesterase in the airway smooth muscle, immune (eosinophils, monocytes, and neutrophils), and proinflammatory cells. Roflumilast is a highly specific (second generation) PDE-4 inhibitor which is most often reserved for use in patients with moderate to severe COPD. Considering that many of the published studies assessing the viability of second-generation PDE-4 inhibitors in patients with COPD involved patients with chronic cough and increased sputum production, it is inferred that these drugs would be of value in patients with chronic bronchitis as well. The GOLD guidelines suggest roflumilast reduces exacerbations in COPD patients with chronic bronchitics treated with oral glucocorticosteroids. A review of clinical trials and observational studies found that roflumilast only provides a net benefit to patients at high risk of severe exacerbations.[37] A lower 30-day readmission rate in patients hospitalized for COPD with roflumilast therapy was reported.[38] Others have found that PDE-4 inhibitors improved lung function over placebo and reduced the likelihood of exacerbations; they had little impact on a patient's symptoms or quality of life. Nevertheless, the major limitation to the use of PDE-4 inhibitors is their side effect profiles. Patients receiving roflumilast often experience nausea, vomiting, headache, decreased appetite, sleep disturbances, and an increased risk of psychiatric events.[39] The exact role of roflumilast in chronic lung disease is evolving but many guidelines suggest its greatest use is in the more severely affected patients.

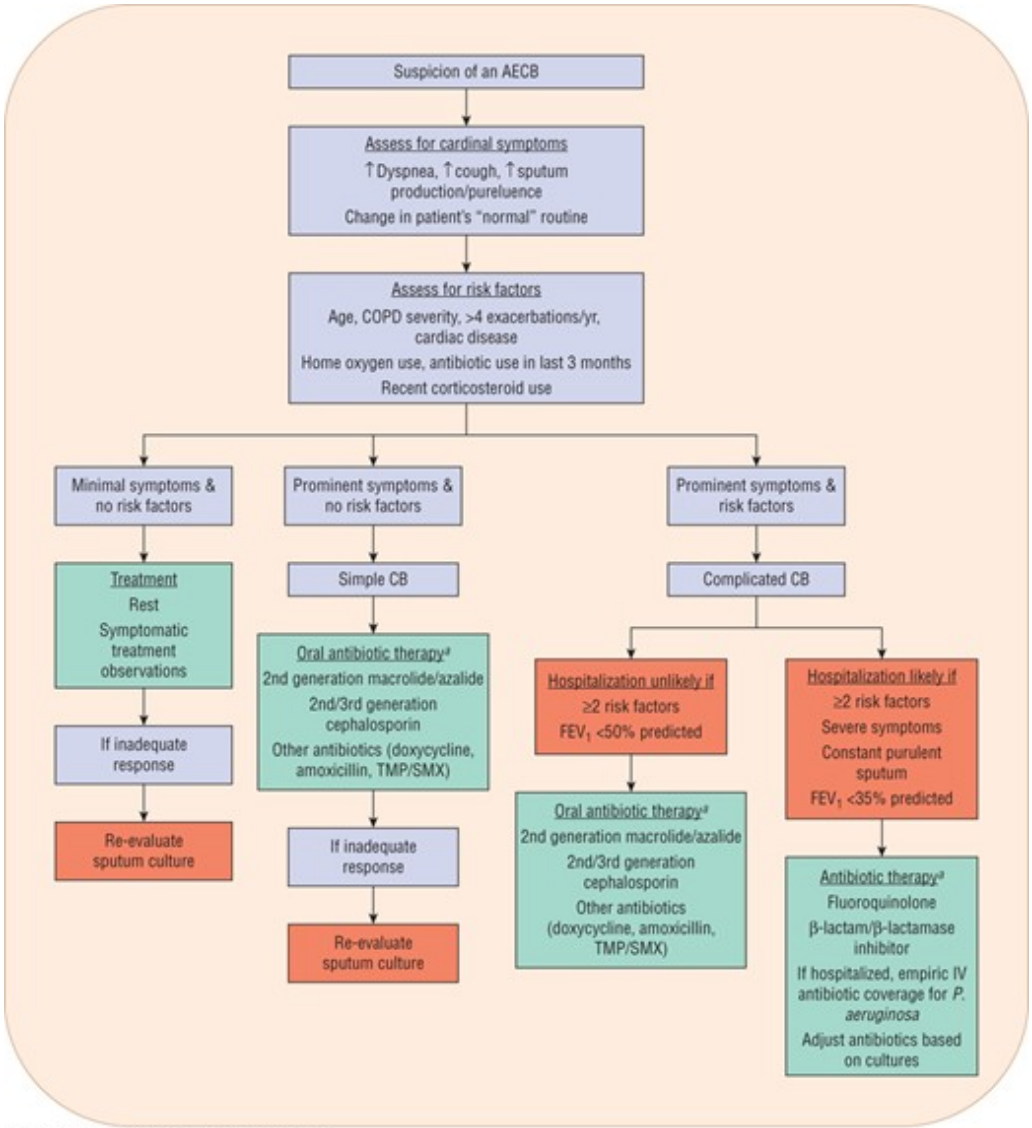
Use of antimicrobials for treatment of chronic bronchitis has been controversial, but is becoming more accepted in specific circumstances. Numerous comparative evaluations, including placebo-controlled studies of antibiotic administration with acute and chronic treatment of chronic

bronchitics, have suggested clinical benefit. The antibiotics selected most frequently possess variable in vitro activity against the common sputum isolates *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *M. pneumoniae*. Conflicting published results appear independent of the antibiotic used or the regimen compared. A wide disparity that existed in the published results from older studies, served as the basis for the enormous controversy that surrounded the use of antibiotics for the treatment of acute exacerbations of chronic bronchitis. Overall, good clinical results have been observed with the use of standard antibiotic regimens (eg, macrolides, azalides, oral cephalosporins, and the combination drug amoxicillin/clavulanate, trimethoprim/sulfamethoxazole, and tetracyclines) as well as with the use of fluoroquinolones.[40,41,42,43,44,45] The goal is to select the most effective antibiotic drug for the patient based on their history of previous exacerbations and response to drug therapy. The introduction of genome expression profiling of sputum and other biologic fluids can facilitate specific pathogen diagnosis and focused therapy.[46]

A useful paradigm for the assessment and treatment of acute exacerbations of chronic bronchitis and antibiotic decision making is shown in **Fig. 107-1**. Many clinicians use the so-called Anthonisen criteria to determine if antibiotic therapy is indicated.[29] With the Anthonisen criteria, if a patient exhibits two of the following three criteria during an acute exacerbation of chronic bronchitis (AECB), the patient will most likely benefit from antibiotic therapy and, thus, should receive a treatment course: (a) increase in shortness of breath; (b) increase in sputum volume; and (c) production of purulent sputum. There are greater healthcare costs for patients who are noncompliant with their antibiotic regimen for their AECB.

FIGURE 107-1

Clinical algorithm for the diagnosis and treatment of chronic bronchitic patients with an acute exacerbation incorporating the principles of the clinical classification system. (AECB, acute exacerbation of chronic bronchitis; COPD, chronic obstructive pulmonary disease; CB, chronic bronchitis; TMP/SMX, trimethoprim/sulfamethoxazole.) [a]See Table 107-3 for commonly used antibiotics and doses. *(Adapted from reference 110.)*



The increasing resistance of the common bacterial pathogens to first-line agents further complicates antibiotic selection. As many as 30% to 40% of *H. influenzae* isolates and 95% to 100% of *M. catarrhalis* isolates produce *β*-lactamases. Moreover, up to 40% of *S. pneumoniae* isolates demonstrate resistance to penicillin (minimum inhibitory concentration [MIC] = 0.1-2 mg/L), with approximately 20% of isolates being highly resistant (MIC greater than 2 mg/L). Concern regarding *S. pneumoniae* resistance is increasing, and resistance is now greater than or equal to 30% for macrolides. Despite these changes in bacterial susceptibility, the current recommendation is to initiate therapy with first-line antimicrobial agents in less severely affected patients (see Fig. 107-1). Trimethoprim/sulfamethoxazole has been extremely useful for patients with less-severe disease.[47] For patients with more moderate to severe disease, many clinicians will begin antibiotic therapy with the second-line agents, amoxicillin/clavulanate, a macrolide (such as azithromycin or clarithromycin, although they are being used less frequently), and more frequently with a fluoroquinolone, such as levofloxacin and moxifloxacin (see Fig. 107-1).

Regardless of the antibiotic selected, predetermined outcome measures should be monitored closely for each patient to determine the success or failure of the therapeutic intervention. Oral antibiotics

with broader antibacterial spectra (eg, amoxicillin/clavulanate and fluoroquinolones) that possess potent in vitro activity against sputum isolates are increasingly becoming first-line antibiotics as initial therapy for treatment of acute exacerbations of chronic bronchitis.

An important clinical outcome variable directing drug selection and criteria for beginning antibiotics in individual patients is the infection-free period when chronic bronchitics are off antibiotics. The length of the infection-free time period and the change in the number of physician office visits and hospital admissions with a particular antibiotic regimen are extremely important to identify, whenever possible, for each patient. The antibiotic regimen that results in the longest infection-free period defines the "regimen of choice" for specific patients for future acute exacerbations of their disease. Trials of long-term prophylactic antibiotic use may provide a slight benefit in decreasing exacerbation rates, but does not appear to decrease mortality, but does markedly increase the emergence and colonization of antibiotic-resistant pathogens. For this reason, most guidelines do not currently support this indication. However, chronic macrolide/azalide use reduces the incidence of acute exacerbations in COPD patients in a clinically significant manner[48,49] (macrolide and anti-inflammatory activity addressed later).

Antibiotics that are effective against responsible pathogens, demonstrate the least risk of drug interactions, and can be administered in a manner that promotes compliance should be selected. Antibiotics, commonly used for treatment of these patients with chronic bronchitis, and their respective adult starting doses are listed in **Table 107-3**. Doses of antibiotics should be adjusted as needed to the desired clinical effect and the lowest incidence of acceptable side effects. A frequently used clinical strategy to enhance the duration of symptom-free periods incorporates higher-dose antibiotic regimens using the upper limit of the recommended daily antibiotic dose for a period of 5 to 7 days. More clinicians are electing to limit their antibiotic treatment regimen to 5 days as compelling data continue to support equal efficacy, less exposure potentially reducing bacterial resistance development and possibly less side effects with short-duration antibiotic therapy versus longer treatment regimens (greater than 7 days).[41,42]

TABLE 107-3 Oral Antibiotics Commonly Used for the Treatment of Acute Respiratory Exacerbations in Chronic Bronchitis

Antibiotic	Brand Name	Usual Adult Dose (mg)	Dose Schedule (Doses/Day)
Preferred Drugs			
Ampicillin	–	250-500	4-3
Amoxicillin	–	500-875	3-2
Amoxicillin/clavulanate	Augmentin®	500-875	3-2
Ciprofloxacin	Cipro®	500-750	2
Levofloxacin	Levaquin®	500-750	1
Moxifloxacin	Avelox®	400	1
Doxycycline	Monodox®	100	2
Minocycline	Minocin®	100	2

Antibiotic	Brand Name	Usual Adult Dose (mg)	Dose Schedule (Doses/Day)
Tetracycline HCl	–	500	4
Trimethoprim/sulfamethoxazole[a]	Bactrim DS™/Septra DS®	1 DS	2
Supplemental Drugs			
Azithromycin	Zithromax®	250-500	1
Erythromycin	Ery-Tab®/Erythrocin®	500	4
Clarithromycin	Biaxin®	250-500	2
Cephalexin	Keflex®	500	4

[a]DS, double-strength tablet (160-mg trimethoprim/800-mg sulfamethoxazole).

With the exception of long-term macrolide/azalide administration, chronic antibiotic therapy is rarely indicated in the management of patients with chronic bronchitis. Such approaches lead to marked increase in cost and occurrence of multidrug resistant (MDR) pathogens. Conversely, long-term macrolide (erythromycin, clarithromycin, and roxithromycin) or azalide (azithromycin) administration has been associated with a clinically significant reduction in the incidence of acute exacerbations in patients with chronic bronchitis and COPD.[48,49,50] The benefit of these drugs is attributed to their antibacterial, anti-inflammatory, and immunomodulatory activity. These drugs reduce bacterial adherence and toxin production, inhibit biofilm function, and reduce the generation of oxygen free radicals, modulate mucin gene protein production controlling mucus hypersecretion, and improve mucociliary clearance. These drugs also decrease neutrophil chemotaxis, promote downregulation of adhesion molecule expression, and inhibit transcription factors leading to decreased production of pro-inflammatory cytokines.[50]

The importance of multifactorial cellular oxidative stress in the pathogenesis of chronic bronchitis and COPD has prompted the study of the efficacy of antioxidants and in particular, the oral administration of NAC, other mucolytic agents and antioxidants.[32,51,52] Some guidelines suggest their use for more severely affected patients. Studies with oral NAC have suggested a dose-dependent response with 600 mg once to twice daily and it may slightly decrease the exacerbation rate in COPD patients not using inhaled steroids; however, there does not appear to any effect on lung function. The exact role of antioxidant in the care of these patients remains to be defined—no specific recommendations can be provided until more data are available regarding which specific compound (as well as dose and duration of therapy) is optimal.

BRONCHIOLITIS

Epidemiology and Etiology

Bronchiolitis is an acute viral infection of the lower respiratory tract that affects approximately

50% of children during the first year of life and 100% by age 2 years. The occurrence of bronchiolitis peaks during the winter months and persists through early spring. Bronchiolitis remains the major reason for hospital admission during the first year of life. The incidence of bronchiolitis appears to be more common in males than in females.[53]

Respiratory syncytial virus is the most common cause of bronchiolitis, accounting for up to 75% of all cases. During epidemic periods, the incidence of RSV-induced bronchiolitis may approach 90% of cases. Other detectable viruses include parainfluenza, adenovirus, and influenza. Bacteria serve as secondary pathogens in a minority of cases.[53,54]

Clinical Presentation

The clinical presentation of bronchiolitis (**Table 107-4**) is often preceded by 1 to 4 days of symptoms (eg, nasal congestion, rhinorrhea, cough, and low-grade fever) indicative of an upper respiratory tract infection. Due to limited oral intake because of coughing combined with fever, vomiting, and diarrhea, infants frequently are dehydrated. The increased work of breathing and tachypnea most likely contribute to increased fluid loss. In most cases, bronchiolitis is self-limiting and typically symptoms improve within 7 to 10 days with resolution within 28 days without the need for hospitalization. In patients who require hospitalization, the average length of stay is approximately 3 days.[54]

TABLE 107-4 Clinical Presentation of Bronchiolitis

Signs and symptoms
Prodrome with irritability, restlessness, and mild fever
Cough and coryza
Vomiting, diarrhea, noisy breathing, and increased respiratory rate as symptoms progress
Labored breathing with retractions of the chest wall, nasal flaring, and grunting
Physical examination
Tachycardia and respiratory rate of 40-80/min in hospitalized infants
Wheezing and inspiratory rales
Mild conjunctivitis in one third of patients
Otitis media in 5%-10% of patients
Laboratory tests
Peripheral white blood cell count normal or slightly elevated
Abnormal arterial blood gases (hypoxemia and, rarely, hypercarbia)

The diagnosis of bronchiolitis is based primarily on history and clinical findings. It is important for the clinician to attempt to differentiate between bronchiolitis and a host of other clinical entities affecting infants, which may produce a similar picture of dyspnea and wheezing. Asthma, congestive heart failure, anatomic airway abnormalities, cystic fibrosis, foreign bodies, and gastroesophageal reflux are the primary disease entities that may present with wheezing in children. Isolation of a viral pathogen in the respiratory secretions of a wheezing child establishes a presumptive diagnosis of infectious bronchiolitis. However, the ability to identify specific viral pathogens often is hindered by the limited availability of special virology laboratories. In addition, in the elderly and in immunocompromised patients, antigen detection lacks adequate sensitivity, and patients frequently seek medical care after the acute stage of the infection, thus compromising the ability of the available tests to diagnose RSV. However, the proliferation of commercial enzyme-linked immunosorbent assays and fluorescent antibody staining techniques of nasopharyngeal secretions has increased the ability to identify viral antigens within several hours. Identification of RSV by PCR should be available from most clinical laboratories, but its relevance to the clinical management of bronchiolitis remains obscure and therefore routine testing is not recommended.[53,54]

Multiple clinical laboratory determinations have been used to assist in the management of cases of bronchiolitis. Radiographic evaluation of the chest in children with bronchiolitis yields variable findings and rarely alters therapeutic decisions. Thus, the routine use of chest radiography is not recommend; however, in hospitalized patients who fail to demonstrate expected improvement, they may help to distinguish bronchiolitis from other entities characterized by wheezing so that appropriate treatment may be initiated. In children requiring hospitalization, abnormalities in blood gas tensions are frequent and appear to relate to disease severity. Hypoxemia is common and increases the respiratory drive, whereas hypercarbia is seen in only the most severe cases. Despite the presence of moderate degrees of hypoxemia, clinical cyanosis is unusual.[54]

TREATMENT

Desired Outcome

7 In the well infant, bronchiolitis usually is a self-limiting illness, and reassurance, antipyretics, and adequate fluid intake usually are all that are necessary while waiting for resolution of the underlying viral infection. In-hospital support is necessary for the child suffering from respiratory failure or marked dehydration; underlying cardiac and pulmonary diseases potentiate these conditions.[54]

General Approach to Treatment

7 Almost all otherwise healthy babies with bronchiolitis can be followed as outpatients. Such infants are treated for fever, provided generous amounts of oral fluids, and observed closely for evidence of respiratory deterioration.[55] In severely affected children, the mainstays of therapy for bronchiolitis are oxygen therapy and IV fluids. In a subset of patients, aerosolized bronchodilators may have a role. For selected infants, particularly those with underlying pulmonary disease, cardiac disease, or both, therapy with the antiviral agent ribavirin can be considered.[54]

Pharmacologic Therapy

7 Aerosolized β_2-adrenergic therapy appears to offer little benefit for the majority of patients and may even be detrimental.[53,56,57] However, this therapy may offer some benefit to the child with a predisposition toward bronchospasm. In addition, although clinical trials have demonstrated varied results, nebulized epinephrine seems to be more efficacious than albuterol in hospitalized patients with bronchiolitis.[53,58] For such patients, bronchodilator therapy may be offered initially, but should not be pursued in the absence of a clear-cut clinical benefit. Furthermore, given their overall ineffectiveness, neither aerosolized β_2-adrenergic nor nebulized epinephrine therapies are recommended by the American Academy of Pediatrics for the treatment of bronchiolitis.[57]

Similarly, controlled trials of corticosteroids in bronchiolitic infants have not shown therapeutic effects or significant harmful effects, though viral shedding may be prolonged.[54,57] As a result, the routine use of systemically administered corticosteroids is not recommended by the American Academy of Pediatrics and is therefore discouraged.[57] Conversely, the combined use of oral dexamethasone with nebulized epinephrine may act synergistically to reduce hospital admissions and shorten the time to discharge and the duration of symptoms; however, more trials are needed to confirm these findings.[58,59] Although placing children with bronchiolitis in mist tents has been common practice, no data have documented the effectiveness of this practice.

The American Academy of Pediatric guidelines support the use of nebulized hypertonic saline (eg, 3% saline) for the treatment of bronchiolitis in hospitalized infants and children. As such, although nebulized hypertonic saline has proven to be safe and effective for the symptomatic improvement in patients with bronchiolitis after 1 day of use, the benefit of a reduction in length of hospital stay appears to be limited to patients whose mean length of hospital stay generally exceeds 3 days. Thus, this latter benefit may be less applicable to patients in the United States where the mean length of hospital stay due to bronchiolitis is approximately 3 days.[56,57]

Ribavirin may offer benefit to a subset of infants with bronchiolitis. Ribavirin, a synthetic nucleoside, possesses in vitro antiviral properties against a variety of RNA and DNA viruses, including influenza A, influenza B, parainfluenza, and adenovirus, it is approved only in aerosolized form against RSV. Use of the aerosol drug formulation requires special equipment (small-particle aerosol generator) and specially trained personnel for administration via oxygen hood or mist tent. Special care must be taken to avoid drug particle deposition and the resulting clogging of respiratory tubing and valves in mechanical ventilators. Among hospital admissions for RSV infection, ribavirin therapy failed to decrease length of hospital stay, number of days in the intensive care unit, or number of days receiving mechanical ventilation. Consequently, the American Academy of Pediatrics does not recommend the routine use of ribavirin in children with bronchiolitis[57] and most experts recommend reserving use of ribavirin for severely ill patients.

Clinical Controversy...

Despite the overall lack of demonstrated benefit of aerosolized β_2-adrenergic agonist, nebulized epinephrine, and corticosteroids in clinical trials, they continue to be prescribed to some patients

presenting with bronchiolitis.

For infants with underlying pulmonary or cardiovascular disease, prophylaxis against RSV may be warranted. When administered monthly during the RSV season, both RSV immune globulin and palivizumab (a monoclonal antibody for RSV) may decrease the number of RSV episodes and the need for hospitalization. Between the two, palivizumab is preferred, given its ease of administration, lack of administration-related adverse effects, and noninterference with select immunizations.[60] Despite continuing research, there is no vaccine marketed for RSV.

PNEUMONIA

Epidemiology

Pneumonia remains one of the most common causes of severe sepsis and infectious cause of death in children and adults in the United States, with a mortality rate of 30% to 40%.[5,61] Pneumonia occurs throughout the year, with the relative prevalence of disease resulting from different etiologic agents varying with the seasons. It occurs in persons of all ages, although the clinical manifestations are most severe in the very young, the elderly, and the chronically ill.

Pathogenesis

Microorganisms gain access to the lower respiratory tract by three routes. They may be inhaled as aerosolized particles, enter the lung via the bloodstream from an extrapulmonary site of infection or via aspiration of oropharyngeal contents. Aspiration is a common occurrence in both healthy and ill people during sleep and is a major mechanism by which pulmonary pathogens gain access to the lower airways and alveoli. When pulmonary defense mechanisms are functioning optimally, aspirated microorganisms are cleared from the region before infection can become established; however, aspiration of potential pathogens from the oropharynx can result in pneumonia if lung defenses are impaired. Factors that promote aspiration, such as altered sensorium and neuromuscular disease, may result in an increase in the size of the inoculum delivered to the lower respiratory tract, thereby overwhelming local defense mechanisms. Lung infections with viruses suppress the antibacterial activity of the lung by impairing alveolar macrophage function and mucociliary clearance, thus setting the stage for secondary bacterial pneumonia. Mucociliary transport is also depressed by ethanol and narcotics and by obstruction of bronchi by mucus, tumor, or extrinsic compression. All these factors can severely impair pulmonary clearance of aspirated bacteria. Any alteration of the normal lung microbiome by infection and/or disease can evolve to pneumonia requiring antimicrobial treatment.[62]

8 The most prominent pathogen causing CAP in otherwise healthy adults is *S. pneumoniae* and accounts for up to 35% (12%-68%) of all acute cases. Other common pathogens include *H. influenza* (2.5%-45%), the atypical pathogens *M. pneumoniae*, *Legionella species*, and *C. pneumoniae* (~20%), and a variety of viruses including influenza.[63,64] Healthcare-associated pneumonia was a classification that has been used to distinguish nonhospitalized patients at risk for MDR pathogens from those

with CAP-however this has fallen out of use.[4,6,65] The term *atypical* may be applied to pneumonia to indicate that the pneumonia may be caused by an atypical pathogen (eg, bilateral lobar pneumonia with a negative sputum Gram stain).[66]

Gram-negative aerobic bacilli, *S. aureus*, and MDR pathogens are the leading causative agents in hospital-acquired pneumonia (HAP).[6] Anaerobic bacteria are the most common etiologic agents in pneumonia that follows the aspiration of gastric or oropharyngeal contents. Ventilator-associated pneumonia (VAP) is also associated with MDR pathogens.

Pneumonia in infants and children is caused by a wider range of microorganisms, and, unlike adults, nonbacterial pathogens predominate. Most pneumonias occurring in the pediatric age group are caused by viruses, especially RSV, parainfluenza, and adenovirus.[5] *M. pneumoniae* is an important pathogen in older children. Beyond the neonatal period, *S. pneumoniae* is the major bacterial pathogen in childhood pneumonia, followed by group A *Streptococcus* and *S. aureus*. *H. influenzae* type b, once a major childhood pathogen, has become an infrequent cause of pneumonia since the introduction of active vaccination against this organism in the late 1980s.

Based on the differences in severity and outcome for patients with CAP, genetic factors likely play a role.[67,68] Multiple variations in genes affecting inflammation, cough and airway protection, pattern recognition molecules, and organ function along with environmental factors may alter a patient's response to CAP. In the future, when disease response is better associated with specific genetic polymorphisms, therapy should become better targeted.

Clinical Presentation

Bacterial pneumonia is caused most commonly by gram-positive streptococci and staphylococci and by gram-negative organisms that normally inhabit the GI tract (enterics) or soil and water (nonenterics). In addition, *Legionella*, itself a weakly staining gram-negative nonenteric organism, accounts for a small percentage of CAP and HAP, although the true incidence may be underreported.[66] Finally, *M. tuberculosis*, an acid-fast staining bacillus, still remains an important cause of pneumonia in urban centers throughout the United States even though the incidence is much lower compared to other countries.[69,70]

Even though a wide array of gram-positive and gram-negative organisms can cause pneumonia, they usually present a similar clinical appearance (**Table 107-5**); thus, the epidemiologic and clinical clues will render one more likely than the other. *S. pneumoniae*, *S. aureus*, the enteric gram-negative rods, and occasionally other organisms may produce local irritation or destruction of blood vessels leading to rust-colored sputum or hemoptysis. Pleural effusions, both sterile and emphysematous, may be associated with many of these entities, as evidenced by distant breath sounds and a wide area of dulled percussion. The chest radiograph and sputum examination and culture are the most useful diagnostic tests for gram-positive and gram-negative bacterial pneumonia, especially for hospitalized patients; urine antigen testing for *L. pneumophila* and *S. pneumoniae* is recommended for patients with severe CAP.[4,71] Typically, the chest radiograph reveals a dense lobar or segmental infiltrate. However, patchy consolidation may be seen occasionally with virtually all these pathogens.

Occasionally, pneumonia resulting from hematogenous spread of the organisms results in a diffuse, alveolar pattern on chest radiograph. Gram stain of the expectorated sputum demonstrates many polymorphonuclear cells per high-powered field in the presence of a predominant organism, which is reflected as heavy growth of a single species on culture. Other laboratory tests are less sensitive or specific. Blood cultures may be helpful in identifying the offending organism, but are positive in only a minority of patients. The complete blood count usually reflects a leukocytosis with a predominance of polymorphonuclear cells; in some instances, particularly with *S. pneumoniae*, elevation of the white blood cell (WBC) count may be pronounced. Normal or mildly elevated WBC counts, however, do not exclude bacterial pneumonic disease. The patient also may be hypoxic, as reflected by low oxygen saturation on arterial blood gas or pulse oximetry.

TABLE 107-5 Clinical Presentation of Pneumonia

Signs and symptoms
Abrupt onset of fever, chills, dyspnea, and productive cough
Rust-colored sputum or hemoptysis
Pleuritic chest pain
Physical examination
Tachypnea and tachycardia
Dullness to percussion
Increased tactile fremitus, whisper pectoriloquy, and egophony
Chest wall retractions and grunting respirations
Diminished breath sounds over affected area
Inspiratory crackles during lung expansion
Chest radiograph
Dense lobar or segmental infiltrate
Laboratory tests
Leukocytosis with predominance of polymorphonuclear cells
Low oxygen saturation on arterial blood gas or pulse oximetry

Community-Acquired Pneumonia

8 *S. pneumoniae* is the most common community-acquired bacterial pneumonia in adult and pediatric patients.[4,5,64] It is particularly prevalent and severe for patients with splenic dysfunction, diabetes mellitus, chronic cardiopulmonary or renal disease, or HIV infection. Community-acquired

disease with *S. aureus* is identified most frequently in young infants, patients with cystic fibrosis, and those recovering from an antecedent respiratory viral infection. Group A *Streptococcus* is an uncommon cause of CAP, but when it does occur, it frequently follows a viral respiratory tract infection. Only occasionally is it associated with streptococcal pharyngitis. The organism is pyogenic, and the presentation can be severe. Community-acquired enteric gram-negative pneumonia is identified most frequently among patients with chronic illness, especially alcoholism and diabetes mellitus. In preschool-aged children, viral pathogens more commonly cause CAP compared with bacterial pathogens.[5]

Severity scores (eg, CRB65, CURB-65, and PSI), with varying strengths and weaknesses, assist healthcare professionals in predicting intensive care hospitalization and outcomes for patients with CAP.[4,71,72,73] Definitions of severe CAP may vary depending on the institution; however, patients with severe CAP are more likely to require intensive care or mechanical ventilation, or develop complications with sepsis, bacteremia, or multiorgan failure. Severe CAP may also be difficult to distinguish from HCAP or HAP; however, the pathogens, *S. pneumoniae*, *H. influenzae*, and anaerobic bacteria are not usually MDR. Patients at greater risk for severe CAP are those with underlying medical conditions or at risk for aspiration, animal exposure, or exposure to other infected patients or seasonal epidemics.[65]

Hospital-Acquired Pneumonia

After the urinary tract and the bloodstream, the lungs are the most frequent site for infections acquired in the hospital. HAP is seen most commonly in critically ill patients and is usually caused by bacteria.[6] Factors predisposing patients to the development of HAP include the severity of illness, duration of hospitalization, supine positioning, witnessed aspiration, coma, acute respiratory distress syndrome, patient transport, and prior antibiotic exposure (**Table 107-6**). The strongest predisposing factor, however, is mechanical ventilation (intubation). The length of stay for hospital admissions is increased by a mean of 7 to 9 days for patients who develop HAP.[6,65]

TABLE 107-6 Pneumonia Classifications and Risk Factors

Type of Pneumonia	Definition	Risk Factors
Community acquired (CAP)	Pneumonia developing in patients with no contact to a medical facility	• Age >65 years • Diabetes mellitus • Asplenia • Chronic cardiovascular, pulmonary, renal and/or liver disease • Smoking and/or alcohol abuse

Type of Pneumonia	Definition	Risk Factors
Hospital acquired (HAP)	Pneumonia developing >48 hours after hospital admission	• Witnessed aspiration • COPD, ARDS, or coma • Administration of antacids, H_2-antagonists, or proton pump inhibitor • Supine position • Enteral nutrition, nasogastric t ube • Reintubation, tracheostomy, or patient transport • Head trauma, ICP monitoring • Age >60 years • MDR risk (eg. MRSA, MDR *Pseudomonas*) if IV antibiotic use within 90 days
Ventilator associated (VAP)	Pneumonia developing >48 hours after intubation and mechanical ventilation	• Same as hospital acquired • MDR risk with septic shock, ARDS, acute renal replacement therapy, or 5+ days of hospitalization

ARDS, adult respiratory distress syndrome; CAP, community-acquired pneumonia; COPD, chronic obstructive pulmonary disease; HAP, hospital-acquired pneumonia; ICP, intracranial pressure; MDR, multidrug resistant; MRSA, methicillin-resistant S. aureus VAP, ventilator-associated pneumonia.

The organisms most commonly associated with HAP are *S. aureus* and enteric (eg, *K. pneumoniae* or *E. coli*) and nonenteric (eg, *P. aeruginosa*) gram-negative bacilli, organisms that colonize the pharynx of the hospitalized, critically ill patient. Patients with longer lengths of hospital admission or IV antibiotic use within the previous 90 days prior to the development of HAP are more likely to have MDR organisms.[6] The diagnosis of HAP usually is established by the presence of a new infiltrate on chest radiograph, fever, worsening respiratory status, and the appearance of thick, neutrophil-laden respiratory secretions. The diagnosis often is difficult to make in the intensively ill patient with underlying lung pathology that itself can be associated with an abnormal changing radiograph, as occurs with congestive heart failure or chronic lung disease. If a patient develops fever, leukocytosis, and purulent sputum, and has positive sputum/tracheal cultures, but radiographic imaging does not indicate new infiltrates, the patient may have tracheobronchitis as opposed to HAP.[6] Broad-spectrum

antibiotics frequently are started empirically even in equivocal circumstances, with bronchoscopy reserved for poorly responsive patients.[6]

Ventilator-Associated Pneumonia

VAP is defined as pneumonia occurring more than 48 hours postendotracheal intubation. The risk for developing pneumonia in the hospital increases by 6 to 21 times after a patient is intubated because the natural airway defenses against the migration of upper respiratory tract organisms into the lower tract are bypassed.[6] This situation is exacerbated by the wide use of acid-reducing drugs (eg, H_2-receptor blocking agents and proton pump inhibitors) in the intensive care unit, which increases the pH of gastric secretions and may promote the proliferation of microorganisms in the upper GI tract. Subclinical microaspirations are events that occur routinely in intubated patients and result in the inoculation of bacteria-contaminated gastric contents into the lung and a higher incidence of nosocomial pneumonia.[75] Pneumonia that develops within 4 days of hospitalization is more likely to be caused by an antibiotic sensitive organism such as *S. pneumoniae*, *S. aureus*, or *Haemophilus* species, whereas infections developing later are more likely to be MDR (eg, *P. aeruginosa*, MRSA, and *Acinetobacter* species). Outbreaks of VAP may be caused occasionally by contaminated respiratory therapy equipment.

To date, there is no "gold standard" for diagnosing VAP; thus, an accurate diagnosis is challenging. Most intensivists agree that VAP should be suspected if new or persistent infiltrates are found on chest radiograph along with two or more of the following: purulent tracheal secretions, leukocytosis or leucopenia, and body temperature greater than 38.3°C (100.9°F).[75,76] Noninvasive sampling techniques are recommended over invasive techniques (eg, bronchoalveolar lavage) for obtaining samples of lower respiratory tract secretions for culture and sensitivity testing.[6]

Special Populations

Pneumonia in the HIV-Infected Patient

A broad range of pathogens can cause pneumonia in HIV infection (**Table 107-7**) including opportunistic infections such as *P. jiroveci* and *Mycobacterium* species.[77] These patients may be afflicted with pneumonia multiple times, particularly in the advanced stages of the disease, and a given episode may be caused by more than one species. The clinical presentation of pneumonia in HIV-infected persons frequently is not helpful in distinguishing one pathogen from another. The pneumonia usually is subacute in onset and consists of fever, nonproductive cough, and dyspnea. Radiographically, most of these entities produce a multilobular or diffuse pattern. Some practitioners initially treat the HIV-infected patient with pneumonia empirically; however, given the wide array of possible pathogens, more frequently a specific microbiologic diagnosis is aggressively pursued early in the patient's course through sputum induction or bronchoalveolar lavage to allow a rational choice of an antimicrobial regimen. The diagnosis and treatment of HIV-infected patients with pulmonary disease is discussed in detail in Chapter 126.

TABLE 107-7 Pulmonary Complications of Human Immunodeficiency Virus Infection

Infections

Viruses

Cytomegalovirus

Herpes simplex virus

Varicella-zoster virus

Respiratory syncytial virus and other common respiratory pathogens (parainfluenza virus, adenovirus)

Measles virus

Bacteria

Pyogenic organisms (especially *S. pneumoniae*, *H. influenzae*; in late disease, *S. aureus* and gram-negative organisms)

M. tuberculosis

M. avium complex and other nontuberculous mycobacteria

Fungi

Histoplasma capsulatum

Coccidioides immitis

Cryptococcus neoformans

Candida species

Aspergillus species

Parasites

Pneumocystis carinii

Toxoplasma gondii

Cryptosporidia

Strongyloides stercoralis

Malignancies

Kaposi's sarcoma

Non-Hodgkin's lymphoma

Smooth muscle tumors

Lymphocytic interstitial pneumonitis

Nonspecific interstitial pneumonitis

Drug-induced pneumonitis

Pneumonia in the Neutropenic Host

Neutropenia in the cancer patient is a common complication of aggressive chemotherapy, but occasionally results from the cancer itself. The risk of infection for the cytopenic patient is increased significantly when the absolute neutrophil count falls less than 500 cell/mm^3 (0.500×10^9/L) and the neutropenia persists for more than 7 days. For many patients, the duration of chemotherapy-induced cytopenia can be reduced by judicious application of colony-stimulating factors.[78]

The organisms that cause pneumonia in the cytopenic cancer patient include a broad range of bacteria and fungi. The most prominent among these are gram-positive bacteria (staphylococci and streptococci); others include enteric and nonenteric (particularly *P. aeruginosa*) gram-negative rods as well as the fungi (*Candida*, *Aspergillus*). The chest radiograph may reveal the lobar pattern typical of bacterial infection in the normal host, or it may exhibit a diffuse pattern. The pneumonia may remain invisible by chest radiograph until the neutropenia resolves. Noninfectious entities that may cause pulmonary symptoms include toxicity from radiation or chemotherapy or infiltration of the lung parenchyma by the tumor itself.

Common Pathogens

Gram-Positive Bacteria

S. aureus is a prominent cause of HAP and may result from hematogenous spread from a distant source. It is characteristically severe and accompanied by the formation of pneumatoceles (air-containing cavities within the lung). Infections caused by MDR organisms, such as MRSA and vancomycin-intermediate and vancomycin-resistant *S. aureus* are increasing among patients with HAP. IV antibiotic use within the past 90 days increases the risk for MRSA and other MDR pathogens causing HAP and VAP.6 Group B *Streptococcus*, although rare in adults, is the most common cause of bacterial pneumonia among neonates and typically causes a clinical and radiographic picture nearly indistinguishable from hyaline membrane disease.[79]

Enteric Gram-Negative Bacteria

The enteric gram-negative bacteria are leading causes of HAP because the upper respiratory tract becomes rapidly colonized with gram-negative organisms after hospitalization, particularly among critically ill patients and those receiving antibiotics.[80] *K. pneumoniae* is the most frequently

encountered pathogen among the gram-negative enteric bacteria, although the relative prominence of these organisms varies among hospitals. The gram-negative bacilli are associated with high mortality, sometimes exceeding 50%; their potential to produce significant morbidity and mortality has been enhanced by the emergence of highly MDR organisms in some hospital settings.[6]

Nonenteric Gram-Negative Bacteria

The most prominent nonenteric gram-negative rods associated with pneumonia include *P. aeruginosa*, *H. influenzae*, and *M. catarrhalis*. Like the enteric gram-negative organisms, *P. aeruginosa* is a frequent cause of HAP and is particularly prominent among neutropenic and burn patients.[6] In addition, cystic fibrosis patients suffer from chronic, multilobar infections with *P. aeruginosa*, as well as other *Pseudomonas* species, and *S. maltophilia* is an emerging pathogen[81]; these infections are punctuated with acute exacerbations. Dual coverage for *P. aeruginosa* is only suggested if patients are at risk for antimicrobial resistance, if resistance is >10% towards a monotherapy agent based on antibiogram, or if resistance patterns are not known.[6] *H. influenzae* type b has been a prominent pathogen in childhood pneumonia. The incidence of all invasive disease due to this organism in the pediatric age group has dropped dramatically since the introduction of the conjugated *Haemophilus* vaccines in the late 1980s. However, two different clinical presentations of *H. influenzae* pneumonia continue to be observed in adults. The most common by far is the bronchopneumonia form, which develops most frequently for patients with underlying chronic lung disease and is believed to represent, in most patients, an exacerbation of chronic bronchitis. In the second form of *H. influenzae* pneumonia, segmental or lobar involvement predominates. The course of this illness is more acute, with sudden onset of cough, fever, and pleuritic chest pain. Finally, *M. catarrhalis*, an important cause of otitis media and sinusitis, is an increasingly important cause of lower respiratory tract infections in immunocompromised and hospitalized patients.

Anaerobic Bacteria

Anaerobic pneumonitis is most likely to occur in individuals predisposed to aspiration by impaired consciousness or dysphagia as the source for the anaerobic bacteria is generally the oral cavity/gingival crevice.[82] Bronchogenic carcinoma is an associated underlying condition. A variety of gram-positive and gram-negative anaerobic bacteria indigenous to the upper airway may cause pneumonitis when large quantities of oropharyngeal secretions are aspirated into the lower airways. The most common organisms identified are *B. melaninogenicus*, *Fusobacteria*, and anaerobic streptococci; polymicrobial infections with anaerobes and aerobes, such as *S. aureus*, *S. pneumoniae*, and gram-negative bacilli, are common.[82]

Early in the infection, clinical symptoms are similar to CAP with patients presenting with cough, low-grade fever, pulmonary infiltrates, and leukocytosis. The course of anaerobic pneumonia is typically indolent and patients are unlikely to have rigors. Other characteristic features are lung abscess, necrotizing pneumonia, and empyema. Anaerobic infections should be suspected if patients are predisposed to aspiration or have a chronic course, putrid sputum/breath, pulmonary necrosis, or empyema.[82] Chest radiographs reveal infiltrates typically located in dependent lung segments, and lung abscesses develop in 20% of patients 1 to 2 weeks into the course of the illness.

Atypical Pneumonia

Legionella species, *Mycoplasma* species, *Chlamydia* species, viruses, and fungi are recognized causes of pneumonia syndromes in all age groups. The designation *atypical pneumonia* has been used to describe pneumonia caused by many of these agents, since it is distinct from the typical bacterial pneumonia course seen most commonly in adults.[67]

Legionella pneumophila

Of the several *Legionella* species known to cause pneumonia in humans, *L. pneumophila* is by far the most important, accounting for 2% to 9% of all CAPs in North America and Europe.[66,83,84] *Legionella*, a small, gram-negative, non–spore-forming bacilli, is an aquatic organism that is transmitted by inhalation of aerosols containing the organism or by microaspiration of contaminated water. Outbreaks of illness caused by *L. pneumophila* have been linked to excavation sites and to contaminated water from air conditioners and showers. Person-to-person transmission has not been demonstrated. In addition to epidemics, *L. pneumophila* causes sporadic illness that peaks in summer and fall. Individuals who are more than 50 years of age, have chronic lung disease, smoke cigarettes, or immunocompromised are at increased risk.[66,83,84]

Infection with *L. pneumophila* is characterized by multisystem involvement and the severity of the infection can range from mild to severe rapidly progressive pneumonia.[73,83] It has a gradual onset with prominent constitutional symptoms (eg, malaise, lethargy, weakness, and anorexia) occurring early in the course of the illness. A dry, nonproductive cough is present initially and becomes productive of mucoid or purulent sputum over several days. Fevers exceeding 38.8°C (101.8°F) develop in more than half of patients (greater than 20% with fevers exceeding 40°C[104°F]) and typically are unremitting and associated with a relative bradycardia. Pleuritic chest pain and progressive dyspnea may be seen. Along with pneumonia, extrapulmonary symptoms, particularly diarrhea, nausea, vomiting, and neurologic symptoms (headache, hallucinations, seizures, and focal neurologic findings), should increase the suspicion for *L. pneumophila*; the GI symptoms may remain evident throughout the course of the illness.[83,84] Myalgias, arthralgias, and chills also occur. Substantial changes in the patient's mental status, often out of proportion to the degree of fever, are seen in approximately one fourth of patients. Chest radiographs initially reveal patchy alveolar infiltrates that may be bilateral and asymmetric. Pulmonary infiltrates may worsen even when the patient is receiving appropriate antibiotics. Progression to lobar or multilobar consolidation is frequent, as are small pleural effusions.

Laboratory findings include leukocytosis with a predominance of mature and immature granulocytes in 50% to 75% of patients. Urinalysis may reveal proteinuria, hematuria, and casts; abnormal liver function tests, increases in serum creatine phosphokinase, hyponatremia, and hypophosphatemia (typically occurring early in infection) have been reported in patients with *L. pneumophila*.[83] Because *L. pneumophila* stains poorly, routine microscopic examination of sputum is of little diagnostic value. Although it exhibits slow growth and has highly selective growth requirements, *L. pneumophila* has been isolated successfully from tissue using a specialized medium. Direct fluorescent antibody examination of respiratory tract secretions, lung tissue, or pleural fluid is the most rapid means of

establishing the diagnosis. The sensitivity of this method approaches 70% for sputum and 90% for lung tissue, and diagnostic specificity is high for both. Commercially available urine antigen tests have been developed for *L. pneumophila* (primarily Lp1, the most virulent strain) that allow for detection within 2 to 3 days from the onset of symptoms. These tests are 56% to 99% sensitive and remain positive for weeks even after effective antibiotics have been started. Thus, routine testing in the United States is not recommended, but should be considered for patients not responding to outpatient therapy, those with severe pneumonia, and those with risk factors mentioned above.[83]

M. pneumoniae

The mycoplasmas are included in their own taxonomy labeled *Mollicutes*. Although their small size and filterability are similar to viruses, the structure of their ribosomal RNA indicates that they have evolved from bacteria, and, unlike any virus, they contain cytoplasm and can replicate in an extracellular environment. They are distinguished from eubacteria by their low genetic content and have a parasitic relationship with their hosts.[66] In addition, the mycoplasmas lack a cell wall and are surrounded instead by a lipid membrane. The latter characteristic explains the resistance of these pathogens to cell wall–active antibiotics.

M. pneumoniae causes human disease throughout the year, with a slightly increased incidence in fall and early winter. During the summer months when other causes of pneumonia are less common, *M. pneumoniae* is responsible for a greater proportion of cases. Both infection and disease from *M. pneumoniae* are common, with 10% to 30% of the cases of CAP in children and young adults attributed to this organism.[85] In enclosed populations, such as military recruits and college dormitory residents, it may cause more than 50% of the cases of CAP. Infection is spread by close person-to-person contact and the incubation period is 2 to 3 weeks. *M. pneumoniae* infections are unusual in children younger than 5 years old and show a peak incidence in older children and young adults. Only 3% to 10% of persons infected with *M. pneumoniae* develop pneumonia, with the majority of respiratory tract involvement manifested as pharyngitis and tracheobronchitis. Asymptomatic infection is common.

M. pneumoniae usually presents with a gradual onset of fever, headache, and malaise, with the appearance 3 to 5 days after the onset of illness of a persistent, hacking cough that initially is nonproductive. Sore throat, ear pain, and rhinorrhea often are present. Chills are seen only occasionally and pleuritic pain is uncommon. Lung findings generally are limited to rales and rhonchi; findings of consolidation are rare. Nonpulmonary manifestations of *M. pneumoniae* are extremely common and include nausea, vomiting, diarrhea, myalgias, arthralgias, polyarticular arthritis, and skin rashes (eg, mucositis and Steven's Johnson Syndrome); myocarditis, pericarditis, hemolytic anemia, meningoencephalitis, cranial neuropathies, and Guillain-Barré syndrome have also been reported.[66,86,87] Systemic symptoms generally clear in 1 to 2 weeks, whereas respiratory symptoms may persist for up to 4 weeks. Although the course of mycoplasma pneumonia usually is benign and self-limited, severe respiratory disease may develop in patients with sickle cell disease, agammaglobulinemia, COPD, and in those who have undergone a splenectomy.[66]

Radiographic and CT findings generally are more impressive than the patient's physical findings and

include patchy or interstitial infiltrates, consolidations, centrilobular nodules, and bronchial wall thickening.[88] Small unilateral, transient pleural effusions are common; large effusions and empyema are rare. Radiographic abnormalities resolve slowly and 4 to 6 weeks may be required for complete resolution.

Sputum Gram stain may reveal mononuclear or polymorphonuclear leukocytes, with no predominant organism. Although *M. pneumoniae* can be cultured from respiratory secretions using specialized medium, its growth is slow as 2 to 3 weeks may be necessary for culture identification. Indirect evidence of infection by *M. pneumoniae* is the presence of elevated levels of serum cold hemagglutinins. These immunoglobulin M antibodies develop in approximately half of patients with mycoplasmal pneumonia and can be elevated in other illnesses, especially viral infections. A definitive diagnosis also can be made by demonstrating a fourfold or greater rise in serum antibodies to *M. pneumoniae*.[88] However, because this test also requires 2 to 4 weeks for results, the diagnosis of mycoplasmal pneumonia during the acute phase of the illness must be based on the characteristic history, appropriate clinical setting, and typical physical findings.

C. pneumoniae

C. pneumoniae has received the new taxonomic classification of *Chlamydophila*; however, it may still be referred to as *Chlamydia pneumoniae* in some references.[89] *C. pneumoniae*, formally designated the Taiwan acute respiratory agent after the laboratory designations for the first two isolates, is antigenically similar to *C. psittaci*. *C. pneumoniae* infection is ubiquitous worldwide; approximately 80% of the population has been infected by adulthood,[66] but only a small percentage of infections result in clinically apparent pneumonia. Conversely, approximately 5% to 15% of pneumonia is associated with this pathogen.[89] Primary infection with *Chlamydia* pneumonia typically occurs in young adults and is characterized by mild respiratory symptoms with a gradual onset (eg, incubation period about 21 days). Constitutional manifestations, particularly fever, headache, and hoarseness, are common.[66] The radiographic findings are nonspecific and usually consist of multilobular interstitial infiltrates with circumscribed lesions. Immunity is incomplete, and reinfection with *C. pneumoniae* is common, particularly among the elderly. Definitive diagnosis of *C. pneumoniae*–associated pneumonia depends on identification of the organism in sputum. Culture of this organism is difficult and commercially available antigen detection systems are insensitive.

Viral Pneumonia

Viruses are an uncommon cause of pneumonia in adults, except in the immunosuppressed.[6] When viral pneumonia does occur, the influenza virus (usually type A) is the most common cause in the adult civilian population[4]; other viruses causing adult CAP include RSV, adenoviruses, parainfluenza, and human metapneumovirus.[4] In contrast, viruses are by far the most common agents producing pneumonia in infants and young children with a prevalence of up to 80% in those less than 2 years of age, with RSV accounting for most cases. Other common viruses in children include parainfluenza, adenovirus, human metapneumovirus, bocavirus, and rhinovirus.[5,53,66]

Viral respiratory tract infections occur more commonly in the winter and typically spread rapidly from person to person through susceptible populations. Underlying cardiac or pulmonary disease predisposes one to an increased incidence and severity of viral lower respiratory tract infection, especially with influenza virus in adults and RSV in children. Radiographic findings are nonspecific, include bronchial wall thickening and perihilar, and diffuse interstitial infiltrates. Pleural effusions may be seen, especially in adenovirus and parainfluenza pneumonia.

The clinical pictures produced by respiratory viruses are sufficiently variable and overlap to such a degree that an etiologic diagnosis cannot be made confidently based on clinical grounds alone. Although virus isolation in tissue culture is still considered the gold standard, it is time consuming and technically demanding; a period of 7 or more days often is required for virus identification[3] and thus this method usually cannot be used for definitive diagnosis during the acute phase of illness. Serologic tests for virus-specific antibodies are used often in epidemiologic and surveillance studies of viral infections since the diagnostic fourfold rise in titer between acute and convalescent phase sera may require 2 to 3 weeks to develop.[3] Rapid antigen testing for the influenza virus (some tests distinguishing types A and B) and RSV is available; however, cost, high false-positive rates, and 50% to 70% sensitivity are considerations for its utility during nonpeak seasons.[3,4,6] Viral testing with molecular techniques provides increased utility for patient care with high sensitivity, rapid results, and the ability to detect new and emerging pathogens. Although not universally available in the United States, these include real-time PCR, solid and liquid microarrays, mass spectrometry, target-enriched multiplexing PCR, and multiplex ligation-dependent probe amplification, to name a few.[3]

Viruses that have emerged in recent decades and caused significant outbreaks include avian influenza H5N1, severe acute respiratory syndrome coronavirus (SARS-CoV), swine influenza H1N1, variant influenza A H3N2, and Middle Eastern respiratory syndrome coronavirus (see Chapter 109 for further discussion of these viruses).[90,91] In general, signs and symptoms of these viral infections are similar to other viral subtypes; however, there have been unique differences with several of the strains. Pneumonia, respiratory distress syndrome, lymphopenia, and clotting abnormalities tend to occur rapidly in patients infected with H5N1. The H1N1 virus affected normally healthy young adults as opposed to other flu viruses, which tend to be more severe in the young and the elderly, and resulted in serious infections requiring hospitalization and death. The SARS-CoV is an extremely contagious atypical pneumonia[92,93] causing high fever, myalgias, headache, diarrhea, and a dry nonproductive cough, however, for unclear reasons, SARS appears to be less severe for pediatric patients.

Tuberculosis

The acid-fast bacillus *M. tuberculosis* causes tuberculosis and is spread person to person by inhalation of droplets. After years of steady decline, the number of cases of pneumonia caused by *M. tuberculosis* in the United States began to increase in the middle to late 1980s. The new epidemic was a consequence of an increased incidence among prison inmates, IV drug abusers, immigrants, and, most prominently, HIV-infected patients. It is most prominent in urban neighborhoods afflicted with crowded conditions and poor access to healthcare; thus, groups prone to tuberculosis include the homeless and patients in chronic care facilities and homes for the elderly. Unlike previous eras in

which tuberculosis was seen most frequently in elderly men, infection currently is identified in increasing numbers of young minority adults. Multidrug resistant strains of *M. tuberculosis* have become more common and treatment regimens for these patients should involve consultation with a specialist. (See Chapter 112 for a detailed discussion of tuberculosis pathophysiology, diagnosis, and treatment.)

TREATMENT

Desired Outcome

Eradication of the offending organism through selection of the appropriate antibiotic and subsequent complete clinical cure are the goals of therapy for all bacterial infections. Therapy should minimize associated morbidity, including one or both of the following: reversible or irreversible disease and drug-induced organ toxicity (eg, renal, lung, or hepatic dysfunction). Most cases of viral pneumonia are self-limiting, although therapy of influenza pneumonia with specific antiviral agents (oseltamivir and zanamivir) may hasten recovery. All efforts should focus on the design of the most cost-effective approach to therapy. Whenever possible, the oral (vs parenteral) route for drug administration should be selected, encouraging outpatient management rather than hospitalization. Optimal treatment of infection/lower respiratory tract infection requires a rapid and accurate diagnosis, rapid initiation of effective antimicrobial therapy, and proper antimicrobial stewardship. The sooner proper antimicrobial therapy is instituted, the better the outcome. Comprehensive principles of optimal antimicrobial therapy and infectious diseases stewardship are discussed in detail in Chapter 105.

General Approach to Treatment

9 The first priority in assessing the patient with pneumonia is to evaluate the adequacy of respiratory function and to determine the presence of signs of systemic illness, specifically dehydration or sepsis with resulting circulatory collapse. Oxygen or, in severe cases, mechanical ventilation and fluid resuscitation should be provided as necessary. Further supportive care of the patient with pneumonia includes humidified oxygen for hypoxemia, administration of bronchodilators (albuterol) when bronchospasm is present, and chest physiotherapy with postural drainage if evidence of retained secretions. Additional therapeutic adjuncts include adequate hydration (IV if necessary), optimal nutritional support, and control of fever. Appropriate sputum samples may be obtained to determine the microbiologic etiology. In more severely ill—hospitalized patients cultures of lower respiratory tract secretions obtained by protected specimen brush bronchoscopy or via BAL along with blood cultures can be helpful in identifying causative pathogens. Rehydration should be provided to replace losses that may have occurred as a result of fever, poor intake, and/or associated vomiting. Selection of an appropriate antimicrobial must be made based on the patient's probable or documented microbiology and its distribution in the respiratory tract, side effects, and cost. Respiratory tract infection diagnosis and treatment guideline reports have been published by authoritative professional organizations that focus on proper treatment regimens and should be consulted for evidence-based treatment recommendations across the spectrum of community- and/or hospital-associated pneumonias.[94]

An increasingly important challenge to effective treatment of lower respiratory tract infections is the ability of bacteria and fungi to form biofilms—colonies of organisms protected by an extracellular polymer matrix of polysaccharides and extracellular DNA. These are complex, multicellular structures that adhere to surfaces (anatomical or devices, eg, indwelling IV lines) and are responsible for the chronicity and poor microbial eradication rates of many hospital-acquired as well as chronic infections, for example, cystic fibrosis (see Chapter 29). Biofilms display specific properties and serve as a reservoir for pathogen dissemination and resultant systemic infection. The colonies of pathogens they harbor can be resistant to antimicrobial drug (eg, aminoglycosides) and immune cell penetration —biofilms may contain single or mixed microbial communities. Other drug classes like fluoroquinolones may penetrate certain biofilms well, but still do not eradicate 100% of the biofilm microorganisms. Biofilm-based microorganisms can produce a number of small, diffusible "communication" molecules—some are signaling molecules regulating cell density within the biofilm and other intracellular functions. An in depth assessment of biofilms is beyond the scope of this chapter, but a good understanding of their many characteristics and approaches to combat them are pivotal to the design of effective treatment of (lower respiratory tract) infections.[95]

Clinical Controversy…

Various adjunctive therapy options have been studied for their potential benefits in CAP in recent years. Drugs that have been studied include corticosteroids, prostaglandin inhibitors, statins, immunoglobulin therapy, mediator-specific immunomodulators, angiotensinogen-converting enzyme inhibitors, and oral hypoglycemic agents. Proposed mechanisms for some of the drugs have centered on protective effects (eg, vasodilation and cough reflex) and antiinflammatory effects. Due to differences in study design and patient populations, the actual benefits of these therapies in the treatment of CAP remains undetermined.[96]

Pharmacologic Therapy

Antibiotic Concentrations

Antibiotic concentrations in respiratory secretions in excess of the pathogen MIC are necessary for successful treatment of pulmonary infections.[97] The concept of a blood–bronchus barrier, analogous but dissimilar to the blood–brain barrier, has been used to describe the characteristics of drug penetration into pulmonary secretions. The ability of a drug to penetrate respiratory secretions depends on multiple physicochemical factors, including molecular size, lipid solubility, and degree of ionization at serum and biologic fluid pH and the extent of protein binding. Studies performed in animals and cystic fibrosis patients suggest that larger molecular size favors the accumulation of drugs in bronchial secretions. This finding contrasts with data on drug penetration of other physiologic compartments, such as the cerebrospinal fluid, and may be a result of the trapping of lower-molecular-weight compounds in mucin pores. Nevertheless, the rate at which a drug may accumulate in certain respiratory secretions appears to remain an important factor relative to the drug's clinical efficacy in treating pulmonary infections. The unionized form of drug and lipid solubility also appears to favor drug penetration. Of note, the pH of the infected bronchi often is more acidic than that of normal tissue and blood. These factors combined underscore the importance

of considering the inhaled route of antimicrobial drugs for the treatment of patients with moderate to severe pneumonia, particularly in high-risk patient groups.[98]

Clinical Controversy...

Prior to the availability of newer β-lactam and fluoroquinolone antibiotics possessing consistently potent activity against multiple gram-negative pathogens, some investigators promoted the administration of antibiotics by direct endotracheal instillation. This method of drug administration attempts to provide increased topical concentrations of antibiotics that do not appear to penetrate respiratory secretions effectively while reducing the likelihood of systemic toxicity. In addition, greater local concentrations of antibiotics, particularly of the polymyxins (eg, colistin) and aminoglycosides are believed to overcome partially the substantial decrease in antibiotic bioactivity observed when these agents interact with the purulent material present in infectious foci. Despite these potential theoretical advantages, the role of antibiotic aerosols or direct endotracheal instillation in clinical practice remains controversial and guidelines do not recommend the routine use of aerosolized antibiotics.[6, 99,100,101,102] Nevertheless, positive efficacy and safety data combined with the increasing incidence of serious infections caused by MDR pathogens is fostering the continued study of antibiotic aerosols.

Limited data are available for assessing the influence of drug protein binding on the rate and amount of respiratory secretion penetration. Clearly, it is the free antibiotic fraction reaching the infected site capable of binding to the bacterial cell target that is responsible for antibacterial activity. Given that the degree of protein binding influences a drug's ability to traverse membranes, a similar relationship would be expected within the lung. However, focusing on the absolute amount of an antibiotic bound to plasma/tissue proteins without accounting for the drug's overall antibacterial potency is errant. To completely assess an antibiotic's therapeutic potential in the treatment of pneumonia or any infectious process, it is prudent to assess the antibiotic's integrated pharmacokinetic-pharmacodynamic (PK-PD) characteristics (eg, bacterial killing may be concentration dependent, time dependent, or a hybrid) that account for the drug's degree of binding to serum proteins, tissue distribution, and in vitro potency. These concepts relating to antibiotic activity and overall drug penetration of respiratory secretions underscore the importance of applying the well-defined concepts of antimicrobial PK and PD to the design of optimal antibiotic dosing regimens. A primary example of effectively applying antibiotic PK-PD–designed optimal dosing is reflected in the clinical practice of administering certain antibiotics (once daily dosing of aminoglycosides) to achieve high peak serum concentrations on the assumption that higher (and possibly more effective) biologic fluid concentrations of the drug will be achieved. The aminoglycosides are large polar molecules that diffuse poorly into tissue and respiratory secretions; however, with increasing concentrations obtained with once-daily dosing, increased target-tissue concentrations would be expected with increasing individual doses. Further, recognizing that the peak drug concentration-to-pathogen MIC ratio (Cmax:MIC) is the primary PK-PD correlate for aminoglycosides and that the target Cmax:MIC ratio for aminoglycosides is approximately 10, the single daily dose strategy is most likely to achieve the desired PK-PD target at the desired anatomic site. Similar is the case for the so-called respiratory fluoroquinolones (eg, levofloxacin, moxifloxacin, and gemifloxacin) higher individual dose therapy targeting a greater Cmax:MIC ratio or the more commonly targeted area under the

concentration–time curve (AUC)-to-pathogen MIC ratio, that is, AUC:MIC, for fluoroquinolones. The target 24-hour AUC:MIC ratio for fluoroquinolones was originally greater than 35 (possible minimum of 25) for gram-positive and greater than 125 (possible minimum of 100) for gram-negative pathogens. However, with the increasing incidence of antibiotic-resistant bacteria many clinicians are targeting higher ratios of greater than 100 to 200 to suppress possibly resistant mutants of gram-negative pathogens. For greatest probability of success, the antibiotic concentrations projected in these PK-PD correlates should include the expected free (not protein-bound) antibiotic concentration. Conversely, concentration-dependent killing characteristics best correlate with successful therapy with the β-lactam/-carbapenem and macrolide classes of antimicrobials (see Chapter e104 and Chapter 105 for more in-depth discussion of antibiotic concepts).[99,103]

Sputum collection and gram-staining and culture can still be helpful in determining the causative pathogens for respiratory tract infections since it may serve as a reservoir for pathogen growth and possibly represent the PD interface for pulmonary infections. Investigators have assessed antibiotic concentrations in sputum, frequently describing sputum drug concentrations as a ratio of serum to sputum drug concentration; however, caution should be exercised in the interpretation of these data. Data describing sputum drug concentrations is often difficult to interpret because of differences in analytic techniques, method of sputum sampling, and random nature of sampling times relative to drug dose. To more accurately describe the distribution characteristics of antimicrobial agents in sputum, research studies should be designed to allow sequential repeated sputum sampling over a specified dosage interval under both first-dose and steady-state conditions. Thus, until greater sophistication is achieved in our understanding of the relationships between antibiotic concentrations in specific anatomic sites, plasma (blood)-based integrated PK-PD correlates should be used for antibiotic and dose selection.

Recognizing the many deficiencies of using sputum drug concentration correlates for prognosticating antibacterial therapy, most investigators now prefer the determination of drug concentrations in pulmonary epithelial lining fluid and alveolar macrophages.[97] Assessing drug concentrations in specific compartments may provide greater insight into drug selection and efficacy (eg, epithelial lining fluid may reflect the extracellular fluid space and thus the important site for extracellular pathogens, *S. pneumoniae*, *M. catarrhalis*, and *H. influenza*). Although characterizing antimicrobial disposition into these compartments is desirable, access to obtain these samples requires invasive procedures (eg, BAL).

Selection of Antimicrobial Agents

Treatment of bacterial pneumonia, like the treatment of most infectious diseases, initially involves the empirical use of a relatively broad-spectrum antibiotic that is effective against probable pathogens after appropriate cultures and specimens for laboratory evaluation have been obtained.[63,94] Therapy should be narrowed to cover specific pathogens after the results of cultures are known. Multiple factors that help to define the potential pathogens involved include patient age, previous and current medication history, underlying disease(s), major organ function, and present clinical status. These factors must be evaluated to select an appropriate and effective empirical antibiotic regimen as well as the most appropriate route for drug administration (oral vs parenteral). (For a more detailed

discussion on the principles of antibiotic selection, see Chapter 105.)

Many antibiotics are effective in the treatment of bacterial pneumonia. Superiority of one antibiotic over another when both demonstrate similar dose-normalized in vitro activity and tissue distribution characteristics is difficult to define. Our opinions on appropriate empirical choices for the treatment of bacterial pneumonias relative to a patient's underlying disease are listed in **Table 107-8** for adults and **Table 107-9** for children. A complete listing of antimicrobial agents for specific pathogens is beyond the scope of this chapter and is presented in Chapter 105.

TABLE 107-8 Evidence-Based Empirical Antimicrobial Therapy for Pneumonia in Adults[a]

Clinical Setting	Usual Pathogens	Empirical Therapy
Outpatient/Community Acquired		
Previously healthy	*S. pneumoniae*, *M. pneumoniae*, *H. influenzae*, *C. pneumoniae*, *M. catarrhalis*	Macrolide/azalide,[b] or tetracycline[c]
Comorbidities (diabetes, heart/lung/liver/renal disease, and alcoholism)	Viral	Oseltamivir or zanamivir if <48° from onset of symptoms
	MDR S. pneumoniae	Fluoroquinolone[d] or β-lactam + macrolide[b]
Elderly		Piperacillin/tazobactam or cephalosporin[e] or carbapenem[f]
Regions with >25% rate of macrolide-resistant *S. pneumoniae*	*S. pneumoniae*, gram-negative bacilli	Fluoroquinolone[d] or β-lactam + macrolide[b]/tetracycline
Inpatient/Community Acquired		
Non-ICU	*S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, *C. pneumoniae*, *Legionella* sp.	Fluoroquinolone[d] or β-lactam + macrolide[b]/tetracycline
ICU	*S. pneumoniae*, *S. aureus*, *Legionella* sp., gram-negative bacilli, *H. influenzae*	β-Lactam + macrolide[b]/fluoroquinolone[d]
	If *P. aeruginosa* suspected	Piperacillin/tazobactam or meropenem or cefepime + fluoroquinolone[d]/AMG/azithromycin; or β-lactam + AMG + azithromycin/respiratory fluoroquinolone[d]
	If MRSA suspected	Above + vancomycin or linezolid
	Viral	Oseltamivir or zanamivir ± antibiotics for 2° infection

Clinical Setting	Usual Pathogens	Empirical Therapy
Hospital Acquired or Ventilator Associated		
No risk factors for MDR pathogens (single agent *Pseudomonal* coverage)	*S. pneumoniae*, *H. influenzae*, MSSA, enteric gram-negative bacilli	Piperacillin/tazobactam, cefepime, levofloxacin, imipenem or meropenem
Risk factors for MDR pathogen (dual agent *Pseudomonal* coverage)	*P. aeruginosa*, *K. pneumoniae* (ESBL), *Acinetobacter* sp.	Antipseudomonal cephalosporin[e] or antipseudomonal carbapenem or β-lactam/β-lactamase + antipseudomonal fluoroquinolone[d] or AMG[g]
	If MRSA or *Legionella* sp. suspected	Above + vancomycin or linezolid
Aspiration	*S. aereus*, enteric gram-negative bacilli	Penicillin or clindamycin or piperacillin/tazobactam + AMG[g]
	Anaerobes	Clindamycin, β-lactam/β-lactamase, or carbapenem
Atypical Pneumonia[h]		
Legionella pneumophila		Fluoroquinolone,[d] doxycycline, or azithromycin
Mycoplasma pneumonia		Fluoroquinolone,[d] doxycycline, or azithromycin
Chlamydophila pneumonia		Fluoroquinolone,[d] doxycycline, or azithromycin
SARS		Fluoroquinolone[d] or macrolides[b]
Avian influenza		Oseltamivir
H1N1 influenza		Oseltamivir

MRSA, methicillin-resistant *Staphylococcus aureus*; AMG, aminoglycoside; SARS, severe acute respiratory syndrome; ESBL, extended-spectrum β-lactamases; MDR, multidrug resistant; MSSA, methicillin-sensitive *Staphylococcus aureus*.

[a]See the section Selection of Antimicrobial Agents.

[b]Macrolide/azalide: erythromycin, clarithromycin, and azithromycin.

[c]Tetracycline: tetracycline, HC1, and doxycycline.

[d]Fluoroquinolone: ciprofloxacin, levofloxacin, and moxifloxacin.

[e]Antipseudomonal cephalosporin: cefepime and ceftazidime.

[f]Antipseudomonal carbapenem: imipenem and meropenem.

[g]Aminoglycoside: amikacin, gentamicin, and tobramycin.

[h]For tuberculosis, see Chapter 112.

Data from references 4, 6, 66.

TABLE 107-9 Empirical Antimicrobial Therapy for Pneumonia in Pediatric Patients[a]

Clinical Setting	Usual Pathogen(s)	Empirical Therapy
Outpatient/Community Acquired		
<1 month	Group B *Streptococcus*, *H. influenzae* (nontypable), *E. coli*, *S. aureus*, *Listeria* CMV, RSV, adenovirus	Ampicillin/sulbactam, cephalosporin,[b] carbapenem[c] Ribavirin for RSV[d]
1-3 months	*C. pneumoniae*, possibly *Ureaplasma*, CMV, *Pneumocystis carinii* (afebrile pneumonia syndrome)	Macrolide/azalide,[e] trimethoprim–sulfamethoxazole
	S. pneumoniae, *S. aureus*	Semisynthetic penicillin[f] or cephalosporin[g]
Preschool-aged children	Viral (rhinovirus, RSV, influenza A and B, parainfluenzae, adenovirus, human metapneumovirus, coronavirus)	Antimicrobial therapy not routinely required
Previously healthy, fully immunized infants and preschool children with suspected mild–moderate bacterial CAP	*S. pneumoniae*	Amoxicillin, cephalosporin[b,g]
	M. pneumoniae, other atypical	Macrolide/azalide or fluoroquinolone
Previously healthy, fully immunized school-aged children and adolescents with mild–moderate CAP	*S. pneumoniae*	Amoxicillin, cephalosporin,[b,g] or fluoroquinolone
	M. pneumoniae, other atypical	Macrolide/azalide, fluoroquinolone, or tetracycline
Moderate–severe CAP during influenza virus outbreak	Influenza A and B, other viruses	Oseltamivir or zanamivir
Inpatient/Community Acquired		
Fully immunized infants and school-aged children	*S. pneumoniae*	Ampicillin, penicillin G, cephalosporin[b]
	CA-MRSA	β-Lactam + vancomycin/clindamycin
	M. pneumoniae, *C. pneumoniae*	β-Lactam + macrolide/fluoroquinolone

Clinical Setting	Usual Pathogen(s)	Empirical Therapy
		/doxycycline
Not fully immunized infants and children; regions with invasive penicillin-resistant pneumococcal strains; patients with life-threatening infections	*S. pneumoniae*, *PCN resistant*	Cephalosporin[b]
	MRSA	Add vancomycin/clindamycin
	M. pneumoniae, other atypical pathogens	Macrolide/azalide[e] + β-lactam/doxycycline /fluoroquinolone

CMV, cytomegalovirus; RSV, respiratory syncytial virus; CAP, community-acquired pneumonia; MRSA, methicillin resistant *Staphylococcus aureus*.

[a]See the section Selection of Antimicrobial Agents.

[b]Third-generation cephalosporin: ceftriaxone and cefotaxime. Note that cephalosporins are not active against *Listeria*.

[c]Carbapenem: imipenem–cilastatin and meropenem.

[d]See text for details regarding possible ribavirin treatment for RSV infection.

[e]Macrolide/azalide: erythromycin and clarithromycin/azithromycin.

[f]Semisynthetic penicillin: nafcillin, and oxacillin.

[g]Second-generation cephalosporin: cefuroxime and cefprozil.

Data from reference 5.

A patient's medical history of responding or not responding to one of these antibiotics in the recent past will assist greatly in the decision to continue their use. For infected patients with risk factors, regardless of whether the patient resides in the community, long-term care facility, or acute care hospital, the fluoroquinolone antibiotics represent important treatment tools based on their highly favorable PK (tissue and intracellular distribution) and PD (potency, broad spectrum) characteristics combined with ease of administration (IV, oral) and patient tolerability. Furthermore, optimal dosing directed by the projected 24-hour free fluoroquinolone AUC-to-pathogen MIC ratio (see earlier) has fostered maximal bacteriologic kill and enhanced patient safety.

Table 107-10 lists dosages for selected antibiotics used for the treatment of bacterial pneumonia. The large number of expensive drugs mandates critical evaluation for formulary selection and clinical use. Similarities of in vitro activity, resistance to bacterial-inactivating enzymes, and overall effectiveness often make rational therapeutic decisions difficult and even appear random. However, some general principles can be applied to guide rational antibiotic choice, including direct comparison of the antibiotic's likely attainment of the defined PK-PD target correlate for specific bacterial species within the infected site. An understanding and application of inherent drug

characteristics appears to be of the utmost importance for the selection of an optimal therapeutic regimen. Thus, whenever possible, identification of the causative pathogen and expected/defined antibiotic susceptibility (eg, MIC) is of paramount importance to the selection/design of the optimal antibiotic regimen. Lastly, the importance of meaningful and continuous antimicrobial stewardship in combating the rate of pathogen resistance cannot be overemphasized.

TABLE 107-10 Antibiotic Doses for Treatment of Bacterial Pneumonia

			Daily Antibiotic Dose[a]	
Antibiotic Class	**Antibiotic**	**Brand Name**	**Pediatric**	**Adult (Total Dose/Day)**
Penicillin	Ampicillin ± sulbactam		150-200 mg/kg/day	6-12 g
	Amoxicillin ± clavulanate[b]	Unasyn®	45-100 mg/kg/day	0.75-1 g
		Augmentin®	200-300 mg/kg/day	12-18 g
	Piperacillin/tazobactam	Zosyn®	100,000-250,000 units/kg/day	12-18 million units
	Penicillin			
Extended-spectrum cephalosporins	Ceftriaxone	Rocephin®	50-75 mg/kg/day	1-2 g
	Cefotaxime	Claforan®	150 mg/kg/day	2-12 g
	Ceftazidime	Fortaz®/Tazicef®	90-150 mg/kg/day	4-6 g
	Cefepime	Maxipime®	100-150 mg/kg/day	2-6 g
Macrolide/azalide	Clarithromycin	Biaxin®	15 mg/kg/day 30-50 mg/kg/day	0.5-1 g 1-2 g
	Erythromycin	Ery-Tab®	10 mg/kg × 1 day (× 2 days if parenteral), and then 5 mg/kg days 2-5	500 mg × 1 day (× 2 days if parenteral), and then 250 mg days 2-5
	Azithromycin	Zithromax®		
Fluoroquinolones[c]	Moxifloxacin	Avelox®	–	400 mg
	Gemifloxacin	Factive®	–	320 mg
	Levofloxacin	Levaquin®	8-20 mg/kg/day	750 mg
	Ciprofloxacin	Cipro®	30 mg/kg/day	1.2 g
Tetracycline[d]	Doxycycline	Monodox®/Doxy 100™	2-5 mg/kg/day	100-200 mg
	Tetracycline HCl		25-50 mg/kg/day	1-2 g

Antibiotic Class	Antibiotic	Brand Name	Daily Antibiotic Dose[a] Pediatric	Adult (Total Dose/Day)
Aminoglycosides	Gentamicin		7.5-10 mg/kg/day	7.5 mg/kg
	Tobramycin		7.5-10 mg/kg/day	7.5 mg/kg
Carbapenems	Imipenem	Primaxin®	60-100 mg/kg/day	2-4 g
	Meropenem	Merrem®	30-60 mg/kg/day	1-3 g
Other	Vancomycin	Zyvox®	45-60 mg/kg/day	2-3 g
	Linezolid		20-30 mg/kg/day	1.2 g
	Clindamycin	Cleocin®	30-40 mg/kg/day	1.8 g

[a]Doses can be increased for more severe disease and may require modification for patients with organ dysfunction.

[b]Higher-dose amoxicillin and amoxicillin/clavulanate (eg, 90 mg/kg/day) are used for penicillin-resistant *S. pneumoniae*.

[c]Fluoroquinolones have been avoided for pediatric patients because of the potential for cartilage damage; however, they have been used for MDR bacterial infection safely and effectively in infants and children (see text).

[d]Tetracyclines are rarely used in pediatric patients, particularly in those younger than 8 years because of tetracycline-induced permanent tooth discoloration.

Community-Acquired Pneumonia

Tables 107-8 and 107-9 provide evidence-based guidelines for the treatment of CAP in adults[4] and children,[5] respectively. The bacterial causes are relatively constant, even across geographic areas and patient populations. Unfortunately, pathogen resistance to standard antimicrobials is increasing (eg, penicillin-resistant pneumococci), which necessitates careful attention by the clinician to local and regional bacterial susceptibility patterns.[104] Thus, whenever possible, initial therapy should be based on presumed antibacterial susceptibility and consist of older, less-expensive agents, with newer and more expensive antibiotics reserved for unresponsive illness or special circumstances. Indiscriminate use of recently introduced agents increases healthcare costs and, in some instances (eg, widespread use of fluoroquinolones), induces resistance among a significant percentage of community-acquired organisms.[4] The rapidly evolving epidemiology of bacterial resistance, including the increasing emergence of penicillin-resistant *S. pneumoniae* in many areas of the United States and Europe, forces the clinician to be vigilant and knowledgeable about antibiotic sensitivity patterns in each community. Interestingly, the European National Institute for Health and Care Excellence pneumonia

guidelines recommend point of care C reactive protein tests to assist in determining if antibiotics should be prescribed to patients with lower respiratory tract infections when pneumonia has not been diagnosed clinically.[71] Indiscriminate use of antimicrobials for treatment of pneumonia has contributed to the problem of antimicrobial resistance, underscoring the need for defining the optimal antibiotic regimen for each patient.

9 Evidence-based empirical therapy differs among outpatients, hospitalized patients, and hospitalized patients admitted to an intensive care unit (see Tables 107-8 and 107-9).[4,5] Antimicrobial therapy should be initiated for hospitalized patients with acute pneumonia within 8 hours of admission because an increase in mortality has been demonstrated when therapy was delayed beyond 8 hours of admission.

Hospital-Acquired Pneumonia

10 Antibiotic selection within the hospital environment demands greater care because of constant changes in antibiotic resistance patterns in vitro and in vivo. Ironically, some β-lactam antibiotics, which were developed to treat MDR hospital-acquired organisms, can themselves induce broad-spectrum bacterial β-lactamases and thereby lead to even greater problems with resistance.[99] These facts underscore the importance of regularly documenting the epidemiology of pathogens and infectious diseases within a specific practice or institution and tailoring empiric antibiotic therapy based on local antibiograms.[6] As a result, an antimicrobial agent for a specific infectious disease favored in one practice site may not be the most desirable selection in another site despite similarities in size and patient profile. Strict and careful control and, possibly, rotation of empirical antibiotics in the hospital environment may help to limit the emergence of resistant organisms. Newer antibiotics developed for treatment of resistant, hospital-acquired pathogens are costly; therefore, their use must be moderated to some extent in an era where capitated hospital costs and mandated budget cuts will not tolerate careless antibiotic use. Broad-spectrum antibiotics are more appropriate choices for patients with risk factors for MDR pathogens or if HAP develops after at least 5 days of hospitalization (see Table 107-8 for recommended antimicrobial therapy).[6] For most patients, a 7 day course of antibiotics is appropriate.[6]

Ventilator-Associated Pneumonia

The approach to treating VAP is similar to antibiotic selection in HAP (see Table 107-8). Patients should be carefully evaluated to determine whether they are at risk for MDR pathogens as this is essential in selecting appropriate empirical antibiotic therapy.[6] Risk factors for MDR VAP include septic shock, ARDS, acute renal replacement therapy, IV antibiotic use within the previous 90 days and/or being hospitalized at least 5 days prior to VAP.[6] It is also important to identify patients with VAP early since delays in initiating appropriate antibiotic therapy are associated with increased mortality. Current guidelines support shorter antibiotic courses (7 days versus 8-15 days) for VAP even for gram negative bacilli infections since mortality and clinical cure rates were not significantly affected with shorter courses.[6] Aerosolized antibiotic delivery has been considered for more targeted therapy; but is currently only recommended if patients are not responding to IV antibiotic

therapy.[6,106] Inhaled plus systemic aminoglycosides or colistin can be used if the identified pathogen is only sensitive to one of those antibiotics.[6]

Atypical Pneumonia

Pneumonia caused by atypical pathogens may be more difficult to treat with antibiotics than "typical" pathogens. It is debatable whether empirical treatment for hospitalized patients with CAP should include antibiotic coverage of atypical pathogens; however, for patients requiring ICU admission, combination therapy including coverage for atypical pathogens has been associated with improved mortality.[107] There does not appear to be any benefit in terms of survival or clinical efficacy to providing atypical coverage for all outpatients unless they have risk factors for a poor outcome (eg, history of CHD, lung or liver disease, immunosuppression, DM, or malignancy) (see Table 107-8 for a summary of the evidence-based guidelines on management).[107]

For *Legionella* pneumonia, azithromycin and levofloxacin are recommended although other respiratory fluoroquinolones, tetracyclines, or macrolides could be utilized but may result in more side effects.[84] Double antibiotic coverage is not recommended if one of these agents is used, even in severe pneumonia, due to limited evidence of improved efficacy.[84] *Mycoplasma* pneumonia is difficult to treat similar to the other atypical pathogens due to the organism's lack of a cell wall, limiting the use of certain antibiotics, and because it is found on epithelial cells in the respiratory tract instead of inside the cells.[66] Macrolides and tetracyclines are generally effective against *Mycoplasma*; however, macrolide-resistant strains have been emerging over the past decade.[85] *Chlamydophila* organisms are sensitive to macrolides, doxycycline, and fluoroquinolones. Symptoms, such as cough and malaise, may be present for months following antibiotic therapy.[66] The management of tuberculosis is further discussed in Chapter 112.

For viral causes of pneumonia, antivirals such as oseltamivir and occasionally amantadine can be used, depending on viral susceptibility.[91] Treatment for H5N1 and H1N1 is primarily supportive; patients with H5N1 generally require aggressive oxygen therapy and intensive monitoring, while the majority of those with H1N1 are treated as outpatients. Both viruses are resistant to amantadine; therefore, the neuraminidase inhibitors oseltamivir and zanamivir are recommended if antivirals are administered. Treatment of SARS involves primarily supportive care and procedures to prevent transmission to others. Owing to the uncertainty associated with the diagnosis of SARS, empirical therapy with broad-spectrum antibiotics should be used including fluoroquinolones or macrolides/azalides. Although evidence for its efficacy is limited, oral ribavirin also has been used to treat patients with noninfluenza respiratory viral infections.[108] High dose systemic corticosteroids are not routinely recommended in severe viral respiratory infections due the risk of avascular osteonecrosis and prolonged viral shedding.[91]

Prevention

Prevention of some cases of pneumonia is possible through the use of vaccines and medications against selected infectious agents. Polyvalent polysaccharide vaccines are available for two of the

leading causes of bacterial pneumonia, *S. pneumoniae* and *H. influenzae* type b. Children should be vaccinated against *S. pneumoniae*, *H. influenzae* type b, pertussis, and influenza while caregivers for infants less than 6 months should also be vaccinated against influenza and pertussis. Immune prophylaxis for RSV is only recommended for high-risk infants during RSV season. To minimize the risk of developing VAP, healthcare providers should seek to minimize colonization of the aerodigestive tract, prevent aspiration (head raised 45 degree), and limit the length of mechanical ventilation of patients.[75] In addition, evidence-based guidelines for preventing HCAP have been published (**Table 107-11**) (see Chapter 109 for a full discussion of influenza postexposure prophylaxis and Chapter 125 for vaccines.)[109]

TABLE 107-11 Evidenced-Based Guidelines for Preventing Healthcare-Associated Pneumonia

Recommendation	Recommendation Grade[a]
For nebulizers, use aerosolized medications in single-dose vials. If multidose medication vials are used, follow manufacturers' instructions for handling, storing, and dispensing the medications	1B
Pneumococcal vaccination is recommended for patients at high risk for severe pneumococcal infections	1A
Unless contraindicated, administer a macrolide to any person who has had close contact with persons having pertussis	1B
In acute care settings, offer vaccine to inpatients and outpatients at high risk for complications from influenza beginning in September and throughout the influenza season	1A
Unless contraindicated, provide prophylactic treatment to all patients without influenza illness in the involved unit with amantadine, rimantadine, or oseltamivir for a minimum of 2 weeks or until approximately 1 week after the end of the outbreak	1A
Unless contraindicated, patients with influenza should receive amantadine, rimantadine, oseltamivir, or zanamivir within 48 hours of the onset of symptoms	1A

[a]Grade 1A, strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies; grade 1B, strongly recommended for implementation and supported by certain clinical or epidemiologic studies and by strong theoretical rationale.

EVALUATION OF THERAPEUTIC OUTCOMES

After therapy has been instituted, appropriate clinical parameters should be monitored to ensure the efficacy and safety of the therapeutic regimen. For patients with bacterial infections of the upper or lower respiratory tract, the time to resolution of initial presenting symptoms and the lack of appearance of new associated symptomatology are important to determine. For patients with CAP or pneumonia from any source of mild to moderate clinical severity, the time to resolution of cough,

decreasing sputum production, and fever as well as other constitutional symptoms of malaise, nausea, vomiting, and lethargy, should be noted. If the patient requires supplemental oxygen therapy, the amount and need should be assessed regularly. A gradual and persistent improvement in the resolution of these symptoms and therapies should be observed. Initial resolution of infection should be observed within the first 2 days of therapy and progression to complete resolution within 5 to 7 days (usually no more than 10 days).

For patients with HAP, substantial underlying diseases, or both, additional parameters can be followed, including the magnitude and character of the peripheral blood WBC count, chest radiograph, and blood gas determinations. Similar to patients with less severe disease, some resolution of symptoms should be observed within 2 days of instituting antibiotic therapy. If no resolution of symptoms is observed within 2 days of starting seemingly appropriate antibiotic therapy or if the patient's clinical status is deteriorating, the appropriateness of initial antibiotic therapy should be critically reassessed. The patient should be evaluated carefully for deterioration of underlying concurrent disease(s). Additionally, the caregiver should consider the possibility of changing the initial antibiotic therapy to expand antimicrobial coverage not included in the original regimen (eg, *Mycoplasma*, *Legionella*, and anaerobes). Furthermore, the need for antifungal therapy (eg, triazoles, echinocandins) should be considered. Some resolution of symptoms should be observed within 2 days of starting proper antibiotic therapy, with complete resolution expected within 10 to 14 days.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

AECB	acute exacerbation of chronic bronchitis
AUC	area under the concentration curve
BAL	bronchoalveolar lavage
CAP	community-acquired pneumonia
Cmax	maximum concentration
COPD	chronic obstructive pulmonary disease
FEV_1	forced expiratory volume in the first second of expiration
GOLD	Global Initiative for Chronic Obstructive Lung Disease
HAP	hospital-acquired pneumonia
HIV	human immunodeficiency virus
LABA	long-acting β-receptor agonist
LAMA	long-acting muscarinic antagonist
MDR	multidrug resistant
MIC	minimum inhibitory concentration
MRSA	methicillin-resistant *Staphylococcus aureus*
NAC	*N*-acetyl cysteine
PCR	polymerase chain reaction

PDE4	phosphodiesterase 4
PK-PD	pharmacokinetic–pharmacodynamic
RSV	respiratory syncytial virus
SARS	severe acute respiratory syndrome
SARS-CoV	severe acute respiratory syndrome coronavirus
VAP	ventilator-associated pneumonia
WBC	white blood cell

Chapter 108: Upper Respiratory Tract Infections

Christopher Frei; Bradi Frei

INTRODUCTION

KEY CONCEPTS

- 1 Many upper respiratory tract infections will resolve spontaneously without pharmacologic therapy.
- 2 The most common bacterial causes are *Streptococcus pneumoniae* (acute otitis media and acute rhinosinusitis) and group A β-hemolytic *Streptococcus* (acute pharyngitis).
- 3 Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media.
- 4 Because upper respiratory tract infections are so common, antibiotics used to treat them serve as catalysts for the emergence and spread of antibiotic resistance, thereby making prudent antibiotic use critically important.
- 5 When antibiotics are prescribed, the empirical medications of choice are amoxicillin or amoxicillin-clavulanate for acute otitis media, amoxicillin-clavulanate for acute rhinosinusitis, and amoxicillin or penicillin for acute pharyngitis.
- 6 For acute otitis media, high-dose amoxicillin (80-90 mg/kg/day in two divided doses) is recommended.

More patients present to physicians' offices and emergency departments for upper respiratory tract infections than any other infectious disease.[1,2] Otitis media, rhinosinusitis, and pharyngitis are the three most common upper respiratory tract infections. Because they are so common, community and emergency health care workers must be familiar with the diagnosis, assessment, and management of patients with these infections. Furthermore, antibiotics used for the treatment of upper respiratory tract infections serve as catalysts for the emergence and spread of antibiotic resistance, thereby making prudent antibiotic use critically important.

ACUTE OTITIS MEDIA

The term *otitis media* comes from the Latin *oto-* for "ear," *itis* for "inflammation," and *medi-* for "middle"; otitis media, then, is an inflammation of the middle ear. There are three subtypes of otitis media: acute otitis media, otitis media with effusion, and chronic otitis media. Acute otitis media is the subtype with the greatest role for antibiotics and will be discussed in detail.

Epidemiology

Otitis media is one of the leading reasons for physicians' office visits and emergency department visits in the United States, accounting for more than 16 million clinic and emergency department visits annually.[1,2] There are more than 709 million cases of otitis media worldwide each year; half of these cases occur in children under 5 years of age.[3] Many patients with otitis media will receive a prescription, and the costs associated with managing otitis media are $2.3 billion annually in the United States.[4]

Etiology

1 When comprehensive and sensitive microbiologic methods have been used in patients with a certain diagnosis of acute otitis media, bacteria have been found in more than 90% of cases; with standard diagnostic and microbiologic testing, bacteria have been found in approximately 70% of cases.[5]

2 Common bacterial pathogens include *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis*.[6] The microbial etiology has changed as a result of the introduction and widespread use of the pneumococcal conjugate vaccines. Specifically, the proportion of *S. pneumoniae* cases has declined, and the proportion of *H. influenzae* cases has risen.[7] Today, these two pathogens occur in approximately equal proportions.[5]

S. pneumoniae, *H. influenzae*, and *M. catarrhalis* can all possess resistance to β-lactams. *S. pneumoniae* develops resistance through alteration of penicillin-binding proteins, whereas *H. influenzae* and *M. catarrhalis* produce β-lactamases. Up to 40% of *S. pneumoniae* isolates in the United States are penicillin nonsusceptible, and up to half of these have high-level penicillin resistance.[8] Approximately 30% to 40% of *H. influenzae* and greater than 90% of *M. catarrhalis* isolates from the upper respiratory tract produce β-lactamases.[9]

Pathophysiology

Acute otitis media usually follows a viral upper respiratory tract infection that impairs the mucociliary apparatus and causes Eustachian tube dysfunction in the middle ear.[6] The middle ear is the space behind the tympanic membrane, or eardrum. A noninfected ear has a thin, clear tympanic membrane. In otitis media, this space becomes blocked with fluid, resulting in a bulging and erythematous

tympanic membrane. Bacteria that colonize the nasopharynx enter the middle ear and are not cleared properly by the mucociliary system. The bacteria proliferate and cause infection. Children tend to be more susceptible to otitis media than adults because the anatomy of their Eustachian tube is shorter and more horizontal, facilitating bacterial entry into the middle ear.

Clinical Presentation

Patients or caregivers frequently characterize acute otitis media as having an acute onset of otalgia (ear pain). For parents of young children, irritability and tugging on the ear are often the first clues that a child has acute otitis media.

The American Academy of Pediatrics (AAP) guidelines have stringent diagnostic criteria to ensure accurate diagnosis. Children should be diagnosed with acute otitis media if they have middle ear effusion *and* either (1) moderate to severe bulging of the tympanic membrane *or* new onset otorrhea not due to acute otitis externa or (2) mild bulging of the tympanic membrane *and* onset of ear pain within the last 48 hours or intense erythema of the tympanic membrane. Middle ear effusion should be identified based on pneumatic otoscopy and/or tympanometry.[5]

CLINICAL PRESENTATION Acute Otitis Media General

- Cases of acute otitis media often follow viral upper respiratory tract infections. Nonverbal children with ear pain might hold, rub, or tug their ear. Very young children might cry, be irritable, and have difficulty sleeping.

Signs and Symptoms

- Bulging of the tympanic membrane
- Otorrhea
- Otalgia (considered to be moderate or severe if pain lasts at least 48 hours)
- Fever (considered to be severe if temperature is 39°C [102.2°F] or higher)

Compiled from references 5 and 6.

The diagnoses of acute otitis media and otitis media with effusion are easily confused, and careful attention to history, signs, and symptoms is important. Otitis media with effusion is characterized by fluid in the middle ear without signs and symptoms of acute ear infection, such as pain and a bulging eardrum.[6,7]

TREATMENT

Desired Outcomes

6 Treatment goals include pain management and prudent antibiotic use. These will be discussed in detail, but, first, it is important to consider primary prevention of acute otitis media through the use

of bacterial and viral vaccines.

3 Clinicians should recommend pneumococcal conjugate vaccine and annual influenza vaccine to all children according the Advisory Committee on Immunization Practices (ACIP) schedule from the United States Centers for Disease Control and Prevention.[5] A systematic review demonstrated that the seven-valent pneumococcal conjugate vaccine (PCV7) reduced the occurrence of acute otitis media episodes by 6% to 7% when the vaccine was administered during infancy.[10] Finally, because acute otitis media cases often follow influenza cases, influenza vaccination should be considered as a possible means to prevent acute otitis media.

General Approach to Treatment

The first step is to differentiate acute otitis media from otitis media with effusion or chronic otitis media, as the latter two types do not benefit substantially from antibiotic therapy. If the child has acute otitis media, then consider if the disease severity warrants antibiotic therapy. Recognize that amoxicillin is the mainstay of therapy and that penicillin resistance can be overcome, in many cases, with higher doses of amoxicillin. Address the child's pain as described below. The therapeutic strategy should be changed if complications develop or if symptoms fail to resolve within 3 days.

Nonpharmacologic Therapy

Children with acute otitis media should be assessed for pain. Those with pain should be offered treatment to reduce pain regardless of the decision to administer antibiotics.[5] This is largely because antibiotics do not reduce pain in the first 24 hours. Furthermore, some children may experience some pain up to 3 to 7 days even after antibiotics are started. Choice of pain treatment depends on possible benefits and risks to the individual patient. Acetaminophen and ibruprofen are mainstays of treatment, are effective analgesics for mild to moderate pain, and are readily available. Eardrops with a local anesthetic may offer additional, but brief, benefit over acetaminophen in patients at least 5 years of age.[5]

Pharmacologic Therapy

National clinical practice guidelines for appropriate diagnosis and management of acute otitis media were updated in 2013, by the AAP.[5] These guidelines are focused on children 6 months to 12 years of age with uncomplicated cases and without underlying conditions that may alter the natural course of the disease.

The decision to administer antibiotics depends on patient age, symptom severity, laterality, and joint decision-making with parents/caregivers. Children 6 months to 12 years of age, with moderate to severe ear pain or temperature of 39°C (102.2°F) or higher should receive antibiotics. Children 6 to 23 months of age, with nonsevere bilateral acute otitis media should also receive antibiotics. Children 6 to 23 months, with nonsevere unilateral acute otitis media, and children 24 months to 12 years of age, with nonsevere acute otitis media, may receive *initial antibiotics* or *initial observation*. Initial observation should be based on joint decision-making with parents/caregivers, and must include a

plan to initiate antibiotics if the child's symptoms worsen or decline within 48 to 72 hours of symptom onset.[5] The central principle is to administer antibiotics quickly when the diagnosis is certain, but to withhold antibiotics, at least initially, when the diagnosis is uncertain.

4 Antibiotic therapy for upper respiratory diseases must be balanced with possible increases in adverse drug events and increased antibiotic pressure. Systematic reviews and randomized controlled trials suggest a moderate benefit of antibiotics for the treatment of acute otitis media, particularly in patients with severe symptoms.[7,11,12,13,14] On the other hand, rates of adverse effects, such as diarrhea and diaper rash, are more than double in children who received antibiotics for acute otitis media.[13,14]

5 If antibiotics are to be administered, then amoxicillin should be given to most children.[5] Exceptions include: children who have received amoxicillin in the last 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent infection unresponsive to amoxicillin. These patients should receive amoxicillin-clavulanate instead of amoxicillin. Patients with otitis conjunctivitis syndrome are more likely to be infected with nontypeable *H. influenzae*, hence the need for a β-lactamase inhibitor.[5] Clinicians should reassess the plan if the child's symptoms worsen or decline within 48 to 72 hours of symptom onset.[5] **Table 108-1** lists antibiotic recommendations for acute otitis media.

TABLE 108-1 Antibiotics and Doses for Acute Otitis Media

Antibiotic	Brand Name	Dose	Comments[a]
Initial Diagnosis			
Amoxicillin	Amoxil®	80-90 mg/kg/day orally divided twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally of amoxicillin plus 6.4 mg/kg/day orally of clavulanate, divided twice daily	First-line if certain criteria are present[b]
Cefdinir, cefuroxime, cefpodoxime	Omnicef®, Ceftin®, Vantin®	cefdinir (14 mg/kg/day orally in 1-2 doses) cefuroxime (30 mg/kg/day orally in 2 divided doses) cefpodoxime (10 mg/kg/day orally in 2 divided doses)	Second-line or nonsevere penicillin allergy
Ceftriaxone (1-3 days)	Rocephin®	50 mg/kg/day IM or IV for 3 days	Second-line or nonsevere penicillin allergy
Failure at 48-72 Hours			
Amoxicillin-clavulanate[b]	Augmentin®	90 mg/kg/day orally of amoxicillin plus 6.4 mg/kg/day orally of clavulanate, divided twice daily	First-line

Antibiotic	Brand Name	Dose	Comments[a]
Ceftriaxone (1-3 days)	Rocephin®	50 mg/kg/day IM or IV for 3 days	First-line or nonsevere penicillin allergy
Clindamycin	Cleocin®	30-40 mg/kg/day orally in 3 divided doses plus third-generation cephalosporin	Second-line or nonsevere penicillin allergy

[a]If a patient has received amoxicillin in the last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent infection unresponsive to amoxicillin.

[b]Amoxicillin-clavulanate 90:6.4 or 14:1 ratio is available in the United States; 7:1 ratio is available in Canada (use amoxicillin 45 mg/kg for one dose, amoxicillin 45 mg/kg with clavulanate 6.4 mg/kg for second dose).

IM, intramuscular; IV, intravenous; po, orally.

Data from reference 5.

High-dose amoxicillin (80-90 mg/kg/day in two divided doses) is recommended for most patients. Amoxicillin has the best pharmacodynamic profile against drug-resistant *S. pneumoniae* of all available oral antibiotics. In addition, amoxicillin has a long record of safety, possesses a narrow spectrum of activity, is inexpensive, and is more palatable than other options. Higher middle ear fluid concentrations of amoxicillin, as a result of higher dosing, overcome most drug-resistant *S. pneumoniae*.[5] Its excellent efficacy against *S. pneumoniae* outweighs the issue of β-lactamase-producing *H. influenzae* and *M. catarrhalis*, against which amoxicillin may not be effective. This is because both *H. influenzae* and *M. catarrhalis* are more likely than *S. pneumoniae* to lead to a spontaneous resolution of the infection.

If a patient has received amoxicillin in the last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent infection unresponsive to amoxicillin, then they should receive high-dose amoxicillin-clavulanate (90 mg/kg/day of amoxicillin, with 6.4 mg/kg/day of clavulanate, in two divided doses) instead of amoxicillin. Amoxicillin-clavulanate has activity against β-lactamase-producing *H. influenzae* and *M. catarrhalis* as well as drug-resistant *S. pneumoniae*.[5] Other antibiotic choices include cefdinir, cefuroxime, cefpodoxime, and intramuscular or intravenous ceftriaxone.[5] Second-generation cephalosporins, though β-lactamase stable, are expensive, have an increased incidence of side effects, and may increase selective pressure for resistant bacteria. Furthermore, most cephalosporins do not achieve adequate middle ear fluid concentrations against drug-resistant *S. pneumoniae* for the desired duration of the dosing interval. Use of trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole is discouraged because of high rates of resistance. Intramuscular ceftriaxone is the only antibiotic, other than amoxicillin, that achieves middle ear fluid concentrations above the minimal inhibitory concentration (MIC) for greater than 40% of the dosing interval. Although single doses of ceftriaxone have been used, daily doses for 3 days are recommended to optimize clinical outcomes.[5] Ceftriaxone is more expensive than amoxicillin and the intramuscular

injections are painful. Patients with a penicillin allergy can be treated with several alternative antibiotics, including a cephalosporin in cases absent severe or type 1 penicillin allergy, or clindamycin. Notably, clindamycin lacks efficacy against *H. influenzae*, whereas macrolides lack efficacy against both *H. influenzae* and *S. pneumoniae*; therefore, macrolides are not recommended. Finally, tympanocentesis can also be considered for treatment failure or persistent acute otitis media. It has a therapeutic effect of relieving pain and pressure and can be used to collect fluid to identify the causative agent.

There is ongoing debate regarding the optimal duration of therapy for acute otitis media. Traditional recommendations call for 10 days of antibiotic therapy; however, some experts have speculated that patients can be treated for as little as 5 to 7 days. Unfortunately, the data to support the shorter courses are inconclusive, with some studies demonstrating similar outcomes and others demonstrating worse outcomes with short-course therapy.[7] Short-course treatment is not recommended in children younger than 2 years of age. In children at least 6 years of age who have mild to moderate acute otitis media, a 5- to 7-day course may be used.[5]

Clinical Controversy…

The 2013 AAP guidelines for acute otitis media recommend an *initial observation* approach prior to administering antibiotics in selected patients.[5] This is because many cases of acute otitis media will resolve without antibiotics, and the guideline authors believe that delayed therapy might serve as a mechanism to reduce antibiotic overuse. A systematic review supports this view, maintaining that antibiotics had only a slight benefit on pain after the first day and only a modest effect on the number of children with tympanic perforations, contralateral otitis episodes, and abnormal tympanometry findings.[12] However, others believe that the modest benefit seen in these systematic reviews is because as many as half of the included patients did not have acute otitis media.[15,16] A placebo-controlled trial, with precise diagnostic criteria, *did* find that antibiotics reduced the time to resolution of middle ear effusion and normal otoscopy findings in children with otitis media.[11] This debate will continue, but there seems to be general agreement that precise diagnostics are key.[5] Unfortunately, there is also debate as to whether such diagnostic approaches are possible in the general clinical setting.[15,17]

Recurrent acute otitis media is defined as at least 3 episodes in 6 months or 4 episodes in 1 year, with 1 episode in the preceding 6 months. Recurrent episodes are of concern because children younger than 3 years of age are at high risk for hearing loss and language and learning disabilities. Clinicians should not prescribe antibiotics as prophylaxis against recurrent episodes, but they may offer tympanostomy tubes (T tubes).[5]

Personalized Pharmacotherapy

Procalcitonin increases in response to bacterial infection and declines as the infection resolves. Clinicians are starting to use procalcitonin blood levels to decide when to initiate and discontinue antibiotics in patients with acute upper respiratory infections (URIs).[18] A Cochrane systematic review of 14 trials with 4,221 participants found that procalcitonin protocols significantly reduced antibiotic

consumption without negatively impacting patient survival or treatment failure.[19] The finding was driven by lower prescription rates in primary care and shorter durations of antibiotic therapy in emergency departments and intensive care units.[19] Despite the enthusiasm for this approach, there are still several aspects of procalcitonin monitoring that need to be resolved, including the timing of levels, the procalcitonin cutoff values for different clinical decision points, and the cost-effectiveness of this technology.[20]

Evaluation of Therapeutic Outcomes

Patients with acute otitis media should be reassessed after 48 to 72 hours. By this time, there should be clinical improvement in the signs and symptoms of infection, including pain, fever, and erythema/bulging of the tympanic membrane. If the patient has not responded and antibiotics were withheld initially, they should be instituted now. If the patient initially received an antibiotic, then the antibiotic should be changed (Table 108-1). Most children will become asymptomatic at 7 days.

Early reevaluation of the eardrum when signs and symptoms are improving can be misleading because effusions persist. Over a period of 1 week, changes in the eardrum normalize, and the pus becomes serous fluid. Air-fluid levels are apparent behind the eardrum, at which point the stage is now referred to as *otitis media with effusion*. This does not represent ongoing infection, nor are additional antibiotics required.[5]

Immediate reevaluation is appropriate if hearing loss results from persistent middle ear effusions following infection. Complications of otitis media are infrequent but include mastoiditis, bacteremia, meningitis, and auditory sequelae with the potential for speech and language impairment.[5]

ACUTE BACTERIAL RHINOSINUSITIS

Sinusitis is an inflammation and/or infection of the paranasal sinuses, or membrane-lined air spaces, around the nose.[21] The term *rhinosinusitis* is now preferred because sinusitis typically also involves the nasal mucosa.[21] Even though the majority of rhinosinusitis infections are viral in origin, antibiotics are frequently prescribed. It is thus important to differentiate between viral and bacterial rhinosinusitis to avoid antibiotic overuse.

Clinical practice guidelines for acute bacterial rhinosinusitis were published in 2012.[21] Several of the recommendations in these guidelines differ substantially from prior guidelines.

Epidemiology

1 Nearly 30 million cases of rhinosinusitis are diagnosed annually in the United States.[22] Acute bacterial rhinosinusitis is overdiagnosed; thus, antibiotics are overprescribed. Most rhinosinusitis infections have a viral etiology, and yet, antibiotics are frequently prescribed. Adults with rhinosinusitis miss an average of 6 workdays/y with these infections.[23] Patients with rhinosinusitis are significantly more likely to use the emergency room, spend more than $500/y on medical care, and

see a medical specialist.[23]

Etiology

2 Acute bacterial rhinosinusitis is caused, most often, by the same bacteria implicated in acute otitis media: *S. pneumoniae* and *H. influenzae*. These organisms are responsible for approximately 50% to 70% of bacterial causes of acute bacterial rhinosinusitis in both adults and children.[21] *M. catarrhalis* is also sometimes implicated in adults and children (approximately 8%-16%).[21] *Streptococcus pyogenes*, *Staphylococcus aureus*, gram-negative bacilli, and anaerobes are associated less frequently with acute bacterial rhinosinusitis.[21] Issues of bacterial resistance are similar to those found with acute otitis media.

Pathophysiology

Similar to acute otitis media, acute bacterial rhinosinusitis is often preceded by a viral respiratory tract infection that causes mucosal inflammation. This can lead to obstruction of the sinus ostia—the pathways that drain the sinuses.[6] Mucosal secretions become trapped, local defenses are impaired, and bacteria from adjacent surfaces begin to proliferate. The maxillary and ethmoid sinuses are most frequently involved.[6] The pathogenesis of chronic rhinosinusitis has not been well studied. Whether it is caused by more persistent pathogens or a subtle defect in the host's immune function, some patients develop chronic symptoms after their acute infection.

Clinical Presentation

The greatest barrier to efficient use of antibiotics in acute bacterial rhinosinusitis is the lack of a simple and accurate diagnostic test. The gold standard for diagnosis is sinus puncture with recovery of bacteria in high density (10^4 colony-forming units/mL [10^7 cfu/L] or greater)[21]; however, sinus puncture is invasive and costly, and can be painful, so it is not routinely done. Sinus radiography can help, but it is not routinely recommended. Because there is no simple and accurate office-based test for acute bacterial rhinosinusitis, clinicians rely on clinical findings to make the diagnosis.

CLINICAL PRESENTATION Acute Bacterial Rhinosinusitis General

- There are three clinical presentations that are most consistent with acute bacterial versus viral rhinosinusitis:
- Onset with *persistent* signs or symptoms compatible with acute rhinosinusitis, lasting for ≥ 10 days without any evidence of clinical improvement
- Onset with *severe* signs or symptoms of high fever (≥39°C [102.2°F]) and purulent nasal discharge or facial pain lasting for at least 3 to 4 consecutive days at the beginning of illness
- Onset with *worsening* signs or symptoms characterized by new-onset fever, headache, or increase in nasal discharge following a typical viral URI that lasted 5 to 6 days and were initially

improving (“double sickening”)

Signs and Symptoms

- Purulent anterior nasal discharge, purulent or discolored posterior nasal discharge, nasal congestion or obstruction, facial congestion or fullness, facial pain or pressure, fever, headache, ear pain/pressure/fullness, halitosis, dental pain, cough, and fatigue

Data from reference 21.

TREATMENT

Desired Outcomes

The goals of treatment for acute bacterial rhinosinusitis are to reduce signs and symptoms, achieve and maintain patency of the ostia, limit antibiotic treatment to those who may benefit, eradicate the bacterial infection with appropriate antibiotic therapy, minimize the duration of illness, prevent complications, and prevent progression from acute disease to chronic disease.

General Approach to Treatment

4 The first step is to delineate viral and bacterial rhinosinusitis. This is based on disease duration, initial severity of illness, and worsening symptomatology. Viral rhinosinusitis typically improves in 7 to 10 days; therefore, a diagnosis of acute bacterial rhinosinusitis requires persistent symptoms (10 days or greater) or a worsening of symptoms after 5 to 6 days. Acute bacterial rhinosinusitis may also be suspected if the patient has severe symptoms at the beginning of his/her illness. Amoxicillin-clavulanate is now recommended as the first-line antibiotic therapy for patients with acute bacterial rhinosinusitis.[21] Adjuvant, nonantibiotic therapies have a limited role.

The next step is to decide if the patient needs to be referred to a specialist. Potential reasons for referral include mental status changes, visual disturbances, immunosuppressive illness, nosocomial infections, anatomic defects causing obstruction and possibly requiring surgery, unusually severe symptoms, multiple recurrent episodes (3-4/y), unilateral findings, significant coexisting illnesses, risk factors for unusual or resistant pathogens, and history of antibiotic failure. The specialist may perform computed tomography to assess the severity and extent of disease and identify the underlying causes.

Nonpharmacologic Therapy

Several nonprescription therapies are used in the management of *nonbacterial rhinosinusitis* for symptomatic relief. These include nasal decongestant sprays that reduce inflammation by vasoconstriction. Use should be limited to no more than 3 days to prevent the development of tolerance and/or rebound congestion. Oral decongestants may also aid in nasal/sinus patency. Irrigation of the nasal cavity with saline and steam inhalation may be used to increase mucosal moisture, and mucolytics (eg, guaifenesin) may be used to decrease the viscosity of nasal secretions.

In contrast, if a patient is suspected of having *acute bacterial rhinosinusitis*, then decongestants and antihistamines are not recommended.[21] These can dry mucosa and disturb clearance of mucosal secretions. Other therapies are recommended to be used as adjuncts to antibiotics for patients with acute bacterial rhinosinusitis. Intranasal saline irrigation with either physiologic or hypertonic saline is recommended for adults,[21] but the evidence from a Cochrane review is unimpressive.[24] Intranasal corticosteroids are now recommended for patients with a history of allergic rhinitis.[25]

Pharmacologic Therapy

Several prestigious groups have published statements and clinical practice guidelines for the management of patients with acute bacterial rhinosinusitis, including the Academy of Pediatrics, the Sinus and Allergy Health Partnership, the American Academy of Otolaryngology—Head and Neck Surgery, the Agency for Healthcare Research and Quality, and the Joint Task Force on Practice Parameters, representing the American Academy of Allergy, Asthma, and Immunology, the American College of Allergy, Asthma, and Immunology, and the Joint Council of Allergy, Asthma, and Immunology. The Infectious Diseases Society of America (IDSA) published their clinical practice guideline in 2012;[21] these guidelines are the primary source for many of the statements in this chapter.

5 Amoxicillin-clavulanate is now the first-line treatment for acute bacterial rhinosinusitis in children and adults (**Tables 108-2** and **108-3**).[21] In contrast, prior guidelines, including the ones published by the Canadian government in 2011,[26] list amoxicillin as the first-line treatment option due to its safety, narrow spectrum of activity, good tolerability, and favorable cost. A randomized controlled trial questioned the value of amoxicillin in nonsevere cases of acute bacterial rhinosinusitis.[27] The IDSA guidelines support the choice of amoxicillin-clavulanate based on (a) the emergence of *H. influenzae* as a more common cause of upper respiratory tract infections in children than in the past[7,28] and (b) the high prevalence of β-lactam-producing respiratory pathogens in acute bacterial rhinosinusitis (particularly *H. influenzae* and *M. catarrhalis*). Recall that approximately 30% to 40% of *H. influenzae* and greater than 90% of *M. catarrhalis* isolates from the upper respiratory tract produce β-lactamases.[9] The advantage of using amoxicillin-clavulanate, as compared with amoxicillin, is a greater spectrum of coverage. The disadvantages are increased cost, greater risk of adverse effects including diarrhea, and an added risk of hypersensitivity to the clavulanate component.[21] No other antibiotics are recommended as first-line for initial empirical therapy.

TABLE 108-2 Antibiotics and Doses for Acute Bacterial Rhinosinusitis in Children

Antibiotic	Brand Name	Dose	Comments
Initial Empirical Therapy			
Amoxicillin-clavulanate	Augmentin®	45 mg/kg/day orally twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally twice daily	Second-line
***β*-Lactam Allergy**			

Antibiotic	Brand Name	Dose	Comments
Clindamycin plus cefixime or cefpodoxime	Cleocin®, Suprax®, Vantin®	Clindamycin (30-40 mg/kg/day orally three times daily) plus cefixime (8 mg/kg/day orally twice daily) or cefpodoxime (10 mg/kg/day orally twice daily)	Non-type 1 allergy
Levofloxacin	Levaquin®	10-20 mg/kg/day orally every 12-24 hours	Type 1 allergy
Risk for Antibiotic Resistance or Failed Initial Therapy			
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally twice daily	
Clindamycin plus cefixime or cefpodoxime	Cleocin®, Suprax®, Vantin®	Clindamycin (30-40 mg/kg/day orally three times daily) plus cefixime (8 mg/kg/day orally twice daily) or cefpodoxime (10 mg/kg/day orally twice daily)	
Levofloxacin	Levaquin®	10-20 mg/kg/day orally every 12-24 hours	
Severe Infection Requiring Hospitalization			
Ampicillin-sulbactam	Unasyn®	200-400 mg/kg/day IV every 6 hours	
Ceftriaxone	Rocephin®	50 mg/kg/day IV every 12 hours	
Cefotaxime	Claforan®	100-200 mg/kg/day IV every 6 hours	
Levofloxacin	Levaquin®	10-20 mg/kg/day IV every 12-24 hours	

Data from reference 21.

TABLE 108-3 Antibiotics and Doses for Acute Bacterial Rhinosinusitis in Adults

Antibiotic	Brand Name	Dose	Comments
Initial Empirical Therapy			
Amoxicillin-clavulanate	Augmentin®	500 mg/125 mg orally three times daily, or 875 mg/125 mg orally twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	2,000 mg/125 mg orally twice daily	Second-line
Doxycycline		100 mg orally twice daily or 200 mg orally once daily	Second-line
***β*-Lactam Allergy**			
Doxycycline		100 mg orally twice daily or 200 mg orally once daily	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Risk for Antibiotic Resistance or Failed Initial Therapy			

Antibiotic	Brand Name	Dose	Comments
Amoxicillin-clavulanate	Augmentin®	2,000 mg/125 mg orally twice daily	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Severe Infection Requiring Hospitalization			
Ampicillin-sulbactam	Unasyn®	1.5-3 g IV every 6 hours	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Ceftriaxone	Rocephin®	1-2 g IV every 12-24 hours	
Cefotaxime	Claforan®	2 g IV every 4-6 hours	

Data from reference 21.

High-dose amoxicillin-clavulanate is recommended as second-line for initial empirical therapy in children and adults; doxycycline is also second-line for adults but should be avoided in children.[21] High-dose amoxicillin-clavulanate is preferred in the following situations: (a) geographic regions with high endemic rates (10% or greater) of invasive penicillin-nonsusceptible *S. pneumoniae*, (b) severe infection, (c) attendance at daycare, (d) age less than 2 or greater than 65 years, (e) recent hospitalization, (f) antibiotic use within the last month, and (g) immunocompromised persons.[21] Severe infections are those with "evidence of systemic toxicity with fever of 39°C (102.2°F) or higher, and threat of suppurative complications."[21]

Clinical Controversy…

The IDSA guidelines support the use of intranasal corticosteroids for patients with acute bacterial rhinosinusitis, especially those who also have a history of allergic rhinitis; however, the guidelines are silent regarding the use of oral corticosteroids.[21] A Cochrane systematic review identified four randomized controlled trials with a total of 1,008 adult participants with acute bacterial rhinosinusitis.[29] All participants received oral antibiotics and either oral corticosteroids (prednisone 24-80 mg daily or betamethasone 1 mg daily) or a control treatment (placebo in three trials, nonsteroidal antiinflammatory drugs in one trial). All four trials observed faster resolution or improvement in symptoms among the patients who received oral corticosteroids. These studies did not report any information regarding the long-term effects of oral corticosteroids, such as relapse and recurrence of acute bacterial rhinosinusitis. This systematic review supports the use of oral corticosteroids as adjuvant therapy to antibiotics for the treatment of acute bacterial rhinosinusitis.

If a child has a β-lactam allergy, he/she may receive levofloxacin monotherapy or clindamycin plus cefixime or cefpodoxime combination therapy.[21] Adults may receive doxycycline, levofloxacin, or moxifloxacin monotherapy.[21] The guidelines also provide several options for patients at risk for

antibiotic resistance, who failed initial therapy, or who have a severe infection requiring hospitalization (Tables 108-2 and 108-3).[21] Notably, cephalosporins are no longer recommended as monotherapy due to variable rates of resistance against *S. pneumoniae*.[21] Macrolides are no longer recommended because of high rates of *S. pneumoniae* resistance.[21] Trimethoprim-sulfamethoxazole has not been recommended for some time due to resistance among *S. pneumoniae* and *H. influenzae*.[21]

The duration of therapy for the treatment of acute bacterial rhinosinusitis is not well established. Most trials have used 10- to 14-day antibiotic courses for uncomplicated rhinosinusitis, and the guidelines support this treatment duration in children.[21] For adults, the recommended duration is only 5 to 7 days.[21]

Personalized Pharmacotherapy

There is limited evidence to suggest that people with certain genetic polymorphisms may be at greater risk for chronic rhinosinusitis[30]; however, no such link has been identified for acute bacterial rhinosinusitis. Furthermore, patient genetics are not currently used to guide selection of antibiotic therapy for this condition. It is important to consider patient weight and renal function when selecting antibiotic therapy for acute bacterial rhinosinusitis. Notice that all of the antibiotics recommended for children are dosed according to patient weight. Furthermore, most of the recommended antibiotics are excreted through the kidneys and should be adjusted for renal function as described in the package labeling.

Evaluation of Therapeutic Outcomes

If symptoms persist or worsen after 48 to 72 hours of appropriate antibiotic therapy, then the patient should be reevaluated and alternative antibiotics should be considered.[21] Patients who do not respond to first- or second-line therapies should be referred to a specialist and worked up more aggressively, potentially with direct sinus aspiration or contrast-enhanced computed tomography.[21]

ACUTE PHARYNGITIS

1 2 Pharyngitis is an acute infection of the oropharynx or nasopharynx.[31] It is responsible for 1% to 2% of all outpatient visits.[32] Although viral causes are most common, group A β-hemolytic *Streptococcus* (GABHS; also known as *S. pyogenes*), is the primary bacterial cause;[31] pharyngitis due to GABHS is commonly known as “strep throat.”

Clinical practice guidelines for GABHS were published in 2012.[31] Several of the recommendations in these guidelines differ substantially from prior guidelines.

Epidemiology

Acute pharyngitis accounts for approximately 2 million emergency department and outpatient

department visits/y,[2] at a cost of up to $539 million for children alone.[31] Although viral causes are most common, GABHS is the primary bacterial cause and is associated with rare but severe sequelae if not treated appropriately.[31] Suppurative and nonsuppurative complications include acute rheumatic fever, acute glomerulonephritis, reactive arthritis, peritonsillar abscess, retropharyngeal abscess, cervical lymphadenitis, mastoiditis, otitis media, rhinosinusitis, and necrotizing fasciitis.

Although all age groups are susceptible, epidemiologic data demonstrate certain groups are at higher risk. Children 5 to 15 years of age are most susceptible; parents of school-age children and those who work with children are also at increased risk. Pharyngitis in a child younger than 3 years of age is rarely caused by GABHS.[31]

Seasonal outbreaks occur, and the incidence of GABHS is highest in winter and early spring.[31] The incubation period is 2 to 5 days, and the illness often occurs in clusters.[31] Spread occurs via direct contact (usually from hands) with droplets of saliva or nasal secretions, and transmission is thus worse in institutions, schools, families, and crowded areas.[31] Untreated, patients with streptococcal pharyngitis are infectious during the acute illness and for another week thereafter. Effective antibiotic therapy reduces the infectious period to about 24 hours.

Acute rheumatic fever is rarely seen in developed countries. In the United States, acute rheumatic fever secondary to GABHS infection was a cause of concern in the 1950s and was the major reason for penicillin therapy, but the annual incidence of this disease today is extremely rare (1 case or more per 1 million population); however, some risk does remain. Outbreaks have been reported in the United States as recently as the late 1980s and early 1990s. Furthermore, acute rheumatic fever is widespread in developing countries.

Etiology

1 Viruses cause the majority of acute pharyngitis cases. Specific etiologies include rhinovirus (20%), coronavirus (5%), adenovirus (5%), herpes simplex virus (4%), influenza virus (2%), parainfluenza virus (2%), and Epstein–Barr virus (1%).[31,32]

4 A bacterial etiology is far less likely. Of all the bacterial causes, GABHS is the most common (10%-30% of persons of all ages with pharyngitis) and is the only commonly occurring form of acute pharyngitis for which antibiotic therapy is indicated.[31] In the pediatric population, GABHS causes 15% to 30% of pharyngitis cases. In adults, GABHS is responsible for 5% to 15% of all symptomatic episodes of pharyngitis.[31]

Other, less common causes of acute pharyngitis, are groups C and G *Streptococcus*, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Mycoplasma pneumoniae*, *Arcanobacterium haemolyticum*, *Yersinia enterocolitica*, and *Chlamydia pneumoniae*.[31] Treatment options for these organisms are not addressed in this chapter.

Pathophysiology

The mechanism by which GABHS causes pharyngitis is not well defined. Asymptomatic pharyngeal carriers of the organism may have an alteration in host immunity (eg, a breach in the pharyngeal mucosa) and the bacteria of the oropharynx may migrate to cause an infection. Pathogenic factors associated with the organism itself may also play a role. These include pyrogenic toxins, hemolysins, streptokinase, and proteinase.

Clinical Presentation

Sore throat is the most common symptom of pharyngitis. Accurate differentiation of GABHS from pharyngitis caused by other agents is important for treatment decisions; however, this can be difficult even for experienced clinicians. Therefore, microbiologic testing is recommended for symptomatic patients unless they have symptoms suggestive of viral etiology or are younger than 3 years of age.[31]

In previous guidelines, clinical scoring systems, such as the Centor criteria or modifications of the Centor criteria, have been advocated for clinical diagnosis in adults as a way to overcome the lack of sensitivity and specificity of clinician judgment and to avoid laboratory testing of all patients; however, guidelines from Infectious Disease Society of America and the American Heart Association suggest testing be done in all patients with signs and symptoms of streptococcal pharyngitis.[31] Only those with a positive test for GABHS require antibiotic treatment.[31,33] Laboratory tests should not be performed unless the patient has symptoms consistent with GABHS pharyngitis. This is because a positive test does not necessarily indicate disease. A positive test may simply indicate that the patient is a carrier for GABHS and is not actively infected.

Approximately 20% of children are carriers; the prevalence is lower among adults.[31] There are several options to test for GABHS. A throat swab can be sent for culture or used for the RADT. Cultures are the gold standard, but they require 24 to 48 hours for results. The RADT is more practical in that it provides results quickly, it can be performed at the bedside, and it is less expensive than culture. If RADT is positive, it does not require a follow-up throat culture.[31] If RADT yields negative test results, it is generally recommended to follow up with a throat culture to confirm the results for children and adolescents, but not necessary in adults.[31] Delaying therapy while awaiting culture results does not affect the risk of complications (although some argue that symptomatic benefit is postponed, and contagion remains), and patients must be educated as to the value of waiting, given the low false-negative rate of RADT.[33]

TREATMENT

Desired Outcomes

The goals of treatment for pharyngitis are to improve clinical signs and symptoms, minimize adverse drug reactions, prevent transmission to close contacts, and prevent acute rheumatic fever and suppurative complications, such as peritonsillar abscess, cervical lymphadenitis, and mastoiditis.[31]

General Approach to Treatment

Once the diagnosis of GABHS pharyngitis has been made, the clinician must decide appropriate supportive care, when to initiate antibiotic therapy, the appropriate antibiotic, and the duration of therapy. The selection of appropriate antibiotic therapy will involve careful consideration of cost, safety, efficacy, potential for regimen adherence, and bacterial resistance rates. Clinicians should be aware of local resistance patterns, which may differ from the national patterns.

4 Antibiotic overuse has been well documented.[31,32] Antibiotics are prescribed for 60% of patients who visit their provider with a complaint of "sore throat."[34,35] This rate is well above the incidence of GABHS pharyngitis. Antibiotic therapy should be reserved for those patients with clinical and epidemiologic features of GABHS pharyngitis, preferably with a positive laboratory test. Empirical therapy is not recommended unless there is a high index of suspicion based on clinical or epidemiologic data and laboratory results are pending. However, it is important to discontinue empirical antibiotics if laboratory results are negative.

Nonpharmacologic Therapy

Supportive care should be offered to all patients with acute pharyngitis. Little evidence is available for nonpharmacologic therapy for pharyngitis. However, pharmacologic supportive care interventions include antipyretic medications, analgesics, and nonprescription lozenges and sprays containing menthol and topical anesthetics for temporary relief of pain.[31] There are limited data for use of corticosteroids to reduce the symptoms of GABHS pharyngitis, and given the risk of adverse effects, their use is not recommended.[31] Because pain is often the primary reason for visiting a physician, emphasis on analgesics such as acetaminophen and nonsteroidal antiinflammatory drugs to aid in pain relief is strongly recommended.

Pharmacologic Therapy

The clinical practice guidelines published by the IDSA in 2012 are the primary source for many of the recommendations in this chapter.[31] **Tables 108-4** and **108-5** outline dosing for acute GABHS pharyngitis and chronic carriers of GABHS.

TABLE 108-4 Antibiotics and Doses for Group A β-Hemolytic Streptococcal Pharyngitis

Antibiotic	Brand Name	Dose	Duration	Rating
Preferred Antibiotics				
Penicillin V	Pen-V®	Children: 250 mg twice daily or three times daily orally Adult: 250 mg four times daily or 500 mg twice daily orally	10 days	IB
Penicillin G benzathine	Bicillin L-A®	< 27 kg: 0.6 million units; 27 kg or greater: 1.2 million units intramuscularly	One dose	IB

Antibiotic	Brand Name	Dose	Duration	Rating
Amoxicillin[a]	Amoxil®	50 mg/kg once daily (maximum 1,000 mg); 25 mg/kg (maximum 500 mg) twice daily	10 days	IB
Penicillin Allergy				
Cephalexin	Keflex®	20 mg/kg/dose orally twice daily (maximum 500 mg/dose)	10 days	IB
Cefadroxil	Duricef®	30 mg/kg orally once daily (maximum 1 g)	10 days	IB
Clindamycin	Cleocin®	7 mg/kg/dose orally thrice daily (maximum 300 mg/dose)	10 days	IIaB
Azithromycin[b]	Zithromax®	12 mg/kg orally once daily (maximum 500 mg) for one day, then 6mg/kg orally once daily (maximum 250 mg) for four days	5 days	IIaB
Clarithromycin[b]	Biaxin®	15 mg/kg orally per day divided in two doses (maximum 250 mg twice daily)	10 days	IIaB

These guidelines provide a systematic weighting of the strength of the recommendation (Class I, conditions for which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective; Class II, conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment; Class IIa, weight of evidence/opinion is in favor of usefulness/efficacy; Class IIb, usefulness/efficacy is less well established by evidence/opinion; Class III, conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful) and quality of evidence (A, data derived from multiple randomized clinical trials or meta-analyses; B, data derived from a single randomized trial or nonrandomized studies; C, only consensus opinion of experts, cases studies, or standard of care).

[a]Standard formulation, not extended release.

[b]Resistance of group A β-hemolytic *Streptococcus* (GABHS) to these agents may vary and local susceptibilities should be considered with these agents.

Data from reference 31.

TABLE 108-5 Antibiotics and Doses for Eradication of Group A *β*-Hemolytic Streptococcal Pharyngitis in Chronic Carriers

Antibiotic	Brand Name	Dose
Clindamycin	Cleocin®	20-30 mg/kg/day orally in three divided doses (maximum 300 mg/dose)
Amoxicillin-clavulanate	Augmentin®	40 mg/kg/day orally in three divided doses (maximum 2,000 mg/day of amoxicillin)

Antibiotic	Brand Name	Dose
Penicillin V and rifampin	Pen-V®, Rifadin®	Penicillin V: 50 mg/kg/day orally in four doses for 10 days (maximum 2,000 mg/day); *and* rifampin: 20 mg/kg/day orally in one dose for the last 4 days of treatment (maximum 600 mg/day)
Penicillin G benzathine and rifampin	Bicillin L-A®, Rifadin®	Penicillin G benzathine: < 27 kg—0.6 million units; 27 kg or greater—1.2 million units intramuscularly; *and* rifampin: 20 mg/kg/day orally in two doses during last 4 days of treatment with penicillin (maximum 600 mg/day)

Data from reference 31.

5 For over 30 years, GABHS isolated in the United States have been susceptible to penicillin, with no reported cases of GABHS resistance to penicillin.[31] Because penicillin and amoxicillin have a narrow spectrum of activity and are readily available, safe, and inexpensive, they are considered to be the treatments of choice.[31,33] In a controlled study that demonstrated that antibiotic therapy prevents rheumatic fever following GABHS pharyngitis was done with procaine penicillin, which was later replaced with benzathine penicillin.[33] Penicillin given by other routes is assumed to be equally efficacious. The ability of other antibiotics to eradicate GABHS has led to extrapolation that these antibiotics will also prevent rheumatic fever.[33]

Amoxicillin may be preferable for children with GABHS pharyngitis because the suspension is more palatable than penicillin.[31] Gastrointestinal (GI) adverse effects and rash are more common with amoxicillin. A once-daily, extended-release formulation of amoxicillin has been approved for treatment of GABHS pharyngitis in adults and children aged 12 years and older.[31]

If patients are unable to take oral medications, intramuscular benzathine penicillin can be given, although it is painful.[31] In penicillin-allergic patients, azithromycin, clarithromycin, clindamycin, or a first-generation cephalosporin such as cephalexin can be used if the reaction is non–immunoglobulin E (IgE)-mediated.[31,33] Newer macrolides, such as azithromycin and clarithromycin, are equally effective as erythromycin and cause fewer GI adverse effects; therefore, these newer macrolides are preferred to erythromycin. GABHS resistance to macrolides is low (5%-8%) in the United States, but is higher in some other areas of the world.[31]

In previous pharyngitis guidelines, clindamycin was only an alternative to erythromycin-resistant strains; however, it is now considered an acceptable alternative for penicillin-allergic patients due to the low GABHS resistance rate of 1%.[31,33] Tonsillectomy is not recommended because a Cochrane review found that its impact on "sore throat" due to pharyngitis is unpredictable.[36]

GABHS resistance rates to tetracyclines are high. Sulfonamides and trimethoprim-sulfamethoxazole have poor eradication rates for GABHS; therefore, use of these antibiotics is no longer recommended.[31] Fluoroquinolones are not recommended due to poor activity of the older agents. The newer fluoroquinolones have activity against GABHS, but are expensive and have a broad spectrum of activity.[31,33]

CLINICAL PRESENTATION Group A Streptococcal Pharyngitis General

- A sore throat of sudden onset that is mostly self-limited
- Fever and constitutional symptoms resolving in about 3 to 5 days
- Clinical signs and symptoms are similar for viral causes and nonstreptococcal bacterial causes

Signs and Symptoms of GABHS Pharyngitis

- Sore throat
- Pain on swallowing
- Fever
- Headache, nausea, vomiting, and abdominal pain (especially in children)
- Erythema/inflammation of the tonsils and pharynx with or without patchy exudates
- Enlarged, tender lymph nodes
- Red swollen uvula, petechiae on the soft palate, and a scarlatiniform rash

Signs Suggestive of Viral Origin for Pharyngitis

- Conjunctivitis
- Coryza
- Cough

Laboratory Tests

- Throat swab and culture
- Rapid antigen-detection test (RADT)

Data from reference 31.

The ideal time to start antibiotics has not been established. The immediate start of antibiotics does not affect the risk of developing rheumatic fever, and no evidence suggests that it reduces recurrent infection.[33] Clinical guidelines recommend withholding antibiotics unless the patient has a positive laboratory result.[31,33]

The impact of appropriate antibiotic therapy is limited to decreasing the duration of signs and symptoms. It can decrease the severity of pharyngitis symptoms and communicability of the disease after 24 hours of antibiotic therapy.[37] The duration of therapy for GABHS pharyngitis is 10 days, except for benzathine penicillin and azithromycin, to maximize bacterial eradication.[31] A Cochrane

review, published in 2012, examined short course therapy and concluded that 3 to 6 days of oral antibiotics had comparable efficacy to oral penicillin for 10 days.[38] Although some clinicians have proposed shorter courses of treatment for pharyngitis, confounding factors from these studies, such as the lack of strict entry criteria or differentiation between new and failed infections, limit the widespread application of short antibiotic courses at this time.[31]

Approximately 33% of household contacts of a person with acute GABHS pharyngitis harbor GABHS in their upper respiratory tracts.[31] Routine testing and/or treating of asymptomatic household contacts of an index patient is not recommended.[31] GABHS carriers do not need antimicrobial therapy due to very low risk of spreading GABHS pharyngitis or developing suppurative or nonsuppurative complications.[31] If tested, it is not necessary to treat these asymptomatic carriers. It is difficult to ascertain the cause of symptomatic pharyngitis in carriers of GABHS if they do develop symptoms. Providers should pay close attention to the symptoms to help differentiate viral versus bacteriologic cause of pharyngitis because laboratory tests will be positive in these patients.[31]

Clinical Controversy…

The ISDA pharyngitis guidelines recommend a 10-day course of appropriate antibiotics to achieve maximal rates of pharyngeal eradication of GABHS.[31] However, there has been increased interest in shorter courses of treatment to help improve adherence. Three antibiotics have been approved for 5-day course of therapy for GABHS pharyngitis, but these agents are not recommended as first-line therapy. The clinical trials for shorter course of antibiotic therapy tend to have less strict entry criteria, no assessment of adherence to therapy, and do not report details of outcomes, such as treatment failure or new infection. A Cochrane Review showed comparable efficacy for 3- to 6-day courses of therapy as compared to a 10-day course of oral penicillin.[38] The feasibility of shorter course therapy becoming a first-line recommendation needs to be determined in additional studies.

When acute GABHS pharyngitis occurs in a carrier, a treatment course of appropriate antibiotics is recommended.[31,33] In the treatment of recurring episodes of culture-positive GABHS pharyngitis, there are limited data to support a particular antibiotic regimen. Several alternative antibiotics are preferred over penicillin or amoxicillin with GABHS carriers and recurrent pharyngitis. Amoxicillin-clavulanate, clindamycin, penicillin/rifampin combination, and benzathine penicillin G/rifampin combination may be considered for recurrent episodes of pharyngitis to maximize bacterial eradication in potential carriers and to counter copathogens that produce β-lactamases.[31] Table 108-5 outlines dosing for eradication of GABHS in chronic carriers and those who experience symptomatic episodes.

Patients with documented histories of rheumatic fever (including cases manifested solely by Sydenham's chorea) and those with definite evidence of rheumatic heart disease should receive continuous prophylaxis initiated as soon as the patient is diagnosed and the initial infection has been treated. The duration of secondary prophylaxis is individualized based on patient risk of recurrence of rheumatic fever and/or rheumatic heart disease. Intramuscular benzathine penicillin G every 4 weeks is the recommended regimen for secondary prevention in the United States in most circumstances.[33] Additional options for secondary prophylaxis include oral penicillin V and sulfadiazine. Medication

adherence is critical for successful secondary prevention with oral antibiotics. Sulfadiazine is an effective antibiotic for the prevention of infection and is appropriate if the patient is penicillin-allergic. Sulfonamides are not appropriate for treatment of GABHS pharyngitis because they are not effective for eradication of GABHS. If individuals are allergic to penicillin and sulfadiazine, a macrolide or azalide is recommended; however, this recommendation is based on expert opinion rather than clinical trial data.[33]

Personalized Pharmacotherapy

Currently, there are no pharmacogenetic or genomic factors involved in the diagnosis or treatment of GABHS pharyngitis. Factors that should be considered when personalizing therapy for a patient include allergy status, prior antibiotic use, and adherence. Those with a history of antibiotic use for acne may be at higher risk for resistant strains of GABHS. Short-course antibiotics or penicillin G benzathine may be considered in patients with a history of nonadherence.

Evaluation of Therapeutic Outcomes

Most pharyngitis cases are self-limited; however, antibiotics hasten resolution when given early for proven cases of GABHS pharyngitis.[31] Generally, fever and other symptoms resolve within 3 to 4 days of onset without antibiotics; however, symptoms will improve 0.5 to 2.5 days earlier with antibiotic therapy.[31] Follow-up testing is generally not necessary for index cases or asymptomatic contacts;[31] however, throat cultures 2 to 7 days after completion of antibiotics are warranted for patients who remain symptomatic or when symptoms recur despite completion of treatment.[33]

Chapter 109: Influenza

Jessica C. Njoku

INTRODUCTION

KEY CONCEPTS

- 1 Influenza is a viral illness associated with high mortality and high hospitalization rates among persons older than 65 years of age. The aging of the population is contributing to an increased disease burden in the United States.
- 2 Seasonal influenza epidemics are the result of viral antigenic drift, which is why the influenza vaccine is changed on an yearly basis. Antigenic drift forms the foundation of the recommendation for annual influenza vaccination.
- 3 The acquisition of a new hemagglutinin and/or neuraminidase by the influenza virus is called *antigenic shift*, which results in a novel influenza virus that has the potential to cause a pandemic.
- 4 The primary route of influenza transmission is person-to-person via inhalation of respiratory droplets, and transmission can occur for as long as the infected person is shedding virus from the respiratory tract.
- 5 Clinical diagnosis of influenza is difficult. Classic signs and symptoms include abrupt onset of fever, muscle pain, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms usually resolve within 1 week of presentation.
- 6 In the United States, the primary mechanism of influenza prevention is annual vaccination. Vaccination not only prevents influenza illness and influenza-related hospitalizations and deaths but may also decrease healthcare resource use and the overall cost to society.
- 7 The inactivated influenza vaccine (IIV) and the live-attenuated influenza vaccine (LAIV) are commercially available for prevention of seasonal influenza. Both vaccines contain influenza A subtypes H3N2 and H1N1, and influenza B virus, which are initially grown in hens' eggs.

- 8 Antiviral drugs for prophylaxis of influenza should be considered adjuncts to vaccine and are not replacements for annual vaccination.
- 9 The sooner antiviral drugs are started after the onset of illness, within 48 hours of symptom onset, the more effective they are.
- 10 Oseltamivir, zanamivir, and peramivir are neuraminidase inhibitors that have activity against both influenza A and influenza B viruses. Although the adamantanes inherently have activity against influenza A H1N1 viruses, they are no longer used clinically due to overwhelming viral resistance.

Influenza causes significant morbidity and mortality, particularly among young children and the elderly. Seasonal influenza epidemics result in 25 to 50 million influenza cases, approximately 200,000 hospitalizations, and more than 30,000 deaths each year in the United States.[1] Globally, influenza causes nearly 500,000 deaths each year. More people die of influenza than of any other vaccine-preventable illness. Significant societal consequences associated with influenza include visits to physicians' offices and emergency departments and days lost from school and/or work. The societal costs associated with influenza are more than $40 billion in the United States[1] and $16 billion in those older than or equal to 50 years alone.[2]

Vaccination is the primary mechanism of influenza prevention in the United States. The antiviral armamentarium for treatment and prophylaxis of influenza is limited, which further emphasizes the importance of prevention with vaccination and appropriate use of infection control measures during outbreaks. Research toward the development of novel antivirals and vaccines is needed for effective control of seasonal epidemics and for pandemic preparedness.

ETIOLOGY AND EPIDEMIOLOGY

Influenza infection can occur at any time during the year with the highest rates of influenza-associated illness during the winter months. The highest rate of infection occurs in children, but the highest rates of severe illness, hospitalization, and death occur among those older than age 65 years, young children (younger than 2 years old), and those who have underlying medical conditions, including pregnancy and cardiopulmonary disorders, that increase their risk of complications from influenza. 1 The seasonal influenza epidemics from 2012 to 2015 resulted in an average annual laboratory confirmed influenza-associated hospitalization rate of 48.1 per 100,000 person-years.[3] In 2012 to 2013 influenza season alone, the rate of influenza associated hospitalization was 202 (95% confidence interval, 143-260) per 100,000 person-years.[4] Influenza-associated hospitalization rates were four times higher among children aged 0 to 4 years compared with among those aged 5 to 17 years.[3] Similarly, influenza-associated hospitalization rates were 17 times higher, and 6 times higher, among persons older than or equal to 65 years compared with among those aged 18 to 49 years, and 50 to 64 years, respectively.[3] During the 2009 pandemic influenza H1N1pdm09 outbreak, an estimated 137,414 hospital discharges were attributed to influenza.[5] Influenza-related deaths is three times higher in high-risk individuals. From 1997 to 2009, influenza A/H3N2 accounted for 71% of

influenza-related mortality, while influenza B was attributed with the most deaths (51%-95%).[7] Approximately 90% of seasonal influenza-related deaths occur in those older than age 65 years, with about 70% of deaths occuring among those older than or equal to 75 years.[6] In 2012 to 2013 influenza season, the rate of influenza associated death was 54.6 (95% confidence interval, 36.2-73.0) per 100,000 person-years among those age 65 years or older, compared to a rate of 1.1, less than18 years or 1.7, 18 to 64 years old.[4] Thus, the aging of the population is contributing to an increased disease burden. Deaths associated with influenza often result from secondary bacterial pneumonia, primary viral pneumonia, and/or exacerbation of underlying comorbidities.[7]

Influenza Viruses A, B, and C

Influenza virus types A, B, and C are members of the Orthomyxoviridae family and affect many species, including humans, pigs, horses, and birds. Influenza A and B viruses are the two types that cause disease in humans. Influenza A viruses are responsible for the regular, seasonal epidemics of the flu, whereas influenza B viruses are typically associated with sporadic outbreaks, particularly among residents of long-term care facilities. Influenza A viruses are further categorized into different subtypes based on changes in two surface antigens—hemagglutinin and neuraminidase (NA). Influenza B viruses are not categorized into subtypes.

Hemagglutinin allows the influenza virus to enter host cells by attaching to sialic acid receptors and is the major antigen to which antibodies are directed on exposure.[8] NA allows the release of new viral particles from host cells by catalyzing the cleavage of linkages to sialic acid.[8]

Sixteen hemagglutinin subtypes (H1-H16) and nine NA subtypes (N1-N9) of influenza A have been isolated from birds. However, the only influenza A subtypes that have circulated among humans since the 1918 pandemic (see Antigenic Drift and Antigenic Shift in the following sections) are H1 to H3 and N1 and N2.[8] The primary subtypes of influenza A that have been circulating among humans for the past three decades are H3N2 and H1N1.

Antigenic Drift and Antigenic Shift

2 Immunity to influenza virus occurs as a result of the development of antibody directed at the surface antigens, particularly hemagglutinin. However, immunity to one influenza subtype does not offer protection against other subtypes or types of influenza. Moreover, immunity to one antigenic variant of a subtype of influenza may not confer protection against other antigenic variants. Antigenic variants are created by point mutations in the surface antigens of a particular subtype, resulting in small changes in the hemagglutinin and/or NA molecules, which is called *antigenic drift*. Antigenic drift is the basis for seasonal epidemics of influenza, the reason for changes in the annual influenza vaccine, and the rationale behind the recommendation for annual vaccination.

Immunity to one subtype of influenza does not confer protection against other subtypes or types. 3 Antigenic shift occurs when the influenza virus acquires a new hemagglutinin and/or NA via genetic reassortment rather than point mutations.[4] Most likely, the genetic reassortment occurs when an

animal that supports the growth of multiple subtypes of influenza, such as a pig, is concurrently infected with two subtypes of the influenza virus. Conversely, antigenic shift may occur directly from avian strains that have gained competency in the human host. Antigenic shift results in the emergence of a novel influenza virus and carries the potential of causing a pandemic. However, novelty alone is insufficient to cause an influenza pandemic; the virus must be able to replicate in humans, spread person-to-person, and affect a susceptible population.[8]

Spanish Influenza of 1918

The influenza pandemic of 1918 was the most significant infectious disease outbreak known to humans, causing approximately 40 to 50 million deaths in a year, with more than 500,000 deaths occurring in the United States.[9,10] The pandemic occurred almost concurrently in Europe, Asia, and North America.[9]

The 1918 pandemic was caused by a particularly virulent influenza A H1N1 virus, which was entirely of avian origin.[10,11] In contrast to the other pandemics of the 20th century, the 1918 pandemic resulted in an unusual mortality pattern. The mortality peaked for those younger than 4 years of age, those between the ages of 25 and 35 years, and those older than 65 years of age, which resulted in a W-shaped mortality curve, as opposed to the U- or J-shaped curve typically associated with influenza.[10,12] Over half of the deaths occurred in persons aged 20 to 40 years. The death toll associated with this pandemic culminated in an almost 10-year drop in the life expectancy of the population at the time.[10]

Asian Influenza of 1957

The Asian flu pandemic began when a new H2 subtype of influenza A surfaced in Hunan province in China in 1957.[10] The virus appeared to have formed from coinfection with an avian H2N2 virus and a human H1N1 virus in a common host, possibly a pig or a human.[11] The H2N2 virus quickly spread to Japan, South America, the United States, New Zealand, and Europe, resulting in approximately 4 million deaths worldwide, with 70,000 deaths occurring in the United States.[10] Unlike the Spanish flu of 1918, the mortality curve for the Asian flu pandemic was U- or J-shaped, with infants and elderly being most affected.[12]

Hong Kong Influenza of 1968

The H2N2 virus of the Asian flu circulated in the human population until 1968, when a new H3 subtype emerged in China and Hong Kong[12] following genetic reassortment with the H2N2 virus.[10,11] The H3N2 virus quickly spread to the United States and later to Europe. This pandemic caused more than 30,000 deaths in the United States and approximately 2 million deaths worldwide.[10,12] The lower morbidity and mortality associated with the Hong Kong flu may be explained by previous exposure of the population to the N2 subtype, and the availability of antibiotics for the management of secondary bacterial pneumonia. Similar to the Asian flu of 1957, the mortality curve for the Hong Kong flu pandemic was U- or J-shaped, primarily affecting infants

and elderly.[12]

Avian Influenza

Influenza viruses are in circulation in southern China during all months of the year.[4] Given this fact and the close proximity of dense populations of people, pigs, and wild and domestic birds, this area proves ideal for the development of new influenza viruses via genetic reassortment (antigenic shift), as demonstrated by the pandemics of 1957 and 1968 and, most recently, the emergence of what is known as avian influenza.[8]

The first report of human infection with the avian H5N1 virus occurred in 1997 in Hong Kong in a 3-year-old who had a direct link with chickens and later died.[13] This was followed by 18 confirmed cases and 6 deaths.[14] The virus reemerged in 2003 as an antigenically and genetically different virus that has spread widely through wild and domestic bird populations in Asia, Africa, and Europe as well as infecting humans in 16 countries: Azerbaijan, Bangladesh, Cambodia, Canada, China, Djibouti, Egypt, Indonesia, Iraq, Lao People's Democratic Republic, Myanmar, Nigeria, Pakistan, Thailand, Turkey, and Vietnam.[12,15] From 2003 to September 10, 2015, a total of 844 cases and 449 deaths caused by H5N1 infection have been reported.[15,16] The current overall case fatality is 53%.

The novel avian influenza H7N9 virus infection was first reported in humans in March 2013, in China.[17] Since the outbreak, only one case of influenza H7N9 has been reported outside of China, and this occurred in Canada in February 2015. Avian influenza A(H7N9) is a subtype of influenza viruses that have been detected in birds in the past, but no previous infection had been documented in animals or people until recently. Other emerging avian H7 virus subtypes with documented infections in humans are H7N3 in Canada, 2004; H7N2 in New York, 2003, and H7N7 in Netherlands, 2003.[18] Majority of avian H7N9 human infection cases have been among those with recent exposure to live poultry or potentially contaminated environments, especially markets where live birds are sold.[17,18] Presently, the virus does not appear to transmit easily from person to person, and sustained human-to-human transmission has not been reported. Nevertheless, the disease is of concern because patients become severely ill. As of July 16, 2015, a total of 677 cases and 275 deaths caused by H7N9 virus infection have been reported.[16,17] The current overall case fatality is 41%.

In May 2013, the first case of novel avian influenza H6N1 human infection, was reported in Taiwan,[18] and since May 2014, four laboratory-confirmed human case of avian influenza A(H5N6) virus infection were reported to World Health Organization (WHO) from China.[16] To date no evidence of human-to-human transmission of the viruses has been documented. Other influenza A(H5) subtypes, such as influenza A(H5N2), A(H5N3), and A(H5N8), continue to be detected in birds in West Africa, Asia, Europe, and North America.[16] Although influenza A(H5N2), A(H5N3), and A(H5N8) viruses might have the potential to cause disease in humans, so far no human cases of infection have been reported.[16] Other novel avian influenza strains emerging in 1999 (H9N2), with two cases of human infections, and in 2013 (H10N8), with three cases of infections, all in China, continue to be of concern.[18]

The spread of avian influenza viruses from person to person has been reported very rarely, and has been limited, inefficient, and unsustained.[18,19] The precise mode of transmission is unknown, but most cases have occurred as a result of contact with poultry, contaminated environment, and prolonged person-to-person contact.[15,16,17,18] Cases of transmission via aerosolization have not been reported.[20] Clinical presentation includes high fever and influenza-like illness, and watery diarrhea without blood may occur up to 1 week prior to respiratory symptoms.[21] Almost all patients have clinically apparent pneumonia. Progression to death, most commonly as a consequence of respiratory failure, occurs a mean of 9 to 10 days after the onset of illness.[15,16,17,20] The NA inhibitors, oseltamivir, zanamivir, and peramivir, have activity against the avian influenza viruses, although higher doses may be needed. Oseltamivir resistance has been detected in several patients infected with the H5N1 virus who were treated with oseltamivir.[20] Amantadine and rimantadine are ineffective against avian influenza viruses. An inactivated monovalent[22] and an adjuvanted monovalent[23] influenza virus vaccine, against H5N1 is available for vaccination of persons 18 to 64 years of age at increased risk of exposure to the H5N1 influenza virus. The recommended dose is two 1-mL injections given intramuscularly 28 days apart (range, 21 to -35 days) if non-adjuvanted vaccine,[22] or two 0.5-mL injections given 21 days apart if adjuvanted vaccine is used.[23] The vaccines are supplied in a 5-mL multi-dose vial, with ~50 mcg thimerosal per dose in the non-adjuvanted vaccine[22], and 5 mcg thimerosal per dose in the adjuvanted vaccine[23], added as a preservative. The monovalent adjuvanted vaccine is supplied in two separate vials, a vial of H5N1 antigen and a vial of AS03 adjuvant, that must be combined before use, for the final volume per vial that provides 10 doses at 0.5 ml per dose.[23] At the present time, the vaccines are being stockpiled for use if H5N1 begins transmitting easily from person to person. Individuals at high risk, for example, those who work with poultry and H5N1 poultry outbreak responders, are encouraged to receive annual seasonal influenza vaccine to minimize the risk of coinfection with human and avian influenza A viruses.

The potential for avian viruses H5N1 and H7N9 to cause a pandemic is of concern as it could spread more quickly than pandemics of the past because of the mobility of people in today's world. International travel has increased 73% since 1990, with 763 million people crossing international borders in 2004.[21] In 2012 alone, international tourist travels worldwide was projected at 1 billion, which was a 48% increase since 2000.[24] In 2009, the US residents made over 61 million travels outside the country, which was a 5% increase since 1999.[24] A severe pandemic, like that of 1918, could cause more than 9 million hospitalizations and more than 1.9 million deaths, whereas a moderate pandemic, like those of 1957 and 1968, could result in more than 800,000 hospitalizations and more than 200,000 deaths in the United States alone.[12,24]

Swine Influenza of 2009

An outbreak of a novel influenza A H1N1 (formerly swine origin influenza virus [SOIV]) was initially detected in Mexico in March 2009 and subsequently in the United States in April 2009 in California and Texas.[25,26] The virus then spread throughout North America, Europe, Asia, and subsequently worldwide, prompting the WHO on June 11, 2009 to declare phase 6, indicating widespread human infection, for the influenza pandemic.[26] Since 1998, triple reassortant swine influenza A (H1) viruses,

containing genes from swine, avian, and human lineages, have circulated among swine in the United States.[25,27]

However, the novel influenza A H1N1 virus is unique in that although much of the genome is similar to the triple reassortant swine viruses previously seen in the United States, the genes encoding for NA and matrix (M) proteins are most similar to those circulating in the Eurasian swine population. This particular genetic combination has not been seen before.[25] The virus, now formally known as influenza A(H1N1) pdm09, has since become the predominant influenza A H1N1 in circulation, effectively replacing traditional seasonal influenza A (H1N1).

Several characteristics of the novel influenza A H1N1 outbreak differ from those of a typical seasonal influenza outbreak. Symptomatology associated with the novel influenza include fever (94%), cough (92%), sore throat (66%), diarrhea (25%), and vomiting (25%).[25,26] An estimated 43 to 89 million cases of 2009 H1N1 occurred between April 2009 and April 2010 with a median 274,000 hospitalizations. Globally, 18,500 laboratory-confirmed H1N1-related deaths were reported; however, this may represent an underestimation of true disease burden.[28] The majority of the cases occurred in otherwise healthy children and young adults younger than 65 years of age including pregnant women, with the highest incidence reported among those aged 18 to 64 years.[28] Contrary to seasonal influenza where about 60% of hospitalizations and 90% of deaths occur in people older than or equal to 65 years, approximately 90% and 87% of 2009 H1N1-related hospitalizations and deaths, respectively, occurred in people younger than 65 years. However, like seasonal influenza, people with underlying health conditions had greater risk of hospitalizations and death. Among those who were deceased due to novel H1N1 infection, the median age was ~40 years and 59% of deaths (respiratory and cardiovascular) occurred in Southeast Asia and Africa.[28]

Variant Influenza A (H3N2v), 2012

H3N2v is a non-human influenza virus that normally circulates in pigs and that has infected humans.[29] In August 2011, the US Centers for Disease Control and Prevention (CDC) reported the first case of an influenza infection due to influenza A H3N2 variant virus (H3N2v).[29] Since then, 345 cases have been documented from 13 states in the United States resulting in 20 hospitalizations and 1 death.[30] Human infections with H3N2v have been limited to the United States. The H3N2v is considered a variant virus because it is different from influenza A viruses circulating among humans. Infections due to variant influenza viruses, for example, A(H1N1)v, A(H3N2)v, and A(H1N2)v of swine origin, have been documented in the past.[29] The H3N2v virus contains genes from avian, swine, and human viruses and the M gene from the 2009 H1N1 pandemic virus (A[H1N1]pdm09).[29] The virus was originally detected in pigs in 2010 but human infection was first documented in July 2011. The virus appears to spread more readily from pigs to people than other variant viruses, but has limited person-to-person transmission. The main risk factor for infection with the virus based on evaluation of available cases is exposure to pigs, mostly in fair settings.[29] Since the virus is related to human flu viruses from the 1990s, most adults have some immunity against it.[29] Hence, most cases to date have occurred in children, who have little immunity against this virus.

The symptoms and severity of H3N2v have mostly been mild and similar to those of seasonal influenza (fever, cough, sore throat, body aches, etc.), but like seasonal influenza, serious illness with H3N2v infection is possible.[29] Vaccination remains key to preventing H3N2v infection. Additionally, the CDC has encouraged people at high risk of influenza complications to stay away from swine barns at fairs.[29,30] People who are at high risk of serious complications from influenza, including H3N2v virus infection, are: children younger than 5 years, people older than or equal to 65 years, pregnant women, and people with certain chronic medical conditions (asthma, diabetes, heart disease, immunocompromised, and neurologic or neurodevelopmental conditions). The treatment of H3N2v virus infection is similar to that of seasonal influenza. NA inhibitors are the mainstay of treatment. The adamantanes should not be used due to high resistance.[29]

PATHOGENESIS

4 The route of influenza transmission is person-to-person via inhalation of respiratory droplets, which can occur when an infected person coughs or sneezes.[31] Transmission may also occur if a person touches an object contaminated with respiratory secretions and then touches his or her mucus membranes. The incubation period for influenza ranges between 1 and 7 days, with an average incubation of 2 days.[31] Transmission can occur for as long as the infected person is shedding virus from the respiratory tract. Adults are considered infectious within 1 day before until 7 days after onset of illness. Children, especially younger children, might potentially be infectious for longer periods (more than 10 days).[29,32] Viral shedding can persist for weeks to months in severely immunocompromised people.

CLINICAL PRESENTATION Diagnosis of Influenza General

- The clinical diagnosis of influenza can be difficult because the presentation is similar to a number of other respiratory illnesses. The sensitivity of clinical diagnosis ranges from 40% for children to 70% for adults and largely depends on the relative prevalence of influenza and other respiratory viruses circulating in a community.[34]
- The clinical course and outcome are affected by age, immunocompetence, viral characteristics, smoking, comorbidities, pregnancy, and the degree of preexisting immunity.
- Complications of influenza may include exacerbation of underlying comorbidities, primary viral pneumonia, secondary bacterial pneumonia or other respiratory illnesses (eg, sinusitis, bronchitis, otitis), encephalopathy, transverse myelitis, myositis, myocarditis, pericarditis, and Reye's syndrome.

Signs and Symptons

- 5 Classic signs and symptoms of influenza include rapid onset of fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis.
- Nausea, vomiting, and otitis media are also commonly reported in children.[35]

- Signs and symptoms typically resolve in approximately 3 to 7 days, although cough and malaise may persist for more than 2 weeks.
- Primary viral pneumonia, occurring predominantly in pregnant women and in those with underlying cardiovascular disease, usually begins with fever and dry cough, which changes to a productive cough of bloody sputum. This rapidly progresses to dyspnea, hypoxemia, and cyanosis with radiologic evidence of bilateral interstitial infiltrates.[34]
- Secondary bacterial pneumonia is usually seen in individuals with underlying pulmonary disorders and presents during the early stages of defervescence from the influenza infection. These patients usually present with fever, productive cough, and radiologic evidence of consolidation.[34]

Laboratory Tests

- Complete blood count and chemistry panels should be obtained to assess the overall status of the patient.
- The gold standard for diagnosis of influenza are reverse-transcription polymerase chain reaction (RT-PCR) or viral culture, which can provide information on the specific strain and subtype. Viral culture has a high sensitivity but can take as long as a week to develop, limiting the clinical relevance of the results.
- Tests such as the antigen-based rapid influenza diagnostic tests ([RIDTs], also known as point-of-care [POC] tests), direct (DFA) or indirect (IFA) fluorescence antibody tests, and the RT-PCR assay may be used for rapid detection of virus.[36]

Other Diagnostic Tests

- Cultures of potential sites of infection should be obtained if coinfection, superinfection, or secondary infection is suspected.
- Chest radiograph should be obtained if pneumonia is suspected.

Rapid Tests

- RIDTs have allowed for prompt diagnosis and initiation of antiviral therapy and decreased inappropriate use of antibiotics. RIDTs use enzyme immunoassay (EIA) technology to provide results within 1 hour of specimen collection. Appropriate specimens for collection, in decreasing order of sensitivity, are nasopharyngeal aspirates, nasopharyngeal swabs/washes, and oropharyngeal swabs.[36] RIDTs allow for differentiation of influenza viruses A and B, with sensitivity and specificity ranging from 50% to 70% and 85% to 99%, respectively.[36,37] In general, the use of RIDTs is contraindicated in those who have had symptoms for longer than 3 days, and results may be confounded following recent immunization with live-attenuated influenza vaccine (LAIV).[36]

- DFA testing requires more technical expertise and infrastructure than RIDTs. The advantages of DFA are increased sensitivity over RIDTs and simultaneous detection of other respiratory viruses, such as respiratory syncytial virus and adenovirus.[36] DFA provides results between 1 and 4 hours after specimen collection.

- RT-PCR assay is a nucleic acid amplification test and is the most sensitive, specific, and versatile diagnostic test for influenza.[36] RT-PCR is a gold standard diagnostic test and can determine the type, subtype, and strain of influenza. Results are provided within 1 to 6 hours of specimen collection.

The pathogenesis of influenza in humans is not well understood. The severity of the infection is determined by the balance between viral replication and the host immune response.[8] Severe illness is likely a result of both a lack of ability of host defense mechanisms to inhibit viral replication and an overproduction of cytokines leading to tissue damage in the host.[33]

PREVENTION

The best means to decrease the morbidity and mortality associated with influenza is to prevent infection through vaccination.[31,32] Appropriate infection control measures, such as hand hygiene, basic respiratory etiquette (eg, cover your cough, throw tissues away), and contact avoidance, are also important in preventing the spread of influenza. Additionally, chemoprophylaxis is useful in certain situations.

Vaccination

6 The primary means of influenza prevention used in the United States is annual vaccination. Vaccination can help prevent hospitalization and death among those at high risk, decrease influenza-like illness, decrease visits to physicians' offices and emergency rooms, decrease otitis media in children, and prevent school and/or work absenteeism. Annual vaccination is recommended for all persons aged 6 months or older and caregivers (eg, parents, teachers, babysitters, nannies) of children younger than 6 months. Vaccination is also recommended for those who live with and/or care for people who are at high risk, including household contacts and healthcare workers.

The ideal time for all influenza vaccination is during October or November to allow for the development and maintenance of immunity during the peak of the influenza season.[31,32] **Table 109-1** lists the vaccination coverage rates and goals for various patient populations.

TABLE 109-1 Influenza Vaccination Rates and Goals by Patient Population[32,42]

Patient Population	Vaccination Coverage (%)	Vaccination Coverage National Goal (2013)
Children aged 6 months-7 years	47[a]	70%
Persons aged 18 or greater	38[a]	70%

Patient Population	Vaccination Coverage (%)	Vaccination Coverage National Goal (2013)
Nursing home residents	62[b]	90%
Pregnant women	27[c]	80%
Healthcare workers	56[a]	90%

[a]2010-2011 data.

[b]2005 data.

[c]2008-2009 data.

The two vaccine types currently available for prevention of seasonal influenza are the inactivated influenza vaccine (IIV), and the LAIV. IIV is available as trivalent (IIV3) and quadrivalent (IIV4) formulations, while LAIV is a quadrivalent formulation. Both vaccines contain two influenza A subtypes (H3N2 and H1N1) and influenza B virus; the specific strains included in the vaccine each year change based on antigenic drift. The viruses used for both vaccines are initially grown in embryonated hens' eggs, which explain the precautionary measures for vaccination of persons with a severe allergic reaction to eggs.[31] Of the two vaccines produced using nonegg based technologies, recombinant trivalent vaccine [RIV3 (Flublok®)] and cell-culture quadrivalent vaccine [ccIIV4 (Flucelvax Quadrivalent®)], only Flublok® is considered egg-free. Flucelvax® contains an estimated maximum of 5x10-8 mcg/0.5 mL dose of total egg protein ovalbumin. The Advisory Committee on Immunization Practices (ACIP) has made the following recommendations regarding the vaccinations of persons with reports of egg allergy: (a) Vaccination with any age appropriate IIV or RIV3 vaccine, for persons with a history of egg allergy that involves only hives. (b) Persons with severe allergic reactions (i.e. symptoms other than hives), such as angioedema, respiratory distress, light-headedness, or recurrent emesis or required epinephrine after an egg exposure may be immunized with any licensed IIV or RIV3 that is appropriate for age and health status. Vaccine should be administered in an inpatient or outpatient medical setting (including but not necessarily limited to hospitals, clinics, health departments, and physician offices), under the supervision of a health care provider who is able to recognize and manage severe allergic conditions. (c) Severe allergic reaction to influenza vaccine is a contraindication to receiving future vaccinations. (d) Vaccine providers should consider observing all patients for 15 minutes after vaccination to decrease the risk for injury should a patient experiences syncope.[31] The CDC encourages individuals to use the Vaccine Adverse Event Reporting System to aide in collecting and analyzing adverse events following influenza vaccinations.[31]

Trivalent and Quadrivalent Influenza Vaccine

Intramuscular IIV is FDA approved for use in people older than 6 months of age, regardless of their immune status. Of note, several commercial products are available and are approved for different age groups (**Table 109-2**). The intradermal IIV4, Fluzone Intradermal®, is approved by FDA

for use in adults 18 to 64 years of age and is another vaccination option for people in this age group. IIV is made with killed viruses, meaning it cannot cause signs and symptoms of influenza-like illness (**Table 109-3**). Age and immune status can affect the efficacy of IIV as can the similarity of the vaccine to the viruses in circulation. Afluria® brand of IIV3 vaccine is contraindicated in patients with hypersensitivity to neomycin or polymyxin. Afluria® is also not recommended first line in children 6 months to 8 years, due to reports of high febrile episodes following administration.[31]

TABLE 109-2 Approved Influenza Vaccines for Different Age Groups—United States, 2016-2017 Season[31,32]

Vaccine	Trade Name	Manufacturer	Dose/Presentation	Thimerosal Mercury Content (mcg Hg/0.5 mL dose)	Age Group	Number of Doses
Inactivated						
IIV3	Fluvirin	Seqirus Vaccines	0.5-mL prefilled syringe	≤1	≥4 years	1 or 2[a]
			5-mL multi-dose vial	25	≥4 years	1 or 2[a]
					≥9 years	
IIV3	Afluria	Seqirus	0.5-mL prefilled syringe	0	≥9 years via needle/ syringe or 18-64 years via jet injector	1
			5-mL multidose vial	24.5		1
ccIIV4	Quadrivalent	Seqirus Vaccines	0.5-mL prefilled syringe	0	≥4 years	1
RIV3	Flublok	Protein Sciences	0.5-ml single dose vial	0	≥18 years	1
IIV3 High Dose	Fluzone HD	Sanofi Pasteur	0.5-mL prefilled syringe	0	≥65 years	1
aIIV3	Fluad	Seqirus	0.5 mL single dose prefilled syringe	0	≥65 years	1
IIV4	Quadrivalent	ID Biomedical Corporation	5-mL multidose vial	<25	≥3 years	1
IIV4	Fluarix Quadrivalent	GlaxoSmithKline	0.5-mL prefilled syringe	0	≥3 years	1

Vaccine	Trade Name	Manufacturer	Dose/Presentation	Thimerosal Mercury Content (mcg Hg/0.5 mL dose)	Age Group	Number of Doses
IIV4	Fluzone Quadrivalent	Sanofi Pasteur	0.25-mL prefilled syringe	0	≥6-35 months	1 or 2[a]
			0.5-mL prefilled syringe	0	≥36 months	1 or 2[a]
			0.5-mL single-dose vial	0	≥36 months	1 or 2[a]
			5-mL multi-dose vial	25	≥6 months	1 or 2[a]
IIV4 intradermal	Fluzone Intradermal Quadrivalent	Sanofi Pasteur	0.1-mL prefilled microinjection system	0	18-64 years	1[b]
LAIV	FluMist Quadrivalent[c]	MedImmune	0.2-mL sprayer	0	2-49 years	1 or 2[d]

LAIV, live-attenuated influenza vaccine; IIV3, trivalent influenza vaccine; IIV4, quadrivalent influenza vaccine; ccIIV3, cell culture-based trivalent influenza vaccine; RIV3, recombinant trivalent influenza vaccine; aIIV3, adjuvanted inactivated influenza vaccine, trivalent, standard dose.

[a]Two doses administered at least 1 month apart are recommended for children aged 6 months to less than 9 years who are receiving influenza vaccine for the first time or received one dose in first year of vaccination during the previous influenza season.

[b]*Given intradermally.* A 0.1-mL dose contains 9 mcg of each vaccine antigen (27 mcg total).

[c]ACIP recommends that FLumist (LAIV4) not be used during the 2016-2017 season.

[d]Two doses administered 4 weeks apart are recommended for children aged 2 to less than 9 years who are receiving influenza vaccine for the first time.

TABLE 109-3 Comparison of Inactivated Influenza Vaccine (IIV) and Live-Attenuated Influenza Vaccine (LAIV)

Characteristic	IIV (IIV3/IIV4)	LAIV
Age groups approved for use	>6 months	2-49 years
Immune status requirements	Immunocompetent or immunocompromised	Immunocompetent

Characteristic	IIV (IIV3/IIV4)	LAIV
Viral properties	Inactivated (killed) influenza A (H3N2), A (H1N1), and B viruses	Live-attenuated influenza A (H3N2), A (H1N1), and B viruses
Route of administration	Intramuscular/Intradermal	Intranasal
Immune system response	High serum IgG antibody response	Lower IgG response and high serum IgA mucosal response

In children between 6 and 24 months of age, a 2-year randomized study of intramuscular IIV3 exhibited 89% seroconversion and efficacy of 66% in year 1 and 7% in year 2 versus culture-confirmed influenza.[38] In children between 1 and 15 years of age, the efficacy of IIV3 was 91.4% and 77.3% against culture-confirmed influenza A H1N1 and H3N2, respectively. Two doses of IIV are important for children under the age of 9 years, supporting the rationale for the recommendation of a booster dose of IIV at least 1 month after the initial dose in children between 6 months and less than 9 years of age if no previous vaccination (see Table 109-2).[31] Booster dose is also recommended for children 2 years to 8 years at least 6 weeks after the initial dose if no previous vaccination.

IIV is also effective in adult populations under and older than the age of 65 years. A double-blind, randomized controlled trial evaluating intramuscular IIV3 in healthy adults younger than the age of 65 years demonstrated an efficacy of 50% against serologically confirmed influenza during a season in which the vaccine and the circulating viruses were not well matched and an efficacy of 86% during a season in which the vaccine and the circulating viruses were well matched.[39] Vaccination of those younger than 65 years old during seasons when the virus and vaccine are well matched results in decreased work absenteeism and healthcare resource use.[38,39]

Intradermal IIV4 in adults 18 to 64 years of age provides immune response similar to the IIV3 intradermal injection for matched strains.[40] However, for both B strains intradermal IIV4, provides immune response superior to intradermal IIV3 without the corresponding B strain. Both vaccines were similar in their safety profile. In clinical trials, Fluzone® intradermal was noninferior to Fluzone® intramuscular in eliciting immune response as measured by hemagglutination inhibition antibody geometric mean titers (GMTs).[41] The rate of seroconversion was similar between the two vaccines against influenza strains A (H1N1 and H3N2), but not for strain B. The most common adverse reactions were injection site related, which were transient (resolving in 3-7 days), and include erythema (greater than 75%), swelling (greater than 50%), induration (greater than 50%), pain (greater than 50%), and pruritus (greater than 40%). Compared with the intramuscular vaccine, Fluzone® intradermal contains 40% less antigen (Table 109-2).

Adults older than the age of 65 years benefit from influenza vaccination, including prevention of complications, decreased risk of influenza-related hospitalization, and death. However, people in this population may not generate a strong antibody response to the vaccine and may remain susceptible to infection. In patients older than the age of 60 years who do not reside in a long-term care facility, IIV efficacy was 58% against influenza illness.[42] Although the efficacy against influenza illness for those living in long-term care facilities is between 30% and 40%, the vaccine is 50% to 60% effective

in preventing influenza-related hospitalization or pneumonia and 80% effective in preventing influenza-related death.[42]

The most frequent adverse effect associated with IIV is soreness at the injection site that lasts for less than 48 hours. IIV may cause fever and malaise in those who have not previously been exposed to the viral antigens in the vaccine.[31,42] Allergic-type reactions (hives, systemic anaphylaxis) rarely occur after influenza vaccination and are likely a result of a reaction to residual egg protein in the vaccine.

The 1976 swine influenza vaccine was linked to a rise in the incidence of Guillain-Barré syndrome (GBS), and this has propagated the belief that IIV may cause GBS.[42] However, there is insufficient evidence to establish causality. Although several studies have failed to establish a relationship between influenza vaccination and increased frequency of GBS, two studies have demonstrated a small but significant increase in GBS following influenza vaccination.[43,44] Therefore, vaccination should be avoided in persons who are not at high risk for influenza complications and who have experienced GBS within 6 weeks of receiving a previous influenza vaccine.[31,42] The potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the risks of GBS, and vaccination is recommended for all groups previously discussed.

The multidose vials and a few of the single-dose preparations of intramuscular IIV contain trace to small amounts of a preservative, thimerosal, which is a mercury-containing compound (see Table 109-2). Some individuals are concerned about thimerosal exposure, particularly among children, because of the unfounded belief that thimerosal exposure is linked to the development of autism. No scientifically persuasive evidence exists to suggest harm from thimerosal exposure from a vaccine. Conversely, accumulating evidence reports the lack of harm from such exposure.[45,46,47] Thus, similar to GBS, the potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the theoretical risk associated with thimerosal exposure, and vaccination is recommended for all groups previously discussed. However, to maximize the public health benefit and placate concerned individuals, thimerosal-free vaccine is available (see Table 109-2).

Live-Attenuated Influenza Vaccine

7 LAIV is made with live, attenuated viruses and is approved for intranasal administration in healthy people between 2 and 49 years of age (see Table 109-3). Advantages of LAIV include its ease of administration, intranasal rather than intramuscular administration, and the potential induction of broad mucosal and systemic immune response.[31] The mucosal response occurs at the site of viral entry and may prevent infection before viral replication occurs. LAIV is more expensive than IIV and is approved for use in a more limited population. Originally licensed as a trivalent vaccine, in February 2012, the FDA approved FluMist® Quadrivalent vaccine for influenza prevention in people aged 2 to 49 years.[48] FluMist® Quadrivalent vaccine contains four strains of the influenza viruses, two influenza A strains and two influenza B strains. The inclusion of a second B strain in the vaccine is thought to increase the likelihood of adequate protection against circulating influenza B strains.

Studies of FluMist® trivalent, in addition to three new clinical trials with the quadrivalent vaccine in 4,000 children (2-17 years) and adults (18-49 years) in the United States, provide supporting evidence on the efficacy and safety of FluMist® Quadrivalent.[48,49,50] The studies show that immune responses were similar between FluMist® Quadrivalent and FluMist® trivalent. LAIV recipients aged 2 to 5 years had 52.5% and 54.4% fewer cases of influenza illness against matched and mismatched strains, respectively, as compared with IIV3 recipients.[49]

Although LAIV is FDA approved for adults younger than the age of 49 years, LAIV is effective in healthy adults between 18 and 64 years old.[50] Vaccination reduced the number of severe febrile illnesses by 18.8% and febrile upper respiratory tract illnesses by 23.6%.[50] Additionally, vaccination led to fewer days of illness, fewer days lost from work, fewer visits to healthcare providers, and decreased use of prescription antibiotics and nonprescription medications.[50]

Adverse reactions of LAIV are similar among those receiving FluMist® Quadrivalent and FluMist® trivalent. The adverse effects typically associated with LAIV administration include runny nose, congestion, sore throat, and headache. Because LAIV contains live, attenuated viruses, viral shedding may occur for several days following vaccination with LAIV, although this should not be equated with person-to-person transmission.[31] Additionally, because LAIV contains live, attenuated viruses, which carry a theoretical infection risk, LAIV should not be given to immunosuppressed patients or given by healthcare workers who are severely immunocompromised. Moreover, for the reasons discussed in IIV above, LAIV should not be administered to persons with a history of GBS or hypersensitivity to eggs. Although the quadrivalent vaccine has replaced the trivalent vaccine since 2012, for 2016-2017 influenza season vaccination, the ACIP has recommended against the use of LAIV due to low effectiveness against influenza A(H1N1)pdm09 in the United States in the past 2 influenza seasons. (Table 109-2).

Clinical Controversy…

LAIV is not recommended in several populations, including people older than 50 years and pregnant women, largely because the vaccine has not been studied extensively in these populations. However, many clinicians believe the use of LAIV in these populations is acceptable.

Postexposure Prophylaxis

8 Antiviral drugs available for prophylaxis of influenza should be considered adjuncts but are not replacements for annual vaccination. Historically, the adamantanes and NA inhibitors are two classes of antiviral drugs available for influenza prophylaxis and treatment. However, the adamantanes are no longer recommended for prophylaxis or treatment in the United States (because of widespread resistance among influenza viruses) until susceptibility is reestablished among influenza A virus.[51,52,53,54] Therefore, the NA inhibitors oseltamivir, zanamivir, and peramivir are the only drugs available for the treatment of influenza infection.[52] Peramivir is not approved for chemoprophylaxis, however, oseltamivir and zanamivir, are effective prophylactic agents against influenza in terms of preventing laboratory-confirmed influenza when used for seasonal prophylaxis (67% and 85%

effective for zanamivir and oseltamivir, respectively) and preventing influenza illness among persons exposed to a household contact who was diagnosed with influenza (79%-81% and 68%-89% effective for zanamivir and oseltamivir, respectively).[52,53] Additionally, oseltamivir was 92% effective against influenza and also reduced associated complications when used as seasonal prophylaxis among immunized, institutionalized, elderly patients.[55] Both of these agents remain active against all influenza viruses, including influenza A H3N2v (**Tables 109-4** and **109-5**). Oseltamivir is FDA approved for the treatment of influenza in individuals 14 days and older, and for chemoprophylaxis in individuals 1 year and older. However, the CDC, the American Academy of Pediatrics (AAP), and the Pediatric Infectious Diseases Society (PIDS) provide an expanded recommendation for treatment in those less than 14 days, and chemoprophylaxis in those 3 months and older.[32,52,54] **Table 109-6** gives dosing recommendations.

TABLE 109-4 Antiviral Susceptibilities of Circulating Viruses

	Oseltamivir	Zanamivir	Peramivir	Adamantanes
Variant influenza A (H3N2), 2015	Susceptible	Susceptible	Susceptible	Resistant
Novel influenza A (H1N1)	Susceptible[a]	Susceptible	Susceptible[a]	Resistant
Seasonal A (H3N2)	Susceptible	Susceptible	Susceptible	Resistant
Influenza B	Susceptible	Susceptible	Susceptible	Resistant
Avian influenza (H5N1)	Susceptible	Susceptible	Susceptible	Variable

[a]Small number of isolates shown to be resistant to oseltamivir and peramivir.

TABLE 109-5 Interim Recommendations for the Selection of Antiviral Treatment Based on Confirmed Influenza Subtypes[32,52]

Laboratory Test	Preferred[a]	Alternative
Not performed or negative, but influenza suspected clinically[a]	Oseltamivir or zanamivir or peramivir	None
Positive variant H3N2v	Oseltamivir or zanamivir or peramivir	None
Positive novel H1N1	Oseltamivir or zanamivir or peramivir	None
Positive A (H3N2), or B	Oseltamivir or zanamivir or peramivir	None
Positive A + B	Oseltamivir or zanamivir or peramivir	None

[a]Viral surveillance data might help guide antiviral choices if oseltamivir resistance becomes more prevalent.

TABLE 109-6 Recommended Daily Dosage of Influenza Antiviral Medications for Treatment and Prophylaxis—United States[32,52,54]

Drug	Adult Treatment	Adult Prophylaxis[a]	Pediatric Treatment[b]	Pediatric Prophylaxis[c]
Oseltamivir	75-mg capsule twice daily for 5 days	75-mg capsule daily	<1 year: 3 mg/kg/dose twice daily 9-11 months[d]: 3.5 mg/kg/dose twice daily ≥1 year ≤15 kg: 30 mg twice daily 16-23 kg: 45 mg twice daily 23-40 kg: 60 mg twice daily >40 kg: 75 mg twice daily Duration: All for 5 days	3-8 months, 3 mg/kg/dose daily Not recommended if <3 months 9-11 months, 3.5 mg/kg/dose daily ≥1 year ≤15 kg: 30 mg daily 16-23 kg: 45 mg daily 23-40 kg: 60 mg daily >40 kg: 75 mg daily Duration: All for 10 days
Zanamivir	2 inhalations twice daily × 5 days	2 inhalations daily	2 inhalations twice daily × 5 days for ≥7 years old	2 inhalations daily for ≥5 years old for 10 days
Peramivir[e]	600 mg via intravenous infusion for 15-30 minutes once	None	None	None
Rimantadine[f]	200 mg/day in one to two doses × 7 days	200 mg/day in one to two doses	1-9 years old or <40 kg: 6.6 mg/kg/day divided twice daily (maximum 150 mg/day) ≥10 years old: 200 mg/day in one to two doses Treat 5-7 days	1-9 years old: 5 mg/kg daily (maximum 150 mg/day) ≥10 years old: 200 mg/day in one to two doses
Amantadine[f]	200 mg/day in one to two doses until 24-48 hours after symptom	Same as treatment doses	>12 years old: same as adult 1-9 years old: 5	Same as treatment doses

Drug	Adult Treatment	Adult Prophylaxis[a]	Pediatric Treatment[b]	Pediatric Prophylaxis[c]
	resolution		mg/kg/day in one to two doses; maximum 150 mg/day ≥10-12 years old: 100 mg orally twice daily	

[a]If influenza vaccine is administered, prophylaxis can generally be stopped 14 days after vaccination for noninstitutionalized persons. When prophylaxis is being administered following an exposure, prophylaxis should be continued for 10 days after the last exposure. In persons at high risk for complications from influenza for whom vaccination is contraindicated or expected to be ineffective, chemoprophylaxis should be continued for the duration that influenza viruses are circulating in the community during influenza season.

[b]Oseltamivir dosing for preterm infants—<38 weeks, 1 mg/kg/dose every 12 h; 38-40 weeks, 1.5mg/kg/dose every 12; >40 weeks, 3mg/kg/dose every 12 hours.[32]

[c]Alternate dosing by IDSA/PIDS (2011) is: 3-8 months—3 mg/kg/dose daily; 9-23 months—3.5 mg/kg/dose daily.[54]

[d]Unlabeled dosing.[54]

[e]Only approved for use in adults ≥18 years. Adjust dose if CrCl <50 mL/min (<0.83 mL/s)

[f]*Note:* Although amantadine and rimantadine have been used historically for the treatment and prophylaxis of influenza A viruses, due to high resistance, the CDC no longer recommends the use of these agents for the treatment and/or prophylaxis of influenza.

In those patients who did not receive the influenza vaccination and are receiving an antiviral drug for prevention of disease during the influenza season, the medication should optimally be taken for the entire duration of influenza activity in the community. The use of prophylaxis requires clinical judgment and depends on a variety of factors, but prophylaxis for seasonal influenza should be considered during influenza season for the following groups of patients after exposure to an infectious source:[52]

1. Persons at high risk of serious illness and/or complications who are exposed to an infectious person and cannot be vaccinated.
2. Persons at high risk of serious illness and/or complications who are vaccinated but exposed to an infectious person during the first two weeks following vaccination. The development of sufficient antibody titers after vaccination takes approximately 2 weeks.
3. Persons with severe immune deficiency or who may have an inadequate response to

vaccination (eg, advanced human immunodeficiency virus [HIV] disease, persons receiving immunosuppressive medications), after exposure to an infectious person.

4. Long-term care facility residents, regardless of vaccination status, when an outbreak has occurred in the institution.

LAIV should not be administered until 48 hours after influenza antiviral therapy has stopped, and influenza antiviral drugs should not be administered for 2 weeks after the administration of LAIV because the antiviral drugs inhibit influenza virus replication.[31,48] No contraindication exists for concomitant use of IIV and influenza antiviral drugs.

Pregnant Women and Immunocompromised Hosts

Pregnant women and immunocompromised hosts are special populations at increased risk of influenza complications and are also populations in whom careful consideration must be given in regard to prevention strategies.

Pregnant women, regardless of trimester, should receive annual influenza vaccination with IIV but not with LAIV.[31,52] No studies have demonstrated an increased incidence of adverse effects in mothers or their infants related or potentially related to IIV, but no such data exist for LAIV.[31] Influenza vaccination of pregnant women reduced hospitalization of their infants by 92% during the first 6 months of life.[56] IIV is also safe for breast-feeding mothers. No data exist for LAIV and breast-feeding, but caution is warranted because of the potential for viral shedding.[31]

Immunocompromised hosts should receive annual influenza vaccination with IIV but not with LAIV. IIV was 100% effective against laboratory-confirmed influenza in HIV-positive patients with no significant effect on viral load or CD4 cell count.[57] However, antibody titers may not be as high as in immunocompetent individuals and are not improved with a second dose of vaccine.[58] Similarly, antibody titers may not be as high in solid-organ transplant patients as in immunocompetent persons, but, conversely, antibody titers were increased significantly after a second dose of IIV in adult liver transplant patients.[59] Although this suggests a potential benefit from a two-dose regimen, such a regimen is not currently recommended for solid-organ transplant recipients. Likewise, immune responses in patients receiving chemotherapy for either solid or hematologic tumors are lower (fourfold rise, 17%-52%) than in those who had completed chemotherapy (50%-83%) and healthy patients (67%-100%).[60] Data are currently limited in this arena for the intradermal IIV. In a study of intradermal IIV3 involving immunocompromised patients compared with healthy controls, humoral responses (GMTs and protection rates [PRs]) were significantly better among healthy controls than those among immunocompromised patients.[61] This is not surprising given an already attenuated immune system. But it was also noted that compared with the standard intramuscular IIV, GMTs and PRs were similar within all tested groups. Immune response to vaccine may be less than desired in immunocompromised patients.[31]

Large clinical trials evaluating the use of influenza antivirals for prophylaxis are lacking in immunocompromised hosts. Viral shedding occurs for prolonged periods in this population and may

promote the development of antiviral resistance, which has been documented with oseltamivir in immunocompromised patients.[62,63,64]

TREATMENT

When prevention efforts fail or are not used, clinicians must turn to the agents available for treatment of influenza. Currently, the antiviral treatment options are limited, particularly in the face of resistance to the adamantanes and oseltamivir.

Goals of Therapy

The four primary goals of therapy of influenza are to control symptoms, prevent complications, decrease work and/or school absenteeism, and prevent the spread of infection.

General Approach to Treatment

In the era of pandemic preparedness and increasing resistance, early and definitive diagnosis of influenza is crucial. The currently available antiviral drugs are most effective if started within 48 hours of the onset of illness. Moreover, the sooner the antiviral drugs are started after the onset of illness, the more effective they are. Antiviral drugs shorten the duration of illness and provide symptom control. Adjunct agents, such as acetaminophen for fever or an antihistamine for rhinitis, may be used concomitantly with the antiviral drugs.

Nonpharmacologic Therapy

Patients suffering from influenza should get adequate sleep and maintain a low level of activity. They should stay home from work and/or school in order to rest and prevent the spread of infection. Appropriate fluid intake should be maintained. Cough/throat lozenges, warm tea, or soup may help with symptom control (cough, sore throat).

Pharmacologic Therapy

The NA inhibitors, oseltamivir, zanamivir, and peramivir are the only antiviral drugs available for the treatment and prophylaxis of influenza.[52] Peramivir is the only intravenous formulation commercially available. The adamantanes (amantadine and rimantadine) are no longer recommended due to high resistance among influenza viruses. A limited discussion of adamantanes can be found in the following section, but the focus will be on oseltamivir, zanamivir, and peramivir.

Adamantanes

The adamantanes (amantadine and rimantadine) block the M2 ion channel, which is specific to influenza A viruses, and inhibit viral uncoating. Historically, the adamantanes were used for the treatment of seasonal influenza A H1N1, as they do not have activity against influenza A H3N2 or influenza B viruses. The novel influenza A H1N1 that emerged during the 2009 to 2010 influenza

season, which has now replaced seasonal influenza A H1N1 as the predominant seasonal virus, was found to be discriminatorily resistant to the adamantanes. Data from the 2014 to 2015 influenza season showed that more than 99% of influenza A H3N2 and H1N1pdm09 were resistant to adamantanes.[51,52] As a result, the CDC only recommends the use of NA inhibitors for the treatment and prophylaxis of influenza A, until susceptibility of adamantanes is reestablished among influenza A viruses. Resistance to adamantanes is often conferred by a single-point mutation, and this is problematic because it results in cross-resistance to the entire class.[53]

Neuraminidase Inhibitors

10 Oseltamivir, zanamivir, and peramivir are NA inhibitors that have activity against both influenza A and influenza B viruses.[52,53] Without NA, release of the virus from infected cells is impaired, and, thus, viral replication is decreased. When administered within 48 hours of the onset of illness, NA inhibitors may reduce the duration of illness by approximately 1 day versus placebo.[53] In a pivotal trial, oseltamivir reduced the time to return to normal health in adults by 1.9 days and the time to return to normal activity by 2.8 days.[65] These reductions have a significant effect on not only the quality of life for the patient but also the societal costs associated with influenza. 9 Of note, the benefits of treatment are highly dependent on the timing of the initiation of treatment, with the ideal initiation period being within 12 hours of illness onset.[66] However, select observational studies have reported a lower risk for severe outcomes with oral oseltamivir started 4 and 5 days after onset of illness in critically ill patients with suspected or confirmed influenza.[67,68]

Oseltamivir treatment in adults and adolescents with documented influenza illness resulted in a 26.7% reduction in overall antibiotic use, a 55% reduction in lower respiratory tract complications (bronchitis, pneumonia), and a 59% reduction in hospitalizations.[69] Zanamivir treatment in adults and adolescents with influenza-like illness resulted in a 28% reduction in antibiotic use and a 40% reduction in lower respiratory tract complications.[70] The data in these studies largely come from healthy individuals rather than those at highest risk for complications associated with influenza. The impact of appropriate treatment in high-risk populations may be even greater than that which has been documented to date.

Oseltamivir is approved for treatment in those 14 days and older, zanamivir for treatment in those older than the age of 7 years, and peramivir for those 18 years and older.[51] The recommended doses vary by agent and age (see Table 109-6). The recommended duration of treatment for both oseltamivir and zanamivir is 5 days, and one dose for one day for peramivir.

The FDA approved single dose peramivir injection (Rapivab®) for intravenous use for the treatment of acute uncomplicated influenza in people 18 years and older.[71] Peramivir is as effective as oseltamivir, without severe adverse events.[72] Therefore, peramivir is an effective option in patients who are unable to tolerate or absorb oral or enterically-administered oseltamivir due to gastric stasis, malabsorption, or gastrointestinal bleeding. Based on an observational study, the 14-day, 28-day, and 56-day survival rates of 31 patients with severe H1N1pdm09 infection treated with peramivir were 77%, 67%, and 59%, respectively.[73] Peramivir shortened duration of influenza symptoms in

outpatient adults with uncomplicated influenza by about 1 day, with a corresponding reduction in median time to resumption of usual activities to about 1.5 days.[74] Studies exploring the use of peramivir beyond 1 day have not shown a benefit. A randomized trial of influenza treatment in hospitalized patients younger than 6 years, with intravenous peramivir at a dosage of 600 mg once daily (10 mg/kg once daily in children) for five days plus standard of care compared with placebo plus standard did not demonstrate a clinical benefit.[75]

Neuropsychiatric complications consisting of delirium, seizures, hallucinations, and self-injury in pediatric patients (mostly from Japan) have been reported following treatment with oseltamivir, and peramivir.[66,76] Since influenza itself can be associated with neuropsychiatric manifestations, a causal relationship between oseltamivir or peramivir and neuropsychiatric effects has not been delineated.[42] However, the labels for oseltamivir and peramivir have been updated to include neuropsychiatric events as a precaution, and their occurrence with use of these agents should not be ignored.

Influenza resistance to the NA inhibitors has been documented but cross-resistance between the NA inhibitors has not been reported.[51,52,53] Antiviral resistance remains relatively low. During the 2014 to 2015 influenza season, 98.4% of the tested 2009 H1N1 viruses were susceptible to oseltamivir and peramivir, and 100% of the 2009 H1N1 viruses tested were susceptible to zanamivir; 100% of influenza A (H3N2) tested were susceptible to both oseltamivir and zanamivir; and 100% of influenza B viruses tested were susceptible to both oseltamivir and zanamivir.[52,77] Antiviral susceptibility testing of circulating viruses confirmed that seasonal influenza A H3N2 and variant influenza H3N2 maintain susceptibility to oseltamivir, peramivir, and zanamivir.[30,51] The burden of surveillance rests on clinicians to identify local patterns of influenza circulation to guide antiviral therapy.

Clinical Controversy…

Some clinicians debate the cost–benefit of the use of diagnostic tests for influenza as well as treatment of influenza in otherwise healthy individuals who are likely to experience resolution without treatment. This controversy is compounded by the fact that the diagnostic tests and the benefits associated with treatment of influenza are highest early in the disease process and many patients present after this time period.

Special Populations

Inadequate data exist regarding the use of antiinfluenza medications in special populations, such as immunocompromised hosts. Furthermore, limited data exist regarding use of influenza antivirals during pregnancy. The adamantanes are embryotoxic and teratogenic in rats, and limited case reports of adverse fetal outcomes following amantadine use in humans have been published. Oseltamivir and zanamivir have been used but lack solid safety clinical data in pregnant women. Pregnancy should not be considered a contraindication to oseltamivir or zanamivir use. Oseltamivir is preferred for the treatment of pregnant women because of its systemic activity; however, the drug of choice for chemoprophylaxis is not yet defined. Zanamivir may be preferred because of its limited systemic absorption, but respiratory complications need to be considered, especially in women with underlying respiratory diseases. Both the adamantanes and the NA inhibitors are excreted in breast

milk and should be avoided by mothers who are breast-feeding their infants. More studies are needed in these populations who are at high risk for serious disease and complications from influenza.

Clinical Controversy…

Some debate exists regarding the benefit of antiviral administration more than 48 hours after onset. While clinicians agree that the most benefit is achieved the earlier the medications are started, some data suggest benefit even beyond 48 hours after onset, albeit more limited.

PANDEMIC PREPAREDNESS

This chapter is not meant to provide an exhaustive review of the biology of influenza or pandemic preparedness. This topic is rapidly changing and interested readers are referred to the following websites: *www.flu.gov*, *www.who.int/influenza/human_animal_interface/en/*, and *www.cdc.gov/h1n1flu*.

A vital component of pandemic preparedness is forethought—plans must be established for how to effectively triage large numbers of ill patients, prioritize and/or ration vaccine and antivirals, and communicate with the public through mass media during a period of severe labor shortage (a result of stress and illness among healthcare workers) and supply shortfall (a result of societal and economic disruption).

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored daily for resolution of signs and symptoms associated with influenza, such as fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms will typically resolve within approximately 1 week. If the patient continues to exhibit signs and symptoms of illness beyond 10 days or a worsening of symptoms after 7 days, a physician visit is warranted as this may be an indication of a secondary bacterial infection. Ideally, antiviral therapy should not be started until influenza is confirmed via the laboratory. However, therapy should be initiated within 48 hours of illness onset, emphasizing the need for rapid diagnosis. Repeat diagnostic tests to demonstrate clearance of the virus are not necessary.

Chapter 110: Skin and Soft-Tissue Infections

Douglas N. Fish

INTRODUCTION

KEY CONCEPTS

- 1 Folliculitis, furuncles (boils), and carbuncles begin around hair follicles and are caused most often by *Staphylococcus aureus*. Folliculitis and small furuncles are generally treated with warm, moist heat to promote drainage; larger furuncles and carbuncles require incision and drainage. Purulent, moderately severe infections (eg, with fever or other systemic signs of infection) have a higher suspicion for community-associated methicillin-resistant *S. aureus* (MRSA) and empiric treatment should include trimethoprim–sulfamethoxazole or a tetracycline such as doxycycline.

- 2 Erysipelas, a superficial skin infection with extensive lymphatic involvement, is caused by *Streptococcus pyogenes*. The treatment of choice is penicillin, administered orally or parenterally, depending on the severity of the infection.

- 3 Impetigo is a superficial skin infection that occurs most commonly in children. It is characterized by fluid-filled vesicles that develop rapidly into pus-filled blisters that rupture to form golden-yellow crusts. Effective therapy includes penicillinase-resistant penicillins (dicloxacillin), first-generation cephalosporins (cephalexin), and topical mupirocin or retapamulin. *S. aureus* is the primary cause of impetigo, with infections caused by MRSA emerging in recent years.

- 4 Lymphangitis, an infection of the subcutaneous lymphatic channels, is generally caused by *S. pyogenes*. Acute lymphangitis is characterized by the rapid development of fine, red, linear streaks extending from the initial infection site toward the regional lymph nodes, which are usually enlarged and tender. Penicillin is the drug of choice.

- 5 Cellulitis is an infection of the epidermis, dermis, and superficial fascia most commonly caused by *S. pyogenes* and *S. aureus*. Lesions generally are hot, painful, and erythematous, with nonelevated, poorly defined margins. Oral trimethoprim–sulfamethoxazole, doxycycline, or minocycline is used for initial treatment of suspected MRSA in patients with purulent, moderately severe cellulitis (ie, lesion with purulent drainage or exudate, or nondrainable

abscess plus systemic signs of infection). Treatment of nonpurulent cellulitis generally consists of penicillin VK, a penicillinase-resistant penicillin (dicloxacillin), first-generation cephalosporin (cephalexin), or clindamycin for 5 days, with the option of adding coverage for MRSA in certain patients. More severe infections in hospitalized and/or immunocompromised patients should receive empiric therapy with parenteral agents active against streptococci (nonpurulent infections) or both streptococci and MRSA (purulent infections).

- 6 Necrotizing fasciitis is a rare but life-threatening infection of subcutaneous tissue that results in progressive destruction of superficial fascia and subcutaneous fat. Early and aggressive surgical debridement is an essential part of therapy for treatment of necrotizing fasciitis. Mixed infections are treated with broad-spectrum regimens that cover streptococci, gram-negative aerobes, and anaerobes. Infections caused by *S. pyogenes* or *Clostridium* species should be treated with the combination of penicillin and clindamycin.

- 7 Diabetic foot infections are managed with a comprehensive treatment approach that includes both proper wound care and antimicrobial therapy. Potential pathogens include staphylococci, streptococci, aerobic gram-negative bacilli, and obligate anaerobes. Antimicrobial regimens for diabetic foot infections are based on severity of the infection, expected treatment setting, and risk factors for infection with more resistant pathogens such as MRSA and *Pseudomonas aeruginosa*. Outpatient therapy with oral antimicrobials should be used whenever possible for less severe infections, while more severe infections initially require IV therapy.

- 8 Prevention is the single most important aspect in the management of pressure sores. After a sore develops, successful local care includes a comprehensive approach consisting of relief of pressure, proper cleaning (debridement), disinfection, and appropriate antimicrobial therapy if an infection is present. Good wound care is crucial to successful management.

- 9 All bite wounds (either animal or human) should be irrigated thoroughly with large volumes of sterile normal saline, and the injured area should be immobilized and elevated. Depending on the severity of the bite wound, amoxicillin–clavulanic acid or ampicillin–sulbactam is often used for treatment of animal bites because of their coverage of *Pasteurella* species, streptococci, *S. aureus*, and anaerobes typically present in the oral flora of dogs and cats.

- 10 Antimicrobial prophylaxis (early preemptive therapy) of animal bites is not recommended routinely; however, patients at high risk of infection (eg, immunocompromised, moderate to severe bite injuries especially to the hands and face, penetration of the periosteum or joint capsule) should be given prophylactic antimicrobial therapy for 3 to 5 days. Infected bite wounds should be treated for 7 to 14 days with oral or IV antibiotics having activity against *Eikenella corrodens*, streptococci, *S. aureus*, and β-lactamase–producing anaerobes.

Skin and soft-tissue infections (SSTIs) may involve any or all layers of the skin (epidermis, dermis, subcutaneous fat), fascia, and muscle. They may also spread far from the initial site of infection and lead to more severe complications, such as endocarditis, gram-negative sepsis, or streptococcal

glomerulonephritis. Sometimes the treatment of SSTIs may necessitate both medical and surgical management. This chapter presents details of the pathogenesis and management of some of the most common infections involving the skin and soft tissues, ranging in severity from superficial to life-threatening.

EPIDEMIOLOGY

Bacterial infections of the skin can be classified as primary or secondary (**Table 110-1**).[1,2,3] Primary bacterial infections usually involve areas of previously healthy skin and are caused by a single pathogen. In contrast, secondary infections occur in areas of previously damaged skin and are frequently polymicrobic. SSTIs are also classified as complicated or uncomplicated. Complicated infections are those that involve deeper skin structures (eg, fascia, muscle layers), require significant surgical intervention, or occur in patients with compromised immune function (eg, diabetes mellitus, human immunodeficiency virus [HIV] infection).[4] Other categories that are crucial for successful treatment are the differentiation of necrotizing versus nonnecrotizing, as well as purulent versus nonpurulent, SSTIs.[4,5,6,7]

TABLE 110-1 Bacterial Classification of Important Skin and Soft-Tissue Infections [1,2,3]

Primary Infections	
Erysipelas	Group A streptococci (*Streptococcus pyogenes*)
Impetigo	*Staphylococcus aureus* (including methicillin-resistant strains), group A streptococci
Lymphangitis	Group A streptococci; occasionally *S. aureus*
Cellulitis	Group A streptococci, *S. aureus* (potentially including methicillin-resistant strains); occasionally other gram-positive cocci, gram-negative bacilli, and/or anaerobes
Necrotizing fasciitis	
Type I	Anaerobes (*Bacteroides* spp., *Peptostreptococcus* spp.) and facultative bacteria (streptococci, Enterobacteriaceae)
Type II	Group A streptococci
Type III	*Clostridium perfringens*
Secondary Infections	
Diabetic foot infections	*S. aureus*, streptococci, Enterobacteriaceae, *Bacteroides* spp., *Peptostreptococcus* spp., *Pseudomonas aeruginosa*
Pressure sores	*S. aureus* including methicillin-resistant strains, streptococci, Enterobacteriaceae, *Bacteroides* spp., *Peptostreptococcus* spp., *P. aeruginosa*
Bite wounds	
Animal	*Pasteurella* spp., *S. aureus*, streptococci, *Bacteroides* spp.
Human	*Eikenella corrodens*, *S. aureus*, streptococci, *Corynebacterium* spp., *Bacteroides* spp., *Peptostreptococcus* spp.
Burn wounds	*P. aeruginosa*, Enterobacteriaceae, *S. aureus*, streptococci

SSTIs are among the most common infections seen in community and hospital settings.[8,9] However, most infections are believed to be mild and are treated in an outpatient setting, making it difficult to accurately quantify community-acquired SSTIs. SSTIs were diagnosed in 0.8% of physician office visits between 1993 and 2005; this corresponded to approximately 82 million diagnoses of SSTI, being more common among those 70 years of age and older.[3] Emergency room visits for SSTIs have increased dramatically in recent years, attributed primarily to an increase in community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) cellulitis and abscesses.[10,11] A study of emergency department visit rates between 1997 and 2007 found a 3.1-fold increase (11% per year) for abscess SSTIs, with only a minimal increase in nonabscess SSTIs.[11] According to an Agency for Healthcare Research and Quality report, in 2009 SSTIs were responsible for nearly 600,000 hospitalizations and represented 2% of all admissions in males and 1.2% in females.[9] While the exact incidence of SSTIs is unknown, the frequency of infections caused by drug-resistant gram-positive cocci has been increasing.[4,5,6,7] The high incidence of healthcare-associated MRSA (HA-MRSA) has been a major concern for many years and the emergence of CA-MRSA is even more problematic.[5,6,7,12,13,14,15,16,17,18] CA-MRSA are characteristically isolated from patients lacking typical risk factors (eg, prior hospitalization, long-term care facility) and are often susceptible to non–β-lactam antibiotics such as trimethoprim–sulfamethoxazole, doxycycline, and clindamycin.[1,12,13,15,17,18,19] They also differ genetically from HA-MRSA with methicillin resistance carried on the type IV or type V staphylococcal chromosomal cassette *mec* (SCC*mec*) element of the *mecA* gene.[1,12,18] CA-MRSA strains often harbor genes for Panton-Valentine leukocidin (PVL), a cytotoxin responsible for leukocyte destruction and tissue necrosis. In contrast, HA-MRSA strains usually lack genes for PVL and are associated with SCC*mec* alleles I to III.[1,12,15,18] While the incidence of HA-MRSA has declined in recent years,[20] the incidence of CA-MRSA has dramatically increased; nearly half (46%) of all culture-positive SSTIs are caused by MRSA.[4,5,6,7,8,19] Clinicians should suspect CA-MRSA in geographic areas with a high prevalence of these strains, or in recurrent or persistent infections that are not responding to appropriate β-lactam therapy. In addition to the emergence of CA-MRSA, treatment choices for SSTIs have been further complicated by the increased incidence of macrolide-resistant strains of *S. aureus* and *Streptococcus pyogenes*.[15,19,21] Data from the Minnesota Department of Health found erythromycin susceptibility among CA-MRSA strains decreased from 45% to 13% during the years 2000 to 2005.[19] There is concern about the use of clindamycin for CA-MRSA infections due to the risk of inducible clindamycin resistance in *S. aureus* strains that are erythromycin-resistant, but clindamycin-susceptible.[18,19] A double-disk test (D-zone test) is recommended to identify erythromycin-resistant strains with inducible clindamycin resistance if treatment with clindamycin is desired.[6,7,12] A positive D-zone test, indicating the presence of inducible resistance conferred by the *erm* gene, suggests the possibility of the emergence of clindamycin resistance during therapy.[12]

ETIOLOGY

The majority of SSTIs are caused by gram-positive organisms present on the skin surface.[7,22] Gram-positive bacteria (coagulase-negative staphylococci, diphtheroids) are the predominant flora of

the skin, with gram-negative organisms being relatively uncommon (**Table 110-2**).[1,2,3] *S. aureus*, as well as a variety of gram-negative bacteria, including *Acinetobacter* species, can be found in moist intertriginous areas (eg, axilla, groin, and toe webs) of the body.[1,2,23] Approximately 30% to 35% of healthy individuals are reported to be colonized with *S. aureus* on the skin or in the anterior nares.[1,3] Colonization, whether transient or permanent, provides a nidus for infection should the integrity of the epidermis be compromised.[1,2,10]

TABLE 110-2 Predominant Microorganisms of Normal Skin [1,2,3]

Bacteria
Gram-positive
Coagulase-negative staphylococci
Micrococci (*Micrococcus luteus*)
Corynebacterium species (diphtheroids)
Propionibacterium species
Gram-negative
Acinetobacter species
Fungi
Malassezia species
Candida species

S. aureus and *S. pyogenes* account for the majority of community-acquired SSTIs.[1,10,22] Data from large surveillance studies showed *S. aureus* to be the most common cause of SSTIs in hospitalized patients, with often 30%-40% of these being caused by MRSA.[3,8,9] Other common nosocomial pathogens included *Pseudomonas aeruginosa* (11%), enterococci (9%), and *Escherichia coli* (7%).[3,8,9]

PATHOPHYSIOLOGY

The skin serves as a barrier between humans and their environment, therefore functioning as a primary defense mechanism against infections. The skin and subcutaneous tissues normally are extremely resistant to infection but may become susceptible under certain conditions. Even when high concentrations of bacteria are applied topically or injected into the soft tissue, resulting infections are rare.[1,2,3,24,25] Although the human skin supports an abundant and diverse microbiome of bacteria and fungi,[1,2] several host factors act together to confer protection against skin infections. Continuous renewal of the epidermal layer results in the shedding of keratocytes, as well as skin bacteria.[2] In addition, sebaceous secretions are hydrolyzed to form free fatty acids that strongly

inhibit the growth of many bacteria and fungi. A normal commensal skin microbiome itself serves a protective function by not allowing space or environmental conditions favorable to colonization with more pathogenic strains.[1,2] Conditions that may predispose a patient to the development of skin infections include (a) high concentrations of bacteria (more than 10^5 microorganisms), (b) excessive moisture of the skin, (c) inadequate blood supply, (d) availability of bacterial nutrients, and (e) damage to the corneal layer allowing for bacterial penetration.[2,3,24,25]

The best defense against SSTI is intact skin.[2,24] The majority of SSTIs result from the disruption of normal host defenses by processes such as skin puncture, abrasion, or underlying diseases (eg, diabetes).[1,2,24,26] The nature and severity of the infection depend on both the type of microorganism present and the site of inoculation.

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

1 Folliculitis is inflammation of the hair follicle and is caused by physical injury, chemical irritation, or infection. Infection occurring at the base of the eyelid is referred to as a stye. While folliculitis is a superficial infection with pus present only in the epidermis,[10,22] furuncles and carbuncles occur when a follicular infection extends from around the hair shaft to involve deeper areas (subcutaneous tissue) of the skin.[26] A furuncle, commonly known as a *boil*, is a walled-off mass of purulent material arising from a hair follicle.[10] The lesions are called *carbuncles* when adjacent furuncles coalesce to form a single inflamed area.[10] This aggregate of infected hair follicles forms deep masses that generally open and drain through multiple sinus tracts.[12,26] *S. aureus* is the most common cause of folliculitis, furuncles, and carbuncles.[12,26] Inadequate chlorine levels in whirlpools, hot tubs, and swimming pools have been responsible for outbreaks of folliculitis caused by *P. aeruginosa*.[1,26] Outbreaks of furunculosis caused by *S. aureus* and CA-MRSA have been reported in settings involving close contact (eg, families, prisons), especially when skin injury was common (such as with sports).[12,26] In addition, some individuals experience repeated episodes of furunculosis.[22] A major predisposing factor in recurrent infection is the presence of *S. aureus* in the anterior nares.[15,22,26]

TREATMENT

Folliculitis, Furuncles, and Carbuncles

Desired Outcomes

The goals of treatment include relieving discomfort, preventing further spread of the infection, and preventing recurrence. Controlling recurrent furunculosis is key due to the difficulty in treating chronic furunculosis.[22] Treatments should be effective and inexpensive and have minimal adverse effects.

CLINICAL PRESENTATION Folliculitis

- Clustering, pruritic papules localized to hair follicles.

- Generally develop in areas subject to friction and perspiration.
- Papules are generally 5 mm or less in diameter and erythematous.
- Papules evolve into pustules that generally spontaneously rupture in several days.
- Systemic signs (fever, malaise) are uncommon.

Furuncles

- Inflammatory, draining nodule involving a hair follicle.
- Generally develop in areas subject to friction and perspiration.
- Lesions are discrete, whether occurring as singular or multiple nodules.
- Lesion starts as a firm, tender, red nodule that becomes painful and fluctuant.
- Lesions often drain spontaneously.
- Lesions caused by CA-MRSA often have necrotic centers characteristic of "spider bites."
- Systemic signs are uncommon.

Carbuncles

- Formed when adjacent furuncles coalesce to form a single inflamed area.
- Form broad, swollen, erythematous, deep, and painful follicular masses.
- Commonly develop on the back of the neck and are more likely to occur in patients with diabetes.
- Commonly associated with systemic signs (fever, chills, malaise).
- Bacteremia with secondary spread to other tissues is common.

Treatment

Table 110-3 summarizes evidence-based treatment recommendations from clinical guidelines for SSTIs.[3,5,6,15,27,28,29] Treatment of folliculitis generally requires only local measures, such as warm moist compresses or topical therapy (eg, clindamycin, erythromycin, mupirocin, or benzoyl peroxide).[3,26] Topical agents generally are applied two to four times daily for 7 days. Small furuncles generally can be treated with moist heat, which promotes localization and drainage of pus.[3,26] Large and/or multiple furuncles and carbuncles require incision and drainage.[3,4,12,15,28] Systemic antibiotics are usually not necessary unless accompanied by fever or extensive cellulitis.[4,15] Treatment of more severe infections (eg, accompanied by systemic signs of infection) should include oral trimethoprim–sulfamethoxazole or a tetracycline (either doxycycline or minocycline) for 5 to 10 days due to a higher

suspicion for MRSA (refer to **Table 110-4** for adult and pediatric doses).[4,6,15,22,28] For individuals with nasal colonization, application of mupirocin ointment twice daily in the anterior nares for the first 5 days of each month decreases recurrent furunculosis by almost half.[15,22] Daily chlorhexidine washes and daily washing of personal items such as towels, bedding, and clothes may also be recommended.[15]

TABLE 110-3 Evidence-Based Recommendations for Treatment of Skin and Soft-Tissue Infections[3,5,6,15,27,28,29]

Recommendations	Recommendation Grade[a]
Folliculitis, Furuncles, Carbuncles	
Gram stain and culture of pus from carbuncles and abscesses are recommended, but treatment without cultures is reasonable in most patients	Strong, moderate
Carbuncles, abscesses and large furuncles of mild severity should be treated with incision and drainage	Strong, high
Administration of antibiotics with activity against *Staphylococcus aureus* as an adjunct to incision and drainage should be based on presence or absence of systemic signs of infection	Strong, low
Antibiotics with activity against MRSA are recommended for patients with carbuncles or abscesses of higher severity who have failed initial antibiotic therapy, have severe systemic signs of infection, or are immunocompromised	Strong, low
Erysipelas	
Most infections are caused by *Streptococcus pyogenes*. Penicillin (oral or IV depending on clinical severity) is the drug of choice	A-I
If *S. aureus* is suspected, a penicillinase-resistant penicillin or first-generation cephalosporin should be used	A-I
Impetigo	
Gram stain and culture of pus or exudates should be obtained to help identify causative pathogens	Strong, moderate
Bullous and nonbullous impetigo should be treated with either mupirocin or retapamulin for 5 days	Strong, high
Impetigo should be treated with oral antibiotics active against S. aureus unless cultures show streptococci alone. Dicloxacillin or cephalexin is recommended for 7 days. Doxycycline, clindamycin, or sulfamethoxazole-trimethoprim should be used when MRSA is suspected or confirmed	Strong, moderate
Cellulitis	
Cultures of blood or cutaneous aspirates, biopsies or swabs are not routinely recommended	Strong, moderate

Recommendations	Recommendation Grade[a]
Blood cultures are recommended, and cultures of cutaneous aspirates, biopsies, or swabs should be considered, in patients receiving chemotherapy for malignancies, neutropenia, severe cell-mediated immunodeficiency, immersion injuries, or animal bites	Strong, moderate (blood) Weak, moderate (other cultures)
Typical cases of mild nonpurulent cellulitis should be treated with antibiotics active against streptococci	Strong, moderate
Systemic antibiotics are recommended for moderate nonpurulent cellulitis with systemic signs of infection. Use of antibiotics active against methicillin-susceptible *S. aureus* could be considered	Weak, low
Patients with severe nonpurulent cellulitis associated with penetrating trauma, MRSA infection in another location, MRSA nasal colonization, injection drug use, or systemic signs of infection should be treated with vancomycin or other antibiotics active against both MRSA and streptococci	Strong, moderate
Broad-spectrum antibiotic therapy with vancomycin plus either piperacillin–tazobactam, imipenem, or meropenem may be considered for empiric treatment of severe nonpurulent cellulitis in severely immunocompromised patients	Weak, moderate (need for broad-spectrum therapy) Strong, moderate (recommended broad-spectrum antibiotic regimen if used)
A treatment duration of 5 days is recommended for cellulitis, but may be extended if lack of clinical response within that time	Strong, high
Elevation of the affected area and treatment of predisposing factors are recommended for cellulitis	Strong, moderate
Systemic corticosteroids for 7 days can be considered for adjunctive treatment of cellulitis in nondiabetic patients	Weak, moderate
Patients with mild nonpurulent cellulitis who do not have systemic signs of infection, altered mental status, or hemodynamic instability should be treated as outpatients	Strong, moderate
Hospitalization is recommended for patients with moderate to severe nonpurulent cellulitis who have failed outpatient therapy, have poor adherence to therapy, are immunocompromised, or in whom there is a concern for deeper or necrotizing infection	Strong, moderate
Empiric antibiotics for outpatients with purulent cellulitis should provide activity against community-associated MRSA; coverage of β-hemolytic streptococci is likely not required. Mild–moderate infections can generally be treated with oral agents (dicloxacillin, cephalexin, clindamycin) unless resistance is high in the community	A-II

Recommendations	Recommendation Grade[a]
Recommended antibiotics for empiric coverage of MRSA in outpatients include orally administered trimethoprim–sulfamethoxazole, doxycycline, minocycline, clindamycin, and linezolid	A-II for all listed options
If coverage of both β-hemolytic streptococci and community-associated MRSA is desired, empiric antibiotic regimens for outpatient therapy include orally administered clindamycin alone; linezolid alone; or trimethoprim–sulfamethoxazole, doxycycline, or minocycline in combination with amoxicillin	A-II for all listed options
Hospitalized patients with complicated or purulent cellulitis should receive IV antibiotics with activity against MRSA pending culture data. Antibiotic options include vancomycin, linezolid, daptomycin, telavancin, and clindamycin	A-I for all except clindamycin; clindamycin A-III
In the treatment of *S. aureus* infections, trough serum vancomycin concentrations should always be maintained >10 mg/L (>7 µmol/L) to avoid development of resistance	B-III
Necrotizing Fasciitis	
Patients with severe nonpurulent cellulitis characterized by aggressive infection and associated with signs of systemic toxicity, necrotizing fasciitis, or gas gangrene should have prompt surgical consultation	Strong, low
Early and aggressive surgical debridement of all necrotic tissue is essential	A-III
Necrotizing fasciitis should be empirically treated with broad-spectrum antibiotics such as vancomycin or linezolid plus piperacillin–tazobactam or a carbapenem, or vancomycin or linezolid plus ceftriaxone and metronidazole	Strong, low
Necrotizing fasciitis caused by *S. pyogenes* should be treated with the combination of clindamycin and penicillin	Strong, low
In the treatment of necrotizing fasciitis caused by methicillin-resistant *S. aureus* infections, trough serum vancomycin concentrations of 15-20 mg/L (10-14 µmol/L) are recommended	B-II
Clostridial gas gangrene (myonecrosis) should be treated with clindamycin and penicillin	B-III
Diabetic Foot Infections	
Clinically uninfected wounds should not be treated with antibiotics	A-III
Empiric antibiotic regimens should be selected based on severity of infection and likely pathogens	A-III

Recommendations	Recommendation Grade[a]
Antibiotic therapy should target only aerobic gram-positive cocci in patients with mild to moderate infection who have not received antibiotics within the previous month	C-III
Broad-spectrum empiric antibiotic therapy should be initiated in most patients with severe infections, until culture and susceptibility data are available	A-III
Empiric antibiotics directed against *Pseudomonas aeruginosa* are usually unnecessary except in patients with specific risk factors for infection with this pathogen: patient has been soaking feet, patient has failed previous antibiotic therapy with nonpseudomonal agents, or clinically severe infection	A-III
Empiric antibiotics directed against MRSA should be considered in patients with specific risk factors, including: prior history of infection or colonization with MRSA, high local prevalence of MRSA (eg, ≥50% for mild infections, ≥30% for severe infection), or clinically severe infection	C-III
Oral agents with high bioavailability may be used in the treatment of most mild, and many moderate, infections	A-II
Parenteral therapy is initially preferred for all severe, and some moderate, infections. After initial response, step-down therapy to oral agents can be considered	C-III
Definitive therapy should be based on results of appropriately collected cultures and sensitivities, as well as clinical response to empiric antimicrobial agents	A-III
Appropriate wound care, in addition to appropriate antimicrobial therapy, is often necessary for healing of infected wounds	A-III
Antibiotic therapy should only be continued until resolution of signs/symptoms of infection, but not necessarily until the wound is fully healed. The duration of therapy should initially be 1-2 weeks for mild infections and 2-3 weeks for moderate to severe infection	C-III
Animal Bites	
Preemptive early antibiotics should be administered for 3-5 days in patients with any of the following: immunocompromised; asplenic; advanced liver disease; preexisting or resultant edema of the bitten area; moderate to severe bite-related injuries, especially to the hands or face; or bite injuries that have penetrated the periosteum or joint capsule	Strong, low
Amoxicillin–clavulanic acid or other antibiotics active against both aerobic and anaerobic bacteria should be used for treatment of	Strong, moderate

Recommendations	Recommendation Grade[a]
infected animal bites	
Serious infections requiring IV antimicrobial therapy can be treated with a β-lactam/β-lactamase inhibitor combination or second-generation cephalosporin with activity against anaerobes (eg, cefoxitin)	B-II
Penicillinase-resistant penicillins, first-generation cephalosporins, macrolides, and clindamycin should not be used for treatment of infected wounds because of their poor activity against *Pasteurella multocida*	D-III
Human Bites	
Antimicrobial therapy should provide coverage against *Eikenella corrodens*, *S. aureus*, and β-lactamase–producing anaerobes	B-III

[a]Cited evidence-based guidelines utilize different systems for grading the strengths of recommendation and quality of the associated evidence. Qualitative (descriptive) recommendations are from reference 16; letter- and roman numeral-based recommendations are from the other cited guidelines. Readers are advised to consult the original documents for full explanations of the grading systems and definitions used in individual guidelines.

Strength of recommendation: A, good evidence for use; B, moderate evidence for use; C, poor evidence for use, optional; D, moderate evidence to support not using; E, good evidence to support not using. *Quality of evidence*: I, evidence from ≥1 properly randomized controlled trials; II, evidence from ≥1 well-designed clinical trials without randomization, case–control analytic studies, multiple time series, or dramatic results from uncontrolled experiments; III, evidence from expert opinion, clinical experience, descriptive studies, or reports of expert committees.

Qualitative (descriptive) recommendations: *Strong, high*: strong recommendation, high-quality evidence from well-performed randomized controlled trials (RCTs) or exceptionally strong evidence from unbiased observational studies; *Strong, moderate*: strong recommendation, moderate quality evidence from RCTs with important limitations or exceptionally strong evidence from unbiased observational studies; *Strong, low*: strong recommendation, low-quality evidence for at least 1 critical outcome from observational studies, RCTs with serious flaws, or indirect evidence; *Weak, moderate*: weak recommendation, moderate quality evidence from RCTs with important limitations or exceptionally strong evidence from unbiased observational studies; *Weak, low*: weak recommendation, low-quality evidence for at least one critical outcome from observational studies, RCTs with serious flaws, or indirect evidence.

TABLE 110-4 Recommended Oral Drugs for Outpatient Treatment of Mild–Moderate Skin and Soft-Tissue Infections

Infection	Adults	Children
Folliculitis	None; warm saline compresses usually sufficient	

Infection	Adults	Children
Furuncles and carbuncles	Trimethoprim–sulfamethoxazole[a,b] Doxycycline[a,b] Minocycline[a,b] Procaine penicillin G	Trimethoprim–sulfamethoxazole[a,b] Clindamycin[a,b]
Erysipelas	Penicillin VK Clindamycin[a] Erythromycin[a]	Penicillin VK Clindamycin[a] Erythromycin[a]
Impetigo	Mupirocin ointment[a] Retapamulin ointment[a] Dicloxacillin Cephalexin Trimethoprim–sulfamethoxazole[a,b] Clindamycin[a,b] Doxycycline[a,b]	Mupirocin ointment[a] Retapamulin ointment[a] Dicloxacillin Cephalexin Trimethoprim–sulfamethoxazole[a,b] Clindamycin[a,b]
Lymphangitis	Initial IV therapy, followed by penicillin VK Clindamycin[a]	Initial IV therapy, followed by penicillin VK Clindamycin[a]
Diabetic foot infections	Dicloxacillin Clindamycin Cephalexin Amoxicillin–clavulanate Levofloxacin ± metronidazole or clindamycin[a,c] Ciprofloxacin ± metronidazole or clindamycin[a,c] Moxifloxacin	
Bite wounds (animal or human)	Amoxicillin–clavulanate Doxycycline[a]	Amoxicillin–clavulanate Trimethoprim–sulfamethoxazole +

Infection	Adults	Children
	Moxifloxacin[a]	
	Trimethoprim–sulfamethoxazole + metronidazole or clindamycin[a]	metronidazole or clindamycin[a]
	Levofloxacin or ciprofloxacin + metronidazole or clindamycin[a]	Cefuroxime axetil + metronidazole or clindamycin
	Cefuroxime axetil + metronidazole or clindamycin	Dicloxacillin + penicillin VK
	Dicloxacillin + penicillin VK	

[a]May be used in patients with penicillin allergy.

[b]Recommended if CA-MRSA is suspected.

[c]Fluoroquinolone alone may be suitable for mild infections, while addition of drugs with antianaerobic activity may be recommended for more severe infections.

Evaluation of Therapeutic Outcomes

Many follicular infections resolve spontaneously without medical or surgical intervention. Lesions should be incised if they do not respond to a few days of moist heat and nonprescription topical agents. Following drainage, most lesions begin to heal within several days without antimicrobial therapy. Any patient who is unresponsive to several days of systemic antibiotic therapy or suffers recurrent infection should have a culture and sensitivity test performed to guide continued antibiotic selection.

ERYSIPELAS

2 Erysipelas is a distinct form of cellulitis involving the more superficial layers of the skin and cutaneous lymphatics.[5,12,22,30] The intense red color and burning pain associated with this skin infection led to the common name of "St. Anthony's fire." The infection is almost always caused by *β*-hemolytic streptococci, with the organisms gaining access via small breaks in the skin. Group A streptococci (*S. pyogenes*) are responsible for most infections.[3,15,22] Infections are more common in infants, young children, the elderly, and patients with nephrotic syndrome.[3,6] Erysipelas also commonly occurs in areas of preexisting lymphatic obstruction or edema.[3,12] Diagnosis is made on the basis of the characteristic lesion.

TREATMENT

Erysipelas

Desired Outcomes

The goal of treatment of erysipelas is rapid eradication of the infection, thereby providing relief of symptoms (pain, tenderness, fever).[30] Preventing recurrent infection is also important, as recurrence is a primary complication, occurring in approximately 20% of patients.[22,30] Treatments should be effective and inexpensive and have minimal adverse effects.

Treatment

Mild to moderate cases of erysipelas are treated with intramuscular procaine penicillin G or penicillin VK for 7 to 10 days (see Table 110-4).[3,22] Recommended doses and monitoring parameters for selected antibiotics are given in **Tables 110-5** and **110-6**. Penicillin-allergic patients can be treated with clindamycin. For more serious infections, the patient should be hospitalized and aqueous penicillin G administered IV.[3,22] Marked improvement usually is seen within 48 hours, and the patient often may be switched to oral penicillin to complete the course of therapy. Although one study has shown that the median time for cure, IV antibiotics, and hospital stay was reduced in patients receiving prednisolone in addition to antibiotics, further studies are needed before corticosteroids can be recommended for routine use.[3,15,31]

TABLE 110-5 Drug Dosing Table[a]

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Oral Agents					
Amoxicillin–clavulanate	Augmentin®	875/125 mg orally two times daily	875/125 mg orally two times daily	Pediatric: 40 mg/kg (of the amoxicillin component) orally in two divided doses	
Cefaclor	Ceclor®	500 mg orally every 8 hours	500 mg orally every 8 hours	Pediatric: 20-40 mg/kg/day (not to exceed 1 g) orally in three divided doses	
Cefadroxil	Duricef®	500 mg orally every 12 hours	250-500 mg orally every 12 hours	Pediatric: 30 mg/kg orally in two divided doses	
Cefuroxime axetil	Ceftin®	500 mg orally every 12 hours	250-500 mg orally every 12 hours	Pediatric: 20-30 mg/kg orally in two divided doses	
Cephalexin	Keflex®	250-500 mg orally every 6	250-500 mg orally every 6	Pediatric: 25-50 mg/kg orally in	

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
		hours	hours	four divided doses	
Ciprofloxacin	Cipro®	500 mg orally every 12 hours	500-750 mg orally every 12 hours		
Clindamycin	Cleocin®	300-600 mg orally every 6-8 hours	300-600 mg orally every 6-8 hours	Pediatric: 10-30 mg/kg/day orally in three to four divided doses[4]	May be used for oral treatment of MRSA infection
Dicloxacillin	Dynapen®	250-500 mg orally every 6 hours	250-500 mg orally every 6 hours	Pediatric: 25-50 mg/kg orally in four divided doses	
Doxycycline	Vibramycin®	100-200 mg orally every 12 hours	100-200 mg orally every 12 hours		May be used for oral treatment of MRSA infection

Tobramycin	Nebcin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours. Alternative: 5-7 mg/kg IV once daily	Traditional dosing: guided by measured serum concentrations	Pediatric: 5-7 mg/kg/day IV in three divided doses; doses guided by serum concentrations	
Vancomycin	Vancocin®	30-40 mg/kg/day IV in two divided doses	Dosing guided by serum concentrations to achieve trough of 15-20 mg/L	Pediatric: 40-60 mg/kg/day IV in three to four divided doses; doses guided by serum concentrations	For MRSA infection

IM, intramuscularly; MRSA, methicillin-resistant *S. aureus*.

[a]Dosing guidelines in patients with normal renal function.

TABLE 110-6 Drug Monitoring

Drug	Adverse Reaction	Monitoring Parameters	Comments
Aminoglycosides	Nephrotoxicity	Serum creatinine,	Extended-interval (“once-daily”)

Drug	Adverse Reaction	Monitoring Parameters	Comments
(tobramycin, gentamicin)		urine output, serum concentrations	dosing potentially associated with less renal toxicity, similar efficacy to traditional dosing. Goal trough concentration <1 mcg/mL (mg/L; <2 µmol/L) during extended-interval dosing
Daptomycin	Myopathy	Serum creatine phosphokinase	Most creatinine phosphokinase elevations will be asymptomatic; risk of myopathy may be increased with concomitant use of HMG-coA reductase inhibitors
Imipenem–cilastatin	CNS toxicities, seizures	Serum creatinine, mental status, CNS function	Increased incidence with higher dose, failure to adjust dose/interval for reduced renal function. Increased risk compared with meropenem or doripenem
Linezolid	Myelosuppression, thrombocytopenia, optic/peripheral neuropathy, serotonin syndrome	CBC, vision changes, serum lactate, heart rate, blood pressure, temperature, myoclonus	Myelosuppression and neuropathy more common with prolonged use. Weak MAO inhibitor, serotonin syndrome possible with other serotonergic drugs such as SSRIs and SNRIs
Nafcillin	Interstitial nephritis	Serum creatinine, urine output	Reversible, requires switch to alternative β-lactam
Vancomycin	Nephrotoxicity, infusion reactions	Serum creatinine, urine output, blood pressure, heart rate, serum concentrations	Dose adjustment required for renal dysfunction. Pretreatment and slow infusion may decrease incidence of infusion reaction. Goal trough concentration 15-20 mcg/mL (mg/L; 10-14 µmol/L) for serious infections, including necrotizing fasciitis

CBC, complete blood count; MAO, monoamine oxidase; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Evaluation of Therapeutic Outcomes

Erysipelas generally responds quickly to appropriate antimicrobial therapy. Temperature and white blood cell count should return to normal within 48 to 72 hours. Erythema, edema, and pain also should resolve gradually.

IMPETIGO

3 Impetigo is a superficial skin infection that is seen most commonly in children.[6,22,33] The infection is generally classified as bullous or nonbullous based on clinical presentation.[10,33] Impetigo is most common during hot, humid weather, which facilitates microbial colonization of the skin.[3,6,22,33] Minor trauma, such as scratches or insect bites, allows entry of organisms into the superficial layers of skin, and infection ensues.[3,22,26,33] Impetigo is highly communicable and readily spreads through close contact, especially among siblings and children in daycare centers and schools.[3,22,33]

CLINICAL PRESENTATION Erysipelas General

- Lower extremities are the most common sites.

Symptoms

- Flu-like symptoms (fever, chills, malaise) common prior to the appearance of the lesion.
- Infected area described as painful or as a burning pain.

Signs

- Lesion is intensely erythematous and edematous, often with lymphatic streaking.
- Lesion has raised border, which is sharply demarcated from uninfected skin.
- Temperature is often mildly elevated.

Laboratory Tests

- Causative organism usually cannot be cultured from the surface skin.
- Needle aspiration or punch biopsies occasionally identify organism.
- Cultures considered for more severe cases (eg, atypical clinical findings such as fluid-filled blisters).

Other Diagnostic Tests

- A complete blood count is often performed because leukocytosis is common.
- C-reactive protein is also generally elevated.

Although historically caused by *S. pyogenes*, *S. aureus* has emerged as a principle cause of impetigo (either alone or in combination with *S. pyogenes*).[22,33] The bullous form is caused by strains of *S. aureus* capable of producing exfoliative toxins.[22,33] The bullous form most frequently affects neonates,[34] and accounts for approximately 30% of all cases of impetigo.[3,33] Similar to other SSTIs, impetigo has been reported to be increasingly due to MRSA.[22,33]

TREATMENT

Impetigo

Desired Outcomes

The goals of treatment include relieving discomfort, improving the cosmetic appearance of lesions, preventing further spread of the infection, and preventing recurrence. Preventing transmission to others is also important.[22,33] Treatments should be effective and inexpensive and have minimal adverse effects.[33]

Treatment

Although impetigo may resolve spontaneously, antimicrobial treatment is indicated to relieve symptoms, prevent formation of new lesions, and prevent complications such as cellulitis. A review of interventions for impetigo by the Cochrane Collaboration found that topical mupirocin and oral antibiotics (except penicillin and erythromycin) were equally effective for the treatment of impetigo;[34] topical mupirocin ointment or retapamulin ointment for 5 days are now recommended as first-line treatment of mild cases of impetigo not involving multiple lesions or the face.[15,22,33] Penicillinase-resistant penicillins (such as dicloxacillin) are preferred for treatment because of the increased incidence of infections caused by *S. aureus*.[15,22,33] First-generation cephalosporins (eg, cephalexin) are also commonly used.[15,22,33] Penicillin, administered as a single intramuscular dose of benzathine penicillin G or as oral penicillin VK, is effective for infections known to be caused by *S. pyogenes*. Penicillin-allergic patients, or those known to be infected with MRSA, can be treated with clindamycin, doxycycline, or trimethoprim–sulfamethoxazole. The duration of therapy is 7 days.[15] With proper treatment, healing of skin lesions generally is rapid and occurs without residual scarring. Removal of crusts by soaking in soap and warm water also may be helpful in providing symptomatic relief.[3,22,33]

CLINICAL PRESENTATION Impetigo General

- Exposed skin, especially the face, is the most common site.

Symptoms

- Pruritus is common.
- Systemic signs and symptoms of infection are minimal.
- Weakness, fever, and diarrhea occasionally seen with bullous form.

Signs

Nonbullous:

- Lesions start as small, fluid-filled vesicles.

- Vesicles rapidly develop into pustules that rupture readily.
- Purulent discharge dries to form characteristic golden yellow crusts.

Bullous:

- Lesions start as vesicles that rapidly progress into bullae containing clear yellow fluid.
- Bullae soon rupture, forming thin, light brown crusts.
- Regional lymph nodes may be enlarged.

Laboratory Tests

- Cultures should be collected.
- Crusted tops of lesions should be raised to obtain purulent material at the base for culture.
- Open, draining pustules should not be cultured as they may be colonized with skin flora.

Other Diagnostic Tests

- Complete blood count often performed as leukocytosis is common.

Evaluation of Therapeutic Outcomes

Clinical response should be seen within 5-7 days of initiating antimicrobial therapy for impetigo. Treatment failures could be a result of noncompliance or antimicrobial resistance. A followup culture of exudates should be collected for culture and sensitivity, with treatment modified accordingly.

LYMPHANGITIS

4 Acute lymphangitis is an inflammation involving the subcutaneous lymphatic channels. Lymphangitis usually occurs secondary to puncture wounds, infected blisters, or other skin lesions. Most infections are caused by *S. pyogenes*.[35]

TREATMENT

Lymphangitis

Desired Outcomes

The goal of treatment of lymphangitis is rapid eradication of the infection, thereby providing relief of symptoms (pain, tenderness, fever). Prevention of systemic complications is also an important goal as thrombophlebitis and abscess formation are possible. Treatments should be effective and inexpensive and have minimal adverse effects.

Treatment

Penicillin is the antibiotic of choice. Because these infections are potentially serious and rapidly progressive, initial treatment should be with IV penicillin G 1 to 2 million units every 4 to 6 hours. Parenteral treatment should be continued for 48 to 72 hours, followed by oral penicillin VK for a total of 10 days.[35] Nondrug therapy includes immobilization and elevation of the affected extremity and warm-water soaks every 2 to 4 hours.[35] For penicillin-allergic patients, clindamycin may be used.

Evaluation of Therapeutic Outcomes

Lymphangitis usually responds rapidly to appropriate therapy; signs and symptoms often are decreased markedly or absent within 24 hours of starting antibiotics.

CELLULITIS

5 Cellulitis is an acute infectious process that initially affects the epidermis and dermis and may spread subsequently within the superficial fascia.[10] Cellulitis is considered a serious disease because of the propensity of the infection to spread through lymphatic tissue and to the bloodstream. *S. pyogenes* and *S. aureus* are the most frequent bacterial causes.[5,7,12,21,26] However, many bacteria have been implicated in various types of cellulitis (Table 110-1). Approximately 4 million patients were hospitalized for cellulitis between 1998 and 2006, representing 10% of all infection-related admissions.[8,9,36] The rising incidence of infections caused by methicillin-resistant *S. aureus* (MRSA) is a major concern in both the community and hospital settings.[13,14,15,16,17,18]

Injection drug users are predisposed to several infectious complications, including abscess formation and cellulitis at the site of injection.[15] These SSTIs are often polymicrobic in nature and are believed to originate from the skin and/or oropharynx, as well as from contaminated needles, syringes, and diluents.[15] *S. aureus*, including MRSA, is the most common pathogen isolated from injection drug users.[15,6,37] Anaerobic bacteria, especially oropharyngeal anaerobes, are also found commonly, particularly in polymicrobic infections.[15] Outbreaks caused by *Clostridium* species have also been reported in injection drug users.[15]

CLINICAL PRESENTATION Lymphangitis General

- Lymphadenitis (acute or chronic inflammation of the lymph nodes) may occur when microorganisms reach the lymph nodes.

Symptoms

- Systemic signs and symptoms (ie, fever, chills, malaise, and headache) often develop rapidly before any sign of infection is evident at the initial site of inoculation, or after the initial lesion has subsided.
- Systemic signs and symptoms often are more profound than would be expected based on

examination of the cutaneous lesion.

Signs

- Peripheral lesion associated with proximal red linear streaks directed toward the regional lymph nodes is diagnostic of acute lymphangitis.
- Lymph nodes usually are enlarged and tender.
- Peripheral edema of the involved extremity often is present.
- Thrombophlebitis and acute lymphangitis in the lower extremities may be confused because both are associated with red linear streaking and tender areas; however, in thrombophlebitis, no portal of entry is identifiable.

Laboratory Tests

- Cultures of the affected lesions often yield negative results.
- Pathogens often identified by Gram stain of the initial lesion if done early in the course of the disease.

Other Diagnostic Tests

- Complete blood count often performed as leukocytosis is common.

CLINICAL PRESENTATION Cellulitis General

- Usually a history of an antecedent wound from minor trauma, abrasion, ulcer, or surgery.

Symptoms

- Patients often experience fever, chills, or malaise and complain that the affected area feels hot and painful.
- Systemic findings such as hypotension, dehydration, and altered mental status are common.

Signs

- Characterized by erythema and edema of the skin.
- Lesions are nonelevated and have poorly defined margins.
- Affected areas generally are warm to touch.
- Inflammation generally is present with little or no necrosis or suppuration of soft tissue.
- Lesions may be associated with purulent drainage, exudates, and/or abscesses.
- Tender lymphadenopathy associated with lymphatic involvement is common.

Laboratory Tests

- Cultures should be collected when possible.
- Gram stain of fluid obtained by injection and aspiration of 0.5 mL of saline (using a small 22-gauge needle) into the advancing edge of the lesion may aid the microbiologic diagnosis but often yields negative results.
- Diagnosis usually is made on clinical grounds rather than by culture.

Other Diagnostic Tests

- Complete blood count often performed as leukocytosis is common.
- Blood cultures often useful because bacteremia may be present in up to 30% of cases.

Acute cellulitis with mixed aerobic and anaerobic pathogens may occur in diabetics, following traumatic injuries, at sites of surgical incisions to the abdomen or perineum, or where host defenses have been otherwise compromised (vascular insufficiency).[6,10,26] In older patients, cellulitis of the lower extremities also may be complicated by thrombophlebitis. Other complications of cellulitis include local abscess, osteomyelitis, and septic arthritis.[15,38]

TREATMENT

Cellulitis

Desired Outcomes

The goals of therapy of acute bacterial cellulitis are rapid eradication of the infection and prevention of further complications. Effective treatment of cellulitis includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Drug and Nondrug Management of Cellulitis

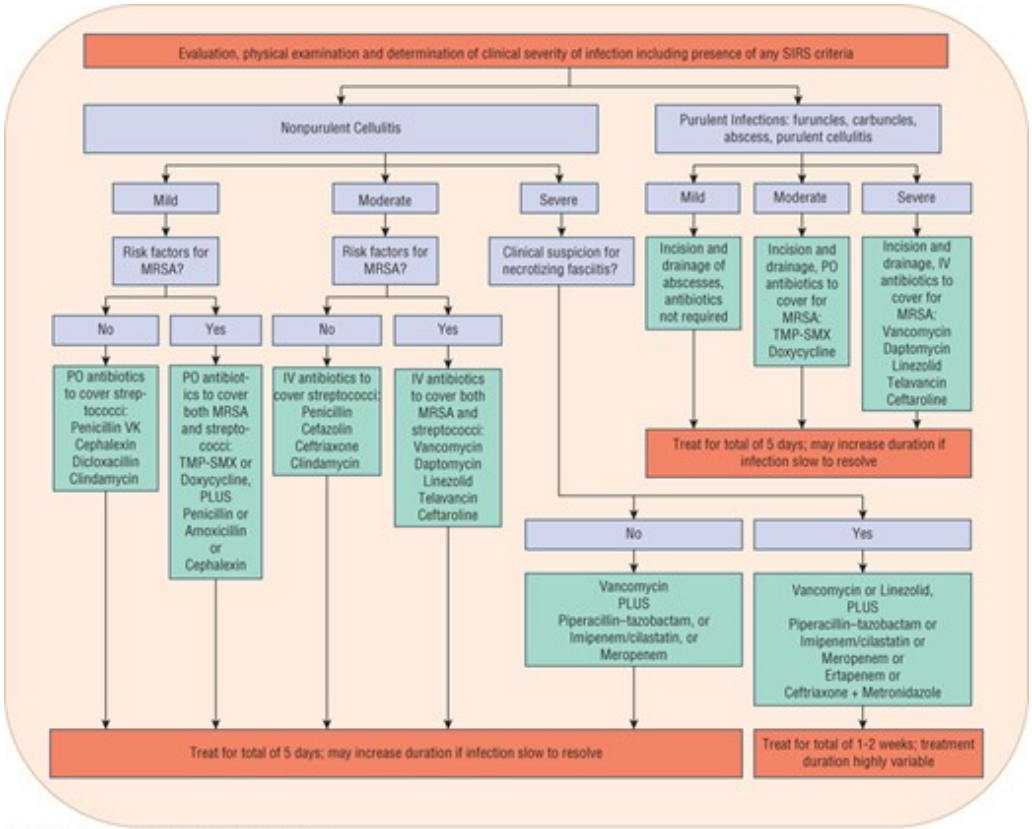
Local care of cellulitis includes elevation and immobilization of the involved area to decrease swelling.[5,15,38] Cool sterile saline dressings may decrease pain and can be followed later with moist heat to aid in localization of the cellulitis. Surgical intervention (incision and drainage) as a mode of therapy is rarely indicated in the treatment of uncomplicated cellulitis, but may play an important role in management of more severe or complicated cases. Antimicrobial therapy is directed against the type of bacteria either documented or suspected to be present based on the clinical presentation. Particular attention must be paid to patients with risk factors for more atypical or resistant bacterial pathogens when selecting antibiotics for treatment of cellulitis. Such organisms include particularly MRSA, but also aerobic gram-negative bacteria and anaerobes.

Because staphylococcal and streptococcal cellulitis are indistinguishable clinically,[21,38] and because of concern regarding appropriate recognition and treatment of MRSA infections, guidelines from the

Infectious Diseases Society of America provide detailed recommendations for empiric antibiotic therapy of cellulitis.[15,28] Antibiotic selection for treatment of cellulitis is chiefly determined by clinical findings such as appearance of the infected lesion and presence of more severe systemic illness. Cellulitis may be broadly classified as either purulent or nonpurulent for purposes of determining likely pathogens and appropriate empiric antibiotic therapy. Purulent cellulitis is defined as infection associated with purulent drainage or exudate in the absence of a simple drainable abscess; the presence of abscesses are also often associated with purulent cellulitis but by definition that is not the only clinical feature.[15,28] Incision and drainage of any abscesses and good wound care are the primary therapies for mild purulent infections when no systemic findings of infection are present. Systemic antibiotic therapy is often unnecessary in such cases.[15,28] Antibiotic therapy is recommended along with incision and drainage in patients with more complicated abscesses and/or moderately severe purulent cellulitis including the following: those with systemic signs of infection; multiple sites of infection; rapidly progressive infection in the presence of associated cellulitis; complicating factors such as extremes of age, comorbidities, or immunosuppression; abscesses in areas that are difficult to drain, such as hands, face, and genitalia; or lack of response to previous drainage alone.[15,28,38,40,41,42,43] Such patients are usually treated as outpatients using orally administered antibiotics with activity against MRSA; infection due to streptococci is less likely in this situation and specific coverage is not required.[28,44,45,46] Oral agents recommended for moderate purulent cellulitis include trimethoprim–sulfamethoxazole and doxycycline (**Fig. 110-1**).[15] Oral linezolid is also recommended in such cases but is significantly more expensive and apparently no more efficacious than other treatment options.[28] Tedizolid, a newer oxazolidinone, is also indicated for the treatment of complicated SSTI but the relative advantages or role of tedizolid compared to linezolid have not been well established.[15]

FIGURE 110-1

Recommended treatment algorithm for initial empiric management of selected purulent and nonpurulent skin and soft tissue infections. (GNR, aerobic gram-negative rods; GPC, aerobic gram-positive cocci; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; PO, oral; SIRS, systemic inflammatory response syndrome; TMP-SMX, trimethoprim–sulfamethoxazole.)



Severe purulent cellulitis is defined as purulent infections occurring in patients who have failed incision and drainage plus oral antibiotic therapy, patients with systemic signs of infection (defined as temperature more than 38°C, heart rate more than 90 beats/minute, respiratory rate more than 24 breaths/minute, or white blood cell count more than 12,000 or less than 400 cells/μL[less than 12 × 10^9/L or <0.4 × 10^9/L]), or immunocompromised patients. Appropriate clinical specimens for culture and susceptibility testing should be collected whenever possible in such patients.[5,15,28,38] Patients with severe purulent cellulitis should be hospitalized for empiric treatment with parenteral antibiotics having activity against MRSA. Vancomycin, daptomycin, linezolid, televancin, and ceftaroline are all acceptable treatment options with comparable efficacy in adults (Fig. 110-1).[3,15,28,47] In children, vancomycin, linezolid, or clindamycin is the preferred treatment option.[15]

Linezolid, tedizolid, daptomycin, ceftaroline, and telavancin all exhibit excellent activity against resistant gram-positive pathogens.[40,41,42,43,47] However, significantly higher cost compared with vancomycin, as well as lack of demonstrated advantages in efficacy, makes them most appropriate for the treatment of complicated or refractory infections, or those documented as caused by multidrug-resistant pathogens, rather than as initial therapy. The availability of orally administered linezolid and tidezolid may provide cost-effective "step-down" options as alternatives to prolonged treatment with parenteral agents for many patients with more complicated infections and/or those patients who require initial hospitalization.[44]

Carbapenems (ie, imipenem, meropenem, ertapenem, and doripenem) and the β-lactam–β-lactamase inhibitor combination antibiotics (ampicillin–sulbactam, ticarcillin–clavulanate, and piperacillin–

tazobactam) appear to be equivalent to standard therapies in adults.[3,5,15,38] However, the greater cost of these agents without increased efficacy compared with other reliable regimens, particularly given the increasing problem of MRSA, makes them less desirable for empiric therapy except in serious polymicrobic infections.[5,15,38]

Clinical Controversy…

The appropriate roles of dalbavancin and oritavancin, two newer drugs indicated for the treatment of complicated SSTI and with good activity against MRSA, are not well defined at this time. Dalbavancin exhibits a terminal elimination half-life of approximately 14 days and is administered as only two doses given one week apart, while oritavancin has a half-life of approximately 10 days and is administered as a single one-time dose. The ability to provide an entire course of therapy with only one or two doses is attractive in terms of convenience, negating any drug adherence concerns with oral therapy, and potentially saving hospitalization costs with administration of effective therapy in the emergency department or even outpatient physician offices. However, the drugs are expensive compared to other treatment options and there are concerns related to potential lack of patient follow-up for monitoring of their infection. The most appropriate roles of these drugs in the routine management of cellulitis and other complicated SSTIs have yet to be determined.

Nonpurulent cellulitis ("typical cellulitis") is defined as cellulitis without purulent drainage or exudate and no associated abscess. The role of MRSA in these types of infection is not clear, so empiric therapy of nonpurulent cellulitis is directed primarily against Group A β-hemolytic streptococci.[48] Recommended empiric therapy of mild nonpurulent cellulitis (ie, no focus of purulence or systemic signs of infection) consists of an orally administered β-lactam such as penicillin VK, cephalexin or dicloxacillin (Fig. 110-1).[15,28,38] Oral cephalosporins, such as cefadroxil, cefaclor, cefprozil, cefpodoxime proxetil, and cefdinir, are also effective in the treatment of cellulitis but are more expensive.[15,38] Oral clindamycin may be used in penicillin-allergic patients.[15,28,38] Alternatively, a first-generation cephalosporin may be used cautiously for patients without a history of immediate or anaphylactic reactions to penicillin. Patients with moderately severe nonpurulent cellulitis (ie, systemic evidence of infection) or poor adherence to oral therapy should be hospitalized and treated with parenteral antibiotics directed against Group A streptococci. Recommended agents include penicillin VK, ceftriaxone, cefazolin, and clindamycin.[15,48] Hospitalization and treatment with parenteral antibiotics are also recommended for patients with severe nonpurulent cellulitis as indicated by the presence of systemic findings of infection (as previously defined for purulent cellulitis), failure of previous oral antibiotic therapy, immunocompromised states, or presence of clinical signs of deeper infection such as bullae, skin sloughing, hypotension, or organ dysfunction.[15] Empiric antibiotics for severe nonpurulent cellulitis should provide a broad spectrum of activity against MRSA and streptococci, as well as gram-negative and anaerobic bacteria. Recommended regimens include vancomycin plus piperacillin–tazobactam, and vancomycin plus imipenem-cilastatin or meropenem.

Empiric treatment of MRSA should be considered for patients with either moderate or severe nonpurulent cellulitis that is associated with penetrating trauma, evidence of MRSA infection at another site or nasal colonization with MRSA, injection drug use, or in patients meeting SIRS criteria (fever, tachycardia, tachypnea, or leukocytosis or leukopenia as previously defined).[15,28]

Recommended drugs for the coverage of MRSA in this setting are the same as those for purulent cellulitis. Clindamycin has reasonably good activity against β-hemolytic streptococci, but the activities of trimethoprim–sulfamethoxazole and the tetracyclines against this organism are not well defined.[28] Therefore, if empiric coverage of both MRSA and β-hemolytic streptococci is desired for patients with nonpurulent cellulitis, they should receive clindamycin alone or amoxicillin in combination with trimethoprim–sulfamethoxazole, doxycycline, or minocycline.[28] Hospitalized patients with nonpurulent cellulitis who are not initially treated for MRSA should have their antibiotic changed to an agent with activity against MRSA if there is unsatisfactory clinical response.[28] Although often used for treatment of uncomplicated outpatient cellulitis, fluoroquinolones (eg, levofloxacin, moxifloxacin) are not recommended for routine use due to their unnecessarily broad spectrum of activity, concerns for resistance, and higher cost compared with other preferred options.

Clinical Controversy…

The administration of systemic corticosteroids (eg, prednisone 40 mg daily for 7 days) has been recommended as a potential option for adjunctive treatment of cellulitis in nondiabetic patients. Since patients who are immunocompromised are at increased risk of severe SSTI and also potentially resistant pathogens such as MRSA, the notion of administering immunosuppressant agents such as corticosteroids to patients with cellulitis seems counterintuitive and even potentially harmful. However, a randomized, double-blind, placebo-controlled trial found that administration of oral corticosteroids plus antibiotics was associated with favorable outcomes including more rapid resolution of the infection without increased risk of relapse or recurrence.[32] Additional studies are needed to define the optimal role of corticosteroids in the treatment of cellulitis.

Patients in whom specific pathogens have been identified by culture should have empiric antibiotics narrowed according to susceptibility test results. If documented to be a mild cellulitis secondary to streptococci, oral penicillin VK or intramuscular procaine penicillin G may be administered. Since *S. aureus* susceptibilities are more variable, treatment of documented staphylococcal infections will depend on test results for specific isolates. The usual duration of therapy for outpatient treatment of cellulitis, either purulent or nonpurulent, is 5 days; a longer duration should be considered if the infection has not sufficiently improved within that time.[3,15,38] A 7 to 14 day course of antibiotics has been recommended for cellulitis in hospitalized patients, but shorter courses (5 to 7 days) are often as effective as longer courses and should be used whenever possible.[15] In all cases, duration of therapy should be individualized based on patient response.[15,28]

For cellulitis caused by gram-negative bacilli or a mixture of microorganisms, immediate antimicrobial chemotherapy, as determined by Gram stain, is essential. Surgical debridement of necrotic tissue and drainage also may be appropriate. Gram-negative cellulitis may be treated appropriately with an aminoglycoside (such as gentamicin or tobramycin), or a first- or second-generation cephalosporin (eg, cephalexin, cefaclor, or cefuroxime). Ceftriaxone, ceftazidime, and the fluoroquinolones are also effective in the treatment of cellulitis caused by both gram-negative and gram-positive bacteria.[3,5,15,38] If gram-positive aerobic bacteria are also present on Gram stain, an additional agent such as penicillin G or a penicillinase-resistant penicillin may need to be added to provide coverage against staphylococci or streptococci as appropriate.[28] Addition of an agent active

against MRSA (eg, vancomycin) may need to be considered for severe, complicated infections in hospitalized patients.[3,5,15,28,38] Ceftaroline is potentially advantageous in this setting since it has activity against MRSA and streptococci as well as gram-negative aerobic bacteria.

Because some polymicrobic infections may also involve anaerobic bacteria, antibiotic therapy may need to be broadened to include agents with good activity against these organisms. Many different treatment regimens are possible depending on the bacteriology of the lesion (Fig. 110-1). Orally administered antibiotics, as monotherapy or in combination regimens, may be appropriately used in the treatment of mild to moderate infections in outpatients. Monotherapy or combination regimens of IV antibiotics may be necessary for more severe infections in hospitalized patients. Therapy should be 5 to 7 days in duration, with longer durations potentially needed in patients who do not respond to therapy in that time.[3,15,38]

Because gram-negative and mixed aerobic–anaerobic cellulitis can progress quickly to serious tissue invasion, therapeutic intervention should be immediate.[3,15,38] If treated early, a rapid response can be seen. Unfortunately, because these infections often occur in patients with compromised immune defenses, they may still progress, even with therapeutic intervention. If the infectious process is secondary to a systemic cause (eg, diabetes), the treatment course often is prolonged and may be associated with high morbidity and mortality.[3,15,38]

Infections in injection drug users generally are treated similarly to those in other types of patients.[3,15,38] It is important that blood cultures be obtained in these cases because 25% to 35% of patients may be bacteremic.[3,15] Also, patients should be assessed for the presence of abscesses; incision, drainage, and culture of these lesions are of extreme importance.[15] Initial antimicrobial therapy while awaiting culture results of abscesses should include broad coverage for gram-negative and anaerobic organisms, in addition to MRSA and streptococci.[3,15,38]

Evaluation of Therapeutic Outcomes

If treated promptly with appropriate antibiotics, the majority of patients with cellulitis are cured rapidly. Culture and sensitivity results should be evaluated carefully for both the adequacy of culture material and the presence of resistant organisms. Additional high-quality samples for culture may be needed for microbiologic analysis. Failure to respond to therapy also may be indicative of an underlying local or systemic problem or a misdiagnosis.

NECROTIZING SOFT-TISSUE INFECTIONS

Necrotizing soft-tissue infections consist of a group of extremely severe infections, associated with high morbidity and mortality, that require early and aggressive surgical debridement in addition to appropriate antibiotics and intensive supportive care.[4,7,49,50,51,52] Different terms have been used to classify necrotizing infections based on factors such as predisposing conditions, onset of symptoms, pain, skin appearance, etiologic agent, gas production, muscle involvement, and systemic toxicity.[5,26,50] However, while many types of necrotizing soft-tissue infections have been designated

as unique infectious processes, they all share similar pathophysiologies, clinical features, and treatment approaches.[49,50,51,52] The major clinical entities of necrotizing infections are *necrotizing fasciitis* and *clostridial myonecrosis* (gas gangrene).[49,50,51]

6 Necrotizing fasciitis is a rare but severe infection of the subcutaneous tissue that may be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat.[3,5,12,50,51] Type I necrotizing fasciitis is the most common and accounts for approximately 80% of necrotizing soft-tissue infections.[50,51] It generally occurs after trauma or surgery and involves a mixture of anaerobes (*Bacteroides*, *Peptostreptococcus*) and facultative bacteria (streptococci and Enterobacteriaceae) that act synergistically to cause destruction of fat and fascia.[7,50] Type I necrotizing fasciitis is also reported more commonly among injection drug users.[49,50,51,52] In type I infections, the skin may be spared, and the speed at which the infection spreads (3 to 5 days) is somewhat slower than that in type II.[26] Necrotizing fasciitis affecting the male genitalia is termed *Fournier gangrene*.[50] Type II necrotizing fasciitis is caused by virulent strains of *S. pyogenes* and is commonly referred to as *streptococcal gangrene*.[7,50] This type of infection has often been called "flesh-eating bacteria" by the lay press. Unlike previous reports of streptococcal gangrene that affected older individuals with underlying diseases, recent reports have occurred primarily in young, previously healthy adults following some type of minor trauma. It differs from type I infections in its clinical presentation. Type II infections have rapidly extending necrosis (ie, 24 to 72 hours) of subcutaneous tissues and skin, gangrene, severe local pain, and systemic toxicity.[26,49,50,51,52] They are also highly associated with an early onset of shock and organ failure and are present in approximately half the cases of streptococcal toxic shock-like syndrome.[26,49,50] Of note, MRSA is increasingly reported in type II infections, either as a single organism or in combination with streptococci.[9,50,51] Clinicians should consider MRSA in areas that are endemic for MRSA or if patients have risk factors for these organisms.

Clostridial myonecrosis (type III necrotizing fasciitis) is a necrotizing infection that involves the skeletal muscle.[9,50] Type III infections account for less than 5% of necrotizing infections.[50] Gas production and muscle necrosis are prominent features of this infection, which readily explains why this infection is commonly referred to as *gas gangrene*.[49,50,51] The infection advances rapidly, often over a matter of a few hours.[49,50,51] Most infections occur after surgery or trauma, with *Clostridium perfringens* identified as the most common etiologic agent.[50]

TREATMENT

Necrotizing Soft-Tissue Infections

Desired Outcomes

The goals of therapy of acute bacterial cellulitis are rapid eradication of the infection, prevention of further complications, and reduction in mortality. Effective treatment of necrotizing soft-tissue infections includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Management of Necrotizing Infections

Immediate and aggressive surgical debridement of all necrotic tissues is essential in all patients with suspected or confirmed necrotizing fasciitis.[9,15,49,50,51,52,53] Initial surgical debridement performed greater than 14 hours after the diagnosis of necrotizing infection was independently associated with increased patient mortality, including a 34-fold increased risk of death in patients with septic shock.[53] Patients often require further surgical intervention following initial debridement to ensure that all necrotic tissue has been removed.[15,49,50,51,52,53] Type I necrotizing fasciitis must be empirically treated with broad-spectrum antibiotics that include coverage against streptococci, Enterobacteriaceae, and anaerobes. Piperacillin–tazobactam plus vancomycin is specifically recommended as appropriate empiric therapy of necrotizing fasciitis, although a number of antibiotic regimens are also appropriate to successfully treat necrotizing soft-tissue infections (see Fig. 110-1). These antibiotic regimens are generally similar to regimens used for polymicrobic cellulitis.[3,49,50,51,52] Antibiotic therapy can be modified after Gram stain and culture reports are available.

If a diagnosis of either type II (streptococcal) or type III (clostridial) necrotizing fasciitis is established, broad-spectrum empiric therapy should be replaced with the combination of penicillin plus clindamycin.[15,49,50,51] Although *S. pyogenes* remains susceptible to penicillin, the combination with clindamycin is more effective.[49,51] Several factors have been postulated to explain the greater efficacy of clindamycin, including the mechanism of action (inhibition of protein synthesis) that may cause decreased production of bacterial exotoxins.[49,50,51,52] In addition, clindamycin has immunomodulatory properties that may account for the higher efficacy.[49,51] Clindamycin is also effective against strains of MRSA.[50] Hyperbaric oxygen is potentially beneficial for clostridial myonecrosis, but its use is not currently recommended due to lack of clear evidence of improved patient outcomes.[15,49,50,51,52] Likewise, the use of intravenous immunoglobulin (IVIG) has not yet been proven beneficial in the treatment of necrotizing streptococcal infections and its use is not routinely recommended.[15]

Evaluation of Therapeutic Outcomes

Because of the high mortality associated with necrotizing infections, rapid and complete debridement of all devitalized and necrotic tissue is essential. Surgical debridement, coupled with appropriate antimicrobial therapy and supportive measures for management of shock and organ failure, should stabilize the patient. Vital signs and laboratory tests should be monitored carefully for signs of resolution of the infection. Change in antimicrobial therapy or additional surgical debridement may be needed in patients who do not show signs of improvement.

CLINICAL PRESENTATION Necrotizing Infections General

- Most frequently involve the abdomen, perineum, and lower extremities.
- Predisposing factors such as diabetes mellitus, local trauma or infection, or recent surgery often present.

- Rapid diagnosis is critical due to the aggressive nature and high associated mortality (20% to 50%).

Symptoms

- Systemic symptoms generally are marked (eg, fever, chills, and leukocytosis) and may include shock and organ failure, especially in patients with type II infections.
- Pain in the affected area and systemic toxicity are characteristically more pronounced than with cellulitis.

Signs

- May be difficult to differentiate between necrotizing fasciitis and cellulitis early in infection.
- Affected area is initially hot, swollen, and erythematous without sharply demarcated margins.
- Affected area is often shiny, exquisitely tender, and painful.
- Diffuse swelling of the area is followed by the appearance of bullae filled with clear fluid.
- Rapidly progressive infection with the frequent development of a maroon or violaceous color of the skin after several days.
- Infection may rapidly evolve into a frank cutaneous gangrene, sometimes with myonecrosis.

Laboratory Tests

- Tissue samples should be obtained for histologic examination, and culture and susceptibility testing.
- Clostridial myonecrosis shows little inflammation on histologic examination.

Other Diagnostic Tests

- Surgical exploration is the best and most rapid diagnosis of necrotizing infections; computed tomography and magnetic resonance imaging may also be helpful.
- Blood samples should be collected for complete blood count and chemistry profile, as well as for bacterial culture.
- Laboratory tests that may aid in the diagnosis of necrotizing infections (LRINEC score) include C-reactive protein, white blood cell count, hemoglobin, sodium, creatinine, and glucose.

DIABETIC FOOT INFECTIONS

Three major types of foot infections are seen in diabetic patients: deep abscesses, cellulitis of the dorsum, and mal perforans ulcers.[54,55] Most deep abscesses involve the central plantar space (arch)

and are caused by minor penetrating trauma or by an extension of infection of a nail or web space of the toes. Infections of the dorsal area generally arise from infections in the toes that are related to routine care of the nails, nail beds, and calluses of the toes. Mal perforans ulcer is a chronic ulcer of the sole of the foot. The ulcer develops on thickened, hardened calluses over the first or fifth metatarsal. Mal perforans ulcers are associated with neuropathic changes, which are responsible for the misalignment of the weight-bearing bones of the foot.[54,55] Osteomyelitis is one of the most serious complications of diabetic foot infection (DFI) and may occur in 30% to 40% of infections.[27,54]

Epidemiology

DFI is among the most common complications of diabetes, accounting for as many as 20% of all hospitalizations in diabetic patients at an annual cost of $200 to $350 million.[27,54,56] Approximately 15% of diabetic patients experience significant soft-tissue infection during their lifetime.[56] Approximately 71,000 lower-extremity amputations, often sequelae of uncontrolled infection, are performed each year on diabetic patients; this represents up to 70% of all nontraumatic amputations in the United States.[27,54,56] Approximately 20% of diabetics will undergo additional surgery or amputation of a second limb within 12 months of the initial amputation.[27,54]

Etiology

Mild cases of DFI are often monomicrobial. However, more severe infections are typically polymicrobic; up to 60% of hospitalized patients have polymicrobial infections (**Table 110-7**).[27,54,55,57,58,59,60,61,62] Wide ranges in the frequency of various bacteria in DFI reflect differences in culture techniques as well as variation among different types and severity of infections. Staphylococci and streptococci are the most common pathogens, although gram-negative bacilli and/or anaerobes occur in up to 50% of cases.[27,57,58,59,60,61,62] Although *P. aeruginosa* is an important pathogen in DFI, it is usually reported to occur in <10% of wounds and is most commonly associated with more severe infections.[27,58] Obligate anaerobes are also more commonly associated with severe infections in patients with chronic foot ischemia.[27,57,58] MRSA is increasingly important in DFI and has been reported in 10% to 30% of infected wounds.[27,58,59,62,63,64] The presence of MRSA in DFI has been associated with increased risk of treatment failure and worse patient outcomes, but these findings have not been consistent among studies and the clinical relevance of MRSA in this setting is still unclear.[27,55,63]

TABLE 110-7 Bacterial Isolates from Foot Infections in Diabetic Patients[27,54,55,57,58,59,60,61,62,63,65]

Organisms	Percentage of Lsolates
Aerobes	63-100
Gram-positive	24-100
Staphylococcus aureus (all)	10-80
S. aureus (MRSA)	1-37
Streptococcus spp.	3-37

Organisms	Percentage of Lsolates
Enterococcus spp.	2-25
Coagulase-negative staphylococci	6-10
Other gram-positive aerobes	0-19
Gram-negative	16-73
Proteus spp.	3-7
Enterobacter spp.	1-9
Escherichia coli	3-10
Klebsiella spp.	1-6
Pseudomonas aeruginosa	1-48
Other gram-negative bacilli	3-13
Anaerobes	1-40
Peptostreptococcus spp.	4-28
Bacteroides fragilis group	2-9
Other *Bacteroides* spp.	3-6
Clostridium spp.	0-2
Other anaerobes	7-19

Identifying causative pathogens from cultures of diabetic wounds is often difficult. The chronic nature of DFI means that these wounds are often heavily colonized by organisms not playing a role in the infection. Superficial swab cultures are not as reliable as culture specimens obtained from deep tissues via biopsy, tissue scraping (curettage), or needle aspiration of drainage or abscess fluid.[59,62] Therefore, cultures and sensitivity tests should be done with specimens obtained from a deep culture of the wound base whenever possible. Before the wound is cultured, it should be scrubbed vigorously with saline-moistened sterile gauze to remove any overlying necrotic debris and further debrided as necessary.[27,59] Bone cultures should also be performed when there is diagnostic uncertainty regarding the presence of osteomyelitis or when therapeutic decisions are dependent on knowing the exact etiology of infection.[27,59]

Pathophysiology

Three key factors are involved in the development of diabetic foot problems: neuropathy, angiopathy and ischemia, and immunologic defects. Any of these disorders can occur in isolation; however, they frequently occur together.[56]

Neuropathic changes to the autonomic nervous system as a consequence of diabetes may affect the motor nerve supply of small intrinsic muscles of the foot, resulting in muscular imbalance, abnormal stresses on tissues and bone, and repetitive injuries.[54,56] Diminished sensory perception causes an absence of pain and unawareness of minor injuries and ulceration. The sympathetic nerve supply may be damaged, resulting in an absence of sweating that may lead to dry cracked skin and secondary infection.[27,54,56]

Atherosclerosis is more common, appears at a younger age, and progresses more rapidly in the diabetic than in the nondiabetic. Diabetics may have problems with both small vessels (microangiopathy) and large vessels (macroangiopathy) that can result in varying degrees of ischemia, ultimately leading to skin breakdown and infection.

Diabetic patients typically have normal humoral immunity, normal levels of immunoglobulins, and normal antibody responses. Patients with diabetes, however, have impaired phagocytosis and intracellular microbicidal function as compared with nondiabetics; this may be related to angiopathy and low tissue levels of oxygen.[27,54,56] These defects in cell-mediated immunity make patients with diabetes more susceptible to certain types of infection and impair the patients' ability to heal wounds adequately.[54,55,56]

TREATMENT

Diabetic Foot Infections

Desired Outcomes

7 The goals of therapy in the management of DFI include the following: (a) successfully treat infected wounds by using effective nondrug and antibiotic therapy; (b) prevent additional infectious complications; (c) preserve as much normal limb function as possible; (d) avoid unnecessary use of antimicrobials that contribute to increased resistance; and (e) minimize toxicities and cost while increasing patient quality of life.

MANAGEMENT

Up to 90% of infections can be treated successfully with a comprehensive treatment approach that includes both wound care and antimicrobial therapy.[27,55,59,60] After carefully assessing the extent of the lesion and obtaining necessary cultures, necrotic tissue must be thoroughly debrided, with wound drainage and amputation as required. Wounds must be kept clean and dressings changed frequently (two to three times daily). Because of the relationship between hyperglycemia and immune system defects, glycemic control must be maximized to ensure optimal wound healing. In addition, the patient's activities should be restricted initially to bedrest for leg elevation and control of edema, if present. Adequate pressure relief from a foot wound (ie, off-loading) is crucial to the healing process.[27,56,59] Finally, appropriate antimicrobials must be initiated.[27,55,56,59,60] However, the optimal antimicrobial therapy for DFI has yet to be defined. Empiric therapy that is totally comprehensive in its coverage of all possible pathogens does not seem to be necessary unless the infection is life- or limb-threatening, assuming that adequate wound care is also being performed.[27,55,59,60] This is particularly true regarding MRSA, *P. aeruginosa*, and anaerobes; the perceived need for empiric coverage of these organisms often leads to use of excessively broad-spectrum drug regimens. Several studies have shown good antimicrobial treatment efficacy despite the fact that the regimens did not have consistently good activity against these particular organisms.[27,59,61,62,63,65]

CLINICAL PRESENTATION Diabetic Foot Infections General

- Infections are often much more extensive than they appear initially.

Symptoms

- Patients with peripheral neuropathy often do not experience pain; simple complaints of swelling or edema are common.

Signs

- Clinical signs of infection may not be present secondary to angiopathy and neuropathy.
- Lesions vary in size and clinical features (eg, erythema, edema, warmth, presence of pus, draining sinuses, pain, and tenderness).
- Foul-smelling odor suggests the presence of anaerobic organisms.
- Temperature may be mildly elevated or normal.

Laboratory Tests

- Specimens for culture and sensitivities should be collected.
- Deep-tissue samples obtained during surgical debridement are most useful for culture and susceptibility testing.
- Wounds must be cultured for both aerobic and anaerobic organisms.

Other Diagnostic Tests

- Possible presence of osteomyelitis also must be assessed via radiograph, bone scan, or both, as appropriate.

Proper selection of empiric antibiotics for DFI begins with thorough patient assessment and classification of the severity of the infection. Specific drug regimens, route of administration, and duration of therapy are all then largely dependent on the severity of infection. Although a number of classification systems are available, the most recent DFI treatment guidelines use those summarized in **Table 110-8**.[27,59] Wounds with no local signs of infection often do not require antibiotic therapy, and the majority of mild, uncomplicated infections can be managed successfully on an outpatient basis with highly bioavailable oral antimicrobials and good wound care (**Tables 110-8** and **110-9**).[37,55,61,62] Antibiotics for treatment of mild infections should be largely limited to those with activity against skin flora such as streptococci and methicillin-susceptible *S. aureus* (MSSA), except in those patients with risk factors for infection with other types of pathogens (**Fig. 110-2**).[27,59] Patients with specific risk factors for MRSA (Table 110-9) should empirically receive trimethoprim–sulfamethoxazole or doxycycline orally, while those who have received antibiotics within the past month should also receive empiric antibiotics that provide activity against gram-negative bacilli. Oral antimicrobials should be used cautiously in DFI complicated by osteomyelitis, extensive ulceration, areas of necrosis, or a combination of these. The use of topical antimicrobials, including

medical-grade honey, has been advocated for the treatment of DFI in an attempt to minimize the cost of therapy and systemic antibiotic exposure leading to adverse effects and resistance. Although the most recent guidelines allow for consideration of topical therapy in mild infection in selected patients, use of topical agents is quite controversial and not routinely recommended.[27,55,59,66,67]

TABLE 110-8 Classifications and Treatment Strategies for Diabetic Foot Infections of Varying Severity[27]

Clinical Signs/Symptoms of Infection	Infection Severity	Treatment Setting
None	Uninfected	Outpatient management; nonantibiotic wound management only
Local infection present (≥2 of the following): local swelling or induration, erythema, local tenderness or pain, local warmth, purulent discharge Local infection involving only skin and subcutaneous tissue, without involvement of deeper tissues or SIRS criteria present; if erythema is present, must be >0.5 and ≤2 cm around ulcer	Mild	Outpatient management; topical or oral antibiotics
Local infection with erythema >2 cm around ulcer, or involving structures deeper than skin and subcutaneous tissue (eg, abscess, osteomyelitis, septic arthritis, fasciitis); no SIRS criteria present	Moderate	Outpatient (or initial inpatient) management; oral (or initial parenteral) antibiotics
Local infection with ≥2 SIRS criteria: • Temperature >38°C or <36°C (>100.4°F or <96.8°F) • HR >90 • RR >20 • WBC >12,000 or <4,000, or >10% bands (>12 x 10^9/L or <4 x 10^9/L, or ≥0.10 bands)	Severe	Inpatient, followed by outpatient, management; initial parenteral antibiotics, followed by switch to oral when possible

TABLE 110-9 Suggested Antibiotic Regimens for Empiric Treatment of Diabetic Foot Infections[27]

Severity of Infection	Probable Pathogens	Drug(s)[a]	Duration of Therapy
Mild	*Staphylococcus aureus* (MSSA)	Amoxicillin–clavulanate	1-2 weeks; may increase up to 4 weeks if infection slow to resolve
	Streptococcus spp.	Cephalexin	
	S. aureus (MRSA)	Dicloxacillin	

Severity of Infection	Probable Pathogens	Drug(s)[a]	Duration of Therapy
Moderate to severe (initially oral or IV antibiotics for moderately severe infections, IV antibiotics for severe infections)	• Patients with history of MRSA infection or colonization in past year • Prevalence of MRSA ≥50% in local geographic area • Recent hospitalization	Clindamycin Levofloxacin Moxifloxacin[b]	Moderately severe infection: 1-3 weeks; severe infection: 2-4 weeks
	MSSA *Streptococcus* spp. Enterobacteriaceae Obligate anaerobes	Ampicillin/Sulbactam Cefoxitin Ceftriaxone Imipenem/cilastatin Ertapenem Levofloxacin Moxifloxacin Tigecycline Levofloxacin or ciprofloxacin + clindamycin	
	MRSA • Patients with history of MRSA infection or colonization in past year • Prevalence of MRSA ≥30% in local geographic area • Recent hospitalization • Infection severe enough that not empirically covering MRSA poses unacceptable risk of treatment failure	Add to one of the above regimens: • Vancomycin • Linezolid • Daptomycin	

MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus*.

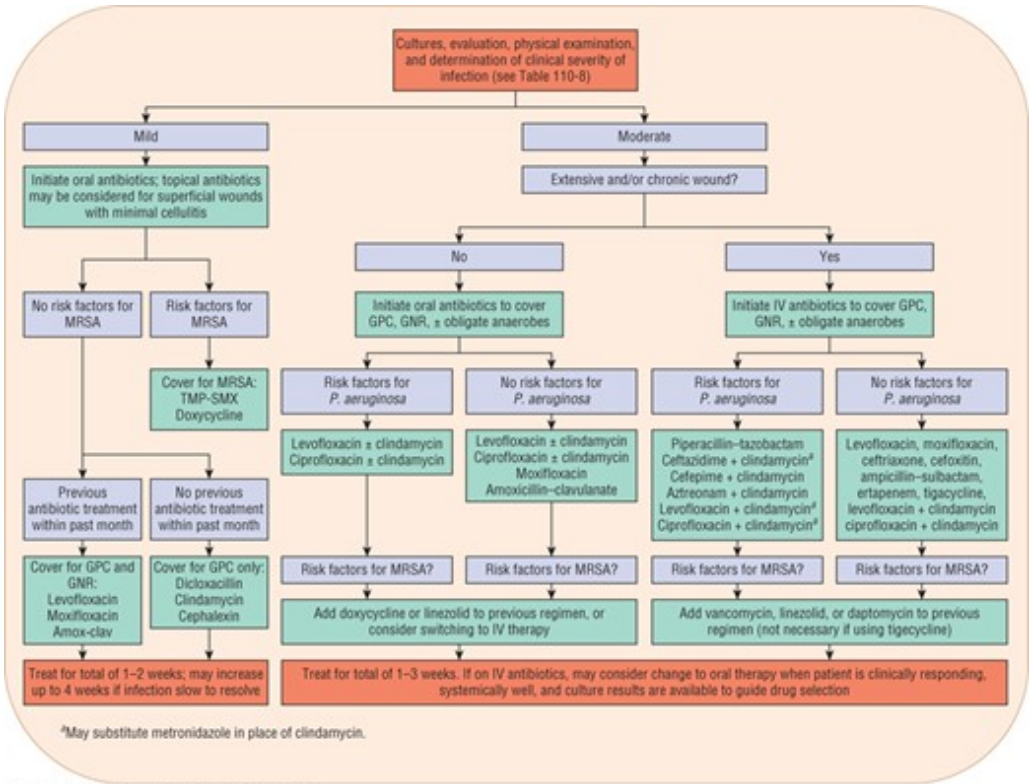
[a]Agents not shown in any particular order of preference.

[b]Not specifically recommended in IDSA guidelines but may be appropriate treatment option.

[c]Linezolid or daptomycin may be used in place of vancomycin.

FIGURE 110-2

Recommended treatment algorithm for initial empiric management of mild to moderate diabetic foot infections. (GNR, aerobic gram-negative rods; GPC, aerobic gram-positive cocci; MRSA, methicillin-resistant *Staphylococcus aureus*; TMP-SMX, trimethoprim–sulfamethoxazole.)

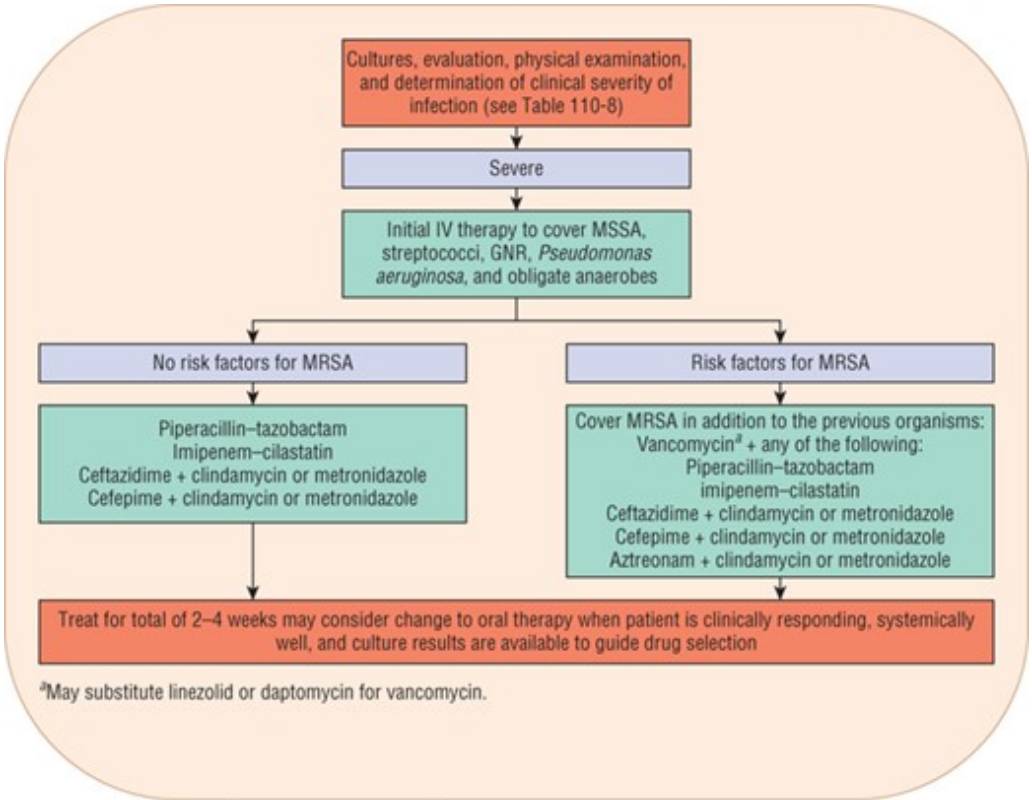


Appropriate initial therapy for patients with moderate to severe infection is also dependent on the presence of specific risk factors that increase the likelihood of infection with more resistant pathogens such as *P. aeruginosa* and MRSA (Table 110-9).[27,59] Many moderate infections can be successfully treated with orally administered antibiotics that provide activity against MSSA, streptococci, and gram-negative aerobic bacilli; coverage of obligate anaerobes may also be considered in patients with chronic or previously treated wounds (**Fig. 110-3**).[27,59] The addition of orally administered agents with activity against MRSA is recommended in patients with moderate or severe infection and specific risk factors for MRSA; such patients may also be considered for hospitalization and initial treatment with parenteral antibiotics in order to ensure adequate antibiotics for potentially more complex infections.[27,59] Patients with more extensive or chronically

unhealed wounds, even though assessed as moderate in severity, may also be more appropriately treated initially with parenteral antibiotics in the hospital setting.[27,59]

FIGURE 110-3

Recommended treatment algorithm for initial empiric management of severe diabetic foot infections. (GNR, aerobic gram-negative rods; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *S. aureus*.)



All patients with severe DFI should be hospitalized initially and treated with broad-spectrum IV antibiotics (Table 110-9 and Fig. 110-3).[27,59] Severe infection is considered a risk factor for *P. aeruginosa*, so most patients with severe DFI will be initially started on antipseudomonal antibiotics.[27,59] Many patients will also be initially started on antibiotics that provide activity against MRSA due to risk-versus-benefit considerations, but assessment of risk factors in individual patients should still be performed in order to minimize the use of excessively broad-spectrum antibiotics when possible.

Clinical Controversy…

The decision whether or not to provide empiric coverage for MRSA and/or *P. aeruginosa* in the empiric treatment of diabetic foot infections remains controversial. Although proposed risk factors and treatment recommendations are provided in recent guidelines, these recommendations are somewhat broad due to lack of definitive data defining patients at high risk for infection with these

pathogens. The nonspecific nature of the current recommendations may potentially lead to use of unnecessarily broad-spectrum antibiotic therapy in order to cover patients who are not actually at risk for infection with such drug-resistant pathogens. Additional studies defining specific patient risk factors are needed in order to more specifically and accurately guide empiric antibiotic management of diabetic foot infections.

Guidelines for management of DFI include options for both monotherapy and combination regimens (Table 110-9).[27] Monotherapy, along with appropriate medical or surgical management, or both, is often effective in treating DFI, including those in which osteomyelitis is present.[27,55,60,61] Monotherapy is particularly attractive because of the potential advantages of convenience, cost, and avoidance of toxicities. Microbiologic and clinical cure rates ranging from 60% to 90% may be expected from any of these agents.[61] Selection of a specific regimen is determined by patient-specific factors including allergies, renal function, history of previous antibiotic use, and cost. In penicillin-allergic patients, metronidazole or clindamycin plus a fluoroquinolone, aztreonam, or possibly a third- or fourth-generation cephalosporin is appropriate.[27,55,60] Vancomycin also is used frequently in severe infections because of its excellent activity against gram-positive pathogens. Linezolid, daptomycin, and tigecycline are specifically recommended alternatives for the treatment of this pathogen.[27,55,59,60] Tigecycline may be particularly useful in this setting because of its activity against gram-negative aerobes and anaerobic bacteria, thus allowing it to be used as monotherapy for the treatment of mixed infections in patients where coverage of *P. aeruginosa* is not of great concern. Ceftaroline fosamil has in vitro activity that is suitable for DFI but has not been studied for this indication and its role is not yet defined. Because many patients already have some degree of diabetic nephropathy that may place them at higher risk of nephrotoxicity, strong recommendations have been made against the use of aminoglycoside antibiotics unless no alternative agents are available.[27,55] When an aminoglycoside is used, care must be taken to avoid further compromising renal function. All antibiotic regimens should be adjusted as necessary for renal dysfunction.

Duration of therapy for DFI depends on the severity of the infection, ranging from 1 to 2 weeks for mild infections up to 2 to 4 weeks or more for severe infections.[27,55] In the cases of underlying osteomyelitis, treatment should continue for 6 to 12 weeks.[27,55,60] After healing of the infection has occurred, a well-designed program for the prevention of further infections should be instituted. The use of adjunctive agents such as colony-stimulating factors, growth factors, and hyperbaric oxygen for either prevention or treatment of DFIs is controversial and not widely recommended.[27]

Evaluation of Therapeutic Outcomes

Therapy should be reevaluated carefully after 48 to 72 hours to assess favorable response. Change in therapy (or route of administration, if oral) should be considered if clinical improvement is not observed at this time. For optimal results, drug therapy should be appropriately modified according to information from deep-tissue culture and the clinical condition of the patient. Infections in diabetic patients often require extended courses of therapy because of impaired host immunity and poor wound healing.

PRESSURE SORES

The terms *decubitus ulcer*, *bed sore*, and *pressure sore* are used interchangeably.[68,69] The decubitus ulcer and the bed sore are types of pressure sores. The term *decubitus ulcer* is derived from the Latin word *decumbere*, meaning "lying down." Pressure sores, however, can develop regardless of a patient's position.

Numerous systems for classification of pressure sores have been described. The 2007 recommendations of the National Pressure Ulcer Advisory Panel are shown in **Table 110-10** and illustrate the various stages of progression through which a pressure sore may pass.[70]

TABLE 110-10 Pressure Sore Classification

Suspected deep-tissue injury	Area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. Area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared with adjacent tissue
Stage 1	Pressure sore is generally reversible, is limited to the epidermis, and resembles an abrasion. Intact skin with nonblanchable redness of a localized area, usually over a bony prominence. The area may be painful, firm, soft, warmer or cooler as compared with adjacent tissue
Stage 2	A stage 2 sore also may be reversible; partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed. May also present as an intact or open/ruptured serum-filled blister, or as a shiny or dry shallow ulcer
Stage 3[a]	Full thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscles are not exposed. May include undermining and tunneling. Depth of the ulcer varies by anatomical location; may range from shallow to extremely deep over areas of significant adiposity
Stage 4[a]	Full thickness tissue loss with exposed bone, tendon, or muscle; can extend into muscle and/or supporting structures (eg, fascia, tendon, or joint capsule) making osteomyelitis possible. Often includes undermining and tunneling; depth of the ulcer varies by anatomical location
Unstageable[a]	Full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. True depth, and therefore stage, cannot be determined

[a]Stage 3, stage 4, and unstageable lesions are unlikely to resolve on their own and often require surgical intervention.

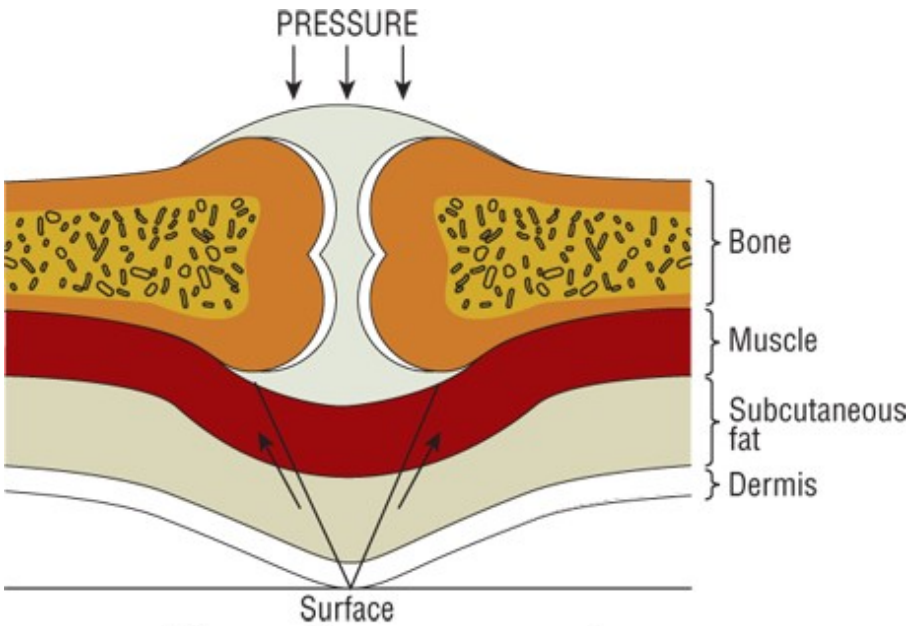
Data from reference 70.

Complications of pressure sores are common and may be life-threatening. Infection is one of the most serious and most frequently encountered complications of pressure ulcers.[69] Although most pressure sore wounds are heavily colonized, the majority of these eventually heal.[71,72,73] When true infection is present, however, there is bacterial invasion of previously healthy tissue. Without

treatment, an initial small, localized area of ulceration can rapidly progress to large ulcers within days. The visible ulcer is just a small portion of the actual wound[74]; up to 70% of the total wound is below the skin. A pressure-gradient phenomenon is created by which the wound takes on a conical nature; the smallest point is at the skin surface, and the largest portion of the defect is at the base of the ulcer (**Fig. 110-4**).

FIGURE 110-4

Distribution of forces involved with sore formation in a conical fashion.



Epidemiology

Pressure sores are most common among chronically debilitated persons, the elderly (70% involve persons greater than 70 years of age), and persons with serious spinal cord injury.[25,69,74,75] Generally, patients who are at risk for pressure sores are elderly or chronically ill young patients who are immobilized, in either bed or a wheelchair, and who may have altered mental status and/or incontinence.[69,74,75]

Etiology

Similar to DFIs, a large variety of aerobic gram-positive and gram-negative organisms, as well as anaerobes, frequently are isolated from wound cultures.[25] Most pressure sores are colonized with microorganisms, making assessment for infection a clinical challenge.[25,71] Curettage of the ulcer base after debridement provides more reliable culture information than does needle aspiration.[71,72,73] Biopsy specimens give the most reliable data but may not be practical to obtain. Deep-tissue cultures from different sites may give different results. Cultures collected from pressure ulcers reveal

polymicrobial growth. A culture collected by swab is likely to identify surface bacteria colonizing the wound rather than to diagnose the infection.[71]

Pathophysiology

Many factors apparently predispose patients to the formation of pressure sores: paralysis, paresis, immobilization, malnutrition, anemia, infection, and advanced age. Factors thought to be most critical to their formation are pressure, shearing forces, friction, and moisture[25,76]; however, there is still debate as to the exact pathophysiology of pressure sore formation.[76]

Pressure is the essential element in the formation of pressure sores.[25,69,74,76] The areas of highest pressure are generated most often over the bony prominences.[25,68,69,71,75,76] Both the degree of pressure and the length of time that the pressure is applied are important.[69,76]

Shearing occurs when two surfaces move in opposite directions.[25,76] This situation can occur when the head of a bed is raised, causing the upper torso to slide downward, transmitting pressure to the sacrum and other areas. This effect results in occlusion or distortion of vessels, leading to compromise of the dermis. At the same time, sitting and gravity create shearing forces; the posterior sacral skin area can become fixed secondary to friction with the bed. The effects of friction and shearing forces combine, resulting in transmission of force to the deep portion of the superficial fascia and leading to further damage of soft-tissue structures.[25,71,76]

Compounding the problems of shearing and friction forces are the macerating effects of excessive moisture in the local environment, resulting from incontinence and perspiration. This factor is of critical importance because when combined with the other forces, it increases the risk of pressure sore formation fivefold.[25,72,76]

CLINICAL PRESENTATION Pressure Sores General

- Most pressure sores are in the pelvic region and lower extremities; see **Fig. 110-5**.
- Most common sites: sacral and coccygeal areas, ischial tuberosities, and greater trochanter.

Symptoms

- Patients commonly have other medical problems that may mask signs and symptoms of infection.
- Pain may be present with or without infection; continuous pain may indicate infection.

Signs

- A dark red color on the surface of a pressure sore may indicate local infection.
- Surrounding erythema, swelling, and heat are commonly present with infection.

- Purulent discharge, foul odor, and systemic signs (eg, fever and leukocytosis) of infection may be present.

Laboratory Tests

- Cultures should be collected from either a biopsy or fluid obtained by needle aspiration.

Other Diagnostic Tests

- Complete blood count often performed for assessment of potential infection.
- Consider magnetic resonance imaging if suspicious of underlying osteomyelitis.

TREATMENT

Pressure Sores

Desired Outcomes

The primary goal for pressure sores is prevention. Once a pressure sore has developed, the goals of therapy are prevention of complications (ie, infections), preventing sores from growing larger, and preventing the development of sores in other locations.[74] Eradication of infection should include good wound care and topical therapies, and avoidance of broad-spectrum antimicrobials unless guided by results from appropriately collected cultures or in patients with bacteremia, sepsis, cellulitis, or osteomyelitis.

Drug and Nondrug Management

8 Prevention is the single most important aspect in the management of pressure sores. Skin surveillance and frequent repositioning (ie, pressure reduction) are key in preventing pressure sores.[69,74] Prevention is far easier and less costly than the intensive care necessary for the healing and eventual closure of pressure sores. Of primary importance, then, is the ability to identify patients who are at high risk so that preventive measures may be instituted. Relief of pressure through proper positioning, and periodic repositioning, is probably the single most important factor in preventing pressure sore formation. Relief for a period of only 5 minutes once every 2 hours is believed to give protection against pressure sore formation.[69,71,72,73,74] Repositioning seated patients every 15 to 60 minutes is also recommended.[25,74] Pressure relief devices such as mattresses or overlays filled with air, water, gel, or foam are helpful in preventing pressure sores.[77] Cushions and ankle or heel protectors should also be encouraged.[69,71] Skin care and prevention of soilage are also important, with the intent being to keep the surface relatively free of moisture. Patients with problems of incontinence should be cleaned frequently, and efforts should be made to keep the involved areas dry.[68]

The medical approach to the treatment of pressure sores depends on the stage of the disease. Medical management generally is indicated for lesions that are of moderate size and relatively shallow depth (stage 1 or 2 lesions) and are not located over a bony prominence. Depending on their location and severity, from 30% to 80% of these ulcers will heal without an operation. Surgical intervention is almost always necessary for ulcers that extend through superficial layers or into bone (stage 3, stage 4, and unstageable lesions).[70]

The goal of therapy is to clean and decontaminate the ulcer in order to permit formation of healthy granulation tissue that promotes wound healing or prepares the wound for an operative procedure. The main factors to be considered for successful topical therapy (local care) are (a) relief of pressure, (b) debridement of necrotic tissue as needed, (c) wound cleansing, (d) dressing selection, and (e) prevention, diagnosis, and treatment of infection.[25,69,71,74,75]

Relief of pressure is important once a pressure sore has developed. The same repositioning methods and pressure-reducing devices used for preventive care also apply to treatment.[25,69]

The goals of debridement and cleansing measures are removal of devitalized tissue and reduction of bacterial contamination, which can slow granulation time and impede healing.[25,69] Debridement can be accomplished by surgical, mechanical, or chemical means.[25,69] Surgical debridement rapidly removes necrotic material from the wound and is recommended for urgent situations (eg, cellulitis and sepsis).[71,72,73] Mechanical debridement generally involves wet-to-drydressing changes. Saline-soaked gauze is applied to the wound; after drying, the gauze is removed and with it any adherent necrotic tissue. Other effective mechanical therapies include hydrotherapy (use of the whirlpool [Hubbard tank] to remove necrotic tissue and debris), wound irrigation, and dextranomers (beads placed in the wound to absorb exudate and bacteria).[25,69] Chemical debridement includes enzymatic and autolytic agents. Enzymatic debridement involves application of topical debriding agents to

remove devitalized tissue. This method is recommended for patients who cannot tolerate surgery or are in a long-term care or home setting.[25,69] Autolytic debridement involves the use of synthetic dressings that allow devitalized tissue to self-digest via enzymes present in wound fluids. Autolytic debridement is contraindicated in the treatment of infected pressure sores.[25]

Pressure sore wounds should be cleaned with normal saline.[69] No cleansing solution or technique has demonstrated greater efficacy on healing.[77] Cleansing agents that are cytotoxic, such as povidone–iodine, iodophor, sodium hypochlorite solution, hydrogen peroxide, and acetic acid, should be avoided.[69,72,73] Many of these agents destroy granulation tissue and impair healing. Many different types of dressings are available for pressure sores.[25] Wound dressing materials should keep the wound moist, allow free exchange of air, act as a physical barrier to bacteria, and prevent physical damage.[25,69] Controlled studies of the various types of wound dressings have shown no significant differences in healing outcomes.[68] Occlusive dressings (hydrocolloid, such as DuoDERMtm or Tegadermtm) and transparent dressings (eg, 3M Tegadermtm) are not recommended for infected wounds.[25,69] If occlusive dressings are used, any infection should be controlled or the dressing frequency increased.

A 2-week trial of topical antibiotics (silver sulfadiazine or triple antibiotic) may be considered for a clean ulcer that is not healing or is producing a moderate amount of exudate despite appropriate care.[72] Systemic treatment of pressure ulcers is generally for infections associated with bacteremia, sepsis, cellulitis, or osteomyelitis.[72,73] Empiric therapy for infected pressure sores or associated infectious complications should cover MRSA, anaerobes, enterococci, and more resistant gram-negative bacteria such as *Pseudomonas* (see Table 110-5).[69] Thereafter, antibiotics should be guided by results from appropriately collected cultures.

Other nonpharmacologic approaches to shorten the healing time have included the use of hyperbaric oxygenation, hydrotherapy, high-frequency/high-intensity sound waves, and electrotherapy.[72,73,77] Electrical stimulation is the only adjunctive therapy that is proven effective.[72,73] Various comorbid conditions (diabetes mellitus, smoking, peripheral vascular disease, malnutrition) may impair wound healing. Eliminating or optimizing these factors is recommended, although studies have not demonstrated benefit.[25,69,74,75,76]

Evaluation of Therapeutic Outcomes

With appropriate wound care and antimicrobial therapy, infected pressure sores can heal. A reduction in erythema, warmth, pain, and other signs and symptoms should be seen in 48 to 72 hours.

ANIMAL AND HUMAN BITE WOUNDS

Approximately half the population in the United States will be bitten by either an animal or another human sometime during their lifetimes.[78,79] Animal bites (typically from dogs or cats) are common causes of injury, particularly to children, and are associated with significant risk of infection without

prompt attention to appropriate management. Likewise, human bite wounds are often deceptively severe and frequently require aggressive management to reduce the risk of infectious complications. If left untreated, soft-tissue infection and osteomyelitis may occur, possibly requiring extensive debridement or amputation.

Epidemiology

Dog bites account for approximately 60% of all animal bite wounds requiring medical attention.[78] The Centers for Disease Control and Prevention reports that nearly 350,000 individuals seek emergency room attention for dog bites annually.[79] The rate of dog bite–related injuries is highest in children aged 5 to 9 years. Most dog bites are to the extremities,[78] but the majority of bites to children less than 5 years of age are to the face and neck.[79] Cat bites are the second most common cause of bite wounds in the United States, accounting for up to 20% of all animal bites.[78] Cat bites occur most commonly on the upper extremities and face, with most injuries reported in women and the elderly.[78,80] Human bites are the third most frequent type of bites requiring medical attention.

Infection rates after dog and cat bites are estimated at 20% overall. However, infection may occur in up to 30% to 80% of serious cat bites, a rate more than double those seen with dog bites.[80] Also, bite wounds to the hands become infected in 30% to 40% of cases.[78] Patients at greatest risk of acquiring animal bite–related infection have had a puncture wound (usually to the hand), have not sought medical attention within 8 hours of the injury, and are older than 50 years of age.[78,80]

Infected human bites can occur as bites from the teeth or from blows to the mouth (clenched-fist injuries). Bites by others can occur to any part of the body, but most often involve the hands. Infectious complications occur in 10% to 50% of patients with human bites.[80]

Etiology

Infections in bite wounds are caused predominantly by mouth flora from the animal or human biter, and from the victim's own skin flora (**Table 110-11**).[78,80,81,82,83,84] Most infections are polymicrobial, with a median of three to nine bacterial isolates per culture.[78,80,81,82,83,84] *Pasteurella* is the most frequent isolate from both dog and cat bites. *Pasteurella multocida* is part of the normal oral flora of up to 90% of cats; dog bites more commonly involve *P. canis* (approximately 26% of infections).[80,82] Tularemia (*Pasteurella tularensis*) and cat scratch disease (*Bartonella henselae*) have also been transmitted by cat bites, while rabies is associated with dog bites, particularly in developing countries.[82,83,85] Human bite wounds are notable for potential involvement of *Eikenella corrodens* in approximately 30% of infections.

TABLE 110-11 Bacterial Isolates from Infections in Animal and Human Bite Wounds [78,80,81,82,83]

Organisms	Percentage of Isolates	
	Dog and Cat	Human
Aerobes	74-90	44

Organisms	Percentage of Isolates	
	Dog and Cat	Human
Pasteurella spp.	50-75	—

Propionibacterium spp.	18-20	4
Peptostreptococcus spp.	8-16	22
Veillonella spp.	2	24
Mixed aerobic and anaerobic	50-75	40-66

Pathophysiology

The potential for infection from an animal bite is great owing to the pressure that can be exerted during the bite and the vast number of potential pathogens that make up the normal oral flora.[78,80,81,82,83] Cats' teeth are slender and extremely sharp. Their teeth easily penetrate into bones and joints, resulting in a higher incidence of septic arthritis and osteomyelitis.[78,80,81,82,83] Although a dog's teeth may not be as sharp, they can exert a pressure of 200 to 450 lb/in^2 (~1,400 to 3,100 kPa) and therefore result in a serious crush injury with much devitalized tissue.[78,80,81,82,83] In addition, the polymicrobic (aerobic and anaerobic) nature of animal bites provides a synergistic relationship, thus making an infection harder to eradicate.[81]

Human bites generally are more serious and more prone to infection than animal bites, particularly clenched-fist injuries.[81] While the force of a punch may sever a tendon or nerve or break a bone, it most often causes a breach in the capsule of the metacarpophalangeal joint, leading to direct inoculation of bacteria into the joint or bone.[81,83] When the hand is relaxed, the tendons carry bacteria into deeper spaces of the hand, resulting in more extensive infection.[81,83]

TREATMENT

Desired Outcomes

The goals of therapy of bite wounds, whether caused by animals or humans, are twofold: to provide effective prophylaxis against infection, when appropriate, and to achieve rapid eradication of established infection and prevent further complications. Effective treatment of bite wounds includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Management of Bite Wounds

9 Bite wounds should be irrigated thoroughly with a copious volume of sterile water or saline, and the wound washed vigorously with soap or povidone–iodine in order to reduce the bacterial count in the wound.[80,83] Surgical debridement and immobilization of the affected area is often required in dog and human bites associated with more extensive tissue injury. Clinical failures due to edema have occurred despite appropriate antibiotic therapy.[78] Therefore, it is important to stress to patients that the affected area should be elevated for several days or until edema has resolved. In the case of animal bites, an immunization history of the animal should be obtained. It is also important for the patient's tetanus immune status to be determined. Because transmission of viruses (HIV, herpes, hepatitis B and C) is a possibility with human bites, information about the biter is important. Although the possibility of acquiring HIV through saliva alone is believed to be unlikely, the presence of virus-containing blood in the saliva makes disease transmission possible.[86,87] Bite victims exposed to blood-tainted saliva may be offered antiretroviral chemoprophylaxis, but each case should be individually assessed based on the potential for significant exposure and potential risks and benefits of antiretroviral therapy.[86,87]

Patients with clenched-fist injuries should be seen by a specialist in hand care to evaluate for penetration into the synovium, joint capsule, and bone.[15,81] Primary closure for human bites generally is not recommended. Tetanus toxoid and antitoxin may be indicated.

10 All patients with human bite injuries should receive prophylactic antibiotic therapy ("early preemptive therapy") for 3 to 5 days due to high infection risk (Table 110-4).[83,84,87] Prophylactic antimicrobial agents should be given as soon as possible to all patients, regardless of the appearance of the wound, unless it can be documented that the wound does not involve hands, feet, or joints and penetrates no deeper than the epidermis.[15,72,83]

The role of prophylactic antimicrobial therapy for early, noninfected animal bite wounds remains controversial.[15,78,80,81,83] Recommendations from the Infectious Diseases Society of America suggest that prophylactic or early preemptive therapy seems to provide only marginal benefit for most patients in the absence of specific factors that increase the risk of infection.[15] The decision to administer prophylactic antibiotics is therefore based on an assessment of wound severity and host immune competence. Specifically, prophylaxis is more strongly recommended in patients with the following factors associated with increased risk for infection: immunocompromised; asplenic; advanced liver disease; preexisting or resultant edema of the affected area; moderate to severe bite-related injuries, especially to the hands or face; or bite injuries that have penetrated the periosteum or joint capsule.[15] A 3- to 5-day course of prophylactic antibiotics is recommended when such therapy is considered to be appropriate.[15,80,81,83]

Empiric antibiotics for the treatment of established infection of bite wounds should be directed at a variety of aerobic and anaerobic flora (Table 110-4). Amoxicillin–clavulanic acid is most commonly recommended for oral outpatient therapy due to excellent activity against all likely pathogens, including *Pasteurella* and *Eikenella*.[15,78,80,81,83] Alternative oral agents include moxifloxacin or doxycycline alone, or trimethoprim–sulfamethoxazole, levofloxacin, ciprofloxacin, or a second- or third-generation cephalosporin in combination with metronidazole or clindamycin to provide activity against oropharyngeal anaerobes. Although the combination of penicillin VK plus dicloxacillin has been recommended traditionally for the treatment of bite wounds, its use has become less common in favor of other alternatives. Failure to provide adequate initial treatment of bite wounds results in treatment failures and increased need for hospitalization for parenteral antibiotics.[15,78,80,81,82,83]

Hospitalization for minor wounds is unnecessary if surgical repair of vital structures has not been performed. Patients with clenched-fist or other serious bite injuries and severe resultant infection may be considered for IV antibiotics. Treatment options for patients requiring IV therapy include β-lactam–β-lactamase inhibitor combinations (ampicillin–sulbactam, piperacillin–tazobactam), second-generation cephalosporins with antianaerobic activity (eg, cefoxitin), and ertapenem.[15,83] The combination of doxycycline or a fluoroquinolone with metronidazole or clindamycin may be used in patients with severe β-lactam allergies. The length of antimicrobial therapy depends on the severity of the injury/infection. However, therapy should generally be continued from 7 to 14 days.[15,78,87,88,89,90,91]

Tetanus does not occur commonly after dog bites; however, it is possible. If the immunization history of a patient with anything other than a clean, minor wound is unknown, or if the last known vaccination was longer than 10 years ago, tetanus–diphtheria (TD) toxoids should be administered.[88,89] Both TD toxoids and tetanus immune globulin should be administered to patients who have never been immunized.[83,90]

CLINICAL PRESENTATION Bite Wounds General

Animal bites:

- Only general wound care is required for most patients with dog bites who present early (<12

hours) after injury; infection is more likely in patients presenting late (≥12 hours) after injury.

Human bites:

- Most patients with clenched-fist injuries present for medical care after infection is already established.

Symptoms

- Patients often seek medical care for infection-related complaints (ie, pain, purulent discharge, and swelling) at the site of the injury.
- Wounds often have a purulent discharge, and decreased range of motion may be present.

Signs

- Erythema, swelling, and clear or purulent discharge at site of infected wound.

Animal bites:

- If *P. multocida* is present, a rapidly progressing cellulitis is observed within 24 to 48 hours of initial injury.
- Fever is uncommon.
- Adenopathy or lymphangitis is uncommon.

Human bites:

- Lymphadenopathy is common.
- In clenched-fist injuries, edema may limit the ability of tendons to glide in their sheaths, thereby limiting a joint's range of motion.

Laboratory Tests

- Samples for bacterial cultures (aerobic and anaerobic) should be obtained from infected wounds.
- Wounds seen <8 hours or more than 24 hours after injury that show no signs of infection may not need to be cultured.
- White blood counts should be monitored for resolution of infection if initially elevated.

Other Diagnostic Tests

- Radiographic evaluation should be performed if damage to a bone or joint is suspected.

Because the rabies virus can be transmitted via saliva, rabies may be a potential complication of a bite. When the symptoms of rabies develop after a bite, the prognosis for survival is poor. Roughly

3% of rabies cases documented in animals were in dogs (the most frequent vectors are skunks, raccoons, and bats).[85,91] In the United States, recommendations for postexposure prophylaxis after a dog bite depend on the health of the dog. If the animal is healthy and able to be observed for a 10-day period, active prophylaxis is only required if the dog develops signs of rabies.[78,80,85] If the dog is known or suspected to be rabid, postexposure procedures should be initiated; current treatment guidelines should be consulted for appropriate management recommendations.[85,91] Outside of the United States, locally applicable guidelines such as those from the World Health Organization should be consulted.[92]

Evaluation of Therapeutic Outcomes

Evaluation of treatment for either animal or human bites should follow the same general guidelines. Bite victims treated on an outpatient basis with oral antimicrobials should be followed up within 24 hours by either phone or office visit.[15] Hospitalization or change to IV therapy should be considered if the infection has progressed. For hospitalized patients with no improvement in signs and symptoms following 24 hours of appropriate therapy, surgical debridement may be needed. Physical therapy may be needed to improve complications such as residual joint stiffness and loss of function, particularly after human bites involving clenched-fist injuries.

PERSONALIZED PHARMACOTHERAPY

Desired treatment outcomes for the various types of SSTIs described in this chapter are achieved through close monitoring and frequent patient assessment, including judicious evaluation of antimicrobial therapies. SSTIs are challenging in that cultures are often not performed due to the unavailability of easily obtained culturable specimens and the low yield of common culturing techniques. Empiric antibiotic selection based on most likely pathogens is an effective strategy in less severe infections such as erysipelas, impetigo, and furuncles. However, treatment of more severe infections such as cellulitis, DFI, and necrotizing fasciitis should be individualized based on properly obtained culture specimens and documented pathogens and susceptibilities whenever possible. Aggressive antimicrobial use must be balanced against unnecessary administration of drugs that may lead to increased antimicrobial resistance, adverse effects, and cost. Proper evaluation of an individual patient's severity of infection and risk of complications allows for selection of appropriate antimicrobials for the treatment of infection and selection of appropriate treatment settings (eg, inpatient vs outpatient), both of which may allow for the most cost-effective therapy.

Chapter 111: Infective Endocarditis

Angie Veverka; Brian L. Odle; Jeffrey A. Kyle

INTRODUCTION

KEY CONCEPTS

- 1 Infective endocarditis usually occurs in adult patients with specific risk factors (eg, IV drug abuse, heart failure, valvular disease, and healthcare exposure) and those with implanted cardiac material (eg, prosthetic heart valves).
- 2 Three groups of organisms cause a majority of infective endocarditis cases: streptococci, staphylococci, and enterococci.
- 3 The clinical presentation of infective endocarditis is highly variable and nonspecific, although a fever and murmur are usually present. Classic peripheral manifestations (eg, Osler's nodes) may or may not occur.
- 4 The diagnosis of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The two major diagnostic criteria are bacteremia and echocardiographic changes (eg, valvular vegetation).
- 5 Treatment of infective endocarditis involves isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.
- 6 Surgical replacement of the infected heart valve is an important adjunct to endocarditis treatment in certain situations (eg, patients with acute heart failure).
- 7 β-Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively.
- 8 Aminoglycoside antibiotics are essential to obtain a synergistic bactericidal effect in the treatment of enterococcal endocarditis. Adjunctive aminoglycosides also may decrease the emergence of resistant organisms (eg, prosthetic valve endocarditis caused by coagulase-

negative staphylococci) and hasten the pace of clinical and microbiologic response (eg, some streptococcal and staphylococcal infections).

- 9 Vancomycin is reserved for patients with immediate β-lactam allergies and the treatment of resistant organisms.

- 10 Antimicrobial prophylaxis is used to prevent infective endocarditis for patients who are at the highest risk (such as persons with prosthetic heart valves) before a bacteremia-causing procedure (eg, dental extraction).

Endocarditis is an inflammation of the endocardium, the membrane lining the chambers of the heart and covering the cusps of the heart valves.[1,2] More commonly, *endocarditis* refers to infection of the heart valves by various microorganisms. Although it typically affects native valves, it also may involve nonvalvular areas or implanted material (eg, prosthetic heart valves, cardiac defibrillators, pacemakers, and catheters). Bacteria primarily cause endocarditis, but fungi and other atypical microorganisms can lead to the disease; hence, the more encompassing term *infective endocarditis* is preferred.[1,3]

Endocarditis is often referred to as *acute* or *subacute* depending on the pace and severity of the clinical presentation. The acute, fulminating form is associated with high fevers and systemic toxicity. Virulent bacteria, such as *Staphylococcus aureus*, frequently cause this syndrome, and if untreated, death may occur within days to weeks. On the other hand, subacute infective endocarditis is more indolent, is caused by less invasive organisms, such as viridans streptococci, and usually occurs in preexisting valvular heart disease. Although infective endocarditis is often referred to as acute or subacute, it is best classified based on the etiologic organism, the anatomic site of infection, and pathogenic risk factors.[1,4,5] Infection may also occur following surgical insertion of a prosthetic heart valve, resulting in prosthetic valve endocarditis (PVE), or insertion of a cardiac implantable electronic device, resulting in cardiac device infective endocarditis (CDIE).[6,7]

EPIDEMIOLOGY AND ETIOLOGY

Infective endocarditis is an uncommon, but not rare, infection. Population-based studies have reported annual incidence rates of 2 to 15 cases per 100,000 person-years.[8,9] In the United States, the infection is listed as the primary or secondary diagnosis of 34,000 hospital discharges.[10] The mean male-to-female ratio is approximately 2:1.[11] As the population ages and as valve replacement surgery becomes more common, the mean age of patients with infective endocarditis increases. Most cases occur in individuals older than 50 years of age, and it is less common in children.[11,12,13,14] PVE and CDIE account for 20% and 6.4% of cases of infective endocarditis, respectively.[5,11,15] Those with a history of IV drug abuse (IVDA) are also at high risk. Of note, the incidence of healthcare-associated infective endocarditis is rising, especially in the elderly population.[11,12] Other conditions associated with a higher incidence of infective endocarditis include diabetes, long-term hemodialysis, and poor dental hygiene.[5,13]

1 Most persons with infective endocarditis have risk factors, such as preexisting cardiac valvular abnormalities. Many types of structural heart disease result in turbulent blood flow that increases the risk for infective endocarditis. A predisposing risk factor, however, may be absent in up to 25% of cases. Some of the more important risk factors include:[4,5,7,11,13,16]

1. Presence of a prosthetic valve (highest risk)
2. Previous endocarditis (highest risk)
3. Healthcare-related exposure (high risk)
4. Congenital heart disease (CHD)
5. Chronic IV access
6. Diabetes mellitus
7. Acquired valvular dysfunction (eg, rheumatic heart disease)
8. Cardiac implantable device
9. Chronic heart failure
10. Mitral valve prolapse with regurgitation
11. IVDA

Rheumatic heart disease was a prevalent risk factor for infective endocarditis, but the incidence of this disease continues to decline. The risk of infective endocarditis in persons with mitral valve prolapse and regurgitation is small; however, because the condition is prevalent, it is an important contributor to the overall number of infective endocarditis cases.[5,11] PVE occurs in 1% to 3% of patients undergoing valve replacement surgery in the first postoperative year.[11,17]

2 Nearly every organism causing human disease may cause infective endocarditis, but three groups of organisms result in a majority of cases: streptococci, staphylococci, and enterococci (**Table 111-1**).[3,4,5,11,16] The incidence of staphylococci, particularly *S. aureus*, continues to increase primarily due to healthcare exposure, and case series have documented that staphylococci have surpassed viridans streptococci as the leading cause of infective endocarditis.[4,11,16] In general, streptococci cause infective endocarditis in patients with community-acquired disease and underlying cardiac abnormalities, such as mitral valve prolapse or rheumatic heart disease. Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common cause of PVE within the first year after valve surgery, and *S. aureus* is common in those with a history of IVDA. Although polymicrobial infective endocarditis is uncommon, it is encountered most often in association with IVDA.[11,16] Enterococcal endocarditis tends to follow genitourinary manipulations or obstetric procedures.[17] There are many exceptions to the preceding generalizations; thus, isolation of the causative pathogen and determination of its antimicrobial susceptibilities offer the best chance for successful therapy.

TABLE 111-1 Etiologic Organisms in Infective Endocarditis[a]

Agent	Percentage of Cases
Staphylococci	30-70
Coagulase positive	20-68
Coagulase negative	3-26
Streptococci	9-38
Viridans streptococci	10-28
Other streptococci	3-14
Enterococci	5-18
Gram-negative aerobic bacilli	1.5-13
Fungi	1-9
Miscellaneous bacteria	<5
Mixed infections	1-2
"Culture negative"	<5-17

[a]Values encompass community-acquired, healthcare-associated, native valve, and prosthetic valve infective endocarditis.

Data from references 3, 11, and 16.

The mitral and aortic valves are affected most commonly in cases involving a single valve. Subacute endocarditis tends to involve the mitral valve, whereas acute disease often involves the aortic valve. Up to 35% of cases involve concomitant infections of both the aortic and the mitral valves. Infection of the tricuspid valve is less common, with a majority of these cases occurring in patients with a history of IVDA. It is rare for the pulmonary valve to be infected.[11,16,17]

Pathophysiology

The development of infective endocarditis via hematogenous spread, the most common route, requires the sequential occurrence of several factors. These components are complex and not fully elucidated.[2,18,19]

1. *The endothelial surface of the heart is damaged.* This injury occurs with turbulent blood flow associated with the valvular lesions previously described.

2. *Platelet and fibrin deposition occurs on the abnormal epithelial surface.* These platelet-fibrin deposits are referred to as *nonbacterial thrombotic endocarditis*.

3. *Bacteremia gives organisms access to and results in colonization of the endocardial surface.* Bacteremia is the result of trauma to a mucosal surface with a high concentration of resident bacteria such as the oral cavity and GI tract. Transient bacteremia commonly follow certain dental, GI, urologic, and gynecologic procedures. Staphylococci, viridans streptococci, and enterococci are most likely to adhere to nonbacterial thrombotic endocarditis, probably

because of production of specific adherence factors such as dextran by some oral streptococci and glycocalyx for staphylococci. Gram-negative bacteria rarely adhere to heart valves and are uncommon causes of infective endocarditis.

4. *After colonization of the endothelial surface, a "vegetation" of fibrin, platelets, and bacteria forms.* The protective cover of fibrin and platelets allows unimpeded bacterial growth to concentrations as high as 10^9 to 10^{10} organisms per gram of tissue.

The pathogenesis of early PVE or CDIE differs from infective endocarditis acquired by the hematogenous route because surgery may directly inoculate prosthetic material with bacteria from the patient's skin or operating room personnel. In the case of early PVE, a recently placed nonendothelialized valve is more susceptible to bacterial colonization than are native valves. Bacteria also may colonize the new valve from contaminated bypass pumps, cannulas, and pacemakers or from a nosocomial bacteremia subsequent to an intravascular catheter.[7,16,17] The mechanism of bacterial colonization and pathogenesis in late PVE is similar to native valve endocarditis (NVE).[17]

The vegetations seen in infective endocarditis may be single or multiple and vary in size from a few millimeters to centimeters. Bacteria within the vegetation grow slowly and are protected from antibiotics and host defenses. The adverse effects of infective endocarditis and the resulting lesions can be far-reaching and include: (a) local perivalvular damage, (b) embolization of septic fragments with potential hematogenous seeding of remote sites, and (c) formation of antibody complexes.[17,19]

Formation of vegetations may destroy valvular tissue, and continued destruction can lead to acute heart failure via perforation of the valve leaflet, rupture of the chordae tendineae or papillary muscle, or, for patients with PVE, valve dehiscence. Occasionally, valvular stenosis may occur. Abscesses can develop in the valve ring or in myocardial tissue itself. Even with resolution of the process, fibrosis of tissue with some residual dysfunction is possible.

Vegetations may be friable, and fragments may be released downstream. These infected particles, termed *septic emboli*, can result in organ abscess or infarction. Septic emboli from right-sided endocarditis commonly lodge in the lungs, causing pulmonary abscesses. Emboli from left-sided vegetations commonly affect organs with high blood flow such as the kidneys, spleen, and brain.[4,17,19]

Circulating immune complexes consisting of antigen, antibody, and complement may deposit in organs, producing local inflammation, and damage (eg, glomerulonephritis in the kidneys). Other potential pathologic changes that result from immune-complex deposition or septic emboli include the development of "mycotic" aneurysms (although the aneurysm is usually bacterial in origin, not fungal), cerebral infarction, splenic infarction and abscess, and skin manifestations such as petechiae, Osler's nodes, and Janeway's lesions.[1,17,19]

CLINICAL PRESENTATION

3 The clinical presentation of infective endocarditis is highly variable and nonspecific. Fever is the

most common finding and is often accompanied by other vague symptoms (**Table 111-2**). Fever may be relatively low grade, particularly in subacute cases. Heart murmurs are found in a majority of patients, most often preexisting, with some documented as new or changing. Infective endocarditis usually begins insidiously and worsens gradually. Patients may present with nonspecific findings such as fever, chills, weakness, dyspnea, night sweats, weight loss, or malaise. In contrast, patients with acute disease, such as those with a history of IVDA and *S. aureus* infective endocarditis, may appear with classic signs of sepsis.

TABLE 111-2 Clinical Presentation of Infective Endocarditis

General
The clinical presentation of infective endocarditis is highly variable and nonspecific
Symptoms
The patient may complain of fever, chills, weakness, dyspnea, night sweats, weight loss, and/or malaise
Signs
Fever is common, as is a heart murmur (sometimes new or changing). The patient may have embolic phenomenon, splenomegaly, or skin manifestations (eg, Osler's nodes, Janeway's lesions)
Laboratory tests
The patient's white blood cell count may be normal or only slightly elevated
Nonspecific findings include anemia (normocytic, normochromic), thrombocytopenia, an elevated erythrocyte sedimentation rate or C-reactive protein, and altered urinary analysis (proteinuria/microscopic hematuria)
The hallmark laboratory finding is continuous bacteremia; three sets of blood cultures should be collected over 24 hours
Other diagnostic tests
An electrocardiogram, chest radiograph, and echocardiogram are commonly performed. Echocardiography to determine the presence of valvular vegetations plays a key role in the diagnosis of infective endocarditis; it should be performed in all suspected cases

Splenomegaly is a frequent finding for patients with prolonged endocarditis. Other important clinical signs especially prevalent in subacute illness may include the following peripheral manifestations ("stigmata") of endocarditis:[11,12,16,19]

1. Osler's nodes: Purplish or erythematous subcutaneous papules or nodules on the pads of the fingers and toes. These lesions are 2 to 15 mm in size and are painful and tender. These nodes are not specific for infective endocarditis and may be the result of embolism, immunologic phenomena, or both.

2. Janeway's lesions: Hemorrhagic, painless plaques on the palms of the hands or soles of the feet.

These lesions are believed to be embolic in origin.

3. Splinter hemorrhages: Thin, linear hemorrhages found under the nail beds of the fingers or toes. These lesions are not specific for infective endocarditis and more commonly are the result of traumatic injuries. Distal lesions are more likely the result of trauma, whereas proximal lesions tend to be associated with infective endocarditis.

4. Petechiae: Small (usually 1-2 mm in diameter), erythematous, painless, hemorrhagic lesions. These lesions appear anywhere on the skin but more frequently on the anterior trunk, buccal mucosa and palate, and conjunctivae. Petechiae are nonblanching and resolve after a few days.

5. Clubbing of the fingers: Proliferative changes in the soft tissues about the terminal phalanges observed in long-standing endocarditis.

6. Roth's spots: Retinal infarct with central pallor and surrounding hemorrhage.

7. Emboli: Embolic phenomena occur in up to one third of cases and may result in significant complications. Left-sided endocarditis can result in renal artery emboli causing flank pain with hematuria, splenic artery emboli causing abdominal pain, and cerebral emboli, which may result in hemiplegia or alteration in mental status. Right-sided endocarditis may result in pulmonary emboli, causing pleuritic pain with hemoptysis.

Patients with infective endocarditis typically have laboratory abnormalities; however, none of these changes is specific for the disease. Anemia (normocytic, normochromic), leukocytosis, and thrombocytopenia may be present. The white blood cell count is often normal or only slightly elevated, sometimes with a mild left shift. Acute bacterial endocarditis, however, may present with an elevated white blood cell count, consistent with a fulminant infection. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be elevated in approximately 60% of patients. Often the urinary analysis is abnormal, with proteinuria and microscopic hematuria occurring in approximately 25% of individuals.[11,19]

The hallmark of infective endocarditis is a continuous bacteremia caused by bacteria shedding from the vegetation into the bloodstream; 90% to 95% of patients with infective endocarditis have positive blood cultures.[1,11,17] In most cases, three sets of blood cultures, each from separate venipuncture sites, should be collected promptly, with the first and last set drawn at least 1 hour apart. This allows expedient initiation of empiric antibiotic therapy and can help guide early decisions regarding other potential interventions. "Culture-negative" endocarditis describes a patient in whom a clinical diagnosis of infective endocarditis is likely but blood cultures do not yield a pathogen. This condition is often the consequence of previous antibiotic therapy, improperly collected blood cultures, or unusual organisms.[4] When blood cultures from patients suspected of having infective endocarditis show no growth after 48 to 72 hours, cultures should be held for up to a month to detect growth of fastidious organisms.[4]

An electrocardiogram, chest radiograph, and echocardiogram are performed for patients suspected of endocarditis. The electrocardiogram rarely shows important diagnostic findings but may reveal heart block, suggesting extension of the infection. The chest radiograph may provide more

diagnostic information, especially in a patient with right-sided endocarditis. Septic pulmonary emboli may occur, leading to multiple lung foci. The echocardiogram is the most important test and should be performed for all patients suspected of this infection.

Echocardiography plays an important role in the diagnosis and management of infective endocarditis.[4,5] The chosen approach, transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE), depends on the clinical setting. The TEE technique is more sensitive for detecting vegetations (85%-90%) as compared with TTE (58%-75%), and TEE maintains good specificity (>90%).[1,5] In addition to helping in the diagnosis of infective endocarditis, the echocardiogram allows the physician to evaluate hemodynamic stability and the need for urgent surgical intervention; it also provides a rough estimate of the likelihood of embolism.[4,20] An initial TTE will be performed in most patients due to the rapidity (ie, fasting state unnecessary) and accessibility (ie, 24-hour service available in most institutions) of testing. This may be the only evaluation needed for children or adults in whom the clinical suspicion of infective endocarditis is relatively low.[4,21] An initial or follow-up TEE is recommended in high-risk patients such as those with many CHDs, previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis.[4,20,22] For those patients with suspected PVE or CDIE, TEE should be considered mandatory. The lack of vegetation on echocardiogram does not exclude infection even if the transesophageal approach is used. In these cases, there is an evolving role for advanced imaging modalities such as 3D TEE, ^{18}F-fluorodeoxyglucose positron emission tomography, single-photon emission computed tomography, and multidetector computed tomography.[4,5,20]

DIAGNOSIS

4 The signs and symptoms of infective endocarditis are not specific, and the diagnosis is often unclear. The identification of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The Duke diagnostic criteria include major and minor variables (**Table 111-3**).[23,24] Based on the number of major and minor criteria that are fulfilled, patients suspected of infective endocarditis are categorized into three separate groups: definite infective endocarditis, possible infective endocarditis, or infective endocarditis rejected.[24]

TABLE 111-3 Diagnosis of Infective Endocarditis According to the Modified Duke Criteria

Major Criteria

Blood culture positive for infective endocarditis

Typical microorganisms consistent with infective endocarditis from two separate blood cultures:

Viridans streptococci, *S. gallolyticus*, HACEK group, *S. aureus*; or

Community-acquired enterococci, in the absence of a primary focus; or

Microorganisms consistent with infective endocarditis from persistently positive blood cultures, defined as follows:

At least two positive cultures of blood samples drawn greater than 12 hours apart; or

All of three or a majority of four or more separate cultures of blood (with first and last sample drawn at least 1 hour apart)

Single positive blood culture for *Coxiella burnetii* or antiphase I immunoglobulin G antibody titer >1:800

Evidence of endocardial involvement

Echocardiogram positive for infective endocarditis (transesophageal echocardiography recommended for patients with prosthetic valves, rated at least "possible infective endocarditis" by clinical criteria, or complicated infective endocarditis [paravalvular abscess]; transthoracic echocardiography as first test for other patients), defined as follows:

Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation; or abscess; or

New partial dehiscence of prosthetic valve

New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor Criteria

Predisposition, predisposing heart condition, or injection drug use

Fever, temperature >38°C (100.4°F)

Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway's lesions

Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor

Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with infective endocarditis

Echocardiographic minor criteria eliminated

HACEK, *Haemophilus* species (*H. parainfluenzae, H. aphrophilus, H. paraphrophilus*), *Aggregatibacter* species, *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*.

Note: Cases are defined clinically as *definite* if they fulfill two major criteria, one major criterion plus three minor criteria, or five minor criteria; cases are defined as *possible* if they fulfill one major and one minor criterion or three minor criteria. Cases are rejected if there is a firm alternate diagnosis explaining evidence of infective endocarditis; resolution of infective endocarditis syndrome with antibiotic therapy for <4 days; no pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for <4 days; or criteria for possible infective endocarditis are not met, as above.

Data from references 23 and 24.

The outcome for endocarditis is improved with rapid diagnosis, appropriate treatment (ie, antimicrobial therapy, surgery, or both), and prompt recognition of complications should they arise. Factors associated with increased mortality include: (a) heart failure, (b) increasing age, (c) endocarditis caused by resistant organisms, such as fungi or gram-negative bacteria, (d) left-sided endocarditis caused by *S. aureus*, (e) paravalvular complications, (f) healthcare-acquired infection, and (g) PVE.[4,5,11,16] The presence of heart failure has the greatest negative impact on the short-term prognosis.[4] For left-sided native valve infective endocarditis, mortality rates range from 15% to 45%; lower rates (4%-16%) occur with community-acquired disease that is most commonly caused by viridans streptococci. Higher rates (25%-45%) occur with healthcare-associated disease that is more commonly caused by enterococci and staphylococci.[25] Even higher rates of mortality are seen with unusually encountered organisms (eg, mortality > 80% for fungi).[4,5] The mortality rate for right-sided infective endocarditis associated with IVDA is generally low (eg, <10%).[4,25] For those who relapse after treatment for infective endocarditis, most will do so within the first 2 months after discontinuation of antimicrobials. Relapse rates for viridans streptococcus are generally low (2%), whereas relapse is more likely in those with enterococcal infection (8%-20%) and PVE (10%-15%).[17] After appropriate treatment and recovery, the risk of morbidity and mortality following infective endocarditis persists for years, although it gradually declines annually. Morbidity remains elevated because of a greater likelihood of recurrent infective endocarditis, heart failure, and embolism or, if a valve is replaced, the risk of anticoagulation, valve thrombosis, or additional valve surgery.[22]

TREATMENT

Desired Outcomes

The desired outcomes for treatment and prophylaxis of infective endocarditis are to:

1. Relieve the signs and symptoms of the disease
2. Decrease morbidity and mortality associated with the infection
3. Eradicate the causative organism with minimal drug exposure
4. Provide cost-effective antimicrobial therapy determined by the likely or identified pathogen, drug susceptibilities, hepatic and renal function, drug allergies, and anticipated drug toxicities
5. Prevent infective endocarditis from occurring or recurring in high-risk patients with appropriate prophylactic antimicrobials

General Approach to Treatment

Specific treatment recommendations from the American Heart Association (AHA) provide guidance for the management of infective endocarditis, and these were last updated in 2015.[4] Guidelines published by the European Society of Cardiology (ESC) remain consistent, for the most part, with the AHA guidelines.[5] Both now provide important recommendations for the combination of early

diagnosis, early antibiotic therapy, and early surgery; but there are some subtle differences. For the first time, the ESC guidelines recommend that an "endocarditis team" is crucial for the management of infective endocarditis. The team should include cardiologists, cardiac surgeons, and specialists in infectious disease. The AHA guidelines place more emphasis on a team-based approach when assessing the timing and need for surgical intervention. The ESC guidelines also provide recommendations for specific situations, including infective endocarditis in the intensive care unit, in patients with cancer, and in patients with nonbacterial endocarditis.[5]

The AHA and ESC guidelines use an evidence-based scoring system where recommendations are given a classification as well as level of evidence. Class I recommendations are conditions for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective. Class II recommendations are conditions for which there is conflicting evidence, a divergence of opinion, or both about the usefulness/efficacy of a procedure or treatment (IIa implies that the weight of evidence/opinion is in favor of usefulness/efficacy, whereas IIb implies that usefulness/efficacy is less well established by evidence/opinion). Class III recommendations are conditions for which there is evidence, general agreement, or both that the procedure/treatment is not useful/effective and in some cases may be harmful. Level of evidence is listed as A (data derived from multiple randomized clinical trials), B (data derived from a single randomized trial or nonrandomized studies), and C (consensus opinion of experts).

5 The most important approach in the treatment of infective endocarditis is isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, and bactericidal antibiotics for an extended period.[1,4,5,6,19] Identification of susceptibilities is crucial given the escalating level of antibiotic resistance to commonly encountered pathogens. Treatment usually is started in the hospital, but for select patients it is often completed in the outpatient setting so long as defervescence has occurred and follow-up blood cultures show no growth.[26] Large doses of parenteral antimicrobials usually are necessary to achieve bactericidal concentrations within vegetations. An extended duration of therapy is required, even for susceptible pathogens, because microorganisms are enclosed within valvular vegetations and fibrin deposits. These barriers impair host defenses and protect microbes from phagocytic cells. In addition, high bacterial concentrations within vegetations may result in an inoculum effect that further resists killing (see Chapter 24 for additional discussion). Many bacteria are not actively dividing, further limiting the rate of bacterial death. For most patients, a minimum of 4 to 6 weeks of therapy is required.[4,5]

Nonpharmacologic Therapy

6 Surgery is an important adjunct in the management of both NVE and PVE and is now performed in up to 50% of patients.[27] In most surgical cases, valvectomy and valve replacement are performed to remove infected tissue and to restore hemodynamic function. Indications for surgery include heart failure, persistent bacteremia, persistent vegetation, an increase in vegetation size, or recurrent emboli despite prolonged antibiotic treatment, valve dysfunction, paravalvular extension (eg, abscess), or endocarditis caused by resistant organisms (eg, fungi or gram-negative bacteria).[4,5,6] More controversial is the appropriate timing of surgery as well as duration of antibiotic therapy

post-surgery. Additionally, studies evaluating postsurgical outcomes and associated mortality are limited such that a specific risk prediction system has not been established.[28,29,30,31,32] Early surgery (eg, within 48 hours) may be appropriate in patients with severe heart failure and large vegetations, whereas patients with septic shock, advanced age, or neurologic complications of infective endocarditis may have more detrimental outcomes.[28,29,33,34] The multiple factors that need to be considered in evaluating the need for and timing of surgery is why a multidisciplinary management approach (ie, "endocarditis team") is critical.[4,5,19]

Clinical Controversy...

The role of surgery in the management of infective endocarditis is increasing; however, the duration of antibiotic therapy post-surgery is unclear and can depend on whether prosthetic material was inserted and if resected tissue is culture positive or culture negative.

Pharmacologic Therapy

7 β-Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively. **Tables 111-4, 111-5, 111-6, 111-7** summarize these recommendations, which are discussed in more detail in the following sections. **Tables 111-8** and **111-9** list drug dosing and monitoring recommendations for adult and pediatric patients. Because these guidelines focus on common causes of endocarditis, readers are referred to other references for more in-depth discussion of unusually encountered organisms.[4,5,35,36,37,38]

TABLE 111-4 Treatment Options for Native Valve Endocarditis by Causative Organism

Agent[a]	Duration	Strength of Recommendation	Comments
Highly Penicillin-Susceptible (MIC ≤ 0.12 mcg/mL [mg/L]) Viridans Group Streptococci and *S. Gallolyticus*			
Aqueous crystalline penicillin G sodium[b]	4 weeks	IIaB	2-week regimens are not intended for the following patients: • Most patients >65 years of age • Children • Impairment of the eighth cranial nerve function • Renal function with a creatinine clearance <20 mL/min (<0.33 mL/s) • Known cardiac or extracardiac abscess
Ceftriaxone	4 weeks	IIaB	
Aqueous crystalline penicillin G sodium[b] plus gentamicin	2 weeks	IIaB	

Agent[a]	Duration	Strength of Recommendation	Comments
Ceftriaxone plus gentamicin	2 weeks	IIaB	• Infection with *Abiotrophia, Granulicatella*, or *Gemalla* species
Vancomycin	4 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Viridans Group Streptococci and *S. Gallolyticus* Relatively Resistant to Penicillin (MIC >0.12 to ≤0.5 mcg/mL [mg/L])			
Aqueous crystalline penicillin G sodium[b] plus gentamicin	4 weeks 2 weeks	IIaB	
Ceftriaxone plus gentamicin	4 weeks 2 weeks	IIbC	
Vancomycin	4 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Oxacillin-Susceptible Staphylococci[c]			
Nafcillin or oxacillin	6 weeks	1C	
Cefazolin	6 weeks	1B	For use in patients with nonanaphylactoid-type penicillin allergies; patients with an unclear history of immediate-type hypersensitivity to penicillin should be considered for skin testing
Vancomycin	6 weeks	1B	For use in patients with anaphylactoid-type hypersensitivity to penicillin and/or cephalosporins
Daptomycin	6 weeks	IIaB	For use in patients with immediate-type hypersensitivity reactions to penicillin
Oxacillin-Resistant Staphylococci			
Vancomycin	6 weeks	1C	
Daptomycin	6 weeks	IIbB	

Please refer to Table 111-6 for treatment of NVE caused by enterococci.

[a]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring information.

[b]May use ampicillin in the event of a penicillin shortage.

[c]Regimens indicate treatment for left-sided endocarditis or complicated right-sided endocarditis;

uncomplicated right-sided endocarditis may be treated for shorter durations and is described in the text.

Data from references 4 and 20.

TABLE 111-5 Treatment Options for Prosthetic Valve Endocarditis (PVE) by Causative Organism

Agent[a]	Duration	Strength of Recommendation	Comments
Highly Penicillin-Susceptible (MIC ≤ 0.12 mcg/mL [mg/L]) Viridans Group Streptococci and *S. Galloyticus*			
Aqueous crystalline penicillin G sodium[b] with or without gentamicin	6 weeks 2 weeks	IIaB	Combination therapy with gentamicin has not demonstrated superior cure rates compared with monotherapy with a penicillin or cephalosporin and should be avoided in patients with CrCl <30 mL/min (<0.50 mL/s)
Ceftriaxone with or without gentamicin	6 weeks 2 weeks	IIaB	
Vancomycin	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Relatively Resistant or Fully Resistant (MIC > 0.12 mcg/mL [mg/L]) Viridans Group Streptococci and *S. Gallolyticus*			
Aqueous crystalline penicillin G sodium[b] plus gentamicin	6 weeks	IIaB	
Ceftriaxone plus gentamicin	6 weeks	IIaB	
Vancomycin[c]	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Oxacillin-Susceptible Staphylococci			
Nafcillin or oxacillin plus rifampin plus gentamicin	≥6 weeks ≥6 weeks 2 weeks	1B	Cefazolin may be substituted for nafcillin or oxacillin in patients with non-immediate-type hypersensitivity
Vancomycin plus rifampin plus gentamicin	≥6 weeks ≥6 weeks 2 weeks	1B	Recommended only for patients with anaphylactoid-type hypersensitivity to penicillin and/or cephalosporins

Agent[a]	Duration	Strength of Recommendation	Comments
Oxacillin-Resistant Staphylococci			
Vancomycin	≥6 weeks		
plus rifampin	≥6 weeks	1B	
plus gentamicin	2 weeks		

Please refer to Table 111-6 for treatment of PVE caused by enterococci.

[a]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring information.

[b]May use ampicillin in the event of a penicillin shortage.

[c]The ESC 2015 guidelines recommend gentamicin (3 mg/kg/day) be administered with vancomycin for the initial 2 weeks of therapy in patients with relatively resistant strains to penicillin.

Data from references 4, 5, and 20.

TABLE 111-6 Treatment Options for Native or Prosthetic Valve Endocarditis Caused by Enterococci

Agent[a]	Duration[b]	Strength of Recommendation	Comments
Ampicillin-, Penicillin-, and Vancomycin-Susceptible Strains			
Ampicillin plus gentamicin	4-6 weeks	IIaB	Native valve plus symptoms present for <3 months: use 4-week regimen
Aqueous crystalline penicillin G sodium plus gentamicin	4-6 weeks	IIAB	Prosthetic valve or native valve plus symptoms present for >3 months: use 6-week regimen
Ampicillin plus ceftriaxone	6 weeks	IIaB	Recommended regimen if creatinine clearance is <50 mL/min (<0.83 mL/s; at baseline or due to therapy with a gentamicin-containing regimen)
Vancomycin plus gentamicin	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ampicillin
Gentamicin-Resistant Strains			
If susceptible, use streptomycin in place of gentamicin in the regimens listed above as long as creatinine clearance is >50 mL/min (>0.83 mL/s), cranial nerve VIII function is intact and there is laboratory capability for rapid streptomycin serum concentrations.			
Penicillin-Resistant Strains			

Agent[a]	Duration[b]	Strength of Recommendation	Comments
Ampicillin–sulbactam plus gentamicin (β-lactamase–producing strain)	6 weeks	IIbC	
Vancomycin plus gentamicin (intrinsic penicillin resistance[c])	6 weeks	IIbC	May also use in patients with β-lactamase–producing strains who have known intolerance to ampicillin–sulbactam
***Enterococcus Faecium* Strains Resistant to Penicillin, Aminoglycosides, and Vancomycin[d]**			
Linezolid	>6 weeks	IIbC	Antimicrobial cure rates may be <50%; bacteriologic cure may only be achieved with cardiac valve replacement
Daptomycin	>6 weeks	IIbC	

[a]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring information.

[b]All patients with prosthetic valves should be treated for at least 6 weeks.

[c]Infectious disease consult highly recommended.

[d]Patients should be managed by a multidisciplinary team that includes specialists in cardiology, cardiovascular surgery, infectious diseases, and clinical pharmacy.

Data from reference 4.

TABLE 111-7 Treatment Options for Culture-Negative Endocarditis and Endocarditis Caused by Gram-Negative Organisms[a]

Agent[b]	Duration[c]	Strength of Recommendation	Comments
HACEK[d] Microorganisms			
Ceftriaxone	4 weeks	IIaB	Other third- or fourth-generation cephalosporins may be used as an alternative
Ampicillin or Ampicillin–sulbactam	4 weeks	IIaB	Should only use if growth is adequate for in vitro susceptibility testing; otherwise, consider organism to be resistant
Ciprofloxacin	4 weeks	IIbC	Recommended for patients with known intolerance to cephalosporins or ampicillin; other fluoroquinolones may be used as an alternative

Agent[b]	Duration[c]	Strength of Recommendation	Comments
Culture-Negative Endocarditis, Native Valve[e]			
Vancomcyin plus cefepime	4-6 weeks	IIaC	Recommended when onset is acute (days); *S. aureus*, *β*-hemolytic streptococci, and aerobic gram-negative bacilli should be covered
Vancomycin plus ampicillin-sulbactam	4-6 weeks	IIaC	Recommended when onset is subacute (weeks); *S. aureus*, viridans group streptococci, HACEK, and enterococci should be covered
Culture-Negative Endocarditis, Early (<1 Year) Prosthetic Valve[e]			
Vancomycin plus cefepime plus rifampin plus gentamicin	6 weeks	IIaC	Staphylococci, enterococci, and aerobic gram-negative bacilli should be covered
Culture-Negative Endocarditis, Late (>1 Year) Prosthetic Valve[e]			
Vancomycin plus ceftriaxone	6 weeks	IIaC	Staphylococci, viridans group streptococci, and enterococci should be covered
Suspected *Bartonella*, Culture-Negative			
Ceftriaxone plus gentamicin with or without doxycycline	6 weeks 2 weeks 6 weeks	IIaB	
Culture-Positive *Bartonella*			
Doxycycline plus gentamicin	6 weeks 2 weeks	IIaB	Rifampin is recommended as an alternative in patient who cannot be given gentamicin

[a]Infectious disease consult highly recommended.

[b]See Tables 111-8 and 111-9 for appropriate dosing, administration, and monitoring.

[c]All patients with prosthetic valves should be treated for 6 weeks.

[d]*Haemophilus species* (*H. parainfluenzae, H. aphrophilus, and H. paraphrophilus*), *Aggregatibacter* species, *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*.

[e]Duration of therapy for culture-negative endocarditis may be variable and should be based on clinical course and recommendations from infectious diseases consult.

Haemophilus parainfluenzae, *Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*.

Data from references 4 and 5.

TABLE 111-8 Drug Dosing Table for Treatment of Infective Endocarditis[a]

Drug	Brand Name	Recommended Dose	Pediatric (Ped) Dose[b]	Additional Information
Ampicillin	NA	2 g IV every 4 hours	50 mg/kg every 4 hours or 75 mg/kg every 6 hours	24-hour total dose may be administered as a continuous infusion: 12 g IV every 24 hours
Ampicillin–sulbactam	Unasyn®	2 g IV every 4 hours	50 mg/kg every 4 hours or 75 mg/kg every 6 hours	
Aqueous crystalline penicillin G sodium • MIC <0.12 mcg/mL (mg/L) (native valve only) • All other indications	NA	3 million units IV every 4 hours or every 6 hours 4 million units IV every 4 hours or 6 million units IV every 6 hours	50,000 units/kg IV every 6 hours 50,000 units/kg IV every 4 hours or 75,000 units/kg IV every 6 hours	24-hour total dose may be administered as a continuous infusion: 12-18 million units IV every 24 hours (Ped: 200,000 units/kg IV/24 hours) 24 million units IV every 24 hours (Ped: 300,000 units/kg IV every 24 hours)
Cefazolin	Ancef®	2 g IV every 8 hours	33 mg/kg IV every 8 hours	
Cefepime	Maxipime®	2 g IV every 8 hours	50 mg/kg IV every 8 hours	
Ceftriaxone sodium	Rocephin®	2 g IV or IM every 24 hours 2 g IV or IM every 12 hours (*E. faecalis only*)	100 mg/kg IV or IM every 24 hours	
Ciprofloxacin	Cipro®	400 mg IV every 12 hours or 500 mg po every 12 hours	20-30 mg/kg IV or po every 12 hours	Avoid use if possible in patients <18 years of age
Daptomycin	Cubicin®	≥8 mg/kg IV every 24 hours	6 mg/kg IV every 24 hours	Doses as high as 10-12 mg/kg IV every 24 hours have been used in adults with enterococcus resistant to

Drug	Brand Name	Recommended Dose	Pediatric (Ped) Dose[b]	Additional Information
				penicillin, aminoglycosides and vancomycin; doses should be calculated using actual body weight
Doxycline	Vibramycin®	100 mg IV or po every 12 hours	1-2 mg/kg IV or po every 12 hours	
Gentamicin sulfate	NA	3 mg/kg IV or IM every 24 hours or 1 mg/kg IV or IM every 8 hours[c]	1 mg/kg IV or IM every 8 hours	Once-daily dosing is only recommended for treatment of streptococcal infections.
Linezolid	Zyvox®	600 mg IV or po every 12 hours	10 mg/kg IV every 8 hours	
Nafcillin or oxacillin	NA	2 g IV every 4 hours	50 mg/kg IV every 6 hours	
Rifampin	Rifadin®	300 mg IV or po every 8 hours	5-7 mg/kg IV or po every 8 hours	
Streptomycin	NA	7.5 mg/kg IV or IM every 12 hours		
Vancomycin	Vancocin®	15-20 mg/kg IV every 8 hours or every 12 hours	15 mg/kg IV every 6 hours	A loading dose of 25-30 mg/kg may be administered in adults; doses should be calculated using actual body weight; single doses should not exceed 2 g

[a]All doses assume normal renal function.

[b]Should not exceed adult dosage.

[c]Actual body weight should be used when the full aminoglycoside dose is administered once daily; when administered in three divided doses, use ideal body weight or adjusted body weight when actual body weight is >120% ideal body weight.

TABLE 111-9 Drug Monitoring of Select Agents

Drug	Major Adverse Drug Reactions	Monitoring Parameters	Comments
Daptomycin	Myopathy, rhabdomyolysis	Creatinine phosphokinase (CPK) at least weekly;	More frequent monitoring may be warranted in patients with renal

Drug	Major Adverse Drug Reactions	Monitoring Parameters	Comments
		monitor for signs and symptoms of muscle pain	dysfunction or receiving concomitant therapy with HMG-CoA reductase inhibitors; discontinue if symptomatic and CPK >5 times the upper limit of normal (ULN) or if CPK ≥10 times ULN
Gentamicin	Nephrotoxicity, ototoxicity, neuromuscular blockade	When dosed three times daily: • Target peak serum concentrations of 3-4 mcg/mL (mg/L; 6.3-8.4 µmol/L) and trough serum concentrations of <1 mcg/mL (mg/L; <2.1 µmol/L)	Avoid concomitant use of other nephrotoxic agents such as diuretics, nonsteroidal antiinflammatory drugs, and radiocontrast media. Avoid rapid IV administration
Linezolid	Thrombocytopenia, optic, or peripheral neuropathy	Platelet counts at baseline and weekly, visual changes	More common with prolonged therapy (≥2 weeks for thrombocytopenia, >28 days for visual symptoms); avoid concomitant myelosuppressive agents
Rifampin	Hepatotoxicity	Baseline liver function tests, and then at least every 2-4 weeks during therapy	Avoid concomitant medications that cause hepatotoxicity; may cause red or orange discoloration of bodily secretions (urine, sweat, tears)
Vancomycin	Nephrotoxicity, red man syndrome	Target trough concentrations of 15-20 mcg/mL[a] (mg/L; 10-14 µmol/L)	Red man syndrome may be managed by prolonging the infusion time from 1 to 2 hours; administration of an antihistamine prior to loading or maintenance doses may also be considered

[a]Measuring peak serum vancomycin concentrations is no longer recommended.

8 For some pathogens, such as enterococci, the use of synergistic antimicrobial combinations (including an aminoglycoside) is essential to obtain a bactericidal effect. Combination antibiotics also may decrease the emergence of resistant organisms during treatment (eg, PVE caused by coagulase-

negative staphylococci) and hasten the pace of clinical and microbiologic response (eg, some streptococcal and staphylococcal infections). Occasionally, combination treatment will result in a shorter treatment course.

Streptococcal Endocarditis

Streptococci are a common cause of infective endocarditis, with most isolates being viridans group streptococci. Viridans group streptococci refers to a large number of different species, such as *Streptococcus sanguinis, Streptococcus oralis, Streptococcus salivarius, Streptococcus mutans*, and *Gemella morbillorum*.[4] These bacteria are common inhabitants of the human mouth and gingiva, and they are especially common causes of endocarditis involving native valves.[4,16,25] During dental surgery, and even when brushing the teeth, these organisms can cause a transient bacteremia. In susceptible individuals, this may result in infective endocarditis. Streptococcal endocarditis is usually subacute, and the response to medical treatment is very good. *Streptococcus gallolyticus* (formerly known as *Streptococcus bovis*) is not a viridans group streptococcus, but it is included in this treatment group because it is penicillin sensitive and requires the same treatment. *S. gallolyticus* is a nonenterococcal group D *Streptococcus* that resides in the GI tract. Infective endocarditis caused by this organism is often associated with a GI pathology, especially colon carcinoma. Endocarditis caused by *Streptococcus pneumoniae, Streptococcus pyogenes*, and group B, C, and G streptococci are uncommon, and their treatment is not well defined.[4,5]

Antimicrobial regimens for viridans group streptococci are well studied, and in uncomplicated cases, the cure rate is expected to be more than 95%.[4,5] Viridans group streptococci are penicillin susceptible, although some are more susceptible than others. Most are highly sensitive to penicillin G and have minimal inhibitory concentrations (MICs) of less than 0.12 mcg/mL (mg/L).[4] Approximately 10% to 20% are moderately susceptible (MIC 0.12-0.5 mcg/mL [mg/L]). This different in vitro susceptibility led to recommendations that the MIC be determined for all viridans streptococci and that the results be used to guide therapy. Some streptococci are deemed tolerant to the killing effects of penicillin, where the minimal bactericidal concentration (MBC) exceeds the MIC by 32 times. A tolerant organism is inhibited but not killed by an antibiotic normally considered bactericidal.[4] Bactericidal activity is required for successful treatment of infective endocarditis; therefore, infections with a tolerant organism may relapse after treatment. Despite some animal studies of endocarditis suggesting that tolerant strains do not respond as readily to β-lactam therapy as nontolerant ones, this phenomenon is primarily a laboratory finding with little clinical significance.[4] Treatment for tolerant strains is identical to that for nontolerant organisms, and measurement of the MBC is not recommended.[4]

An assortment of regimens can be used to treat uncomplicated NVE caused by fully susceptible viridans group streptococci (see Table 111-4). Two single-drug regimens consist of high-dose parenteral penicillin G or ceftriaxone for 4 weeks. If short term, 2 week therapy is desired, the guidelines suggest either high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside.[4] When used in select patients, this combination is as effective as 4 weeks of penicillin alone. Although streptomycin was listed in previous guidelines, gentamicin is the preferred

aminoglycoside because serum drug concentrations are obtained easily, clinicians are more familiar with its use, and the few strains of streptococci resistant to the effects of streptomycin-penicillin remain susceptible to gentamicin–penicillin. Other aminoglycosides are not recommended.

The decision of which regimen to use depends on the perceived risk versus benefit. For example, a 2-week course of gentamicin in an elderly patient with renal impairment may be associated with ototoxicity, worsening renal function, or both. Furthermore, the 2-week regimen is not recommended for patients with known extracardiac infection. On the other hand, a 4-week course of penicillin alone generally entails greater expense, especially if the patient remains in the hospital. Monotherapy with once-daily ceftriaxone offers ease of administration, facilitates home healthcare treatment, and may be cost-effective.[4,5,25]

The British Society for Antimicrobial Chemotherapy guidelines suggest that all of the following conditions be present to consider a 2-week treatment regimen for penicillin-sensitive streptococcal endocarditis:[35]

1. Penicillin-sensitive viridans streptococcus or *S. gallolyticus* (penicillin MIC <0.1 mcg/mL [mg/L])
2. No cardiovascular risk factors such as heart failure, aortic insufficiency, or conduction abnormalities
3. No evidence of thromboembolic disease
4. Native valve infection
5. No vegetation of greater than 5 mm diameter on echo-cardiogram
6. Low risk of nephrotoxicity
7. Not at risk for *Clostridium difficile*
8. Clinical response within 7 days (the temperature should return to normal, the patient should feel well, and the patient's appetite should return to normal)

9 When a patient has a history of an immediate-type hypersensitivity to penicillin, vancomycin should be chosen for infective endocarditis caused by viridans streptococci. When vancomycin is used, the addition of gentamicin is not recommended.[4] Most patients who report a penicillin allergy have a negative penicillin skin test and consequently are at low risk of anaphylaxis.[39] The published experience with penicillin is more extensive than with alternative regimens; consequently, a thorough allergy history must be obtained before a second-line therapy is administered.

For patients with complicated infections (eg, extracardiac foci) or when the streptococcus has an MIC of 0.12 to less than or equal to 0.5 mcg/mL (mg/L), combination therapy with an aminoglycoside for the first 2 weeks and penicillin (higher dose) or ceftriaxone is recommended, followed by penicillin or ceftriaxone alone for an additional 2 weeks (see Table 111-4).[4] Some viridans streptococci, previously referred to as nutritionally variant streptococci, have biologic characteristics that complicate

diagnosis and treatment. *Abiotrophia defectiva* and *Granulicatella* species have nutritional deficiencies that hinder growth in routine culture media.[4] These organisms require special broth supplemented with pyridoxal hydrochloride or cysteine. For patients infected with nutritionally variant streptococci or when the *Streptococcus* has an MIC of more than 0.5 mcg/mL (mg/L), treatment should follow the enterococcal endocarditis treatment guidelines.[4]

The rationale for combination therapy of penicillin-susceptible viridans streptococci is that enhanced activity against these organisms usually is observed when cell-wall–active agents are combined with aminoglycosides in vitro.[40] Combined treatment results in quicker sterilization of vegetations in animal models of endocarditis and probably explains the high response rates observed for patients treated for a total of 2 weeks.[4,41] The combined treatment, however, is not superior to penicillin alone. Some authors question the need for combination therapy in relatively resistant streptococci, emphasizing that few human data suggest that patients with endocarditis caused by these organisms respond less well to penicillin alone.[40,42]

For patients with endocarditis of prosthetic valves or other prosthetic material caused by viridans group streptococci and *S. gallolyticus*, choices of treatment are similar to those without prosthetic material (eg, penicillin or ceftriaxone); however, treatment courses are extended to 6 weeks (see Table 111-5) for both the β-Lactam and the aminoglycoside. Whether extended-interval aminoglycoside dosing has a role in infective endocarditis continues to be debated. At this time, data support extended-interval dosing for the treatment of streptococcal infective endocarditis, and as compared with three-times-daily dosing this approach may have greater efficacy.[43,44] One study specifically evaluated the combination of ceftriaxone (2 g daily) with gentamicin (3 mg/kg daily) for 2 weeks compared with ceftriaxone (2 g daily) alone for 4 weeks for penicillin-sensitive streptococci. Both regimens were safe and effective with similar clinical cure rates at 3 months following treatment.[41]

Staphylococcal Endocarditis

Endocarditis caused by staphylococci has become more prevalent, mainly because of increased IVDA, more frequent use of peripheral and central venous catheters, and increased frequency of valve replacement surgery.[45,46] *S. aureus* is the most common organism causing infective endocarditis among those with IVDA and persons with venous catheters. Coagulase-negative staphylococci (usually *Staphylococcus epidermidis*) and *S. aureus* are prominent causes of PVE.

Staphylococcal endocarditis is not a homogeneous disease; appropriate management requires consideration of several questions: Is the organism methicillin resistant? Should combination therapy be used? Is the infection on a native or prosthetic valve? Does the patient have a history of IVDA? Is the infection on the left or right side of the heart? Another consideration in staphylococcal endocarditis is that some organisms may exhibit tolerance to antibiotics. Similar to streptococci, however, the concern for tolerance among staphylococci should not affect antibiotic selection.[4]

Any patient who develops staphylococcal bacteremia is at risk for endocarditis. Many investigators have attempted to develop criteria that identify the bacteremic patient likely to have infective endocarditis.[45] In the past, patients were considered to be at high risk for infective endocarditis if *S.*

aureus bacteremia was community acquired versus hospital acquired; however, nosocomial *S. aureus* bacteremia is now considered as a major criterion for development of infective endocarditis.[23,24] The prevalence of infective endocarditis in patients with *S. aureus* bacteremia is approximately 25%, leading some authors to suggest that screening echocardiography be performed in all patients.[47] In hospitalized patients with *S. aureus* bacteremia and an identified focus of infection, such as a vascular catheter, the risk of concomitant infective endocarditis is low, and treatment of the bacteremia can be reduced to 2 weeks. This approach applies only if the patient does not have a prosthetic valve or additional clinical evidence for endocarditis.[48] Additionally, the following parameters predict higher risk of infective endocarditis for patients with *S. aureus* bacteremia: (a) the absence of a primary site of infection, (b) metastatic signs of infection, and (c) valvular vegetations detected by echocardiography.[24,47]

The recommended therapy for patients with left-sided, native valve infective endocarditis caused by methicillin-sensitive *S. aureus* (MSSA) is 6 weeks of nafcillin or oxacillin; a longer duration of therapy may be needed for complicated infections (ie, presence of perivalvular abscess or septic metastases). The AHA and ESC guidelines no longer recommend the addition of gentamicin because clinical benefit has not been demonstrated and there is an increase risk of toxicity (see Table 111-4). From in vitro studies, the combination of an aminoglycoside and penicillinase-resistant penicillin or vancomycin enhances the activity of these drugs for MSSA. In animal models of endocarditis, combinations of penicillin with an aminoglycoside eradicate organisms from vegetations more rapidly than penicillins alone.[5,40,49] In most human studies, the addition of an aminoglycoside to nafcillin hastens the resolution of fever and bacteremia, but it does not affect survival or relapse rates and can increase renal toxicity.[40,50,51] One small cohort study has demonstrated a decrease in recurrent bacteremia with combination therapy.[52]

If a patient has a mild, delayed allergy to penicillin, first-generation cephalosporins (such as cefazolin) are effective alternatives, but they should be avoided for patients with a history of immediate-type hypersensitivity reactions to penicillins (see Table 111-4). The potential for a true immediate-type allergy should be assessed carefully. A penicillin skin test should be conducted before giving antibiotic treatment to any patient with infective endocarditis caused by MSSA if there is a questionable penicillin allergy.[53] For a patient with a positive skin test or a history of immediate hypersensitivity to penicillin, vancomycin is an option. Vancomycin, however, kills *S. aureus* slowly and is regarded as inferior to penicillinase-resistant penicillins for MSSA.[4] Alternatively, patients with immediate-type hypersensitivity reactions to penicillin can be considered for penicillin desensitization or daptomycin, a lipopeptide antibiotic approved for right sided infective endocarditis and *S. aureus* bacteremia.[4,5] Unfortunately, left-sided infective endocarditis caused by *S. aureus* continues to have a poor prognosis, with a mortality rate between 25% and 40%.[4] For reasons discussed in the following section, those with infective endocarditis associated with IVDA have a more favorable response to therapy.

During the past decade, staphylococci more commonly have become resistant to penicillinase-resistant penicillins (ie, methicillin-resistant *S. aureus* [MRSA]). Although vancomycin is still the most commonly selected alternative in these cases (see Table 111-4), susceptibility reports with MIC

more than 2 mcg/mL (mg/L) and reports of vancomycin-resistant *S. aureus* strains are increasing.[21] Success with daptomycin or linezolid has been demonstrated for these patients.[54,55,56,57,58,59] Based on available data, daptomycin (at a dose of 6 mg/kg/day) was approved by the FDA in 2006 for the treatment of *S. aureus* bacteremia associated with right-sided NVE and is now a recommended alternative.[21,55] Higher doses of daptomycin (8-10 mg/kg/day) have been used in clinical practice and may be preferred by some experts, although prospective, randomized clinical trials are lacking.[21,60,61,62,63] To date, linezolid has not been approved by the FDA for use in endocarditis as most available data are based on case reports, and there is concern regarding use of a bacteriostatic agent for this condition.[21,54] Furthermore, the FDA issued a warning for linezolid in 2007 following reports from one study that patients with catheter-related bacteremia treated with linezolid had an increased incidence of death due to gram-negative bacillary infections.[64] The presence or lack of a prosthetic heart valve in patients with a methicillin-resistant organism guides therapy and determines whether vancomycin should be used alone or, if a prosthetic valve is present, whether combination therapy is necessary (see Table 111-5).[4]

Clinical Controversy…

Use of daptomycin in clinical practice may extend beyond the FDA-indication of right-sided NVE. Selection as an alternative to vancomycin in patients with left-sided NVE (MRSA or MSSA) and in those with MSSA NVE and severe allergy to penicillins or cephalosporins may be observed (ie, in the setting of vancomycin failure or resistance). Furthermore, although the data for use of high-dose daptomycin (8-10 mg/kg/day) is limited, the favorable drug tolerability and the potential for decreased treatment-emergent resistance may compel some prescribers to opt for high-dose therapy in complicated cases.

Staphylococcus Endocarditis: IV Drug Abuser

Infective endocarditis in those with IVDA is frequently (60%-70%) caused by *S. aureus*, although other organisms may be common in certain geographic locations.[25] In this setting, the tricuspid valve is frequently infected, resulting in right-sided infective endocarditis. Most patients have no history of valve abnormalities, are usually otherwise healthy, and have a good response to medical treatment. Nonetheless, surgery may be required.

As previously mentioned, an uncomplicated, left-sided MSSA endocarditis may be treated sufficiently with 6 weeks of monotherapy with penicillinase-resistant penicillin.[4] However, the clinical response with right-sided MSSA endocarditis in the IVDA is usually excellent and may be treated effectively (clinical and microbiologic cure exceeding 85%) with a 2-week course of nafcillin, oxacillin or daptomycin.[4] Previous guidelines emphasized combination therapy with an aminoglycoside for the 2-week duration based on earlier studies.[65,66,67] The current recommendation for monotherapy is based on data showing that a 2-week regimen of a penicillinase-resistant penicillin alone, without the addition of an aminoglycoside, is as effective as combined therapy in MSSA tricuspid valve endocarditis.[68] Additionally, a post-hoc analysis comparing daptomycin monotherapy with combination treatment (daptomycin plus 4 days of gentamicin) showed no difference in success rates

but higher rates of renal toxicity.[50] Selection of a 2-week duration of treatment may be appropriate as long as the following criteria are fulfilled:[5]

- Pathogen identified as MSSA
- Good response to treatment
- Absence of metastatic sites of infection or empyema
- Absence of cardiac and extracardiac complications
- Absence of associated prosthetic valve or left sided valve infection
- Vegetation size less than 20 mm
- Absence of severe immunosuppression (<200 CD4 cells/μL [<0.200 × 10^9/L]) with or without acquired immune deficiency syndrome (AIDS)

Short, 2-week, courses of vancomycin in IVDAs are not recommended because of limited bactericidal activity, poor penetration into vegetations, and increased drug clearance in this population. The standard 6-week regimen should therefore be used. While vancomycin and daptomycin are both options for native valve MRSA infective endocarditis in IVDAs, daptomycin would be the drug of choice in cases where the vancomycin MIC is more than 1 mcg/mL (mg/L).[5]

An intriguing therapeutic approach for staphylococcal endocarditis in those with IVDA is oral treatment. One study indicated that short-course IV treatment (primarily nafcillin; mean: 16 days) followed by oral treatment (dicloxacillin or oxacillin; mean: 26 days) might be effective for tricuspid valve MSSA endocarditis.[69] The positive results of this trial can be explained by the relatively long duration of IV antibiotics (>2 weeks). Two other studies that predominantly used oral therapy (ciprofloxacin and rifampin) demonstrated efficacy (cure rates exceeding 90%) in addicts with uncomplicated right-sided endocarditis caused by MSSA.[70,71] At this time, concerns with resistance (eg, ciprofloxacin), patient adherence, and limited published data preclude routine use of oral antibacterial regimens for the treatment of infective endocarditis in IVDAs.[4]

Staphylococcal Endocarditis: Prosthetic Valves

Prosthetic valve endocarditis accounts for 10% to 30% of all infective endocarditis cases.[5,8] Staphylococcal, fungi, and gram-negative bacilli are the main causes of early PVE, while the microbiology of late PVE mirrors that of NVE. An episode of PVE occurring within 2 months of surgery strongly suggests that the cause is staphylococci implanted during the procedure. Yet the risk of staphylococcal endocarditis remains elevated for up to 12 months after valve replacement.[72] Because this type of infective endocarditis is typically a nosocomial infection, methicillin-resistant organisms are common, and vancomycin is the cornerstone of therapy. Combination antimicrobials are recommended because of the high morbidity and mortality associated with PVE and its refractoriness to therapy.[4,5,11,21] Although the addition of rifampin to a penicillinase-resistant

penicillin or vancomycin does not result in predictable bacterial synergism, rifampin may have unique activity against staphylococcal infection that involves prosthetic material, where its addition results in a higher microbiologic cure rate.[4] Combination therapy also decreases the emergence of resistance to rifampin, which frequently occurs when it is used alone. For methicillin-resistant staphylococci (both MRSA and coagulase-negative staphylococci), vancomycin is recommended with rifampin for 6 weeks or more (see Table 111-5). An aminoglycoside is added for the first 2 weeks if the organism is aminoglycoside susceptible; traditional dosing should be used as once-daily regimens have not been adequately evaluated in PVE and are not recommended.[4]

For MSSA, penicillinase-resistant penicillin is administered in place of vancomycin. PVE responds poorly to medical treatment and has a higher mortality compared with NVE. Valve dehiscence and incompetence can result in acute heart failure, and surgery is often a component of treatment.[4,33]

The use of anticoagulation is controversial in PVE. In general, those who require anticoagulation for a prosthetic valve should continue the anticoagulant cautiously during endocarditis therapy, unless a contraindication to therapy exists. It is recommended to hold all anticoagulation for at least 2 weeks for patients with *S. aureus* PVE if a recent CNS embolic event has occurred.[4]

Enterococcal Endocarditis

Enterococci are normal inhabitants of the human GI tract and, occasionally, of the anterior urethra. These organisms are usually of low virulence but can become pathogens following healthcare intervention or in predisposed patients (most commonly elderly with comorbid conditions such as diabetes or need for hemodialysis).[25] Historically, enterococci were considered group D streptococci, but they have been reclassified into the genus *Enterococcus* (*E. faecalis* and *E. faecium*). *E. faecalis* is the most common clinical isolate (approximately 97%) of the two species. Enterococci are the third leading cause of infective endocarditis, but they are more resistant to therapy than staphylococci and streptococci.[73] Enterococci are noteworthy for the following reasons: (a) no single antibiotic is bactericidal, (b) MICs to penicillin are relatively high (1-25 mcg/mL [mg/L]), (c) intrinsic resistance occurs to all cephalosporins and relative resistance occurs to aminoglycosides (eg, “low-level” aminoglycoside resistance), (d) combinations of a cell-wall–active agent such as a penicillin or vancomycin and an aminoglycoside are necessary for killing, and (e) resistance to all available drugs is increasing.[4,74,75,76]

Monotherapy with penicillin for infective endocarditis caused by enterococci results in relapse rates of 50% to 80%. When used alone, penicillins are only bacteriostatic against enterococci, and thus combination therapy is always recommended for susceptible strains.[4,75] The killing of enterococci by the bactericidal combination of an aminoglycoside antibiotic and a penicillin is the best clinical example of antibiotic synergy. Because the aminoglycoside cannot penetrate the bacterial cell in the absence of the penicillin, enterococci usually will appear to be resistant to aminoglycosides by routine susceptibility testing (low-level resistance). However, in the presence of an agent that disrupts the cell wall such as penicillin, the aminoglycoside can gain entry, attach to bacterial ribosomes, and cause rapid cell death. An aminoglycoside–vancomycin combination is also synergistic against enterococci and is appropriate therapy for the penicillin-allergic patient.[4,75,76,77]

Enterococcal endocarditis ordinarily requires 4 to 6 weeks of ampicillin or high-dose penicillin G plus an aminoglycoside for cure (see Table 111-6). Recent literature suggests that ampicillin plus ceftriaxone is as effective as ampicillin plus gentamicin and should be considered as a treatment option.[4,5] Ampicillin has greater in vitro activity than penicillin G, although there are no clinical data to document differences in efficacy. A 6-week course is recommended for patients with symptoms lasting longer than 3 months and those with PVE. Streptomycin and gentamicin have similar efficacy, but gentamicin is preferred due to the inability to obtain streptomycin serum levels in most labs.[75] Because of resistance, other aminoglycosides, such as tobramycin and amikacin, cannot be substituted routinely. In the treatment of enterococcal endocarditis, relatively low serum concentrations of aminoglycosides appear adequate for successful therapy, such as a gentamicin peak concentration of approximately 3 to 4 mcg/mL (mg/L; 6.3-8.4 µmol/L).[4,75,77] Treatment of enterococcal endocarditis does not have the high success rate seen with infective endocarditis caused by viridans streptococci, presumably because the organism is more resistant to killing.

Although some data support the use of extended-interval aminoglycoside dosing for other types of endocarditis (ie, streptococci), the data are more vague regarding this strategy in enterococcal infective endocarditis.[78] Some studies suggest that extended-interval aminoglycoside dosing and short-interval (traditional) dosing are clinically equivalent, discordant studies imply otherwise.[79,80,81,82,83] Newer evidence suggests that extended-interval dosing is appropriate in the setting of non-high level aminoglycoside resistant (MIC < 500 mcg/mL [mg/L]) *E. faecalis* IE and this strategy has been adopted by the new European Society of Cardiology Guidelines.[5,84,85] As such, the duration of therapy can be shortened from 4 to 6 weeks to 2 weeks. This recommendation differs from the current AHA guidelines, which continue to support traditional dosing.[4]

Resistance among enterococci to penicillins and aminoglycosides is increasing.[4] Enterococci that exhibit high-level resistance to streptomycin (MIC > 2,000 mcg/mL [mg/L]) are not synergistically killed by penicillin and streptomycin because the aminoglycoside either no longer binds to the ribosome or is inactivated by an aminoglycoside-modifying enzyme, streptomycin adenylase.[75] Because enterococci will appear resistant to aminoglycosides on routine susceptibility testing, the only way to distinguish high-level from low-level resistance is by performing special susceptibility tests using 500 to 2,000 mcg/mL (mg/L) of the aminoglycoside.[77] High-level streptomycin-resistant enterococci occur with a frequency approaching 60%, and high-level resistance to gentamicin is now found in 10% to 50% of isolates. Although most gentamicin-resistant enterococci are resistant to all aminoglycosides (including amikacin), 30% to 50% remain susceptible to streptomycin.[86] High-level gentamicin resistance is mediated by a bifunctional aminoglycoside-modifying enzyme, 6-acetyltransferase/2-phosphotransferase, and most strains also possess streptomycin adenylase. The incidence of high-level aminoglycoside resistance is increasing; however, data on appropriate therapy are sparse, and therapeutic options are few.[75,86,87]

In addition to isolates with high-level aminoglycoside resistance, *β*-lactamase–producing enterococci (especially *E. faecium*) have been reported. If these organisms are discovered, use of vancomycin or ampicillin–sulbactam in combination with gentamicin should be considered. Vancomycin-resistant enterococci are reported increasingly, primarily with *E. faecium*. Vancomycin resistance occurs when

the bacterium replaces the normal vancomycin target with a peptidoglycan precursor that does not bind vancomycin.[76,87,88]

Treating multidrug-resistant enterococci is difficult, and data on appropriate therapy are sparse. Guidelines suggest either linezolid or daptomycin, although the latter agent has produced conflicting results.[89,90,91,92,93,94,95] Surgery and replacement of the infected cardiac valve may be the only cure.

HACEK Group

Fastidious gram-negative bacteria from the group of bacteria including *Haemophilus parainfluenzae, Haemophilus aphrophilus, Aggregatibacter* species, *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae* (HACEK group) account for 0.8% to 6% of infective endocarditis cases.[96] Frequently, these types of infective endocarditis present as subacute illnesses with large vegetations and emboli.[96,97] These oropharyngeal organisms typically are slow growing and should be considered as possible causes of "culture-negative" endocarditis.[97] With proper treatment, infectious endocarditis caused by HACEK organisms has a low mortality rate.[96] β-lactamase–producing organisms are occurring more often; hence, HACEK organisms should be considered resistant to ampicillin alone and should not be used unless in vitro susceptibility testing is adequate. Ceftriaxone, or an alternate third- or fourth-generation cephalosporin, is the preferred treatment in most cases. Ciprofloxacin may be considered as an option if an allergy to cephalosporins is present (see Table 111-7).[4,5] Treatment is usually for 4 weeks, but it should be extended to 6 weeks in PVE caused by one of these organisms.

Less Common Types of Infective Endocarditis

Atypical Microorganisms

Endocarditis caused by organisms, such as *Bartonella*; *Coxiella burnetii*; *Brucella, Candida*, and *Aspergillus* spp.; *Legionella*; and gram-negative bacilli (eg, *Pseudomonas*), is relatively uncommon. Medical therapy for infective endocarditis caused by these organisms is usually unsuccessful.[4,5] Consultation with an infectious disease expert is warranted when these microorganisms are identified.

In addition to *Pseudomonas* spp., other gram-negative bacilli that have been implicated include *Salmonella* spp., *Escherichia coli, Citrobacter* spp., *Klebsiella–Enterobacter* spp., *Serratia marcescens, Proteus* spp., and *Providencia* spp.[37] Generally, these infections have a poor prognosis, with mortality rates as high as 60% to 80%.[37] Cardiac surgery in concert with extended-course antibacterial therapy is recommended (class IIa; level of evidence: B) for most patients with gram-negative bacillary infective endocarditis. Readers are referred to the AHA guidelines for more extensive review of treatment regimens for infective endocarditis *due to Pseudomonas* spp. and unusual gram-negative bacteria.[4]

Fungi cause less than 2% of endocarditis cases; most patients with fungal endocarditis have undergone recent cardiovascular surgery, are IV drug abusers, have received prolonged treatment

with indwelling central venous catheters, or are immunocompromised.[36,98] *Candida* spp. and *Aspergillus* spp. are the most commonly involved, and the mortality rate is high (>80%) for the following reasons: (a) large, bulky vegetations that often form, (b) systemic septic embolization that may occur, (c) the tendency of fungi to invade the myocardium, (d) poor penetration of vegetations by antifungals, (e) the low toxic-to-therapeutic ratio of agents such as amphotericin B, and (f) the lack of consistent fungicidal activity of available antifungal agents.[3,5,99] When fungal infective endocarditis is identified, a combined medical–surgical approach is warranted. Because these infections occur infrequently, scant clinical data are available to make solid treatment recommendations. Amphotericin B with or without flucytosine or an enchinocandin (high dose) is the recommended pharmacologic approach for *Candida* IE while voriconazole with the addition of amphotericin B or enchinocandin is suggested for those with Aspergillus IE.[5,37] Greater than 6 weeks of therapy is usually recommended; subsequent life-long suppressive therapy with an oral azole may be recommended for some.[4,5,37]

C. burnetii (Q fever) may be recovered from blood cultures, but infection is more likely to be identified via serologic tests. It is a common cause of infective endocarditis in certain areas of the world where goat, cattle, and sheep farming are widespread. The most favorable therapy for Q fever is unknown but may include doxycycline with hydroxychloroquine, trimethoprim–sulfamethoxazole, rifampin, or fluoroquinolones for at least 18 months.[100] *Brucella* are facultative intracellular gram-negative bacilli. Humans are infected by this organism after ingesting infected unpasteurized milk or undercooked meat, inhaling infectious aerosols, or contacting infected tissues. This type of infective endocarditis is more common in veterinarians and livestock handlers. Cure requires valve replacement and antimicrobial agents including doxycycline with streptomycin or gentamicin or doxycycline with trimethoprim–sulfamethoxazole or rifampin for an extended period (6 weeks to months).[101]

Culture-Negative Endocarditis

Sterile blood cultures are reported in up to 31% of patients with infective endocarditis if strict diagnostic criteria are used.[1,5] This type of infective endocarditis may occur as a result of unidentified subacute right-sided infective endocarditis, previous antibiotic therapy, slow-growing fastidious organisms, nonbacterial etiologies (eg, fungi), noninfective endocarditis, and improperly collected blood cultures. When blood cultures from patients suspected of infective endocarditis show no growth after 48 to 72 hours, cultures should be held for up to a month and special testing techniques (eg, serological analysis, polymerase chain reaction) pursued to detect fastidious or nonbacterial organisms.[4,36,97]

The AHA guidelines provide very general recommendations for culture-negative infective endocarditis (see Table 111-7) and suggest that therapy should be guided based on the individual patient's past medical history and epidemiological risks identified. Selection of treatment can be difficult, balancing the need to cover all likely organisms against potential toxic drug effects (eg, aminoglycosides). Antimicrobial selection should involve consultation with an infectious disease specialist. Irrespective of the chosen treatment, extended antimicrobial therapy is required. The empirical approaches for culture-negative infective endocarditis highlight the need for proper

collection and monitoring of blood cultures and an extensive medication history.

PERSONALIZED PHARMACOTHERAPY

Infective endocarditis remains an uncommon disease, but the cost of treatment can be substantial. In the past, the long duration of hospitalization required to administer IV antimicrobials was the major expense. In select cases, abbreviated and/or outpatient, oral antimicrobial therapy may appreciably reduce the cost of care.

Shorter-course antimicrobial regimens are advocated when possible. For instance, in sensitive streptococcal endocarditis (MICs <0.12 mcg/mL [mg/L]), a 2-week regimen of high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside is as effective as 4 weeks of penicillin alone.[4] Uncomplicated right-sided MSSA endocarditis in the IV drug abuser may be treated with a 2-week course of nafcillin, oxacillin, or daptomycin.

The initiation of outpatient parenteral antibiotics should be considered early in the treatment of infective endocarditis, after the patient is stable clinically and responds favorably to initial antibiotics. Outpatient treatment is safe and cost-effective in select situations.[26,102,103] Patients considered for home therapy must be hemodynamically stable, compliant with therapy, have careful medical monitoring, understand the potential complications of the disease, and have immediate access to medical care. Advances in technology allow for the outpatient administration of complex antibiotic regimens that significantly reduce the cost of therapy. Simple regimens, such as single daily doses of ceftriaxone for streptococcal infective endocarditis, are particularly attractive. Although endocarditis is common in those with a history of IVDA and home healthcare would substantially reduce the cost of treatment, many clinicians are uncomfortable with outpatient IV therapy because central venous access is required. Sudden cardiac decompensation in an outpatient setting is also of concern.[4]

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of patients treated for infective endocarditis includes assessment of disease signs and symptoms, blood cultures, microbiologic tests, inflammatory markers, serum drug concentrations, and other tests that evaluate organ function.

Signs and Symptoms

Fever usually subsides within 1 week of initiating therapy.[17] Persistence of fever may indicate ineffective antimicrobial therapy, emboli, right-sided endocarditis, intravascular catheter infections, or drug reactions. For some patients, low-grade fever may persist even with appropriate antimicrobial therapy. With defervescence, the patient should begin to feel better, and other symptoms, such as lethargy or weakness, should subside. Echocardiography should be performed when antibiotic therapy has been completed to determine new baseline cardiac function (ie, ventricular size and function). A TTE is usually sufficient.

Blood Cultures

After initiation of appropriate therapy, blood cultures should be negative within a few days, although microbiologic response to vancomycin may be slower. If bacteria continue to be isolated from blood beyond the first few days of therapy, it may indicate that the antimicrobials are inactive against the pathogen or that the doses are not producing adequate concentrations at the site of infection. If this is the case, therapeutic adjustments should be made and blood cultures should be rechecked until negative. During the remainder of therapy, frequent blood cultures are not necessary but should be obtained if fever recurs.[4]

Microbiologic Tests

For all isolates from blood cultures, MICs should be determined; MBCs are no longer recommended.[4] The agent currently being used should be tested, as well as alternatives that may be required if intolerance, allergy, or resistance occurs. Occasionally, it is useful to determine whether synergy exists for antimicrobial combinations, although synergistic regimens usually can be predicted from the literature. Chapter 24 summarizes the methods for in vitro determinations of synergy.

Inflammatory Markers

Inflammatory markers are commonly used in infectious disease processes for diagnosing, monitoring of clinical outcomes, as well as assisting clinicians with evaluating the efficacy of antibiotic therapy. Currently only one inflammatory marker, rheumatoid factor (RF), is part of the modified Duke criteria for diagnosis. Other inflammatory markers, such as ESR, CRP, and procalcitonin (PCT), have all been investigated for evaluating the outcomes of patients with in endocarditis.[104] High PCT levels (eg, >0.5 ng/mL [mcg/L]) indicate the need for surgical intervention and correlate with poor outcomes (ie, death or serious infectious complications).[105,106] While these markers may be beneficial in assessing clinical outcomes, further evidence is needed to establish routine use for infective endocarditis.

Serum Drug Concentrations

Of the agents used commonly for infective endocarditis, measurement of serum drug concentrations is routinely available for aminoglycosides (except streptomycin) and vancomycin. Few data, however, support attaining any specific serum concentrations for patients with infective endocarditis. In general, serum concentrations of the antimicrobial should exceed the MIC of the organisms.

When aminoglycosides are administered for infective endocarditis caused by gram-positive cocci with a traditional three-times-daily regimen, peak serum concentrations are recommended to be on the low side of the traditional ranges (3-4 mcg/mL [mg/L; 6.3-8.4 µmol/L] for gentamicin). If extended-interval dosing is used, which is only recommended in streptococcal infective endocarditis, the most appropriate method of monitoring has not been determined. When vancomycin is administered, the primary goal is to ensure adequate trough concentrations, in this case 15 to 20 mcg/mL (mg/L; 10-14 µmol/L), are achieved.[107]

PREVENTION

10 Antimicrobial prophylaxis is used as an attempt to prevent infective endocarditis for patients who are at the highest risk.[6,5,18] The use of antimicrobials for this purpose requires consideration of (a) cardiac conditions associated with endocarditis, (b) procedures causing bacteremia, (c) organisms likely to cause endocarditis, and (d) pharmacokinetics, spectrum, cost, adverse effects, and ease of administration of available antimicrobial agents. The objective of prophylaxis is to diminish the likelihood of infective endocarditis in high-risk individuals from procedures that result in bacteremia. Although there are no prospective, controlled human trials demonstrating that prophylaxis in high-risk individuals protects against the development of endocarditis during bacteremia-inducing procedures, animal studies suggest possible benefit.[18] However, other studies have questioned the benefit of antibiotic prophylaxis prior to invasive procedures.[108] Furthermore, many causes of infective endocarditis appear not to be secondary to an invasive procedure. Bacteremia as a consequence of daily activities may, in fact, be the major culprit, and the value of antibiotic prophylaxis before bacteremia-causing procedures has been questioned.[109] The literature lacks adequate evidence to prove the effectiveness or ineffectiveness of antibiotic prophylaxis, and the common practice of using antimicrobial therapy in this setting remains controversial.[110] The mechanism of a beneficial effect in humans is unclear, but antibiotics may decrease the number of bacteria at the surgical site, kill bacteria after they are introduced into the blood, and prevent adhesion of bacteria to the valve.

Clinical Controversy...

The common practice of administering antibiotics to high-risk individuals before a bacteremia-causing procedure is controversial. Despite limited data supporting this approach and the fact that 100% compliance with AHA preventative guidelines would have only a modest benefit, the use of single-dose antibiotics for the prevention of endocarditis remains a standard of care.

Regardless of the controversy about whether prophylactic antibiotics should be used, infective endocarditis prophylaxis is recommended in select situations, specifically dental procedures, in those with underlying high-risk cardiac conditions. The AHA released updated guidelines that better define who should and should not receive infective endocarditis prophylaxis.[18] The appropriateness of the new guidelines, however, has been called into question due to epidemiological studies showing an increase in the overall incidence of IE, especially due to *Streptococcus*.[8]

Key points of this report are that (a) only a small number of cases of infective endocarditis might be prevented with antibiotic prophylaxis for dental procedures, even if 100% effective; (b) infective endocarditis prophylaxis for dental procedures should be recommended only for patients with underlying cardiac conditions associated with the highest risk; (c) for those with high-risk underlying cardiac conditions, prophylaxis is recommended for all dental procedures involving manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa; (d) prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis; and (e) administration of antibiotics solely to prevent endocarditis is not recommended for patients

who undergo a genitourinary or GI tract procedure.

To determine whether a patient should receive prophylactic antibiotics, one needs to assess the patient's risk and whether he or she is undergoing a procedure resulting in bacteremia. When antibiotic prophylaxis is appropriate, a single 2 g dose of amoxicillin is recommended for adult patients at risk, given 30 to 60 minutes before undergoing procedures associated with bacteremia. Because the duration of antimicrobial prophylaxis appears to be relatively short, guidelines do not advocate a second oral dose of amoxicillin, which was recommended previously. Alternative prophylaxis regimens for patients allergic to penicillins or those unable to take oral medications are also provided. A summary of guideline recommendations is available in **Table 111-10**. Consultation of the full AHA guideline is suggested for more detailed information.[18]

TABLE 111-10 Prophylaxis of Infective Endocarditis

Highest Risk Cardiac Conditions	Presence of a prosthetic heart valve Prior diagnosis of infective endocarditis Cardiac transplantation with subsequent valvulopathy Congenital heart disease (CHD)[a]	
Types of procedures	Any that require perforation of the oral mucosa or manipulation of the periapical region of the teeth of gingival tissue	
Antimicrobial Options	**Adult Doses[b]**	**Pediatric Doses[b] (mg/kg)**
Oral amoxicillin	2 g	50
IM or IV ampicillin[c]	2 g	50
IM or IV cefazolin or ceftriaxone[c,d,e]	1 g	50
Oral cephalexin[d,e,f]	2 g	50
Oral clindamycin[e]	600 mg	20
Oral azithromycin or clarithromycin[e]	500 mg	15
IV or IM clindamycin[c,e]	600 mg	20

[a]Includes only the following: unrepaired cyanotic CHD, prophlyaxis within the first 6 months of implanting prosthetic material to repair a congenital heart defect, and repaired CHD with residual defects at or adjacent to prosthetic material.

[b]All one-time doses administered 30-60 minutes prior to initiation of the procedure.

[c]For patients unable to tolerate oral medication.

[d]Should be avoided in patients with immediate-type hypersensitivity reaction to penicillin or ampicillin (eg, anaphylaxis, urticaria, or angioedema).

[e]Option for patients with nonimmediate hypersensitivity reaction to penicillin or ampicillin.

[f]May substitute with an alternative first- or second-generation cephalosporin at an equivalent dose.

Data from reference 18.

Chapter 112: Tuberculosis

Rocsanna Namdar; Michael Lauzardo; Charles A. Peloquin

INTRODUCTION

KEY CONCEPTS

- 1 Tuberculosis (TB) is the most prevalent communicable infectious disease on earth; and it remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of TB globally.
- 2 In the United States, TB disproportionately affects the foreign born and other ethnic minorities, reflecting immigration patterns and greater ongoing transmission in these communities. Additional TB surveillance and preventive treatments are required within these communities.
- 3 TB is the leading cause of death in human immunodeficiency virus (HIV) infection worldwide. Coinfection with HIV and TB accelerates the progression of both diseases, thus requiring rapid diagnosis and treatment of both diseases.
- 4 Mycobacteria are slow-growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.
- 5 TB can produce atypical signs and symptoms in infants, the elderly, and immunocompromised hosts, and it can progress rapidly in these patients.
- 6 Latent TB infection (LTBI) can lead to reactivation disease years after the primary infection occurred.
- 7 The patient suspected of having active TB disease must be isolated until the diagnosis is confirmed and the patient is no longer contagious. Often, isolation takes place in specialized “negative-pressure” hospital rooms to prevent the spread of TB.
- 8 Isoniazid and rifampin are the two most important drugs in the treatment of TB. Organisms resistant to both these drugs (multidrug-resistant TB [MDR-TB]) are much more difficult to treat.
- 9 Directly observed treatment (DOT) should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.

- 10 To avoid the development of resistance, never add a single drug to a failing TB treatment regimen.

1 Tuberculosis (TB) remains a leading infectious killer globally. TB is caused by *Mycobacterium tuberculosis*, which can produce either a silent, latent infection or a progressive, active disease.[1] Left untreated or improperly treated, TB causes progressive tissue destruction and, eventually, death. Because of renewed public health efforts, TB rates in the United States continue to decline. In contrast, TB remains out of control in many developing countries and—one third of the world's population currently is infected.[1] Given increasing drug resistance, it is critical that a major effort be made to control TB before the most potent drugs are no longer effective.

TB rates generally have risen with increasing urbanization and overcrowding because it is easier for an airborne disease to spread when people are living in closer proximity to each other. Hence, TB became a significant pathogen in Europe during the Middle Ages and peaked during the Industrial Revolution, when it caused significant mortality in Europe and in the United States.[1] This dire threat led to the rise of public health departments and to procedures such as the isolation of infected patients. Thus, TB was directly responsible for many of the healthcare practices that are used today. Unfortunately, in developing nations, some of these practices are not widely available, and TB continues to rage unabated.

EPIDEMIOLOGY

Globally, approximately 2 billion people are infected by *M. tuberculosis*, and roughly 1.5 million people die from active TB each year despite the fact that it is curable.[1] In the United States, an estimated 9 million people are latently infected with *M. tuberculosis*, meaning that they are not currently sick but that they could fall ill with TB at any time.[2] In 2014, 9,412 new TB cases were reported in the United States, which is 2.2% lower than in 2013.[2] The annual incidence of TB in the United States declined by approximately 5% per year from 1953 to 1983.[2] In 1984, this decline slowed, and then the incidence of TB rose from 1988 reaching its peak in 1992 (**Fig. 112-1**). Since 1993, more effective infection control practices and treatment protocols have reduced TB rates significantly as mentioned above. Despite this good news, the eradication of TB from the United States remains difficult. One reason is that TB among immigrants to the United States from high incidence countries remains a problem.[1,2]

Risk Factors for Infection

The following section will discuss the risk factors for infection including location, race, ethnicity, and human immunodeficiency virus (HIV) coinfection. Risk factors and likelihood of progression from infection to disease will also be discussed.

Location and Place of Birth

California, Florida, New York, and Texas accounted for 51% of the TB cases reported nationally in 2014.[2] Within these states, TB is most prevalent in large urban areas and among those born outside the United States in high TB incidence countries.[2]

In 2014, the TB rate among foreign-born persons was 13.4 times that of US-born persons.[2] The percentage of foreign-born TB patients in the United States has increased annually, reaching 66.5% in 2014.[2] with a total of 6,181 TB cases reported among foreign-born persons. In 2014, 55.3% of foreign-born persons with TB originated from five countries: Mexico, the Philippines, Vietnam, India, and China.[2] Therefore, healthcare workers must consider TB when caring for patients from these countries who experience symptoms such as cough, fever, and weight loss. Furthermore, in 2013, foreign-born persons accounted for 90.6% of the multidrug-resistant (MDR) TB cases.

Close contacts of pulmonary TB patients such as family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes are the most likely to become infected. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.[2,3] TB patients frequently have limited access to healthcare, live in crowded conditions, or are homeless.[2,3] Many patients have histories of alcohol abuse or illicit drug use, and are coinfected with hepatitis B or HIV. These concurrent social and health problems make treating some TB patients particularly difficult.

Race, Ethnicity, Age

2 In the United States, TB disproportionately affects the foreign born and other ethnic minorities. In 2014,

Asians had the largest percentage of total TB cases; however, the incidence rate among Asians decreased from 18.6 per 100,000 in 2013 to 17.9 in 2014.[2,4] TB rates among Hispanics remained relatively constant whereas rates decreased among blacks, whites, and Asians. In the American Indian/Alaska Native, Native Hawaiian or other Pacific Islander TB rates increased from 3.8 in 2013 to 4.3 in 2014.[2,4] Despite declines in the rates of TB among foreign and US-born individuals, the TB rate among foreign-born individuals was 13 times higher than among US-born individuals.[2,4] Among US-born group, non-Hispanic blacks were the ethnic group with the greatest number of TB cases and the largest disparity compared with US-born whites.[2,4]

TB is most common during adulthood primarily in the 25- to 44-year-age group and the 45- to 64-year-age group. In 2013, the case rates of TB declined from the previous years in all age groups except among children aged 14 years or younger, which remained the same from the previous year.[2]

Coinfection with Human Immunodeficiency Virus

3 In patients who have latent TB infection, HIV is the most important risk factor for progressing to active TB, especially among people between ages 25 and 44 years.[2,4,5] TB and HIV to act synergistically within patients and across populations, making each disease worse than it might otherwise be. In 2014, 6.3% of incident cases of TB in the United States were coinfected with HIV.[2,5] These numbers are estimates because laws and regulations in some states prohibit sharing HIV status of TB patients with the TB program. HIV coinfection may not increase the risk of acquiring *M. tuberculosis* infection, but it does increase the likelihood of progression to active disease.[1,5] There is evidence for higher mortality rates in HIV coinfected with MDR and extensively drug-resistant (XDR) TB.[5]

Risk Factors for Disease

Close contacts of pulmonary TB patients such as family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes are the most likely to become infected. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.[2,3,4] TB patients frequently have limited access to healthcare, live in crowded conditions, or are homeless.[2,3,4] Many patients have histories of alcohol abuse or illicit drug use, and are coinfected with hepatitis B or HIV. These concurrent social and health problems make treating some TB patients particularly difficult.

Once infected with *M. tuberculosis*, a person's lifetime risk of active TB is approximately 10%.[2,3,4] The greatest risk for active disease occurs during the first 2 years after infection. Children younger than 2 years and adults older than 65 years have two to five times greater risk for active disease compared with other age groups. Patients with underlying immune suppression (eg, renal failure, cancer, and immunosuppressive drug treatment) have 4 to 16 times greater risk than other patients.[2] Finally, HIV-infected patients with *M. tuberculosis* infection are 100 times more likely to develop active TB than normal hosts.[2,3,4] HIV-infected patients have an annual risk of active TB of approximately 10%, rather than a lifetime risk at that rate.[5] Therefore, all patients with HIV infection should be screened for tuberculous infection, and those known to be infected with *M. tuberculosis* should be tested for HIV infection.

ETIOLOGY

M. tuberculosis is a slender bacillus with a waxy outer layer.[2,6] It is 1 to 4 µm in length, and under the microscope, it is either straight or slightly curved in shape.[6] It does not stain well with Gram stain, so the Ziehl-Neelsen stain or the fluorochrome stain must be used instead.[6] After Ziehl-Neelsen staining with carbol-fuchsin, mycobacteria retain the red color despite acid–alcohol washes. Hence, they are called *acid-fast bacilli* (AFB).[6] On culture, *M. tuberculosis* grows slowly, doubling about every 20 hours. This is slow compared with gram-positive and gram-negative bacteria, which double about every 30 minutes.

Culture and Susceptibility Testing

All clinical specimens suspected of containing mycobacteria should be cultured. Culture is required for species identification and for drug susceptibility testing.

4 Direct susceptibility testing involves inoculating specialized media with organisms taken directly from a concentrated, smear-positive specimen.[1,6] This approach produces susceptibility results in 2 to 3 weeks. Indirect susceptibility testing involves inoculating the test media with organisms obtained from a pure culture of the organisms, which can take several more weeks. The most common agar method, known as the *proportion method*, uses the ratio of colony counts on drug-containing agar to that on drug-free agar.[1,6] In the United States, the critical proportion for resistance is 1%. That means that if a drug-containing plate shows 1% or more of the growth seen on a drug-free plate, some of the organisms from the specimen were resistant to that drug. Therefore, it is likely that many of the organisms in the patient also are resistant to that drug, and in general it should not be used to treat that patient.

The proportion method's limitations include many weeks to obtain results, drug degradation during the incubation, and a qualitative result (susceptible or resistant). The newer mycobacterial growth indicator tube (Becton Dickson, Sparks, MD) systems use liquid media and detect live mycobacteria in as few as 9 to 14 days.[6,7]

Rapid-identification tests are now available, but cost and care of equipment, remain an issue in many parts of the world. Nucleic acid amplifications tests use DNA probes to identify the presence of complementary ribosomal ribonucleic acid (rRNA) for several mycobacterial species.[6,7] DNA fingerprinting using restriction-fragment-length polymorphism analysis has been used to identify clusters of cases.[1,7,8] Amplification of the genetic material can be achieved through polymerase chain reaction (PCR), the amplified *M. tuberculosis* direct (MTD) test, and strand-displacement amplification.[7] Thin-layer chromatography, high-performance liquid chromatography for mycolic acid identification, and gas chromatography for short-chain fatty acids (methyl esters) have been used to speciate mycobacterial isolates.[6,7,8,9] The Enhanced Amplified *Mycobacterium Tuberculosis* Direct Test (E-MTD) has been approved for use by the US Food and Drug Administration in AFB smear-positive and smear-negative specimen in patients with fewer than 7 days of antimycobacterial therapy and the Gene X-pert MTB/RIF assay in patients with fewer than 3 days of treatment. The Amplicor *Mycobacterium Tuberculosis* Test has been approved for smear-positive samples.[9,10,11,12]

The Hain test, a line-probe assay that diagnoses resistance to isoniazid and rifampin by detecting several gene mutations responsible for drug resistance, has also entered into limited clinical use in the United States. The Gene X-pert MTB/RIF test simultaneously identifies *M. tuberculosis* and rapidly determines if resistance to rifampin is present.[9,13] The test has excellent performance in both smear-positive and

-negative patients, and high accuracy for determination of rifampicin resistance.[11] Colorimetric redox indicator and nitrate reduction assays for rapid detection of rifampicin and isoniazid resistance are both inexpensive and have rapid turnaround times of 1 week. Microscopic observation drug susceptibility assay is simple test using sputum samples to detect characteristic patterns of growth of *M. tuberculosis* and resistance patterns. Time to diagnosis is 7 days and drug susceptibilities are available at the time of diagnosis.[11] Most patients with microscopic observation drug susceptibility assays are diagnosed within 2 weeks and it is similarly efficient irrespective of bacterial burden.[12]

Other tests are designed to detect common genetic changes associated with drug resistance, such as changes in the *katG* gene associated with isoniazid resistance and the *rpoB* gene associated with rifampin resistance.[5,8,13] Probe assays do not eliminate the need for conventional culture and susceptibility testing; conventional drug susceptibility testing is needed to diagnose XDR TB. The decision to use nucleic acid amplification tests should be individualized.

Transmission

M. tuberculosis is transmitted from person to person by coughing or other activities that cause the organism to be aerosolized.[2,3] These particles, called *droplet nuclei*, contain one to three bacilli and are small enough (1-5 mm) to reach the alveolar surface. This produces "droplet nuclei" that are dispersed in the air. Each droplet nuclei contains one to three organisms. Approximately 30% of individuals who experience prolonged contact with an infectious TB patient will become infected.

A person with cavitary, pulmonary TB and a cough is considered very infectious and may infect greater than 30% of contacts until that person is treated effectively, although this percentage and the absolute number can vary significantly. A person with the uncommon laryngeal form of TB can spread organisms even when talking, so the transmission rates can be even higher.

PATHOPHYSIOLOGY

The following section will discuss the pathophysiology of primary infection, reactivation disease, and the influence of HIV on the pathogenesis of *M. tuberculosis* infections.

Immune Response

T-lymphocyte responses are essential to controlling *M. tuberculosis* infections.[2,3,14,15] In the mouse model, two different T-cell responses—the T-helper type 1 (TH_1) response and the T-helper type 2 (TH_2) response—have been described. The TH_1 response is the preferred response to TB, and the TH_2 response, including the potentially subversive influence of interleukin (IL) 4, is undesirable.[2,14,15] Some workers have argued that this dichotomy is clearer in the mouse model, and in many humans, the T-cell response may be classified as TH_0 (elements of both TH_1 and TH_2).[14] In either case, T lymphocytes activate macrophages that, in turn, engulf and kill mycobacteria. T lymphocytes also destroy immature macrophages that harbor *M. tuberculosis* but are unable to kill the invaders.[14,15] CD4+ cells are the primary T cells involved, with contributions by γ δ T cells and CD8+ T cells.[14] CD4+ T cells produce interferon-*γ* (INF-*γ*) and other cytokines, including IL-2 and IL-10, that coordinate the immune response to TB.[14] Because CD4+ cells are depleted in HIV-infected patients, these patients are unable to mount an adequate defense to TB.[14,15]

Although B-cell responses and antibody production can be demonstrated in TB-infected mammals, these humoral responses do not appear to contribute much to the control of TB within the host.[3,14] Tumor necrosis factor-α (TNF-α) and INF-γ are important cytokines involved in coordinating the host's cell-mediated response. Rheumatoid arthritis patients treated with TNF-α inhibitors (such as infliximab) have high rates of reactivation TB.[16] Therefore, patients known to be deficient in the activity of TNF-α or INF-γ should be screened for TB infection and offered appropriate treatment.

M. tuberculosis has several ways of evading or resisting the host immune response.[14,15] In particular, *M. tuberculosis* can inhibit the fusion of lysosomes to phagosomes inside macrophages. This prevents the destructive enzymes found in the lysosomes from getting to the bacilli captured in the phagosomes. This inhibition of destructive mechanisms allows time for *M. tuberculosis* to escape into the cytoplasm. Virulent *M. tuberculosis* is able to multiply in the macrophage cytoplasm, thus perpetuating their spread. Finally, lipoarabinomannan (LAM), the principal structural polysaccharide of the mycobacterial cell wall, inhibits the host immune response.[14,15] LAM induces immunosuppressive cytokines, thus blocking macrophage activation; additionally, LAM scavenges O_2, thus preventing attack by superoxide anions, hydrogen peroxide, singlet oxygen, and hydroxyl radicals.[14,15] These survival mechanisms make *M. tuberculosis* a particularly difficult organism to control. Any defects in the host immune system make it likely that *M. tuberculosis* will not be controlled and that active disease will ensue.

Primary Infection

Primary infection usually results from inhaling airborne particles that contain *M. tuberculosis*.[3,15] The progression to clinical disease depends on three factors: (a) the number of *M. tuberculosis* organisms inhaled (infecting dose), (b) the virulence of these organisms, and (c) the host's cell-mediated immune response.[3,15,17] At the alveolar surface, the bacilli that were delivered by the droplet nuclei are ingested by pulmonary macrophages. If these macrophages inhibit or kill the bacilli, infection is aborted.[15] If the macrophages cannot do this, the organisms continue to multiply. The macrophages eventually rupture, releasing many bacilli, and these mycobacteria are then phagocytized by other macrophages. This cycle continues over several weeks until the host is able to mount a more coordinated response.[15] During this early phase of infection, *M. tuberculosis* multiplies logarithmically.[15]

Some of the intracellular organisms are transported by the macrophages to regional lymph nodes in the hilar, mediastinal, and retroperitoneal areas. The cycle of phagocytosis and cell rupture continues. During lymph node involvement, the mycobacteria may be held in check. More frequently, *M. tuberculosis* spreads throughout the body through the bloodstream.[3,15] When this intravascular dissemination occurs, *M. tuberculosis* can infect any tissue or organ in the body. Most commonly, *M. tuberculosis* infects the posterior apical region of the lungs. This may be so because of the high oxygen content, and it may be because of a less vigorous immune response in this area.

After about 3 weeks of infection, T lymphocytes are presented with *M. tuberculosis* antigens. These T cells become activated and begin to secrete INF-γ and the other cytokines noted earlier. The processes described in the Immune Response section above then begin to occur. First, T lymphocytes stimulate macrophages to become bactericidal.[15] Large numbers of activated microbicidal macrophages surround the solid caseous (cheese-like) tuberculous foci (the necrotic area of infection).[15] This process of creating activated microbicidal macrophages is known as *cell-mediated immunity* (CMI).[15]

At the same time that CMI occurs, delayed-type hypersensitivity (DTH) also develops through the activation and multiplication of T lymphocytes. DTH refers to the cytotoxic immune process that kills nonactivated immature macrophages that are permitting intracellular bacillary replication.[15] These immature macrophages are killed when the T lymphocytes initiate Fas-mediated apoptosis (programmed cell death).[15] The bacilli released from the immature macrophages then are killed by the activated macrophages.[15]

By this time (more than 3 weeks), in most recently infected individuals, macrophages have begun to form granulomas to contain the organisms. In a typical tuberculous granuloma, activated macrophages accumulate around a caseous lesion and prevent its further extension.[15] At this point, the infection is largely under control, and bacillary replication falls off dramatically. Depending on the inflammatory response, tissue necrosis and calcification of the infection site plus the regional lymph nodes may occur.

Over 1 to 3 months, activated lymphocytes reach an adequate number, and tissue hypersensitivity results. In practical terms, this is the reason why tests to diagnose latent TB infection, purified protein derivative (PPD) skin test, and the INF-γ release assays, take between 2 and 12 weeks to become positive. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis, although some residual bacilli have been found in various types of cells.[3,14]

Approximately 90% of infected patients have no further clinical manifestations. Most patients only show a positive skin test (70%), whereas some also have radiographic evidence of stable granulomas. This radiodense area on chest radiograph is called a *Ghon's complex*. Approximately 5% of patients (usually children, the elderly, and the immunocompromised) experience "progressive primary" disease that occurs before skin test conversion, which presents as a progressive pneumonia, usually in the lower lobes.[18] Disease frequently spreads, leading to meningitis and other severe forms of TB.[18] Because of this risk of severe disease, very young, elderly, and immunocompromised patients, including those with HIV, should be evaluated and treated for latent or active TB.

Reactivation Disease

6 Roughly 10% of infected patients develop reactivation disease at some point in their lives. Nearly half of these cases occur within 2 years of infection.[3,15] In the United States, most cases of TB are believed to result from reactivation. Reinfection is uncommon in the United States because of the low rate of exposure and because previously sensitized individuals possess some degree of immunity to reinfection.[3,15] Exceptions include patients coinfected with HIV who live in areas of higher exposure to *M. tuberculosis*.

The apices of the lungs are the most common sites for reactivation (85% of cases).[3] For reasons that are not entirely known (waning cellular immunity, loss of specific T-cell clones, blocking antibody), organisms within granulomas emerge and begin multiplying extracellularly.[15] The inflammatory response produces caseating granulomas, which eventually will liquefy and spread locally, leading to the formation of a hole (cavity) in the lungs.

The immune response contributes to the severity of the lung damage, and DTH allows for intracellular mycobacterial multiplication.[14,15] In addition, there is "innocent bystander" killing of host cells and locally thrombosed blood vessels.[15] The killing of mycobacteria, macrophages, and neutrophils that have entered

the battle releases cytokines and lysozymes into the infectious foci. This toxic mixture can be too much for the surrounding alveoli and airway cells, causing regional necrosis and structural collapse.[3,15] These unstable foci liquefy, spreading the infection to neighboring areas of the lung, creating a cavity. Some of this necrotic material is coughed out, producing droplet nuclei. Bacterial counts in the cavities can be as high as 10^8 per milliliter (or 10^{11}/L) of cavitary fluid. Partial healing may result from fibrosis, but these lesions remain unstable and may continue to expand.[3,15] If left untreated, pulmonary TB continues to destroy the lungs, resulting in hypoxia, respiratory acidosis, and eventually death.

Extrapulmonary and Miliary Tuberculosis

Caseating granulomas at extrapulmonary sites can undergo liquefaction, releasing tubercle bacilli and causing symptomatic disease.[3] Extrapulmonary TB without concurrent pulmonary disease is uncommon in normal hosts but more common in HIV-infected patients. Because of these unusual presentations, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.[3] Lymphatic and pleural diseases are the most common forms of extrapulmonary TB, followed by bone, joint, genitourinary, meningeal, and other forms.[3] Occasionally, a massive inoculum of organisms enters the bloodstream, causing a widely disseminated form of the disease known as *miliary TB*. It is named for the millet seed appearance of the small granulomas seen on chest radiographs, and it can be rapidly fatal.[14] Miliary TB is a medical emergency requiring immediate treatment.

Influence of Human Immunodeficiency Virus Infection on Pathogenesis

3 HIV infection is the strongest single risk factor for progressing to active TB.[3,14] As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them. In turn, the TB-fighting lymphocytes are depleted.[14] This vicious cycle puts HIV-infected patients at 100 times the risk of active TB compared with HIV-negative people.[19,20] In addition, the combination of HIV infection and certain social behaviors increases the risk of newly acquired TB. In select areas of the United States during the resurgence of TB during the early 1990s, up to 50% of new TB cases were the result of recent infection, particularly among HIV-infected individuals.[1,19,20]

As mycobacteria spread throughout the body, HIV replication accelerates in lymphocytes and macrophages. This leads to progression of HIV disease.[14,19,20] HIV-infected patients who are infected with TB deteriorate more rapidly unless they receive antimycobacterial chemotherapy.[19,20] Most clinicians now recommend integrated antiretroviral therapy (ART) beginning TB treatment first, and then beginning HIV treatment within 2 to 12 weeks.[21,22,23] However, the timing needs to be individualized based on degree of immunosuppression from HIV and the patient's tolerance of the treatment regimen. Immune reconstitution inflammatory syndrome or a paradoxical worsening of TB can occur, especially in patients with more severe immunosuppression; this appears to result from a reinvigorated inflammatory response to TB.[21,23,23] HIV-positive patients, should be screened for tuberculous infection or disease soon after they are shown to be HIV-positive.[21,22]

CLINICAL PRESENTATION

The classical presentation of TB is weight loss, fatigue, a productive cough, fever, and night sweats. The

onset of TB may be gradual, and the diagnosis may not be considered until a chest radiograph is performed. Unfortunately, many patients do not seek medical attention until more dramatic symptoms, such as hemoptysis, occur. At this point, patients typically have large cavitary lesions in the lungs. These cavities are loaded with *M. tuberculosis*. Expectoration or swallowing of infected sputum may spread the disease to other areas of the body.[1,3,17] Physical examination is nonspecific but suggestive of progressive pulmonary disease.

Human Immunodeficiency Virus

5 Patients coinfected with HIV may have atypical presentations.[1,3,17] As their CD4+ counts decline, HIV-positive patients are less likely to have positive skin tests, cavitary lesions, or fever. Pulmonary radiographic findings may be minimal or absent. HIV-positive patients have a higher incidence of extrapulmonary TB and are more likely to present with progressive primary disease. Because their symptoms are not specific to TB, a thorough workup for TB is essential.[3,14,15]

CLINICAL PRESENTATION Tuberculosis Signs and Symptoms

- Patients typically present with cough weight loss, fatigue, fever, and night sweats.[3,14,15]
- Frank hemoptysis usually occurs late in the course of disease but may present earlier.

Physical Examination

- Dullness to chest percussion, rales, and increased vocal fremitus are observed frequently on auscultation but a normal lung examination is very common compared to the degree of radiological lung involvement.
- Patient is usually thin with evidence or recent weight loss.

Laboratory Tests

- Moderate elevations in the white blood cell (WBC) count with a lymphocyte predominance.
- High platelet count (thrombocytosis) and mild to moderate anemia are common.

Diagnostic Considerations

- Positive-sputum smear
- Fiber-optic bronchoscopy (if sputum tests are inconclusive and suspicion is high)

Chest Radiograph

- Patchy or nodular infiltrates in the apical areas of the upper lobes or the superior segment of the lower lobes.[3,14,15]
- Cavitation that may show air–fluid levels as the infection progresses.

Extrapulmonary

Extrapulmonary TB typically presents as a slowly progressive decline in organ function.[3,17] Patients may have low-grade fever and other constitutional symptoms. Patients with genitourinary TB may present with sterile pyuria and hematuria. Lymphadenitis often involves the cervical and supraclavicular nodes and may appear as a neck mass with spontaneous drainage. Tuberculous arthritis and osteomyelitis occur most commonly in the elderly and usually affect the lower spine and weight-bearing joints. TB of the spine is known as *Pott's disease*.[3] Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis. Involvement of the peritoneum, pericardium, larynx, and adrenal glands also occurs.[3,17]

The Elderly

5 TB in the elderly is easily confused with other respiratory diseases. Many clinical findings are muted or absent altogether. Compared with younger patients, TB in the elderly is far less likely to present with positive skin tests, fevers, night sweats, sputum production, or hemoptysis.[2,19,24] Weight loss may occur but is nonspecific. In contrast, mental status changes are twice as common in the elderly, and mortality is six times higher.[3,17] TB is a preventable cause of death in the elderly that should not be overlooked.

Children

5 TB in children, especially those younger than 12 years, may present as a typical bacterial pneumonia and is called *progressive primary TB*.[17,18] Clinical disease often begins 1 to 2 months after exposure and precedes skin-test positivity. Unlike adults, pulmonary TB in children often involves the lower and middle lobes.[17,18] Dissemination to the lymph nodes, GI and genitourinary tracts, bone marrow, and meninges is common. Because of delays in recruitment of cellular immunity, cavitary disease is infrequent, and the number of organisms present typically is smaller than in an adult. Because cavitary lesions are uncommon, children do not spread TB readily. However, TB can be rapidly fatal in a child, and it requires prompt chemotherapy.

DIAGNOSIS

The following section focuses on diagnostic testing for infection with *M. tuberculosis*. If active disease is suspected based on clinical presentation, additional diagnostic tests are also reviewed to confirm active disease.

Diagnostic Testing

The key to stopping the spread of TB is early identification of infected individuals.[3,17] **Table 112-1** lists the populations most likely to benefit from testing (column 1 patients are at highest risk for TB, followed by those in column 2). Members of these high-risk groups should be tested for TB infection and educated about the disease.

TABLE 112-1 Criteria for Tuberculin Positivity by Risk Group

Reaction 5 mm of Induration	Reaction ≥10 mm of Induration	Reaction ≥15 mm of Induration
HIV-positive persons	Recent immigrants (ie, within the last 5 years) from	Persons with

Reaction 5 mm of Induration	Reaction ≥10 mm of Induration	Reaction ≥15 mm of Induration
	high-prevalence countries	no risk factors for TB
Recent contacts of TB case patients	Injection-drug users	
Fibrotic changes on chest radiograph consistent with prior TB	Residents and employees[a] of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term care facilities for the elderly, hospitals and other healthcare facilities, residential facilities for patients with AIDS, homeless shelters	
	Mycobacteriology laboratory personnel	
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of ≥15 mg/day of prednisone for 1 month or more)[b]	Persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (eg, leukemias and lymphomas), other specific malignancies (eg, carcinoma of the head or neck and lung), weight loss of ≥10% of ideal body weight, gastrectomy, jejunoileal bypass	
	Children younger than 4 years or infants, children, and adolescents exposed to adults at high risk	

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; TB, tuberculosis.

[a]For persons who are otherwise at low risk and who are tested at the start of employment, a reaction of ≥15 mm induration is considered positive.

[b]Risk of TB for patients treated with corticosteroids increases with higher dose and longer duration.

Adapted from Screening for tuberculosis and tuberculosis infection in high-risk populations: Recommendations of the Advisory Council for the Elimination of Tuberculosis. MMWR Recomm Rep *1995;44(RR-11):19-34*.

The Mantoux test is a quantitative TB skin test that uses tuberculin PPD. The standard 5-tuberculin-unit PPD dose is placed intracutaneously on the volar aspect of the forearm with a 26- or 27-gauge needle.[3,17,24] This injection should produce a small, raised, blanched wheal. An experienced professional should read the test in 48 to 72 hours. The area of induration (the "bump") is the important end point, not the area of redness. Table 113-1 lists the criteria for interpretation.[3,17,24] The Centers for Disease Control and Prevention (CDC) does not recommend the routine use of anergy panels.[24,25,26] Aplisol and Tubersol 5-tuberculin-unit products are available commercially and are similar in sensitivity, specificity, and reactivity. It is important, however, to use one product and notify appropriate users when switching between products.[27,28]

The "booster effect" occurs for patients who do not respond to an initial skin test but show a positive

reaction if retested about a week later or longer.[17,26] Patients with past *M. tuberculosis* infection and some patients with past immunization with bacillus Calmette-Guérin (BCG) vaccine or past infection with other mycobacteria may "boost" with a second skin test. Individuals who require periodic skin testing, such as healthcare workers, should receive a two-stage test initially.[17,26,29] Once they are shown to be skin-test negative, any positive skin test later shows recent infection, and this requires an evaluation to consider treatment.

The PPD skin test is an imperfect diagnostic tool. Up to 20% of patients with active TB are falsely skin-test negative, presumably because they may be immunocompromised.[14,26] False-positive results are more common in low-risk patients and those recently vaccinated with BCG. Despite BCG vaccination, one should not ignore a positive PPD result especially if the induration is more than 15 mm.[24] These patients require careful evaluation for active disease, and they may be offered preventive treatment because many come from areas where TB infection is common.

Interferon-γ release assays (IGRA) measure the release of INF-γ in blood in response to the TB antigens.[30] They may provide quick and specific results for identifying *M. tuberculosis*. IGRAs do not trigger a booster effect and are more specific for testing *M. tuberculosis* than the PPD. The QuantiFERON-TB Gold test (QFT-G) is an enzyme-linked immunosorbent assay (ELISA) and the T-SPOT.TB, is an enzyme-linked immunospot assay[30,31] Both tests can be used for diagnosing latent TB infection (LTBI) and TB disease caused by *M. tuberculosis*. However, these are tests desgined to diagnose LTBI and are not to be used to confirm or reject a diagnosis of active TB disease. For active TB, the IGRAs provide supporting evidence for the diagnosis but need to be interpreted in light of other evidence of active TB disease such as epidemiological risk factors and other studies. The antigenic proteins are absent from BCG vaccine strains and from most non-TB mycobacteria. Therefore, QFT-G does not trigger a booster effect and is more specific for testing of *M. tuberculosis* than the PPD. Although these tests can provide results to diagnose both latent infection and disease, they cannot differentiate between the two. Results are available within 24 hours, instead of the 2 to 3 days required for the traditional PPD skin test; and the patient does not have to return to the clinic as required by the PPD skin test. The CDC has approved the use of these tests in all circumstances in which the PPD is currently used. IGRAs may be preferred for testing in patients that are suspected not to return for follow up PPD reads or in patients who have received the BCG vaccine. The sensitivity for young children (younger than 5 years) and in immunocompromised patients has not clearly established.[30,31,32,33,34] The American Academy of Pediatrics recommends IGRAs in place of PPD skin test in immunocompetent children aged 5 years or older who have received BCG vaccination to confirm TB infection.[32] However, an increasing number of experts are using the IGRAs in children 2 years or older.

IGRAs perform similarly to the PPD in detecting TB in HIV-infected patients with LTBI. Both PPD and IGRA have suboptimal sensitivity for active TB especially in the severely immunocompromised.[30,35]

Culture and Staining

When active TB is suspected, attempts should be made to isolate *M. tuberculosis* from the site of infection.[3,17,26] Sputum collected in the morning usually has the highest yield.[3,17] Daily sputum collection over 3 consecutive days is recommended. Microscopic examination is the most rapid and inexpensive TB diagnostic tool. After staining, microscopic examination ("smear") detects about 8,000 to 10,000 organisms per milliliter (8×10^6/L to 10×10^6/L) of specimen, so a patient can be "smear-negative" but still grow *M. tuberculosis* on culture. Microscopic examination also cannot determine which of the more than 100

mycobacterial species is present or whether the organisms in the original samples were alive or dead.[1,6]

For patients unable to expectorate, sputum induction with aerosolized hypertonic saline may produce a diagnostic sample. Bronchoscopy, in older children, or aspiration of gastric fluid via a nasogastric tube, in children (5 years or younger), may be attempted for select patients.[17] For patients with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in acquired immunodeficiency syndrome (AIDS) patients.[17,36]

TREATMENT

Drugs used in the treatment of active disease are divided into first-line and second-line agents. First-line agents should be the preferred options unless susceptibility results dictate otherwise. Treatment in special populations is also addressed.

Desired Outcome

The desired outcomes during the treatment of TB are:

1. Rapid identification of a new TB case.
2. Initiation of specific anti-TB treatment.
3. Eradicating *M. tuberculosis* infection.
4. Achievement of a noninfectious state in the patient, thus ending isolation.
5. Preventing the development of resistance.
6. Adherence to the treatment regimen by the patient.
7. Cure of the patient as quickly as possible (generally at least 6 months of treatment).

It is also important that patients with active disease are isolated to prevent spread of the disease and that appropriate samples for smears and cultures are collected. Secondary goals are identification of the index case that infected the patient, identification of all persons infected by both the index case and the new case of TB ("contact investigation"), and completion of appropriate treatments for those individuals.

General Approaches

Drug treatment is the cornerstone of TB management.[3,37] Monotherapy can be used only for infected patients who do not have active TB (latent infection, as shown by a positive skin test or positive IGRA). Once active disease is present, a minimum of two drugs, and generally three or four drugs, must be used simultaneously.[37] The duration of treatment depends on the condition of the host, extent of disease, presence of drug resistance, and tolerance of medications. The shortest duration of treatment generally is 6 months, and 18 to 24 months of treatment may be necessary for cases of MDR-TB.[37] Because the duration of treatment is so long and because many patients feel better after a few weeks of treatment, careful follow-up is required. Directly observed therapy (DOT) by a healthcare worker is a cost-effective

way to ensure completion of treatment and is considered the standard of care.[37,38,39]

Principles for Treating Latent Infection and for Treating Disease

Asymptomatic patients with tuberculous infection have a bacillary load of about 10^3 organisms, compared with 10^{11} organisms in a patient with cavitary pulmonary TB.[3,7] As the number of organisms increases, the likelihood of naturally occurring drug-resistant mutants also increases. Naturally occurring resistant mutants are found at rates of 1 in 10^6 to 1 in 10^8 organisms for the anti-TB drugs.[3,7,37] When treating asymptomatic latent infection with isoniazid monotherapy, the risk of selecting out isoniazid-resistant organisms is low. The isoniazid mutation rate is about 1 in 10^6, but only about 10^3 organisms are present in the body. In contrast, the risk of selecting out isoniazid-resistant organisms is unacceptably high for patients with cavitary TB. One can prevent selection of these resistant mutants by adding more drugs because the rates for resistance mutations to multiple drugs are additive functions of the individual rates. For example, only 1 in 10^{13} organisms would be naturally resistant to both isoniazid (1 in 10^6) and rifampin (1 in 10^7).[3,7,37] It is unlikely that such rare organisms are present in a previously untreated patient.

Combination chemotherapy is required for treating active TB disease. The patient should receive at least two drugs to which the isolate is susceptible, and, generally, four drugs are given at the outset of treatment. Rifampin and isoniazid are the best drugs for preventing drug resistance, followed by ethambutol, streptomycin, and pyrazinamide.[3,7,37,40]

Three subpopulations of mycobacteria are proposed to exist within the body, and each appears to respond to certain drugs.[7,37] Most numerous are the extracellular, rapidly dividing bacteria, often found within cavities (about 10^7 to 10^9 organisms). These are killed most readily by isoniazid, followed by rifampin, streptomycin, and the other drugs. A second group resides within caseating granulomas (possibly 10^5 to 10^7 organisms). These organisms appear to be in a semidormant state, with occasional bursts of metabolic activity. Pyrazinamide, through its conversion within *M. tuberculosis* to pyrazinoic acid, appears most active against these organisms. Rifampin and isoniazid also may be active against this subpopulation. The third subset is the intracellular mycobacteria present within macrophages (10^4 to 10^6). Rifampin, isoniazid, and the quinolones appear to be most active against intracellular *M. tuberculosis*. While this appears to explain what happens during the treatment of TB, there is no practical way to quantitate these populations within a given patient.

Nonpharmacologic Therapy

7 Nonpharmacologic interventions aim to (a) prevent the spread of TB, (b) find where TB has already spread using contact investigation, and (c) replenish the weakened (consumptive) patient to a state of normal weight and well-being. The first two items are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB.

Workers in hospitals and other institutions must prevent the spread of TB within their facilities.[7,24,27] All such workers should learn and follow each institution's infection control guidelines. This includes using personal protective equipment, including properly fitted respirators, and closing doors to "negative-pressure" rooms. These hospital isolation rooms draw air in from surrounding areas rather than blowing air

(and *M. tuberculosis*) into these surrounding areas. The air from the isolation room may be treated with ultraviolet lights and then vented safely outside. However, these isolation rooms work properly only if the door is closed.

Debilitated TB patients may require therapy for other medical problems, including substance abuse and HIV infection, and some may need nutritional support. Therefore, clinicians involved in substance abuse rehabilitation and nutritional support services should be familiar with the needs of TB patients. Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (*tuberculomas*), and certain extrapulmonary lesions.[37] BCG is the only clinically relevant vaccine for TB in use today. Although it is one of the most commonly administered vaccines in history, it is of limited value, and cannot prevent infection by *M. tuberculosis*. BCG (discussed further) may prevent extreme forms of TB in infants.[37,41]

Pharmacologic Therapy

Treating Latent Infection

Isoniazid is the preferred drug for treating LTBI.[24,37] Generally, isoniazid alone is given for 9 months. The treatment of LTBI reduces a person's lifetime risk of active TB from approximately 10% to approximately 1%. Because TB is spread easily through the air, each case prevented also prevents a second wave of cases that each prevented case would have produced. The treatment of LTBI has is called *prophylaxis*. **Table 112-2** lists the LTBI treatment options.

TABLE 112-2 Recommended Drug Regimens for Treatment of LTBI in Adults

Drug	Interval and Duration	Comments	Rating[a] (Evidence)[b]	
			HIV–	HIV+
Isoniazid	Daily for 9 months[b,c]	In HIV-infected patients, isoniazid may be administered concurrently with NRTIs, protease inhibitors, or NNRTIs	A (II)	A (II)
	Twice weekly for 9 months[b,c]	DOT must be used with twice-weekly dosing	B (II)	B (II)
Isoniazid	Daily for 6 months[c]	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children	B (I)	C (I)
	Twice weekly for 6 months[c]	DOT must be used with twice-weekly dosing	B (II)	C (I)
Rifampin	Daily for 4 months	For persons who are contacts of patients with isoniazid-resistant, rifampin-susceptible TB who cannot tolerate pyrazinamide	B (II)	B (III)
Isoniazid and rifapentine	Once weekly for 3 months	DOT must be used with once-weekly dosing. Not recommended for the following: children <2 years old, HIV/AIDS patients taking antiretroviral treatment, isoniazid- or rifampin-resistant strains, pregnant women or women expecting to become pregnant within the 12-week regimen	B (II)	B (II)

AIDS, acquired immunodeficiency syndrome; DOT, directly observed therapy; HIV, human immunodeficiency virus; LTBI, latent tuberculosis infection; NNRTIs, non-nucleoside reverse transcriptase inhibitors; NRTIs, nucleoside reverse transcriptase inhibitors.

[a]Strength of recommendation: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given.

[b]Quality of evidence: I, randomized clinical trial data; II, data from clinical trials that are not randomized or were conducted in other populations; III, expert opinion.

[c]Recommended regimen for children younger than 18 years of age.

Adapted from Targeted tuberculin testing and treatment of latent tuberculosis infection. American Thoracic Society. MMWR Recomm Rep 2000;49(RR-6):31.

Because young children, the elderly, and HIV-positive patients are at greater risk of active disease once infected with *M. tuberculosis*, they require careful evaluation. Once active TB is ruled out, they should receive treatment for latent infection.[24,37]

The keys to successful treatment of LTBI are (a) infection by an isoniazid-susceptible isolate, (b) adherence to the regimen, and (c) no exogenous reinfection.[24] Isoniazid adult doses are usually 300 mg daily (5-10 mg/kg of body weight)[37] (see Table 112-2). Lower doses are less effective.[24,42,43] Isoniazid should be given on an empty stomach, and antacids should be avoided within 2 hours of dosing. Rifampin 600 mg daily for 4 months can be used when isoniazid resistance is suspected or when the patient cannot tolerate isoniazid.[24,37] There is a growing body of evidence that 4 months of rifampin may be a safer and more cost-effective alternative to 9 months of isoniazid. Four months of rifampin was significantly cheaper per patient completing treatment because of better completion and fewer adverse events.[44] The combination of pyrazinamide plus rifampin is no longer recommended because of higher than expected rates of hepatotoxicity. Rifabutin 300 mg daily might be substituted for rifampin for patients at high risk of drug interactions. When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there are no randomized controlled trials to prove what regimen should be used to treat LTBI among contacts.[24,37] However, a course of 12-month regimen of a fluoroquinolone was effective in reducing the incidence of progression to active TB disease for MDR-TB contacts.[45] Regimens that *might* be effective include ethambutol plus levofloxacin, but data regarding efficacy are lacking.

In 2011, a randomized controlled trial compared 12 weeks of once-weekly isoniazid and rifapentine by DOT with daily self-administered isoniazid for 9 months.[46] This study, with over 8,000 participants, showed that the 12 weeks of weekly isoniazid and rifapentine given by DOT was not inferior in efficacy to 9 months of self-administered isoniazid, had a significantly higher completion rate (82% vs 69%), and was associated with fewer grade 3 or 4 adverse reactions (1.6% vs 3%).[46] Hypersensitivity reactions were more common with the isoniazid/rifapentine regimen and close clinical follow-up should be undertaken while experience is gained with this new regimen for LTBI therapy. The CDC now recommends the 12-week isoniazid/rifapentine regimen as an equal alternative to 9 months of daily isoniazid for treating LTBI in otherwise healthy patients aged older than or 12 years who have a predictive factor for greater likelihood of TB developing, which included recent exposure to contagious TB, conversion from negative to positive on an indirect test for infection (ie, IGRA or tuberculin skin test), and radiographic findings of healed pulmonary TB.[47] HIV-infected patients who are otherwise healthy and are not taking antiretroviral

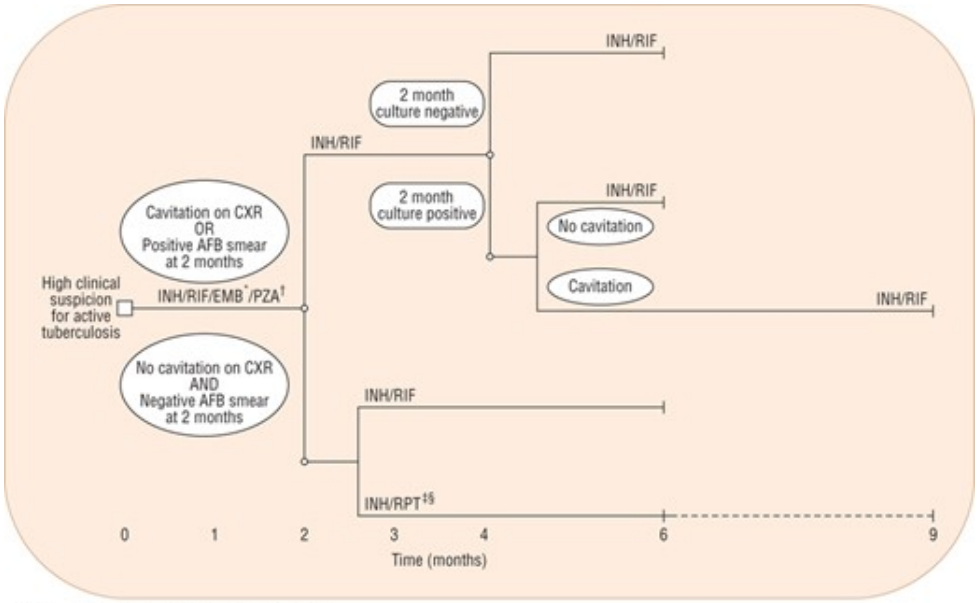
medications are also included in this category. However, precautions should be taken as HIV-infected patients are more likely to have extrapulmonary TB or pulmonary TB with normal findings on chest radiograph. For recent skin-test converters of all ages, the risk of active TB outweighs the risk for drug toxicity.[24,37] Pregnant women, alcoholics, and patients with poor diets who are treated with isoniazid should receive pyridoxine (vitamin B_6) 10 to 50 mg daily to reduce the incidence of central nervous system (CNS) effects or peripheral neuropathies. All patients who receive treatment of LTBI should be monitored monthly for adverse drug reactions and for possible progression to active TB.

Treating Active Disease

8 The CDC, American Thoracic Society (ATS), and the Infectious Diseases Society of America have published an algorithm for the treatment of TB (**Fig. 112-2**). The treatment of active TB requires the use of multiple drugs. There are two primary anti-TB drugs, isoniazid and rifampin, with the rest of the drugs having specific roles.[37,40] Isoniazid and rifampin should be used together whenever possible. Typically, *M. tuberculosis* is either very susceptible or very resistant to a given drug. Theoretically, minimal inhibitory concentration (MIC) results could be used to guide dosing in the treatment of moderately resistant *M. tuberculosis*, but this remains to be studied prospectively.[37,42]

FIGURE 112-2

Treatment algorithm for tuberculosis (TB). Note: Patients in whom TB is proved or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide, and ethambutol for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph or the acid-fast smear is positive at completion of 2 months of treatment, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial chest radiograph and the culture at the time of completion of 2 months of therapy is positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the CD^+ cell count is <100/μL (<100 × 10^6/L), the continuation phase should consist of daily or three-times-weekly isoniazid and rifampin. In HIV-uninfected patients having no cavitation on chest radiograph and negative acid-fast smears at completion of 2 months of treatment, the continuation phase may consist of either once-weekly isoniazid and rifapentine, or daily or twice-weekly isoniazid and rifampin, to complete a total of 6 months (bottom). Patients receiving isoniazid and rifapentine, and whose 2-month cultures are positive, should have treatment extended by an additional 3 months (total of 9 months). (CXR, chest radiograph; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.) [a]EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. [b]PZA may be discontinued after it has been taken for 2 months (56 doses). [c]RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. [d] Therapy should be extended to 9 months if the 2-month culture is positive. *(Reproduced from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep 2003;52(RR-11):1-7.)*



Drug susceptibility testing should be done on the initial isolate for all patients with active TB. These data should guide the selection of drugs over the course of treatment.[12,37] However, some patients are unable to provide a suitable specimen for laboratory testing. If susceptibility data are not available for a given patient, the drug susceptibility data for the suspected source case or regional susceptibility data should be used.[12,37]

Drug resistance should be expected for patients presenting for the retreatment of TB. These patients require retesting of drug susceptibility using freshly collected specimens. It is imperative to learn what drugs the patient received and for how long the patient received them.[12,37] A treatment history, often called a "*drug-o-gram*," shows the start and stop dates of all antimycobacterial drugs on a horizontal bar graph.[37] A drug-o-gram should be constructed for all retreatment patients.

9 The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, a total of 6 months of treatment.[37] If susceptibility to isoniazid, rifampin, and pyrazinamide is shown, ethambutol can be stopped at any time. Without pyrazinamide, a total of 9 months of isoniazid and rifampin treatment is required. **Table 112-3** shows the recommended treatment regimens. When intermittent therapy is used, DOT is essential. Doses missed during an intermittent TB regimen decrease its efficacy and increase the relapse rate. Note that Table 112-3 shows recommendations that differ for HIV-negative and HIV-positive patients. HIV-positive patients should not receive highly intermittent regimens. In general, regimens given daily five times each week or three times weekly can be used for HIV-positive patients. Less frequent dosing is associated with higher failure and relapse rates and the selection of rifampin-resistant organisms.[37]

TABLE 112-3 Drug Regimens for Culture-Positive Pulmonary TB Caused by Drug-Susceptible Organisms

Regimen	Initial Phase		Continuation Phase		Range of Total Doses (Minimal Duration)	Rating[a] (Evidence)[b]	
	Drugs	Interval and Dose[c] (Minimal Duration)	Drugs	Interval and Doses[c,d] (Minimal		HIV–	HIV+

				Duration)			
1	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 56 doses (8 weeks) or 5 days/wk for 40 doses (8 weeks)[e]	Isoniazid/rifampin	Seven days per week for 126 doses (18 weeks) or 5 days/wk for 90 doses (18 weeks)[e]	182-130 (26 weeks)	A (I)	A (II)
			Isoniazid/rifampin	Twice weekly for 36 doses (18 weeks)	92-76 (26 weeks)	A (I)	A (II)[f]
			Isoniazid/rifapentine[g]	Once weekly for 18 doses (18 weeks)	74-58 (26 weeks)	B (I)	E (I)
2	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 14 doses (2 weeks), then twice weekly for 12 doses (6 weeks) or 5 days/wk for 10 doses (2 weeks),[e] and then twice weekly for 12 doses (6 weeks)	Isoniazid/rifampin	Twice weekly for 36 doses (18 weeks)	62-58 (26 weeks)	A (II)	B (II)[f]
			Isoniazid/rifapentine[g]	Once weekly for 18 doses (18 weeks)	44-40 (26 weeks)	B (I)	E (I)
3	Isoniazid, rifampin, pyrazinamide, ethambutol	Three times weekly for 24 doses (8 weeks)	Isoniazid/rifampin	Three times weekly for 54 doses (18 weeks)	78 (26 weeks)	B (I)	B (II)
4	Isoniazid, rifampin, ethambutol	Seven days per week for 56 doses (8 weeks) or 5 days/wk for 40 doses (8 weeks)[e]	Isoniazid/rifampin	Seven days per week for 217 doses (31 weeks) or 5 days/wk for 155 doses (31 weeks)[e]	273-195 (39 weeks)	C (I)	C (II)
			Isoniazid/rifampin	Twice weekly for 62 doses (31 weeks)	118-102 (39 weeks)	C (I)	C (II)

[a]Ratings: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given.

[b]Evidence ratings: I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.

[c]When directly observed therapy is used, drugs may be given 5 days/wk, and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.

[d]Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31-week; either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.

[e]Five-day-a-week administration is always given by directly observed therapy. Rating for 5-day-per-week regimens is A (III).

[f]Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/μL (<100 × 10^6/L).

[g]Should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

Adapted from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep *2003;52(RR-11):1–77*.

When a patient's sputum smears convert to a negative, the risk of the patient infecting others is greatly reduced, but it is not zero.[15,17,37] Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet with others only in well-ventilated places. Smear-negative patients still may be culture positive, so they still can transmit TB to others.

Clinical Controversy…

Effective therapy exists for the treatment of patients latently infected with drug susceptible TB; however, the data are limited for the latent treatment of drug-resistant strains of *M. tuberculosis*. Data for treatments of MDR-TB exposure are even more limited and treatment is often based on the resistance profile. Two or three drugs are used for 6 to 12 months while the patient is monitored in hopes that active disease does not develop. Randomized controlled trials are still needed to determine the best approach to treating those with exposure to MDR-TB.[48]

Patients who are slow to respond clinically, those who remain culture-positive at 2 months of treatment, those with cavitary lesions on chest radiograph, and perhaps HIV-positive patients should be treated for a total of 9 months and for at least 6 months from the time that they convert to smear and culture negativity.[37] Some authors recommend therapeutic drug monitoring (TDM) the use of serum drug concentrations to optimize therapy for such patients.[40,42,49] When isoniazid and rifampin cannot be used, treatment durations become 2 years or more regardless of immune status.[37,40]

Adjustments to the regimen should be made once the susceptibility data are available.[37] If the organism is drug-resistant, careful consideration of the remaining therapeutic options must be made. Two or more drugs with in vitro activity against the patient's isolate and that the patient has not received previously

should be added to the regimen, as needed.[37,40,48] There is no standard regimen for MDR-TB.[37,48] Each patient's exposure history, treatment history (including toxicity and adherence issues), and current susceptibility data must be considered simultaneously. *It is critical to avoid monotherapy, and it is critical to never add a single drug to a failing regimen.*[37,40] Adding one drug at a time leads to the sequential selection of drug resistance until there are no drugs left. TB specialists should be consulted regarding cases of MDR-TB. It may take several months for a patient with MDR-TB to become culture-negative because the drugs used lack the potency of isoniazid and rifampin.[37,40] Consequently, prolonged respiratory isolation may be required.

Drug resistance should be considered in the following situations:

1. Patients who have received prior therapy for TB.
2. Patients from areas with a high prevalence of resistance (South Africa, Dominican Republic, Peru, Southeast Asia, the Baltic countries, and the former Soviet states).
3. Patients who are homeless, institutionalized, IV drug abusers, or infected with HIV.
4. Patients who still have AFB-positive sputum smears after 1 to 2 months of therapy.
5. Patients who still have positive cultures after 2 to 4 months of therapy.
6. Patients who fail treatment or relapse after treatment.
7. Patients known to be exposed to MDR-TB cases.

Empirical therapy with four or more drugs may be needed for acutely ill patients.[37] These regimens may be altered when the susceptibility pattern becomes known. If the index case is known, then the same effective regimen should be employed for the new case. Again, MDR-TB cases should be referred to specialists. A new term in use, *XDR-TB*, refers to "extensively drug-resistant TB." Such organisms are resistant to at least isoniazid, rifampin, a fluoroquinolone, and one second-line injectable drug (amikacin, capreomycin, or kanamycin).[48,49,50]

Special Populations

Tuberculous Meningitis and Extrapulmonary Disease

Patients with CNS TB usually are treated for longer periods (9-12 months instead of 6 months).[37] In general, isoniazid, pyrazinamide, ethionamide, and cycloserine penetrate the cerebrospinal fluid readily, but rifampin, ethambutol, and streptomycin have variable CNS penetration.[43] Of the quinolones, levofloxacin may be preferred based on current data. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.[37] TB of the bone typically is treated for 9 months, occasionally with surgical debridement.[37]

Children

TB in children may be treated with regimens similar to those used in adults, although some physicians still prefer to extend treatment to 9 months.[17,18,37] Pediatric doses of isoniazid and rifampin on a milligram-

per-kilogram basis are higher than those used in adults (**Table 112-4**).[37]

TABLE 112-4 Doses[a] of Antituberculosis Drugs for Adults and Children[b,c]

Drug	Preparation	Adults/Children	Typical Doses			
			Daily	1× Per Week	2× Per Week	3× Per Week
First-Line Drugs						
Isoniazid	Tablets (50, 100, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for IV or intramuscular injection	Adults[c]	5 mg/kg	15 mg/kg	15 mg/kg	15 mg/kg
		Children[c]	10-15 mg/kg	—	20-30 mg/kg	—
Rifampin	Capsule (150, 300 mg); powder may be suspended for oral administration; aqueous solution for IV injection	Adults[d,c]	10 mg/kg	—	10 mg/kg	10 mg/kg
		Children[c]	10-20 mg/kg	—	10-20 mg/kg	—
Rifabutin	Capsule (150 mg)	Adult[d,c]	5 mg/kg	—	5 mg/kg	5 mg/kg
		Children	Appropriate dosing for children is unknown	Appropriate dosing for children is unknown	Appropriate dosing for children is unknown	Appropriate dosing for children is unknown
Rifapentine	Tablet (150 mg, film coated)	Adults[c]	—	10 mg/kg (continuation phase) (600 mg usual adult dose)	—	—
		Children	The drug is not approved for use in children	The drug is not approved for use in children	The drug is not approved for use in children	The drug is not approved for use in children
Pyrazinamide	Tablet (500 mg, scored)	Adults[c]	40-55 kg: 1,000 mg	—	40-55 kg: 2,000 mg	40-55 kg: 1,500 mg
		Children[c]	56-75 kg:	—	56-75 kg:	56-75 kg:

Drug	Preparation	Adults/Children	Typical Doses			
			Daily	1× Per Week	2× Per Week	3× Per Week
Ethambutol	Tablet (100, 400 mg)	Adults[c]	1,500 mg		3,000 mg	2,500 mg
			76-90 kg: 2,000 mg	—	76-90 kg: 4,000 mg	76-90 kg: 3,000 mg
		Children[d,c]	15-30 mg/kg		50 mg/kg	—
			40-55 kg: 800 mg	—	40-55 kg: 2,000 mg	40-55 kg: 1,200 mg
			56-75 kg: 1,200 mg	—	56-75 kg: 2,800 mg	56-75 kg: 2,000 mg
			76-90 kg: 1,600 mg	—	76–90 kg: 4,000 mg	76-90 kg: 2,400 mg
			15-20 mg/kg daily		50 mg/kg	—
Second-Line Drugs						
Cycloserine	Capsule (250 mg)	Adults[c]	10-15 mg/kg/day, usually 500-750 mg/day in two doses[e]	No data	No data	No data
		Children[c]		—	—	—
Ethionamide	Tablet (250 mg)	Adults[f,c]	10-15 mg/kg/day			
			15-20 mg/kg/day, usually 500-750 mg/day in a single daily dose or two divided doses[f]	No data	No data	No data
		Children[c]		No data	No data	No data
Streptomycin	Aqueous solution (1-g vials) for IV or intramuscular	Adults[c]	15-20 mg/kg/day			
			15 mg/kg/day[g]	*g*	*g*	*g*
		Children[c]	20-40 mg/kg/day	—	20 mg/kg	—

Drug	Preparation	Adults/Children	Typical Doses			
			Daily	1× Per Week	2× Per Week	3× Per Week
	administration					
Amikacin/kanamycin	Aqueous solution (500-mg and 1-g vials) for IV or intramuscular administration	Adults[c]	15 mg/kg/day[g] 15-30 mg/kg/day IV or intramuscular as a single daily dose	[g]	[g]	[g]
		Children[c]		—	15-30 mg/kg	—
Capreomycin	Aqueous solution (1-g vials) for IV or intramuscular administration	Adults[c]	15 mg/kg/day[g] 15-30 mg/kg/day as a single daily dose	[g]	[g]	[g]
		Children[c]		—	15-30 mg/kg	—
p-Aminosalicylic acid (PAS)	Granules (4-g packets) can be mixed with food; tablets (500 mg) are still available in some countries, but not in the United States; a solution for IV administration is available in Europe	Adults[c]	8-12 g/day in two or three doses	No data	No data	No data
		Children[c]	200-300 mg/kg/day in two to four divided doses	No data	No data	No data
Levofloxacin	Tablets (250, 500, 750 mg); aqueous solution (500-mg vials) for IV injection	Adults[c]	500-1,000 mg daily	No data	No data	No data
		Children[c]	[h]	[h]	[h]	[h]
Moxifloxacin	Tablets (400 mg); aqueous solution (400 mg/250 mL) for IV injection	Adults[c]	400 mg daily	No data	No data	No data
		Children[c]	[i]	[i]	[i]	[i]

Higher doses of rifampin and rifapentine are being studied. Rifabutin dose may need to be adjusted when there is concomitant use of protease inhibitors or non-nucleoside reverse transcriptase inhibitors.

[a]Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

[b]For purposes of this document, adult dosing begins at age 15 years.

[c]The authors of this chapter do not agree with the use of maximum doses, since this arbitrarily caps doses for patients who otherwise might need larger doses. These maximum doses were not based on prospective studies in large or overweight individuals, and do not consider patients with documented malabsorption of their medications. Clinical judgment should be used in such circumstances.

[d]The drug can likely be used safely in older children but should be used with caution in children younger than 5 years, in whom visual acuity cannot be monitored. In younger children, ethambutol at the dose of 15 mg/kg/day can be used if there is suspected or proven resistance to isoniazid or rifampin.

[e]It should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

[f]The single daily dose can be given at bedtime or with the main meal.

[g]Dose: 15 mg/kg/day (1 g), and 10 mg/kg in persons older than 59 years (750 mg). Usual dose: 750–1,000 mg administered intramuscularly or IV, given as a single dose 5–7 days/wk and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.

[h]The long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both isoniazid and rifampin. The optimal dose is not known.

[i]The long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

Data from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep *2003;52(RR-11):1–77*.

Pregnancy

Women with TB should be cautioned against becoming pregnant because the disease poses a risk to the fetus and to the mother. If already pregnant, the usual treatment is isoniazid, rifampin, and ethambutol for 9 months.[51] Isoniazid and ethambutol are relatively safe for use in pregnant women.[37,43,51] B vitamins are particularly important during pregnancy and should be provided to women being treated for TB. Rifampin is associated rarely with birth defects, including limb reduction and CNS lesions.[43] In general, rifampin is used in pregnant women with TB. Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.[37]

Streptomycin use during pregnancy may lead to hearing loss in the newborn, including complete deafness. Streptomycin and the other aminoglycosides must be reserved for critical situations where alternatives do not exist.[37] Although the polypeptide capreomycin has not been studied, it probably carries the same risks.

Ethionamide may cause premature delivery and congenital deformities when used during pregnancy.[37,43] Down syndrome also has been reported with ethionamide, so it cannot be recommended in this setting. *p*-Aminosalicylic acid has been used safely in pregnancy, but specific data are lacking.[37,43] Cycloserine is known to cross the placenta, but the effects on the developing fetus are not known. Therefore, cycloserine generally cannot be recommended during pregnancy.[43]

Ciprofloxacin, levofloxacin, moxifloxacin, and the other quinolones are associated with permanent damage to cartilage in the weight-bearing joints of immature animals, especially dogs and rabbits.[37,43] Although these drugs do not frequently cause joint problems in humans, other anti-TB agents should be used during pregnancy.

Pregnant women with LTBI are not at the same level of risk compared with those with active disease. Therapy with isoniazid for LTBI may be delayed until after pregnancy. However in the case of recent infection documented by a skin-test conversion or a newly positive IGRA and in immunosuppressed women who are found to have LTBI while pregnant, treatment for LTBI is started during the second trimester of pregnancy.[37,43,51] Although most anti-TB drugs are excreted in breast milk, the amount of drug received by the infant through nursing is insufficient to cause toxicity. Quinolones should be avoided in nursing mothers, if possible.

HIV Infection

For drug susceptible strains of tuberculosis, patients with AIDS and other immunocompromised hosts may be managed with chemotherapeutic regimens similar to those used in immunocompetent individuals, although treatment is often extended to 9 months (see Table 112-3).[37] The precise duration to recommend remains a matter of debate. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients. Rifamycin based treatments are most effective; however, agents should be selected based on susceptibility and HIV drug interactions. Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB, so all efforts should be made to reduce the time between clinical presentation, diagnosis of TB, and start of appropriate treatment. Recommendations for management of HIV and TB published by the World Health Organization and others have provided guidance on monitoring of treatment, side effects, and drug interactions of HIV and TB, MDR, XDR-TB.[5,50,52,53] Differentiation must be made between infection with *M. tuberculosis* and nontuberculous mycobacteria, such as *Mycobacterium avium* complex (MAC), because the drugs used are different. While awaiting laboratory results, the patient can be treated empirically for TB if there is any doubt about the causative organism. Some patients with AIDS malabsorb their oral medications; this is discussed in Therapeutic Drug Monitoring below.[40,42,49]

Renal Failure

For nearly all patients, isoniazid and rifampin do not require dose modification in renal failure. They are eliminated primarily by the liver.[40,43,54] In the unlikely event that peripheral neuropathies develop, the frequency of isoniazid dosing may be reduced. Pyrazinamide and ethambutol typically require a reduction

in dosing frequency from daily to three times weekly (**Table 112-5**).[37,54]

TABLE 112-5 Dosing Recommendations for Adult Patients with Reduced Renal Function and for Adult Patients Receiving Hemodialysis

Drug	Change in Frequency?	Recommended Dose and Frequency for Patients with Creatinine Clearance <30 mL/min (<0.50 mL/s)or for Patients Receiving Hemodialysis[a,b,c,d]
Isoniazid	No change	300 mg once daily, or 900 mg three times per week
Rifampin	No change	600 mg once daily, or 600 mg three times per week
Pyrazinamide	Yes	25-35 mg/kg per dose three times per week (not daily)
Ethambutol	Yes	15-25 mg/kg per dose three times per week (not daily)
Levofloxacin	Yes	750-1,000 mg per dose three times per week (not daily)
Cycloserine	Yes	250 mg once daily, or 500 mg/dose three times per week[e]
Ethionamide	No change	250-500 mg/dose daily
p-Aminosalicylic acid	No change	4 g/dose, twice daily
Streptomycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Capreomycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Kanamycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Amikacin	Yes	12-15 mg/kg per dose two or three times per week (not daily)

[a]Standard doses are given unless there is intolerance.

[b]The medications should be given after hemodialysis on the day of hemodialysis.

[c]Monitoring of serum drug concentrations should be considered to ensure adequate drug absorption, without excessive accumulation, and to assist in avoiding toxicity.

[d]Data currently are not available for patients receiving peritoneal dialysis. Until data become available, begin with doses recommended for patients receiving hemodialysis and verify adequacy of dosing, using serum concentration monitoring.

[e]The appropriateness of 250-mg daily doses has not been established. There should be careful monitoring for evidence of neurotoxicity.

Adapted from American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR Recomm Rep *2003;52(RR-11):1–77*.

Renally cleared TB drugs include the aminoglycosides (amikacin, kanamycin, and streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.[37,43,55] Dosing intervals need to be extended for these drugs (Table 112-5). Ciprofloxacin and moxifloxacin are approximately 50% cleared by the kidneys but may not require a change in dose from once daily, as used for TB. The metabolites of isoniazid, pyrazinamide, and *p*-aminosalicylic acid are cleared primarily by the kidneys. The role of these metabolites in causing toxicity is unknown, so their accumulation in renal failure may carry some risk.

Ethionamide and its sulfoxide metabolite are hepatically cleared, so dosing is unchanged.[37,55] *p*-Aminosalicylic acid is converted largely to metabolites prior to renal elimination; these metabolites may accumulate in renal failure.[55] For patients on hemodialysis, the usual 12-hour dosing interval for *p*-aminosalicylic acid granules seems to be safe. Dialysis will remove the metabolites. Serum concentration monitoring must be performed for cycloserine to avoid dose-related toxicities in renal failure patients.[40,42,55]

Hepatic Failure

Anti-TB drugs that rely on hepatic clearance for most of their elimination include isoniazid, rifampin, pyrazinamide, ethionamide, and *p*-aminosalicylic acid.[43] Ciprofloxacin and moxifloxacin are approximately 50% cleared by the liver. Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used as guides for drug dosing. Furthermore, isoniazid, rifampin, pyrazinamide, and, to a lesser degree, ethionamide, *p*-aminosalicylic acid, and, rarely, ethambutol may cause hepatotoxicity.[37,40,43] For some patients with drug-susceptible TB, a "liver-sparing" regimen of streptomycin, levofloxacin, and ethambutol may be used, at least temporarily.[37,40,43] Because this regimen requires 18 or more months of treatment to be successful, patients usually are switched to isoniazid- and rifampin-containing regimens as soon as they are able.

Morbid Obesity

Data are not available for dosing the TB drugs for patients with morbid obesity.[43] Relatively hydrophilic drugs (isoniazid, pyrazinamide, the aminoglycosides, capreomycin, ethambutol, *p*-aminosalicylic acid, and cycloserine) can be dosed initially based on ideal body weight. Very low or very high serum concentrations can be avoided by checking the serum concentrations.[42]

The TB Drugs

The interested reader is referred to several other publications for more detailed information regarding these drugs.[37,40,42,43] Note that although the 2003 ATS/CDC guidelines recommend "maximum" doses (see Table 112-4),[37] in the authors' view, the "maximum" dose for a given patient is the dose that produces the desired response with an acceptable level of toxicity.[40,42] This can only be determined on a case-by-case basis. Artificially capping doses may deprive patients of needed drug.

Primary Antituberculosis Drugs

Isoniazid

Isoniazid is one of the two most important TB drugs. It is highly specific for mycobacteria, with a MIC against *M. tuberculosis* of 0.01 to 0.25 mcg/mL (mg/L). It is bactericidal and is thought to inhibit mycolic acid synthesis and disruption of the cell wall in susceptible organisms. Most nontuberculous mycobacteria such as *M. avium* are resistant to isoniazid, although *Mycobacterium kansasii* and *Mycobacterium xenopi* are susceptible. The most common mechanisms of resistance result from mutations in the *katG* or *inhA* genes.

Isoniazid is readily absorbed from the GI tract and from intramuscular injection sites. It also can be given as a short IV infusion over 5 minutes if diluted in about 20 mL of normal saline.[56] Isoniazid should be given on

an empty stomach whenever possible.[57] *N*-Acetyltransferase 2 forms the principal metabolite acetylisoniazid, which lacks antimycobacterial activity. The rate at which humans acetylate isoniazid is determined genetically; slow acetylation is an autosomal recessive trait and reflects a relative lack of *N*-acetyltransferase 2. Fast acetylators have isoniazid half-lives of less than 2 hours. Approximately 50% of whites and blacks and 80% to 90% of Asians and Native Alaskans are rapid acetylators. Slow acetylators have isoniazid half-lives of 3 to 4 hours and may be at an increased risk of neurotoxicity. The association of acetylator status and risk of hepatotoxicity, however, appears to be weak.[58] Poor absorption and rapid clearance of isoniazid for patients receiving highly intermittent therapy are associated with poor clinical outcomes.[59,60]

Transient elevations of the serum transaminases occur in 12% to 15% of patients receiving isoniazid and usually occur within the first 8 to 12 weeks of therapy.[37] Overt hepatotoxicity, however, occurs in only 1% of cases. Risk factors for hepatotoxicity include patient age, preexisting liver disease, excessive alcohol intake, pregnancy, co-administration of other medications that are potentially hepatotoxic, and the postpartum state. Isoniazid also may result in neurotoxicity, most frequently presenting as peripheral neuropathy or, in overdose, as seizures and coma. Patients with pyridoxine deficiency, such as pregnant women, alcoholics, children, and the malnourished, are at increased risk. Isoniazid may inhibit the metabolism of phenytoin, carbamazepine, primidone, and warfarin.[40] Patients who are being treated with these agents should be monitored closely, and appropriate dose adjustments should be made when necessary.

Rifampin

The introduction of rifampin into routine use during the 1970s allowed for true short-course treatment of TB (6-9 months).[37] Without rifampin, treatment is generally 18 months or longer. Drug resistance to rifampin is an ominous prognostic factor because it is frequently associated with isoniazid resistance and leaves the patient with few good therapeutic options. Clinicians *must* take care to protect susceptibility to rifampin by carefully treating their patients. Rifampin shows bactericidal activity against *M. tuberculosis* and several other mycobacterial species, including *Mycobacterium bovis* and *M. kansasii*.[61] It also is active against a broad array of other bacteria. Alteration of the target site on RNA polymerase, primarily through changes in the *rpoB* gene, leads to most forms of rifampin resistance.[37,61]

Rifampin usually is given orally, but it also can be given as a 30-minute IV infusion.[61] Oral doses are best given on an empty stomach.[62] Patients with AIDS, diabetes, and other GI problems appear to have difficulty absorbing rifampin after oral doses, and this has been associated with therapeutic failures in some cases.[40,42,60,63] Rifampin is metabolized to 25-desacetyl rifampin, which retains some of rifampin's activity; most of rifampin and its metabolite are cleared in the bile. Rifampin generally is given at 600 mg daily or intermittently, although this dose does not take full advantage of rifampin's concentration-dependent killing.[40,42] Higher doses should be tested in humans within the context of clinical trials.

Elevations in hepatic enzymes have been attributed to rifampin in 10% to 15% of patients, with overt hepatotoxicity occurring in less than 1%.[37,61] More frequent adverse effects of rifampin include rash, fever, and GI distress. Allergic reactions to rifampin have been reported and occur more frequently with intermittent rifampin doses 900 mg or more twice weekly. These reactions may take the form of a flu-like syndrome with development of fever, chills, headache, arthralgias, and, rarely, hypotension and shock.[37] Alternatively, hemolytic anemia or acute renal failure may occur, requiring permanent discontinuation.

Rifampin's potent induction of hepatic enzymes, especially cytochrome P450 3A4, may enhance the elimination of many other drugs, most notably the protease inhibitors used to treat HIV (**Table 112-6**). HIV-positive patients may benefit from the use of rifabutin instead of rifampin.[25,37,52,64] Furthermore, women who use oral contraceptives must use another form of contraception during therapy because increased clearance of the hormones may lead to unexpected pregnancies. Patient records should be reviewed for potential drug interactions before dispensing rifampin. Rifampin may turn urine and other secretions orange-red and may permanently stain some types of contact lenses.

TABLE 112-6 Recommended Regimens for the Concomitant Treatment of TB and HIV Infection in Adults

Combined Regimen for Treatment of HIV and TB	PK Effect of the Rifamycin	Tolerability/Toxicity	Antiviral Activity When Used with Rifamycin	Recommendations (Comments)
Efavirenz-based antiretroviral therapy[a] with rifampin-based TB treatment	Well-characterized, modest decrease in concentrations in some patients	Low rates of discontinuation	Excellent	Preferred (efavirenz should not be used during the first trimester of pregnancy)
PI-based antiretroviral therapy[a] with rifabutin-based TB treatment	Little effect of rifabutin on PI concentrations, but marked increases in rifabutin concentrations	Low rates of discontinuation (if rifabutin is appropriately dose-reduced)	Favorable, although published clinical experience is not extensive	Preferred for patients unable to take efavirenz[b] (caution to ensure patients who discontinue PI not to continue to receive reduced rifabutin dose)
Nevirapine-based antiretroviral therapy with rifampin-based TB treatment	Moderate decrease in concentrations	Concern about hepatotoxicity when used with isoniazid, rifampin, and pyrazinamide	Suboptimal when nevirapine is initiated using once-daily dosing largely favorable when nevirapine is given twice daily throughout co-treatment	Alternative for patients who cannot take efavirenz, though efavirenz is preferred (nevirapine should not be initiated among women with CD4>250 [>200 × 10^6/L] or men with CD4>400 cells/μL[>400 ×10^6/L])
Raltegravir-based antiretroviral therapy with rifampin-based TB treatment	Significant decrease in concentrations with standard dosing	Limited experience	Limited published clinical experience	Alternative at higher doses for patients who cannot take efavirenz and who have baseline viral load <100,000

Combined Regimen for Treatment of HIV and TB	PK Effect of the Rifamycin	Tolerability/Toxicity	Antiviral Activity When Used with Rifamycin	Recommendations (Comments)
				copes/mL (<100 × 10^6/L)
Zidovudine/lamivudine/abacavir/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	No published clinical experience, but this regimen is less effective than efavirenz or atazanavir basd regimens in person not taking rifampin	Alternative for patients who cannot take efavirenz or nevirapine and if rifabutin not available
Zidovudine/lamivudine/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, no other effects predicted	Anemia	Favorable, but not evaluated in a randomized trial	Alternative for patients who cannot take efavirenz and abacavir and if rifabutin not available
Zidovudine/lamivudine/abacavir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	Early favorable experience, but this combination is less effective than efavirenz or nevirapine based regimens in persons not taking rifampin	Alternative for patients who cannot take efavirenz and tenofovir and if rifabutin not available
Superboosted[c] lopinavir-based antiretroviral therapy or double dose lopinavir/ritonavir based therapy with rifampin-based TB treatment	Moderate decrease in concentrations	Hepatitis	Early favorable experience of super-boosting among young children and double dose among adults already on	Alternative if rifabutin not available; double dose an option among adults already taking lopinavir based antiretroviral therapy and virologically suppressed at the time of tuberculosis

Combined Regimen for Treatment of HIV and TB	PK Effect of the Rifamycin	Tolerability/Toxicity	Antiviral Activity When Used with Rifamycin	Recommendations (Comments)
			antiretroviral drugs at the time of rifampin initiation	treatment initiation; super boosting has not been adequately tested in adults ut may be effective

ART, antiretroviral therapy; HIV, human immunodeficiency virus; TB, tuberculosis.

[a]With two nucleoside analogues.

[b]Includes patients with NNRTI-resistant HIV, those unable to tolerate efavirenz, and women during the first one to two trimesters of pregnancy.

[c]Super boosting of lopinavir is achieved by giving lopinavir 400 mg together with 400 mg ritonavir twie daily. Doble dose lopinavir/ritonavir is lopinavir 800 mg plus ritonavir 200 mg twice daily.

Adapted from Centers for Disease Control and Prevention. Managing Drug Interactions in the Treatment of HIV Related Tuberculosis. 2013.

Other Rifamycins

Rifabutin is used for disseminated *M. avium* infection in AIDS patients and is quite active against *M. tuberculosis*. Most rifampin-resistant organisms are resistant to rifabutin. Because rifabutin is a less potent enzyme inducer than rifampin, it may be used for patients who are receiving protease inhibitors.[37,52,64,65] For HIV-positive patients, the ATS/CDC recommends regimens with three or more doses of the TB drugs per week (see Table 112-3). Rifapentine is a long-acting rifamycin that can be used once weekly in the continuation phase of treatment (after the first 2 months) in carefully selected HIV-negative patients. It is approximately as potent an enzyme inducer as rifampin, so similar drug interactions are likely.[37,52,64,65]

Pyrazinamide

Adding pyrazinamide to the first 2 months of treatment with isoniazid and rifampin shortens the duration to 6 months for most patients.[37] Pyrazinamide may be bacteriostatic or bactericidal depending on the concentration and the susceptibility of the organism. It is usually well absorbed and displays a fairly long half-life.[66,67] The most common toxicities of pyrazinamide are GI distress, arthralgias, and elevations in the serum uric acid concentrations.[37] Most patients do not experience true gout. Hepatotoxicity is the major limiting adverse effect and is dose-related when pyrazinamide is given daily.

A fixed-combination product (Rifater, Aventis) of rifampin 120 mg, isoniazid 50 mg, and pyrazinamide 300 mg is designed to prevent drug resistance by keeping the self-medicating patient from using only one drug at a time. If the patient is receiving DOT, there is no particular advantage to this product. The typical dose of Rifater will be five to six tablets daily. When pyrazinamide is discontinued after 2 months of treatment, the combination product Rifamate (isoniazid 150 mg and rifampin 300 mg) can be substituted.

Ethambutol

Ethambutol replaced *p*-aminosalicylic acid as a first-line agent in the 1960s because it was better tolerated by patients.[37] It is used as a fourth drug for TB while awaiting susceptibility data.[37] If the organism is susceptible to isoniazid, rifampin, and pyrazinamide, ethambutol can be stopped. Ethambutol is active against most mycobacteria, by inhibiting synthesis of metabolites and impairing cell metabolism, and is generally bacteriostatic.

Ethambutol should not be given with antacids.[68] For patients with renal failure, the ethambutol dose should be reduced to three times per week.[54,69] Retrobulbar neuritis is the major adverse effect. Patients may complain of a change in visual acuity, the inability to see the color green, or both. They should be monitored monthly while on the drug using Snellen wall charts for visual acuity and Ishihara red-green color discrimination cards.[31,37]

Second-Line Antituberculosis Drugs

Streptomycin

Streptomycin is one of three aminoglycoside antibiotics (along with amikacin and kanamycin) that are active against mycobacteria. It is quite active against MAC and several other mycobacteria, enterococci, *Brucella, Yersinia*, and various other bacteria. Although labeled only for intramuscular dosing, streptomycin can be given safely as IV infusions (100 mL of 5% dextrose in water or normal saline) over 30 minutes, similar to the other aminoglycosides.[70] Streptomycin, like other aminoglycosides, is renally cleared by glomerular filtration and must be given less often to patients with renal dysfunction.[37,40]

Streptomycin occasionally causes nephrotoxicity, although it tends to be mild and reversible. It also is capable of causing ototoxicity (vestibular and cochlear), which may become permanent with continued use.[37] Older patients and those receiving long durations of treatment are most likely to experience hearing loss, whereas vestibular toxicity is highly unpredictable.

Resistance to amikacin and kanamycin is frequently linked but independent of resistance to streptomycin and independent of resistance to capreomycin. Therefore, susceptibility tests should guide the selection of these injectable drugs.

p-Aminosalicylic Acid

In the United States, only the enteric-coated, sustained-release granule form (Paser) is available.[71,72,73] GI disturbances are the most common adverse effects from *p*-aminosalicylic acid. Diarrhea is usually self-limited, with symptoms improving after the first 1 to 2 weeks of therapy. Occasionally, a few doses of an opioid will resolve the problem. It also is important to tell the patient that the empty granules will appear in the stool. Although FDA-approved for three daily doses, pharmacokinetic data support twice-daily dosing.[72]

Various types of malabsorption, including steatorrhea, were reported with previous dosage forms of *p*-aminosalicylic acid. Hypersensitivity and, rarely, severe hepatitis may occur. *p*-Aminosalicylic acid is known to produce goiter, with or without myxedema, which seems to occur more frequently with concomitant ethionamide therapy.

Cycloserine

Cycloserine is only used to treat MDR-TB. It is well absorbed orally and is best taken on an empty stomach.[74] It is cleared primarily through the kidneys by glomerular filtration and requires dosage reduction in renal failure. Cycloserine can produce dose-related CNS toxicity, including lethargy, confusion, or unusual behavior. Seizures, although reported, are exceedingly rare in US patients.[37] Therapy is improved by maintaining 2-hour postdose serum concentrations between 20 and 35 mcg/mL (mg/L; 200 and 349 µmol/L).[40,42] Most patients reach a dose of 750 mg daily, divided unevenly into two doses. This can be achieved by starting with 250 mg daily for 2 days, followed by 250 mg increments over 2-day intervals. This dose of cycloserine can be maintained if the patient complains of only occasional mild CNS effects, such as difficulty concentrating. Serum concentrations can be checked 1 to 2 weeks into therapy. The addition of pyridoxine 50 mg daily may improve patient tolerance of cycloserine.

Ethionamide

Ethionamide shares structural features with two other antimycobacterial agents, isoniazid and, more distantly, thiacetazone, a drug not used in the United States. Prothionamide, the *n*-propyl derivative of ethionamide, is used in Europe. Ethionamide is only active against organisms of the genus *Mycobacterium*, and it should be considered primarily bacteriostatic because it is difficult to achieve serum concentrations that would be bactericidal.[37,40,42]

GI toxicity is the dose-limiting adverse effect. The drug should be introduced gradually in 250 mg increments, as described earlier for cycloserine. Rarely will a patient tolerate more than 1,000 mg daily in divided oral doses. Ethionamide may be administered with a light snack or prior to bedtime to minimize GI intolerance. Food does not affect absorption significantly.[75] Little ethionamide is recovered in the urine, so doses remain the same in renal failure. Ethionamide may cause goiter with or without hypothyroidism (especially when given with *p*-aminosalicylic acid), gynecomastia, alopecia, impotence, menorrhagia, photodermatitis, and acne. The management of diabetes also may be more difficult for patients receiving ethionamide. Because of these problems, ethionamide only is used when necessary.

Clofazimine

Clofazimine is a drug with good activity against *Mycobacterium leprae* and some activity against *M. tuberculosis* and *M. avium*. It is used in doses of 100 mg daily in advanced cases of MDR-TB or MAC, especially when therapeutic options are limited.[37,40] The drug has a terminal elimination half-life that is weeks long. GI distress and skin discoloration are the most important adverse reactions. Although uncommon, severe GI pain may occur because of deposition of clofazimine crystals within the intestines; this may require surgical correction.

Thiacetazone

This is a weak agent used rarely in parts of the developing world because of its low cost. Skin reactions, including rash and Stevens-Johnson syndrome, may occur. Thiacetazone must be discontinued permanently as soon as a rash appears. Similar to trimethoprim–sulfamethoxazole, the incidence of skin reactions is much higher for AIDS patients.[76]

Quinolones

Levofloxacin, moxifloxacin, and gatifloxacin (outside of the United States), are sometimes used to treat MDR-TB because of their excellent activity against *M. tuberculosis*. Several studies have suggested a potential role for moxifloxacin as a possible replacement for certain first-line agents.[40,77,78,79] Moxifloxacin has been compared with isoniazid and ethambutol during the first 8 weeks of therapy for pulmonary TB. It did not demonstrate a significant increase in 8-week culture negativity when compared with isoniazid. However, shorter time to culture conversion was seen when compared with ethambutol.[78] Quinolones are useful because most are available in oral and IV dosage forms, so they can be used in critically ill patients. However, resistance of MTB to the fluoroquinolones is a major concern. Resistance is attributed to mutations in the *gyrA* and *gyrB* genes and can develop in a relatively short period of time.[80]

Macrolides/Azalides

The macrolide clarithromycin and azalide azithromycin represent substantial advances in the treatment of MAC but demonstrate limited activity against *M. tuberculosis* and are not used frequently for TB.[37,40]

New Drugs and Delivery Systems

Several promising compounds are currently under development for the treatment of MTB.

Bedaquiline is a diarylquinoline, approved for use by the FDA, which works through targeting the ATP synthase pump, and does not demonstrate cross-resistance with existing TB drugs. The WHO and CDC have issued recommendations stating that bedaquiline may be used at a dose of 400 mg daily for 2 weeks and then 200 mg three times a week for 22 weeks of treatment in adults with pulmonary MDR-TB when an effective treatment regimen cannot otherwise be provided.[81] Bedaquiline may be used on a case-by-case basis in children, HIV-infected persons, pregnant women, and extrapulmonary TB. Patients treated with bedaquiline should be closely monitored every week for potential side effects and an electrocardiogram (QT monitoring) should be performed at baseline and at weeks 2, 12, and 24.[81] The QT monitoring is required due to a black box warning issued by the FDA as a result of increased rates of death due to QT prolongation in patients receiving bedaquiline.

Delamanid, PA-824 and TBA-354 are all nitroimidazole derivatives which are chemically related to metronidazole and work through inhibiting mycolic acid synthesis. All of these agents have potent in vitro and in vivo activity with very low MICs against *M. tuberculosis*.[82,83,84] Delamanid has centralized marketing authorization by the European Medicines Agency for use in the European Union.[81,83,85] PA-824 is undergoing phase two studies and TBA-354 has shown benefit in preclinical trials. Combinations of PA-824 with other anti-TB drugs are also being investigated. AZD-5847 is another potentially new drug currently being investigated in Phase 2a trials.[86] Linezolid has also been used in some patients with MDR-TB.[87] Long-term use of linezolid requires careful monitoring of hematologic indices for potential anemia and thrombocytopenia. It may be possible to reduce the incidences of these toxicities by giving linezolid 600 mg daily or 300 mg twice daily for the slow-growing *M. tuberculosis* rather than the usual 600 mg twice-daily dose used for gram-positive organisms. Liposomes have been investigated as delivery systems for various agents against mycobacteria, including isoniazid, rifampin, and the aminoglycosides. By changing the pharmacokinetic profile of such agents, their use in the treatment of mycobacterial infections could be enhanced greatly. Currently, no such product is licensed for use against TB.

Corticosteroids

Adjunctive therapy with corticosteroids may be of benefit for some patients with tuberculous meningitis or pericarditis to relieve inflammation and pressure.[37] They should be avoided in most other circumstances because they detract from the immune response to TB.

Bacille Calmette-Guérin Vaccine

The BCG vaccine is an attenuated, hybridized strain of *M. bovis*. It was developed in 1921 and is used as a prophylactic vaccine against TB. Administration of BCG vaccine is compulsory in many developing countries and is officially recommended in many others. Vaccination with BCG produces a subclinical infection resulting in sensitization of T lymphocytes and cross-immunity to *M. tuberculosis*, as well as cutaneous hypersensitivity and, in many cases, a positive tuberculin skin test.

The efficacy of several different BCG preparations ranged from negative 56% (some patients did worse with the vaccine) to positive 80%.[37] Trials within the United States and Puerto Rico have shown efficacy rates of 6% to 29%. The primary benefit of BCG vaccination appears to be the prevention of severe forms of TB in children. Data from the BCG trials show that the incidence of tuberculous meningitis and miliary TB is 52% to 100% lower and that the incidence of pulmonary TB is 2% to 80% lower in vaccinated children younger than 15 years than it was in unvaccinated controls.

Unfortunately, BCG does not appear to be reliable in preventing disease by *M. tuberculosis* in other segments of the population. Side effects occur in 1% to 10% of vaccinated persons and usually include severe or prolonged ulceration at the vaccination site, lymphadenitis, and lupus vulgaris. Pregnant women and patients with impaired immune systems, including those with HIV infection, should avoid vaccination. The World Health Organization had recommended, however, that in populations where the risk of TB is high, HIV-infected infants who are asymptomatic should receive BCG vaccine at birth or as soon as possible thereafter. Because BCG infection has occurred in AIDS patients given the vaccine, individuals with symptomatic HIV infection should not be vaccinated.[37]

In the United States, BCG vaccination is recommended only for uninfected children who are at unavoidable risk of exposure to TB and for whom other methods of prevention and control have failed or are not feasible.[37] Its use is very limited.

PERSONALIZED PHARMACOTHERAPY

Desired treatment outcomes for tuberculosis infections require aggressive treatment and rapid identification and both latent and active disease states. Treatment must be individualized based antimicrobial susceptibilities. Appropriate treatment selection is critical to avoid resistance. TDM may be necessary in certain populations. Extended durations of therapy are required for treatment of Mycobacterial diseases so health care professionals should develop a plan to monitor efficacy, adherence, adverse drug reactions, and interactions to TB therapy through regular assessments and monitoring. Directly observed therapy may be required to assure compliance. Patients coinfected with HIV will require special attention because of their immunocompromised state and increased risk of drug interactions.

Therapeutic Drug Monitoring

TDM, or applied pharmacokinetics, generally should be used if patients are failing appropriate treatment (no clinical improvement after 2-4 weeks or smear positive after 4-6 weeks).[40,42,88,89] Patients with AIDS,

diabetes, obesity, cystic fibrosis, various GI disorders, or MDR-TB may be tested prospectively, before problems arise, to ensure adequate treatment. Blood samples collected at 2 and 6 hours after a dose have been used with some success, although they may not be the optimal sampling times for all the drugs. Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place.[90,91]

Clinical Controversy…

Some TB centers employ TDM for many of their patients at the outset of treatment in order to identify drug-delivery problems early. Other centers wait to see how the patient responds and perform TDM only if problems arise. An argument can be made for either approach. The latter can save money in the short-term, but delays in effective treatment can affect the patient's outcome adversely.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.[92] Unfortunately, there is no reliable way to identify such patients a priori. Noncompliance rates of up to 89% have been reported with TB therapy.[92] It is critical to the control of TB that such adherence rates be improved dramatically. The most effective way to achieve this end is with DOT.[37] Despite criticisms that it will cost more money, it is far cheaper in the long run to prevent the further spread of disease with DOT than to track down and treat additional cases of TB continuously.

The homeless and other underprivileged individuals are assumed to constitute the group of patients considered "unreliable," and DOT should be reserved for them; it is also assumed that "responsible" patients cared for by private physicians may be treated with daily, unsupervised therapy. A study conducted in Baltimore, however, compared outcomes (sputum culture conversion to negative at 3 months) for patients with pulmonary TB who were treated by private physicians with outcomes for patients treated via DOT in a city-run clinic. Surprisingly, 3-month culture conversion occurred in only 40% of the private-care patients, compared with 90% in the city clinic-care patients.[3] Clearly, expansion of the use of DOT to nearly all patients with TB may be of benefit.

Patients who are AFB-smear positive should have sputum samples sent for AFB stains every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.[37] Once on maintenance therapy, sputum cultures can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

Serum chemistries, including blood urea nitrogen, creatinine, aspartate transaminase, and alanine transaminase, and a complete blood count with platelets should be performed at baseline and periodically thereafter, depending on the presence of other factors that may increase the likelihood of toxicity (eg, advanced age, alcohol abuse, pregnancy)[37] (**Table 112-7**). Hepatotoxicity should be suspected for patients whose serum transaminases exceed five times the upper limit of normal or whose total bilirubin concentration exceeds 3 mg/dL (51.3 µmol/L) and for patients with symptoms such as nausea, vomiting, or

jaundice. At this point, the offending agent(s) should be discontinued. Sequential reintroduction of the drugs with frequent testing of liver enzymes is often successful in identifying the offending agent; other agents may be continued. Alternative agents should be selected as needed. Audiometric testing should be performed at baseline and monthly for patients who must receive aminoglycosides for more than 1 to 2 months. Vision testing (Snellen visual acuity charts and Ishihara color discrimination plates) should be performed on all patients who receive ethambutol. All patients diagnosed with TB should be tested for HIV infection.

TABLE 112-7 Antituberculosis Drug Monitoring Table

Drug	Adverse Effects	Monitoring
Isoniazid	Asymptomatic elevation of aminotransferases, clinical hepatitis, fatal hepatitis, peripheral neurotoxicity, CNS effects, lupus-like syndrome, hypersensitivity, monoamine poisoning, diarrhea	LFT monthly in patients who have preexisting liver disease or who develop abnormal liver function that does not require discontinuation of drug; dosage adjustments may be necessary in patients receiving anticonvulsants or warfarin
Rifampin	Cutaneous reactions, GI reactions (nausea, anorexia, abdominal pain), flu-like syndrome, hepatotoxicity, severe immunologic reactions, orange discoloration of bodily fluids (sputum, urine, sweat, tears), drug interactions due to induction of hepatic microsomal enzymes	Liver enzymes and interacting drugs as needed (eg, warfarin)
Rifabutin	Hematologic toxicity, uveitis, GI symptoms, polyarthralgias, hepatotoxicity, pseudojaundice (skin discoloration with normal bilirubin), rash, flu-like syndrome, orange discoloration of bodily fluids (sputum, urine, sweat, tears)	Drug interactions are less problematic than rifampin
Rifapentine	Similar to those associated with rifampin	Drug interactions are being investigated and are likely similar to rifampin
Pyrazinamide	Hepatotoxicity, GI symptoms (nausea, vomiting), nongouty polyarthralgia, asymptomatic hyperuricemia, acute gouty arthritis, transient morbilliform rash, dermatitis	Serum uric acid can serve as a surrogate marker for adherence; LFTs in patients with underlying liver disease
Ethambutol	Retrobulbar neuritis, peripheral neuritis, cutaneous reactions	Baseline visual acuity testing and testing of color discrimination; monthly testing of visual acuity and color discrimination in patients taking >15–20 mg/kg, having renal insufficiency, or receiving the drug for >2 months

Drug	Adverse Effects	Monitoring
Streptomycin	Ototoxicity, neurotoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr Monthly assessments of renal function and auditory or vestibular symptoms
Amikacin/kanamycin	Ototoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr; monthly assessments of renal function and auditory or vestibular symptoms
Capreomycin	Nephrotoxicity, ototoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr Monthly assessments of renal function and auditory or vestibular symptoms Baseline and monthly serum K^+ and Mg^{2+}
p-Aminosalicylic acid	Hepatotoxicity, GI distress, malabsorption syndrome, hypothyroidism, coagulopathy	Baseline LFTs and TSH TSH every 3 months
Moxifloxacin	GI disturbance, neurologic effects, cutaneous reactions	No specific monitoring recommended

CNS, central nervous system; GI, gastrointestinal; LFT, liver function test; SCr, serum creatinine; TSH, thyroid-stimulating hormone.

Chapter 113: Gastrointestinal Infections and Enterotoxigenic Poisonings

Andrew Roecker; Brittany Bates; Steven Martin

INTRODUCTION

KEY CONCEPTS

- 1 Infectious diarrhea is a disease that causes significant morbidity and mortality worldwide. Its etiology includes various bacteria, viruses, and protozoans, with viral causes being most predominant globally.
- 2 Two types of infectious diarrhea include watery or enterotoxigenic diarrhea and dysentery or bloody diarrhea. Common pathogens responsible for watery diarrhea are viruses and enterotoxigenic *Escherichia coli*. Common pathogens responsible for dysentery diarrhea are *Shigella* spp., *Campylobacter jejuni*, nontyphoid *Salmonella*, and enterohemorrhagic *E. coli*.
- 3 Fluid and electrolyte replacement is the cornerstone of therapy for diarrheal illnesses. Oral rehydration therapy is preferred in most cases of mild and moderate diarrhea.
- 4 The use of antibacterial therapy for infectious diarrhea is not commonly indicated due to the mild and self-limited nature of the infection, or viral etiology. Antibiotic therapy is recommended in cases of severe diarrhea, moderate-to-severe cases of traveler's diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea in high-risk patients.
- 5 Loperamide and diphenoxylate/atropine may offer symptomatic relief in patients with moderate watery diarrhea; however, use of antimotility agents should be avoided in patients with watery and dysentery diarrhea.
- 6 Diarrheal illness can be largely prevented by procedures to prevent contaminated food or water supplies and with appropriate personal hygiene.
- 7 Oral vancomycin is recommended in patients with severe *Clostridium difficile* infection

(CDI). Metronidazole is the drug of choice for mild to moderate disease and fidaxomicin may offer an advantage in patients at high risk for disease recurrence.

- 8 Common traveler's diarrheal pathogens include enterotoxigenic *E. coli*, *Shigella* spp., *Campylobacter* spp., *Salmonella* spp., and viruses.
- 9 Patient education on prevention strategies and appropriate self-treatment of traveler's diarrhea is preferred, and prophylaxis with antibacterials is not recommended.
- 10 Pathogens commonly responsible for food poisoning include *Staphylococcus* spp., *Salmonella* spp., *Shigella* spp., and *Clostridium* spp.

Gastrointestinal (GI) infections and enterotoxigenic poisonings encompass a wide variety of medical conditions characterized by inflammation of the GI tract. Inflammation-induced vomiting and diarrhea are responsible for much of the morbidity and mortality of these conditions. Diarrhea is defined as a decrease in consistency of bowel movements (ie, unformed stool) and an increase in frequency of stools to three or more per day.[1,2] Acute disease is commonly associated with diarrhea lasting 14 days or less in duration while persistent diarrhea lasts more than 14 days.

This chapter focuses on infectious etiologies of acute GI infections and enterotoxigenic poisonings. A wide variety of viral, bacterial, and parasitic pathogens are responsible for these infections. Chapter 115 discusses the common protozoans that cause gastroenteritis. This chapter will focus on pathogenesis and management of common viral and bacterial etiologies. Because the clinical consequences of dysenteric diarrhea can be more severe compared with cases of watery diarrhea, the chapter is organized accordingly. Epidemiology, clinical presentation, diagnosis, treatment, and prevention strategies are discussed for all GI infections generally, and further elaborated in subsequent sections for specific diseases such as *Clostridium difficile*–associated diarrhea, traveler's diarrhea, and foodborne illnesses.

EPIDEMIOLOGY

Dehydration resulting from acute infectious diarrhea is the second leading cause of mortality in children younger than 5 years, killing 760,000 annually.[2] Globally, 1.7 billion cases of infectious diarrhea occur yearly and cause over 2 million deaths.[2] The incidence of diarrhea for all children younger than age 5 years is estimated to be 2.9 episodes per child per year. The incidence of diarrhea is higher in younger children, with 4.5 episodes per child per year among children aged 6 to 11 months, compared with 2.3 episodes per child per year for children aged 24 to 59 months.[3] Younger children also have a higher risk of death from acute dehydrating diarrhea, and diarrheal disease is still the leading global cause of malnutrition in children younger than 5 years.[2] Although the incidence of childhood diarrhea has been declining, diarrhea remains a major health problem in children, especially in those younger than 1 year.

In the United States, 179 million episodes of acute gastroenteritis occur each year, resulting in more than 600,000 hospitalizations and more than 5,000 deaths.[4,5] The highest mortality risk from

infectious diarrhea in the United States occurs in the elderly, which contrasts to the developing world where the risk of death is highest among young children.[4] A study of the McDonnell-Douglas Health Information System database revealed that 25% of all hospitalizations and 85% of all mortality associated with diarrhea involved the elderly (age 60 years and older).[4] In addition to children and the elderly, other groups at risk for GI infections include travelers and campers, patients in chronic care facilities, military personnel stationed abroad, and immunocompromised patients.

ETIOLOGY

The etiology of GI infections and enterotoxigenic poisonings includes a wide variety of viruses, bacteria, and parasites, although the specific incidence of each is difficult to quantify. Etiologic agents are rarely identified due to the infrequent collection of stool samples, or inability of many laboratories to detect the full range of pathogenic organisms. In this chapter, discussions of pathogens responsible for enterotoxigenic diarrhea focus on viral pathogens (rotavirus and norovirus), enterotoxigenic *Escherichia coli* (ETEC), and cholera. Common pathogens associated with dysenteric diarrhea discussed will be *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., enterohemorrhagic *E. coli* (EHEC), *Yersinia enterocolitica*, and *Clostridium difficile*. Characteristics of watery and dysenteric diarrhea and common pathogens responsible for them are outlined in **Table 113-1**.

TABLE 113-1 Acute Infectious Diarrhea Clinical Syndromes: Watery versus Dysentery

	Watery	Dysentery
Percentage of patients	90-95	5-10
Stools		
Appearance	Watery	Bloody
Volume	Increased: ++/+++	Increased: +/++
Number per day	<10	>10
Reducing substances	0 to +++	0
pH	5-7.5	6-7.5
Occult blood	Negative	Positive
Fecal polymorpho-nuclear cells	Absent or few	Many
Mechanisms	Toxins	Toxins
	Reduced absorption	Mucosal invasion
Complications		
Dehydration	Could be severe	Mild
Others	Acidosis, shock, electrolyte imbalance	Tenesmus, rectal prolapse, seizures
Etiology	*Vibrio cholerae*	*Shigella* spp.

	Watery	Dysentery
	Enterotoxigenic *Escherichia coli* (ETEC)	*Salmonella* spp.
	Rotaviruses	*Campylobacter* spp.
	Noroviruses	*Yersinia* spp.
		Enterohemorrhagic *E. coli* (EHEC)
		Clostridium difficile

Viruses are now recognized as the leading global cause of infectious diarrhea. Noroviruses, previously known as Norwalk-like viruses, account for greater than 90% of viral gastroenteritis among all age groups, and 50% of outbreaks worldwide. In the United States, noroviruses have been estimated to cause 21 million cases of acute gastroenteritis annually including more than 70,000 hospitalizations and nearly 800 deaths.[5,6] Outbreaks occur throughout the year and have been documented in families, healthcare systems, cruise ships, and college dormitories.

In infants and children, rotavirus, a double-stranded, wheel-shaped, RNA virus, is the most common cause of infectious diarrhea globally, and 1 million people die annually from the infection.[7] In the United States, approximately 3.5 million cases of diarrhea, 500,000 physician visits, 50,000 hospitalizations, and 20 deaths occur each year in children younger than 5 years.[7] Rotavirus is a ubiquitous contagion, infecting the vast majority of children younger than 5 years. After the initial infection, 40% of children are protected against subsequent rotavirus infection, 75% are protected against subsequent gastroenteritis, and up to 88% are protected against severe gastroenteritis. Other viral etiologies include astrovirus, enteric adenovirus, pestivirus, coronavirus, and enterovirus. These viruses are increasingly identified as causative etiologies of diarrhea. Characteristics of viral pathogens causing gastroenteritis are outlined in **Table 113-2**.

TABLE 113-2 Characteristics of Agents Responsible for Acute Viral Gastroenteritis

Virus	Peak Age of Onset	Time of Year	Duration	Mode of Transmission	Common Symptoms
Rotavirus	6 months to 2 years	October to April	3-7 days	Fecal–oral, water, food	Nausea, vomiting, diarrhea, fever, abdominal pain, lactose intolerance
Norovirus	All age groups	Peak in winter	2-3 days	Fecal–oral, food, water, environment	Nausea, vomiting, diarrhea, abdominal cramps, myalgia
Astrovirus	<7 years	Winter	1-4 days	Fecal–oral, water, shellfish	Diarrhea, headache, malaise, nausea
Enteric adenovirus	<2 years	Year-round	7-9 days	Fecal–oral	Diarrhea, respiratory symptoms, vomiting, fever
Pestivirus	<2 years	NR	3 days	NR	Mild

Virus	Peak Age of Onset	Time of Year	Duration	Mode of Transmission	Common Symptoms
Coronavirus-like particles	<2 years	Fall and early winter	7 days	NR	Respiratory disease
Enterovirus	NR	NR	NR	NR	Mild diarrhea, secondary organ damage

NR, not reported.

2 In the United States, bacterial causes of acute gastroenteritis account for more than 5.2 million cases of diarrhea annually, including 46,000 hospitalizations and 1,500 deaths.[4] However, there appears to be substantial underreporting of disease, and the cause is identified in less than 3% of cases. Common pathogens responsible for watery diarrhea in the United States are norovirus and ETEC, while those most commonly associated with dysentery diarrhea are *Campylobacter* spp., EHEC, *Salmonella* spp., and *Shigella* spp. Other organisms that are responsible for dysentery include *Aeromonas* spp., noncholera *Vibrio*, and *Y. enterocolitica*. Characteristics of acute bacterial pathogens causing gastroenteritis are summarized in **Table 113-3**.

TABLE 113-3 Characteristics of Acute Bacterial Gastroenteritis

Bacteria	Incubation Period	Duration	Mode of Transmission	Common Symptoms
Watery Diarrhea				
Vibrio cholerae	2-3 days	1-3 days	Contaminated food or water with human feces usually in areas of inadequate treatment of sewage and drinking water	Profuse watery diarrhea, vomiting, and leg cramps Death can occur within hours without treatment
Enteroaggregative *E. coli*	NR	NR	Contaminated food or water with animal or human feces	Chronic, watery, mucoid, secretory diarrhea with low-grade fever in immunocompromised persons (HIV infections)
Enteroinvasive *E. coli*	10-18 hours	NR	Contaminated food or water with animal or human feces	Watery diarrhea in young children in the developing world
Enteropathogenic *E. coli*	9-12 hours	NR	Contaminated food or water with animal or human feces	Acute onset of profuse watery diarrhea, vomiting, and low-grade fever in young children (<2 years of age) in the developing world

Bacteria	Incubation Period	Duration	Mode of Transmission	Common Symptoms
Enterotoxigenic *E. coli*	1-3 days	3-4 days	Contaminated food or water with animal or human feces	Watery diarrhea and abdominal cramping
Dysentery Diarrhea				
Campylobacter jejuni	2-5 days	5-7 days	Contaminated food (particularly poultry), water, or contact with infected animals	Diarrhea (often bloody), cramping, abdominal pain, and fever
Enterohemorrhagic *E. coli*	3-4 days	5-7 days	Contaminated food (particularly cattle) or water with animal or human feces	Severe stomach cramps, diarrhea (often bloody), and vomiting Approximately 5-10% develop hemolytic uremic syndrome
Nontyphoid *Salmonella*	12-36 hours	1-5 days	Contaminated food, water, or contact with infected animals	Diarrhea (sometimes bloody), fever, and abdominal cramps
Shigella	1-3 days	1-7 days	Fecal–oral Contaminated food or water with infected human feces	Watery or bloody diarrhea (8-10 stools/day), severe abdominal pain, fever, and malaise
Yersinia	4-7 days	1-3 weeks	Contaminated food or water	Fever, abdominal pain, and diarrhea (often bloody)

NR, not reported.

Cholera has been rare in the United States because of advanced water and sanitation systems; although slight increases in its incidence have occurred in recent years without clear causes.[8] It is endemic on the Indian subcontinent and sub-Saharan Africa. *Vibrio cholerae* is a gram-negative bacillus sharing similar characteristics with the family Enterobacteriaceae. Cholera is caused by toxigenic *V. cholerae* serogroups O1 or O139. Infections due to *V. cholerae* result in severe and voluminous diarrhea that can quickly result in dehydration. Approximately half of those persons infected with *V. cholerae* O1 are symptomatic, whereas only 1% to 5% of those infected with *V. cholerae* O139 manifest symptoms.[9]

E. coli is a gram-negative bacillus commonly found in the human GI tract, and *E. coli*-associated diarrhea may be differentiated into several distinct categories based on pathogenic features of diarrheal disease: enteroaggregative *E. coli* (EAEC), EHEC, enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), and ETEC. ETEC occurs most commonly, and accounts for about half

of all cases of *E. coli* diarrhea. There are an estimated 79,000 cases of ETEC in the United States each year.[4] ETEC is also the most common cause of traveler's diarrhea and a common cause of food- and water-associated outbreaks. Infections with EIEC and EPEC are primarily a disease of children in developing countries.[10] EAEC strains are implicated in persistent diarrhea (≥14 days) in human immunodeficiency virus (HIV)-infected patients.[11] EHEC, also known as Shiga toxin–producing *E. coli* (STEC), causes watery diarrhea that becomes bloody in 1 to 5 days in 80% of patients.[10]

EHEC is believed to be the major etiologic factor responsible for the development of hemorrhagic colitis and hemolytic uremic syndrome (HUS). The annual disease burden of STEC in the United States is more than 20,000 infections and as many as 250 deaths; however, the failure of many clinical laboratories to screen for this organism greatly complicates any estimates.[12] In the United States, STEC causes 50% to 60% of all EHEC infections, but in the southern hemisphere, including Argentina, Australia, Chile, and South Africa, non-STEC serotypes are often more prevalent. Non-STEC strains generally produce a lower frequency of dysentery than STEC-positive strains (62% vs 85%).

The *Campylobacter* spp., are flagellated, curved, gram-negative rods. Although there are 14 different species, *Campylobacter jejuni* is the species responsible for more than 99% of *Campylobacter*-associated gastroenteritis. Approximately 2.4 million persons are affected each year in the United States, involving almost 1% of the entire population.[4]

Salmonella enterica is a gram-negative bacilli belonging to the family Enterobacteriaceae. The most prevalent *S enterica* serotypes are Typhi and Paratyphi, which cause enteric fever. Gastroenteritis is caused by *S enterica* serotypes Typhimurium or Enteritidis. In the United States, the largest burden of *Salmonella* infection is due to nontyphoidal serotypes, causing approximately 1.4 million cases of salmonellosis, 16,000 hospitalizations, and 600 deaths, occurring annually.[13]

Approximately 165 million cases of shigellosis occur worldwide with 450,000 cases from the United States annually.[14] *Shigella* spp., are gram-negative bacilli belonging to the family Enterobacteriaceae. Four species most often associated with disease are *Shigella dysenteriae* type 1, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*.[14] *Shigella sonnei* and *S. flexneri* are the most common causes of gastroenteritis in the United States. The other two *Shigella* spp., are more commonly acquired during travel to developing countries. Poor sanitation or personal hygiene, inadequate water supply, malnutrition, and increased population density are associated with an increased risk of *Shigella* gastroenteritis epidemics.

Yersinia spp., are non–lactose-fermenting gram-negative coccobacilli that are widely distributed in nature. The genus *Yersinia* includes six species known to cause disease in humans. *Yersinia enterocolitica* and, to a lesser extent, *Y. pseudotuberculosis* are most likely associated with intestinal infection, but overall both are a relatively infrequent cause of diarrhea and abdominal pain. More than 50 serotypes of *Y. enterocolitica* exist; of these, serotypes 0:3, 0:8, and 0:9 are associated most frequently with enterocolitis.[15] Children are most likely to experience illness with *Y. enterocolitica* infection.

PATHOPHYSIOLOGY

Acute gastroenteritis and its resulting diarrhea are caused by altered movement of ions and water resulting in increased colonic secretion. Under normal conditions, the GI tract has tremendous capacity to absorb fluid and electrolytes, allowing only 100 to 200 mL of fluid to be excreted in the stool daily.[16] The classic enteric pathogen that causes secretary diarrhea is *V. cholerae*, but ETEC and rotavirus also cause watery diarrhea and are much more predominant etiologies in the United States.

V. cholerae is an enteric pathogen that causes classical secretory diarrhea due to changes in ion secretion and absorption. Among the toxins produced by *V. cholerae*, the most important is cholera toxin.[9] Cholera toxin consists of two subunits, A and B. The B subunits are responsible for delivery of the A subunit into the cell. The A subunit stimulates adenylate cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and results in protein kinase A-mediated activation of cystic fibrosis transmembrane conductance regulator. This leads to increased chloride secretion and decreased sodium absorption producing the severe watery diarrhea characteristic of the disease.[17] The toxin likely acts along the entire intestinal tract, but most fluid loss occurs in the duodenum. The net effect of the cholera toxin is isotonic fluid secretion early in the intestinal tract that exceeds the absorptive capacity of the latter intestinal tract.

ETEC also causes watery diarrhea characterized by severe intestinal water secretion by producing plasmid-mediated enterotoxins: heat-labile toxin and heat-stable toxin. The heat-labile toxin has two subunits (A and B) that have similar antigenic properties and action on the gut mucosa as cholera toxin. Heat-labile toxins increase chloride secretion via activation of cAMP. The net effect is luminal accumulation of electrolytes that draws water into the intestine, and production of a cholera-like secretory diarrhea.[18] Heat-stable toxin is thought to be non-antigenic and produces watery diarrhea by acting on the small intestine.

Rotavirus induces changes in transepithelial fluid balance, and causes malabsorption as a consequence of destruction of the epithelial lining of intestine, and vascular damage and ischemia in villi. Once rotavirus infects small intestinal villus cells, viroplasms are formed and its toxin, nonstructural protein 4, is released. The viral enterotoxin increases intracellular calcium, and the increase in calcium disrupts microvillus cytoskeleton, as well as barrier function. Changes to the villi include shortening of villus height, crypt hyperplasia, and mononuclear cell infiltration of the lamina propria.[19]

Inflammatory diarrhea is caused by two groups of organisms—enterotoxin-producing, noninvasive bacteria (eg, EAEC, EHEC) or invasive organisms (eg, *Campylobacter* spp., *Salmonella* spp., *Shigella* spp.). The enterotoxin-producing organisms adhere to the mucosa, activate cytokines, and stimulate the intestinal mucosa to release inflammatory mediators. Invasive organisms, which can also produce enterotoxin, invade the intestinal mucosa to induce an acute inflammatory reaction, involving the activation of local and systemic cytokines and inflammatory mediators.

Ingestion of as few as 10 to 200 viable organisms of the *Shigella* spp., causes disease in healthy adults.[14] *Shigella* multiply and spread within the submucosa of the small bowel, but they rarely extend beyond the mucosa. Inflammatory diarrhea is caused by the pathogens invading the epithelial barrier through M cells where they encounter and eliminate macrophages. The destruction of

macrophages after emergence from M cells causes an initial release of interleukin (IL)-1β. This initial inflammatory process is exacerbated by free bacteria binding to toll-like receptor that causes the production of IL-6 and IL-8. Both IL-1β and IL-8 attract polymorphonucleocytes.[20] Release of polymorphonucleocytes activates chloride secretion and subsequent diarrhea. Degranulation and release of toxic substances by neutrophils cause ulceration of the epithelium, distortion of the crypts, death to intestinal epithelium, sloughing of mucosal cells, bloody mucoid exudate into the gut lumen, and submucosal accumulation of inflammatory cells with microabscess formation.[21] Microabscesses eventually may coalesce, forming larger abscesses. *Shigella* will frequently affect the entire colon. In addition to the virulence characteristics of invasiveness, *S. dysenteriae* type 1 and, to a lesser degree, *S. flexneri* and *S. sonnei* produce a cytotoxin or Shiga toxin, which can lead to HUS.[10]

The pathogenicity of EHEC is related to the production of Shiga-like toxins, so named because of their resemblance to the Shiga toxin of *S. dysenteriae*.[16] The cytotoxic effect of Shiga-like toxins disrupts the mucosal integrity of the large intestine, causing diarrhea. In addition, the toxin is able to pass through the intestinal epithelium to reach the endothelial cells lining small blood vessels that supply the gut, kidney, and other viscera, causing the myriad metabolic events that could eventually lead to HUS.

CLINICAL PRESENTATION

Gastroenteritis is an illness characterized by diarrhea, which may be accompanied by nausea, vomiting, fever, and abdominal pain. For effective diagnosis and management, it is important to distinguish noninflammatory diarrhea that produces watery diarrhea from inflammatory diarrhea or dysentery. Most enteric pathogens produce acute diarrhea and pathogens associated with dysentery will often result in grossly bloody stools and mucus. Systemic symptoms of gastroenteritis, such as fever, are often associated with dysentery of infectious origin. Symptoms of enteric pathogens that cause watery and dysentery diarrhea are listed in Table 113-1.

A physical examination and careful history that includes information about symptoms and symptom duration, the number of individuals affected, and recent history of travel, diet, and medications are important factors in making a diagnosis. Infections with norovirus or ETEC will often result in mild, self-limiting disease, whereas cholera will commonly produce severe dehydrating diarrhea. Infections with enteric pathogens such as *Campylobacter* spp., EHEC, *Salmonella* spp., *Shigella* spp., and *Y. enterocolitica* can result in severe symptomatology due to dysentery. The utilization of serum C-reactive protein (CRP) in young adult patients with infectious diarrhea may be able to help differentiate between noninflammatory and inflammatory causes.[22] Assessing CRP could assist with diagnosis, prognosis, and treatment selection. The clinical presentation of acute viral and bacterial gastroenteritis is summarized in Tables 113-2 and 113-3, respectively.

3 Stool culture is an important tool in making an organism-specific diagnosis and determining susceptibility to antimicrobial agents. Due to the low yield, stool cultures are not recommended in most mild to moderate watery diarrhea. Instead, indications for stool cultures include dysenteric diarrhea, persistent diarrhea in immunocompromised patients (ie, persons aged 65 years and older

with comorbid diseases, neutropenia, or HIV infection), and diarrhea where an outbreak is suggested.[1] An appropriately-obtained stool culture identifies the presence of *Campylobacter*, *Salmonella*, and *Shigella* spp. The yield of stool cultures for other pathogens is increased if the test is ordered specifically based on history and physical examination. For dysenteric diarrhea, the laboratory should be instructed to evaluate for EHEC including STEC (*E. coli* O157:H7). In hospitalized patients who develop diarrhea 3 days after hospitalization or in those with recent exposure to antimicrobials or chemotherapy, stool specimen should be sent for *C. difficile* toxins A and B. In addition to stool cultures, microscopic examination for fecal polymorphonuclear cells, or a simple immunoassay for the neutrophil marker lactoferrin, can further provide evidence of an inflammatory process and increase the yield of cultures in patients presenting with dysenteric diarrhea.[1]

Complications

Complications associated with acute diarrhea most likely result from dehydration so treatment focuses primarily on rehydration therapy, regardless the etiology. Dysenteric diarrhea is more likely to have severe complications, especially in children younger than 5 years and in elderly. Bacteremia is the most common complication of gastroenteritis and can be seen after infections with nontyphoid *Salmonella*, *C. jejuni* or *C. fetus*, and *Y. enterocolitica*.[12] Nontyphoid *Salmonella* is most common in children younger than 5 years, elderly, and patients with hemoglobinopathy, malaria, or immunosuppression. Bacteremia due to *Campylobacter* spp., has been reported in patients with HIV infection, malignancy, transplantation, and hypogammaglobulinemia. *Y. enterocolitica* bacteremia has been rarely reported, but has an increased prevalence in patients with diabetes mellitus, severe anemia, hemochromatosis, iron overload (frequent transfusion), cirrhosis, malignancy, and in the elderly.[23] Persistent bacteremia with these pathogens will commonly result in prolonged intermittent fever with chills. Potentially complicating the diagnosis, stool cultures frequently are negative and leukocyte counts are often within the normal range. Vascular complications such as seeding of atherosclerotic plaques or aneurysms in arterial vessels occur in 10% to 25% of adults with bacteremia. Localized infections involving bone, cysts, heart, kidney, liver, lungs, pericardium, and spleen develop in 5% to 10% of patients with bacteremia.

A severe complication in patients infected with EHEC is HUS. HUS is defined by the triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia and is more commonly observed in children younger than 5 years and in the elderly.[24] Approximately 2% to 7% of cases infected with STEC strains are complicated by development of HUS, which increases mortality associated with this infection. *S. dysenteriae* type 1 can also cause HUS, although more rarely than observed with EHEC.[14]

Shigella infection may also lead to complications such as generalized seizures, sepsis, toxic megacolon, perforated colon, arthritis, and protein-losing enteropathy. Mortality is rare, but it may be more likely with *S. dysenteriae* type I. Less than 3% of persons who are infected with *S. flexneri* will later develop Reiter syndrome, characterized by pains in the joints, irritation of the eyes, and painful urination. This can lead to chronic arthritis.[25]

Infection with *C. jejuni* has been associated with Guillain-Barré syndrome (GBS), but the relationship is

not well understood.[26] The risk of developing GBS after *C. jejuni* infection appears to be low (approximately 1 case of GBS per 1,000 *C. jejuni* infections). The weakness associated with GBS usually starts in the legs, with difficulty in walking, and may progress to a complete paralysis of all extremities that lasts several weeks and usually requires intensive care.

Approximately 10% to 30% of adult patients develop a reactive arthritis 1 to 2 weeks after recovery from gastroenteritis secondary to *S. flexneri*, *Salmonella* spp., *C. jejuni*, and *Y. enterocolitica*. This arthritis, involving the knees, ankles, toes, fingers, and wrists, usually resolves in 1 to 4 months but may persist in approximately 10% of patients.[26] This complication is more common in persons with the HLA-B27 antigen.

A general complication that could occur long after an infectious gastroenteritis, especially with dysentery and toxin-mediated dysentery, is postinfectious irritable bowel syndrome (IBS). This is classified as IBS symptoms for at least 3 months following an episode of gastroenteritis or traveler's diarrhea showing recurrent abdominal pain or discomfort.[27] Albeit rare, some long-term complications associated with these infections strengthen the need for appropriate diagnosis and treatment.

TREATMENT

Mortality associated with infectious diarrhea has declined substantially in the past 2 decades, especially among children younger than 1 year. Preventative measures including improved sanitation, breast-feeding and weaning practices, and increased use of oral rehydration therapy (ORT) for affected individuals, are responsible for the decrease in case-fatality rates.

General Approach to Treatment

The cornerstone of management for all GI infections and enterotoxigenic poisonings is to prevent dehydration by correcting fluid and electrolyte imbalances. In mild, self-limiting acute gastroenteritis, a diet of oral fluids and easily digestible foods is recommended. In patients with severe dehydrating watery diarrhea and dysenteric diarrhea, IV rehydration therapy, antibiotics, and/or antimotility treatments are needed.

Rehydration Therapy

Initial assessment of fluid loss is essential for successful rehydration therapy and should include acute weight loss, as it is the most reliable means of determining the extent of water loss. However, if accurate baseline weight is not available, clinical signs are helpful in determining approximate deficits (**Table 113-4**). Physical assessment generally is more reliable in young children and infants than in adults.

TABLE 113-4 Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss[a]

Variable	Minimal or No Dehydration (<3%	Mild to Moderate (3%-9% Loss of Body	Severe (≥10% Loss of Body Weight)

	Loss of Body Weight)	Weight)	
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Weak, thready, or not palpable
Heart rate	Normal	Normal to increased	Increased (bradycardia in severe cases)
Breathing	Normal	Normal to fast	Deep
Mental status	Normal	Normal to listless	Apathetic, lethargic, or comatose
Eyes	Normal	Sunken orbits/decreased tears	Deeply sunken orbits/absent tears
Mouth and tongue	Moist	Dry	Parched
Thirst	Normal	Eager to drink	Drinks poorly; too lethargic to drink
Skin fold	Normal	Recoil in <2 seconds	Recoil in >2 seconds
Extremities	Warm, normal capillary refill	Cool, prolonged capillary refill	Cold, mottled, cyanotic, prolonged capillary refill
Urine output	Normal to decreased	Decreased	Minimal
Hydration therapy	None	ORS 50-100 mL/kg over 3-4 hours	Lactated Ringer's solution or normal saline 20 mL/kg over 15-30 minutes IV until mental status or perfusion improves Followed by 5% dextrose/0.45% sodium chloride IV at higher maintenance rates or ORS 100 mL/kg over 4 hours.
Replacement of ongoing losses	For each diarrheal stool or emesis <10 kg body weight: 60-120 mL ORS >10 kg body weight: 120-240 mL ORS	Same as minimal dehydration	If unable to tolerate ORS, administer through nasogastric tube or administer 5% dextrose/0.45% sodium chloride with 20 mEq/L (20 mmol/L) potassium chloride IV

ORS, oral rehydration solution.

[a]Percentages vary among authors for each dehydration category; hemodynamic and perfusion status is most important; when unsure of category, therapy for more severe category is recommended.

3 Fluid replacement is the cornerstone of therapy for dehydration due to diarrhea regardless of

etiology. For the treatment of mild to moderate dehydration, ORT is superior to administration of IV fluids. Oral replacement therapy reverses dehydration in nearly all patients with mild to moderate diarrhea with 94% to 97% efficacy.[1] It offers advantages of being inexpensive, noninvasive, and not requiring inpatient administration. Moreover, thirst drives use of ORT and provides a safeguard against overhydration. Replacement of ongoing losses as well as continuation of normal feeding should also be addressed.

The necessary components of oral rehydration solutions (ORS) include carbohydrates (typically glucose), sodium, potassium, chloride, and water. Using both salt and glucose in the ORS takes advantage of glucose-coupled sodium transport in the small bowel and enhances sodium and subsequently water transport across intestinal walls. In 2002, the World Health Organization/United Nations Children's Fund (WHO/UNICEF) endorsed a reduced osmolarity solution (osmolarity ≤250 mOsm/L) as the use of these solutions reduced stool volume, shortened duration of diarrhea, and decreased need for unscheduled IV therapy when compared with previously used ORS more than or equal to 310 mOsm/L.[28] The newer formulation of ORS less than or equal to 250 mOsm/L was, however, more likely to cause hyponatremia (blood sodium levels <130 mmol/L).[29] If commercial ORS are unavailable, one can be roughly duplicated by mixing ½ teaspoon of salt with 6 teaspoons of sugar in 1 L of water.[30]

In restoring fluid and electrolyte balance in cholera infections, polymer-based ORS may be more efficacious than glucose-based ORS. Polymer-based ORS contains rice, wheat, sorghum, or maize. This polymer-based ORS releases glucose more slowly after digestion, and when absorbed in the small bowel, enhances the reabsorption of water and electrolyte secreted into the bowel lumen during diarrhea. In a meta-analysis of 34 trials, polymer-based ORS has been shown to reduce the duration of diarrhea in adults with cholera when compared with glucose-based ORS more than or equal to 310 and less than or equal to 270 mOsm/L.[31]

Guidelines for rehydration therapy based on the degree of dehydration and replacement of ongoing losses are outlined in Table 113-4. ORS should be given in small and frequent volumes (5 mL every 2 to 3 minutes in a teaspoon or oral syringe). Nasogastric administration of ORS is an alternative method of administration in a child with persistent vomiting. For breast-fed infants, nursing should be continued. The composition of commercial ORS and commonly consumed beverages is listed in **Table 113-5**. Clear fluids, such as soft drinks, sweetened fruit drinks, chicken broth, and sports drinks, should be avoided in the treatment of dehydration. These hyperosmolar solutions may cause an osmotic diarrhea.

TABLE 113-5 Comparison of Common Solutions Used in Oral Rehydration and Maintenance

Product	Na (mEq/L)[b]	K (mEq/L)[b]	Base (mEq/L)	Carbohydrate (mmol/L)	Osmolarity (mOsm/L)
WHO/UNICEF (2002)	75	20	30	75	245
Pedialyte	45	20	30	140	250
Infalyte	50	25	30	70	200

Product	Na (mEq/L)[b]	K (mEq/L)[b]	Base (mEq/L)	Carbohydrate (mmol/L)	Osmolarity (mOsm/L)
Oralyte	60	20	0	90	260
Rehydralyte	75	20	30	140	250
Cola[a]	2	0	13	700	750
Apple juice[a]	5	32	0	690	730s
Chicken broth[a]	250	8	0	0	500
Sports beverage[a]	20	3	3	255	330

[a]These solutions should be avoided in dehydration.

[b]Concentration of monovalent ions expressed in mEq/L is numerically equivalent to mmol/L concentration.

In the treatment of severe dehydration, the primary goal of therapy is rapid restoration of fluid losses, correction of metabolic acidosis, and replacement of potassium deficiency. Severely dehydrated patients should be resuscitated initially with IV lactated Ringer solution or normal saline to restore hemodynamic stability. Lactated Ringer solution is preferred initially over normal saline because normal saline does not assist in correcting a metabolic acidosis. As GI and renal perfusion should be addressed aggressively, rapid IV administration is preferred over prolonged administration regimens for restoring extracellular fluids and electrolytes.[32] After rehydration, maintenance fluid is given based on accurate recording of intake and output volumes. ORT should be instituted as soon as it can be tolerated.

Early refeeding with age-appropriate unrestricted diet is recommended in children. A meta-analysis of 12 trials showed that early refeeding during or immediately following the start of rehydration did not increase the risk of complications such as unscheduled IV fluids, vomiting, or development of persistent diarrhea compared with late refeeding that ranged from 20 to 48 hours after start of rehydration.[32] Initially, easily digested foods such as bananas, applesauce, and cereal should be introduced and foods high in fiber, sodium, and sugar should be avoided. One caveat would be that lactase deficiency may be exacerbated among known lactase-deficient patients and may persist up to 10 days.

Antimicrobial Therapy

4 The indiscriminate use of antimicrobial therapy produces increases in antimicrobial resistance, side effects of antimicrobial agents, and the threat of superinfections owing to eradication of normal flora. Increasing fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella* spp. worldwide reinforces the importance of judicious use of antibiotics and prudent infection control measures.[33,34] Antibiotic therapy is recommended in severe cases of diarrhea, moderate-to-severe cases of traveler's diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea. Antimicrobial therapy is not recommended in EHEC diarrhea as it may increase HUS risk.

Antibiotic therapy is recommended in severe cases of cholera and ETEC diarrhea. In cases of cholera, antibiotics shorten the duration of diarrhea, decrease fluid loss, and shorten the duration of the carrier state.[9] It is important to consider local susceptibility patterns in the selection of the antimicrobial regimen. In areas of high fluoroquinolone resistance, azithromycin has been effective in patients with cholera. In patients with ETEC diarrhea, empiric antibiotics reduce severity and duration of diarrhea. A short course of therapy with fluoroquinolones is the most commonly recommended therapy due to increased resistance among other drug classes.[35] Rifaximin has been effective for ETEC for travel in Mexico.[36] Further discussions of antibiotic prophylaxis and treatment can be found in the section on traveler's diarrhea. **Table 113-6** summarizes antibiotic recommendations. Further details regarding treatment of *C. difficile*–associated diarrhea, traveler's diarrhea, and foodborne illnesses are discussed in respective sections.

TABLE 113-6 Recommendations for Antibiotic Therapy

Pathogen	Children	Adults
Watery Diarrhea		
Enterotoxigenic *Escherichia coli*	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Ciprofloxacin 750 mg orally once daily × 1-3 days. Alternatives: rifaximin 200 mg orally three times daily × 3 days; azithromycin 1,000 mg orally × 1 day *or* 500 mg orally daily × 3 days
Vibrio cholerae O1	Erythromycin 30 mg/kg/day divided every 8 hours orally × 3 days; azithromycin 10 mg/kg/day given orally once daily × 3 days	Doxycycline 300 mg orally × 1 day Alternatives: tetracycline 500 mg orally four times daily × 3 days; erythromycin 250 mg orally every 8 hours × 3 days; azithromycin 500 mg orally once daily × 3 days
Dysenteric Diarrhea		
Campylobacter species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3-5 days; erythromycin 30 mg/kg/day divided into two to four doses orally × 3-5 days	Azithromycin 500 mg orally once daily × 3 days; erythromycin 500 mg orally every 6 hours × 3 days
Salmonella Nontyphoidal[a]	Ceftriaxone 100 mg/kg/day divided IV every 12 hours × 7-10 days; azithromycin 20 mg/kg/day orally once daily × 7 days	Ciprofloxacin 750 mg orally once daily × 7-10 days; levofloxacin 500 mg orally once daily × 7-10 days Alternatives: azithromycin 500 mg orally once daily × 7 days For immunocompromised patients, duration should be increased to 14 days for both fluoroquinolones and azithromycin

Pathogen	Children	Adults
Shigella species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Ciprofloxacin 750 mg orally once daily × 3 days; levofloxacin 500 mg orally once daily × 3 days Alternatives: azithromycin 500 mg orally once daily × 3 days
Yersinia species[a]	Treat as shigellosis	Treat as shigellosis
***Clostridium difficile*-Associated Diarrhea**		
Clostridium difficile	Metronidazole 7.5 mg/kg (maximum: 500 mg) orally or IV every 8 hours × 10-14 days; vancomycin 10 mg/kg (maximum: 125 mg) orally every 6 hours × 10-14 days	Mild to moderate disease: metronidazole 500 mg orally or IV every 8 hours daily × 10-14 days Severe disease: vancomycin 125 mg orally every 6 hours × 10-14 days Alternatives: fidaxomicin 200 mg orally every 12 hours × 10-14 days
Traveler's Diarrhea		
Prophylaxis[a]		Norfloxacin 400 mg or ciprofloxacin 750 mg orally daily; rifaximin 200 mg one to three times daily up to 2 weeks
Treatment		Ciprofloxacin 750 mg orally × 1 day or 500 mg orally every 12 hours × 3 days; levofloxacin 1,000 mg orally × 1 day or 500 mg orally daily × 3 days; rifaximin 200 mg three times daily × 3 days; azithromycin 1,000 mg orally × 1 day or 500 mg orally daily × 3 days

[a]For high-risk patients only. See the preceding text for the high-risk patients in each infection.

Antibiotic therapy is indicated in at-risk and febrile patients with dysenteric diarrhea. In shigellosis, antibiotics shorten the period of fecal shedding and attenuate the clinical illness. Antibiotic therapy is reserved for the elderly, those who are immunocompromised, children in daycare centers, malnourished children, and healthcare workers. In the United States, *Shigella* spp., remain susceptible to fluoroquinolones. Fluoroquinolone resistance among *Shigella* spp., is of increasing concern in developing countries, and azithromycin may be a better choice in patients with a recent history of travel to a developing region.[14] Similar antibiotic regimens can be used for high-risk patients who develop *Yersinia* bacteremia (ie, infants younger than 3 months and patients with cirrhosis or iron overload) or in patients with bone and joint infections.[37] With Campylobacteriosis, antibiotics are not useful unless started within 4 days of the start of the illness because they do not shorten the duration or severity of diarrhea and only shorten the duration of bacterial excretion. Antibiotics are warranted in patients with high fevers, severe bloody diarrhea, prolonged illnesses (more than 1 week), pregnancy, and immunocompromised states, including HIV infection. Fluoroquinolone resistance

among *Campylobacter* spp., has increased, and is now 10% to 13% in the United States and 41% to 88% in Europe and Asia. Resistance may be the result of the use of fluoroquinolone antibiotics in poultry and other animal feed, and the frequent use of these agents internationally in treating enteric infections. Macrolides such as erythromycin and azithromycin are recommended especially in patients with a recent history of travel to Asia.[35]

Nontyphoid *Salmonella* infection leads to bacteremia in approximately 8% of otherwise healthy adults. However, patients with increased risk of bacteremia should be treated with antibiotics if appropriate diagnosis is made. High-risk patients include neonates or infants younger than 1 year, persons older than 50 years, and patients with primary or secondary immunodeficiency such as acquired immunodeficiency syndrome (AIDS) or chemotherapy-induced inflammatory bowel disease, sickle cell disease, vascular abnormalities (prostatic heart valve or abdominal aneurysm), or prosthetic joints.[14] If cultures are positive for Salmonellosis and antibacterial therapy is warranted, susceptibility testing should be done for appropriate targeted therapy due to concern of resistance.

Outcomes of some bacterial diarrheal illnesses may be worsened by the use of antibacterials, therefore precluding their use. In patients infected with EHEC, use of a fluoroquinolone or trimethoprim–sulfamethoxazole may increase the risk of HUS by increasing the production of Shiga-like toxin.[37] Empiric antimicrobial therapy should be withheld when clinical suspicion is high due to the high local prevalence EHEC, patient clinical presentation suggestive of EHEC infection, or a known foodborne outbreak of dysentery with an incubation period of longer than 2 days. Antibiotics should not be given to infants or children due to a higher incidence of HUS in this population. Treatment of EHEC infection is primarily limited to supportive care, which may include fluid replacement therapy, hemodialysis, hemofiltration, transfusion red blood cells and/or platelets, and other interventions as indicated clinically. Severe disease may lead to chronic kidney failure and potential need of renal transplantation.

Antimotility Agents

5 Antimotility drugs such as diphenoxylate/atropine and loperamide offer symptomatic relief in patients with watery diarrhea by reducing the number of stools. However, in both enterotoxigenic and dysenteric diarrhea, slowing of fecal transit time with these agents is thought to result in extended toxin-associated damage, worsening symptomatology and leads to complications. Therefore, antimotility drugs should be avoided if possible and are not recommended in patients with toxin-mediated dysenteric diarrhea (ie, EHEC, pseudomembranous colitis, shigellosis). However, some evidence suggests that in adults with dysenteric diarrhea these agents do not appear to be harmful if given concomitantly with antibacterial therapy.[37]

Clinical Controversy…

Diphenoxylate/atropine and loperamide slow gastric motility and can prolong exposure to enterotoxins in watery and toxin-mediated dysentery diarrheas. Caution is warranted with use of these agents in infectious diarrhea and further, these agents should not be administered to patients with dysenteric symptomatology.

Probiotics

Probiotics are preparations of microorganisms and most commercial products have been derived from food sources, particularly cultured milk products (ie, lactobacilli and bifidobacteria). When used in the treatment or prophylaxis of infectious diarrhea and antibiotic-associated diarrhea, efficacy is variable. Most individual studies have not shown significant benefit from the use of probiotics and meta-analyses have shown conflicting results, with one demonstrating efficacy when trials were assessed in aggregate[38] and another demonstrating no benefit.[39] No serious adverse effects have been reported in otherwise healthy persons, however, there are data suggesting a rare but increased incidence of fungemia or bacterial sepsis with probiotic use. With these potential adverse events and limited efficacy data, probiotics should not be recommended for prophylaxis or treatment of initial antibiotic-associated diarrhea.

Oral Zinc Supplementation

Zinc deficiency is largely due to inadequate dietary intake and is common in many developing countries where morbidity and mortality associated with acute diarrhea in children remains high. In children older than 6 months who demonstrate moderate signs of malnutrition, zinc supplementation may shorten the duration of diarrhea by approximately 27 hours (95% CI –14.62 to –39.34).[40] Therefore, oral zinc supplementation of 20 mg/day for 1 to 2 weeks may have an additional benefit over ORS alone in reducing childhood mortality in developing countries. Common side effects include metallic taste and vomiting. At high doses, zinc supplementation may cause epigastric pain, lethargy, and fatigue.

PREVENTION OF GASTROINTESTINAL INFECTIONS

6 Public health measures of improved water supply and sanitation facilities and the quality control of commercial products are important for the control of the majority of GI infections. In addition, following simple rules of personal hygiene and safe food preparation can prevent many diarrheal diseases. Hand washing with soap and running water is instrumental in preventing the spread of illness and should be emphasized for caregivers and persons with diarrheal illnesses. Safe food handling and preparation practices can significantly decrease the incidence of certain enteric infections.

Reporting suspected outbreaks and cases of notifiable illness to local health authorities is vital to investigation of threats of enteric infection arising from increasingly global and industrialized food supplies. The reporting of specific infectious diseases to the appropriate public health authorities is the cornerstone of public health surveillance, outbreak detection, and prevention and control efforts.

Vaccines are used to boost specific immune processes directed against the bacteria themselves or against adherence appendages, cytotoxins, or enterotoxins. Unfortunately, there are only a few vaccines available for prevention of gastroenteritis. Vaccines for typhoid fever are the parenteral Vi capsular polysaccharide vaccine (ViCPS) and the oral live-attenuated Ty21a vaccine.[41] Efficacy rates for both vaccines range from 50% to 80%. The ViCPS is indicated for children who are 2 years or

older a booster dose is administered 2 years later. The Ty21a vaccine is indicated for children 6 years or older; one capsule should be swallowed whole every other day for a total of four doses at least 1 week before the potential exposure. A booster should be taken every 5 years if continued protection is needed.

In the United States, routine rotavirus vaccination is recommended for all infants beginning at age 2 months. There are two vaccines, RotaTeq (RV5) and Rotarix (RV1), available for reducing rotaviral gastroenteritis.[42] The RV5 vaccine is a live, oral vaccine that offers 74% efficacy against gastroenteritis of any severity and 98% efficacy against severe disease. This vaccine also decreased office visits by 86%, emergency department visits by 94%, and hospitalizations by 96%. The RV1 vaccine is a live-attenuated human rotavirus vaccine. This vaccine has clinical efficacy of 79% against gastroenteritis of any severity and 96% efficacy against severe rotavirus disease. Rotarix reduced hospitalizations by 100% and medically attended visits by 92% in the first rotavirus season, and reduced hospitalizations by 96% through two seasons.[42] The RV5 vaccine is administered orally in a three-dose series at ages 2, 4, and 6 months while the RV1 vaccine is administered orally in a two-dose series at ages 2 and 4 months. The first dose may be given between 6 weeks and 14 weeks and 6 days of age and all doses should be given before 8 months of age. The vaccines are contraindicated in infants with severe allergic reactions to vaccine components, diagnosed with severe combined immunodeficiency, and with history of intussusception.[43]

Although not available in the United States, two oral vaccines against diarrheal pathogens are available in other countries. Dukoral consists of killed *V. cholerae* O1 organisms and the cholera B subunit, and is licensed in over 60 countries. Shanchol consists of killed whole cells from a mix of pathogenic strains of *V. cholerae* (O1 and O139) and is licensed in India.[9] Both vaccines are given in two doses (three doses of Dukoral are required for children aged 2-5 years) and administered about 7 to 14 days apart (up to 42 days apart for Dukoral). Dukoral must be administered with a buffer that requires 75 to 150 mL of clean water while Shanchol does not require the buffer. Both vaccines demonstrated protective efficacy of 47% to 87% after two doses but almost none after a single dose. Protection is achieved in approximately 1 week following the last dose and persists for approximately 2 years. The common side effects of the vaccines were considered mild and included abdominal pain, headache, fever, and nausea. The WHO does not require vaccination for international travel to or from endemic areas because vaccines require two doses and provide incomplete protection for a relatively short period of time.

There are vaccines in development for common enteric pathogens including ETEC and *Shigella* spp., with the potential for combining them in a single vaccine. These are still in preliminary and animal-based studies, but could significantly affect global public health if they come to fruition for human administration, especially in the infants and children.[44]

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate follow-up care of patients with acute diarrhea is based on successful restoration of fluid losses. The clinical signs and symptoms that lead to the diagnosis also can assess adequate rehydration, and should be monitored frequently. With ORT preferred, routine laboratory testing

often is unnecessary. Electrolytes should be measured in those receiving IV fluids, when oral replacement fails, or when signs of hypernatremia or hypokalemia are present. Follow-up stool samples to ensure complete evacuation of the infecting pathogen may be necessary only in patients who are at high risk to initiate or contribute to a community outbreak. All patients should be monitored for complications associated with the infecting pathogen, resolution of the diarrhea, and adverse reactions to the pharmacologic agents used. Prompt discharge of hospitalized patients is recommended when rehydration is achieved, IV fluids have not been required, oral intake equals or exceeds losses, or adequate education and medical follow-up are ensured. For most patients, discharge can occur in 16 to 24 hours.

CLOSTRIDIUM DIFFICILE

Epidemiology

C. difficile is the most commonly recognized cause of infectious diarrhea in healthcare settings with high rates of disease in long-term care facilities and in the elderly. CDI is associated with use of broad-spectrum antimicrobials and accounts for approximately 20% to 30% of all cases of antibiotic-associated diarrhea.[45] The antibiotics most commonly associated with CDI include clindamycin, ampicillin, cephalosporins, and fluoroquinolones. Other agents that have been implicated, albeit at a lower incidence rate, include aminoglycosides, macrolides, trimethoprim-sulfamethoxazole, vancomycin, and metronidazole. CDI often occurs during or shortly after completion of antimicrobial therapy, however, disease onset can be delayed for 2 or more months.[46] Those at high risk for CDI include the elderly or debilitated, patients undergoing surgery or nasogastric intubation, those with cancer, and those receiving antibiotics, proton pump inhibitors (PPIs), or frequent laxatives. A meta-analysis of 23 studies (~300,000 patients) suggests that PPIs increase the incidence of CDI by 65%.[47,48]

Clinical Controversy…

Decreasing gastric acid has been suggested as the mechanism by which PPIs may allow for *C. difficile* toxins to proliferate. This relationship has been observed in both chronic PPI users, as well as inpatients on PPIs for stress ulcer prophylaxis. PPIs have been successful in reducing ICU-related upper GI hemorrhage; however, PPI use has been identified as an independent risk factor for CDI.

Attributable mortality from CDI has been steadily increasing over the past 2 decades and has been reported as high as 38%, with many studies demonstrating a mortality rate of 15% or greater.[49] Increased mortality is thought to be due to the emergence of a hypervirulent strain, North American pulsed-field type [NAP-1], which carries a gene mutation producing higher concentrations of toxin, and responsible for more serious disease.[50] The NAP-1 strain has been associated with fluoroquinolone use, and may be refractory to standard antibiotic therapy.

Pathogenesis

C. difficile is a gram-positive spore-forming anaerobic bacillus and causes a toxin-mediated disease.

Once antibiotics disrupt normal colonic flora and colonization of *C. difficile* occurs, two toxins (A and B) are released to mediate diarrhea and colitis. Toxin production is essential for disease manifestation. Toxin A is the major pathogenic factor and has been characterized as an enterotoxin that causes intestinal fluid secretion, mucosal injury, and inflammation through actin disaggregation, intracellular calcium release, and damage to neurons. Toxin B is a nonenterotoxic cytotoxin that causes depolymerization of filamentous actin and mediates more potent damage to human colonic mucosa than toxin A. Initially, raised white and yellowish plaques form in the colon, and the surrounding mucosa may be inflamed. With progression of disease, pseudomembranous plaques become enlarged and scatted over the colorectal mucosa.[46]

Clinical Presentation

Clinical diagnosis is based on the onset of diarrhea, defined as 3 unformed stools in 24 hours, during or after antimicrobial use, and often associated with abdominal discomfort, fever, and polymorphonuclear leukocytosis. The spectrum of disease ranges from mild diarrhea to life-threatening toxic megacolon and pseudomembranous entercolitis.[45,46] In colitis without pseudomembrane formation, patients present with malaise, abdominal pain, nausea, anorexia, watery diarrhea, low-grade fever, and leukocytosis. Fulminant disease is characterized by severe abdominal pain, perfuse diarrhea, high fever, marked leukocytosis, and classic pseudomembrane formation evident with sigmoidoscopic examination.

CDI should be suspected in patients experiencing diarrhea with a recent history of antibiotic use (within the previous 3 months) or in those whose diarrhea began 72 hours after hospitalization. Diagnosis can be established by detection of toxin A or B in the stool, stool culture for *C. difficile*, or endoscopy. The most common methods of laboratory diagnosis includes cytotoxin assay, enzyme-linked immunosorbent assay (ELISA), and molecular methods such as polymerase chain reaction (PCR) testing. The cytotoxin assay was the traditional gold standard, however, today its use is limited due to its long time to test completion (1-3 days) and high cost. ELISA tests are easy to perform and provide rapid results within hours, but have a low sensitivity leading to the possibility of false-negative results. PCR is quickly becoming the test of choice in the United States due to its high sensitivity and specificity coupled with a quick turnaround time of less than 2 hours.[50] Endoscopy should be reserved for situations where rapid diagnosis is needed, ileus is present, stool is not available, or other colonic diseases are in the differential diagnosis. Many hospitalized patients may be colonized with *C. difficile*, so a careful history should be taken and routine screening is not recommended.[45]

TREATMENT

Supportive care of CDI includes fluid and electrolyte replacement therapy, in addition to discontinuation of the offending antimicrobial if possible. Antibiotic therapy is based on disease severity and may vary for first episode or recurrent infection.[45,51] **Table 113-7** outlines CDI disease severity and treatment regimens for initial episodes.

TABLE 113-7 *Clostridium difficile* Infection Severity and Treatment[45,51]

Severity	Markers of Disease Severity	Recommended Treatment
Mild to moderate	WBC ≤15,000 cells/mm^3 (15×10^9/L) SCr <1.5 × premorbid level	Metronidazole 500 mg orally every 8 hours for 10-14 days
Severe	WBC >15,000 cells/mm^3 (15×10^9/L) SCr >1.5 × premorbid level Temperature >38.3°C Albumin <2.5 g/dL (25 g/L) Age ≥60 Pseudomembranes present ICU admission Hypotension or shock	Vancomycin 125 mg orally every 6 hours for 10-14 days
Severe, complicated	Ileus and/or megacolon Organ failure Coagulopathy	Metronidazole 500 mg IV every 8 hours *PLUS* vancomycin 500 mg every 6 hours via NG or orally (if ileus present use rectally)

NG, nasogastric; SCr, serum creatinine; WBC, white blood cell.

7 Once determination of disease severity has been made, treatment should be initiated with an antibiotic effective against *C. difficile*. In the United States, metronidazole, vancomycin, and fidaxomicin are the most commonly prescribed agents.[52] Treatment courses are typically 10 to 14 days and repeat stool testing is not recommended as a test of cure.[44] Metronidazole is the drug of choice for mild to moderate CDI because its oral formation is less expensive than vancomycin or fidaxomicin, and there are concerns for vancomycin resistant-enterococci with oral vancomycin use.[51] In patients with severe disease, contraindication or intolerance to metronidazole, and inadequate response to metronidazole, oral vancomycin or fidaxomicin is recommended. Vancomycin must be administered orally because IV vancomycin does not achieve adequate gut lumen concentrations for effective bacterial elimination. Due to cost, many institutions choose to use the injectable form of vancomycin to prepare an oral formulation. Fidaxomicin is a macrocyclic antibiotic (200 mg

administered orally twice daily) that has minimal bioavailability, and is bacteriostatic against *C. difficile*. Fidaxomicin was approved by the FDA after the current Infectious Diseases Society of America (IDSA)/Society for Healthcare Epidemiology of America (SHEA) guidelines were published; thus its place in therapy remains unclear. When vancomycin has been compared to fidaxomicin, the rate of initial cure was not significantly different between treatment groups; however, fidaxomicin demonstrated a significant improvement in recurrence.[53]

In patients with severe or complicated CDI, practice guidelines suggest combination therapy with IV metronidazole and vancomycin. The route of vancomycin administration is patient-dependent; oral is preferred, but if ileus is present, rectal administration via retention enema is suggested. This recommendation for combination therapy was based on expert opinion and has been supported by a small retrospective study of 88 patients, but further studies are suggested to define optimal regimens and dosing.[54]

Recurrence of CDI occurs in approximately 25% of cases within 30 days and the risk doubles after two or more recurrences.[55] Risk factors for recurrent CDI include a history of recurrence, emergency hospital admission, previous GI hospital admission, recent (within 4-12 weeks) hospitalization, increasing age, use of additional antimicrobials, and an inadequate protective immune response to *C. difficile* toxins.[56] Management of the first relapse is identical to a primary episode because relapse is rarely due to resistance to the initial agent of treatment. Instead, relapse occurs because treatment fails to eradicate the spore forms of the pathogen, or treatment leads to opportunistic infection. Fidaxomicin inhibits *C. difficile* spore production. Clinical trials have demonstrated fewer episodes of recurrence with fidaxomicin treatment compared to vancomycin.[54,57]

The optimal management of patients with multiple relapses is not clear. A prolonged tapered and pulse-dosing of oral vancomycin has been suggested for second episodes of relapse.[58] Other regimens that have shown efficacy include stepped therapy with vancomycin followed by rifaximin.[59] Alternative treatments effective against CDI include intravenous immunoglobulin (IVIG) and fecal microbiota transplantation (FMT). Individuals with low concentration of circulating IgG antitoxin are susceptible to more severe disease and frequent relapses. IVIG has been investigated in patients with intractable, recurrent CDI, and while case reports suggest promising results, high cost may preclude its use.[60] Initial methods of FMT involved preparing a small amount of fresh feces from a healthy donor suspended in saline, filtering the suspension and administering through a nasogastric tube or by retention enema. Data from case series show that FMT is efficacious; however, many practitioners are reluctant to offer this therapy to patients. Administering frozen, prepared capsules of FMT from healthy volunteers is safe and effective in treating CDI, resulting in a 90% resolution rate.[61] The FDA states that FMT should only be used in patients with recurrent CDI who have signed consents and if donor stool has been tested for transmittable diseases.

Agents in clinical trials for treatment or prevention of CDI include new antibiotics, monoclonal antibodies, and *C. difficile* toxoid vaccines.[55] Rifampin, bacitracin, and fusidic acid have lost favor in the treatment of CDI. Concerns with these regimens include drug interactions, development of resistance, and a potential increase in mortality with rifampin observed in several studies.[52] Anion exchange resins such as cholestyramine and colestipol have been used to treat CDI; however, they

bind vancomycin and are no longer recommended. Drugs that inhibit peristalsis, such as diphenoxylate/atropine and loperamide, are contraindicated in CDI.[46] Slowing of fecal transit time is thought to result in extended toxin-associated damage.

Prevention of CDI involves both preventing the acquisition of the infection and stopping transmission of *C. difficile* and its spores to other patients. CDI has become the focus of antimicrobial stewardship efforts aimed at eliminating unnecessary antibiotics and reducing durations of therapy. The use of probiotics to prevent CDI has been studied in adults and children. While some studies and meta-analyses have shown no benefit, some evidence supports probiotic safety and efficacy in preventing CDI.[55] Hand washing and contact precautions are imperative measures in preventing the spread of the organism. Alcohol-based hand gels are ineffective against *C. difficile* spores; use of soap and water is recommended to prevent disease transmission. Proper environmental disinfecting measures in healthcare settings include use of chloride-containing cleaning agents or other sporicidial agents.[45]

TRAVELER'S DIARRHEA

Traveler's diarrhea describes the clinical syndrome manifested by malaise, anorexia, and abdominal cramps followed by the sudden onset of diarrhea that incapacitates many travelers. It interferes with planned activities or work in 30% of those affected. In particular, an increased risk lies with North Americans and Northern Europeans traveling to Latin America, southern Europe, Africa, and Asia. The highest risk is observed with patients with immunocompromised conditions, achlorhydria, inflammatory bowel disease, and people with chronic debilitating medical conditions. Overall, 20% to 50% of people traveling to high-risk areas will develop the illness.[35]

8 The onset of symptoms usually occurs during the first week of travel but can occur anytime during the visit or after returning home. Traveler's diarrhea is caused by contaminated food or water. The most common pathogens are bacterial and include ETEC (20%-72%), *Shigella* spp., (3%-25%), *Campylobacter* spp., (3%-17%), and *Salmonella* spp., (3%-7%).[8] Viral causes could occur in up to 30% of cases. Parasitic etiologies are rare during short-term travels, accounting for less than 5% of cases of traveler's diarrhea. Enterotoxigenic *E. coli* is predominantly pathogenic in Latin America, Africa, and South Asia. The invasive enteric pathogens (*Campylobacter* spp., *Salmonella* spp., and *Shigella* spp.) are more important causes of traveler's diarrhea in Asia.

The severity of the syndrome is determined by the number of stools per day and the presence of cramping, nausea, and vomiting. Mild diarrhea is defined as 1 to 3 loose stools per day that are associated with abdominal cramps lasting less than 14 days. Moderate diarrhea indicates more than 4 loose stools daily associated with dehydration, and severe diarrhea is defined as the presence of blood in stools or a fever. Traveler's diarrhea is rarely life-threatening and in most cases, symptoms resolve in several days without treatment. Travelers to high-risk areas should pack a kit that includes a thermometer, loperamide, antibiotics (3-day course) (see "Treatment" section below), ORS salts, and a water purification method.[35]

Prevention

9 Patient education in avoiding high-risk food and beverages should be the best method for minimizing the risk. High-risk foods and beverages include raw or undercooked meat and seafood, moist foods served at room temperature, fruits that cannot be peeled, vegetables, milk from a questionable source, hot sauces on the table, tap water, unsealed bottled water, iced drinks, and food from street vendors. Although education is readily available, a meta-analysis concluded that the incidence of diarrhea was similar in travelers who followed advice and those who engaged in riskier eating habits.[62] Rationales for this include that cooking foods does not always kill pathogens and food should not be considered safe unless it is cooked until steaming hot. Nonetheless, advisement of avoidance measures regarding safe foods, beverages, and eating establishments is recommended to heighten awareness.

Bismuth subsalicylate 524 mg (2 tablets or 2 tablespoonfuls) orally four times daily for up to 3 weeks is a commonly recommended prophylactic regimen.[35] Bismuth subsalicylate may inhibit enterotoxin activity and prevent diarrhea. Persons taking this regimen should be informed of adverse events, including temporary black discoloration of tongue and stools, and, rarely, tinnitus.

Although the efficacy of prophylactic antibiotics has been documented, their use is not recommended for most travelers due to the potential side effects of antibiotics (eg, photosensitivity), predisposition to other infections such as CDI or vaginal candidiasis, the increased risk of selection of drug-resistant organisms, cost, lack of data on the safety and efficacy of antibiotics given for more than 2 or 3 weeks, and availability of rapidly effective antibiotics for treatment. Prophylactic antibiotics are recommended only in high-risk individuals or in situations in which short-term illness could ruin the purpose of the trip, such as a military mission. A fluoroquinolone is the drug of choice when traveling to most areas of the world.[35] Due to fluoroquinolone resistance among *Campylobacter* spp., azithromycin can be considered when traveling to South and Southeast Asia.

Rifaximin is a nonabsorbed oral rifamycin that has activity against enteric pathogens and may have a role in the prevention of traveler's diarrhea in select populations. A randomized, double-blind trial of rifaximin 200 mg once, twice, or three times daily with meals for 2 weeks resulted in equal protection of 72% for each of the three dosing regimens compared with placebo.[36] Since rifaximin is effective against traveler's diarrhea due to noninvasive strains of *E. coli*, this agent should be reserved for travel regions where *E. coli* predominates, such as Latin America and Africa. Rifaximin has a tolerability and safety profile comparable to that of placebo. The concern with the class rifamycin is the emergence of resistance when used as monotherapy.

TREATMENT

The goals of treatment are to avoid dehydration, reduce the severity and duration of symptoms, and prevent interruption of planned activities. Fluid and electrolyte replacement should be initiated at the onset of diarrhea. ORT is generally not required in otherwise healthy individuals; flavored mineral water offers a good source of sodium and glucose. In infants and young children, elderly, and those with chronic debilitating medical conditions, ORT is recommended. For symptom relief, loperamide is preferred because of its quicker onset and longer duration of relief relative to bismuth. Standard

dosing of loperamide is 4 mg orally initially and then 2 mg with each subsequent loose stool to a maximum of 16 mg/day in patients without bloody diarrhea and fever. Loperamide should be discontinued if symptoms persist for more than 48 hours. Other symptomatic therapy in mild diarrhea includes bismuth subsalicylate 524 mg every 30 minutes for up to eight doses.[35] As previously discussed, there is insufficient evidence to warrant the recommendation of probiotics.

Since behavioral modification has limited efficacy and chemoprophylaxis is not recommended in most travelers, the current recommendation relies on self-treatment. A single dose of antibiotic and up to 3 days of treatment will improve the condition within 24 to 36 hours, shortening the duration of diarrhea by 1 to 2 days.[35] A single dose of fluoroquinolone is recommended initially and if diarrhea is improved within 12 to 24 hours, antibiotics should be discontinued. Otherwise, it can be continued for up to 3 days. A fluoroquinolone is recommended when traveling to most areas of the world. Where fluoroquinolone-resistant *Campylobacter* is common, such as in South and Southeast Asia, azithromycin should be used.[35] Azithromycin can also be used in pregnant women and children younger than age 16 years. Empiric treatment of young children should be instituted with caution.

Rifaximin was as effective as a 3-day course of ciprofloxacin in shortening the duration of diarrhea in noninvasive traveler's diarrhea. However, rifaximin was not as effective in patients with fever and bloody diarrhea and in those with invasive pathogens. Therefore, a 3-day course of rifaximin has been approved for the treatment of traveler's diarrhea caused by noninvasive strains of *E. coli* in people 12 years or older and can be considered when traveling to areas where *E. coli*–associated traveler's diarrhea is common, such as Mexico and Jamaica.[35]

For rapid improvement in symptoms, antibiotic therapy with adjunctive treatment with loperamide has shown benefit.[63] All clinical trials concluded that the combination therapy was safe, and the worsening of the disease with the use of antimotility treatment has not been encountered.

Clinical Controversy…

Prevention strategies are the most important measure for traveler's diarrhea. Although rifaximin is indicated for some traveler's diarrhea associated with ETEC, its cost and availability versus fluoroquinolones and macrolides may make it a nonpreferred choice.

FOOD POISONING

10 Foodborne illnesses result from the ingestion of food containing pathogenic microorganisms that cause GI infections or preformed toxins that were produced by microorganisms that cause enterotoxigenic poisonings. In the United States, foodborne diseases cause approximately 76 million illnesses, 325,000 hospitalizations, and 5,200 deaths each year.[4] Foodborne transmission may account for up to 80% of acute gastroenteritis. However, the incidence and outbreaks of foodborne illness has declined in recent years.[64] Common enteric pathogens responsible for foodborne diseases have been discussed in the previous sections (*Campylobacter* spp., *E. coli*, norovirus, nontyphoidal *Salmonella*, *Shigella*). Common foodborne pathogens that cause enterotoxigenic poisonings include *Bacillus cereus*, *Clostridium botulinum, Clostridium perfringens*, and *Staphylococcus aureus*. Characteristics of

pathogens responsible for foodborne illnesses are summarized in **Table 113-8**.

TABLE 113-8 Food Poisonings

Organism	Principal Foods	Peak Incidence (United States)	Time to Symptoms	Duration	Common Symptoms
Enterotoxigenic Poisonings					
Bacillus cereus	Fried rice, dairy products, spices, bean sprouts, vegetables	None	1-6 hours	1 day	Nausea, vomiting
			6-24 hours	1 day	Diarrhea
Clostridium botulinum	Home-canned fruits, vegetables, meats, honey	None	18-36 hours		Double vision, blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness
Clostridium perfringens (type A)	Meats, poultry, gravies, dried or precooked foods	Fall, winter, spring	8-12 hours	1 day	Abdominal cramps, diarrhea
Staphylococcus aureus	Salad, pastries, ham, sandwiches, puddings, unpasteurized milk, cheese products	Summer	1-6 hours	1 day	Nausea, vomiting, abdominal cramps, diarrhea
GI Infections					
Campylobacter spp.	Poultry, dairy products, clams, water	Spring, summer	2-5 days	7 days	Diarrhea (may be bloody), cramping, abdominal pain, fever
Enteropathogenic *E. coli*	Water	None	1-3 days	5-7 days	Severe diarrhea, vomiting, dehydration
Enterotoxigenic *E. coli*	Water, ice, food	None	1-3 days	3-4 days	Profuse watery diarrhea, abdominal cramping
Salmonella spp.	Beef, poultry, water, eggs, dairy products	Summer	12-72 hours	4-7 days	Diarrhea (sometimes bloody), fever, abdominal cramps
Shigella spp.	Salad, water	Summer	1-2 days	5-7 days	Diarrhea (often bloody), fever, abdominal cramps

Organism	Principal Foods	Peak Incidence (United States)	Time to Symptoms	Duration	Common Symptoms
Vibrio cholerae	Water	None	2 hours to 5 days	2-3 days	Profuse watery diarrhea, vomiting, leg cramps
Vibrio parahemolyticus	Shellfish (oysters)	Spring, summer, fall	24 hours	3 days	Watery diarrhea, abdominal cramping, nausea, vomiting, fever, chills
Yersinia enterocolitica	Dairy products, raw or undercooked pork products	None	4-7 days	1-3 weeks	Fever, abdominal pain, diarrhea (often bloody)

Because foodborne disease can appear as sporadic cases or outbreaks, the diagnosis should be suspected whenever two or more people present with acute GI or neurologic manifestations after sharing a meal within the previous 72 hours. Important clues about etiologic agents can be gathered from demographic information (age, gender, etc.), the clinical syndrome, incubation period, and medical history, type of foods consumed, seasonality, and geographic location of the outbreak.

Enterotoxigenic poisonings result from ingestion of food contaminated by preformed toxins. Therefore, symptoms are rapid in onset, but most cases of food poisoning are of short duration with recovery occurring within 1 to 2 days. *B. cereus* causes two different types of clinical syndromes. The first one is characterized by a short incubation period and vomiting. The second syndrome has a longer incubation period and is characterized by diarrhea. Foodborne *C. perfringens* infection may present as two distinct syndromes. Type A organisms are seen in Western Hemisphere nations and result in a 24-hour illness characterized by watery diarrhea and epigastric pain. Type C organisms can be found in undercooked pork and occur in underdeveloped tropical regions. They can produce a toxin-related syndrome called *enteritis necroticans*, which is a coagulative transmural necrosis of the intestinal wall.[65] This syndrome can result in intestinal perforation leading to sepsis and mortality in approximately 40% of victims.

Foodborne botulism results from the ingestion of food contaminated with preformed toxins or toxin-producing spores from *C. botulinum*. *C. botulinum* poisoning is rare; only 110 cases are reported per year in the United States.[65] Botulism is almost always associated with improper preparation or storage of food. Seven distinct toxins (A to G) have been described. The toxins prevent the release of acetylcholine at the peripheral cholinergic nerve terminal. Toxin activity has prompted the use of minute locally injected doses to treat select spastic disorders, such as blepharospasm, hemifacial spasm, and certain dystonias. Foodborne botulism is suspected when patients present with acute GI symptoms concurrently or just prior to the onset of a symmetric descending paralysis without sensory or central nervous system involvement. Diagnosis is made by culturing *C. botulinum* from the stool. The clinical presentation may resemble GBS associated with *C. jejuni* infection. The difference lies in the onset of neurologic symptoms, which typically occur 1 to 3 weeks after the onset of *C.*

jejuni infection, and the condition usually is manifested by an ascending paralysis in *C. jejuni*–associated GBS.

Treatment consists primarily of respiratory support and use of botulinum antitoxin.[66] If evaluation is performed within several hours of ingestion, gastric lavage or induction of vomiting is suggested. Cathartics and enemas also can be used to remove residual toxin from the bowel, but they are contraindicated in cases of ileus. Botulinum antitoxin is a concentrated preparation of equine globulins obtained from horses immunized with toxins A, B, and E. Because trivalent antitoxin is equine in origin, patients should be tested for hypersensitivity before receiving the product intravenously. Newer and more effective methods of treatment and prevention are under development, including a botulinum toxin vaccine consisting of nontoxic botulinum fragments. Prevention always should be stressed. Botulinum toxins are heat labile and readily destroyed by 10 minutes of boiling. All home-canned foods should be processed according to directions and boiled, not just warmed, prior to consumption.

In foodborne illnesses, the cornerstone of therapy remains supportive care. ORT is preferred in replenishing and maintaining fluid and electrolyte balance, and IV fluid therapy should be reserved for those who are severely ill and cannot tolerate oral therapy. Antiemetics and antimotility agents offer symptomatic relief, but the latter should not be given in patients who present with high fever, bloody diarrhea, or fecal leukocytes. Antimicrobial therapy is not effective in the management of *S. aureus*, *C. perfringens*, or *B. cereus* food poisonings. In developed countries, many of the foodborne illnesses can be prevented with proper food selection, preparation, and storage. However, in developing countries, sanitation and clean water supply are larger concerns.

Chapter 114: Intra-Abdominal Infections

Alan E. Gross; Keith M. Olsen; Joseph T. DiPiro

INTRODUCTION

KEY CONCEPTS

- 1 Most intra-abdominal infections are "secondary" infections that are polymicrobial and are caused by a defect in the gastrointestinal (GI) tract that must be treated by surgical drainage, resection, and/or repair.
- 2 Primary peritonitis is generally caused by a single organism (*Staphylococcus aureus* in patients undergoing chronic ambulatory peritoneal dialysis [CAPD] or *Escherichia coli* in patients with cirrhosis).
- 3 Secondary intra-abdominal infections are usually caused by a mixture of bacteria, including enteric Gram-negative bacilli and anaerobes, which enhance the pathogenic potential of the bacteria.
- 4 For peritonitis, early and aggressive IV fluid resuscitation and electrolyte replacement therapy are essential. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume and tissue perfusion.
- 5 Treatment is generally initiated on a "presumptive" or empirical basis and should be based on the likely pathogen(s) and local resistance patterns.
- 6 Antimicrobial regimens for secondary intra-abdominal infections should include coverage for enteric Gram-negative bacilli and anaerobes. Antimicrobials that may be used for the treatment of secondary intra-abdominal infections depending on severity of illness and microbiology data include (a) third-generation cephalosporin (ceftriaxone) with metronidazole, (b) piperacillin–tazobactam, (c) a carbapenem (imipenem, meropenem, doripenem, and ertapenem), and (d) quinolone (levofloxacin or ciprofloxacin) plus metronidazole or moxifloxacin alone.
- 7 Treatment of patients with peritoneal dialysis-associated peritonitis should include an

antistaphylococcal antimicrobial such as a first-generation cephalosporin (cefazolin) or vancomycin (intraperitoneal administration is preferred).

- 8 The duration of antimicrobial treatment should be for 4 days after source control for most secondary intra-abdominal infections.

- 9 Patients treated for intra-abdominal infections should be assessed for the occurrence of drug-related adverse effects, particularly hypersensitivity reactions (*β*-lactam antimicrobials), diarrhea (most agents), fungal infections (most agents), and nephrotoxicity (aminoglycosides).

Intra-abdominal infections are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. Intra-abdominal infections may be generalized or localized, complicated or uncomplicated, and community or healthcare-associated. Uncomplicated intra-abdominal infections are confined within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs while complicated intra-abdominal infections involve anatomical disruption, extend beyond a single organ, and yield peritonitis and/or abscess. *Peritonitis* is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign-body injury. This chapter deals only with peritonitis of infectious origin.

An *abscess* is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. These processes differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary.[1,2,3,4,5] Primary peritonitis, also called *spontaneous bacterial peritonitis*, is an infection of the peritoneal cavity without an evident source in the abdomen.[6] Bacteria may be transported from the bloodstream to the peritoneal cavity, where the inflammatory process begins. In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients and is infection that persists or recurs at least 48 hours after apparently adequate management of primary or secondary peritonitis.[7,8]

1 Primary peritonitis occurs in both children and adults, although the incidence and mortality rates in both populations have been declining.[4] Primary peritonitis develops in up to 10% to 30% of patients with alcoholic cirrhosis.[4,5,6,9,10] Patients undergoing chronic ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 20 to 33 months.[11,12] Epidemiologic data for secondary and tertiary intra-abdominal infections are less understood. Secondary peritonitis may be

caused by perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory bowel disease; cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract, such as septic abortion, postoperative uterine infection, endometritis, and salpingitis. Appendicitis is one of the most common causes of intra-abdominal infection. In 2010, 305,000 appendectomies were performed in the United States for suspected appendicitis.[13] Most healthcare-associated intra-abdominal infections occur as complications following intra-abdominal surgeries.

ETIOLOGY

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in its end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, or nephritic syndrome. It may also result from the use of a peritoneal catheter for dialysis or CNS ventriculoperitoneal shunting for hydrocephalus. Rarely, primary peritonitis occurs without apparent underlying disease.

Table 114-1 summarizes many of the potential causes of bacterial peritonitis. Causes include inflammatory processes of the GI tract or abdominal organs, bowel obstruction, vascular occlusions that may lead to gangrene of the intestines, and neoplasia that may cause intestinal perforation or obstruction. Other possible causes include those resulting from traumatic injuries, postoperative infections, or solid organ transplant in the abdomen.

TABLE 114-1 Causes of Bacterial Peritonitis

Primary (spontaneous) bacterial peritonitis
Peritoneal dialysis
Cirrhosis with ascites
Nephrotic syndrome
Secondary bacterial peritonitis
Miscellaneous causes
Diverticulitis
Appendicitis
Inflammatory bowel diseases
Salpingitis
Biliary tract infections
Necrotizing pancreatitis

Neoplasms

Intestinal obstruction

Perforation

Mechanical GI problems

Any cause of small bowel obstruction (adhesions, hernia)

Vascular causes

Mesenteric arterial or venous occlusion (atrial fibrillation)

Mesenteric ischemia without occlusion

Trauma

Blunt abdominal trauma with rupture of intestine

Penetrating abdominal trauma

Iatrogenic intestinal perforation (endoscopy)

Intraoperative events

Solid organ transplant in the abdomen

Peritoneal contamination during abdominal operation

Leakage from GI anastomosis

GI, gastrointestinal.

Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within one of the spaces of the peritoneal cavity or within one of the visceral organs, and may range from a few milliliters to a liter or more in volume. These collections often have a fibrinous capsule and may take from a few weeks to years to form.

The causes of intra-abdominal abscess overlap those of peritonitis and, in fact, may occur sequentially or simultaneously. Appendicitis is the most frequent cause of abscess. Other potential causes of intra-abdominal abscess include pancreatitis, diverticulitis, lesions of the biliary tract, genitourinary tract infections, perforation in the abdomen, trauma, and leaking intestinal anastomoses. In addition, pelvic inflammatory disease in women may lead to tuboovarian abscess. For some diseases, such as appendicitis and diverticulitis, abscesses occur more frequently than generalized peritonitis.

Microflora of the Gastrointestinal Tract and Female Genital Tract

A full appreciation of intra-abdominal infection requires an understanding of the normal microflora within the GI tract. There are striking differences in bacterial species and concentrations of flora within the various segments of the GI tract (**Table 114-2**), and this bacterial environment usually determines the severity of infectious processes in the abdomen. Generally, the low gastric pH eradicates bacteria that enter the stomach. With achlorhydria, bacterial counts may rise to 10^5 to 10^7 organisms/mL (10^8 to 10^{10}/L). The normally low bacterial count may also increase by 1,000-or 10,000-fold with gastric outlet obstruction, hemorrhage, gastric cancer, and in patients receiving histamine 2 (H_2)-receptor antagonists, proton pump inhibitors, or antacids.[14,15] A two to threefold increase in Spontaneous bacterial peritonitis has been demonstrated with the use of proton pump inhibitors.

TABLE 114-2 Usual Microflora of the GI Tract

Site	Commonly Found Bacteria	Approximate Concentration (No. Organisms/mL [$\times 10^3$/L])	
		Aerobes	Anaerobes
Stomach[a]	*Streptococcus, Lactobacillus*	10-100	Rare
Biliary tract	Normally sterile (*Escherichia coli, Klebsiella*, or enterococci in some patients)	0	0
Proximal small bowel	*Streptococcus* (including enterococci), *E. coli, Klebsiella, Lactobacillus*, diphtheroids	100	Few
Distal ileum	*E. coli, Klebsiella, Enterobacter*, enterococci, *Bacteroides fragilis, Clostridium*, peptostreptococci	10^4-10^6	10^5-10^7
Colon	*Bacteroides* spp., peptostreptococci, *Clostridium, E. coli, Klebsiella*, enterococci, *Enterobacter*, *Candida*, and many others	10^5-10^8	10^9-10^{11}

GI, gastrointestinal.

[a]With achlorhydria, acid suppressive therapy, gastric cancer, or gastric outlet obstruction, bacterial counts may rise to 10^5/mL (10^8/L).

The biliary tract (gallbladder and bile ducts) is sterile in most healthy individuals, but in people older than 70 years, those with acute cholecystitis, jaundice, or common bile duct stones, it is likely to be colonized by aerobic Gram-negative bacilli (particularly *Escherichia coli* and *Klebsiella* spp.) and enterococci.[16,17] Patients with biliary tract bacterial colonization are at greater risk of intra-abdominal infection.

In the distal ileum, bacterial counts of aerobes and anaerobes are quite high. In the colon, there may be 500 to 600 different types of bacteria in stool, with concentrations often reaching 10^{11} organisms/mL (10^{14}/L) and anaerobic bacteria outnumbering aerobic bacteria by more than 1,000 to 1.[2,18] In fact, up to 50% of the dry mass of stool is *Bacteroides* spp. Fortunately, most colonic bacteria are not pathogens because they cannot survive in environments outside the colon. Perforation of the

colon results in the release of large numbers of anaerobic and aerobic bacteria into the peritoneum.

The colonic flora are generally consistent unless broad-spectrum antimicrobials have been used. Depending on the type of antibiotic and spectrum, the duration of use, route of administration, and the pharmacokinetic and pharmacodynamic properties, antibiotics can cause shifts in the normal GI microflora including causing increased drug resistance.[19]

The lower female genital tract is generally colonized by a large number of aerobic and anaerobic bacteria. Anaerobes may number 10^9 organisms/mL (10^{12}/L) and often include lactobacilli, eubacteria, clostridia, anaerobic streptococci, and, less frequently, *Bacteroides fragilis*. Aerobic bacteria most often are streptococci and *Staphylococcus epidermidis*, and these may number 10^8 organisms/mL (10^{11}/L).

PATHOPHYSIOLOGY

Intra-abdominal infection results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intra-abdominal organs. In primary peritonitis, bacteria may enter the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis catheter, or via the fallopian tubes in females. Hematogenous bacterial spread (through the bloodstream) occurs more frequently with tuberculosis peritonitis or peritonitis associated with cirrhotic ascites. When peritonitis results from peritoneal dialysis, skin surface flora are introduced via the peritoneal catheter. In secondary peritonitis, bacteria most often enter the peritoneum or retroperitoneum as a result of perforation of the GI or female genital tracts caused by diseases or traumatic injuries. In addition, peritonitis or abscess may result from contamination of the peritoneum during a surgical procedure or following anastomotic leak.

The physiologic characteristics of the peritoneal cavity determine the nature of the response to infection or inflammation within it.[1,4] The peritoneum is lined by a highly permeable serous membrane with a surface area approximately that of skin. The peritoneal cavity is lubricated with less than 100 mL of sterile, clear yellow fluid, normally with fewer than 250 cells/mm^3 (0.25×10^9/L), a specific gravity below 1.016, and protein content below 3 g/dL (30 g/L). These conditions change drastically with peritoneal infection or inflammation, as described below.

After bacteria are introduced into the peritoneal cavity, there is an immediate response to contain the insult. Humoral and cellular defenses respond first; then the omentum adheres to the affected area. A limited bacterial inoculum is handled rapidly by defense mechanisms, including complement activation and a leukocyte response. Under certain conditions, the bacterial insult is not contained, and bacteria disseminate throughout the peritoneal cavity, resulting in peritonitis. This is more likely to occur in the presence of a foreign body, hematoma, dead tissue, a large bacterial inoculum, continuing bacterial contamination, and contamination involving a mixture of synergistic organisms. Protein–calorie malnutrition, antecedent steroid therapy, and diabetes mellitus may also contribute to the formation of an intra-abdominal abscess.

When bacteria become dispersed throughout the peritoneum, the inflammatory process involves

most of the peritoneal lining. There is an outpouring into the peritoneum of fluid containing leukocytes, fibrin, and other proteins that form exudates on the inflamed peritoneal surfaces and begin to form adhesions between peritoneal structures. This process, combined with a paralysis of the intestines (ileus), may result in confinement of the contamination to one or more locations within the peritoneum. Fluid also begins to collect in the bowel lumen and wall, and distension may result.

The fluid and protein shift into the abdomen (called *third-spacing*) may be so dramatic that circulating blood volume is decreased, which may cause decreased cardiac output and hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by sweating, tachycardia, and vasoconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock.[1,4,5] Other foreign substances present in the peritoneal cavity potentiate peritonitis. These adjuvants, notably feces, dead tissues, barium, mucus, bile, and blood, have detrimental effects on host defense mechanisms, particularly on bacterial phagocytosis.

Many of the manifestations of intra-abdominal infections, particularly peritonitis, result from cytokine activity. Inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), interleukin (IL) 1, IL-6, IL-8, and interferon γ (INF-γ), are produced by macrophages and neutrophils in response to bacteria and bacterial products or in response to tissue injury resulting from the surgical incision.[1,4] These cytokines produce wide-ranging effects on the vascular endothelium of organs, particularly the liver, lungs, kidneys, and heart. With uncontrolled activation of these mediators, sepsis may result (see Chapter 119 Sepsis and Septic Shock).[20,21,22]

Peritonitis may result in death because of the effects on major organ systems. Fluid shifts, cytokines and endotoxin may result in hypovolemia, hypoperfusion, and shock. Hypoalbuminemia may result from protein loss into the peritoneum exacerbating intravascular volume loss. Pulmonary function may be compromised by the inflamed peritoneum, producing splinting (muscle rigidity caused by pain) that inhibits adequate diaphragmatic movement leading to atelectasis and pneumonia. Increased lung vascular permeability and resulting shunting of blood may induce onset of the respiratory distress syndrome and associated hypoxemia and hypercarbia. With fluid loss and hypotension, renal and hepatic perfusion may be compromised, and acute renal and hepatic failure are potential threats.

If peritoneal contamination is localized but bacterial elimination is incomplete, an abscess results. This collection of necrotic tissue, bacteria, and white blood cells may be at single or multiple sites and may be within one of the spaces of the peritoneal cavity or in one of the visceral organs. The location of the abscess is often related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis.

An abscess begins by the combined action of inflammatory cells (such as neutrophils), bacteria, fibrin, and other inflammatory mediators. Bacteria may release heparinases that cause local thrombosis and tissue necrosis or fibrinolysins, collagenases, or other enzymes that allow extension of the process into surrounding tissues. Neutrophils gathered in the abscess cavity die in 3 to 5 days, releasing

lysosomal enzymes that liquefy the core of the abscess. A mature abscess may have a fibrinous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

Within the abscess, the oxygen tension is low and anaerobic bacteria thrive; thus, the size of the abscess may increase because it is hypertonic, resulting in an additional influx of fluid. Hypertonicity promotes the formation of bacterial L forms, which are resistant to antimicrobial agents that disrupt cell walls. Abscess formation may continue and mature for long periods of time and may not be readily evident to either patient or physician. In some instances, the abscess may resolve spontaneously, and, infrequently, it may erode into adjacent organs or rupture and cause diffuse peritonitis. If the abscess erodes through the skin, it may result in an enterocutaneous fistula, connecting bowel to skin, or in a draining sinus tract.

The overall outcome from an intra-abdominal infection depends on key factors: inoculum size, virulence of the contaminating organisms, the presence of adjuvants within the peritoneal cavity that facilitate infection, the adequacy of host defenses, source control, and the adequacy of initial treatment.[9,23,24]

Microbiology of Intra-Abdominal Infection

2 Primary bacterial peritonitis is often caused by a single organism. In children, the pathogen is usually group A *Streptococcus*, *E. coli*, *Streptococcus pneumoniae*, or *Bacteroides* species.[4,25,26,27,28] When peritonitis occurs in association with cirrhotic ascites, *E. coli* is isolated most frequently. Other potential pathogens are: *Haemophilus influenzae*, *Klebsiella* spp., *Pseudomonas* spp., anaerobes, and *S. pneumoniae*.[29] Occasionally, primary peritonitis may be caused by *Mycobacterium tuberculosis*. Peritonitis in patients undergoing peritoneal dialysis is caused most often by common skin organisms, such as coagulase-negative staphylococci, *Staphylococcus aureus*, streptococci, and enterococci. Gram-negative bacteria associated with peritoneal dialysis infections include *E. coli*, *Klebsiella* spp., and *Pseudomonas* spp.[6] The mortality rate from primary peritonitis caused by Gram-negative bacteria is much greater than that from Gram-positive bacteria.[4,5]

3 Because of the diverse bacteria present in the GI tract, secondary intra-abdominal infections are often polymicrobial.[2] The mean number of different bacterial species isolated from infected intra-abdominal sites ranged from 2.9 to 3.7, including an average of 1.3 to 1.6 aerobes and 1.7 to 2.1 anaerobes.[29,30] With proper anaerobic specimen collection, anaerobic organisms are isolated in most patients. In one report of patients with gangrenous and perforated appendicitis, an average of 10.2 different organisms was isolated from each patient, including 2.7 aerobes and 7.5 anaerobes.[31] Purely aerobic or anaerobic infections are uncommon, as are infections caused by fungi. **Table 114-3** gives the frequencies with which specific bacteria were isolated from patients with peritonitis and other intra-abdominal infections.[3,32] Nosocomial infections tend to have a more diverse array of pathogens, are more likely to involve *Pseudomonas* spp., and have a higher likelihood of multidrug-resistance compared with isolates from community-acquired infections.[33]

TABLE 114-3 Pathogens Isolated from Patients with Intra-Abdominal Infection

	Secondary Peritonitis[3,33] (%)	Community-Acquired Infection[33] (%)	Nosocomial Infection[33] (%)
Gram-Negative Bacteria			
Escherichia coli	32-61	29	22.5
Enterobacter	8-26	5.2	8.0
Klebsiella	6-26	2.8	4.5
Proteus	4-23	1.7	2.4
Pseudomonas	5-13	5	13
Gram-Positive Bacteria			
Enterococcus	18-24	10.6	18
Streptococcus	6-55	13.7	10
Staphylococcus	6-16	3.1	4.8
Anaerobic Bacteria			
Bacteroides	25-80	13.7	10.3
Clostridium	5-18	3.5	3.4
Fungi	2-5	3	4

Visceral organ abscesses differ in character from the typical intra-abdominal abscess. Hepatic abscesses may be polymicrobial (involving *E. coli*, *Klebsiella* spp., and anaerobes) or occasionally may be caused by amoeba.[18] Pancreatic abscesses are often polymicrobial, involving enteric bacteria that ascend through the biliary system. Splenic abscesses usually result from hematogenous dissemination of bacteria, such as *E. coli, S. aureus*, *Proteus mirabilis*, *Enterococcus* spp., and *Klebsiella pneumoniae*, as well as anaerobes.[18] Pelvic inflammatory disease is associated initially with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. However, tuboovarian abscesses are usually polymicrobial, having a mix of Gram-positive and Gram-negative aerobes and anaerobes.

Bacterial Synergism

The size of the bacterial inoculum and the number and types of bacterial species present in intra-abdominal infections influence patient outcome. The combination of aerobic and anaerobic organisms appears to greatly increase the severity of infection. In animal studies, combinations of aerobic and anaerobic bacteria were much more lethal than infections caused by aerobes or anaerobes alone.

Facultative bacteria may provide an environment conducive to the growth of anaerobic bacteria.[2] Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.[9] The role of facultative bacteria in mixed infections can include (a) promotion of an appropriate environment for anaerobic bacterial growth through oxygen consumption, (b) production of nutrients necessary for anaerobes, and (c) production of extracellular enzymes that promote tissue invasion by anaerobes.

Rat models of intra-abdominal infection demonstrate that uncontrolled infection with an implanted mix of aerobes and anaerobes leads to a two-stage (biphasic) infectious process. There is an early peritonitis phase with a high mortality rate and isolation of *E. coli* from blood and a late abscess formation phase in all survivors with isolation of anaerobes such as *B. fragilis* and *Fusobacterium varium*. These experiments and others support the concept that aerobic enteric organisms and anaerobes are pathogens in intra-abdominal infection. Aerobic bacteria, particularly *E. coli*, appear responsible for the early mortality from peritonitis, whereas anaerobic bacteria are major pathogens in abscesses, with *B. fragilis* predominating.[34]

Enterococcus can be isolated from many intra-abdominal infections in humans, but its role as a pathogen is not clear. Enterococcal infection occurs more commonly in postoperative peritonitis, in the presence of specific risk factors indicating failure of the host's defenses (immunocompromised patients), or with the use of broad-spectrum antibiotics.[35,36]

CLINICAL PRESENTATION

Intra-abdominal infections have a wide spectrum of clinical features often depending on the specific disease process, the location and magnitude of bacterial contamination, and concurrent host factors. Peritonitis is usually recognized easily, but intra-abdominal abscess may often continue for considerable periods of time, either going unrecognized or being attributed to an unrelated disease process. Patients with primary and secondary peritonitis present quite differently (**Table 114-4**).[1,4,5]

TABLE 114-4 Clinical Presentation of Peritonitis

Primary Peritonitis

General

The patient may not be in acute distress, particularly with peritoneal dialysis

Signs and symptoms

The patient may complain of loss of appetite, bloating, nausea, vomiting (sometimes with diarrhea), and abdominal tenderness

Temperature may be only mildly elevated or not elevated in patients undergoing peritoneal dialysis

Bowel sounds are hypoactive

The cirrhotic patient may have worsening encephalopathy

Cloudy dialysate fluid with peritoneal dialysis

Laboratory tests

The patient's WBC count may be only mildly elevated

Ascitic fluid usually contains greater than 250 leukocytes/mm^3 (0.25×10^9/L), and bacteria may be evident on Gram stain of a centrifuged specimen

In 60%-80% of patients with cirrhotic ascites, the Gram stain is negative

Other diagnostic tests

Culture of peritoneal dialysate or ascitic fluid should be positive, particularly if collected prior to initiation of antibiotics

Procalcitonin in conjunction with clinical findings is a sensitive test for bacterial peritonitis[37]

Secondary Peritonitis

Signs and symptoms

Generalized abdominal pain

Tachypnea

Tachycardia

Nausea and vomiting

Temperature is normal initially then increases to 37.8-38.9°C (100-102°F) within the first few hours and may continue to rise for the next several hours

Hypotension, hypoperfusion, and shock if volume is not restored

Decreased urine output due to vascular volume depletion

Physical examination

Voluntary abdominal guarding changing to involuntary guarding and a “board-like abdomen”

Abdominal tenderness and distension

Faint bowel sounds that cease over time

Laboratory tests

Leukocytosis (15,000-20,000 WBC/mm^3 [15×10^9 to 20×10^9/L]), with neutrophils predominating and an elevated percentage of immature neutrophils (bands)

Elevated hematocrit and blood urea nitrogen because of dehydration

Patient progresses from early alkalosis because of hyperventilation and vomiting to metabolic acidosis

Other diagnostic tests

Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident

WBC, white blood cell.

Primary peritonitis can develop over a period of days to weeks and is usually a more indolent process than secondary peritonitis. The first sign of peritonitis may be a cloudy dialysate in patients undergoing peritoneal dialysis or worsening encephalopathy in a cirrhotic patient.

The patient with generalized bacterial peritonitis presents most often in acute distress. The patient lies still, usually on his or her back, possibly with the hips slightly flexed. Any movement of the patient, including rocking the bed or breathing, worsens the generalized abdominal pain.

If peritonitis continues untreated, the patient may experience hypovolemic shock from third-space fluid loss into the peritoneum, bowel wall, and lumen. This may be accompanied by sepsis because the inflamed peritoneum absorbs bacteria and toxins into mesenteric blood vessels and lymph nodes, initiating production of inflammatory cytokines. Hypovolemic shock is the major factor contributing to mortality in the early stage of peritonitis.

Intra-abdominal abscess may pose a difficult diagnostic challenge because the symptoms are neither specific nor dramatic. The patient may complain of abdominal pain or discomfort, but these symptoms are not reliable. Fever is usually present; often it is low grade, but it may be high, with a spiking pattern. The patient may have a paralytic ileus and abdominal distension. The abdominal examination is unreliable; tenderness and pain may be present, and a mass may be palpated.

Peritonitis may result from an abscess that ruptures, spreading bacteria and toxins throughout the peritoneum. In other patients, the entry of bacterial toxins into the systemic circulation from the abscess may lead to sepsis and progressive multisystem organ failure (eg, renal, hepatic, pulmonary, or cardiovascular).

Laboratory studies are not generally helpful in the diagnosis of intra-abdominal abscess, although most patients will have leukocytosis. Some patients may have positive blood cultures, whereas others, particularly diabetics, may have hyperglycemia. The finding of *Bacteroides* or any two enteric bacteria in the bloodstream is often indicative of an intra-abdominal infectious process.

Radiographic methods are used to make the diagnosis of an intra-abdominal abscess. Plain radiographs may show air–fluid levels or a shift of normal intra-abdominal contents by the abscess mass. GI contrast studies may also demonstrate this displacement of abdominal structures. Both of these modalities provide indirect evidence of abscess presence but are not generally helpful in precisely locating the abscess.

Ultrasound is a frequent first diagnostic method used when an intra-abdominal abscess is suspected. The procedure may be done at the bedside, which is particularly helpful when the patient is in the intensive care unit.

Computed tomographic (CT) scanning is the preferred modality used to evaluate the abdomen for

the presence of an abscess and is the imaging study of greatest value. If not contraindicated, an oral radiocontrast agent should be given to allow differentiation of the abscess from the bowel. IV radiocontrast material will be taken up preferentially in the wall of the abscess, creating a unique radiographic appearance, so-called rim enhancement. Magnetic resonance imaging offers no significant advantage when compared with CT scanning.

Intra-abdominal infection caused by disease processes at specific sites often produces characteristic manifestations that are helpful in diagnosis. For example, a patient with diverticulitis may exhibit stabbing left-lower-quadrant abdominal pain and constipation. Fever and leukocytosis are frequently present, and a tender mass is sometimes palpable. With appendicitis, the findings may be inconsistent, but many patients have a sudden onset of periumbilical or epigastric pain that is usually colicky and later shifts to the right lower quadrant. The location of pain may vary because the appendix can be in many locations (eg, retrocecal or pelvic) in the abdomen. A mass may be palpable on abdominal, pelvic, or rectal examination. The patient's temperature is generally mildly elevated early and then increases. If perforation and peritonitis occur, findings would include diffuse abdominal pain, rigidity, and sustained fever. More often, however, appendiceal perforation results in a local abscess.

TREATMENT

Desired Outcome

The primary goals of treatment are correction of the intra-abdominal disease processes or injuries that have caused infection and the drainage of purulent collections (abscesses). A secondary objective is to achieve a resolution of infection without major organ system complications (pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital after treatment with full function for self-care and routine daily activities.

General Approach to Treatment

The treatment of intra-abdominal infection most often requires hospitalization and the coordinated use of three major modalities: (a) prompt drainage of the infected site, (b) hemodynamic resuscitation and support of vital organ functions, and (c) early administration of appropriate antimicrobial therapy to treat infection not eradicated by surgery.[2]

Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary intra-abdominal infections; however, the use of antimicrobial agents without surgical intervention is usually inadequate. For most cases of primary peritonitis, drainage procedures may not be required, and antimicrobial agents become the mainstay of therapy.

4 In the early phase of serious intra-abdominal infections, attention should be given to the maintenance of organ system functions. With generalized peritonitis, large volumes of IV fluids are required to restore vascular volume, to improve cardiovascular function, and to maintain adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure adequate

resuscitation and proper renal function. Respiratory function can be assisted by a variety of methods, including oxygen therapy, pulmonary physiotherapy, and ventilatory support in severely ill patients. Often the critically ill patient with intra-abdominal infection will require intensive care management, particularly if there is cardiovascular or respiratory instability. In addition, isolation procedures may be required if the infectious process poses a threat to other hospitalized patients.

An additional important component of therapy is nutrition. Intra-abdominal infections often directly involve the GI tract or disrupt its function (paralytic ileus). The return of GI motility may take days, weeks, and, occasionally, months. In the interim, enteral or parenteral nutrition as indicated facilitates improved immune function and wound healing to ensure recovery.

Nonpharmacologic Treatment

Drainage Procedures

Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical correction of the underlying pathology. The drainage of the purulent material is the critical component of management of an intra-abdominal abscess. Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail.

Secondary peritonitis is treated surgically; this is often called *source control*, which refers to all the physical measures undertaken to eradicate the focus of infection.[2,5] At the time of laparotomy (surgical opening and exploration of the abdomen), attempts are made to correct the cause of the peritonitis. This may include patching a perforated ulcer with omentum, removal of a segment of perforated colon, or excision of a portion of gangrenous small intestine. In addition, the surgeon may elect to leave the abdomen open after the laparotomy, plan a re-laparotomy at a later time regardless of the patient's condition, or, perform re-laparotomy if the patient develops reinfection.[5] The goal of all these procedures is to repair or remove the inflamed or gangrenous viscus and to prevent further bacterial contamination. The presence of active inflammation increases the difficulty of the surgical procedure, which results in a higher morbidity and mortality rate than if the same procedures were performed in an elective setting without inflammation.

The presence of active inflammation may make it technically impossible to perform the definitive surgical procedure. In this situation, attempts are made to provide drainage of the infected or gangrenous structures. If an intra-abdominal abscess, separate from any intra-abdominal organ, is discovered during an exploratory laparotomy, it may be debrided, excised, or drained. If the intra-abdominal abscess involves an abdominal structure, then a resection of part or of the entire organ may be required. An example of this situation is an abscess associated with diverticular disease of the colon. Management may include drainage of the abscess and resection of the involved part of the colon. All foreign material, necrotic tissue, feces, blood, or pus should be removed from the operative field, and the peritoneum should be copiously irrigated with 0.9% sodium chloride to decrease the concentrations of bacteria or other noxious substances.

After an abscess is located, it must be drained. This may be performed surgically or with percutaneous, image-guided techniques.[5,38] Typically, image-guided techniques employ

ultrasonography or CT scanning. The management of an intra-abdominal abscess with percutaneous catheter drainage may be sufficient to resolve the infection. Some patients may require a subsequent procedure to treat the underlying GI conditions; however, a significant advantage is obtained by first draining the abscess percutaneously. This allows the surgical procedure to be performed on a patient who is no longer suffering the systemic manifestations of uncontrolled infection. Drainage techniques may be performed using endoscopy or laparoscopy. These minimal-access techniques may offer advantages when compared with traditional surgery but will probably be used less often than radiologically assisted percutaneous drainage techniques.

The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage. If pus or fluid is found that is believed to be infected, it is best to aspirate 2 to 3 mL into a syringe, remove any air, and tightly cap the syringe. The specimen should be taken promptly to the microbiology laboratory, where a Gram stain should be performed immediately and cultures prepared for identification of aerobic and anaerobic bacteria. If no fluid is available for collection, culture swab devices may be applied to the infected area; however, anaerobic organisms often are not isolated from swabs.

Fluid Therapy

4 Patients should be evaluated for signs of hypovolemia, hypoperfusion, and shock. Aggressive fluid repletion and management are required for successful treatment of intra-abdominal infections. The Surviving Sepsis Campaign: International Guidelines for Management of Severe Sepsis and Septic Shock recommend treatment goals during the first 6 hours or resuscitation: (a) central venous pressure (CVP) 8 to 12 mm Hg, (b) mean arterial pressure (MAP) more than or equal to 65 mm Hg, and (c) maintain urine output more than or equal to 0.5 mL/kg/h.[39,40] If the patient is mechanically ventilated a target CVP 12 to 15 mm Hg should be achieved.[39] Fluid therapy is instituted for the purposes of achieving or maintaining proper intravascular volume to ensure adequate cardiac output, tissue perfusion, and correction of acidosis. Loss of fluid through vomiting, diarrhea, or nasogastric suction contributes to dehydration. Intravascular volume can be assessed by blood pressure and heart rate but more accurately by measurement of CVP or urinary output. When a contracted vascular volume is accompanied by hemorrhage, the initial hematocrit may be normal, but if there is no associated hemorrhage, the hematocrit is usually elevated as an indication of hemoconcentration. Urine output should be monitored continuously in severely ill patients by use of a urinary bladder catheter, quantitated hourly, and should equal or exceed 0.5 mL/kg of body weight per hour.

In patients with peritonitis, hypovolemia is often accompanied by metabolic acidosis. IV fluids should consist of a bolus of crystalloids or colloids with additional fluids targeting predefined therapeutic goals.[39,40] In the initial hour of treatment, large volumes of solution may be required to restore intravascular volume. Thereafter, fluids may be required at a rate of 1 L/h or higher. Once targeted therapeutic goals are reached, maintenance fluids should be instituted with 0.9% sodium chloride and potassium chloride (20 mEq/L [mmol/L]) or 5% dextrose and 0.45% sodium chloride with potassium chloride (20 mEq/L [mmol/L]). The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1 L for insensible fluid loss. Potassium would not be included routinely if the patient is hyperkalemic or has renal insufficiency. If

appropriate fluid management fails to restore target goals of perfusion, vasopressor therapy should be initiated.[39] A more thorough discussion of fluid and vasopressor therapy are presented elsewhere in this text (23, 24, and 119).

In patients with significant blood loss, blood transfusion may be indicated. This is generally in the form of packed red blood cells. The criteria for blood transfusion are controversial, but a hematocrit of 25% is generally accepted. In the individual patient, the decision is often determined by the overall clinical status and the ability of the patient to compensate for the reduction in oxygen-carrying capacity associated with an acute anemia. Additional blood component therapy with fresh-frozen plasma or platelets is also based on the needs of the individual patient. Aggressive fluid therapy must often be continued in the postoperative period because fluid will continue to sequester in the peritoneal cavity, bowel wall, and lumen.

Pharmacologic Treatment

Antimicrobial Therapy

The goals of antimicrobial therapy are (a) to control any bacteremia and prevent the establishment of metastatic foci of infection, (b) to reduce suppurative complications (eg, abscess formation) after bacterial contamination, and (c) to prevent local spread of existing infection. After suppuration has occurred, a cure by antibiotic therapy alone is very difficult to achieve; antimicrobials may serve to improve the results obtained with surgery.

5 An empirical antimicrobial regimen should be started as soon as the presence of intra-abdominal infection is suspected. Therapy must be initiated based on the likely pathogens, potential resistance, and severity of patient illness. Increased resistance among Gram-negative pathogens to fluoroquinolones and ampicillin–sulbactam emphasize the importance of using local susceptibility data to guide empiric therapy and tailoring the antibiotic regimen based on susceptibility results. Predominant pathogens, as discussed in the preceding section, vary depending on the site of intra-abdominal infection and the underlying disease process. **Table 114-5** lists the likely pathogens against which antimicrobial agents should be directed.

TABLE 114-5 Likely Intra-Abdominal Pathogens

Type of Infection	Aerobes	Anaerobes
Primary (Spontaneous) Bacterial Peritonitis		
Children	Group A *Streptococcus*, *E. coli*, pneumococci	—
Cirrhosis	*E. coli*, *Klebsiella*, pneumococci (many others)	—
Peritoneal dialysis	*Staphylococcus*, *Streptococcus*, *E. coli*, *Klebsiella*, *Pseudomonas*	—
Secondary Bacterial Peritonitis		
Gastroduodenal	*Streptococcus*, *E. coli*	—

Type of Infection	Aerobes	Anaerobes
Biliary tract	*E. coli*, *Klebsiella*, enterococci	*Clostridium* or *Bacteroides* (infrequent)
Small or large bowel	*E. coli*, *Klebsiella*, *Proteus*	*B. fragilis* and other *Bacteroides*, *Clostridium*
Appendicitis	*E. coli*, *Pseudomonas*	*Bacteroides*
Abscesses	*E. coli*, *Klebsiella*, *Streptococcus*, enterococci	*B. fragilis* and other *Bacteroides*, *Clostridium*, anaerobic cocci
Liver	*E. coli, Klebsiella*, *Streptococcus*, enterococci, *Staphylococcus*, amoeba	*Bacteroides* (infrequent)
Spleen	*Staphylococcus*, *Streptococcus*, *E. coli*, *Salmonella*	

Antimicrobial Experience

Many studies have been conducted evaluating or comparing the effectiveness of antimicrobials for the treatment of intra-abdominal infections. Substantial differences in patient outcomes from treatment with a variety of agents have not generally been demonstrated.[41]

Important findings from over 20 years of clinical trials regarding selection of antimicrobials for intra-abdominal infections are the following:

1. Antimicrobial regimens used for secondary infections should cover a broad spectrum of aerobic and anaerobic bacteria from the GI tract. Empiric treatment should be guided by the local epidemiology of resistant pathogens, patient-specific risk factors for resistant pathogens, and patient severity of illness.

2. Single-agent regimens (such as cephalosporins with anaerobic activity, extended-spectrum penicillins with β-lactamase inhibitors, and carbapenems) are as effective but have the benefit of being less nephrotoxic compared to combinations of aminoglycosides with antianaerobic agents. This is also true for antimicrobial treatment of acute bacterial contamination from penetrating abdominal trauma.[42,43]

3. Resistance is prevalent among *B. fragilis* to clindamycin and cefotetan and Enterobacteriaceae to ampicillin–sulbactam and quinolones and therefore these agents should not be routinely used empirically for complicated intra-abdominal infections.[44,45]

4. If the causative pathogens are susceptible and the patient has clinically responded, antimicrobial treatment can be completed orally with amoxicillin–clavulanate, metronidazole with either ciprofloxacin or levofloxacin, or moxifloxacin.[46]

5. Four days of antimicrobial treatment is sufficient for most intra-abdominal infections with adequate source control.[47,48]

Intra-abdominal infections present in many different ways and with a wide spectrum of severity. The regimen employed and duration of treatment depends on the specific clinical circumstances (ie, the nature of the underlying disease process, severity of illness, and risk of resistant pathogens).

Recommendations

6 For most intra-abdominal infections, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria.[48,49] When initial antimicrobial therapy is inactive, morbidity and mortality rates are higher than when initially active therapy is used.[48] Generally, agents with activity against enteric Gram-negative bacilli such as *E. coli* and *Klebsiella* spp., and anaerobes including *B. fragilis* should be administered. If most of the organisms can be eliminated through drainage or antimicrobials, the synergistic effect may be removed, and the patient's defenses may be able to resolve the remaining infection.

Table 114-6 presents the recommended agents for treatment of community-acquired complicated intra-abdominal infections from the Infectious Diseases Society of America and the Surgical Infection Society.[48] These recommendations were formulated using an evidence-based approach. **Table 114-7** lists additional evidence-based recommendations for the treatment of complicated intra-abdominal infections. Most community-acquired infections are of mild-to-moderate severity whereas healthcare-associated infections tend to be more severe, more difficult to treat, and more commonly due to resistant pathogens. **Table 114-8** presents guidelines for treatment and alternative regimens for specific situations. These are general guidelines; there are many factors that cannot be incorporated into such a table including local resistance patterns to commonly used agents such as quinolones.

TABLE 114-6 Recommended Agents for the Treatment of Community-Acquired Complicated Intra-Abdominal Infections in Adults

Agents Recommended for Mild-to-Moderate Infections	Agents Recommended for High Risk or High Severity Infections
Single Agent	
Cefoxitin[a]	Piperacillin–tazobactam
Moxifloxacin[b]	Imipenem–cilastatin,[c] meropenem,[c] doripenem[c]
Ertapenem[c]	
Combination Regimens	
Cefazolin,[a] cefuroxime,[a] ceftriaxone, cefotaxime each in combination with metronidazole	Cefepime or ceftazidime each in combination with metronidazole
Ciprofloxacin[b] or levofloxacin[b] each in combination with metronidazole	Ciprofloxacin[b] or levofloxacin[b] each in combination with metronidazole

[a]Empiric first- and second-generation cephalosporin use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to these agents.

[b]Use of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to quinolones.

[c]Carbapenems should be reserved for settings where there is a high risk of resistance to other agents.

Data from reference 48.

TABLE 114-7 Evidence-Based Recommendations for Treatment of Complicated Intra-abdominal Infections

	Grade of Recommendation[a]
Elements of Appropriate Intervention	
An appropriate source control procedure to drain infected foci, control ongoing peritoneal contamination by diversion or resection, and restore anatomic and physiological function to the extent feasible is recommended for nearly all patients with intra-abdominal infection	B-2
Community-Acquired Infections of Mild-to-Moderate Severity in Adults	
Antibiotics used for empiric treatment of community-acquired intra-abdominal infections should be active against enteric Gram-negative aerobic and facultative bacilli and enteric Gram-positive streptococci	A-1
For patients with mild-to-moderate community-acquired infections regimens with substantial anti-pseudomonal activity are not required (Table 114-6)	A-1
Empiric coverage of *Enterococcus* is not necessary in patients with mild-to-moderate severity community-acquired intra-abdominal infection	A-1
The use of agents listed as appropriate for higher-severity community-acquired infection and healthcare-associated infection is not recommended for patients with mild-to-moderate community-acquired infection, because such regimens may carry a greater risk of toxicity and facilitate acquisition of more resistant organisms	B-2
High-Risk or High-Severity Community-Acquired Infections in Adults[b]	
The empiric use of antimicrobial regimens with broad-spectrum activity against Gram-negative organisms including *Pseudomonas* spp., such as meropenem, imipenem–cilastatin, doripenem, piperacillin–tazobactam, ciprofloxacin or levofloxacin in combination with metronidazole, or ceftazidime or cefepime in combination with metronidazole, is recommended for patients with high-severity community-acquired intra-abdominal infection (Table 114-6)	A-1
Aztreonam plus metronidazole is an alternative, but addition of an agent effective against Gram-positive cocci is recommended	B-3
Healthcare-Associated Infections in Adults	

	Grade of Recommendation[a]
Empiric antibiotic therapy for healthcare-associated intra-abdominal infection should be driven by local microbiologic results	A-2
To achieve empiric coverage of likely pathogens, multidrug regimens that include agents with expanded spectra of activity against Gram-negative aerobic and facultative bacilli may be needed. These agents include meropenem, imipenem–cilastatin, doripenem, piperacillin–tazobactam, or ceftazidime or cefepime in combination with metronidazole. Aminoglycosides or colistin may be required	B-3
Antimicrobial Agents Not Recommended	
Ampicillin–sulbactam is not recommended for use because of high rates of resistance to this agent among community-acquired *E. coli*	B-2
Quinolone-resistant *E. coli* have become common in some communities, and quinolones should not be used unless hospital surveys indicate 90% susceptibility of *E. coli* to quinolones	A-2
Cefotetan and clindamycin are not recommended for use because of increasing prevalence of resistance to these agents among *Bacteroides fragilis*	B-2
Because of the availability of less toxic agents demonstrated to be at least equally effective, aminoglycosides are not recommended for routine use in adults with community-acquired intra-abdominal infection	B-2
Oral Completion Therapy	
For adults recovering from intra-abdominal infection, completion of the antimicrobial course with oral forms of moxifloxacin, ciprofloxacin plus metronidazole, levofloxacin plus metronidazole, an oral cephalosporin with metronidazole, or amoxicillin–clavulanic acid is acceptable in patients able to tolerate an oral diet and in patients in whom susceptibility studies do not demonstrate resistance	B-2
Duration of Therapy	
Antimicrobial therapy of established infection should be limited to 4 days, unless it is difficult to achieve adequate source control. Longer durations of therapy have not been associated with improved outcome[c]	A-1
For acute stomach and proximal jejunum perforations, in the absence of acid-reducing therapy or malignancy and when source control is achieved within 24 hours, prophylactic anti-infective therapy directed at aerobic Gram-positive cocci for 24 hours is adequate	B-2
Bowel injuries attributable to penetrating, blunt, or iatrogenic trauma that are repaired within 12 hours and any other intraoperative contamination of the operative field by enteric contents should be treated with antibiotics for ≤24 hours	A-1

	Grade of Recommendation[a]
Acute appendicitis without evidence of perforation, abscess, or local peritonitis requires only prophylactic administration of narrow spectrum regimens active against aerobic and facultative and obligate anaerobes; treatment should be discontinued within 24 hours	A-1
The administration of prophylactic antibiotics to patients with severe necrotizing pancreatitis prior to the diagnosis of infection is not recommended	A-1
Anaerobic Coverage	
Coverage for obligate anaerobic bacilli should be provided for distal small bowel, appendiceal, and colon-derived infection and for more proximal GI perforations in the presence of obstruction or paralytic ileus	A-1
Antifungal Therapy	
Antifungal therapy for patients with severe community-acquired or healthcare-associated infection is recommended if *Candida* is grown from intra-abdominal cultures	B-2
Anti-MRSA Therapy	
Empiric antimicrobial coverage directed against MRSA should be provided to patients with healthcare-associated intra-abdominal infection who are known to be colonized with the organism or who are at risk of having an infection due to this organism because of prior treatment failure and significant antibiotic exposure	B-2
Vancomycin is recommended for treatment of suspected or proven intra-abdominal infection due to MRSA	A-3
Antienterococcal Therapy	
Antimicrobial therapy for enterococci should be given when enterococci are recovered from patients with healthcare-associated infection	B-III
Empiric antienterococcal therapy is recommended for patients with high-risk community-acquired infections and healthcare-associated intra-abdominal infections, particularly those with postoperative infection, those who have previously received cephalosporins or other antimicrobial agents selecting for *Enterococcus* species, immunocompromised patients, and those with valvular heart disease or prosthetic intravascular materials	B-II
Initial empiric antienterococcal therapy should be directed against *Enterococcus faecalis*. Antibiotics that can potentially be used against this organism, on the basis of susceptibility testing of the individual isolate, include ampicillin, piperacillin/tazobactam, and vancomycin	B-III
Empiric therapy directed against vancomycin-resistant *Enterococcus faecium* is not recommended unless the patient is at very high risk for an infection due to this organism, such as a liver transplant recipient with an intra-abdominal infection originating in the hepatobiliary tree or a patient known to be	B-III

		Grade of Recommendation[a]
colonized with vancomycin-resistant *E. faecium*		

MRSA, methicillin-resistant *Staphylococcus aureus*.

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from ≥1 properly randomized, controlled trial. 2 = Evidence from ≥1 well-designed clinical trial without randomization, from cohort or case-controlled analytic studies; from multiple time series, or from dramatic results from uncontrolled experiments. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

[b]Criteria for high risk or high severity community-acquired infection: APACHE II score ≥15, delay in initial intervention >24 hours), advanced age, comorbidity and degree of organ dysfunction, low albumin level, poor nutritional status, degree of peritoneal involvement or diffuse peritonitis, inability to achieve adequate debridement or control of drainage, and presence of malignancy.

[c]After IDSA/SIS guideline publication a randomized controlled trial was published and demonstrated that 4 days of therapy after source control is adequate[47]

Data from reference 48.

TABLE 114-8 Guidelines for Empiric Antimicrobial Agents for Intra-Abdominal Infections[48,70]

	Primary Agents	Alternatives
Primary (Spontaneous) Bacterial Peritonitis		
Cirrhosis	Ceftriaxone, cefotaxime	1. Piperacillin–tazobactam, carbapenems 2. Aztreonam combined with an agent active against *Streptococcus* spp. (eg, vancomycin) or quinolones with significant *Streptococcus* spp. activity (levofloxacin, moxifloxacin)
Peritoneal dialysis	Initial empiric regimens should be active against both Gram-positive (including *S. aureus*) and Gram-negative pathogens: Gram-positive agent (first-generation cephalosporin or vancomycin) plus a Gram-negative agent (third-generation cephalosporin or aminoglycoside)	1. Cefepime or carbapenems may be used alone 2. Aztreonam or an aminoglycoside may be used in place of ceftazidime or cefepime as long as combined with a Gram-positive agent 3. Quinolones may be used in place of Gram-negative agents if local

	Primary Agents	Alternatives
		susceptibilities allow
	1. *Staphylococcus* spp.: oxacillin/nafcillin or first-generation cephalosporin	1. Vancomycin should be used if concern for methicillin-resistant *Staphylococcus* spp. 2. Add rifampin for 5-7 days with vancomycin for methicillin-resistant *S. aureus*
	2. *Streptococcus* or *Enterococcus*: ampicillin	1. An aminoglycoside may be added for *Enterococcus* spp. 2. Linezolid or daptomycin should ideally be used to treat vancomycin-resistant *Enterococcus* spp. not susceptible to ampicillin
	3. Aerobic Gram-negative bacilli: ceftazidime or cefepime 4. *Pseudomonas aeruginosa*: two agents with differing mechanisms of action, such as an oral quinolone plus ceftazidime, cefepime, tobramycin, or piperacillin	1. The regimen should be based on in vitro sensitivity tests
Secondary Bacterial Peritonitis		
Perforated peptic ulcer	First-generation cephalosporins	1. Ceftriaxone, cefotaxime, or antianaerobic cephalosporins[a]
Other	Third- or fourth-generation cephalosporin with metronidazole, piperacillin–tazobactam or carbapenem	1. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or *moxifloxacin*[b] alone 2. Aztreonam with vancomycin and metronidazole 3. Antianaerobic cephalosporins[a]
Abscess		
General	Third- or fourth-generation cephalosporin with metronidazole, or piperacillin–tazobactam	1. Imipenem–cilastatin, meropenem, doripenem, or ertapenem 2. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin alone
Liver	As above	Use metronidazole if amoebic liver abscess is suspected

	Primary Agents	Alternatives
Spleen	Ceftriaxone or cefotaxime	Moxifloxacin[b] or levofloxacin[b]
Other Intra-abdominal Infections		
Appendicitis	Same management as for community-acquired complicated intra-abdominal infections as listed in Table 114-6[39]	
Community-acquired acute cholecystitis	Ceftriaxone or cefotaxime	Severe infection, piperacillin/tazobactam, antipseuodomonal carbapenem, aztreonam with metronidazole
Cholangitis	Ceftriaxone or cefotaxime each with or without metronidazole	Vancomycin with aztreonam with or without metronidazole
Acute contamination from abdominal trauma	Antianaerobic cephalosporins[a] or metronidazole with either ceftriaxone or cefotaxime	1. Piperacillin/tazobactam or a carbapenem 2. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin alone

[a]Cefoxitin or ceftizoxime; these agents should be avoided empirically unless local antibiograms show >80% to 90% susceptibility of *E. coli* to these agents.

[b]Use of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to quinolones.

Most patients with severe intra-abdominal infection, sepsis of intra-abdominal source, or healthcare-associated infection should be placed on piperacillin–tazobactam, cefepime with metronidazole, or a carbapenem with *Pseudomonas* activity such as imipenem, doripenem, or meropenem. In patients with IgE-mediated allergic reactions to β-lactams (hives/urticaria, bronchospasm, angioedema, or anaphylaxis), combination therapy with aztreonam, vancomycin and metronidazole may be used. The benefits of systemic empiric antifungal (with fluconazole or an echinocandin antifungal) have not been established for intra-abdominal infection and should not be routinely used.[50]

Aminoglycoside-based treatment regimens are not routinely recommended due to their narrow therapeutic index (nephrotoxicity, ototoxicity) relative to the recommended agents such as β-lactams. Aminoglycosides are reserved primarily for infections due to presumed or proven multidrug-resistant pathogen(s) or perhaps in patients with IgE-mediated allergic reactions to alternative agents.[41,48]

The initial dosage for aminoglycosides should be determined based on the patient's weight and renal function. Traditionally, gentamicin and tobramycin were administered multiple times daily with specific peak (6-10 mcg/mL) [mg/L; 13-21 µmol/L]) and trough (less than 1-2 mcg/mL) [mg/L; less than 2-4 µmol/L]) concentration targets. Because aminoglycosides have concentration-dependent

killing and have a relatively long postantibiotic effect for aerobic Gram-negative bacilli, extended-interval dosing of aminoglycosides is possible. For most patients and indications, extended-interval aminoglycoside dosing (ie, 5-7 mg/kg once daily for tobramycin or gentamicin, 15-20 mg/kg once daily for amikacin) has replaced traditional dosing given equivalent efficacy and decreased nephrotoxicity.[51,52,53]

Antimicrobial resistance continues to rise worldwide.[54,55,56] These problematic multidrug-resistant bacteria include enteric pathogens producing extended-spectrum β-lactamases (ESBL) which have been increasingly isolated from intra-abdominal cultures.[44] For patients with ESBL-producing pathogens, carbapenems are typically the drugs of choice. With the increased use of carbapenems, pathogens continue to evolve with the development of β-lactamases that hydrolyze carbapenems (e.g., *Klebsiella pneumoniae* carbapenemase [KPC]), multidrug-resistant *Pseudomonas* spp., and carbapenem-resistant *Acinetobacter* spp. Especially in patients with healthcare-associated intra-abdominal infections, these multidrug-resistant pathogens have forced clinicians to use more toxic and potentially less effective agents such as the polymyxins, tigecycline, and aminoglycosides. For example, the product labeling for tigecycline now carries a Black Box Warning as it has been associated with an increased risk of mortality relative to comparator agents based on pooled data collected from randomized controlled trials including patients with intra-abdominal infections, skin and skin structure infections, and ventilator-associated pneumonia.[57,58,59] The limited safe and effective therapeutic options for resistant organisms highlights the need, from an individual patient and public health standpoint, for pharmacists and other clinicians to ensure that antimicrobials are selected appropriately, at the optimal dose, and for the correct duration.[60,61]

Clinical Controversy…

Ceftolozane/tazobactam and ceftazidime/avibactam were FDA-approved in 2014 and 2015, respectively, for the treatment of complicated intra-abdominal infections in combination with metronidazole.[62,63] These agents are useful as they may be active against multidrug-resistant pathogens including *Pseudomonas* spp., ESBL-producing *Enterobacteriaceae* and KPC-producing *Enterobacteriaceae* (ceftazidime/avibactam only). However, clinical effectiveness and safety data are limited, especially with ceftazidime/avibactam, which was approved prior to completion of Phase III studies. Ceftolozane/tazobactam may not be as effective as meropenem and metronidazole inthe treatment of complicated intra-abdominal infections.[64,65,66] Despite this, these agents are highly valuable in terms of their activity against multidrug-resistant pathogens and as such, their use should be reserved for patients with a suspected or confirmed infection due to a pathogen resistant to all other β-lactams, including carbapenems.

With intra-abdominal contamination from the upper GI tract (perforation of a peptic ulcer or biliary tract disease), anaerobes such as *B. fragilis* are uncommon pathogens, and therefore other empiric agents such as ampicillin, penicillin, or first-generation cephalosporins are reasonable. Anaerobic coverage is also not necessary for primary peritonitis associated with cirrhosis and third-generation cephalosporins, such as cefotaxime or ceftriaxone, remain the treatments of choice.[67]

Coverage of *Enterococcus* in mild-to-moderate community-acquired intra-abdominal infections is not

recommended.[48] The failure of host defenses may be a critical factor in the pathogenicity of enterococci. In patients with severe community-acquired intra-abdominal infection or patients with healthcare-associated infection, it is recommended to include coverage of *Enterococcus faecalis* in the initial regimen.[48] Ampicillin remains the drug of choice for this indication because it is most active in vitro against *E faecalis*. Vancomycin is active against most enterococci; however, rates of vancomycin-resistant enterococci are increasing, particularly in select patient populations (eg, liver transplantation, immunocompromised patients).[68] Agents including linezolid or daptomycin are commonly used for vancomycin-resistant *Enterococcus* infections. Table 114-7 lists additional evidence-based recommendations for *Enterococcus* spp. coverage.

7 Intraperitoneal administration of antibiotics is preferred over IV therapy in the treatment of peritonitis that occurs in patients undergoing CAPD.[69] The International Society of Peritoneal Dialysis guidelines for the diagnosis and pharmacotherapy of peritoneal dialysis-associated infections provide dosing recommendations for intermittent and continuous therapy based on the modality of dialysis (continuous or intermittent) and the extent of the patient's residual renal function.[70]

Antimicrobial agents effective against both Gram-positive (including *S. aureus*) and Gram-negative organisms should be used for initial intraperitoneal empiric therapy for peritonitis in peritoneal dialysis patients. The most important factors to take into consideration for initial antimicrobial selection are the dialysis center's and the patient's history of infecting organisms and their sensitivities. For empiric intraperitoneal therapy in patients on continuous peritoneal dialysis, cefazolin (loading dose [LD] 500 mg/L; maintenance dose [MD] 125 mg/L) or vancomycin (LD 1,000 mg/L; MD 25 mg/L) in cases of high prevalence of methicillin-resistant *S. aureus* (MRSA) or β-lactam allergy may be used for Gram-positive coverage. A meta-analysis based on a limited number of studies found that glycopeptide-containing regimens (vancomycin or teicoplanin) were more likely to achieve complete cure compared to first generation cephalosporins.[69] However the study contributing most of the weight in this meta-analysis used a lower than recommended cefazolin dose.[71] One of these Gram-positive agents should be combined with a Gram-negative agent such as ceftazidime (LD 500 mg/L; MD 125 mg/L) or cefepime (LD 500 mg/L; MD 125 mg/L) or an aminoglycoside (gentamicin or tobramycin LD 8 mg/L; MD 4 mg/L). Another option is monotherapy with cefepime or imipenem–cilastatin (LD 250 mg/L; MD 50 mg/L). Antimicrobial doses should empirically be increased by 25% in patients with residual renal function (more than 100 mL/day urine output).[70] Antimicrobial therapy should be continued for at least 1 week after the dialysate fluid is clear and for a total of at least 14 days. The reader is referred to these guidelines for additional information.[70]

After acute bacterial contamination, such as with abdominal trauma where GI contents spill into the peritoneum, antibiotics should be administered. If the patient is seen soon after injury (within 2 hours) and surgical measures are instituted promptly, antianaerobic cephalosporins (such as cefoxitin), a third-generation cephalosporin (such as ceftriaxone) with metronidazole, or piperacillin/tazobactam are effective in preventing most infectious complications. Antimicrobials should be administered as soon as possible after injury.

For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix

at the time of operation, which may be normal, inflamed, gangrenous, or perforated. Because the condition of the appendix is unknown preoperatively, it is advisable to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, piperacillin–tazobactam or an anti-pseudomonal carbapenem. If, at operation, the appendix is normal or inflamed, postoperative antimicrobials are not required. If the appendix is gangrenous or perforated, a treatment course of 4 days with the agents listed in Table 114-6 is appropriate.

8 Acute intra-abdominal contamination, such as after a traumatic injury, may be treated with a very short antimicrobial course (24 hours).[72] For established infections (ie, peritonitis or intra-abdominal abscess), an antimicrobial course limited to 4 days is appropriate.[47] This allows eradication of bacteria remaining in the peritoneum after a surgical procedure that may enter the peritoneum through healing suture lines. Under certain conditions, therapy for longer than 4 days would be justified (eg, when a focus of infection in the abdomen is still present). For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer.

Clinical Controversy…

The Infectious Diseases Society of America/Surgical Infection Society guidelines for complicated intra-abdominal infections recommend 4 to 7 days of antimicrobial therapy after attainment of source control.[48] Despite this, therapy has historically continued for longer durations, likely due to an initial lack of high quality data supporting this recommendation.[73] A subsequent randomized controlled trial of 518 patients with intra-abdominal infection and adequate source control compared the clinical outcomes of 4 days of antimicrobial therapy after the index source control procedure versus 2 days of therapy after normalization of leukocytosis, temperature, and diet (median 8 days of therapy).[47] This study found no difference in the rate of surgical site infections, recurrent intra-abdominal infections, or mortality between treatment groups; this suggests 4 days of therapy after source control is likely adequate. Although the study was stopped after enrolling approximately 50% of the patients initially planned, the proportion of patients meeting primary or secondary outcomes were similar in the total cohort as well as in multiple patient subgroups defined a priori. Because the study only assessed patients with source control, the optimal duration of antimicrobial therapy in patients with uncontrolled sources of intra-abdominal infection remains unknown. In these cases, should antimicrobial therapy be continued until the source is controlled? Or, if source control is not possible in the near term and the patient is clinically stable with minimal signs of systemic inflammatory response, can antimicrobial therapy be safely withheld and the patient closely monitored so as to limit long durations of antimicrobial therapy and associated adverse effects?

Intraperitoneal irrigation of antimicrobial agents for treatment of intra-abdominal infection has been studied, often with conflicting results.[74] Intraoperative antimicrobial irrigation does not improve patient outcomes in comparison with copious intraoperative irrigation with normal saline. Possibly the most important aspect of peritoneal irrigation is the dilutional effect on bacteria and adjuvants that promotes infection (intestinal contents and hemoglobin). Most systemically administered antimicrobials easily cross the peritoneal membrane so that peritoneal fluid concentrations are similar to serum. Confined areas, such as an abscess, can be expected to attain much lower antimicrobial

concentrations.

EVALUATION OF THERAPEUTIC OUTCOMES

Whichever antimicrobial regimen is chosen, the patient should be reassessed continually to determine the success or failure of therapies. The clinician should recognize that there are many reasons for poor patient outcomes with intra-abdominal infections; improper antimicrobial administration is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. There may be surgical reasons for poor patient outcome. Failure to identify all intra-abdominal foci of infection or leaks from a GI anastomosis may cause continued infection. Finally, antimicrobial resistance may contribute to treatment failure as isolates from intra-abdominal infections are increasingly drug resistant.[75]

The outcome from intra-abdominal infection is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with intra-abdominal infections may result from complications that arise in other organ systems, including renal or respiratory failure. Furthermore, pneumonia is a complication that is commonly associated with mortality after intra-abdominal infection.[76] A high APACHE (Acute Physiology and Chronic Health Evaluation) II score, low serum albumin concentration, and high New York Heart Association cardiac function status were independently associated with increased mortality from intra-abdominal infection.[77]

9 Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days. Usually, temperature will return to near normal, vital signs should stabilize, and the patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and the nasogastric tube. At 24 to 48 hours, aerobic bacterial culture results should return. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed if the patient has not shown sufficient improvement. If the isolated pathogen is susceptible to a narrower spectrum agent, therapy should be deescalated.

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes are often not identified until 4 to 7 days after culture. A report indicating that anaerobes were not isolated should not be the sole justification for discontinuing antianaerobic drugs because anaerobic bacteria that were present in the infectious process may not have been transported properly to the microbiology laboratory, or other problems may have led to cell death in vitro.

Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible in vitro to the antimicrobial agent, therapeutic failures may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. In addition, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for intra-abdominal infection can be caused by *Candida*; however, enterococci or opportunistic Gram-negative bacilli such as *Pseudomonas* may be involved.

Treatment regimens for intra-abdominal infection can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intra-abdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks. The costs of treatment can be significantly reduced if parenteral antimicrobials can be switched to oral agents for completion of therapy.[78]

Chapter e115: Parasitic Diseases

Jason M. Cota; JV Anandan

INTRODUCTION

KEY CONCEPTS

- 1 Nitazoxanide and tinidazole are Food and Drug Administration (FDA)-approved for giardiasis treatment. While the FDA has not approved metronidazole for this indication, it has been widely accepted as the mainstay of giardiasis therapy for the past 50 years.
- 2 Human immunodeficiency virus (HIV)-infected patients with cryptosporidiosis must receive antiretroviral therapy as the mainstay of therapy in addition to antiparasitic therapy.
- 3 Serologic detection assays are required to diagnose *Entamoeba histolytica* infection because stool sample analysis is insensitive and does not distinguish between *E. histolytica* and the nonpathogenic *E. dispar* or *E. moshkovskii*.
- 4 Metronidazole and tinidazole are tissue-acting agents against amoeba; whereas, paromomycin, iodoquinol, and diloxanide furoate are luminal amebicides.
- 5 The drugs that have been used to treat *Trypanosoma cruzi* infections include benznidazole and nifurtimox, but are not currently approved by the FDA. Both are available from the Centers for Disease Control and Prevention (CDC) under an Investigational New Drug program.
- 6 Chloroquine has been the recommended drug for malaria chemoprophylaxis, but clinicians have increasingly prescribed alternative antimalarial drugs such as atovaquone-proguanil, doxycycline, primaquine, and mefloquine because these regimens retain effectiveness in areas where chloroquine-resistant *Plasmodium falciparum* exposure is likely.
- 7 Administration of corticosteroids or other immunosuppressive drugs to an infected individual can result in hyperinfections and disseminated strongyloidiasis.
- 8 Antihelminthic therapy destroys parasites and may cause increased inflammation and worsening of neurocysticercosis symptoms.

- 9 For head lice, the American Academy of Pediatrics recommends either nonprescription 1% permethrin or pyrethrins plus piperonyl butoxide topical preparations as agents of choice unless local resistance to these agents is documented.

- 10 A single application of 5% permethrin results in cure rates in more than 90% of subjects with scabies at 14 and 28 days, but a second dose should be applied 1 week later because its ovicidal efficacy remains unclear.

Parasitic diseases remain a significant global health problem causing approximately one million deaths per year and affecting more than 1.7 billion people worldwide.[1,2,3,4,5] In the United States, immunocompromised patients, ethnic/racial minorities, immigrants, those with recent travel to developing regions, individuals living in poor sanitary conditions, and people who lack access to basic health care services appear to be at highest risk for developing parasitic disease.[6] However, people in every income and social strata can become infected. In fact, the Centers for Disease Control and Prevention (CDC) has referred to five diseases as neglected parasitic infections and has prioritized these for increased public health action.[7] They include Chagas disease, cysticercosis, toxocariasis, toxoplasmosis, and trichomoniasis.[8]

This chapter discusses the major parasitic diseases including protozoan disease (giardiasis, cryptosporidiosis, Chagas disease, amebiasis, and malaria), helminthic infections (strongyloidiasis, cysticercosis, and toxocariasis), and ectoparasitic infestations (lice and scabies).

HOST–PARASITE RELATIONSHIP

Symbiosis is the association of two species for the purpose of obtaining food for either one or the other. *Parasitism* is a symbiotic relationship in which one species, the host, is injured through the activities of the other. Through evolution, parasites have made specific morphologic adaptations. Adaptation to the host has taken a number of forms: loss of locomotor organelles in the protozoan *Sporozoa*; partial and complete lack of digestive systems in the trematodes and cestodes, respectively; elaboration of proteolytic enzymes to penetrate the host intestinal mucosa by *Entamoeba histolytica*; the cercariae of the blood fluke that penetrate the skin of the host by elaborate enzymes; and, finally, the ability to infect an intermediate host to increase reproductive capacity, as seen among the cestodes and trematodes.[9]

Parasites normally inflict some degree of injury to the host, the extent of which depends on such factors as parasite load, nutritional status, and immunologic competence of the host. *E. coli* is considered commensal because it subsists on the bacterial flora of the gut and does not cause any harm to the host. Unlike *E. coli*, *Fasciolopsis buski*, the giant intestinal fluke, can produce severe local damage to the intestinal wall. *Ascaris*, the roundworm, can perforate the bowel wall, cause intestinal obstruction, and invade the appendix and bile duct. Malarial parasites destroy red blood cells by multiplying inside them. *Diphyllobothrium latum*, or the broad fish tapeworm, removes vitamin B_{12} from the gastrointestinal (GI) tract, resulting in megaloblastic anemia.[9]

PROTOZOAN DISEASES

Giardiasis

Epidemiology and etiology

Giardia lamblia (also known as *Giardia intestinalis* and *Giardia duodenalis*) is a flagellated protozoan and is the most frequently identified intestinal parasite in US patients. Since 2005, the annual incidence rate of reported giardiasis cases in the United States has ranged from 5.8 to 7.9 cases per 100,000 people with the highest number of reports occurring in the Northwest states.[10] It is most frequently reported in children between ages 1 and 4 years and peak illness occurs in late summer. This may be due to increased contact with contaminated water during the summer months or decreased immunity in children.

There are two stages in the life cycle of *G. lamblia*: the trophozoite and the cyst. *G. lamblia*, which is found in the small intestine, gallbladder, and biliary drainage, is a pear-shaped trophozoite with four pairs of flagella. Two nuclei lie in the area of the sucking disk, giving the protozoan a characteristic face-like image.

Pathophysiology and Clinical Presentation

Giardiasis results from ingestion of *G. lamblia* cysts in fecally contaminated water or food. Person-to-person and animal-to-person transmission has been reported, but is rare. The protozoan cysts are moderately tolerant to chlorinated water and release trophozoites in low gastric pH.[12] Ingestion of as few as 10 cysts may cause infection and those infected may shed 10^8 to 10^9 cysts in their stool per day for months. Primary risk factors include ingestion of contaminated untreated water, swimming, occupational exposure to infected human waste, and sexual contact that may involve fecal contact.[10] In countries where giardiasis is endemic, infection risk and diarrhea severity may increase among immunocompromised human immunodeficiency virus (HIV)-infected adults. Colonization and multiplication of the trophozoite lead to mucosal invasion, localized edema, and flattening of the villi, and nutrient malabsorption. Lactose intolerance precipitated by giardiasis and iron deficiency can persist even after eradication of the protozoan.

Giardiasis should be suspected in patients with aforementioned risk factors who present with prolonged diarrhea that is associated with malabsorption or weight loss (**Table e115-1**). Diagnosis of giardiasis may be made by examination of fresh stool or a preserved specimen during the acute diarrheal phase. Fresh stool specimens may show the trophozoites, whereas preserved specimens usually yield the cysts. Three stool specimens collected on separate days for ova and parasites (O&P) will yield up to 90% of the parasites.[11,12] However, direct fluorescent antibody (DFA) is becoming a standard in *Giardia* testing because it is 85% to 98% sensitive, 90% to 100% specific, rapid, reproducible, cost-effective, and does not require a trained microscopist.[13,14] Immunochromagraphic (IC) tests, enzyme immunoassays (EIA), and various multiplex polymerase chain reaction (PCR) diagnostics also have high sensitivity and specificity.[13,14,15] However, these methods may be

unavailable in microbiology laboratories due to limited commercial availability and the additional expense and technical expertise that may be required to perform these tests.

TABLE e115-1 Clinical Presentation of Protozoan Diseases

Giardiasis[10,14]	Cryptosporidiosis[22,26]	Amebiasis[11,12,16]	Chagas Disease[34,35]
Acute	Immunocompetent	Intestinal disease	Acute
Diarrhea: foul-smelling, copious, light-colored, fatty stools	Diarrhea: profuse, watery, nonbloody	Diarrhea: bloody (heme-positive in 100% of cases) with mucus	Granuloma or "chagoma"
Cramp-like abdominal pain, bloating, and flatulence	Abdominal pain, fever, and vomiting	Vague abdominal discomfort to severe abdominal cramps, flatulence	Unilateral orbital edema ("Roman sign")
Malaise, anorexia, nausea, and belching	Malaise, anorexia, joint pain, headache	Eosinophilia is usually absent, although moderate leukocytosis is not unusual	Fever, hepatosplenomegaly, and lymphadenopathy
Chronic	Immunocompromised	Amebic liver abscess	Chronic
Periods of diarrhea alternating with constipation	Diarrhea: cholera-like large amounts of watery diarrhea, weight loss, malabsorption	High fever, rigors and profuse sweating, significant leukocytosis with left shift, and elevated alkaline phosphatase	Cardiomyopathy and heart failure First-degree heart block, right bundle-branch block, and arrhythmias
Weight loss, lactose intolerance, vitamin B12, and fat-soluble vitamin deficiencies	Biliary, respiratory, or pancreatic dissemination	Right upper quadrant pain, hepatomegaly, and liver tenderness with referred pain to left or right shoulder	Enlargement of esophagus and colon ("mega" syndrome) Meningoencephalitis, strokes, seizures, and focal paralysis

Treatment

Patients with symptomatic giardiasis confirmed by positive stool samples or *Giardia* antigen detection should receive antiparasitic therapy. Since the primary clinical manifestation of giardiasis is prolonged diarrhea, clinicians must ensure patients receive adequate oral or intravenous fluids to maintain hydration, correct electrolyte abnormalities, and provide oral, enteral, or parenteral nutrition in severe cases. The antimotility agent loperamide and the antisecretory agent bismuth subsalicylate are available without a prescription, but are not recommended because patients may delay seeking care and may not receive appropriate antiparasitic treatment in a timely manner.[16,17,18] A guideline

sponsored by the United States Department of Health and Human Services and another jointly written by the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition and the European Society of Pediatric Infectious Diseases are the only published references where available evidence for each giardiasis treatment option is systematically reviewed and graded.[17,18] All symptomatic adults and children with giardiasis should be treated with one of the agents found in **Table e115-2**. The primary differences between these regimens are frequency of administration and duration of therapy. Nitazoxanide and tinidazole are Food and Drug Administration (FDA)-approved for giardiasis treatment. While the FDA has not approved metronidazole for this indication, it has been widely accepted as the mainstay of giardiasis therapy for the past 50 years. Alternative drugs include albendazole 400 mg daily for 5 days, paromomycin 25 to 35 mg/kg/day in three divided doses for 1 week, and quinacrine.[17,18,19] Paromomycin is a safe agent in all pregnancy trimesters because it is not systemically absorbed. Metronidazole has been used in the second and third trimesters of pregnancy. Quinacrine, which was the drug of choice in giardiasis, has been discontinued by the manufacturer but is obtained in the United States from a specialized pharmacy (**Appendix e115-1**).

TABLE e115-2 Treatment of Protozoan Diseases

	Adults	Children
Giardiasis[17,20]		
Metronidazole	250 mg orally every 8 hours × 5-10 days	5 mg/kg orally every 8 hours × 5-7 days (maximum 250 mg/dose)
Tinidazole	2 grams × 1 dose with food	≥3 years: 50 mg/kg orally × 1 dose with food (maximum 2 grams) 1-3 years: 100 mg orally every 12 hours with food × 3 days
Nitazoxanide	500 mg orally every 12 hours with food × 3 days	4-11 years: 200 mg orally every 12 hours with food × 3 days ≥12 years: 500 mg orally every 12 hours with food × 3 days
Cryptosporidiosis[23,26]		
Nitazoxanide	Same as giardiasis dosing recommendations above for both adults and children	
Amebiasis[28,29]		
Asymptomatic Cyst Passer		
Paromomycin	8-12 mg/kg orally every 8 hours × 7 days	8-12 mg/kg orally every 8 hours × 7 days
Iodoquinol	650 mg orally every 8 hours × 20 days	10-13 mg/kg orally every 8 hours × 20 days (maximum 2 g/day)
Intestinal/Amebic Liver Abscess		

	Adults	Children
Metronidazole	750 mg orally or iv every 8 hours × 7-10 days	17 mg/kg orally or iv every 8 hours × 7-10 days (maximum 750 mg/dose)
Tinidazole	2 grams daily × 3-5 days	≥3 years: 50 mg/kg daily × 3-5 days (maximum 2 g/dose)
	Each regimen for intestinal amebiasis/amebic liver abscess should be followed by a luminal agent	
Chagas disease[34,35]		
Benznidazole (CDC IND protocol only)	150 mg orally twice daily × 60 days	5-7 mg/kg orally twice daily × 60 days (maximum 150 mg/dose)
Nifurtimox (CDC IND protocol only)	2-2.5 mg/kg orally every 6 hours × 90 days	≤10 years: 3.75-5 mg/kg orally every 6 hours × 90 days 11-16 years: 3.125-3.75 mg/kg orally every 6 hours × 90 days

Appendix e115-1 Antiparasitic Drugs

Drug	Indications	Side Effects	Comments	References
Albendazole 200 mg tablet (Albenza)	Giardiasis, ascariasis, neurocysticercosis	GI: abdominal pain, nausea, diarrhea, increase in liver function enzymes	Not recommended in children <2 years old	9, 16, 42, 45, 46
Artemether 20 mg/Lumefantrine 120 mg tablet (Coartem)	Acute uncomplicated Falciparum malaria	Headache, dizziness, asthenia, fatigue, and arthralgia	Approved for patients >5 kg body weight	52, 75
Artesunate[a]	Severe falciparum malaria	Rash, dizziness, and pruritus	Obtained by IND from CDC	16, 58
Atovaquone 250 mg *plus* proguanil 100 mg (Malarone)[b]	Prevention and treatment of *P. falciparum* malaria	Abdominal pain, nausea, vomiting, and headache		9, 16, 48, 49, 52, 61, 62, 75
Chloroquine phosphate (Aralen, Nivaquine) 250- and 500-mg tablets; 50 mg/mL (as HCl); 5-mL ampule	Malaria	GI: nausea, vomiting, and diarrhea CNS: dizziness, headache, blurring of vision, confusion, and fatigue Derm: pruritus	Administer oral dose after meals IV route: recommend ECG monitoring *Contraindication:* patients with psoriasis or porphyria	9, 16, 48, 49, 52, 61, 75

Drug	Indications	Side Effects	Comments	References
Diloxanide furoate[b] (Furamide) 500-mg tablet[c]	Amebiasis	GI: nausea and flatulence Derm: pruritus		9, 16, 19, 20, 21, 75
Furazolidone (Furoxone) 100-mg tablet Suspension: 50 mg/5 mL	Giardiasis Alternative to metronidazole	GI: nausea and vomiting Hypersensitivity: hypotension, fever, arthralgia, and urticaria Other: headache	Disulfiram-like reaction with alcohol; avoid in G6PD deficiency; may cause hemolysis; changes color of urine to brown	9, 16
Iodoquinol (Yodoxin) 210-mg tablet	Amebiasis	GI: abdominal pain and diarrhea Derm: rash	May interfere with the thyroid function test *Contraindication:* patients with iodine intolerance	9, 16, 19,20,21, 75
Ivermectin (Stromectol) 6-mg tablet	Strongyloidiasis Pediculosis Scabies	Dizziness, somnolence, tremor, vertigo, pruritus, and abdominal pain	Should be taken with a full glass of water	9, 16, 34, 39, 92
Mebendazole (Vermox) 100-mg chewable tablet	Ascariasis, trichuriasis, hookworm, and pinworm	GI: abdominal pain and diarrhea CNS: headache and dizziness Other: pyrexia and neutropenia Incidence 17%	Drug should be taken with meals *Contraindication:* pregnancy *Drug interaction:* can increase serum levels of theophylline	9, 16, 25
Mefloquine (Lariam) 250-mg tablet	*P. falciparum* malaria	GI: nausea, vomiting, abdominal pain, and diarrhea Card: sinus bradycardia CNS: vertigo, dizziness, confusion,	Patients given doses in excess of 12 mg/kg should be monitored carefully because the side effects are dose related	9, 16, 48,49,50, 52, 55, 61, 62, 75

Drug	Indications	Side Effects	Comments	References
		hallucinations, psychosis, and convulsions Derm: itching, skin rash		
Metronidazole (Flagyl) Oral: 250-mg, 500-mg tablets	Amebiasis Giardiasis	GI: nausea, anorexia, vomiting, diarrhea, abdominal cramping, glossitis, and metallic taste CNS: dizziness, vertigo, headache, and paresthesia GI: anorexia and nausea	Avoid alcohol; alcohol ingestion will cause the disulfiram reaction: abdominal distress, vomiting, and hypotension *Contraindication*: First trimester of pregnancy	9, 11,12,13, 16, 19,20,21
Nifurtimox[c] (Lampit, Bayer 2502)	South American trypanosomiasis	CNS: peripheral neuritis and psychosis Hemat: hemolysis in G6PD deficiency patients	Monitor pulmonary function and hematologic parameters	9, 16, 75, 76, 78, 79
Nitazoxanide (Alinia) 100-mg/5-mL suspension	Cryptosporidiosis Giardiasis	Abdominal pain, diarrhea, vomiting, and headache	Rarely may produce yellow sclerae	12, 16, 17
Primaquine phosphate 26.3-mg tablet	Malaria (*P. vivax*) (*P. ovale*)	GI: nausea and abdominal pain CNS: mental depression	In patients with G6PD deficiency, it can cause hemolysis	9, 16, 48, 49, 52
Pyrimethamine 25 mg *plus* sulfadoxine 500 mg (Fansidar)	*P. falciparum*-resistant malaria	GI: nausea, abdominal pain, stomatitis, headache, and glossitis Hemat: agranulocytosis, aplastic anemia, leukopenia, megaloblastic	Combination was recently reported to cause the Stevens–Johnson syndrome; patients should be advised to call their physician/pharmacist if a skin rash or other reaction is seen	9, 16, 48, 49, 75

Drug	Indications	Side Effects	Comments	References
		anemia, hemolytic anemia, and hemolysis in patients with G6PD defi ciency		
Quinacrine 100 mg[c]	Giardiasis	GI: nausea, anorexia, and vomiting Headache, toxic psychosis, hepatitis, and aplastic anemia	Avoid in pregnancy, psychosis, and psoriasis	9, 12, 16
Quinidine gluconate 500 mg base/mL; 10 mL	Acute malaria	GI: nausea, vomiting, and diarrhea Card: hypotension, widening of QRS and QT on ECG, and heart block	Administration of IV quinidine requires close monitoring; should normally monitor ECG and all vital signs	9, 16, 48, 49, 52
Quinine sulfate 325-mg and 650-mg tablets	Acute malaria	Cinchonism: flushing, dizziness, nausea, vomiting, and diarrhea (levels over 10 mcg/mL [mg/L; 31 µmol/L]) Card: hypotension and widening of QRS complex Hemat: hemolysis, leukopenia, thrombocytopenia	When drug is administered IV, it should be administered by slow infusion (600 mg over 8 hours); close monitoring of vitals and ECG *Avoid use:* IM administration	9, 16, 48, 49, 52, 75

Card, cardiologic; Derm, dermatologic; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase; Hemat, hematologic; IND, investigational new drug.

[a]Investigational new drug from Centers for Disease Control and Prevention, Atlanta, GA 30333 (404-639-3670).

[b]Atovaquone 62.5 mg/proguanil 25 mg (Malarone), pediatric strength.

[c]Investigational drugs obtained from Panorama Compounding Pharmacy, 6744 Balboa Blvd, Van Nuys, CA 91406 (800-247-9767).

Available from CDC drug service, Centers for Disease Control and Prevention, Atlanta, GA 30333

(404-639-3670).

Evaluation of Therapeutic Outcomes

Diarrhea will stop within a few days, although it may take 1 to 2 weeks in some patients. Cyst excretion will cease within days. However, intestinal dysfunction (manifested as increased transit time) and radiologic changes (irregular thickening of the folds in the upper small intestine) may take a few months to resolve. Average parasitological cure rates at 1 to 4 weeks are above 90% for metronidazole (range 77%-100%) and tinidazole (range 80%-100%) and above 75% for nitazoxanide (range 64%-94%).[17,20] Patients who fail initial therapy should preferably be treated with a drug from a different class. Giardiasis can be prevented by good personal hygiene and by caution in food and drink consumption.

Cryptosporidiosis

Epidemiology and Etiology

The protozoa genus *Cryptosporidium* was the leading cause of waterborne outbreaks of GI illness in the United States in the past decade and caused almost 42,000 deaths worldwide in 2013.[2,21] Over 17,000 cryptosporidiosis cases were reported in 2011 and 2012.[22] *C. hominis* and *C. parvum* cause the majority of human cryptosporidiosis cases, but human infection with at least eight other *Cryptosporidium* species has been documented. Disease manifestations may differ based on the infecting species. Each of these species is morphologically similar under microscopy. Thus, serologic and molecular methods must be used to distinguish between each subtype.

Pathophysiology and Clinical Presentation

Like giardiasis, cryptosporidiosis primarily occurs when *Cryptosporidium* oocytes are ingested from fecally contaminated water or food. Oocytes excreted in the stool are fully mature and can immediately infect other hosts upon oral ingestion of less than 10 oocytes. The parasite's outer shell allows it to be extremely tolerant to chlorinated water and can remain viable up to 10 days in recreational pools.[22] Infected patients may shed infectious oocytes up to 60 days after diarrhea resolution.

Cryptosporidiosis causes prolonged diarrhea of 1 to 2 weeks and should be suspected in those with diarrhea lasting greater than 14 days (see Table e115-1). Prolonged infection causes malnutrition, inadequate nutrient absorption, and dehydration. Extraintestinal complications such as pancreatitis, cholestasis, hepatitis, and pulmonary cryptosporidiosis may occur in immunocompromised patients. A diagnosis may be made by oocyst visualization on trichrome, or modified acid fast staining, antigen detection, or molecular testing on stool specimens.[6] Stool antigen testing is most commonly used because these point-of-care tests are rapid, widely available, and have high specificity and sensitivity of approximately 90%.[23]

Treatment

Cryptosporidiosis treatment is limited at present.[24] Correction of fluid and electrolyte abnormalities remains essential. Only nitazoxanide is FDA-approved for treatment and its efficacy is suboptimal in HIV-infected patients. Nitazoxanide dosing for cryptosporidiosis is the same as giardiasis treatment (see Table e115-2). Randomized controlled trials have confirmed nitazoxanide benefits in adults and children without HIV including a decrease in mortality in malnourished children.[23] However, only a 33% increase in diarrhea resolution was documented compared to placebo.[23] No improvement was observed in HIV-infected patients who received nitazoxanide, but did not also receive effective antiretroviral therapy.[25] As a result, it is imperative that HIV-infected patients with cryptosporidiosis receive antiretroviral therapy as the mainstay of therapy in addition to antiparasitic therapy.[26] Other drugs that may have activity against cryptosporidium, but lack robust clinical data include paromomycin, azithromycin, rifaximin, rifabutin, and HIV protease inhibitors. Guidelines for treating cryptosporidiosis in HIV-infected adults recommend antimotility agents such as tincture of opium and loperamide.[26]

Evaluation of Therapeutic Outcomes

Rehydration, correction of electrolyte abnormalities, restoration of nutritional deficiencies, and resolution of diarrhea are key therapeutic outcomes. Antiparasitic therapy alone is not curative in immunosuppressed patients. As such, HIV-infected patients should be started on antiretrovirals and CD4+ T cell counts may be followed. In solid organ or stem cell transplant patients, immunosuppression should be minimized as much as possible. Since cryptosporidiosis outbreaks are the most commonly caused by recreational water contamination, severely immunosuppressed patients should avoid swimming or drinking untreated water.

Amebiasis

Epidemiology and Etiology

E. histolytica is the major causative organism in amebiasis. Invasive amebiasis is almost exclusively the result of *E. histolytica* infection. *E. histolytica* must be differentiated from *E. dispar* and *E. moshkovskii* because the latter are associated with an asymptomatic carrier state. *E. dispar* is considered nonpathogenic, while the status of *E. moshkovskii* remains to be defined.[9,11] Although *E. histolytica* and *E. dispar* are indistinguishable morphologically on microscopy, monoclonal antibodies have been used to separate the two.[12]

Since older epidemiologic studies have relied on microscopy to diagnose amebiasis cases, past prevalence estimates vary widely. Some experts have adjusted World Health Organization estimates from the late 1990s to suggest that worldwide amebiasis prevalence may be as high as 5 million.[6] According to the most recent data from the Global Burden of Disease Study, amebiasis caused an estimated 11,300 deaths and represented almost 1% of all deaths due to diarrheal illness in 2013.[2] *E. histolytica* infection in the United States is less common than other parasitic diseases. In the United States, the annual incidence of hospitalization due to amoebic liver abscess is approximately 1.4 per million patients, has decreased each year, and most commonly affects young Hispanic men living in

southwestern states along the Mexican border.[27]

Pathophysiology and Clinical Presentation

E. histolytica is endemic in developing countries and at-risk individuals include immigrants and travelers from tropical climates. Infection occurs when one ingests food or water contaminated with *E. histolytica* cysts. *E. histolytica* invades mucosal cells of colonic epithelium, producing necrotizing ulcers in the submucosa.[9,11,12] The trophozoite has a cytolethal effect on cells through a toxin. If the trophozoite gets into the portal circulation, it will be carried to the liver, where it produces abscess and periportal fibrosis.[9,11,12] Amebic ulcerations can affect the colon, perineum, and genitalia, and abscesses may occur in the lung and brain.

The most frequent clinical manifestations of the disease are GI, but liver abscess may also occur (see **Table e115-1**). *E. histolytica* infection can cause dysentery, amebic colitis, intestinal ameboma, and invasive disease.[6] Amebic liver abscesses can spread to the lungs and pleura.[11,12] Pericardial infections, although rare, may be associated with extension of the amebic abscess from the left lobe of the liver. Erosion of liver abscesses also present as peritonitis.[11,12]

Review of the patient's history and recent travel should be strongly emphasized. Intestinal amebiasis is diagnosed by demonstrating *E. histolytica* cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by sigmoidoscopy. 3 Stool sample analysis is insensitive and does not distinguish between *E. histolytica* and the nonpathogenic *E. dispar* or *E. moshkovskii*. As a result, serologic detection assays are required to diagnose *E. histolytica* infection. FDA-approved stool enzyme immunoassays have sensitivities and specificities that range from 93% to 100%.[14] Serum-based EIAs, immunoglobulin (Ig)G, and antibody detection tests have sensitivities greater than 92%, but may have specificity that ranges from 80% to 100%.[14] Endoscopy with scraping or biopsy may provide more definitive diagnosis where stool examinations do not provide adequate evidence.

When amebic liver abscess is suspected from initial physical examination and history, confirmatory diagnostic procedures will include serology and liver scans (using isotopes by ultrasound or computed tomography [CT]) or magnetic resonance imaging. Leukocytosis (more than 10,000/mm^3 [more than 10×10^9/L]) and an elevated alkaline phosphatase concentration (more than 75%) are common findings. In rare instances, needle aspiration of the hepatic abscess may be attempted using ultrasound guidance.[12]

Treatment

Different regimens have been suggested depending on the category of amebiasis: asymptomatic cyst passers, intestinal amebiasis, and amebic liver abscess. Treatment for each category may be found in Table e115-2. Electrolyte replacement, antibiotic therapy, and nutritional support are essential adjunctive treatment modalities. Large hepatic abscesses or amebic pericarditis may require needle aspiration, percutaneous catheter drainage, or, rarely, surgery before drug therapy.[11,12] Most regimens require a combination of drugs administered concurrently or sequentially.[11,12]

4 Metronidazole and tinidazole are tissue-acting agents; whereas, paromomycin, iodoquinol, and diloxanide furoate are luminal amebicides. A systemic agent may be so well absorbed that only small amounts of the drug stay in the bowel, which might prove ineffective as a luminal agent. A luminal-acting agent, on the other hand, may be too poorly absorbed to be effective in the tissue. In the asymptomatic cyst passer, it is necessary to eradicate the causative agent from the lumen to prevent intestinal amebiasis or the development of amebic liver abscess. Drug effectiveness may be monitored by stool examination, although the enzyme-linked immunosorbent assay (ELISA) test should be used to verify eradication of *E. histolytica*.

Asymptomatic cyst passers and patients with mild intestinal amebiasis should receive one of the following luminal agents: paromomycin, iodoquinol, or diloxanide furoate 500 mg three times daily for 10 days.[28,29] Diloxanide furoate is not commercially available in the United States, but may be obtained from a compounding pharmacy or Abbott India Ltd.[23] Paromomycin is the preferred luminal agent in pregnant patients. Patients with severe intestinal disease or liver abscess should receive metronidazole or tinidazole followed by a course of one of the luminal agents indicated earlier.[28]

Evaluation of Therapeutic Outcomes

Follow-up in patients with amebiasis should include repeat stool examination, serology, colonoscopy (for colitis), or CT (for liver abscess) between days 5 and 7, at the end of the course of therapy, and a month after the end of therapy. Most patients with either intestinal amebiasis or colitis will respond in 3 to 5 days with amelioration of symptoms. Patients with liver abscesses may take from 7 to 10 days to respond. Patients not responding during this period may require aspiration of abscesses or exploratory laparotomy. Serial liver scans have demonstrated healing of liver abscesses over 4 to 8 months after adequate therapy.[12]

Travelers and tourists visiting an epidemic area should avoid local tap water, ice, salads, and unpeeled fruits. Water can be disinfected by the use of iodine (tincture of iodine or commercial sources: Potable Aqua tablet [Wisconsin Pharmacal] or 5%-10% acetic acid), but boiled water is probably the safest. An alternative or additional measure may be to carry a portable water purifier (such as MSR Mini Works Ex Water Filter). Because food handlers in Asia and Latin America may be a source of amebiasis, travelers should avoid eating at food stalls and open markets.

Chagas Disease (American Trypanosomiasis)

Epidemiology and Etiology

Trypanosoma brucei gambiense, *T. brucei*, and *T. brucei rhodesiense* are protozoan parasites that cause African trypanosomiasis (sleeping sickness) and *T. cruzi* is the agent that causes American trypanosomiasis (Chagas disease).[11,12] African trypanosomiasis is transmitted by various species of tsetse fly belonging to the genus *Glossina*; while Chagas disease is transmitted by a number of reduviid bug species (*Triatoma infestans*, *Rhodnius prolixus*) that live in wall cracks of houses in rural areas of North, Central, and South America.[11,12] The reduviid bug is infected by sucking blood from

animals (eg, opossums, dogs, and cats) or humans infected with circulating trypomastigotee. Further discussion of this subject will focus on American trypanosomiasis.

Chagas disease is also considered a neglected parasitic infection by the CDC.[7,8] Over 10,000 deaths due to Chagas disease occurred globally in 2013 and approximately 300,000 infected patients reside in the United States.[2,64] The majority of *T. cruzi* infections occur in Latin America where over 5.7 million patients were infected in 2010 with over 15% from Mexico.[65,66] Thus, Latin American immigrants are thought to be at highest risk for Chagas disease in the United States.

Pathophysiology and Clinical Presentation

In chronic trypanosomiasis, 20% to 30% of patients present with cardiomyopathy and heart failure (see Table e115-1).[67,68,69] Electrocardiograms (ECGs) are usually abnormal, demonstrating extrasystoles, first-degree heart block, right bundle-branch block, and other serious conduction disturbances.[68] Degeneration of the autonomic ganglia in the smooth muscle of the esophagus and colon leads to uncoordinated peristalsis. The end result is "megasyndromes" of affected organs.[67,68,69] Penetration of the central nervous system (CNS) results in meningoencephalitis, strokes, seizures, and focal paralysis.

A history to verify the possible exposure to *T. cruzi* should be an important initial diagnostic workup. Recovery of *T. cruzi* is definitive, but this is not always possible, especially in chronic disease. Positive serologic tests using the indirect immunofluorescent antibody test and ELISA may be diagnostic for the disease. A PCR test has also been used for diagnosis of *T. cruzi* and may be best used for early detection in acute infection or in monitoring for reactivation.[69] Specimens may be sent to the CDC for testing. All candidates from an endemic area for Chagas disease who are candidates for transplantation should be tested for *T. cruzi*.[69]

Treatment

All patients with chronic Chagas should receive treatment except elderly patients with irreversible cardiomyopathy.[68] 5 The drugs that have been used to treat *T. cruzi* infections include benznidazole (Rochagan) and nifurtimox (Lampit, Bayer 2502), but are not currently approved by the FDA.[67,68,69] Both are available from the CDC under an Investigational New Drug program. Clinicians should contact the CDC by email at parasites@cdc.gov or at 410-718-4745, 404-639-3670, or 770-488-7100 for further information. Benznidazole may be preferred based on its improved tolerability over nifurtimox. Approximately 30% to 50% of benznidazole-recipients experience allergic dermatitis.[67,68] Half of patients receiving nifurtimox will discontinue therapy due to adverse effects, which include gastrointestinal disturbances (anorexia, nausea, vomiting), CNS toxicity (headache, vertigo, insomnia), myalgias, and peripheral neuropathy.[69,70]

Evaluation of Therapeutic Outcomes

Clinical Controversy...

Unfortunately, reliable tests of cure are currently unavailable because serologic markers used to diagnose Chagas disease may remain positive for years after completion of therapy.[68,69] While quantitative PCR results may become a useful monitoring tool, data supporting its use are lacking at present. Patients should receive annual 12-lead ECG evaluations regardless of the extent of cardiac involvement on presentation.[68]

MALARIA

Malaria represents the most devastating disease in terms of human suffering and economics. Nearly half the world's population or an estimated 3.3 billion people are at risk of malaria with 1.2 billion at high risk.[46] Between 124 and 283 million infections and approximately 855,000 deaths were estimated to have occurred in 2013.[2,46] Malaria was the third leading cause of infection-related death in children younger than 5 years with an estimated 456,000 deaths occurring in this global pediatric population in 2013.[1] In the United States, over 99% of malaria cases are imported and are preventable.[47] The primary reasons for malaria infection and death are failure to take chemoprophylaxis, inappropriate chemoprophylaxis, delay in seeking medical care, and misdiagnosis.[47]

Epidemiology and Etiology

Malaria is transmitted by the bite of an infected *Anopheles* mosquito that introduces the sporozoites (tissue parasites) of the plasmodia (*Plasmodium falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*) into the bloodstream. The asexual reproduction stage develops in humans, whereas the sexual stage occurs in the mosquito.[11,12] The sporozoites invade parenchymal hepatocytes, multiply in stages referred to as *exoerythrocytic stages*, and become hepatic vegetative forms or schizonts. Schizonts rupture to release daughter cells, or merozoites, that then infect erythrocytes.

P. falciparum and *P. malariae* remain in the primary exoerythrocytic stage in the liver for about 4 weeks before invading erythrocytes, whereas *P. vivax* and *P. ovale* can exist in the liver in the latent exoerythrocytic form for extended periods and, therefore, infected subjects can experience relapses. The merozoites that invade the erythrocytes develop sequentially into ring forms, trophozoites, schizonts, and finally, merozoites, which can invade other erythrocytes or can develop into gametocytes, which undergo the sexual stage in the *Anopheles* vector. Because erythrocytic forms never reinvade the liver without developing into sporozoites in the vector, malaria infections from transfusion never result in the exoerythrocytic or "liver" form.[9,12] *P. falciparum* can result in high levels of parasitemia because of its ability to invade erythrocytes of all ages, unlike *P. vivax* and *P. ovale*, which only invade young cells.[12]

The exact geographic distribution of the various species is not well documented. *P. vivax* is more prevalent in India, Pakistan, Bangladesh, Sri Lanka, and Central America; whereas *P. falciparum* is predominant in Africa, Haiti, Dominican Republic, the Amazon region of South America, and New Guinea. Most of the infections with *P. ovale* occur in Africa, and the distribution of *P. malariae* is considered worldwide.[48,49,50] Determining species geographic distribution is important for choosing

chemoprophylaxis and empiric treatment regimens.

Pathophysiology and Clinical Presentation

The erythrocytic phase causes extensive hemolysis, which results in anemia and splenomegaly. The most serious complications usually are associated with *P. falciparum* infections.[50] Infants and children younger than 5 years and pregnant women are at high risk for severe complications from falciparum malaria.[50,51] The complications associated with falciparum malaria are primarily a result of the high parasitemia and the ability of the parasites to sequester in capillaries and postcapillary vessels of organs such as the brain and the kidney. Tissue hypoxia from anemia, together with *P. falciparum*-parasitized red blood cell adherence to endothelial cells in capillaries, likely contribute to extensive vascular disease and severe metabolic effects.[11,12] *P. malariae* is implicated in immune-mediated glomerulonephritis and nephrotic syndrome (Table e115-3).[11,12]

TABLE e115-3 Clinical Presentation of Malaria[12,41]

Initial presentation
Nonspecific fever, chills, rigors, diaphoresis, malaise, vomiting, orthostatic hypotension, electrolyte abonormalities
Erythrocytic phase
Prodrome: headache, anorexia, malaise, fatigue, and myalgia
Nonspecific complaints such as abdominal pain, diarrhea, chest pain, and arthralgia
Paroxysm: high fever, chills, and rigor
Cold phase: severe pallor and cyanosis of the lips
Hot phase: fever between 40.5°C (104.9°F) and 41°C (105.8°F)
Sweating phase: Follows hot phase by 2-6 hours where fever resolves
Marked fatigue and drowsiness, warm, dry skin, tachycardia, cough, severe headache, nausea, vomiting, abdominal pain, diarrhea, and delirium
Lactic acidosis and hypoglycemia (with falciparum malaria)
Anemia and splenomegaly
P. falciparum infections
Hypoglycemia, acute renal failure, pulmonary edema, severe anemia, thrombocytopenia, high-output heart failure, cerebral congestion, seizures and coma, and adult respiratory syndrome

The primary goal in the management of malaria is the rapid diagnosis of the *Plasmodia* spp. by blood smears (repeated every 12 hours for 3 days) so as to initiate timely antimalarial therapy to eradicate

the infection within 48 to 72 hours and to avoid complications such as hypoglycemia, pulmonary edema, and renal failure that are responsible for increased mortality in malaria. To ensure a positive diagnosis, thick and thin blood smears should be obtained every 12 to 24 hours for 3 consecutive days.[12,50] The presence of parasites in the blood 3 to 5 days after initiation of therapy suggests drug resistance. Point-of-care rapid detection tests that require finger-prick blood are widely available. These antibody-based tests detect *P. falciparum* histidine-rich protein 2, *Plasmodium*-specific lactate dehydrogenase, or aldolase antigens and have high sensitivity and specificity.[50,52] However, microscopy remains the gold standard for malaria diagnosis.

Chemoprophylaxis and Prevention

Along with nonpharmacologic measures to avoid mosquito bites (diethyltoluamide [DEET]- or picaridin-containing repellants use, full coverage clothing, window screens, insecticide-impregnated nets, and air-conditioned rooms), chemoprophylaxis is recommended for all those travelling to areas where malaria exposure is possible. Non-adherence to chemoprophylaxis regimens is a significant risk factor for malaria infection.[47] Specific antimalarial recommendations vary depending on local susceptibility patterns and can be found in the CDC Yellow Book or on the CDC Web site.[53] Chloroquine has been the recommended drug for malaria chemoprophylaxis, but clinicians have increasingly prescribed alternative antimalarial drugs such as atovaquone-proguanil, doxycycline, primaquine, and mefloquine because these regimens retain effectiveness in areas where chloroquine-resistant *P. falciparum* exposure is likely (**Table e115-4**). Antimalarial drugs that lack activity against the liver stage or preerythrocytic stage of infection must be given during and at least four weeks after leaving an endemic area.[50,53,54]

TABLE e115-4 Chemoprophylaxis of Malaria[41,45,46]

	Adults	Children	Notes
Chloroquine-susceptible area			
Chloroquine	300 mg base orally once weekly	5 mg/kg base orally once weekly (max 300 mg/dose)	Begin 1-2 weeks before travel. Continue 4 weeks after leaving.
Hydroxychloroquine	310 mg base orally once weekly	5 mg/kg base orally once weekly (max 310 mg/dose)	
Mefloquine	228 mg base orally once weekly	≤9 kg: 4.6 mg/kg base orally once weekly 9-19 kg: ¼ tablet orally once weekly	Begin ≥2 weeks before travel. Continue 4 weeks after leaving. Contraindicated in those with psychiatric disorders. Caution in those with cardiac conduction abnormalities.

	Adults	Children	Notes
		19-30 kg: ½ tablet orally once weekly 30-45 kg: ¾ tablet orally once weekly >45 kg: 1 tablet orally once weekly	
Chloroquine-resistant area			
Atovaquone-progaunil Adult tablet: 250 mg/100 mg Pedi tablet: 62.5 mg/25 mg	1 adult tablet orally daily	5-8 kg: ½ pediatric tablet orally daily 8-10 kg: ¾ pediatric tablet orally daily 10-20 kg: 1 pediatric tablet orally daily 20-30 kg: 2 pediatric tablets orally daily 30-40 kg: 3 pediatric tablets orally daily >40 kg: 1 adult tablet orally daily	Begin 1-2 days before travel. Continue 7 days after leaving. Contraindicated in those with a CrCl < 30 mL/min.
Doxycycline	100 mg orally daily	≥8 years: 2.2 mg/kg orally daily (max 100 mg/dose)	Begin 1-2 days before travel. Continue 4 weeks after leaving. Contraindicated in pregnancy.
P. vivax endemic areas			
Primaquine	30 mg base orally once daily	0.5 mg/kg base orally daily (max 30 mg/dose)	Begin 1-2 days before travel. Continue 7 days after leaving. Contraindicated in G6PD deficiency and pregnancy.

Treatment

Malaria treatment has changed in recent years with the availability of artemisinin-based antimalarials. Only artemether-lumefantrine is approved for use in the United States, but parenteral artesunate can be obtained through an Investigational New Drug (IND) program.[55] Other artemisinin-based antimalarial drugs found worldwide include dihydroartemisinin-piperaquine, artesunate-amodiaquine, and artesunate-pyronaridine.[50] *P. falciparum* malaria is associated with serious complications, including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death. Careful monitoring of fluid status and hemodynamic parameters is mandatory. Either hemofiltration or hemodiafiltration is indicated in renal failure. In the past, those patients with severe illness including *P. falciparum* have received parenteral quinine as the drug of choice, but evidence from randomized controlled trials support the superiority of artesunate over quinine.[50,56] Artesunate is only available through an IND program in the United States. Clinicians should call the CDC Malaria Hotline at (770) 488-7788, (855) 856-4713, or (770) 488-7100 to obtain this drug or on the CDC Web site at http://www.cdc.gov/malaria/diagnosis_treatment/artesunate.html. Severe malaria is defined as those patients with a confirmed malaria diagnosis who also have one of the following: impaired consciousness, severe normocytic anemia, acute kidney injury, pulmonary edema, acute respiratory distress syndrome (ARDS), septic shock, disseminated intravascular coagulation (DIC), spontaneous bleeding, acidosis, hemoglobinuria, jaundice, seizures, or parasitemia of more than 5%.[55] Once a patient completes the artesunate regimen (**Table e115-5**), therapy should be completed with atovaqone-proguanil, doxycycline (clindamycin in pregnant women), or mefloquine.

TABLE e115-5 Treatment of Malaria[41,46]

	Adults	Children	Notes
Severe malaria			
Artesunate	2.4 mg/kg IV × 1, then at 12, 24, and 48 hours (may continue once daily if necessary)		Artesunate is only available under CDC IND protocol at 770-488-7788 or 770-488-7100
Quinidine gluconate	6.25 mg/kg base IV load over 1-2 hours × 1, then 0.0125 mg/kg/min base continuous IV infusion for at least 24 hours		
Uncomplicated *P. falciparum* or chloroquine-resistant			
Artemether-lumafantrine Tablet: 20 mg/120 mg	4 tablets orally twice daily × 3 days	5-15 kg: 1 tablet orally twice daily × 3 days 15-25 kg: 2 tablets orally twice daily ×	Second dose should be taken 8 hours after initial dose. Take with food or milk. Equal recommendation given in 2013 malaria guidelines to atovaquone- and quinine-based regimens.

	Adults	Children	Notes
		3 days 25-35 kg: 3 tablets orally twice daily × 3 days ≥35 kg: 4 tablets orally twice daily × 3 days	
Atovaquone-proguanil Adult tablet: 250 mg/100 mg Pedi tablet: 62.5 mg/25 mg	4 adult tabs orally daily × 3 days	5-8 kg: 2 pediatric tablets orally daily × 3 days 8-10 kg: 3 pediatric tablets orally daily × 3 days 10-20 kg: 1 adult tablet orally daily × 3 days 20-30 kg: 2 adult tablets orally daily × 3 days 30-40 kg: 3 adult tablets orally daily × 3 days >40 kg: 4 adult tablets orally daily × 3 days	Take with food or milk. Equal recommendation given in 2013 malaria guidelines to artemisinin- and quinine-based regimens.
Quinine sulfate plus: either doxycycline or clindamycin	542 mg base orally three times daily × 3-7 days 100 mg orally twice daily × 7 days 6.7 mg/kg/orally t id × 7 days	8.3 mg/kg base orally three times daily × 3-7 days ≥8 years: 2.2 mg/kg orally twice daily × 7 days 6.7 mg/kg/orally three times daily × 7 days	Equal recommendation given in 2013 malaria guidelines to artemisinin- and atovaquone-based regimens.

	Adults	Children	Notes
Mefloquine	648 mg base orally × 1, then 456 mg base orally 6-12 hours later	13.7 mg/kg base orally × 1, then 9.1 mg/kg base orally given 6-12 hours later	High rate of severe neuropsychiatric reactions.
Uncomplicated chloroquine-susceptible malaria			
Chloroquine	600 mg base orally × 1, then 300 mg base orally at 6, 24, 48 hours	10 mg/kg base orally × 1, then 5 mg/kg base orally at 6, 24, 48 hours	May also use above regimens.
Hydroxychloroquine	620 mg base orally × 1, then 310 mg base orally at 6, 24, 48 hours	10 mg/kg base orally × 1, then 5 mg/kg base orally at 6, 24, 48 hours	May also use above regimens.
P. vivax or P. ovale malaria			
Primaquine	30 mg base orally daily × 14 days	0.5 mg/kg base orally daily × 14 days	Add to above regimens to eradicate dormant liver hypnozoites; Contraindicated in G6PD deficiency

If intravenous quinidine gluconate is used, close monitoring of the ECG and other vital signs (eg, hypotension, QT interval prolongation, and hypoglycemia) is required. Once parasite density is less than 1% and the patient can take oral medications, parenteral quinidine should be changed to oral quinine plus doxycycline to complete a total of 7 days of therapy.[55] Children younger than age 8 and pregnant women should receive clindamycin instead of doxycycline.[55]

In an uncomplicated attack of malaria due to *P. falciparum* or a chloroquine-resistant species, artemether-lumefantrine, atovaquone-progaunil, quinine plus doxycycline, or quinine plus clindamycin regimens are recommended (see Table e115-5). In uncomplicated infection due to chloroquine-susceptible malaria, the recommended regimen is chloroquine or hydroxychloroquine for 2 days. It should be noted that patients with *P. vivax* and *P. ovale* infections should also be given a 14-day course of primaquine to eradicate dormant hypnozoites found in the liver (radical cure).[50]

Malarial infection does not produce immunity in patients, and active research has been initiated to develop a malaria vaccine.[57,58,59] A vaccine that blocks the entry of sporozoites into the liver cells will prevent malaria at this stage. However, immunity to sporozoites does not protect the host against parasites in the erythrocytic cycle. Infective sporozoites of *P. falciparum* are covered by a polypeptide, circumsporozoite protein. Isolation and identification of the gene encoding for this circumsporozoite

protein have led to the development of a monoclonal antibody; *P. falciparum* sporozoite vaccine (RTS,S/AS01). RTS,S/AS01 is farthest along in its development among other candidate malaria vaccines and specifically targets *P. falciparum*. Phase 3 trials have enrolled over 15,000 infants and young children. Vaccine efficacy against clinical malaria 6- to 12 week-old infants was approximately 27% and was 39% in children between ages 5 and 17 months.[57,58,59] Low efficacy of the vaccine may be due to mismatched sporozoite protein alleles.[60] The World Health Organization has not yet recommended the RTS,S/AS01 malaria vaccine for use.

Evaluation of Therapeutic Outcomes

Increasing incidence of artemisinin-resistant and chloroquine-resistant malaria found in Western Cambodia, Thailand, and Myanmar appear to be a great threat to malaria control.[61,62,63] Blood smears should be checked every 12 hours until parasitemia is less than 1%. For severe infection, resolution of fever should take place between 36 and 48 hours after initiation of parenteral therapy and the blood should be clear of parasites in 5 days.[12,50] Patients receiving intravenous quinidine should have a central venous catheter to follow fluid status and the ECG should be monitored closely. Quinidine infusion should be slowed temporarily or stopped if ECG shows a QT interval of greater than 0.6 seconds, an increase in the QRS complex to greater than 50%, or hypotension unresponsive to fluid challenge results. The suggested quinidine levels should be maintained at 3 to 7 mg/L (9-22 µmol/L).[12] Hypoglycemia that is associated with *P. falciparum* should be checked and corrected with dextrose infusions.[12]

HELMINTHIC DISEASES

Helminthic infections are not endemic in the United States, but the infection prevalence may be as high as 1.7 billion in Asia, Latin America, the Caribbean, and Sub-Saharan Africa.[30] Most intestinal helminthic infections may not be associated with clearly defined manifestation of disease, but they can cause significant pathology.[9,11,12] One factor that determines the pathogenicity of helminths is their population density. Light infections may be fairly well tolerated, whereas high populations of intestinal helminths can result in predictable disease presentations. In the United States, these infections are seen most frequently in recent immigrants from Southeast Asia, the Caribbean, Mexico, and Central America.[30] Other populations that have a high risk of infestation include institutionalized patients (both young and elderly), preschool children in daycare centers, residents of Indian reservations, and in men who have sex with men.[12] Certain conditions and drugs (fever, corticosteroids, and anesthesia) can cause atypical localization of worms.[12]

Strongyloidiasis

Epidemiology and Etiology

Strongyloidiasis is caused by the nematode *Strongyloides stercoralis*, which has a worldwide distribution and is predominantly prevalent in South America (Brazil and Columbia) and in Southeast

Asia. Strongyloidiasis is primarily seen among institutionalized populations (residences for developmental disabilities or psychiatric illness) and immunocompromised individuals (patients with HIV, AIDS, and hematologic malignancies).[31,32,33,34]

Pathophysiology and Clinical Presentation

The worm is usually found in the upper intestine where the eggs are deposited and hatch to form the rhabditiform larvae. The rhabditiform larvae (male and female) migrate to the bowel where they may be excreted in the feces. If excreted in the feces, the larvae can evolve into either one of two forms after copulation: (a) free-living noninfectious rhabditiform larvae or (b) infectious filariform larvae.[9,11] The filariform larvae can penetrate host skin, travel to the lungs via the bronchi and glottis, and make their way to the small intestine. At times, the filariform larvae may not pass out in the feces but instead migrate to the lungs and produce progeny, a process called autoinfection. This can result in hyperinfection (ie, increased number of larvae in intestine, lungs, and other internal organs), especially in immunocompromised hosts.[32,33,34]

Symptoms with acute infection may appear with localized pruritic rash, but heavy infestations can produce eosinophilia (10%-15%), diarrhea, abdominal pain, and intestinal obstruction (**Table e115-6**).[12,31]

TABLE e115-6 Clinical Presentation of Helminthic Diseases

	Strongyloides[61]	Cysticercosis[63,65]	Toxocariasis[68,69]
GI	Abdominal pain, bloating, nausea, constipation, and small bowel obstruction	Abdominal pain, nausea, diarrhea	Hepatomegaly or splenomegaly
Cardiopulmonary	Cough, wheezing, pleural effusion, chest pain, and dyspnea	Cardiopulmonary symptoms are absent	Cough, fever, wheezing
Dermatologic/hematologic	Pruritic linear streaks of lower thighs and buttocks and eosinophilia	Painless nodules on arms, chest, legs, and myalgia	Urticaria, nodules, eosinophilia with leukocytosis
CNS/Ophthalmic	Headache, altered mental status, and meningitis	Headache, intracranial hypertension, hydrocephalus, and seizures	Unilateral vision loss, chorioretinal granuloma in the posterior pole

CNS, central nervous system; GI, gastrointestinal.

7 Administration of corticosteroids or other immunosuppressive drugs to an infected individual can result in hyperinfections and disseminated strongyloidiasis.[34] Diagnosis of strongyloidiasis is made by identification of the rhabditiform larvae in stool, sputum, duodenal fluid, and cerebrospinal fluid, by

small bowel biopsy specimens, or by antigen testing (ELISA assay).[35]

Treatment

The drug of choice for strongyloidiasis is oral ivermectin and the alternative is albendazole (**Table e115-7**).[31,32,36] In a patient with hyperinfection or disseminated strongyloidiasis, immunosuppressive drugs should be discontinued and ivermectin treatment should be prolonged until all symptoms are resolved (duration of 5-14 days). Patients should be tested periodically to ensure the elimination of the larvae.[34] Individuals from endemic areas, who are candidates for organ transplantation, must be screened for *S. stercoralis*.

TABLE e115-7 Treatment of Helminthic Diseases

	Primary	Alternative
Strongyloides[61]	Ivermectin 200 mcg/kg/day orally daily × 2 days	Albendazole 400 mg orally twice daily × 7 days
Neurocysticercosis[63,64]	Albendazole 400 mg orally twice daily × 10-14 days	Albendazole 15 mg/kg/day + praziquantel 50 mg/kg/day × 10-14 days
Toxocariasis[68,69]	Albendazole 400 mg orally twice daily × 5-14 days	Mebendazole 100-200 mg orally twice daily × 5-14 days

Cysticercosis and Neurocysticercosis

Epidemiology and etiology

Cysticercosis is considered a neglected parasitic infection by the CDC.[7,8] From 1998-2011, an estimated 33,000 cysticercosis-related hospitalizations were documented in the United States.[38] In disease-endemic countries, neurocysticercosis is the leading cause of acquired epilepsy. The prevalence of neurocysticercosis in patients presenting to US emergency departments with seizures is estimated to be approximately 2%.[40] In the United States, the highest incidence of cysticercosis has been reported in immigrants from Mexico.[39,40] Comprehensive US epidemiologic data is scarce because cysticercosis is only a reportable disease in Arizona, California, New Mexico, Oregon, and Texas.

Pathophysiology and Clinical Presentation

Tapeworm infection caused by *Taenia solium* is a result of ingestion of poorly cooked pork that contains the larvae or cysticercus.[11,12] Cysticercus, when released from the contaminated meat by host digestive juices, matures into the adult tapeworm and attaches to the host jejunum. Cysticercosis is a systemic disease caused by the larva of *T. solium* (oncosphere) and is usually acquired by ingestion of eggs in contaminated food or by autoinfection. The larvae can penetrate the bowel and migrate through the bloodstream to infect different organs including the CNS (neurocysticercosis).[7,8,40] The larvae matures in about 8 weeks and remain as a semitransparent, oval-shaped, fluid-filled bladder in tissues. Cysticercosis in most tissues may not produce major

symptoms and usually manifest as subcutaneous nodules, primarily in the arms, legs, and chest. However, penetration of the larval stage (cysticercus) into the CNS can produce hydrocephalus, intracranial hypertension, stroke, and seizure activity.[39,40]

The most serious complication of cysticercosis is invasion of the CNS, which results in neurocysticercosis. Neurocysticercosis can cause obstructive hydrocephalus, strokes, and seizures. Epileptic seizures (50%-80%) may be the presenting symptoms in patients with neurocysticercosis (see Table e115-6).[38,40] Clinical presentation, primarily seizure history, together with radiographic demonstration (CT and magnetic resonance imaging) of the cysticercus within the bladder or calcified cysts in the CNS, is diagnostic for neurocysticercosis.[38,40] Serologic diagnosis is made by the use of an enzyme-linked immunoelectrotransfer blot assay, which is considered highly sensitive and specific for cysticercosis.[38,40]

Treatment

Cysticercosis (excluding neurocysticercosis) is normally not treated. Three approaches to neurocysticercosis management include surgery, symptomatic relief with corticosteroids or antiepileptic drugs, and antihelminthic therapy. Patients with neurocysticercosis-related epilepsy generally have parenchymal brain cysts and should receive antiepileptic drugs, although evidence from randomized controlled trials is unavailable.[38]

Clinical Controversy…

Close collaboration with neurosurgery and/or neuroradiology specialists is required because approaches differ based on whether cysts are found in the brain parenchyma or extraparenchymal spaces. Even when the location is known, therapy remains controversial. 8 Antihelminthis therapy destroys parasites and may cause increased inflammation and worsening of neurocysticercosis symptoms. As a result, antihelminthic therapy is usually delayed until symptoms are controlled and corticosteroids are co-administered for the entire antiparasitic course of therapy. Dexamethasone at a dose of 0.1 mg/kg per day is usually given 1 day before antihelminthic therapy and tapered 1 to 2 weeks after antiparasitic treatment completion.[38] A randomized controlled trial suggested increased intraparenchymal cyst resolution with albendazole and praziquantel combination therapy compared to albendazole monotherapy.[39] While albendazole monotherapy in neurocysticercosis treatment has been unclear in the past, these new data further complicate the definitive role of antihelminthic therapy.

Toxocariasis

Epidemiology and Etiology

Toxocariasis is a parasitic disease caused by the nematode *Toxocara canis* (canine roundworm) and less commonly *T. cati* (feline roundworm) and is also on the CDC list of neglected parasitic diseases.[7,8,12] Since it is a zoonotic parasite, cases occur due to the large number of dogs and cats as household pets. United States *Toxocara* seroprevalence rates range from approximately 12% to 15%

using the National Health and Nutrition Examination Survey (NHANES III) data from 1988-1994.[41] The highest prevalence was found in non-Hispanic blacks, those living in poverty, and predominantly in southern and nonmetropolitan northeastern states.[42]

Pathophysiology and Clinical Presentation

Toxocara species infect dogs and cats and eggs are shed in feces into the environment. Transmission occurs when humans ingest viable ova in contaminated soil. Children are at highest risk because of poor hand hygiene and time spent in playgrounds or sandboxes.[43,44]

Toxocariasis most commonly affects children younger than 6 years and may present in three different ways: covert or common toxocariasis, ocular toxocariasis, and visceral larva migrans with the liver and lungs being most frequently affected (see Table e115-6). A significantly higher prevalence of *T. canis* infection has been observed in those with asthma suggesting that toxocariasis may contribute to the development of atopy.[45] A *Toxocara* ELISA is recommended for diagnosis and a titer greater than or equal to 1:32 has a 73% to 78% sensitivity and greater than 90% specificity for diagnosing ocular and visceral toxocariasis.[43,46]

Treatment

The antihelminthic drugs albendazole and mebendazole are recommended for toxocariasis (**Table e115-7**).[43,46] Neither drug is FDA-approved for this indication and the lack of large randomized controlled trials precludes definitive dosing and duration recommendations. Most sources recommend 5-day courses at standard doses. While the safety of albendazole in children younger than 6 years is unclear, World Health Organization recommends 200 mg doses for those at least 12 months of age. Mebendazole use is also limited in those younger than 2 years.

ECTOPARASITES

Lice

Epidemiology and Etiology

A parasite that lives on the outside of the body of the host is called an *ectoparasite*. Three types of human lice belong to two genera: *Pediculus* and *Phtirus*. *Pediculus humanus capitis* causes head lice and *Pediculus humanus corporis* causes body lice. *Phthirus pubis* is a crab louse that causes pubic lice.[71,72] The human louse is detectable to the human naked eye and measures approximately 2 to 3 mm in length. Reliable data on prevalence of lice in the United States are unavailable, but anecdotal reports estimate that direct and indirect costs due to head lice may be as high as $1 billion per year.[73] Using pediculicide sales estimates in the United States, over 6 million people per year may be affected.[71]

Pathophysiology and Clinical Presentation

Female lice deposit eggs on the hair. The eggs (or nits) remain firmly attached to the hair, and in about 10 days, the lice hatch to form nymphs, which mature in 2 weeks. Using both their piercing mouthparts and a pumping device, the larva and adults feed on the blood of the host. The body louse and head louse are essentially identical, although they live on different parts of the body. Unlike the head louse, which lives on the hair, the body louse is more frequently found on clothing of the infected host.

Pubic or crab lice are found on the hair around the genitals, although they can occur in other areas of the body (eg, eyelashes, beards, and axillae). Patients usually complain of severe pruritus from papular lesions produced by the bite of the louse. Hypersensitivity to foreign material injected by the lice can produce macular swellings and occasionally can lead to secondary bacterial infections.[71,72]

Treatment

9 For head lice, the American Academy of Pediatrics recommends either nonprescription 1% permethrin or pyrethrins plus piperonyl butoxide topical preparations as agents of choice unless local resistance to these agents is documented.[73] Permethrin is a derivative of the flowers of the plant *Chrysanthemum cinerariifolium*. The term *pyrethrin* is usually applied to several esters of chrysanthemic acid and pyrethric acid. Individuals who have a history of ragweed or chrysanthemum allergy should use pyrethrins with caution. The side effects reported with permethrin products are mild and include itching, burning, stinging, and tingling. Permethrin 1% is applied to the scalp after the hair has been dried following a shampooing. The scalp should be saturated with permethrin liquid, and a towel should be wrapped around the scalp to allow the application to stay on for 10 minutes. The hair then should be rinsed thoroughly. Permethrin and pyrethrins plus piperonyl butoxide should be used with nit combs because these agents are pediculocidal, but nonovidicidal.[71,72,73] To ensure complete eradication, especially of newly hatched lice, it may be necessary to repeat the application.

Clinical Controversy...

Given sporadic reports of lice resistance to permethrin and pyrethrins, prescription-only spinosad 0.9% topical suspension may become the drug of choice for head lice.[71] Randomized controlled trials have shown spinosad to be more effective than permethrin.[74] In addition to spinosad effectiveness in permethrin-resistant lice, nit combs are unnecessary because it kills both lice and their ova. Widespread use of spinosad as an alternative first-line agent may be limited by its prescription-only availability and higher cost compared to over-the-counter permethrin.

Other topical preparations for lice are 0.5% malathion, 5% benzyl alcohol, and 0.5% ivermectin.[71,72,73,74] Lindane 1% shampoo is no longer recommended.[71,72,73] For the relief of pruritus, a soothing lotion of calamine liniment or lotion with 0.1% menthol may be used. Other members of the family should be treated. All bedding and clothes should be sterilized by boiling or washing in the hot water cycle of the washing machine to avoid reinfections. Seams of clothes should be examined to verify that all organisms are eradicated. An ocular lubricant (eg, Lacri-Lube S.O.P.) applied twice daily may be used to remove crab louse infection of the eyelids.

Scabies

Epidemiology and Etiology

The worldwide prevalence of scabies was estimated at 100 million according to the Global Burden of Disease Study 2010.[75] While data from North America are lacking, prevalence ranged from less than 2.2% in European countries to as high as 15% and 30% in Central and South American coutnries.[75] Scabies is caused by the itch mite *Sarcoptes scabiei*, which affects both humans and animals. Mange in domestic animals is caused by the same organism. *S. scabiei* burrows under the skin and is transmitted through direct skin-to-skin contact for 15 to 20 minutes.[76,77]

Pathophysiology and Clinical Presentation

Infection usually affects the interdigital and popliteal folds, axillary folds, the umbilicus, and the scrotum. Patients will complain of severe itching and an inability to sleep and may have excoriations in the interdigital web spaces, wrists, elbows, buttocks, groin, and scalp with the face and neck unaffected.[76,77] Excoriations may lead to secondary bacterial infections. The diagnosis is made by looking for burrows formed by the mite and taking skin scrapings, which will demonstrate the mite on a wet mount. Typically, 10 to 15 mites may be present.

Treatment

These infections cause a great deal of discomfort and distress to patients and families. Therefore, the goals of therapy are to eradicate the infestations rapidly, to institute symptomatic treatment, and to provide counseling and reassurance. The treatment of choice remains permethrin 5% cream despite concerns of increased resistance.[76,77,78] To initiate the treatment, the skin should be scrubbed thoroughly in a warm soapy bath using a soft brush to remove all scabs. The lotion is then applied to the whole body, avoiding the face, mucous membranes, and eyes. The application should be left on for 8 to 14 hours before bathing. [10] A single application of 5% permethrin results in cure rates in greater than 90% of subjects with scabies at 14 and 28 days, but a second dose should be applied 1 week later because its ovicidal efficacy remains unclear.[71,78] All close contacts should be checked and treated appropriately.

Other agents used to treat scabies include topical crotamiton 10% (Eurax) and oral ivermectin (Stromectol) 200 mcg/kg as a single dose, which may be repeated in 2 weeks.[76,77,78,79] Crotamiton and oral ivermectin may be used in patients who have hypersensitivity to permethrin preparations. Topical corticosteroids and antihistamines may be used to decrease pruritus.

Chapter 116: Urinary Tract Infections and Prostatitis

Elizabeth A. Coyle; Randall A. Prince

INTRODUCTION

KEY CONCEPTS

- 1 Urinary tract infections (UTIs) can be classified as uncomplicated and complicated. *Uncomplicated* refers to an infection in an otherwise healthy, premenopausal female who lacks structural or functional abnormalities of the urinary tract. Most often complicated infections are associated with a predisposing lesion of the urinary tract; however, the term may be used to refer to all other infections, except for those in the otherwise healthy, premenopausal adult female.

- 2 Recurrent UTIs are considered either reinfections or relapses. Reinfection usually happens more than 2 weeks after the last UTI and is treated as a new uncomplicated UTI. Relapse usually happens within 2 weeks of the original infection, and is a relapse of the original infection either because of unsuccessful treatment of the original infection, a resistant organism, or anatomical abnormalities.

- 3 Majority (75%-90%) of uncomplicated UTIs are caused by *Escherichia coli* and the remainder are caused primarily by *Staphylococcus saprophyticus*, *Proteus* spp., and *Klebsiella* spp. Complicated infections may be associated with other gram-negative organisms and *Enterococcus faecalis*.

- 4 Symptoms of lower UTIs include dysuria, urgency, frequency, nocturia, and suprapubic heaviness, whereas upper UTIs involve more systemic symptoms such as fever, nausea, vomiting, and flank pain.

- 5 Significant bacteriuria traditionally has been defined as bacterial counts of greater than 10^5 organisms (colony-forming unit [CFU])/mL (10^8 CFU/L) of a midstream clean catch urine. However, this is too general and significant bacteriuria in patients with symptoms of a UTI may be defined as greater than 10^2 organisms (CFU)/mL (10^5 CFU/L).

- 6 The goals of treatment of UTIs are to eradicate the invading organism(s), prevent or treat systemic consequences of infections, prevent the recurrence of infection, and prevent antimicrobial resistance.

- 7 Uncomplicated UTIs can be managed most effectively with short-course therapy (3 days) with either trimethoprim–sulfamethoxazole, one dose of fosfomycin, or 5 days of nitrofurantoin. Fluoroquinolones should be reserved for suspected pyelonephritis or complicated infections.

- 8 In choosing appropriate antibiotic therapy, practitioners need to be cognizant of antibiotic resistance patterns, particularly to *E. coli*. Trimethoprim–sulfamethoxazole has diminished activity against *E. coli* in some areas of the country, with reported resistance in some areas greater than 20%.

- 9 Acute bacterial prostatitis can be managed with many agents that have activity against the causative organism. Chronic prostatitis requires prolonged therapy with an agent that penetrates the prostatic tissue and secretions. Therapy with fluoroquinolone or trimethoprim–sulfamethoxazole is preferred for up to 6 weeks.

Infections of the urinary tract represent a wide variety of syndromes, including urethritis, cystitis, prostatitis, and pyelonephritis. Urinary tract infections (UTIs) are the most commonly occurring bacterial infections and one of the most common reasons for antibiotic exposure, especially in females of childbearing age.[1,2,3] Approximately 60% of females will develop a UTI during their lifetime with about one-fourth having a recurrence within a year.[2] Infections in men occur much less frequently until the age of 65 years at which point the incidence rates in men and women are similar.

A UTI is defined as the presence of microorganisms in the urinary tract that cannot be accounted for by contamination. The organisms present have the potential to invade the tissues of the urinary tract and adjacent structures. Infection may be limited to the growth of bacteria in the urine, which frequently may not produce symptoms. A UTI can present as several syndromes associated with an inflammatory response to microbial invasion and can range from asymptomatic bacteriuria (ASB) to pyelonephritis with bacteremia or sepsis.

UTIs are classified by lower and upper UTIs. Typically, they have been described by anatomic site of involvement. Lower tract infections correspond to cystitis (bladder), and pyelonephritis (an infection involving the kidneys) represents upper tract infection.

1 Also, UTIs are designated as uncomplicated or complicated. Uncomplicated infections occur in individuals who lack structural or functional abnormalities of the urinary tract that interfere with the normal flow of urine or voiding mechanism. These infections occur in premenopausal females of childbearing age (15-45 years) who are otherwise normal, healthy individuals. Infections in males generally are not classified as uncomplicated because these infections are rare and most often represent a structural or neurologic abnormality.

Complicated UTIs are usually the result of a predisposing lesion of the urinary tract, such as a congenital abnormality or distortion of the urinary tract, a stone, indwelling catheter, prostatic

hypertrophy, obstruction, or neurologic deficit that interferes with the normal flow of urine and urinary tract defenses. Complicated infections occur in both genders and frequently involve the upper and lower urinary tract.

2 Recurrent UTIs in healthy nonpregnant women—two or more UTIs occurring within 6 months or three or more UTIs within 1 year—are a common problem. They are characterized by multiple symptomatic infections with asymptomatic periods occurring between each episode and may be either reinfections or relapses. Reinfections are caused by a different organism than originally isolated and account for the majority of recurrent UTIs. Relapses are the development of repeated infections with the same initial organism and usually indicate a persistent infectious source.[2]

ASB is a common finding, particularly among those 65 years of age and older when there is significant bacteriuria (more than 10^5 bacteria/mL [more than 10^8/L] of urine) in the absence of symptoms. Symptomatic abacteriuria or acute urethral syndrome consists of symptoms of frequency and dysuria in the absence of significant bacteriuria. This syndrome is commonly associated with *Chlamydia* infections.

Significant abacteriuria is a term used to distinguish the presence of microorganisms that represent true infection versus contamination of the urine as it passes through the distal urethra prior to collection. Historically, bacterial counts equal to or greater than 100,000 organisms/mL (10^8/L) of urine in a "clean-catch" specimen were judged to indicate true infection.[4,3,6] Counts less than 100,000 organisms/mL (10^8/L) of urine, however, may represent true infection in certain situations. For example, with concurrent antibacterial drug administration, rapid urine flow, low urinary pH, or upper tract obstruction.[6] **Table 116-1** lists the clinical definitions of significant bacteriuria, which are dependent on the clinical setting and the method of specimen collection.[6] These criteria allow for more appropriate specificity and sensitivity in documenting infection under differing clinical circumstances.

TABLE 116-1 Diagnostic Criteria for Significant Bacteriuria

≥10^2 CFU coliforms/mL (≥10^5 CFU/L) or ≥10^5 CFU noncoliforms/mL (≥10^8 CFU/L) in a symptomatic female
≥10^4 CFU bacteria/mL (≥10^7 CFU/L) in a symptomatic male
≥10^5 CFU bacteria/mL (≥10^8 CFU/L) in asymptomatic individuals on two consecutive specimens
Any growth of bacteria on suprapubic catheterization in a symptomatic patient
≥10^{2-5} CFU bacteria/mL (≥10^{5-8} CFU/L) in a catheterized patient

CFU, colony-forming unit.

EPIDEMIOLOGY

The prevalence of UTIs varies with age and gender. In newborns and infants up to 6 months of age, the prevalence of abacteriuria is approximately 1% and is more common in boys. Most of these infections are associated with structural or functional abnormalities of the urinary tract and also have been correlated with noncircumcision.[7] Between the ages of 1 and 6 years, UTIs occur more frequently in females. The prevalence of abacteriuria in females and males of this age group is 3% to 7% and 1% to 2%, respectively.[7,8] Infections occurring in preschool boys usually are associated with congenital abnormalities of the urinary tract. These infections are difficult to recognize because of the age of the patient, but they often are symptomatic. In addition, the majority of renal damage associated with UTI develops at this age.[7,8]

Through grade school and before puberty, the prevalence of UTI is approximately 1%, with 5% of females reported to have significant bacteriuria prior to leaving high school. This percentage increases dramatically to 1% to 4% after puberty in nonpregnant females primarily as a result of sexual activity. Approximately one in five women will suffer a symptomatic UTI at some point in their lives. Many women have recurrent infections with a significant proportion of these women having a history of childhood infections. In contrast, the prevalence of bacteriuria in adult men is very low (less than 0.1%).[9]

In the elderly, the ratio of bacteriuria in women and men is dramatically altered and is approximately equal in persons older than 65 years.[10] The overall incidence of UTI increases substantially in this population with the majority of infections being asymptomatic. The rate of infection increases further for elderly persons who are residing in nursing homes, particularly those who are hospitalized frequently. The increase is probably the result of factors such as obstruction from prostatic hypertrophy in males, poor bladder emptying as a result of prolapse in females, fecal incontinence in demented patients, and neuromuscular disease including strokes and increased urinary instrumentation (catheterization).

ETIOLOGY

3 The bacteria causing UTIs usually originate from bowel flora of the host. Although virtually every organism is associated with UTIs, certain organisms predominate as a result of specific virulence factors. The most common cause of uncomplicated UTIs is *Escherichia coli*, which accounts for 80% to 90% of community-acquired infections. Additional causative organisms in uncomplicated infections include *Staphylococcus saprophyticus*, *Klebsiella pneumoniae*, *Proteus* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp.[11] Because *S. epidermidis* is frequently isolated from the urinary tract, it should be considered initially a contaminant. Repeat cultures should be performed to help confirm the organism as a real pathogen.

Organisms isolated from individuals with complicated infections are more varied and generally are more resistant than those found in uncomplicated infections. *E. coli* is a frequently isolated pathogen, but it accounts for less than 50% of infections. Other frequently isolated organisms include *Proteus* spp., *K. pneumoniae*, *Enterobacter* spp., *P. aeruginosa*, staphylococci, and enterococci. Enterococci represent the second most frequently isolated organisms in hospitalized patients.[11,12,13] In part, this

finding may be related to the extensive use of third-generation cephalosporin antibiotics, which are not active against the enterococci. Vancomycin-resistant *E. faecalis* and *E. faecium* (vancomycin-resistant enterococci) have become more widespread, especially in patients with long-term hospitalizations or underlying malignancies. Vancomycin-resistant enterococci are major therapeutic and infection control issues because these organisms are susceptible to few antimicrobials.[12,13]

S. aureus infections may arise from the urinary tract, but they are more commonly a result of bacteremia producing metastatic abscesses in the kidney. *Candida* spp. are common causes of UTI in the critically ill and chronically catheterized patient.

Most UTIs are caused by a single organism; however, in patients with stones, indwelling urinary catheters, or chronic renal abscesses, multiple organisms may be isolated. Depending on the clinical situation, the recovery of multiple organisms may represent contamination and a repeat evaluation should be done.

PATHOPHYSIOLOGY

Route of Infection

Organisms typically gain entry into the urinary tract via three routes: the ascending, hematogenous (descending), and lymphatic pathways. The female urethra usually is colonized by bacteria believed to originate from the fecal flora. The short length of the female urethra and its proximity to the perirectal area make colonization of the urethra likely. Other factors that promote urethral colonization include the use of spermicides and diaphragms as methods of contraception.[2,3] Although there is evidence in females that bladder infections follow colonization of the urethra, the mode of ascent of the microorganisms is incompletely understood. Massage of the female urethra and sexual intercourse allow bacteria to reach the bladder.[14] Once bacteria have reached the bladder, the organisms quickly multiply and can ascend the ureters to the kidneys. This sequence of events is more likely to occur if vesicoureteral reflux (reflux of urine into the ureters and kidneys while voiding) is present. UTIs are more common in females than in males because the anatomic differences in location and length of the urethra tend to support the ascending route of infections as the primary acquisition route.

Infection of the kidney by hematogenous spread of microorganisms usually occurs as the result of dissemination of organisms from a distant primary infection in the body. Infections via the descending route are uncommon and involve a relatively small number of invasive pathogens. Bacteremia caused by *S. aureus* may produce renal abscesses. Additional organisms include *Candida* spp., *Mycobacterium tuberculosis*, *Salmonella* spp., and enterococci. Of particular interest, it is difficult to produce experimental pyelonephritis by IV administration of common gram-negative organisms such as *E. coli* and *P. aeruginosa*. Overall, less than 5% of documented UTIs result from hematogenous spread of microorganisms.

There appears to be little evidence supporting a significant role for renal lymphatics in the pathogenesis of UTIs. There are lymphatic communications between the bowel and kidney, as well as

between the bladder and kidney. There is no evidence, however, that microorganisms are transferred to the kidney via this route.

After bacteria reach the urinary tract, three factors determine the development of infection: the size of the inoculum, the virulence of the microorganism, and the competency of the natural host defense mechanisms. Most UTIs reflect a failure in host defense mechanisms.

Host Defense Mechanisms

The normal urinary tract generally is resistant to invasion by bacteria and is efficient in rapidly eliminating microorganisms that reach the bladder. The urine under normal circumstances is capable of inhibiting and killing microorganisms. The factors thought to be responsible include a low pH, extremes in osmolality, high urea concentration, and high organic acid concentration. Bacterial growth is further inhibited in males by the addition of prostatic secretions.[14,15]

The introduction of bacteria into the bladder stimulates micturition with increased diuresis and efficient emptying of the bladder. These factors are critical in preventing the initiation and maintenance of bladder infections. Patients who are unable to void urine completely are at greater risk of developing UTIs and frequently have recurrent infections. Also, patients with even small residual amounts of urine in their bladder respond less favorably to treatment than patients who are able to empty their bladders completely.[16]

An important virulence factor of bacteria is their ability to adhere to urinary epithelial cells resulting in colonization of the urinary tract, bladder infections, and pyelonephritis. Various factors that act as anti-adherence mechanisms are present in the bladder preventing bacterial colonization and infection. The epithelial cells of the bladder are coated with a urinary mucus or slime called *glycosaminoglycan*. This thin layer of surface mucopolysaccharide is hydrophilic and strongly negatively charged. When bound to the uroepithelium, it attracts water molecules and forms a layer between the bladder and urine. The anti-adherence characteristics of the glycosaminoglycan layer are nonspecific and when the layer is removed by dilute acid solutions, rapid bacterial adherence results.[17]

In addition, the Tamm–Horsfall protein is a glycoprotein produced by the ascending limb of Henle and distal tubule that is secreted into the urine and contains mannose residues. These mannose residues bind *E. coli* that contain small surface-projecting organellae on their surfaces called *pili* or *fimbriae*. Type 1 fimbriae are mannose-sensitive and this interaction prevents the bacteria from binding to similar receptors present on the mucosal surface of the bladder. Other factors that possibly prevent adherence of bacteria include immunoglobulins (Ig) G and A. Investigators have documented both systemic and local kidney Ig synthesis in upper tract infections. The role of Igs in preventing bladder infection is less clear. Patients with reduced urinary levels of secretory IgA are, however, at increased risk of infections of the urinary tract.

After bacteria have invaded the bladder mucosa, an inflammatory response is stimulated with the mobilization of polymorphonuclear leukocytes (PMNs) and resulting phagocytosis. PMNs are primarily responsible for limiting the tissue invasion and controlling the spread of infection in the

bladder and kidney. They do not play a role in preventing bladder colonization or infections and actually contribute to renal tissue damage.

Other host factors that may play a role in the prevention of UTIs are the presence of *Lactobacillus* in the vaginal flora and circulating estrogen levels. In premenopausal women, circulating estrogen supports the vaginal tract growth of lactobacilli, which produce lactic acid to help maintain a low vaginal pH, thereby preventing *E. coli* vaginal colonization.[18] Topical estrogens are used for the prevention of UTI in postmenopausal women who have more than three recurrent UTI episodes per year and are not on oral estrogens.[19]

Bacterial Virulence Factors

Pathogenic organisms have differing degrees of pathogenicity (virulence), which play a role in the development and severity of infection. Bacteria that adhere to the epithelium of the urinary tract are associated with colonization and infection. The mechanism of adhesion of gram-negative bacteria, particularly *E. coli*, is related to bacterial fimbriae that are rigid, hair-like appendages of the cell wall.[9] These fimbriae adhere to specific glycolipid components on epithelial cells. The most common type of fimbriae is type 1, which binds to mannose residues present in glycoproteins. Glycosaminoglycan and Tamm–Horsfall protein are rich in mannose residues that readily trap those organisms that contain type 1 fimbriae, which are then washed out of the bladder.[20] Other fimbriae are mannose resistant and are associated more frequently with pyelonephritis, such as P fimbriae, which bind avidly to specific glycolipid receptors on uroepithelial cells. These bacteria are resistant to washout or removal by glycosaminoglycan and are able to multiply and invade tissue, especially the kidney. In addition, PMNs, as well as secretory IgA antibodies, contain receptors for type 1 fimbriae, which facilitate phagocytosis, but are lacking receptors for P fimbriae.

Other virulence factors include the production of hemolysin and aerobactin.[21] Hemolysin is a cytotoxic protein produced by bacteria that lyses a wide range of cells, including erythrocytes, PMNs, and monocytes. *E. coli* and other gram-negative bacteria require iron for aerobic metabolism and multiplication. Aerobactin facilitates the binding and uptake of iron by *E. coli*; however, the significance of this property in the pathogenesis of UTIs remains unknown.[22]

PREDISPOSING FACTORS TO INFECTION

The normal urinary tract typically is resistant to infection and colonization by pathogenic bacteria. In patients with underlying structural abnormalities of the urinary tract, the typical host defenses previously discussed usually are lacking or compromised. There are several known abnormalities of the urinary tract system that interfere with its natural defense mechanisms, the most important of which is obstruction. Obstruction can inhibit the normal flow of urine disrupting the natural flushing and voiding effect in removing bacteria from the bladder and resulting in incomplete emptying. Common conditions that result in residual urine volumes include prostatic hypertrophy, urethral strictures, calculi, tumors, bladder diverticula, and drugs such as anticholinergic agents. Additional causes of incomplete bladder emptying include neurologic malfunctions associated with stroke,

diabetes, spinal cord injuries, tabes dorsalis, and other neuropathies. Vesicoureteral reflux represents a condition in which urine is forced up the ureters to the kidneys. Urinary reflux is associated not only with an increased incidence of UTIs and pyelonephritis, but also with renal damage.[8,16] Reflux may be the result of a congenital abnormality or, more commonly, bladder overdistension from obstruction.

Other risk factors include urinary catheterization, mechanical instrumentation, pregnancy, and the use of spermicides and diaphragms.

CLINICAL PRESENTATION

4 The presenting signs and symptoms of UTIs in adults are recognized easily. Women frequently will report gross hematuria. Systemic symptoms, including fever, typically are absent in this setting. Unfortunately, large numbers of patients with significant bacteriuria are asymptomatic. These patients may be normal, healthy patients, elderly patients, children, pregnant patients, and patients with indwelling catheters. It is important to note that attempts at differentiating upper tract from lower tract infections on the basis of symptoms alone are not reliable.

CLINICAL PRESENTATION Urinary Tract Infections in Adults Signs and Symptoms

- **Lower UTI: Dysuria, urgency, frequency, nocturia, and suprapubic heaviness**
- **Gross hematuria**
- **Upper UTI: Flank pain, fever, nausea, vomiting, and malaise**

Physical Examination

- **Upper UTI: Costovertebral tenderness**

Laboratory Tests

- **Bacteriuria**
- **Pyuria (WBC count more than 10/mm^3 [more than 10 × 10^6/L])**
- **Nitrite-positive urine (with nitrite reducers)**
- **Leukocyte esterase-positive urine**
- **Antibody-coated bacteria (upper UTI)**

Elderly patients frequently do not experience specific urinary symptoms, but they will present with altered mental status, change in eating habits, or gastrointestinal (GI) symptoms. In addition, patients with indwelling catheters or neurologic disorders commonly will not have lower tract symptoms. Instead, they may present with flank pain and fever. Many of the aforementioned patients, however, frequently will develop upper tract infections with bacteremia and no or minimal urinary tract symptoms.

Symptoms alone are unreliable for the diagnosis of bacterial UTIs. The key to the diagnosis of UTI is the ability to demonstrate significant numbers of microorganisms in an appropriate urine specimen to distinguish contamination from infection. The type and extent of laboratory examination required depends on the clinical situation.

Urine Collection

Examination of the urine is the cornerstone of laboratory evaluation for UTIs. There are three acceptable methods of urine collection. The first is the *midstream clean-catch method*. After cleaning the urethral opening area in both men and women, 20 to 30 mL of urine is voided and discarded. The next part of the urine flow is collected and should be processed immediately (refrigerated as soon as possible). Specimens that are allowed to sit at room temperature for several hours may result in falsely elevated bacterial counts. The midstream clean-catch is the preferred method for the routine collection of urine for culture. When a routine urine specimen cannot be collected or contamination occurs, alternative collection techniques must be used.

The two acceptable alternative methods include catheterization and suprapubic bladder aspiration. Catheterization may be necessary for patients who are uncooperative or who are unable to void urine. If catheterization is performed carefully with aseptic technique, the method yields reliable results. Note, however, that introduction of bacteria into the bladder may result and the procedure is associated with infection in 1% to 2% of patients. Suprapubic bladder aspiration involves inserting a needle directly into the bladder and aspirating the urine. This procedure bypasses the contaminating organisms present in the urethra and any bacteria found using this technique generally are considered to represent significant bacteriuria.[23,24,25,26] Suprapubic aspiration is a safe and painless procedure that is most useful in newborns, infants, paraplegics, seriously ill patients, and others in whom infection is suspected and routine procedures have provided confusing or equivocal results.

Bacterial Count

5 The diagnosis of UTI is based on the isolation of significant numbers of bacteria from a urine specimen. Microscopic examination of a urine sample is an easy-to-perform and reliable method for the presumptive diagnosis of bacteriuria. The examination may be performed by preparing a Gram stain of unspun or centrifuged urine. The presence of at least one organism per oil-immersion field in a properly collected uncentrifuged specimen correlates well with more than 100,000 CFU/mL (10^5 CFU/mL or 10^8 CFU/L) of urine. For detecting smaller numbers of organisms, a centrifuged specimen is more sensitive. Such examinations detect more than 10^5 bacteria (CFU)/mL (10^8 CFU/L) with a sensitivity of greater than 90% and a specificity of greater than 70%.[23,24] A quantitative count of greater than or equal to 10^5 CFU/mL (10^8 CFU/L) is considered indicative of a UTI; however, up to 50% of women will present with clinical symptoms of a UTI with lower counts (10^3 CFU/mL) [10^6 CFU/L].[4]

Pyuria, Hematuria, and Proteinuria

Microscopic examination of the urine for leukocytes is used to determine the presence of pyuria. The presence of pyuria in a symptomatic patient correlates with significant bacteriuria.[25] Pyuria is defined as a white blood cell (WBC) count of greater than 10 WBC/mm^3 (10×10^6/L) of urine. A count of 5 to 10 WBC/mm^3 (5×10^6 to 10×10^6/L) is accepted as the upper limit of normal. It should be emphasized that pyuria is nonspecific and signifies only the presence of inflammation and not necessarily infection. Thus patients with pyuria may or may not have infection. Sterile pyuria has long been associated with urinary tuberculosis, as well as chlamydial and fungal urinary infections.

Hematuria, microscopic or gross, is frequently present in patients with UTI, but is nonspecific. Hematuria may indicate the presence of other disorders, such as renal calculi, tumors, or glomerulonephritis. Proteinuria is found commonly in the presence of infection.

Chemistry

Several biochemical tests have been developed for screening urine for the presence of bacteria. A common dipstick test detects the presence of nitrite in the urine, which is formed by bacteria that reduce nitrate normally present in the urine. False-positive tests are uncommon. False-negative tests are more common and frequently are caused by the presence of gram-positive organisms or *P. aeruginosa* that do not reduce nitrate.[26] Other causes of false tests include low urinary pH, frequent voiding, and dilute urine.

The leukocyte esterase dipstick test is a rapid screening test for detecting the presence of pyuria. Leukocytes esterase is found in primary neutrophil granules and indicates the presence of WBCs. The leukocyte esterase test is a sensitive and highly specific test for detecting more than 10 WBC/mm^3 (10×10^6/L) of urine. When the leukocyte esterase test is used with the nitrite test, the reported positive predictive value and specificity is 79% and 82%, respectively, for the detection of bacteriuria.[27,28] These tests can be useful in the outpatient evaluation of uncomplicated UTIs. However, urine culture is still the “gold standard” test in determining the presence of UTIs.

Culture

The most reliable method of diagnosing UTI is by quantitative urine culture. Urine in the bladder is normally sterile making it statistically possible to differentiate contamination of the urine from infection by quantifying the number of bacteria present in a urine sample. This criterion is based on a properly collected midstream clean-catch urine specimen. Patients with infection usually have greater than 10^5 bacteria/mL (10^8/L) of urine. It should be emphasized that as many as one-third of women with symptomatic infection have less than 10^5 bacteria/mL (10^8/L). Also, a significant portion of patients with UTIs, either symptomatic or asymptomatic, have less than 10^5 bacteria/mL (10^8/L) of urine.

Several laboratory methods are used to quantify bacteria present in the urine. The most accurate method is the pour-plate technique. This method is unsuitable for a high-volume laboratory because it is expensive and time-consuming. The streak-plate method is an alternative that involves using a calibrated-loop technique to streak a fixed amount of urine on an agar plate. This method is used

most commonly in diagnostic laboratories because it is simple to perform and less costly.

After identification and quantification are complete, the next step is to determine the susceptibility of the organism. There are several methods by which bacterial susceptibility testing may be performed. Knowledge of bacterial susceptibility and achievable urine concentration of the antibiotics puts the clinician in a better position to select an appropriate agent for treatment.

Infection Site

Several methods have been evaluated to determine the location of infection within the urinary system and differentiate upper tract from lower tract involvement. The most direct method is a ureteral catheterization procedure as described by Stamey and colleagues.[29] The method involves the passage of a catheter into the bladder and then into each ureter, where quantitative cultures are obtained. History and physical examination were of little value in predicting the site of infection. Although this method provides direct quantitative evidence for UTI, it is invasive, technically difficult, and expensive. The Fairley bladder washout technique is a modification of the Stamey procedure that involves Foley catheterization only.[30] After the catheter is passed into the bladder, bladder samples are obtained and the bladder is washed out with culture samples taken at 10, 20, and 30 minutes. The procedure shows that up to 50% of patients have renal involvement, regardless of signs and symptoms. Other investigators found 10% to 20% of tests to be equivocal.[30]

Noninvasive methods of localization may be more acceptable for routine use; however, they have limited clinical value. Patients with pyelonephritis can have abnormalities in urinary concentrating ability. The use of concentrating ability for localization of UTIs, however, is associated with high false-positive and false-negative responses and is not useful clinically.[26] The antibody-coated bacteria test is an immunofluorescent method that detects bacteria coated with Ig in freshly voided urine indicating upper UTI. The sensitivity and specificity of this test to localize the site of infection are reported to average 88% and 76%, respectively.[31] Because of the high incidence of false-positive and false-negative results, antibody-coated bacteria testing is not used routinely in the management of UTIs.

Virtually all patients with uncomplicated lower tract infections can be cured with a short course of antibiotic therapy and this assumption sometimes can be used to distinguish between patients with lower and upper tract infections. Patients who do not respond or who relapse may do so because of upper tract involvement. It is rarely necessary to localize the site of infection to direct the clinical management of such patients.

TREATMENT

Desired Outcomes

6 The goals of UTI treatments are (a) to eradicate the invading organism(s), (b) to prevent or to treat systemic consequences of infection, (c) to prevent the recurrence of infection, and (d) to decrease the potential for collateral damage with too broad of antimicrobial therapy.

Management

The management of a patient with a UTI includes initial evaluation, selection of an antibacterial agent, and duration of therapy and follow-up evaluation. The initial selection of an antimicrobial agent for the treatment of UTI is based primarily on the severity of the presenting signs and symptoms, the site of infection and whether the infection is determined to be uncomplicated or complicated. Other considerations include antibiotic susceptibility, side-effect potential, cost, current antimicrobial exposure, and the comparative inconvenience of different therapies.[1]

Various pharmacologic factors may affect the action of antibacterial agents. Certainly, the ability of the agent to achieve appropriate concentrations in the urine is of utmost importance. Factors that affect the rate and extent of excretion through the kidney include the patient's glomerular filtration rate and whether or not the agent is actively secreted. Filtration depends on the molecular size and degree of protein binding of the agent. Agents such as sulfonamides, tetracyclines, and aminoglycosides enter the urine via filtration. As the glomerular filtration rate is reduced, the amount of drug that enters the urine is reduced. Most β-lactam agents and quinolones are filtered and are actively secreted into the urine. For this reason, most of these agents achieve high urinary concentrations despite unfavorable protein-binding characteristics or the presence of renal dysfunction.

The ability to eradicate bacteria from the urine is related directly to the sensitivity of the microorganism and the achievable concentrations of the antimicrobial agent in the urine. Unfortunately, most susceptibility testing is directed at achievable concentrations in the blood. There is a poor correlation between achievable blood concentrations of antimicrobial agents and the eradication of bacteria from the urine.[32] In the treatment of lower tract infections, plasma concentrations of antibacterial agents may not be important, but achieving appropriate plasma concentrations appears critical in patients with bacteremia and renal abscesses.

Nonspecific therapies have been advocated in the treatment and prevention of UTIs. Fluid hydration has been used to produce rapid dilution of bacteria and removal of infected urine by increased voiding. A critical factor appears to be the amount of residual volume remaining after voiding. As little as 10 mL of residual urine can alter the eradication of infection significantly.[16] Paradoxically, increased diuresis also may promote susceptibility to infection by diluting the normal antibacterial properties of the urine. Often in clinical practice the concentrations of antimicrobial agents in the urine are so high that dilution has little effect on efficacy.

The antibacterial activity of the urine is related to the low pH, which is the result of high concentrations of various organic acids. Large volumes of cranberry juice increase the antibacterial activity of the urine and prevent the development of UTIs.[3,33,34] Apparently, the fructose and other unknown substances (condensed tannins, proanthocyanidin) in cranberry juice may act to interfere with adherence mechanisms of some pathogens, thereby preventing infection or reinfection. Acidification of the urine by cranberry juice does not appear to play a significant role. The use of other agents (ascorbic acid) to acidify the urine to hinder bacterial growth does not achieve significant acidification. Consequently, attempts to acidify urine with systemic agents are not

recommended. *Lactobacillus* probiotics also may aid in the prevention of female UTIs by decreasing the vaginal pH, thereby decreasing *E. coli* colonization.[19,34,35] In postmenopausal women, estrogen replacement may be of help in the prevention of recurrent UTIs. After 1 month of topical estrogen replacement, decreases in vaginal *Lactobacillus*, as well as decreases in vaginal pH and *E. coli* colonization, have been found.[18,34]

Clinical Controversy…

The use of cranberry juice or lactobacilli in the prevention of UTIs has long been discussed. *Lactobacillus* potentially helps keep the vaginal pH in the normal range (pH 4-4.5), regulating genitourinary bacteria therefore aiding in the prevention of UTIs.[33] Possible clinical benefits with cranberry juice in sexually active adult women with recurrent UTI by decreasing the adherence of bacteria to the bladder epithelial cells. However, adhesion research and clinical trials show no significant effectiveness with cranberry juice.[33,36] Unfortunately, the consistency of study results has varied, as have the types of cranberry products tested, leading to overall inconclusive evidence.[33,34,37,38] More reliable and thorough studies on the overall effectiveness of cranberry juice or lactobacilli need to be performed before a uniform opinion on the role of these agents in UTIs can be stated.

Urinary analgesics such as phenazopyridine hydrochloride are used frequently by many clinicians.[3] If the pain or dysuria present in a UTI is a consequence of infection, then urinary analgesics have little clinical role because most patients' symptoms respond quite rapidly to appropriate antibacterial therapy. Also, urinary analgesics may mask signs and symptoms of UTIs not responding to antimicrobial therapy.[35,39,40]

Clinical Controversy…

Phenazopyridine hydrochloride is an over-the-counter urinary anesthetic/analgesic that can be used for symptom relief in UTIs. Common brand names are Pyridium®, Azo-Standard®, and Uristat®. It is used frequently by patients as self-medication to alleviate the dysuria associated with UTIs. The use of phenazopyridine in the treatment of UTIs is controversial. It has no antimicrobial properties and has a number of adverse effects such as red-orange discoloration of body fluids, rash, anaphylaxis, and rare effects such as hemolytic anemia, methemoglobinemia, and acute renal failure. In addition, its use can mask the symptoms of an untreated or inappropriately treated UTI. Unfortunately, there are not any guidelines for its role in the treatment of UTIs; however, experts agree that if phenazopyridine is used, only use the recommended dose (maximum 200 mg three times a day) and it should be limited to 1 to 2 days for symptomatic relief of the dysuria with UTIs.[35,39] In addition, it should be used with the combination of appropriate antibiotic therapy.

Pharmacologic Therapy

Ideally, the antimicrobial agent chosen should be well tolerated, well absorbed, achieve high urinary concentrations, and have a spectrum of activity limited to the known or suspected pathogen(s). **Table 116-2** lists the most common agents used in the treatment of UTIs along with comments concerning

their general use. **Table 116-3** presents an overview of various therapeutic options for outpatient therapy of UTI. **Table 116-4** describes empirical treatment regimens for selected clinical situations.

TABLE 116-2 Commonly Used Antimicrobial Agents in the Treatment of UTIs

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Oral Therapy			
Trimethoprim–sulfamethoxazole	Rash, Stevens–Johnson Syndrome, renal failure, photosensitivity, hematologic (neutropenia, anemia, etc.)	Serum creatinine, BUN, electrolytes, signs of rash, and CBC	This combination is highly effective against most aerobic enteric bacteria except *P. aeruginosa*. High urinary tract tissue concentrations and urine concentrations are achieved, which may be important in complicated infection treatment. Also effective as prophylaxis for recurrent infections
Nitrofurantoin	GI intolerance, neuropathies, and pulmonary reactions	Baseline serum creatinine and BUN	This agent is effective as both a therapeutic and prophylactic agent in patients with recurrent UTIs. Main advantage is the lack of resistance even after long courses of therapy
Fosfomycin trometamol	Diarrhea, headache, and angioedema	No routine tests recommended	Single-dose therapy for uncomplicated infections, low levels of resistance, use with caution in patients with hepatic dysfunction
Fluoroquinolones			
Ciprofloxacin Levofloxacin	Hypersensitivity, photosensitivity, GI symptoms, dizziness, confusion, and tendonitis (black box warning)	CBC, baseline serum creatinine, and BUN	The fluoroquinolones have a greater spectrum of activity, including *P. aeruginosa*. These agents are effective for pyelonephritis and prostatitis. Avoid in pregnancy and children. Moxifloxacin should not be used owing to inadequate urinary concentrations
Penicillins			
Amoxicillin–clavulanate	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Due to increasing *E. coli* resistance, amoxicillin–clavulanate is the preferred penicillin for uncomplicated cystitis
Cephalosporins			
Cefaclor Cefpodoxime-	Hypersensitivity (rash, anaphylaxis), diarrhea,	CBC, signs of rash, or hypersensitivity	There are no major advantages of these agents over other agents in the treatment of UTIs, and they are more

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
proxetil	superinfections, and seizures		expensive. These agents are not active against enterococci
Parenteral Therapy			
Aminoglycosides			
Gentamicin Tobramycin Amikacin	Ototoxicity, nephrotoxicity	Serum creatinine and BUN, serum drug concentrations, and individual pharmacokinetic monitoring	These agents are renally excreted and achieve good concentrations in the urine. Amikacin generally is reserved for multidrug-resistant bacteria
Penicillins			
Ampicillin–sulbactam Piperacillin–tazobactam	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	These agents generally are equally effective for susceptible bacteria. The extended-spectrum penicillins are more active against *P. aeruginosa* and enterococci and often are preferred over cephalosporins. They are very useful in renally impaired patients or when an aminoglycoside is to be avoided
Cephalosporins			
Ceftriaxone Ceftazidime Cefepime	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Second- and third-generation cephalosporins have a broad spectrum of activity against gram-negative bacteria, but are not active against enterococci and have limited activity against *P. aeruginosa*. Ceftazidime and cefepime are active against *P. aeruginosa*. They are useful for nosocomial infections and urosepsis due to susceptible pathogens
Carbapenems/monobactams			
Imipenem–cilistatin Meropenem Doripenem Ertapenem	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Carbapenems have a broad spectrum of activity, including gram-positive, gram-negative, and anaerobic bacteria. Imipenem, meropenem, and doripenem are active against *P. aeruginosa* and enterococci, but ertapenem is not. Aztreonam is a monobactam that is only active against

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Aztreonam			gram-negative bacteria, including some strains of *P. aeruginosa*. Generally useful for nosocomial infections when aminoglycosides are to be avoided and in penicillin-sensitive patients
Fluoroquinolones			
Ciprofloxacin Levofloxacin	Hypersensitivity, photosensitivity, GI symptoms, dizziness, confusion, and tendonitis (black box warning)	CBC, baseline serum creatinine, and BUN	These agents have broad-spectrum activity against both gram-negative and gram-positive bacteria. They provide urine and high-tissue concentrations and are actively secreted in reduced renal function

BUN, blood urea nitrogen; CBC, complete blood count; GI, gastrointestinal; UTIs, urinary tract infections.

TABLE 116-3 Overview of Outpatient Antimicrobial Therapy for Lower Tract Infections in Adults

Indications	Antibiotic	Dose	Interval	Duration
Lower tract infections				
Uncomplicated	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	3 days
	Nitrofurantoin monohydrate	100 mg	Twice a day	5 days
	Fosfomycin trometamol	3 g	Single dose	1 day
	Ciprofloxacin	250 mg	Twice a day	3 days
	Levofloxacin	250 mg	Once a day	3 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	5-7 days
	Pivmecillinam	400 mg	Twice a day	3 days
Complicated	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	7-10 days
	Ciprofloxacin	250-500 mg	Twice a day	7-10 days
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	7-10 days
Recurrent infections	Nitrofurantoin	50 mg	Once a day	6 months
	Trimethoprim–sulfamethoxazole	1/2 SS tablet	Once a day	6 months
Acute pyelonephritis	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	14 days
	Ciprofloxacin	500 mg	Twice a day	14 days
		1,000 mg ER	Once a day	7 days

Indications	Antibiotic	Dose	Interval	Duration
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	14 days

DS, double strength; SS, single strength.

Dosing intervals for normal renal function.

TABLE 116-4 Evidence-Based Empirical Treatment of UTIs and Prostatitis

Diagnosis	Pathogens	Treatment Recommendation	Comments
Acute uncomplicated cystitis	*Escherichia coli*, *Staphylococcus saprophyticus*	1. Nitrofurantoin × 5 days (A,I)[a] 2. Trimethoprim–sulfamethoxazole × 3 days (A,I)[a] 3. Fosfomycin trometamol × 1 dose (A,I)[a] 4. Fluoroquinolone × 3 days (A,I)[a] 5. β-Lactams × 3-7 days (B,I)[a] 6. Pivmecillinam × 3-7 days (A,I)	Short-course therapy more effective than single dose Reserve fluoroquinolones as alternatives to development of resistance (A-III)[a] β-Lactams as a group are not as effective in acute cystitis then trimethoprim–sulfamethoxazole or the fluoroquinolones, do not use amoxicillin or ampicillin[a] Pivmecillinam not available in United States
Pregnancy	As above	1. Amoxicillin–clavulanate × 7 days 2. Cephalosporin × 7 days 3. Trimethoprim–sulfamethoxazole × 7 days	Avoid trimethoprim–sulfamethoxazole during the third trimester
Acute pyelonephritis			

Diagnosis	Pathogens	Treatment Recommendation	Comments
Uncomplicated	*E. coli*	1. Quinolone × 7 days (A,I)[a] 2. Trimethoprim–sulfamethoxazole (if susceptible) × 14 days (A,I)[a]	Can be managed as outpatient
Complicated	Gram-positive bacteria *E. coli* *P. mirabilis* *K. pneumoniae* *P. aeruginosa* *Enterococcus faecalis*	1. Amoxicillin or amoxicillin–clavulanic acid × 14 days 1. Quinolone × 14 days 2. Extended-spectrum penicillin plus aminoglycoside	Severity of illness will determine duration of IV therapy; culture results should direct therapy Oral therapy may complete 14 days of therapy
Prostatitis	*E. coli* *K. pneumoniae* *Proteus* spp. *P. aeruginosa*	1. Trimethoprim–sulfamethoxazole × 4-6 weeks 2. Quinolone × 4-6 weeks	Acute prostatitis may require IV therapy initially Chronic prostatitis may require longer treatment periods or surgery

UTI, urinary tract infection.

[a]Strength of recommendations: A, good evidence for; B, moderate evidence for; C, poor evidence for and against; D, moderate against; E, good evidence against. Quality of evidence: I, at least one proper randomized, controlled study; II, one well-designed clinical trial; III, evidence from opinions, clinical experience, and expert committees.

Data from reference 1.

8 The therapeutic management of UTIs is best accomplished by first categorizing the type of infection: acute uncomplicated cystitis, symptomatic abacteriuria, ASB, complicated UTIs, recurrent infections, or prostatitis. In choosing the appropriate antibiotic therapy, it is important to be aware of

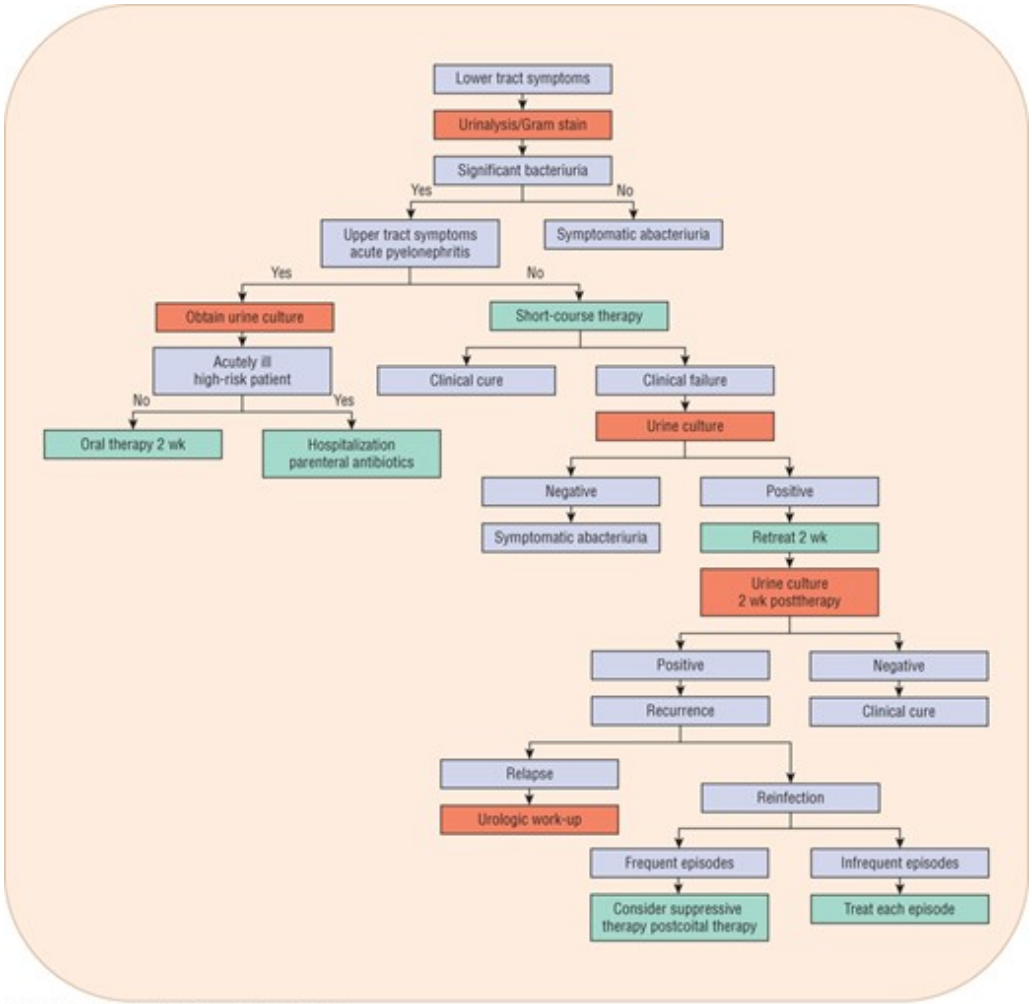
the increasing resistance of *E. coli* and other pathogens to many frequently prescribed antimicrobials.[41] Resistance to *E. coli* is as high as 37% for amoxicillin and ampicillin.[1,42] Overall, most *E. coli* remain susceptible to trimethoprim–sulfamethoxazole, although resistance is continuing to increase and has been reported as high as 27%.[43] Although resistance to the fluoroquinolones remains low, these agents are being used more frequently and the incidence of fluoroquinolone-resistant *E. coli* is increasingly being reported and is of great concern.[42,43,44,45,46,47,48] Current or recent antibiotic exposure is the most significant risk factor associated with *E. coli* resistance and with the extensive use of the fluoroquinolones and trimethoprim–sulfamethoxazole for various infections, including UTIs, resistance will continue to increase.[42,43,44,45,46,47] In addition, broad-spectrum antimicrobials such as fluoroquinolones and broad-spectrum cephalosporins have a high impact on GI flora, increasing the risk of collateral damage (term used to refer to ecological adverse effects of antibiotic therapy) or the selection of resistant *E. coli* pathogens.[42,43,44,45,48,49] In light of rising resistance and in order to decrease the overuse of broad-spectrum antimicrobials, agents such as nitrofurantoin and fosfomycin are now considered first-line treatments along with trimethoprim–sulfamethoxazole in acute uncomplicated cystitis. Both nitrofurantoin and fosfomycin have little effects on the gut flora and *E. coli* susceptibility still remains high.[33,49,50,51,52,53] Antibiotic therapy should be determined based on the geographic resistance patterns, as well as the patient's recent history of antibiotic exposure.

Acute Uncomplicated Cystitis

Acute uncomplicated cystitis is the most common form of UTI. These infections typically occur in women of childbearing age and often are related to sexual activity. Although the presence of dysuria, frequency, urgency, and suprapubic discomfort frequently is associated with lower tract infection, a significant number of patients have upper tract involvement as well.[3] Because these infections are predominantly caused by *E. coli*, antimicrobial therapy initially should be directed against this organism. Other common causes include *S. saprophyticus* and occasionally *K. pneumoniae* and *Proteus mirabilis*. Because the causative organisms and their susceptibility generally are known, many clinicians advocate a cost-effective approach to management. This approach includes a urinalysis and initiation of empirical therapy without a urine culture (**Fig. 116-1**).[1] Therefore, the susceptibility patterns of the geographic area drive the choice of empiric therapy.

FIGURE 116-1

Management of urinary tract infections in females.



The goal of treatment for uncomplicated cystitis is to eradicate the causative organism and to reduce the incidence of recurrence caused by relapse or reinfection. The ability to reduce the chance of recurrence depends on the agent's efficacy in eradicating the uropathogenic bacteria from the vaginal and GI reservoir. In the past, conventional therapy consisted of an effective oral antibiotic administered for 7 to 14 days. However, acute cystitis is a superficial mucosal infection that can be eradicated with much shorter courses of therapy (3 days). Advantages of short-course therapy include increased adherence, fewer side effects, decreased cost, and less potential for the development of resistance.

7 Three-day courses of trimethoprim–sulfamethoxazole or a fluoroquinolone (eg, ciprofloxacin or levofloxacin, not moxifloxacin) are superior to single-dose therapies.[52,54,55,56] Although the fluoroquinolones have shown excellent efficacy in acute cystitis, the newest guidelines recommend reserving these agents for patients with suspected or possible pyelonephritis due to the collateral damage risk. Instead, a 3-day course of trimethoprim–-sulfamethoxazole, a 5-day course of nitrofurantoin, or a one-time dose of fosfomycin should be considered as first-line therapy[1,50,51,55,57] In areas where there is more than 20% resistance of *E. coli* to trimethoprim–sulfamethoxazole, nitrofurantoin or fosfomycin should be used. Amoxicillin or ampicillin should not be used due to the high incidence of resistant *E. coli*. Instead, if a β-lactam must be used, amoxicillin/-clavulanate,

cefdinir, cefaclor, or cefpodoxime proxetil for 3 to 7 days are the preferred choices. For most adult females, short-course therapy is the treatment of choice for uncomplicated lower UTIs. Short-course therapy is inappropriate for patients who have had previous infections caused by resistant bacteria, for male patients, and for patients with complicated UTIs. If symptoms recur or do not respond to therapy, a urine culture should be obtained and conventional therapy with a suitable agent instituted.[1]

Symptomatic Abacteriuria

Symptomatic abacteriuria or acute urethral syndrome represents a clinical syndrome in which females present with dysuria and pyuria, but the urine culture reveals less than 10^5 bacteria/mL (10^8/L) of urine. Acute urethral syndrome accounts for more than half the complaints of dysuria seen in the community today. These women most likely are infected with small numbers of coliform bacteria, including *E. coli*, *Staphylococcus* spp., or *Chlamydia trachomatis*. Additional causes include *Neisseria gonorrhoeae*, *Gardnerella vaginalis*, and *Ureaplasma urealyticum*.

Most patients presenting with pyuria will, in fact, have infection that requires treatment. If antimicrobial therapy is ineffective, a culture should be obtained. If the patient reports recent sexual activity, therapy for *C. trachomatis* should be considered. Chlamydial treatment should consist of 1 g azithromycin or doxycycline 100 mg twice daily for 7 days. Often, concomitant treatment of all sexual partners is required to cure chlamydial infections and prevent reacquisition (see Chapter 117).

Asymptomatic Bacteriuria

ASB is the finding of two consecutive urine cultures with more than 10^5 organisms/mL (more than 10^8/L) of the same organism in the absence of urinary symptoms. Most patients with ASB are elderly and female. Also, pregnant women frequently present with ASB. Although this group of patients typically responds to treatment, relapse and reinfection are very common and chronic ASB is difficult to eradicate.

The management of ASB depends on the age of the patient and whether or not the patient is pregnant. In children, because of a greater risk of developing renal scarring and long-standing renal damage, treatment should consist of the same conventional courses of therapy as used for symptomatic infection. The greatest risk of renal damage occurs during the first 5 years of life.[58] In nonpregnant females, therapy is controversial; however, treatment has little effect on the natural course of infections. Two groups characterize ASB in the elderly: those with persistent bacteriuria and those with intermittent bacteriuria.

Several studies in hospitalized elderly subjects, however, have not found antimicrobial therapy to be efficacious for abacteruria.[59,60,61,62] A number of questions remain unanswered. For example: What is the effect of eradication of bacteriuria on life expectancy? What are the cost-effectiveness and risk-to-benefit ratio of therapy? What is the effect on morbidity? Certainly with the information available and the high adverse reaction rate in the elderly, vigorous treatment and screening programs cannot be advocated.

Complicated Urinary Tract Infections

Acute Pyelonephritis

The presentation of high-grade fever (more than 38.3°C [more than 100.9°F]) and severe flank pain should be treated as acute pyelonephritis and warrants aggressive management. Severely ill patients with pyelonephritis should be hospitalized and IV antimicrobials administered initially (see Table 116-4). However, milder cases may be managed with orally administered antibiotics in an outpatient setting. Signs and symptoms of nausea, vomiting, and dehydration may require hospitalization.

At the time of presentation, a Gram stain of the urine should be performed along with a urinalysis, culture, and sensitivity tests. The Gram stain should indicate the morphology of the infecting organism(s) and help direct the selection of an appropriate antibiotic. However, the precise identity and susceptibility of the infecting organism(s) will be unknown initially, warranting empirical therapy. The goals of treatment include the achievement of therapeutic concentrations of an antimicrobial agent in the bloodstream and urinary tract to which the invading organism is susceptible and sufficient therapy to eradicate residual infection in the tissues of the urinary tract.

In the mildly to moderately symptomatic patient in whom oral therapy is considered, an effective agent should be administered for 7 to 14 days, depending on the agent used.[1,63,64,65,66,67,68] Oral antibiotics that are highly active against the probable pathogens and that are sufficiently bioavailable are preferred. Fluoroquinolones (ciprofloxacin or levofloxacin) orally for 7 to 10 days are the first-line choice in mild to moderate pyelonephritis. Other options include trimethoprim–sulfamethoxazole for 14 days. If amoxicillin/clavulanate or an oral cephalosporin is used, it is recommended to give an initial long-acting parenteral antimicrobial such as ceftriaxone first and continue the oral agent for 10 to 14 days. If a Gram stain reveals gram-positive cocci, *Enterococcus faecalis* should be considered and treatment directed against this potential pathogen (ampicillin). Close follow-up of outpatient treatment is mandatory to ensure success.

In the seriously ill patient, parenteral therapy should be administered initially. Therapy should provide a broad spectrum of coverage and should be directed toward bacteremia or sepsis, if present. A number of antibiotic regimens have been used as empirical therapy, including an IV fluoroquinolone, an aminoglycoside with or without ampicillin, and extended-spectrum cephalosporins with or without an aminoglycoside.[1,69] Other options include aztreonam, the β-lactamase inhibitor combinations (eg, ampicillin–sulbactam, ticarcillin–clavulanate, and piperacillin–tazobactam), carbapenems (eg, imipenem, meropenem, doripenem, or ertapenem), or IV trimethoprim–sulfamethoxazole.[70] If the patient has been hospitalized within the past 6 months, has a urinary catheter, or is a nursing home resident, the possibility of *P. aeruginosa* and enterococci, as well as multiple resistant organisms, should be considered. In this setting, ceftazidime, ticarcillin–clavulanate, piperacillin, aztreonam, meropenem, or imipenem in combination with an aminoglycoside is recommended. Ertapenem should not be used in this situation owing to its inactivity against enterococci and *P. aeruginosa*.[67] The rationale for combination therapy is that in experimental animals 3 days of aminoglycoside combination therapy followed by nonaminoglycoside single-agent therapy for 7 days resulted in a 100% cure rate.[63,68] If the patient responds to initial combination therapy, the aminoglycoside may

be discontinued after 3 days. Although the aminoglycoside therapy is stopped, renal tissue concentrations of the aminoglycoside will persist for days. Based on antimicrobial sensitivity data, the patient then can be maintained or switched to a less expensive single agent and ultimately, an appropriate oral agent may be used.

Effective therapy should stabilize the patient within 12 to 24 hours. A significant reduction in urine bacterial concentrations should occur in 48 hours. If bacteriologic response has not occurred, an alternative agent should be considered based on susceptibility testing. If the patient fails to respond clinically within 3 to 4 days or has persistently positive blood or urine cultures, further investigation is needed to exclude bacterial resistance, possible obstruction, papillary necrosis, intrarenal or perinephric abscess, or some other disease process. Usually by the third day of therapy, the patient is afebrile and significantly less symptomatic. In general, after the patient has been afebrile for 24 hours, parenteral therapy may be discontinued and oral therapy instituted to complete a 2-week course. Follow-up urine cultures should be obtained 2 weeks after completion of therapy to ensure a satisfactory response and detect possible relapse.

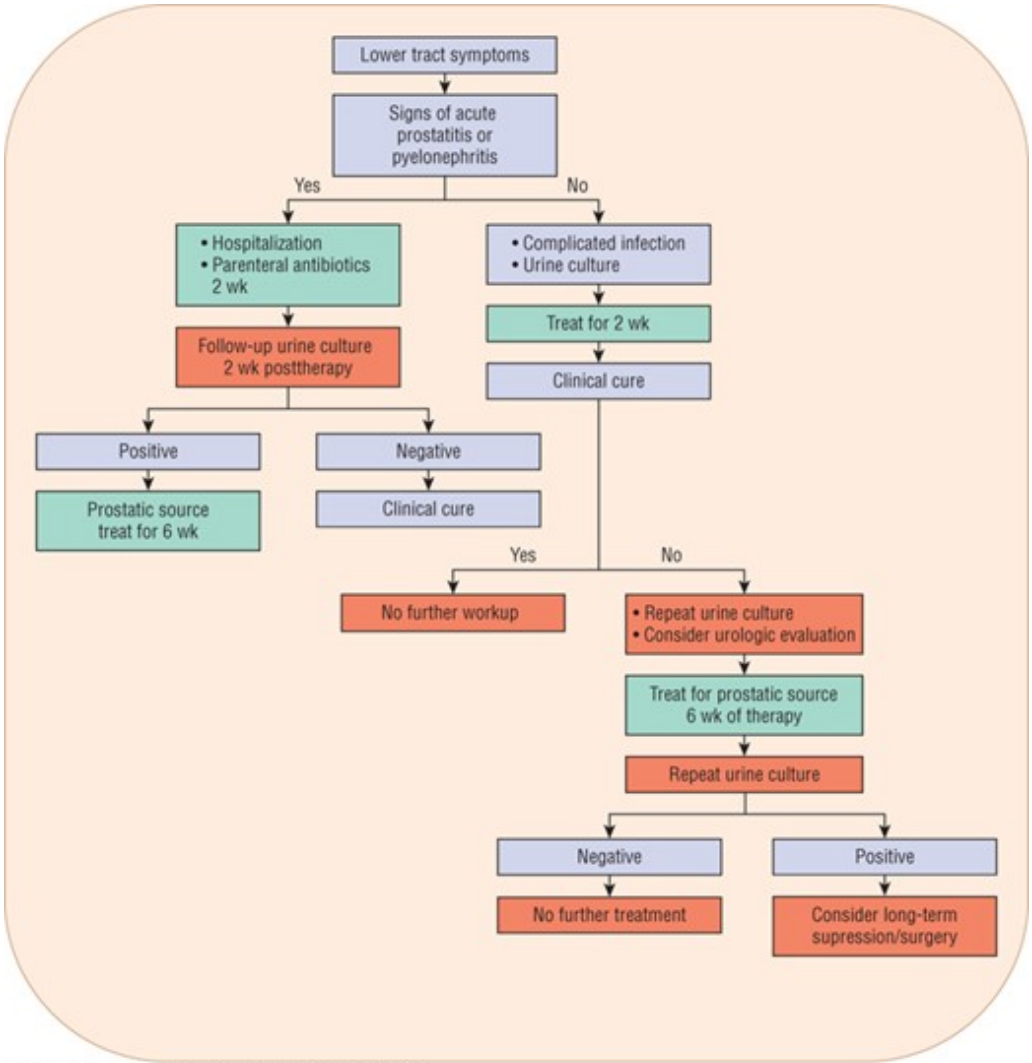
Urinary Tract Infections in Males

The management of UTIs in males is distinctly different and often more difficult than in females. Infections in male patients are considered to be complicated because endogenous bacteria in the presence of functional and/or structural abnormalities that disrupt the normal defense mechanisms of the urinary tract cause them. The incidence of infections in males younger than 60 years is much less than the incidence in females. During the adult years, the occurrence of infection can be related directly to some manipulation of the urinary tract. The most common causes are instrumentation of the urinary tract, catheterization, and renal and urinary stones. Uncomplicated infections are rare, but they may occur in young males as a result of homosexual activity, noncircumcision, and having sex with partners who are colonized with uropathogenic bacteria. As the patient ages, the most common cause of infection is related to bladder outlet obstruction because of prostatic hypertrophy. In addition, the prostate gland may become infected and provide a nidus for recurrent infection in males.

The conventional view is that therapy in males requires prolonged treatment (**Fig. 116-2**). A urine culture should be obtained before treatment because the cause of infection in men is not as predictable as in women. Single-dose or short-course therapy is not recommended in males. Considerably fewer data are available comparing various antimicrobial agents in males as compared with females. If gram-negative bacteria are presumed, trimethoprim–sulfamethoxazole or the quinolone antimicrobials should be considered because these agents achieve high renal tissue, urine, and prostatic concentrations.[71]

FIGURE 116-2

Management of urinary tract infections in males.



Initial therapy should be for 10 to 14 days. Factors associated with treatment success are isolation of a single organism, the absence of significant obstruction or anatomic abnormalities, a normally functioning urinary tract, and the absence of prostatic involvement. Parenteral therapy may be required in certain situations, such as in severely ill patients, in the presence of acute prostatitis or epididymitis and in patients who cannot tolerate oral medications. A comparison of 2-week versus 6-week therapy in males with recurrent infections who were given trimethoprim–sulfamethoxazole had cure rates of 29% and 62%, respectively.[72] Other investigators advocate longer treatment periods in males, as well.[73] Follow-up cultures at 4 to 6 weeks after treatment are important in males to ensure bacteriologic cure. Many patients require longer periods of treatment and possible alterations in antibiotics, depending on culture and sensitivity results and clinical response.

Recurrent Infections

Recurrent episodes of UTI account for a significant portion of all UTIs. Of the patients suffering from recurrent infections, 80% can be considered reinfections, that is, the recurrence of infection by an organism different from the organism isolated from the preceding infection. These patients most commonly are female and recurrence develops in approximately 20% of females with cystitis.

Reinfections can be divided into two groups: those with less than three episodes per year and those who develop more frequent infections. Treatment strategies are continuing to develop, as well as, an understanding of the role of the microbiome.[74,75] An excellent overview of the various treatment modalities for recurrent UTI in women has been published.[76]

Management strategies depend on predisposing factors, number of episodes per year, and the patient's preference. Factors commonly associated with recurrent infections include sexual intercourse and diaphragm or spermicide use for birth control. Therapeutic options include self-administered therapy, postcoital therapy, and continuous low-dose prophylaxis. In patients with infrequent infections (less than three infections per year), each episode may be treated as a separately occurring infection. Short-course therapy is appropriate in this setting. Many women have been treated successfully with self-administered short-course therapy at the onset of symptoms.[40,77]

In patients with more frequent symptomatic infections and no apparent precipitating event, long-term prophylactic antimicrobial therapy may be instituted. Prophylactic therapy reduces the frequency of symptomatic infections in elderly men, women, and children. In women, most studies show a reinfection rate of two to three per patient-year reduced to 0.1 to 0.2 per patient-year with treatment.[77] Before prophylaxis is initiated, patients should be treated conventionally with an appropriate agent. Trimethoprim–sulfamethoxazole (one-half of a single-strength tablet), trimethoprim (100 mg daily), a fluoroquinolone (levofloxacin 500 mg daily), and nitrofurantoin (50 or 100 mg daily) all reduce the rate of reinfection as single-agent therapy.[77] Full-dose therapy with these agents is unnecessary and single daily doses can be used. Therapy generally is prescribed for a period of 6 months, during which time urine cultures are followed monthly. If symptomatic episodes develop, the patient should receive a full course of therapy with an effective agent and then resume prophylactic therapy. Therapy with methenamine hippurate for short term use may be beneficial, but its overall utility is not well documented, especially for long-term prophylaxis.[78] The utility of OM-89 oral immunotherapy has been demonstrated to be an effective therapy for some women with recurrent UTI; however, its use is not approved in the United States.[79]

In women who experience symptomatic reinfections in association with sexual activity, voiding after intercourse may help prevent infection. Also, single-dose prophylactic therapy with trimethoprim–sulfamethoxazole taken after intercourse reduces the incidence of recurrent infection significantly.[77]

In postmenopausal women with recurrent infections, the lack of estrogen results in changes in the bacterial flora of the vagina, resulting in increased colonization with uropathogenic *E. coli*. Topically administered estrogen cream reduces the incidence of infections in this population.[18,19]

The remaining 20% of recurrent UTIs are relapses, that is, persistence of infection with the same organism after therapy for an isolated UTI. The recurrence of symptomatic or ASB after therapy usually indicates that the patient has renal involvement, a structural abnormality of the urinary tract or chronic bacterial prostatitis. In the absence of structural abnormalities, relapse often is related to renal infection and requires a long duration of treatment. Women who relapse after short-course therapy should receive a 2-week course of therapy. In patients who relapse after 2 weeks of therapy, therapy should be continued for another 2 to 4 weeks. If relapse occurs after 6 weeks of therapy,

urologic evaluation should be performed and any obstructive lesion should be corrected. If this is not possible, therapy for 6 months or longer may be considered. Asymptomatic adults who have no evidence of urinary obstruction should not receive long-term therapy.

In males, relapse usually indicates bacterial prostatitis, the most common cause of persistent bacteriuria. Although many agents have been used for long-term therapy of relapses, trimethoprim–sulfamethoxazole and the fluoroquinolones appear to be highly effective.

Special Conditions

Urinary Tract Infections in Pregnancy

During pregnancy, significant physiologic changes occur to the entire urinary tract that dramatically alter the prevalence of UTIs and pyelonephritis. Severe dilation of the renal pelvis and ureters, decreased ureteral peristalsis, and reduced bladder tone occur during pregnancy.[80] These changes result in urinary stasis and reduced defenses against reflux of bacteria to the kidneys. In addition, increased urine content of amino acids, vitamins, and nutrients encourages bacterial growth. All of these factors increase the incidence of bacteriuria resulting in symptomatic infections, especially during the third trimester.

ASB occurs in 4% to 7% of pregnant patients. Of these, 20% to 40% will develop acute symptomatic pyelonephritis during pregnancy. If untreated, ASB has the potential to cause significant adverse effects, including prematurity, low birth weight, and stillbirth.[81,82] Because pyelonephritis is associated with significant adverse events during pregnancy, routine screening tests for bacteriuria should be performed at the initial prenatal visit and again at 28 weeks gestation. In patients with significant bacteriuria, symptomatic or asymptomatic, treatment is recommended so as to avoid possible complications. Organisms associated with bacteriuria are the same as those seen in uncomplicated UTIs with *E. coli* isolated most frequently.

Therapy should consist of an agent administered for 7 days that has a relatively low adverse effect potential and is safe for the mother and baby. The administration of amoxicillin, amoxicillin–clavulanate, or cephalexin is effective in 70% to 80% of patients. Nitrofurantoin has been used in pregnancy; however, it must be used with caution as occurrences of birth defects have been reported. Tetracyclines should be avoided because of teratogenic effects and sulfonamides should not be administered during the third trimester because of the possible development of kernicterus and hyperbilirubinemia. In addition, the available fluoroquinolones should not be given because of their potential to inhibit cartilage and bone development in the newborn. A follow-up urine culture 1 to 2 weeks after completing therapy and then monthly until gestation is complete is recommended. Optimal treatment for preventing recurrent UTI and ASB has yet to be defined.[83]

Catheterized Patients

The use of an indwelling catheter frequently is associated with infection of the urinary tract and represents the most common cause of hospital-acquired infection. The incidence of catheter-associated infection is related to a variety of factors, including method and duration of

catheterization, the catheter system (open or closed), the care of the system, the susceptibility of the patient, and the technique of the healthcare personnel inserting the catheter. Catheter-related infections are reasonably preventable infections and are now considered one of the hospital-acquired complications chosen by the Centers for Medicare and Medicaid Services in which hospitals will no longer receive reimbursement for treatment.[84,85]

Bacteria may enter the bladder in a number of ways. During the catheterization, bacteria may be introduced directly into the bladder from the urethra. Once the catheter is in place, bacteria may pass up the lumen of the catheter via the movement of air bubbles, by motility of the bacteria, or by capillary action. In addition, bacteria may reach the bladder from around the exudative sheath that surrounds the catheter in the urethra. Cleaning the periurethral area thoroughly and applying an antiseptic (povidone-iodine) can minimize infection occurring during insertion of the catheter. The use of closed drainage systems has reduced significantly the ability of bacteria to pass up the lumen of the catheter and cause infection. Presently, a bacterium passing around the catheter sheath in the urethra is probably the most important pathway for infection. Avoiding manipulation of the catheter and trauma to the urethra and urethral meatus can minimize this path of acquisition.

Patients with indwelling catheters acquire UTIs at a rate of 5% per day.[84,85,86] The closed systems are capable of preventing bacteriuria in most patients for up to 10 days with appropriate care. After 30 days of catheterization, however, there is a 78% to 95% incidence of bacteriuria, despite use of a closed system.[85,87] Unfortunately, UTI symptoms in catheterized patient are not clearly defined. Fever, peripheral leukocytosis, and urinary signs and symptoms may be of little predictive value.[84,85] When bacteriuria occurs in the asymptomatic, short-term catheterized patient (less than 30 days), the use of systemic antibiotics should be withheld and the catheter removed as soon as possible. If the patient becomes symptomatic, the catheter should be removed and treatment as described for complicated infections started. The optimal duration of therapy is unknown. In the long-term catheterized patient (more than 30 days), bacteriuria is inevitable.[84,85] The administration of systemic antibiotics active against the infecting organism will sterilize the urine; however, reinfection occurs rapidly in more than 50% of patients. In addition, resistant organisms recolonize the urine. Symptomatic patients must be treated because they are at risk of developing pyelonephritis and bacteremia. Bacteria adhere to the catheter and produce a biofilm consisting of bacterial glycocalyces, Tamm–Horsfall protein, as well as apatite and struvite salts, that act to protect the bacteria from antibiotics.[86] Biofilm mechanisms and their treatment continue to be examined and more fully understood.[88] Recatheterization with a new sterile unit should be performed in those symptomatic patients, if the existing catheter has been in place for more than 2 weeks.

Various methods have been proposed to prevent the development of bacteriuria and infection in the patient with an indwelling catheter (see Table 116-4). The success of these methods depends on the type of catheter and the length of time it is in place. The use of constant bladder irrigation with antiseptic or antibacterial solutions reduces the incidence of infection in those with open drainage systems, but this approach has no advantage in those with closed systems. The use of prophylactic systemic antibiotics in patients with short-term catheterization reduces the incidence of infection over the first 4 to 7 days.[85,87] In long-term catheterized patients, however, antibiotics only postpone the development of bacteriuria and lead to the emergence of resistant organisms. Therefore,

antibiotic prophylaxis should not be utilized in short-term or long-term catheterized patients.

PROSTATITIS

Bacterial prostatitis is an inflammation of the prostate gland and surrounding tissue as a result of infection. It is classified as either acute or chronic. By definition, pathogenic bacteria and significant inflammatory cells must be present in prostatic secretions and urine to make the diagnosis of bacterial prostatitis. Prostatitis occurs rarely in young males, but it is commonly associated with recurrent infections in persons older than 30 years. As many as 50% of all males develop some form of prostatitis at some period in their life.[89,90,91] The acute form typically is an acute infectious disease characterized by a sudden onset of fever, tenderness, and urinary and constitutional symptoms. Chronic prostatitis presents with few symptoms related to the prostate but rather symptoms of urinating difficulty, low back pain, perineal pressure, or a combination of these. It represents a recurring infection with the same organism that results from incomplete eradication of bacteria from the prostate gland.

Pathogenesis and Etiology

The exact mechanism of bacterial infection of the prostate is not well understood. The possible routes of infection are the same as those for UTIs. Reflux of infected urine into the prostate gland is thought to play an important role in causing infection. Intraprostatic reflux of urine occurs commonly and results in direct inoculation of infected urine into the prostate.[89,90,91] In addition, intraprostatic reflux of sterile urine can result in a chemical prostatitis and may be the cause of nonbacterial prostatitis. Sexual intercourse may contribute to infection of the prostate gland because prostatic secretions from men with chronic prostatitis and vaginal cultures from their sexual partners grow identical organisms. Other known causes of bacterial prostatitis include indwelling urethral and condom catheterization, urethral instrumentation, and transurethral prostatectomy in patients with infected urine.

Physiologic factors are believed to contribute to the development of prostatitis. Functional abnormalities found in bacterial prostatitis include altered prostate secretory functions. Prostatic fluid obtained from normal males contains prostatic antibacterial factor. This heat-stable, low-molecular-weight cation is a zinc-complexed polypeptide that is bactericidal to most urinary tract pathogens.[92] The antibacterial activity of prostatic antibacterial factor is related directly to the zinc content of prostatic fluid. Prostate fluid zinc levels and prostatic antibacterial factor activity also appear diminished in patients with prostatitis, as well as in the elderly.[92] Whether these changes are a cause or effect of prostatitis remains to be determined.

The pH of prostatic secretions in patients with prostatitis is altered.[93] Normal prostatic secretions have a pH in the range of 6.6 to 7.6. With increasing age, the pH tends to become more alkaline. In patients with inflammation of the prostate, prostatic secretions may have an alkaline pH in the range of 7 to 9. These changes suggest a generalized secretory dysfunction of the prostate that not only can affect the pathogenesis of prostatitis but also can influence the mode of therapy.

Gram-negative enteric organisms are the most frequent pathogens in acute bacterial prostatitis.[89,90,91] *E. coli* is the predominant organism, occurring in 75% of cases. Other gram-negative organisms frequently isolated include *K. pneumoniae*, *P. mirabilis*, and less frequently, *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp. Infrequently, cases of gonococcal and staphylococcal prostatitis occur.

E. coli most commonly causes chronic bacterial prostatitis with other gram-negative organisms isolated less frequently. The importance of gram-positive organisms in chronic bacterial prostatitis remains controversial. *S. epidermidis*, *S. aureus*, and diphtheroids have been isolated in some studies.

Clinical Presentation

Acute bacterial prostatitis presents as other acute infections. Massage of the prostate will express a purulent discharge that will readily grow the pathogenic organism. Prostatic massage is contraindicated in acute bacterial prostatitis, however, because of the risk of inducing bacteremia and the associated local pain. The diagnosis of acute bacterial prostatitis can be made from the patient's clinical presentation and the presence of significant bacteriuria. As with other UTIs, the infecting organism can be isolated from a midstream specimen.

CLINICAL PRESENTATION Bacterial Prostatitis Signs and Symptoms

- Acute bacterial prostatitis: High fever, chills, malaise, myalgia, localized pain (perineal, rectal, sacrococcygeal), frequency, urgency, dysuria, nocturia, and retention
- Chronic bacterial prostatitis: Voiding difficulties (frequency, urgency, dysuria), low back pain, and perineal and suprapubic discomfort

Physical Examination

- Acute bacterial prostatitis: Swollen, tender, tense, or indurated gland
- Chronic bacterial prostatitis: Boggy, indurated (enlarged) prostate in most patients

Laboratory Tests

- Bacteriuria
- Bacteria in EPSs

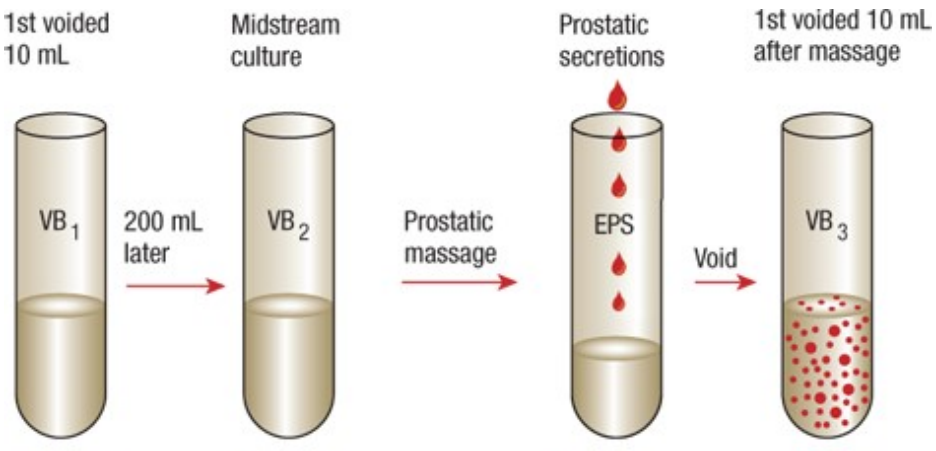
In contrast, chronic bacterial prostatitis is more difficult to diagnose and treat. Chronic bacterial prostatitis typically is characterized by recurrent UTIs with the same pathogen and is the most common cause of recurrent UTI in males. The patient's clinical presentation can vary widely. Many adults, however, are asymptomatic.

Because physical examination of the prostate is often normal, urinary tract localization studies are critical to the diagnosis of chronic bacterial prostatitis. The method of quantitative localization culture, as described by Meares and Stamey,[15,94] remains the diagnostic standard (**Fig. 116-3**). The

method compares the bacterial growth in sequential urine and prostatic fluid cultures obtained during micturition. The first 10 mL of voided urine is collected (voiding bladder 1, or VB_1) and constitutes urethral urine. After approximately 200 mL of urine has been voided, a 10-mL midstream sample is collected (VB_2). This specimen represents bladder urine. After the patient voids, the prostate is massaged and expressed prostatic secretions (EPS) are collected. After prostatic massage, the patient voids again and 10 mL of urine is collected (VB_3).

FIGURE 116-3

Segmented cultures of the lower tract in men. (EPS, expressed prostatic secretions; VB_1, voiding bladder 1; VB_2, voiding bladder 2; VB_3, voiding bladder 3.)



The diagnosis of bacterial prostatitis is made when the number of bacteria in EPS is 10 times that of the urethral sample (VB_1) and midstream sample (VB_2). If no EPS is available, the urine sample following massage (VB_3) should contain a bacterial count 10-fold greater than that of VB_1 or VB_2. If significant bacteriuria is present, ampicillin, cephalexin, or nitrofurantoin should be given for 2 to 3 days to sterilize the urine prior to performing the localization study.

TREATMENT

9 In general, the goals in the management of bacterial prostatitis are the same as those for UTIs. Acute bacterial prostatitis responds well to appropriate antimicrobial therapy that is directed at the most commonly isolated organisms. Prostatic penetration of antimicrobials occurs because the acute inflammatory reaction alters the cellular membrane barrier between the bloodstream and the prostate. Most patients can be managed with oral antimicrobial agents, such as trimethoprim–sulfamethoxazole and the fluoroquinolones (eg, ciprofloxacin, levofloxacin) (see Table 116-4). Other effective agents in this setting include cephalosporins and β-lactam–β-lactamase combinations. Although IV therapy is rarely necessary for total treatment, IV to oral sequential therapy with trimethoprim–sulfamethoxazole or the fluoroquinolones is appropriate. The conversion to an oral

antibiotic can be considered after the patient is afebrile for 48 hours or after 3 to 5 days of IV therapy. The total course of antibiotic therapy should be 4 weeks in order to reduce the risk of development of chronic prostatitis, although in some cases 2 weeks may be sufficient. Therapy may be prolonged with chronic prostatitis (6-12 weeks). Long-term suppressive therapy also may be initiated for recurrent infections, such as three times weekly ciprofloxacin, trimethoprim–sulfamethoxazole regular-strength tablet daily, or nitrofurantoin 100 mg daily.[94]

Chronic bacterial prostatitis often presents a more vexing situation because cures are obtained rarely. Despite high serum concentrations of antibacterial drugs in excess of the minimal inhibitory concentrations of the infecting organisms, bacteria persist in prostatic fluid. Most likely the failure to eradicate sensitive bacteria is caused by the inability of antibiotics to reach sufficient concentrations in the prostatic fluid and cross the prostatic epithelium.

Several factors that determine antibiotic diffusion into prostatic secretions were delineated from the canine model. Lipid solubility is a major determinant in the ability of drugs to diffuse from plasma across epithelial membranes. The degree of ionization in plasma also affects the diffusion of drugs. Only unionized molecules can cross the lipid barrier of prostatic cells, and the drug's pK_a (negative logarithm of acid ionization constant) directly determines the fraction of unchanged drug.

The pH gradient across the membrane has an influence on tissue penetration, as well. A pH gradient of at least one pH unit between separate compartments allows for ion trapping. As the unionized drug crosses the epithelial barrier into prostatic fluid, it becomes ionized allowing less drug to diffuse back across the lipid barrier. In early studies with the canine model, the prostatic pH was reported to be acidic (6.4).[93] In humans, however, the pH of prostatic secretions from an inflamed prostate is actually basic (8.1-8.3).[93]

The choice of antibiotics in chronic bacterial prostatitis should include agents that are capable of reaching therapeutic concentrations in the prostatic fluid and which possess the spectrum of activity to be effective. Agents that achieve therapeutic prostatic concentrations include trimethoprim and the fluoroquinolones. Sulfamethoxazole penetrates poorly and probably contributes very little to trimethoprim activity when used in combination. The fluoroquinolones appear to provide the best therapeutic options in the management of chronic bacterial prostatitis. Therapy should be continued for 4 to 6 weeks initially. Longer treatment periods may be necessary in some cases. If therapy fails with these regimens, chronic suppressive therapy may be used or surgery considered.

PERSONALIZED PHARMACOTHERAPY

Patient-centered pharmacotherapy and management of UTIs require knowledge of the pathogenesis and causative organisms associated with the various clinical syndromes described in this chapter.[22] Individualizing the antimicrobial therapy will depend on many factors, first and foremost being the susceptibility of the offending pathogen. As was discussed in the chapter, *E. coli* resistance is continuing to increase, therefore, it is imperative for the healthcare professional to be familiar with the resistance trends in their geographical area when prescribing therapy. In addition, the prevention of increasing resistance and collateral damage should be considered when selecting antimicrobial

therapy.[1] Other factors to consider in selecting therapy would be a patient's allergies and recent antimicrobial exposure. Lastly, cost may factor into compliance enhancing the effectiveness of therapy. The costs include both direct and indirect costs associated with treatment.

Direct costs are those associated with diagnosis, treatment, and follow-up. The cost of pharmaceuticals varies according to the agents used and the duration of therapy. Trimethoprim–sulfamethoxazole and amoxicillin–clavulanate are rather inexpensive. However, when considering rates of resistance leading to therapeutic failure, overall costs increase dramatically. The fluoroquinolones also are highly effective agents, but generally are more expensive and a rise in their utilization is now being associated with increasing resistance.[69,95] In general, the outcome and total cost depend on whether therapy is empirical or definitive (based on a culture diagnosis for acute infection) and if the individual patient is adherent with the regimen. As a healthcare professional, working with and/or within the healthcare team is necessary to select appropriate therapies and maximize the possibility of positive therapeutic outcomes.

Chapter 117: Sexually Transmitted Diseases

Leroy C. Knodel; Bryson Duhon; Jacqueline Argamany

The editors are deeply appreciative for the excellent contributions of Dr Leroy Knodel over all 10 editions of this book. This chapter was in preparation at the time of Dr Knodel's death. We thank Dr. Bryson Duhon for his timely work to complete the chapter.

INTRODUCTION

KEY CONCEPTS

- 1 All recommended treatment regimens for gonorrhea include antibiotic therapy directed against *Chlamydia* species because of the high prevalence of coexisting infections, unless chlamydia has been ruled out.
- 2 Parenteral penicillin is the treatment of choice for all syphilis infections. For patients who are penicillin-allergic, few well-studied alternative agents are available, and most are oral medications that require 2 to 4 weeks of therapy to be effective. Patient compliance and thus efficacy are a concern when alternative regimens must be used.
- 3 Chlamydia genital tract infections represent the most frequently reported communicable disease in the United States. In females, these infections are frequently asymptomatic or minimally symptomatic and, if left untreated, are associated with the development of pelvic inflammatory disease and attendant complications such as ectopic pregnancy and infertility. As a result, all sexually active females younger than 25 years and sexually active women with multiple sexual partners should be screened annually for this infection.
- 4 Oral acyclovir, famciclovir, and valacyclovir are effective in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. The benefit of these agents for recurrent infections has not been demonstrated. Patient-initiated, episodic antiviral therapy started within one day of lesion onset or during the prodrome preceding an outbreak offers an alternative to continuous suppressive therapy of recurrent infection in some individuals.

- Metronidazole and tinidazole are the only agents currently approved in the United States to treat trichomoniasis. Although a single 2-g dose of either agent is widely used for compliance and other reasons, single-dose therapy should be avoided for treating recurrent infections.

The spectrum of sexually transmitted diseases (STDs) has broadened from the classic venereal diseases—gonorrhea, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale—to include a variety of pathogens known to be spread by sexual contact (**Table 117-1**). Because of the large number of infected individuals, the diversity of clinical manifestations, the changing drug-susceptibility patterns of some pathogens, and the high frequency of multiple STDs occurring simultaneously in infected individuals, the diagnosis and management of patients with STDs are much more complex today than they were even a decade ago.[1,3,4] Approximately 20 million new infections occur annually in the United States, with a total prevalence of 110 million infections resulting in a total medical cost of $116 billion to the US healthcare system.[5,6]

TABLE 117-1 Sexually Transmitted Diseases

Disease	Associated Pathogens
Bacterial	
Gonorrhea	*Neisseria gonorrhoeae*
Syphilis	*Treponema pallidum*
Chancroid	*Haemophilus ducreyi*
Granuloma inguinale	*Calymmatobacterium granulomatis*
Enteric disease	*Salmonella* spp., *Shigella* spp., *Campylobacter* fetus
Campylobacter infection	*Campylobacter jejuni*
Bacterial vaginosis	*Gardnerella vaginalis, Mycoplasma hominis, Bacteroides* spp., *Mobiluncus* spp.
Group B streptococcal infections	Group B *Streptococcus*
Chlamydial	
Nongonococcal urethritis	*Chlamydia trachomatis*
Lymphogranuloma venereum	*C. trachomatis*, type L
Viral	
Acquired immunodeficiency syndrome	Human immunodeficiency virus
Herpes genitalis	Herpes simplex virus, types I and II
Viral hepatitis	Hepatitis A, B, C, and D viruses
Condylomata acuminata	Human papillomavirus
Molluscum contagiosum	Poxvirus
Cytomegalovirus infection	Cytomegalovirus
Mycoplasmal	
Nongonococcal urethritis	*Mycoplasma genitalium*
Protozoal	

Disease	Associated Pathogens
Trichomoniasis	*Trichomonas vaginalis*
Amebiasis	*Entamoeba histolytica*
Giardiasis	*Giardia lamblia*
Fungal	
Vaginal candidiasis	*Candida albicans*
Parasitic	
Scabies	*Sarcoptes scabiei*
Pediculosis pubis	*Phthirus pubis*
Enterobiasis	*Enterobius vermicularis*

Although the annual number of new infections is roughly equal between genders, the complications of STDs generally are more frequent and severe in women.[5] In particular, serious effects on maternal and infant health during pregnancy are well documented.[1,4] Damage to reproductive organs, increased risk of cancer, complications associated with pregnancy, and transmission of disease to the fetus or newborn are associated with several STDs. As a result of the physiologic, psychosocial, and economic consequences of STDs, and because of the increasing prevalence of some viral STDs, such as human immunodeficiency virus (HIV) and genital herpes, for which curative therapy is not available, there is continuing research into STDs and the primary prevention of these diseases.[2,3,4,7]

With the exception of HIV infection, which is reviewed in detail in Chapter 126, the most frequently occurring STDs in the United States are discussed in this chapter. For other less common STDs, only recommended treatment regimens are presented. The most current information on the epidemiology, diagnosis, and treatment of STDs provided by the US Centers for Disease Control and Prevention (CDC) can be obtained at the CDC Web site (www.cdc.gov).

Numerous interrelated factors contribute to the epidemic nature of STDs. Sociocultural, demographic, and economic factors, together with patterns of sexual behavior, host susceptibility to infection, changing properties of the causative pathogens, disease transmission by asymptomatic individuals, and environmental factors, are important determinants of the frequency and distribution of STDs in the United States and worldwide.

Age is one of the most important demographic determinants of STD incidence. Approximately half of all new STD cases each year occur in persons in their teens and twenties, the peak years of sexual activity. With increasing age, the incidence of most STDs decreases exponentially. In sexually active teenagers, STD rates are highest in the youngest, suggesting that physiologic differences may contribute to increased susceptibility.[2,3,4,7]

Age-specific rates of STDs are historically higher in men than in women; however, reported rates may not represent true gender differences but rather may reflect greater ease of detection in men. In recent years, the ratio of male-to-female cases for most STDs has declined, and in some cases reversed, possibly reflecting improvements in the diagnosis of STDs in asymptomatic women or changes in female sexual behavior following the availability of improved methods of contraception.

Although some racial disparity exists for rates of STD infection, it is possible that this is a reflection of socioeconomic differences.[1,2,3,4,5,7]

The single greatest risk factor for contracting STDs is the number of sexual partners. As the number of sexual partners increases, the risk of being exposed to someone infected with an STD increases. Sexual preference also plays a major role in the transmission of STDs. For all major STDs, rates are disproportionately greater in men who have sex with men (MSM) than in heterosexuals. In addition, a number of less common STDs, including several caused by enteric protozoans and bacterial pathogens, occur primarily in MSM. The major risk factors for MSM appear to be related to the greater number of sexual partners and the practice of unprotected anal–genital, oral–genital, and oral–anal intercourse. In addition, prostitution and illicit drug use are associated with a higher incidence of most STDs.[1,3,4,7]

Some of the most serious sequelae of STDs are associated with congenital or perinatal infections. Most neonatal infections are acquired at birth, after infant passage through an infected cervix or vagina. Neonatal *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus (HSV) infections are associated with this type of spread. For pregnant women with syphilis, infection is usually transmitted transplacentally, producing a congenital infection. Depending on the organism, neonatal infections can manifest in a variety of ways, produce significant morbidity, and in some cases result in infant death.[1,3,4]

Other than complete abstinence, the most effective way to prevent STD transmission is by maintaining a mutually monogamous sexual relationship between uninfected partners. Short of this, use of barrier contraceptive methods, such as the male and female condoms, diaphragm, cervical cap, vaginal sponges, and vaginal spermicides alone or in combination, provides varying degrees of protection from a number of STDs. When used correctly and consistently, male latex condoms with or without spermicide are more effective than natural skin condoms in protecting against STD transmission, including HIV, gonorrhea, chlamydia, trichomoniasis, HSV, and human papillomavirus (HPV). When lubrication is desired with latex condoms, water-based products, such as K-Y jelly, are recommended because oil-based agents (eg, petroleum jelly) can weaken latex condoms and reduce their effectiveness. For latex-allergic individuals, other synthetic condoms (eg, polyurethane) appear to possess efficacy against STD transmission similar to latex condoms. The female condom is a lubricated polyurethane sheath with a diaphragm-like ring on each end that can be used as a protective device for women with male sexual partners who do not desire to use a condom. Limited data suggest that the female condom blocks penetration of viruses, including HIV; for nonviral STDs, the female condom provides STD protection similar to the male condom.[1,3,7,8] At one time, use of nonoxynol-9, a vaginal spermicide with cytolytic activity, was advocated to reduce the transmissibility of several STDs. This was based in large part on in vitro and animal data. However, nonoxynol-9 does not reduce the risk of transmission of common STDs and actually can increase the risk of HIV transmission. Frequent use of nonoxynol-9 damages vaginal, cervical, and rectal epithelium, leading to increased transmissibility of HIV and possibly other STDs. Diaphragms may protect against cervical gonorrheal, chlamydial, and trichomonal infections.[1,7,8,9,10]

The varied spectrum of clinical syndromes produced by common STDs is determined not only by the

etiologic pathogen(s) but also by differences in male and female anatomy and reproductive physiology. For a number of STDs, the signs and symptoms overlap sufficiently to prevent accurate diagnosis without microbiologic confirmation. Frequently, symptoms are minimal or absent despite the presence of infection. **Table 117-2** lists common clinical syndromes associated with STDs.[1,3,4]

TABLE 117-2 Selected Syndromes Associated with Common Sexually Transmitted Pathogens

Syndrome	Commonly Implicated Pathogens	Common Clinical Manifestations[a]
Urethritis	*Chlamydia trachomatis*, herpes simplex virus, *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, *Ureaplasma Mycoplasma genitalium*	Urethral discharge, dysuria
Epididymitis	*C. trachomatis*, *N. gonorrhoeae*	Scrotal pain, inguinal pain, flank pain, urethral discharge
Cervicitis/vulvovaginitis	*C. trachomatis, Gardnerella vaginalis*, herpes simplex virus, human papillomavirus, *N. gonorrhoeae, T. vaginalis*	Abnormal vaginal discharge, vulvar itching/irritation, dysuria, dyspareunia
Genital ulcers (painful)	*Haemophilus ducreyi*, herpes simplex virus	Usually multiple vesicular/pustular (herpes) or papular/pustular (*H. ducreyi*) lesions that can coalesce; painful, tender lymphadenopathy[b]
Genital ulcers (painless)	*Treponema pallidum*	Usually single papular lesion
Genital/anal warts	Human papillomavirus	Multiple lesions ranging in size from small papular warts to large exophytic condylomas
Pharyngitis	*C. trachomatis* (?), herpes simplex virus, *N. gonorrhoeae*	Symptoms of acute pharyngitis, cervical lymphadenopathy, fever[c]
Proctitis	*C. trachomatis*, herpes simplex virus, *N. gonorrhoeae, T. pallidum*	Constipation, anorectal discomfort, tenesmus, mucopurulent rectal discharge
Salpingitis	*C. trachomatis, N. gonorrhoeae*	Lower abdominal pain, purulent cervical or vaginal discharge, adnexal swelling, fever[d]

[a]For some syndromes, clinical manifestations can be minimal or absent.

[b]Recurrent herpes infection can manifest as a single lesion.

[c]Most cases of pharyngeal gonococcal infection are asymptomatic.

[d]Salpingitis increases the risk of subsequent ectopic pregnancy and infertility.

GONORRHEA

Epidemiology and Etiology

The gram-negative diplococcus *N. gonorrhoeae* is the causative organism of gonorrhea. Although the rate of reported cases in the United States has remained relatively stable over the past decade, 333,000 new cases were reported in 2013, representing an 8.2% increase from 2009.[11] Due to the increasing incidence of resistance to available antibiotics, there is concern that this number may continue to increase in the future.[1,12] Of concern also are the substantial number of infections that remain undiagnosed and unreported.[1,12] Humans are the only known natural host of this intracellular parasite. Because of its rapid incubation period and the large number of infected individuals with asymptomatic disease, gonorrhea is difficult to control.[1,13,14,15,16,17,18]

Although the risk of a female acquiring a cervical infection after a single episode of vaginal intercourse with an infected male partner is high and increases with multiple exposures, the risk of transmission from an infected female to an uninfected male is not as great following a single act of coitus. No data are available on the risk of transmission after other types of sexual contact.[13,14,15,16,17]

Pathophysiology

On contact with a mucosal surface lined by columnar, cuboidal, or noncornified squamous epithelial cells, the gonococci attach to cell membranes by means of surface pili and are then pinocytosed. The virulence of the organism is mediated primarily by the presence of pili and other outer membrane proteins. After mucosal damage is established, polymorphonuclear (PMN) leukocytes invade the tissue, submucosal abscesses form, and purulent exudates are secreted.[13,14,15,16,17,18]

Clinical Presentation

Individuals infected with gonorrhea can be symptomatic or asymptomatic, have complicated or uncomplicated infections, and have infections involving several anatomic sites. Interestingly, most of the symptomatic patients who are not treated become asymptomatic within 6 months, with only a few becoming asymptomatic carriers of the disease.[13,14,15,16] Up to 50% of women experience nonspecific symptoms, including mucopurulent vaginal discharge and vaginal bleeding, especially following sexual intercourse. In comparison, 90% of males experience symptoms within 2 to 6 days following exposure, most commonly mucopurulent penile discharge and dysuria.[19] The most common clinical features of gonococcal infections are presented in **Table 117-3**.

TABLE 117-3 Presentation of Gonorrhea Infections

	Males	Females
General	Incubation period 1-14 days	Incubation period 1-14 days

	Males	Females
Site of infection	Symptom onset in 2-8 days	Symptom onset in 10 days
	Most common: urethra	Most common: endocervical canal
	Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Commonly symptomatic, may be asymptomatic	Can be asymptomatic or minimally symptomatic
	Urethral infection: dysuria and urinary frequency	Endocervical infection: usually asymptomatic or mildly symptomatic
	Anorectal infection: asymptomatic to severe rectal pain	Urethral infection: dysuria, urinary frequency
	Pharyngeal infection: asymptomatic to mild pharyngitis	Anorectal and pharyngeal infection; symptoms same as for men
Signs	Purulent urethral or rectal discharge can be scant to profuse Anorectal: pruritus, mucopurulent discharge, bleeding	Abnormal vaginal discharge or uterine bleeding; purulent urethral or rectal discharge can be scant to profuse
Complications	Rare (epididymitis, prostatitis, inguinal lymphadenopathy, urethral stricture)	Pelvic inflammatory disease and associated complications (ie, ectopic pregnancy, infertility)
	Disseminated gonorrhea	Disseminated gonorrhea (three times more common than in men)

MSM, men who have sex with men.

Complications associated with untreated gonorrhea appear more pronounced in women, likely a result of a high percentage who experience signs and symptoms that are nonspecific and minimally symptomatic. As a result, many women do not seek treatment until after the development of serious complications, such as pelvic inflammatory disease (PID). Approximately 15% of women with gonorrhea develop PID. Left untreated, PID can be an indirect cause of infertility and ectopic pregnancies. In 0.5% to 3% of patients with gonorrhea, the gonococci invade the bloodstream and produce disseminated disease. Disseminated gonococcal infection (DGI) is three times more common in women than in men. The usual clinical manifestations of DGI are tender necrotic skin lesions, tenosynovitis, and monoarticular arthritis.[1,13,14,15,16,17] Additionally, HIV infection is more easily transmitted in patients coinfected with gonorrhea.

Diagnosis

Diagnosis of gonococcal infections can be made by gram-stained smears, culture, or methods based on the detection of cellular components of the gonococcus (eg, enzymes, antigens, DNA, or lipopolysaccharide [LPS]) in clinical specimens. Various stains have been used to identify gonococci

microscopically, with the Gram stain the most widely used in clinical practice. Gram-stained smears are positive for gonococci when gram-negative diplococci of typical kidney bean morphology are identified within PMN leukocytes.[1,13,14,15,16,17] In urethral smears from men with symptomatic urethritis, the smear is highly sensitive and specific, and is considered diagnostic for infection. However, due to lower sensitivity, gram-stained smears are not recommended in the diagnosis of endocervical, rectal, cutaneous, and asymptomatic male urethral infections. Because of the presence of nonpathogenic *Neisseria* in the pharynx, the Gram stain is not useful in the diagnosis of pharyngeal infection.[1,13,15,16,17]

Although culture is highly sensitive and specific, limitations including prolonged turnaround times and difficulty maintaining viable samples preclude widespread usage. Additionally, culture requires invasive specimen collection for processing (endocervical or urethral swab). As a result, direct culture is primarily utilized in cases of suspected or documented treatment failures, as a test of cure following use of an alternative treatment regimen, or for detection of rectal, oropharyngeal, and conjunctival gonococcal infections.[1]

With the exception of Gram stain for symptomatic gonococcal urethritis, alternative methods of diagnosis, including enzyme immunoassay (EIA), DNA probe techniques, and nucleic acid amplification techniques (NAATs) offer increased sensitivity and/or specificity over traditional diagnostic methods.[13,16,17,20] Additionally, many of these tests can provide a more rapid means of diagnosis than culture. Of particular clinical importance is the high sensitivity of NAATs for detecting *N. gonorrhoeae* using noninvasive specimens (eg, self-collected urine specimens, vaginal swabs). NAAT is recommended by the CDC for detection of gonorrhea in FDA-cleared specimen types specific to each NAAT manufacturer.[1] This technology is also being used to concurrently test for *C. trachomatis* using a single specimen. However, a major drawback of NAATs is their inability to provide resistance data on isolated gonococcal strains. In cases of documented treatment failure, antimicrobial susceptibility testing is recommended, as previously mentioned.[1,12,17,18,20]

TREATMENT

In 2010, the CDC issued an update to their recommended treatment regimens for gonorrhea. This update eliminated oral cephalosporins from the recommended treatment regimens for gonorrhea, leaving single-dose intramuscular ceftriaxone as the only recommended agent for treating gonorrhea[18] (**Table 117-4**). The ceftriaxone-based regimens are the only regimens that have well-documented efficacy in the treatment of urethral, cervical, rectal, and pharyngeal infections, curing 99.2% of uncomplicated cases and 98.9% of pharyngeal cases.[12] A 400 mg oral dose of cefixime may be substituted if ceftriaxone is unavailable, however, a test of cure is often recommended two weeks later due to reduced bactericidal levels and efficacy (97.5% in uncomplicated cases and 92.3% in pharyngeal gonorrhea) compared to ceftriaxone. Additionally, only ceftriaxone is effective in treating pharyngeal gonorrhea and eradicating both gonorrhea and incubating syphilis in a patient coinfected with both organisms. The latter is particularly beneficial in areas with a high rate of syphilis.[1,13,15,16,17,18]

Coexisting chlamydial infection, which is documented in up to 50% of women and 20% of men with

gonorrhea, constitutes the major cause of postgonococcal urethritis, cervicitis, and salpingitis in patients treated for gonorrhea for whom concurrent chlamydial infection has not been ruled out.[1,17] As a result, concomitant treatment with azithromycin or doxycycline is recommended in all patients treated for gonorrhea. Azithromycin 1,000 mg given orally as a one-time dose is currently preferred to doxycyline due to advantages of single-dose therapy and increased resistance of gonococcal resistance to tetracycline. Doxycycline 100 mg orally twice a day may be used in cases of azithromycin allergy.[1] While azithromycin (2 g) as a single dose appears highly effective in eradicating both gonorrhea and chlamydia, it is not recommended as a preferred alternative to ceftriaxone because of concerns regarding the development of resistance. Alternative therapies can be used for in cephalosporin-allergic individuals. Single-dose regimens consisting of oral gemifloxacin or intramuscular gentamicin in combination with azithromycin were associated with high cure rates (99.5% and 100%, respectively), however, high rates gastrointestinal side effects may limit their applicability [1,17,21,22,23] Pregnant women infected with *N. gonorrhoeae* should be treated with ceftriaxone. For presumed or diagnosed concurrent *C. trachomatis* infection, azithromycin is the preferred treatment.[1,13,14]

TABLE 117-4 Treatment of Gonorrhea

Type of Infection	Recommended Regimens[a]	Alternative Regimens[a]
Uncomplicated infections of the cervix, urethra, and rectum in adults	Ceftriaxone 250 mg IM once *plus* Azithromycin 1 g orally once	Cefixime 400 mg orally once *plus* Azithromycin 1 g orally once, or doxycycline 100 mg PO twice daily for 7 days[b,c] or Gemifloxacin 320 mg orally once or gentamicin 240 mg IM[e] *plus* Azithromycin 2 g orally once
Uncomplicated infections of the pharynx	Ceftriaxone 250 mg IM once *plus* Azithromycin 1 g orally once	Consult with infectious disease expert
Disseminated gonococcal infection in adults (>45 kg)	Ceftriaxone 1-2 g IM or IV every 12-24 hour[e] *plus*	Cefotaxime 1 g IV every 8 hours[e] or ceftizoxime 1 g IV every 8 hours[e]

Type of Infection	Recommended Regimens[a]	Alternative Regimens[a]
		plus
	Azithromycin 1 g orally once	Azithromycin 1 g orally once
Uncomplicated infections of the cervix, urethra, pharynx, and rectum in children (<45 kg)	Ceftriaxone 25-50 mg/kg IV or IM once (not to exceed 125 mg)	
Disseminated gonococcal infection in children (<45 kg)	Ceftriaxone 50 mg/kg IV or IM once daily (not to exceed 1 g)	
Gonococcal conjunctivitis in adults	Ceftriaxone 1 g IM once[f]	
Ophthalmia neonatorum	Ceftriaxone 25-50 mg/kg IV or IM once (not to exceed 125 mg)	
Disseminated gonococcal infection in neonates	Ceftriaxone 25-50 mg/kg/day IV or IM once daily or cefotaxime 25 mg/kg IV or IM twice daily for 7 days, or 10-14 days if meningitis is suspected[h]	
Infants born to mothers with gonococcal infection (prophylaxis)	Erythromycin (0.5%) ophthalmic ointment in a single application[g] Ceftriaxone 25-50 mg/kg IM or IV once (not to exceed 125 mg)	

CDC, Centers for Disease Control and Prevention; *C. trachomatis*, *Chlamydia trachomatis*; NAAT, Nucleic Acid Amplification Test; *N. gonorrhoeae, Neisseria gonorrhoeae*.

[a]Recommendations are those of the CDC.

[b]Tetracyclines are contraindicated during pregnancy. Pregnant women should be treated with recommended cephalosporin-based combination therapy. In severe cephalosporin allergy, consulation with an infectious diseases expert is recommended.

[c]Patients who are treatment failures with alternative regimens should be treated with ceftriaxone 250 mg IM once plus azithromycin 1 g PO once in consultation with an infectious disease expert.

[d]For patients with severe cephalosporin allergy.

[e]Parenteral treatment duration should be determined in consultation with an infectious diseases expert. Parenteral therapy for meningitis should be continued for at least 10-14 days and at least 4 weeks in endocarditis.

[f]A single lavage of the infected eye with normal saline should be considered; empiric therapy for *C. trachomatis* is recommended.

[g]Efficacy in preventing chlamydial ophthalmia is unclear.

[h]Caution should be taken when administering ceftriaxone to hyperbilirubinemic neonates.

Ceftriaxone is the recommended therapy for DGI, gonococcal meningitis, endocarditis, and any type of gonococcal infection in children. In cases of DGI, patients should be hospitalized and treated with ceftriaxone or one of the alternative parenteral cephalosporin antibiotics (see Table 117-4). Although marked improvement is usually noted within 48 hours of initiating therapy, treatment should be continued for at least 7 days, with longer durations necessary for serious infections, such as meningitis and endocarditis[1,16,17] Gonococcal ophthalmia is highly contagious in adults and neonates and requires ceftriaxone therapy. Single-dose therapy is adequate for gonococcal conjunctivitis, although some physicians recommend continuing therapy until cultures are negative at 48 to 72 hours. Topical antibiotics are not sufficiently effective when used alone for ocular infections and are not necessary with appropriate systemic therapy. Infants with any evidence of ocular infection should be evaluated for signs of DGI.[1,13,16,17,24]

Clinical Controversy…

The American College of Obstetricians and Gynecologists (ACOG) supports expedited partner therapy, or the treatment of sexual partners of those infected with gonorrhea and chlamydial without first examining these partners, in order to reduce reinfection rates. This is particularly useful in cases when the patient's partner is unwilling to seek medical care. However, many legal and social barriers exist which prevent widespread acceptance of this philosophy.

Treatment of gonorrhea during pregnancy is essential to prevent ophthalmia neonatorum. Gonococcal infection in newborns results primarily from passage through an infected birth canal, but it also can be transmitted in utero. Conjunctival involvement usually develops within 7 days of delivery and is characterized by intense, bilateral conjunctival inflammation with chemosis. If not treated promptly, corneal ulceration and blindness can develop. Because the law in most states requires neonatal prophylaxis with topical ocular antimicrobials, gonococcal ophthalmia neonatorum is rare in the United States. The CDC recommends that erythromycin (0.5%) ophthalmic ointment be instilled in each conjunctival sac immediately postpartum.[1,13,14,15,16,17,24]

Recent sex partners (within 60 days of preceding onset of symptoms or diagnosis) should be referred to for evaluation and treatment. Sex partners should abstain from unprotected sexual intercourse for 7 days after both have completed treatment and symptoms have resolved.[1]

Evaluation of Therapeutic Outcomes

In the past, persistence of gonorrhea symptoms a short time following treatment with a recommended regimen against gonorrhea usually indicated reinfection rather than treatment failure and, as such, reflected the need for improved patient education and sex partner referral. However, with antimicrobial resistance increasingly being reported in recent years, reinfection can no longer be assumed as the cause. As a result, the CDC recommends that all apparent treatment failures be assessed using culture and sensitivity testing. Persistence of symptoms also can be due to other

infectious causes, such as *C. trachomatis*.[1,13,14,15,16,17,18] While the CDC does not recommend a test-of-cure of patients treated with a recommended regimen, it is recommend that any patient treated for gonorrhea be retested 3 months after treatment, and if not possible, whenever the patient next presents for medical care in the following 12 months. Patients who require retreatment should be tested for cure 7-14 days following the second regiment.[1]

SYPHILIS

Epidemiology and Etiology

Although nearly eradicated in 2000, cases of syphilis more than doubled in the United States from 2005 to 2013, with an annual total of primary and secondary syphilis diagnoses of around 16,000. Of these newly diagnosed cases, 91% were reported in men, the majority of whom were reported as MSM.[25] In addition to being highly contagious, syphilis is of major concern because, if left untreated, it can progress to a chronic systemic disease that can be fatal or seriously disabling.[26,27,28,29,30,31,32,33,34,35] Syphilis usually is acquired by sexual contact with infected mucous membranes or cutaneous lesions, although on rare occasions it can be acquired by nonsexual personal contact, accidental inoculation, or blood transfusion. The causative organism of syphilis is *Treponema pallidum*, a spirochete. The risk of acquiring syphilis from an infected individual after a single sexual encounter is approximately 50% to 60%. After sexual contact, the organism penetrates the intact mucous membrane or a break in the cornified epithelium, and spirochetemia occurs.[27,30,31,32,33,34,35]

There is strong evidence of an association between syphilis and HIV infection. Syphilis, similar to other sexually transmitted genital ulcer diseases, can increase the risk of acquiring HIV in exposed individuals. In addition, immunologic defects in HIV-infected individuals can produce an atypical serologic response to syphilis. In particular, the possibility of delayed seroreactivity, markedly elevated serologic titers, and increased false-positive results could complicate the diagnosis, as well as assessment of treatment efficacy, in HIV-positive individuals infected with syphilis. Furthermore, anecdotal evidence suggests that compromised immune function can result in an accelerated progression of syphilis, particularly to neurosyphilis, requiring more aggressive antibiotic therapy in comparison with an immunocompetent host. As a result of this association, the CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.[1,26,28,29,30,32,33]

Clinical Presentation

The clinical presentation of syphilis is varied with progression through multiple stages possible in untreated or inadequately treated patients (**Table 117-5**).

TABLE 117-5 Presentation of Syphilis Infections

General	
Primary	Incubation period 10-90 days (mean, 21 days)

Secondary	Develops 2-8 weeks after initial infection in untreated or inadequately treated individuals
Latent	Develops 4-10 weeks after secondary stage in untreated or inadequately treated individuals
Tertiary	Develops in approximately 30% of untreated or inadequately treated individuals 10-30 years after initial infection
Site of Infection	
Primary	External genitalia, perianal region, mouth, and throat
Secondary	Multisystem involvement secondary to hematogenous and lymphatic spread
Latent tertiary	Potentially multisystem involvement (dormant)
	CNS, heart, eyes, bones, and joints
Signs and Symptoms	
Primary	Single, painless, indurated lesion (chancre) that erodes, ulcerates, and eventually heals (typical); regional lymphadenopathy is common; multiple, painful, purulent lesions possible but uncommon
Secondary	Pruritic or nonpruritic rash, mucocutaneous lesions, flulike symptoms, lymphadenopathy
Latent	Asymptomatic
Tertiary	Cardiovascular syphilis (aortitis or aortic insufficiency), neurosyphilis (meningitis, general paresis, dementia, tabes dorsalis, eighth cranial nerve deafness, blindness), gummatous lesions involving any organ or tissue

CNS, central nervous system.

Primary Syphilis

The primary stage, characterized by the appearance of a chancre on cutaneous or mucocutaneous tissue exposed to the organism, is highly infectious. Even without treatment, chancres persist only for 1 to 8 weeks before healing spontaneously. Because syphilitic chancres can be confused with other infectious etiologies, appropriate diagnostic testing is important.[26,27,28,29,30,32,34]

Secondary Syphilis

The secondary stage of syphilis is characterized by a variety of mucocutaneous eruptions resulting from widespread hematogenous and lymphatic spread of *T. pallidum*. Skin lesions can be either generalized or localized to a small portion of the body and, with the exception of follicular lesions, are nonpruritic. Generalized lymphadenopathy also is seen in the majority of patients, as are nonspecific symptoms such as mild and transitory malaise, fever, pharyngitis, headache, anorexia, and arthralgia. If untreated, secondary syphilis disappears in 4 to 10 weeks; however, lesions can recur at any time within 4 years.[26,27,28,29,30,31,32,33,34]

Latent Syphilis

By definition, persons with a positive serologic test for syphilis but with no other evidence of disease have latent syphilis. Latent syphilis is further divided into early and late latency. During early latency, the patient is considered potentially infectious because of the 25% risk of spontaneous mucocutaneous relapse. The CDC defines early latency as 1 year from the onset of infection, although other investigators propose a longer interval, such as 2 to 4 years. With the exception of pregnancy in which the mother can pass the disease to the fetus, late latency is considered noninfectious, although the patient remains a host.[1,26,27,28,29,30,31,32,33,34]

Most untreated patients with late latent syphilis have no further sequelae; however, approximately 25% to 30% progress either to neurosyphilis or to late syphilis with clinical manifestations other than neurosyphilis. Treatment of all patients with latent syphilis is essential because there is no way to predict which patients will have progression of their disease.[26,27,28,29,30,31,32,33,34]

Tertiary Syphilis and Neurosyphilis

If left untreated, syphilis can slowly produce an inflammatory reaction in virtually any organ in the body. Manifestations of this disease progression were referred to previously as *tertiary syphilis*. These clinical manifestations now are differentiated into two subgroups based on the presence or absence of central nervous system (CNS) involvement: neurosyphilis or tertiary syphilis (ie, gumma and cardiovascular syphilis).[1,26,27,28,29,30,31,32,33,34]

Currently, the term *neurosyphilis* encompasses any patient with cerebrospinal fluid (CSF) abnormalities consistent with CNS infection. Approximately 40% of patients with primary or secondary syphilis exhibit such abnormalities, although most remain asymptomatic. Persistence of CSF abnormalities into late latency is associated with a greater risk of progression to symptomatic neurosyphilis. Although data are conflicting, some investigators suggest that HIV-infected patients are at greater risk of developing symptomatic neurosyphilis than patients with intact immune systems.[1,26,27,28,29,30,31,32,33,34]

Rarely seen, the most common manifestations of disease progression from late latency are benign gumma formation and cardiovascular syphilis. The gumma, a nonspecific granulomatous lesion, is the classic lesion of late syphilis and develops in 50% of patients with disease progression. These chronic, destructive lesions characteristically infiltrate the skin, bone, soft tissue, and liver but can be found in any organ or tissue. Gummas of critical organs, such as the heart or brain, can be fatal.[1,26,27,28,29,30,33]

Congenital Syphilis

In pregnant women with syphilis, *T. pallidum* can cross the placenta at any time during pregnancy. The risk of fetal infection is greatest in pregnant women with primary and secondary syphilis and declines in pregnant women with late disease. Transmission of syphilis during pregnancy occurs primarily transplacentally and can result in fetal death, prematurity, or congenital syphilis. Symptoms can be seen during the first months of life (early congenital syphilis) or later in childhood or adolescence (late congenital syphilis). Manifestations of early congenital syphilis resemble those of secondary syphilis, whereas those of late congenital syphilis correspond to the tertiary stage in

adults.[26,28,29,30]

Diagnosis

Because *T. pallidum* is difficult to culture in vitro, diagnosis is based primarily on microscopic examination of serous material from a suspected syphilitic lesion or on results from serologic testing. In primary syphilis, diagnosis is established by the presence of *T. pallidum* on dark-field microscopic examination of material from cutaneous lesions and enlarged lymph nodes in patients with secondary syphilis. In incubating syphilis, confirmation frequently is by dark-field microscopic examination because serologic tests can be unreactive early in the disease. Another method of direct microscopic examination, the direct fluorescent-antibody (test) for *T. pallidum* (DFA-TP), which uses monoclonal or polyclonal antibodies specific for *T. pallidum*, has greater specificity and sensitivity than dark-field examination, and does not require the immediate examination of fresh specimens.[30,31,32,33,34,35]

Serologic tests are the mainstay in the diagnosis of syphilis and traditionally are categorized as nontreponemal or treponemal. Common nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) slide test, rapid plasma reagin (RPR) card test, unheated serum reagin (USR) test, and the toluidine red unheated serum test (TRUST). Nontreponemal tests, which are inexpensive and easily performed, rely on the detection of treponemal antibodies directed against an alcoholic solution of cardiolipin, lecithin, and cholesterol contained in these tests. A positive nontreponemal test can indicate the presence of any stage of syphilis or congenital syphilis, although incubating syphilis and very early primary syphilis produce a negative reaction; however, because they are nonspecific tests, false-positive reactions occur, making them inappropriate to confirm the diagnosis alone. Transiently false-positive results can be seen in patients with acute febrile illnesses, after immunizations, and during pregnancy. Chronic false-positive results are commonly associated with heroin addiction, aging, chronic infections, autoimmune diseases, and malignant disease. In some cases, false-positive reactions are familial and are related to abnormal serum globulin levels. As such, patients with a positive nontreponemal test should always receive a treponemal test for diagnosis confirmation.[1,29,30,31,32,33,34,35]

Nontreponemal tests are used primarily as screening tests; however, because *T. pallidum* antibody titers also can be quantitated by testing serial dilutions of the patient's serum for reactivity, they are useful in following the progression of the disease, recovery after therapy, and possible reinfection. Because antibody titers vary to some extent between tests, it is important that sequential serologic testing be performed using the same method each time. In patients treated successfully for primary and secondary syphilis, nontreponemal tests usually decline over time and may return to seronegativity. If these tests are going to return to negative in patients with early latent syphilis, they will do so within the first 4 years after adequate therapy; patients with disease of longer duration usually remain seropositive for life. In addition to their use in serologic testing, nontreponemal tests often are used on CSF to diagnose neurosyphilis.[29,30,31,32,33,34,35]

In some patients with secondary syphilis, a prozone phenomenon occurs that produces a negative VDRL test despite the presence of high reaginic antibody titers. This is corrected by diluting the

patient's serum prior to testing.[32,33] For HIV-positive individuals with syphilis, the reactivity of nontreponemal tests can vary depending on the stage of the HIV infection. In the early stages, reaginic titers higher than in non–HIV-infected patients have been seen, resulting in the prozone phenomenon. During the later stages of HIV infection, however, when immune function deteriorates to a greater extent, serologic responses can be reduced or delayed. As a result, the diagnosis of syphilis in HIV-infected individuals can be more difficult.[1,30,31,32,33,34,35]

Use of only one serologic test for diagnosis of syphilis is insufficient as false-positives can occur in those without syphilis and false-negatives in those with primary syphilis. In diagnosing all stages of syphilis, treponemal tests are more sensitive than nontreponemal tests. Because these tests are technically more demanding and are more expensive, they have been used as confirmatory rather than as screening tests. However, patients with a positive treponemal test should have a nontreponemal test with titer reflexively drawn in order to guide management decisions and to monitor response to therapy. If the nontreponemal test is negative, a different treponemal test should be used to confirm the initial positive result. If a second treponemal test is positive, previously untreated patients should be offered treatment. Those with a previous history of treatment require no further management unless sexual history indicates likelihood of re-exposure, in which case a repeat nontreponemal test is recommended in 2 to 4 weeks.[1]

For many years, the fluorescent treponemal antibody absorption (FTA-ABS) test was the most frequently used treponemal test. The FTA-ABS test uses the *T. pallidum* antigen to detect specific antibodies to treponemal organisms. However, the FTA-ABS test has largely been replaced by card assays such as the *T. pallidum* hemagglutination assay (TPHA), the microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination assay (TPPA) which can be automated and are less expensive to perform. Despite adequate antibiotic therapy for any stage of syphilis, the antibody tests usually remain reactive for life and therefore are not useful in assessing serologic response to therapy, relapse, or reinfection, hence the need for a reflex nontreponemal test.[1,30,31,32,33,34,35]

Several EIAs for *T. pallidum* have become available and are gaining wide use as confirmatory tests. Polymerase chain reaction (PCR)-based tests also are being investigated, particularly in situations in which serologic testing has poor sensitivity and specificity (eg, congenital syphilis, early primary syphilis, and neurosyphilis). Additionally, multiplex PCR tests that can identify the presence of *T. pallidum*, herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2), and *Haemophilus ducreyi* from genital ulcer specimens are under study. The CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.[1,28,29,30,35]

TREATMENT

Table 117-6 presents the CDC's treatment recommendations.[1] Parenteral penicillin G is the treatment of choice for all stages of syphilis. Because *T. pallidum* multiplies slowly, single doses of short- or intermediate-acting penicillins do not provide the prolonged, low-level exposure to penicillin required for eradication of the treponeme. As a result, benzathine penicillin G is the only penicillin effective for single-dose therapy.[1,28,39,30,31,32,33,34]

TABLE 117-6 Drug Therapy and Follow-up of Syphilis

Stage/Type of Syphilis	Recommended Regimens[a,b]	Follow-up Serology
Primary, secondary, or early latent syphilis (<1 year's duration)	Adults: Benzathine penicillin G 2.4 million units IM in a single dose Children: Benzathine penicillin G 50,000 units/kg IM in a single dose, up to 2.4 million units	Quantitative nontreponemal tests at 6 and 12 months for primary and secondary syphilis; at 6, 12, and 24 months for early latent syphilis[c]
Late latent syphilis (>1 year's duration) or latent syphilis of unknown duration or tertiary syphilis or retreatment	Adults: Benzathine penicillin G 2.4 million units IM once a week for 3 successive weeks (7.2 million units total) Children: Benzathine penicillin G 50,000 units/kg IM once a week for 3 successive weeks, up to 7.2 million units total	Quantitative nontreponemal tests at 6, 12, and 24 months[d,e]
Neurosyphilis	Aqueous crystalline penicillin G 18-24 million units IV (3-4 million units every 4 hours or by continuous infusion) for 10-14 days[f] *or* Aqueous procaine penicillin G 2.4 million units IM daily plus probenecid 500 mg orally four times daily, both for 10-14 days[f]	CSF examination every 6 months until the cell count is normal; if it has not decreased at 6 months or is not normal by 2 years, retreatment should be considered
Congenital syphilis (infants with proven or highly probable disease)	Aqueous crystalline penicillin G 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days *or* Procaine penicillin G 50,000 units/kg IM daily for 10 days	Serologic follow-up only recommended if antimicrobials other than penicillin are used
Penicillin-Allergic Patients[g]		
Primary, secondary, or early latent syphilis	Doxycycline 100 mg orally two times daily for 14 days[g,h] *or*	Same as for non–penicillin-allergic patients

Stage/Type of Syphilis	Recommended Regimens[a,b]	Follow-up Serology
Late latent syphilis (>1 year's duration) or syphilis of unknown duration	Tetracycline 500 mg orally four times daily for 14 days[h] *or* Ceftriaxone 1-2 g IM or IV daily for 10-14 days Doxycycline 100 mg orally twice a day for 28 days[h,i] *or* Tetracycline 500 mg orally four times daily for 28 days[h,i]	Same as for non–penicillin-allergic patients

CDC, Centers for Disease Control and Prevention; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus.

[a]Recommendations are those of the CDC.

[b]The CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.

[c]More frequent follow-up (ie, 3, 6, 9, 12, and 24 months) recommended for HIV-infected patients.

[d]More frequent follow-up (ie, 6, 12, 18, and 24 months) recommended for HIV-infected patients.

[e]No specific recommendations exist for tertiary syphilis because of the lack of available data.

[f]Some experts administer benzathine penicillin G 2.4 million units IM once per week for up to 3 weeks after completion of the neurosyphilis regimens to provide a total duration of therapy comparable to that used for late syphilis in the absence of neurosyphilis.

[g]For nonpregnant patients; pregnant patients should be treated with penicillin after desensitization.

[h]Pregnant patients allergic to penicillin should be desensitized and treated with penicillin.

[i]Limited data suggest that ceftriaxone may be effective, although the optimal dosage and treatment duration are unclear.

The recommended treatment for syphilis of less than 1 year's duration is benzathine penicillin G 2.4 million units as a single dose. Although the relapse rate for this regimen is less than 3%, some investigators advocate that 2.4 million units be administered once a week for two consecutive weeks. In patients with late latent syphilis and normal CSF examination, benzathine penicillin G is administered weekly for three successive doses. Although not specifically recommended by the CDC, this three-dose regimen is used by some experts to treat HIV-infected patients with syphilis of less

than 1 year's duration based on data suggesting a greater risk of treatment failure with single-dose therapy.[1,30,31,32,33,34]

Patients with abnormal CSF findings should be treated as having neurosyphilis. Preferred regimens for neurosyphilis provide treatment over 10 to 14 days with 18 to 24 million units per day of parenteral penicillin G administered as 3 to 4 million units every 4 hours or by continuous infusion. Benzathine penicillin G alone in standard weekly doses and procaine penicillin G in doses under 2.4 million units do not consistently provide treponemicidal levels in the CSF and have resulted in treatment failures. Because *T. pallidum* resistance to penicillin has not emerged, the primary need for alternative drugs in treating syphilis is for penicillin-allergic patients.[1,30,31,32,33,34]

2 Alternative regimens recommended for penicillin-allergic patients are doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times daily for 2 to 4 weeks depending on the duration of syphilis infection. These regimens should be used only in cases of documented penicillin allergy, and given concerns regarding patient compliance with these regimens, follow-up serologic testing is of particular importance.[1,30,31,32,33,34]

Other antibiotics used successfully in treating syphilis include various beta lactam antibiotics; however, none offers significant advantages over benzathine penicillin G. Even though ceftriaxone is considered effective in eradicating incubating syphilis when given as a single 125-mg dose, higher doses and more frequent administration (eg, 1-2 g daily for 10-14 days) appear necessary for more advanced syphilis, and treatment failures are reported in HIV-infected patients. Although azithromycin 2 g as a single dose produces good results in patients with early syphilis, treatment failures and resistance to azithromycin are reported.[1,27,30,31,32,33,34]

Clinical Controversy...

One clinical trial recently reported positive results on the use of high dose amoxicillin (3 g) plus probenecid for treatment of patients coinfected with HIV and syphilis. This method might prove particularly useful in countries where benzathine penicillin is not available or for treatment of patients who are unlikely to follow-up for weekly injections.

For pregnant patients, penicillin is the treatment of choice at the dosage recommended for that particular stage of syphilis. To ensure treatment success and prevent transmission to the fetus, some experts advocate an additional IM dose of benzathine penicillin G 2.4 million units 1 week after completion of the recommended regimen. In women allergic to penicillin, safe and effective alternatives are not available; therefore, skin testing should be performed to confirm a penicillin allergy. It is recommended that women with positive skin tests undergo penicillin desensitization and receive the appropriate treatment regimen for their stage of disease.[1,28,29,30]

Most patients treated for primary and secondary syphilis experience the Jarisch-Herxheimer reaction after treatment. This benign, self-limiting reaction is characterized by flulike symptoms, such as transient headache, fever, chills, malaise, arthralgia, myalgia, tachypnea, peripheral vasodilation, and aggravation of syphilitic lesions. The exact mechanism of the reaction is unknown, although proposed etiologies, including immunologic mechanisms and release of endotoxin or other toxic

treponemal products, are not substantiated. The Jarisch-Herxheimer reaction is independent of the drug and dose used and should not be confused with penicillin allergy. It usually begins within 2 to 4 hours of initiating therapy, peaks at 8 hours, and is complete within 12 to 24 hours. Most reactions can be managed symptomatically with analgesics, antipyretics, and rest. Steroids and antihistamines have been administered prior to initiation of syphilitic therapy but are of limited value.[1,28,29,30]

Evaluation of Therapeutic Outcomes

Table 117-6 lists the CDC recommendations for serologic follow-up of patients treated for syphilis.[1] Quantitative nontreponemal tests should be performed at 6 and 12 months in all patients treated for primary and secondary syphilis and at 6, 12, and 24 months for early and late latent disease. Patients indicated for retreatment should receive three weekly treatments of IM 2.4 million units of benzathine penicillin G, unless neurosyphilis is present. The CDC recommends more frequent monitoring of HIV-infected individuals (ie, 3, 6, 9, 12, and 24 months after therapy). In general, the time to reach seronegativity is proportional to the duration of the disease. Table 117-6 also includes specific testing recommendations for other stages of syphilis. Despite adequate therapy, some patients can remain seropositive based on nontreponemal test results. In these cases, stabilization of low antibody titers is indicative of adequate therapy. For women treated during pregnancy, monthly quantitative nontreponemal tests are recommended in those at high risk of reinfection.[28,29,30]

CHLAMYDIA TRACHOMATIS

Epidemiology and Etiology

Based on CDC data for 2013, over 1.4 million cases of chlamydia infection were reported, making it the second most frequently reported infectious disease in the United States behind HPV.[1,5] Because of the silent nature of many infections, the presumptive treatment of many cases, and the underreporting of many cases, it is estimated that more than double this number of cases actually occur annually. Chlamydial infections also are the primary causes of nongonococcal urethritis (NGU), accounting for as much as 50% of such infections.[1,36,37,38,39,40]

Pathophysiology

C. trachomatis is an obligate intracellular parasite that shares properties of both viruses and bacteria. Like viruses, chlamydiae require cellular material from host cells for replication; however, unlike viruses, chlamydiae maintain their cellular identity throughout development. Although *C. trachomatis* lacks a cell-wall peptidoglycan, its major outer membrane is similar to gram-negative bacteria. At least 18 serovars (subspecies) of *C. trachomatis* exist, of which only the lymphogranuloma venereum strains produce potentially invasive infections. The remaining serovars are involved primarily with superficial infection of epithelial cells.[36,37,38,39,40]

The risk of transmissibility of chlamydia after exposure is unknown but is believed to be less than that following exposure to *N. gonorrhoeae*. Coinfection with chlamydia occurs in a substantial number of

individuals with gonorrhea and all individuals diagnosed with *N. gonorrhoeae* should be assumed also to have *C. trachomatis* present, if chlamydial infection has not been ruled out.[1] Of major concern is that chlamydial infections are associated with a significantly increased risk of acquiring HIV infection. In addition to genital infections, ocular infections in adults owing to autoinoculation and infants owing to vaginal delivery through an infected birth canal are reported. Pharyngeal and rectal infections can develop secondary to orogenital or receptive anal intercourse, respectively, with an infected individual.[1,36,37,38,39,40,41,42,43]

Clinical Presentation

In comparison with gonorrhea, chlamydial genital tract infections are more frequently asymptomatic, and when present, symptoms tend to be less noticeable. Urethral discharge usually is less profuse and more mucoid or watery than the urethral discharge associated with gonorrhea.[37,38,39,40] **Table 117-7** summarizes the usual clinical presentation of chlamydial infections.

TABLE 117-7 Presentation of *Chlamydia* Infections

	Males	Females
General	Incubation period: 35 days	Incubation period: 7-35 days
	Symptom onset: 7-21 days	Usual symptom onset: 7-21 days
Site of infection	Most common: urethra	Most common: endocervical canal
	Others: rectum (receptive anal intercourse), oropharynx, eye	Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	More than 50% of urethral and rectal infections are asymptomatic	More than 66% of cervical infections are asymptomatic
	Urethral infection: mild dysuria, discharge	Urethral infection: usually subclinical; dysuria and frequency uncommon
	Pharyngeal infection: asymptomatic to mild pharyngitis	Rectal and pharyngeal infection: symptoms same as for men
Signs	Scant to profuse, mucoid to purulent urethral or rectal discharge	Abnormal vaginal discharge or uterine bleeding, purulent urethral or rectal discharge can be scant to profuse
	Rectal infection: pain, discharge, bleeding	
Complications	Epididymitis, Reiter's syndrome (rare)	Pelvic inflammatory disease and associated complications (ie, ectopic pregnancy, infertility)
		Reiter's syndrome (rare)

Similar to gonorrhea, chlamydia can be transmitted to an infant during contact with infected

cervicovaginal secretions. Nearly two-thirds of infants acquire chlamydial infection after endocervical exposure, with the primary morbidity associated with seeding of the infant's eyes, nasopharynx, rectum, or vagina. In exposed infants, neonatal conjunctivitis develops in as many as 50%, and pneumonia develops in up to 16%. Inclusion conjunctivitis in newborns is usually self-limited, but it can result in scarring and micropannus of the cornea. Interstitial pneumonitis occurring secondary to carriage in the nasopharynx typically is mild, but it can be severe and require hospitalization.[1,37,38,39,40,42]

Diagnosis

3 Because of the high rate of asymptomatic disease and the high prevalence of chlamydial infection in sexually active females 25 years of age or younger and sexually active women with new sex partners or multiple sex partners, the CDC recommends routine annual screening in these individuals. Laboratory confirmation of chlamydial infection is important because of the relative lack of specificity of symptoms when present.[1]

Cell culture is the reference standard against which all other diagnostic tests are measured. Because chlamydiae are obligate intracellular parasites, specimens for culture must be obtained from endocervical (women) or urethral (men) epithelial cell scrapings rather than from urine or urethral discharges. Although tissue culture techniques have close to 100% specificity, the sensitivity is reported to be as low as 70% in part because of problems of improper specimen collection, transport, or processing. Because of the technical demands, expense, and length of time until results are available (3-7 days), culture is not used widely for diagnostic purposes today. However, culture remains the diagnostic standard in medicolegal cases such as sexual assault and child abuse because of its high specificity and ability to detect only viable organisms.[37,38,39,40,43,44,45,46]

Tests that detect chlamydial antigens and nucleic acid provide more rapid results, are technically less demanding to perform, are less costly, and in some situations have greater sensitivity than culture. Commonly used nonculture tests for detection of *C. trachomatis* are the enzyme immunosorbent assay (EIA), DNA hybridization probe, and NAATs.[38,40,43,45]

Although still widely used both as rapid office tests and as laboratory-based tests, EIA methods for diagnosis of *C. trachomatis* are no longer recommended because of their poor sensitivity in comparison to NAATs. NAATs, which can detect small amounts of chlamydial DNA, are highly sensitive and specific for detecting infection in urogenital and anal specimens, as well as in urine. Use of self-collected vaginal or anal specimens or first-void urine samples offers greater patient acceptability, particularly when used to screen asymptomatic individuals. A further advantage of tests that can screen urine for the presence of infection is that up to 30% of women are reported to have urethral infection only, which would be missed using a test on endocervical samples. Because of their ability to detect as little as a single gene copy in a specimen, nucleic acid residues that persist following successful antibiotic therapy of a chlamydial infection can result in a false-positive test for several weeks following eradication of the organism.[39,40]

TREATMENT

A number of antimicrobials, including tetracyclines, macrolides, azithromycin, and some fluoroquinolones, display good in vitro and in vivo activity against *C. trachomatis*. In most clinical trials, cure rates exceeding 90% are reported for these agents. All these antimicrobials also appear to have good efficacy against *Ureaplasma urealyticum*, the second most common cause of NGU.[37,38,39,40]

Azithromycin 1 g orally as a single dose and doxycycline 100 mg orally twice daily for 7 days are the regimens of choice for the treatment of uncomplicated chlamydial infections[1] (**Table 117-8**). Because of its prolonged serum and tissue half-life, azithromycin is the only single-dose therapy that is effective in treating *C. trachomatis*. Delayed-release doxycycline (Doryx) given as 200 mg orally once daily for 7 days may be considered as an alternative regimen for the treatment of urogenital *C. trachomatis* infection. In a double-blind, randomized, controlled trial it was as effective as generic doxycycline and was associated with a lower frequency of gastrointestinal side effects, but this regimen is more costly.[47] Of the fluoroquinolones, ofloxacin and levofloxacin are included in the CDC recommendations, but neither appears to offer an advantage over other first-line nor alternative therapies. Although ciprofloxacin and some other fluoroquinolones have activity against *C. trachomatis* and *U. urealyticum*, high dosages have not consistently eradicated chlamydial infections.[1,37,38,39,40,41,42,43]

TABLE 117-8 Treatment of *Chlamydial* Infections

Infection	Recommended Regimens[a]	Alternative Regimen
Uncomplicated urethral, endocervical, or rectal infection in adults	Azithromycin 1 g orally once, or doxycycline 100 mg orally twice daily for 7 days	Erythromycin base 500 mg orally four times daily for 7 days, or erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, or levofloxacin 500 mg orally once daily for 7 days, or ofloxacin300 mg orally twice daily for 7 days
Urogenital infections during pregnancy	Azithromycin 1 g orally as a single dose or amoxicillin 500 mg orally three times daily for 7 days	Amoxicillin 500 mg orally three times daily for 7 days, or erythromycin base 500 mg orally four times daily for 7 days, or erythromycin base 250 mg orally four times daily for 14 days, or erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, or erythromycin ethylsuccinate 400 mg orally four times daily for 14 days
Conjunctivitis of the newborn or pneumonia in infants	Erythromycin base or ethylsuccinate 50 mg/kg/day orally in four divided doses for 14 days[b,c]	Azithromycin suspension 20 mg/kg/day orally once daily for 3 days[c]

CDC, Centers for Disease Control and Prevention; IHPS, infantile hypertrophic pyloric stenosis.

[a]Recommendations are those of the CDC.

[b]Topical therapy alone is inadequate for ophthalmia neonatorum and is unnecessary when systemic therapy is administered. Effectiveness of erythromycin treatment is approximately 80%; therefore, a second course of therapy may be required.

[c]An association between oral erythromycin and azithromycin and IHPS has been reported in infants aged <6 weeks. Infants treated with either of these antimicrobials should be followed for signs and symptoms of IHPS.

For pregnant women with chlamydial urogenital infections, treatment can reduce the risk of pregnancy complications and transmission to the newborn significantly. Because the use of tetracyclines and fluoroquinolones is contraindicated during pregnancy, azithromycin is the recommended drug treatment (see Table 117-8). When compliance with a multiday regimen is a concern, azithromycin is the preferred treatment in women, regardless of pregnancy status. Additionally, adherence can be maximized by providing onsite, directly observed single-dose therapy with azithromycin. It is recommended that test-of-cure be obtained for pregnant patients treated for chlamydial infections to ensure eradication of the infection. Persons treated for chlamydia should abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen and resolution of symptoms if present.[1,40,41,42,43,48,49]

C. trachomatis transmission during perinatal exposure can result in infections of the eye, oropharynx, lungs, urogenital tract, and rectum of the neonate or infant. Despite its efficacy in preventing gonococcal ophthalmia, topical erythromycin ointment (0.5%) appears less effective in preventing chlamydial ophthalmia. Additionally, topical therapy has no effect on nasal carriage or colonization of other parts of the infant's body, so the potential for other infections, including pneumonia, remains. Because of the high percentage of treatment failures, topical therapy is not recommended to treat ophthalmia caused by *C. trachomatis*. Instead, an oral erythromycin regimen is recommended.[1,37,38,39,40]

Evaluation of Therapeutic Outcomes

Treatment of chlamydial infections with the recommended regimens is highly effective; therefore, posttreatment laboratory testing is not recommended routinely unless symptoms persist or there are other specific concerns (eg, pregnancy). Posttreatment tests should not be performed for at least 3 weeks following completion of therapy.[1] When posttreatment tests are positive, they usually represent noncompliance, failure to treat sexual partners, or laboratory error rather than inadequate therapy or resistance to therapy. Infants with pneumonitis should receive follow-up testing because erythromycin is only 80% effective, and a second course of therapy can be necessary.[1,37,38,39,40]

GENITAL HERPES

Epidemiology and Etiology

Genital herpes infections represent the most common cause of genital ulceration seen in the United States. More than 50 million Americans have genital herpes, and this number is increasing by at least

500,000 each year.[1,50,51,52,53,54,55] Because of its morbidity, recurrent nature, and potential for complications, as well as its ability to be transmitted asymptomatically, genital herpes is of major public health importance.[52,53,54,55,56,57,58,59,60,61] Of note, the CDC does not recommend screening for HSV in the general population.[1] Similar to syphilis and other STDs, the presence of genital herpes lesions is associated with an increased risk of acquiring HIV following exposure.[1,50,51,52,53,54,55,56]

Pathophysiology

Herpes comes from the Greek word meaning "to creep" and is used to describe two distinct but antigenically related serotypes of HSV. HSV-1 is associated most commonly with oropharyngeal disease, and HSV-2 is associated most closely with genital disease; however, each virus is capable of causing clinically indistinguishable infections in both anatomic areas.[50,51,52,55]

Humans are the sole known reservoir for HSV. Infection is transmitted via inoculation of virus from infected secretions onto mucosal surfaces (eg, urethra, oropharynx, cervix, and conjunctivae) or through abraded skin. Evidence that the virus survives for a limited time on environmental surfaces suggests the possibility of fomitic transfer as a nonvenereal route of transmission.[50,51,52,55]

The cycle of HSV infection occurs in five stages: primary mucocutaneous infection, infection of the ganglia, establishment of latency, reactivation, and recurrent infection. After viral inoculation, HSV infection is associated with cytoplasmic granulation, ballooning degeneration of cells, and production of mononucleated giant cells. Initially, the cellular response is predominantly PMN, followed by a lymphocytic response. Replication occurs with viral spread to contiguous cells and peripheral sensory nerves. Latency then is established in sensory or autonomic nerve root ganglia. Latency appears to be lifelong, interrupted only by reactivation of the viral infection. It is unclear what factors are important in maintaining latency, but immune responses and emotional and physical stresses appear important in reactivating latent virus.[50,51,52,55]

Clinical Presentation

The signs and symptoms of genital herpes infection are influenced by many factors, including previous exposure to HSV, viral type, and host factors such as age and site of infection. Because a high percentage of initial and recurrent infections are asymptomatic, and because viral shedding can occur in the absence of apparent lesions or symptoms, identification and education of individuals with genital herpes are essential in controlling its transmission.[50,51,52,53,54,55,56,57,58,59] A summary of the clinical presentation of genital herpes is provided in **Table 117-9**.

TABLE 117-9 Presentation of Genital Herpes Infections

General	Incubation period 2-14 days (mean, 4 days)
	Can be caused by either HSV-1 or HSV-2
Classification of infection	

First-episode primary	Initial genital infection in individuals lacking antibody to either HSV-1 or HSV-2
First-episode nonprimary	Initial genital infection in individuals with clinical or serologic evidence of prior HSV (usually HSV-1) infection
Recurrent	Appearance of genital lesions at some time following healing of first-episode infection
Signs and symptoms	
First-episode infections	Most primary infections are asymptomatic or minimally symptomatic
	Multiple painful pustular or ulcerative lesions on external genitalia developing over a period of 7-10 days; lesions heal in 2-4 weeks (mean, 21 days)
	Flulike symptoms (eg, fever, headache, malaise) during first few days after appearance of lesions
	Others—local itching, pain, or discomfort; vaginal or urethral discharge, tender inguinal adenopathy, paresthesias, urinary retention
	Severity of symptoms greater in females than in males
	Symptoms are less severe (eg, fewer lesions, more rapid lesion healing, fewer or milder systemic symptoms) with nonprimary infections
	Symptoms more severe and prolonged in the immunocompromised
	On average viral shedding lasts approximately 11-12 days for primary infections and 7 days for nonprimary infections
Recurrent	Prodrome seen in approximately 50% of patients prior to appearance of recurrent lesions; mild burning, itching, or tingling are typical prodromal symptoms
	Compared to primary infections, recurrent infections associated with (1) fewer lesions that are more localized, (2) shorter duration of active infection (lesions heal within 7 days), and (3) milder symptoms
	Severity of symptoms greater in females than in males
	Symptoms more severe and prolonged in the immunocompromised
	On average viral shedding lasts approximately 4 days
	Asymptomatic viral shedding is more frequent during the first year after infection with HSV

Therapeutic implications of HSV-1 versus HSV-2 genital infection	Primary infections caused by HSV-1 and HSV-2 virtually indistinguishable Recurrent infections and subclinical viral shedding are less frequent with HSV-1 Recurrent infections with HSV-2 tend to be more severe
Complications	Secondary infection of lesions; extragenital infection because of autoinoculation; disseminated infection (primarily in immunocompromised patients); meningitis or encephalitis; neonatal transmission

HSV-1, herpes simplex virus type 1; HSV-2, herpes simplex virus type 2.

Complications

Complications from genital herpes infections result from both genital spread and autoinoculation of the virus and occur most commonly with primary first episodes. Lesions at extragenital sites, such as the eye, rectum, pharynx, and fingers, are not uncommon. CNS involvement is seen occasionally and can take several forms, including an aseptic meningitis, transverse myelitis, or sacral radiculopathy syndrome.[50,51,52,53,54,55,56,57,58,59]

A major concern is the effect of genital herpes on neonates exposed during pregnancy. Neonatal herpes is associated with a high mortality and significant morbidity. It is transmitted to the newborn primarily through exposure to HSV in the birth canal but, in rare cases, also is transmitted transplacentally. The risk of transmission during birth appears much greater for first-episode primary infections than for recurrent infections. Neonatal herpes infection has a case-fatality rate of approximately 50%, with a large proportion of surviving infants experiencing significant morbidity, including permanent neurologic damage.[50,51,55]

Diagnosis

Confirmation of a genital herpes infection can be made only with laboratory testing. Tissue culture is the most specific (100%) and sensitive method (80%-90%) of confirming the diagnosis of first-episode genital herpes; however, culture is relatively insensitive in detecting HSV in ulcers in the latter stages of healing and in recurrent infections, as a result, in part, of reduced viral load. Viral culture is expensive and time-consuming, and improper collection or transport of specimens can result in false-negative results. In most situations, HSV isolation on tissue culture takes 48 to 96 hours. Following isolation, it is recommended that typing of the virus be performed because of prognostic implications. HSV-1 is associated with a lower rate of asymptomatic and symptomatic recurrence, while HSV-2 is characterized by more frequent recurrences and subclinical shedding. In instances in which rapid detection is necessary, such as an impending birth, other detection methods can be more useful. Amplified culture techniques that combine cell culture for 24 hours and subsequent staining for HSV antigen have sensitivities and specificities only slightly less than those of

culture.[50,51,52,53,54,55,60,61,62]

Several serologic tests capable of distinguishing HSV-1 and HSV-2 antibodies are available. These tests detect antibodies to type-specific HSV-1 and HSV-2 proteins gG-1 and gG-2, respectively. Although antibody formation begins immediately following a primary herpes infection, complete seroconversion (ie, complete antibody development) can take several months. Until the full expression of all antigenic determinants of HSV-1 and HSV-2 occurs, these tests are not useful in differentiating HSV-1 and HSV-2 infection. Older antibody detection tests, some of which are still marketed, are unable to distinguish between HSV-1 and HSV-2 owing to the considerable cross-reactivity between the two serotypes. Given the high prevalence of HSV-1 antibody in the adult population, accurate interpretation of positive results is not possible.[50,51,52,53,54,55,60,61,62]

PCR assays that detect HSV DNA and differentiate HSV-1 and HSV-2 infections are more sensitive than culture and are considered the diagnostic test of choice for suspected CNS infections (ie, HSV encephalitis and HSV meningitis). PCR assays are highly sensitive in detecting asymptomatic viral shedding.[50,51,52,53,54,55,60,61,62]

Although the diagnosis of genital herpes can be confirmed only by laboratory tests, less stringent diagnostic criteria (eg, characteristic physical findings or clinical history) frequently are used in clinical practice. A presumptive diagnosis of genital herpes commonly is made based on the presence of dark-field-negative, vesicular, or ulcerative genital lesions. A history of similar lesions or recent sexual contact with an individual with similar lesions also is useful in making the diagnosis. Other STDs, including chancroid, lymphogranuloma venereum, and granuloma inguinale, and causes such as trauma, allergic reactions, and bacterial or fungal infections are considered in the differential diagnosis.[50,51,52,53,54,55,60,61,62]

TREATMENT

The most achievable goals in the management of genital herpes are to relieve symptoms and to shorten the clinical course, to prevent complications and recurrences, and to decrease disease transmission. Although research has focused primarily on the treatment of active infection and suppression of recurrences, increasing emphasis is being placed on various approaches, including immunotherapy that might provide protection from disease transmission or possibly eliminate established latency.[54,51,52,53,54,55]

Palliative and supportive measures are the cornerstone of therapy for patients with genital herpes. Pain and discomfort usually respond to warm saline baths or the use of analgesics, antipyretics, or antipruritics; good genital hygiene can prevent the development of bacterial superinfection.

4 Specific chemotherapeutic approaches to treating genital herpes include antiviral compounds, topical surfactants, photodynamic dyes, immune modulators, vaccines, and interferons. Few of these have undergone extensive evaluation, however, and only the antiviral agents have demonstrated any consistent clinical efficacy. The most recent CDC recommendations for the treatment of genital herpes include the antiviral agents acyclovir, valacyclovir, and famciclovir (**Table 117-10**).[1] The overall efficacy of these agents in treating genital HSV infection appears comparable, although patient

compliance can be improved with regimens requiring less frequent dosing.[1,50,51]

TABLE 117-10 Treatment of Genital Herpes

Type of Infection	Recommended Regimens[a,b]	Alternative Regimen
First clinical episode of genital herpes[c]	Acyclovir 400 mg orally three times daily for 7-10 days,[d] *or* Acyclovir 200 mg orally five times daily for 7-10 days,[d] *or* Famciclovir 250 mg orally three times daily for 7-10 days,[d] *or* Valacyclovir 1 g orally twice daily for 7-10 days[d]	Acyclovir 5-10 mg/kg IV every 8 hours for 2-7 days or until clinical improvement occurs, followed by oral therapy to complete at least 10 days of total therapy[e]
Recurrent infection		
Episodic therapy	Acyclovir 400 mg orally three times daily for 5 days,[f] *or* Acyclovir 800 mg orally twice daily for 5 days,[f] *or* Acyclovir 800 mg orally three times daily for 2 days,[f] *or* Famciclovir 125 mg orally twice daily for 5 days,[f] *or* Famciclovir 1 g orally twice daily for 1 day,[f] *or* Famciclovir 500 mg orally once, followed by 250 mg orally twice daily for 2 days,[f] *or* Valacyclovir 500 mg orally twice daily for 3 days,[f] *or* Valacyclovir 1 g orally once daily	

Type of Infection	Recommended Regimens[a,b]	Alternative Regimen
	for 5 days[f] Acyclovir 400 mg orally twice daily, *or*	
Suppressive therapy	Famciclovir 250 mg orally twice daily[h], *or*	
	Valacyclovir 500 mg or 1,000 mg orally once daily[i]	

CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus; IV, intravenous.

[a]Recommendations are those of the CDC.

[b]HIV-infected patients can require more aggressive therapy.

[c]Primary or nonprimary first episode.

[d]Treatment duration can be extended if healing is incomplete after 10 days.

[e]Only for patients with severe symptoms or complications that necessitate hospitalization. HSV encephalitis requires 21 days of IV therapy.

[f]Requires initiation of therapy within 24 hours of lesion onset or during the prodrome that precedes some outbreaks.

[g]Consider discontinuation of treatment after one year to assess frequency of recurrence.

[h]Famcicolvir appears less effective for suppression of viral shedding.

[i]Valacyclovir 500 mg appears less effective than other valacyclovir and acyclovir regimens in patients with 10 or more recurrences per year.

First-Episode Infections

Oral formulations of acyclovir, famciclovir, and valacyclovir have demonstrated efficacy in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. Table 117-10 lists the recommended acyclovir, famciclovir, and valacyclovir oral regimens for first-episode infections. The CDC recommends that all patients with first episodes of genital herpes receive systemic antiviral therapy to prevent severe or prolonged symptoms associated with newly acquired genital herpes. Additionally, topical antiviral therapy offers minimal clinical benefit and is not recommended.[1] In immunocompromised patients or those with severe symptoms or complications

necessitating hospitalization, parenteral acyclovir can be beneficial; however, the IV regimen has been associated with renal, GI, bone marrow, and CNS toxicity, particularly in patients with renal dysfunction receiving high doses. No antiviral regimen is known to prevent latency or alter the subsequent frequency and severity of recurrences in humans.[1,50,51,52,53,54,55,58,59,63,64,65,66]

Recurrent Infections

There are two approaches to management of recurrent episodes: episodic or chronic suppressive therapy. Episodic therapy is initiated early during the course of the recurrence, preferably within 6 to 12 hours of the onset of prodromal symptoms but no more than 24 hours after the appearance of lesions. Patients should be instructed to initiate treatment immediately when symptoms begin. In most patients, appreciable effects on symptomatology are not seen. Patients with prolonged episodes of recurrent infection or severe symptomatology are most likely to benefit from episodic therapy. Table 117-10 lists the recommended acyclovir, famciclovir, and valacyclovir suppressive regimens. One concern with episodic therapy is that some patients continue to shed virus despite the absence of lesions or presence of prodromal symptoms. Because of the relative mildness and brevity of recurrent infections, parenteral administration of acyclovir usually is not justifiable.[1,50,51,52,53,54,55,58,59,63,64,65,66]

Suppressive therapy with recommended antivirals reduces the frequency and severity of recurrences in 70% to 80% of patients experiencing frequent recurrences. Furthermore, many patients with frequent recurrences experience an improved quality of life with suppressive therapy as compared to episodic therapy.[1,67] Asymptomatic viral shedding is markedly reduced in patients receiving suppressive therapy; however, the extent to which this decreases disease transmission to sexual partners remains to be determined. Despite antiviral suppressive therapy, low-level virus shedding still occurs. However, this virus shedding may be less than that seen in patients treated episodically for recurrences, and thus may be associated with a lower risk of disease transmission. Although antiviral therapy with acyclovir, famciclovir, or valacyclovir appears equally effective for episodic treatment, famciclovir appears somewhat less effective for suppression of viral shedding.[1,68] Because the frequency of recurrences tends to diminish over time, periodic “drug holidays” are advocated to assess changes in the underlying recurrence rate and determine if continued suppressive therapy is warranted.[1,50,51,52,53,54,55,58,59,63,64,65,66]

Resistant HSV isolates have been identified in some patients experiencing breakthrough recurrences while taking acyclovir. Strains resistant to acyclovir are also resistant to valacycylovir, and most are also resistant to famciclovir. Although there is concern about the development of resistant strains with suppressive therapy, clinical trials have found no evidence of cumulative toxicity or significant resistance in patients treated continuously with the recommended antivirals.[50,51,52,53,54,55]

Selected Populations

Immunocompromised patients are at greatest risk for severe and recurrent HSV infections. Acyclovir, valacyclovir, and famciclovir have been used to prevent reactivation of infection in patients seropositive for HSV who undergo transplantation procedures or induction chemotherapy for acute

leukemia. Immunocompromised individuals, such as patients with acquired immunodeficiency syndrome (AIDS), who fail treatment or prophylaxis with recommended antiviral doses frequently demonstrate improved response with higher doses. If resistance is suspected or confirmed with recommended first-line antivirals, foscarnet is usually effective. However, its use is associated with a greater risk of serious adverse effects. Intravenous cidofovir or topical imiquimod may be effective alternatives to forscarnet. Lesional application of an extemporaneous compounded cidofovir (1%) gel or trifluridine ophthalmic solution appears to offer some benefits also.[1,50,51,52,53,54,55]

The safety of acyclovir, famciclovir, and valacyclovir during pregnancy is not established, although considerable experience with acyclovir in pregnant patients has produced no evidence of teratogenic effects. Because of the high maternal and infant morbidity associated with first-episode primary genital infections or severe recurrent infections at or near term, many clinicians advocate the use of systemic acyclovir as the standard of care in such cases; however, the effectiveness of such therapy is unknown. The use of acyclovir to suppress recurrent episodes near term is more controversial primarily because of the lack of data demonstrating significant benefits in this situation.[1,50,51,52,53,54,55,69,70,71,72]

With the increasing prevalence of genital herpes worldwide, the potential exists for widespread use and misuse of acyclovir, valacyclovir, and famciclovir, resulting in development of resistant HSV isolates. In vitro resistance to these three agents usually is mediated by alterations in viral thymidine kinase; most resistant isolates are either thymidine kinase-deficient or have altered thymidine kinase. The incidence and clinical implications of HSV resistance require further study particularly with respect to immunocompromised hosts, in whom resistance can develop with greater frequency and be of greater clinical importance. Importantly, a study in hematopoietic stem-cell transplant recipients found that persons receiving daily suppressive antiviral therapy were less likely to develop acyclovir-resistance as compared with those receiving episodic therapy.[73] Unlike acyclovir, valacyclovir, and famciclovir, foscarnet does not require the presence of thymidine kinase to be effective.[50,51,52,53,54,55]

Numerous agents for the prophylaxis and treatment of genital herpes infections are being studied. Neither topical nor systemic interferons have demonstrated consistent beneficial effects in genital HSV infections; however, a reduction in pain and time of healing of lesions has been reported with an interferon preparation incorporated into a gel containing nonoxynol-9. Other treatments under investigation include cidofovir and immune modulators such as topical imiquimod and resiquimod.[50,51,52,53,54,55] Agents that can eliminate ganglionic latency and prevent recurrent HSV infections are not expected to be available in the near future. Development of vaccines capable of protecting against HSV infection has proved challenging given the relative lack of protection offered by humoral and cell-mediated immunity in preventing naturally occurring recurrent infections. Safety concerns with live attenuated virus vaccines resulted in research focused primarily on recombinant protein vaccines that have exhibited relatively poor immunogenicity. Use of heterologous vaccines (bacillus Calmette–Guérin and influenza vaccines) to stimulate the immune system in patients with recurrent genital herpes has proved of no significant benefit.[50,51,52,53,54,55,74]

Evaluation of Therapeutic Outcomes

Available antiviral compounds are of greatest benefit in patients experiencing first-episode primary infections, immunocompromised patients, and patients with frequent or severe recurrent infections. Antivirals, however, are palliative and not curative, and patients receiving these agents should be monitored closely for adverse drug effects. CDC guidelines suggest that discontinuation of suppressive therapy after 1 year should be considered to assess for possible changes in the patient's intrinsic pattern of recurrence. In many patients, decreases in recurrence rates and the severity of symptoms occur over time. However, some clinicians prefer to continue suppressive therapy indefinitely because it significantly reduces asymptomatic viral shedding, a potential benefit in reducing the risk of disease transmission to uninfected sexual partners.[1,50,51,52,53,54,55]

TRICHOMONIASIS

Epidemiology and Etiology

Trichomonas vaginalis, a flagellated, motile protozoan is responsible for 3 to 5 million cases of trichomoniasis annually in the United States. Humans are host to two other *Trichomonas* species, *T. tenax* and *T. hominis*, but *T. vaginalis* is the only species thought to be pathogenic. Although infection by nonsexual contact is reported, it is rare. Contamination of inanimate objects and spread of infection via communal bathing or contact with infected bath or toilet articles is possible because *T. vaginalis* can survive for up to 45 minutes on moist surfaces. Neonatal infections also represent another possible nonvenereal route of disease transmission.[75,76,77,78,79]

Coinfection with other STDs is not unusual in patients diagnosed with trichomoniasis. Women infected with *T. vaginalis* are three times more likely to have gonorrhea than those who do not have trichomoniasis; approximately 20% of men with gonococcal urethritis also have trichomoniasis.[65,66,67,68,69] In patients treated appropriately for genital *C. trachomatis* or *U. urealyticum* infection, persistent urethritis can result from coexisting trichomonal infection. Although not well documented, the inflammatory response produced by trichomoniasis may increase the risk of acquiring HIV by two- to threefold.[1,75,76,77,78,79,80,81]

Pathophysiology

Trichomonads typically can be isolated from the vagina, urethra, and paraurethral ducts and glands in the majority of infected women. Infrequently, they are recovered from the endocervix. Extragenital sites are epidemiologically important because infection can persist and result in reinfection of the vagina if local therapy alone is used. This may account for the higher relapse rates reported for local versus systemic therapy. After attachment to the vaginal or urethral mucosa, trichomonads usually elicit an inflammatory response that manifests as a discharge containing large numbers of PMN leukocytes.[75,76,77,78,79,80,82,83,84,85]

Clinical Presentation

Trichomonal infections are reported more commonly in women than in men. In part this might be

because of the smaller number of organisms found in the male urethra making detection more difficult, greater disease transmission rates from males to females, and the nature of male infections, which have a high spontaneous cure rate even in the absence of treatment.[76,77,80,82,82,86] The typical clinical presentation of trichomoniasis in males and females is presented in **Table 117-11**.

TABLE 117-11 Presentation of Trichomonas Infections

	Males	Females
General	Incubation period 3-28 days Organism can be detectable within 48 hours after exposure to infected partner	Incubation period 3-28 days
Site of infection	Most common: urethra Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Can be asymptomatic (more common in males than females) or minimally symptomatic Urethral discharge (clear to mucopurulent) Dysuria, pruritus	Can be asymptomatic or minimally symptomatic Scant to copious, typically malodorous vaginal discharge (50%-75%) and pruritus (worse during menses) Dysuria, dyspareunia
Signs	Urethral discharge	Vaginal discharge Vaginal pH 4.5-6 Inflammation/erythema of vulva, vagina, and/or cervix Urethritis
Complications	Epididymitis and chronic prostatitis (uncommon) Male infertility (decreased sperm motility and viability)	Pelvic inflammatory disease and associated complications (ie, ectopic pregnancy, infertility) Premature labor, premature rupture of membranes, and low–birth-weight infants (risk of neonatal infections is low) Cervical neoplasia

MSM, men who have sex with men.

Diagnosis

T. vaginalis produces nonspecific symptoms also consistent with bacterial vaginosis; as a result, laboratory diagnosis is required. Because *T. vaginalis* requires a pH range of 4.9 to 7.5 for survival, a vaginal discharge pH of greater than 5 usually indicates the presence of either *T. vaginalis* or *Gardnerella vaginalis*, a common cause of bacterial vaginosis. The simplest and most reliable means of diagnosis is a wet-mount examination of the vaginal discharge.[77,80,82,83,86] Trichomoniasis is confirmed if characteristic pear-shaped, flagellating organisms are observed. The wet mount is only 51% to 65% sensitive in detecting the presence of trichomonads, with lower sensitivities reported in men and in women with low-grade, subacute, or chronic infections.[78,79,80,83,85,87]

Although the presence of trichomonads may be reported on a Papanicolaou smear (Pap), the sensitivity of this cytologic technique is less than for wet mount and also is associated with a high number of false-positive and false-negative results. Stained smears of cervical specimens have been used in diagnosis, but they are less sensitive and more time-consuming than the wet mount and therefore are not recommended. Culture techniques for trichomonads are highly specific up to 100% and more sensitive, 75% to 96% than the wet mount, but they are not useful in rapid diagnosis because up to 48 hours or longer is necessary for growth. Cultures can be necessary, however, to confirm the diagnosis in the absence of a positive wet mount or to determine antimicrobial susceptibility in intractable cases.[1,75,76,77,78,79,80,82,83,85,86,88]

Newer diagnostic tests such as monoclonal antibody or DNA probe techniques, as well as PCR tests that can detect small amounts of trichomonal DNA, have been developed. These office-based tests are highly sensitive and specific for detecting infection in both vaginal specimens and urine. The CDC now recommends the use of these highly sensitive and specific tests for detecting *T. vaginalis*.[75,76,77,78,79]

In males, demonstration of trichomonads in urethral specimens or urine sediment by wet mount is difficult, and diagnosis depends largely on culture. Specimens from males should be taken prior to first voiding because the small number of trichomonads in males may be reduced by micturition.[75,76,77,78,79,80,82]

TREATMENT

Recommended and alternative treatment regimens for *T. vaginalis* include either metronidazole or tinidazole, both of which produce high cure rates in these infections. In only a few cases have *T. vaginalis* isolates been resistant to standard metronidazole or tinidazole doses. In these instances, longer courses of therapy or doses higher than those recommended routinely as initial therapy usually produce a cure.[1,75,76,77,78,79,83,86,89]

Table 117-12 provides treatment recommendations for trichomonas infections.[1] The standard therapy for trichomoniasis is either metronidazole or tinidazole 2 g orally as a single dose; cure rates are comparable with the recommended alternative regimen of metronidazole 500 mg twice daily for 7 days. When sexual partners are treated simultaneously, cure rates greater than 95% are reported. If sexual partners are not treated concurrently, cure rates are somewhat lower. In limited clinical testing, single metronidazole doses of less than 1.5 g are associated with high failure

rates.[1,75,76,77,78,79,83,86,89]

TABLE 117-12 Treatment of Trichomoniasis

Type	Recommended Regimen[a]	Alternative Regimen
Symptomatic and asymptomatic infections	Metronidazole 2 g orally in a single dose *or* Tinidazole 2 g orally in a single dose[b]	Metronidazole 500 mg orally two times daily for 7 days[c,d]
Persistent or recurrent infections	Metronidazole 500 mg orally two times daily for 7 days[c]	Metronidazole 2 g orally for 7 days[e]
Treatment in pregnancy	Metronidazole 2 g orally in a single dose[e]	*or* Tinidazole 2 g orally for 7 days[e]

CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus.

[a]Recommendations are those of the CDC.

[b]Randomized controlled trials comparing single 2 g doses of metronidazole and tinidazole suggest that tinidazole is equivalent to, or superior to, metronidazole in achieving parasitologic cure and resolution of symptoms.

[c]Metronidazole labeling approved by the FDA does not include this regimen. Dosage regimens for treatment of trichomoniasis included in the product labeling are the single 2 g dose; 250 mg three times daily for 7 days; and 375 mg twice daily for 7 days. The 250 mg and 375 mg dosage regimens are currently not included in the CDC recommendations.

[d]Recommended treatment regimen for women with HIV coinfection.

[e]For treatment failures with metronidazole 2 g as a single dose and metronidazole 500 mg orally two times daily for 7 days.

[f]Symptomatic pregnant women can be treated with this regimen at any stage of pregnancy.

Advantages of single-dose therapy over the multidose alternative regimen include better patient compliance, lower total dose, lower cost, and shorter exposure of the patient's GI and urogenital anaerobic bacterial flora to the drug. As a result of the latter, the likelihood of developing pseudomembranous colitis or symptomatic candidal vulvovaginitis is decreased.[75,76,77,78,79,83] Because high doses of metronidazole have mutagenic effects in bacteria and oncogenic effects in mice, a reduced time of exposure in humans can be beneficial. There is no conclusive evidence for either of these effects in humans after short-term therapy with recommended doses. GI complaints

(eg, anorexia, nausea, vomiting, and diarrhea) are more common with the single 2-g dose of either metronidazole or tinidazole, occurring in 5% to 10% of treated patients. Some patients also complain of a bitter metallic taste in the mouth with metronidazole. Patients intolerant of the single 2-g dose because of GI adverse effects usually tolerate the alternative metronidazole multidose regimen.[75,76,77,78,79,83,86,89]

5 To achieve maximal cure rates and prevent relapse with either metronidazole or tinidazole as a single 2-g dose, simultaneous treatment of infected sexual partners is necessary. Tinidazole is at least equivalent, or potentially superior, to metronidazole in achieving microbiologic and clinical cure.[90] In women treated with the alternative 7-day course, however, relapse rates are not appreciably different regardless of whether or not sexual partners are treated. It is speculated that in men, spontaneous resolution of trichomonal infection or a reduction in the number of trichomonads below the inoculum necessary to transmit disease may occur during the 7 days of a female's therapy. The 7-day metronidazole treatment regimen is also recommended in women coinfected with HIV and may be more effective than a single 2-g dose in these patients.[91] In patients who fail to respond to an initial course of metronidazole therapy, a second course of therapy with metronidazole 500 mg twice daily for 7 days or a single 2-g dose of tinidazole is recommended. Patients refractory to a second course of treatment usually respond to a regimen using higher 2 g daily for 7 days of either agent. Good response rates also are reported for tinidazole 2 to 3 g orally plus intravaginal tinidazole for 14 days.[1,70,75,76,77,78,79,82,89,92] Topical vaginal therapy alone is associated with low cure rates because infections involving the urethra or periurethral glands are unaffected and can serve as the source of reinfection.[77] Use of IV metronidazole can be warranted for rare cases of intolerance to oral medication or infections resistant to high-dose oral metronidazole. Sexual partners of all patients who require retreatment also should be treated or retreated because the majority of apparent treatment failures appear to be caused by reinfection or noncompliance.[75,76,77,78,79]

Concerns regarding the use of metronidazole in women who are pregnant or breast-feeding have been raised. Because metronidazole is secreted in breast milk, it is recommended that breast-feeding be interrupted for 12 to 24 hours after maternal ingestion of a single 2-g dose. Metronidazole (pregnancy category B) and tinidazole (pregnancy category C) are contraindicated during the first trimester of pregnancy based on FDA-approved labeling. Although some experts recommend avoiding use of either agent throughout pregnancy, others advocate the use of metronidazole during any stage of pregnancy because of the potential adverse pregnancy outcomes associated with trichomoniasis. The CDC now recommends that all symptomatic pregnant women, regardless of pregnancy stage, be tested and considered for treatment with metronidazole 2 g orally in a single dose.[1,75,76,77,78,79]

Several other nitroimidazole antibiotics related to metronidazole and tinidazole (eg, nimorazole, ornidazole, and carnidazole) are being investigated worldwide for the treatment of trichomoniasis. Unfortunately, none of these agents differs significantly from metronidazole or tinidazole in terms of efficacy (ie, cross-resistance is high) or toxicity against metronidazole-susceptible strains of *T. vaginalis*.[75,76,77,78,79]

EVALUATION OF THERAPEUTIC OUTCOMES

Follow-up was previously considered unnecessary in patients who become asymptomatic after treatment with recommended therapy; however, retesting is now recommended for all sexually active women within 3 months following initial treatment due to the high rates or reinfection. When patients remain symptomatic, it is important to determine if reinfection has occurred. In these cases, a repeat course of therapy, as well as identification and treatment or retreatment of infected sexual partners, is recommended. In situations in which reinfection can be excluded, a relative resistance to metronidazole or tinidazole should be assumed, and an alternative regimen should be prescribed. Culture and sensitivity are warranted for infections unresponsive to alternative regimens.

HUMAN PAPILLOMAVIRUS AND OTHER SEXUALLY TRANSMITTED DISEASES

Several STDs other than those just discussed occur with varying frequency in the United States and throughout the world. Although an in-depth discussion of these diseases is beyond the scope of this chapter, **Table 117-13** lists recommended treatment regimens.[1] Of notable importance among these other STDs, however, is genital HPV infection, the most common viral STD in the United States. More than 100 HPV types have been characterized by genomic makeup, with approximately 30 types associated with genital tract lesions.[94,95,96] Of these, types 6 and 11 are associated most commonly with the development of low-grade dysplasia manifested as exophytic genital warts. In most individuals, genital infection with HPV is subclinical, and patients with visible acuminate warts represent less than 1% of all infected individuals. When present, genital warts can be large and multifocal, producing variable degrees of discomfort. Based on HPV DNA detection methods, most warts will regress spontaneously within 1 to 2 years of their initial appearance. However, reinfection is common in young, sexually active populations.[1,93,94]

TABLE 117-13 Treatment Regimens for Miscellaneous Sexually Transmitted Diseases

Infection	Recommended Regimen[a]	Alternative Regimen
Chancroid (*Haemophilus ducreyi*)	Azithromycin 1 g orally in a single dose, *or* Ceftriaxone 250 mg IM in a single dose, *or* Ciprofloxacin 500 mg orally twice daily for 3 days,[b] *or* Erythromycin base 500 mg orally four times daily for 7 days	
Lymphogranuloma venereum	Doxycycline 100 mg orally twice daily for 21 days[c]	Erythromycin base 500 mg orally four times daily for 21 days[d]
HPV infection		

Infection	Recommended Regimen[a]	Alternative Regimen
External genital/perianal warts	*Provider-Administered Therapies:* Cryotherapy (eg, liquid nitrogen or cryoprobe); repeat weekly as necessary, *or* Podophyllin resin 10%-25% in compound tincture of benzoin applied to lesions; repeat weekly as necessary,[e,f] *or* TCA 80%-90% *or* BCA 80%-90% applied to warts; repeat weekly as necessary, *or* Surgical removal (tangential scissor excision, tangential shave excision, curettage, or electrosurgery) *Patient-Applied Therapies:* Podofilox 0.5% solution or gel applied twice daily for 3 days, followed by 4 days of no therapy; cycle is repeated as necessary for up to four cycles,[f] *or* Imiquimod 3.75% or 5% cream applied at bedtime three times weekly for up to 16 weeks,[f] *or* Sinecatechins 15% ointment applied three times daily for up to 16 weeks	Intralesional interferon *or* Photodynamic therapy *or* Topical cidofovir
Vaginal and anal warts	Cryotherapy with liquid nitrogen, or TCA or BCA 80%-90% as for external HPV warts; repeat weekly as necessary[g] Surgical removal (not for vaginal or urethral meatus warts)	
Urethral meatus warts	Cryotherapy with liquid nitrogen, or podophyllin resin 10%-25% in compound tincture of benzoin applied at weekly intervals[f,h]	
Prevention	Gardasil® (HPV quadrivalent [types 6, 11, 16, and 18]) recombinant vaccine 0.5 mL IM on day 1; a second and third dose are administered 2 and 6 months following the first dose[i,j,k] Cervarix® (HPV bivalent [types 16 and 18]) recombinant vaccine 0.5 mL IM on day 1; a second	

Infection	Recommended Regimen[a]	Alternative Regimen
	and third dose are administered 1 and 6 months following the first dose[i,l] Gardasil9® (HPV 9-valent [types 6, 11, 16, 18, 31, 33, 45, 52, 58]) recombinant vaccine 0.5 mL IM on day 1; a second and third dose are administered 1 and 6 months following the first dose[i]	

BCA, bichloracetic acid; HPV, human papillomavirus; TCA, trichloroacetic acid.

[a]Recommendations are those of the Centers for Disease Control and Prevention (CDC).

[b]Ciprofloxacin is contraindicated for pregnant and lactating women and for persons aged <18 years.

[c]Azithromycin 1 g PO once weekly for 3 weeks can be effective.

[d]Pregnant patients should be treated with erythromycin.

[e]Some experts recommended washing podophyllin off after 1-4 hours to minimize local irritation.

[f]Safety during pregnancy is not established.

[g]Surgical removal of anal warts is also a recommended treatment.

[h]Some specialists recommend the use of podofilox and imiquimod for treating distal meatal warts.

[i]CDC recommendations: vaccination is recommended in girls 11-12 years of age, and in females aged 13-26 years who either were not previously vaccinated, or who did not complete the vaccination series.

[j]FDA approved labeling for Gardasil®: indicated in girls and women 9 through 26 years of age for the prevention of cervical, vulvar, vaginal, and anal cancer caused by HPV types 16 and 18, genital warts (condyloma acuminata) caused by HPV types 6 and 11, and precancerous or dysplastic lesions caused by HPV types 6, 11, 16, and 18.

[k]Vaccination is recommended in males aged 9-26 years to prevent genital warts and anal cancer.

[l]FDA approved labeling for Cervarix®: indicated in females 9 through 25 years of age for the prevention of cervical cancer, cervical intraepithelial neoplasia grade 2 or worse, adenocarcinoma in situ, and cervical intraepithelial neoplasia grade 1 caused by HPV types 16 and 18.

Infection with several HPV types, particularly HPV-16 and HPV-18, is considered the major risk factor for the development of cervical neoplasia, the second most common cancer in women worldwide. Although epidemiologic, virologic, and clinical data strongly support this association, HPV infection

alone is insufficient to cause cervical cancer development because only a small percentage of infected women develop the disease. It appears that the interplay of host immune defenses, genetic factors, and infection with HPV types containing a more aggressive variant all contribute to the risk of developing cervical neoplasia.[93,94]

The Pap smear is the most frequently used and cost-effective diagnostic test for detecting clinical and subclinical (ie, no visible signs of condylomata) HPV in women. However, Pap smears are neither specific for HPV nor useful in detecting latent infections. Frequently, visual inspection of genital surfaces under magnification can assist in making the diagnosis. Various tests for detecting HPV DNA, RNA, or capsid protein also are available, and unlike the Pap smear do not require subjective interpretation of the results. The HPV-specific tests are only approved in women with abnormal Pap smears or women older than 30 years. However, use of HPV DNA testing as a routine screening test in lieu of Pap smears is expected in the near future. In women identified to have high-risk HPV infections by these tests, follow-up cytology would be performed.[93,94]

No consensus exists on the best approach to treating patients with genital HPV infection, particularly because most cases appear to be transient with spontaneous regression of lesions. A number of treatments are recommended (see Table 117-13), but none is clearly superior to the others. Treatment generally is directed toward patients with manifestations of genital warts, with the goal of removing or destroying these lesions and grossly infected surrounding tissue. Because such treatment neither stops viral expression in surrounding tissue nor eliminates viral latency, recurrence of lesions is not uncommon.[93,94]

Clinical Controversy...

Recent research has indicated that HPV (particularly HPV-16) may be implicated in the development of intractable childhood epilepsy. As such, women of child-bearing age should be educated regarding the fetal risk associated with the HPV infection in order to improve vaccination rates.

Three HPV vaccines are marketed in the United States. Cervarix, a bivalent vaccine for HPV-16 and 18, Gardasil, a quadrivalent vaccine for HPV-6, 11, 16, and 18, and Gardasil 9, a 9-valent vaccine for HPV-6, 11, 16, 18, 31, 33, 45, 52, and 58. All vaccines are indicated for preventing cervical precancers and cervical cancer in females 9 to 26 years of age. In addition, Gardasil and Gardasil 9 are indicated in unvaccinated males 9 to 21 years of age. Specific populations (MSM, immunocompromised) are recommended to receive the vaccination up to the age of 26.[1] Clinically important differences in the magnitude and duration of the immune response, as well as prevention of HPV infections and cervical cancer remain to be determined.[95,96,97]

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

AIDS	acquired immunodeficiency syndrome
CDC	Centers for Disease Control and Prevention
CSF	cerebrospinal fluid

DFA-TP	direct fluorescent-antibody (test) for *T. pallidum*
DGI	disseminated gonococcal infection
EIA	enzyme immunoassay
FTA-ABS	fluorescent treponemal antibody absorption
HIV	human immunodeficiency virus
HPV	human papillomavirus
HSV	herpes simplex virus
HSV-1	herpes simplex virus type 1
LPS	lipopolysaccharide
MHA-TP	microhemagglutination assay for antibodies to *T. pallidum*
MSM	men who have sex with men
NAATs	nucleic acid amplification tests
NGU	nongonococcal urethritis
Pap	Papanicolaou smear
PCR	polymerase chain reaction
PID	pelvic inflammatory disease
PMN	polymorphonuclear
RPR	rapid plasma reagin
STD	sexually transmitted disease
TPHA	*T. pallidum* hemagglutination assay
TPPA	*T. pallidum* particle agglutination assay
TRUST	toluidine red unheated serum test
USR	unheated serum reagin
VDRL	Venereal Disease Research Laboratory

Chapter 118: Bone and Joint Infections

FIGURE 118-1

Marcella N. Honkonen; Ziad Shehab; Edward P. Armstrong

INTRODUCTION

KEY CONCEPTS

- 1 The most common cause of osteomyelitis (particularly that acquired by hematogenous spread) and infectious arthritis is *Staphylococcus aureus*.
- 2 Culture and susceptibility information are essential as a guide for antimicrobial treatment of osteomyelitis and infectious arthritis.
- 3 Joint aspiration and examination of synovial fluid are extremely important to evaluate the possibility of infectious arthritis.
- 4 The most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time.
- 5 Antibiotics generally are given in high doses so that adequate antimicrobial concentrations are reached within the infected bone and joints.
- 6 Oral antimicrobial therapies can be used for osteomyelitis to follow a parenteral regimen in children who have a good clinical response to IV antibiotics and in adults without diabetes mellitus or peripheral vascular disease when the organism is susceptible to the oral antimicrobial, a suitable oral agent is available, and adherence is ensured.
- 7 The standard duration of antimicrobial treatment for acute osteomyelitis is 4 to 6 weeks.
- 8 The three most important therapeutic approaches to the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest.

- 9 Monitoring of antibiotic therapy is important and typically involves noting clinical signs of inflammation, periodic white blood cell (WBC) counts, C-reactive protein, and erythrocyte sedimentation rate (ESR) determinations.

Bone and joint infections are comprised of two disease processes known, respectively, as *osteomyelitis* and *septic* or *infectious arthritis*. They are unique and separate infectious entities with different signs and symptoms and infecting organisms. Despite advances in therapy, these infections continue to cause significant morbidity from residual damage and chronic or recurring infections. Emphasis on initiating antibiotic therapy as soon as possible is important in reducing long-term complications.

EPIDEMIOLOGY

Osteomyelitis

1 Osteomyelitis generally is an uncommon disease. One classic publication reported that 247 patients had osteomyelitis in a prominent American teaching hospital during a 4-year period.[1] Acute osteomyelitis has an estimated annual incidence of 0.4 per 1,000 children. In adults, osteomyelitis caused by contiguous spread, including postoperative, direct puncture, and that associated with adjacent soft tissue infections, comprises 47% of infections. *Hematogenous osteomyelitis* comprises 19% of infections, and osteomyelitis occurring in patients with significant peripheral vascular disease comprises 34% of infections.

The bacteriology of *hematogeous osteomyelitis* is unique in that one pathogen, *Staphylococcus aureus*, is responsible for more than 80% of these infections, with group A Streptococci and *Streptococcus pneumoniae* accounting for a few cases. *Kingellakingae*, an organism that is part of the oral flora is emerging as a pathogen in children less than 3 years of age. *Haemophilus influenzae* type b which used to be an important pathogen has been almost completely eliminated with the use of the conjugate vaccine and is now a rare pathogen in bone and joint infections.[2] Pneumococcal disease will likely decrease in prevalence as invasive pneumococcal disease is prevented by the use of the conjugate pneumococcal vaccine in infants. *Osteomyelitis* in neonates can result from infections with group B streptococcus, *Escherichia coli*, and most commonly *S. aureus*.

Vertebral osteomyelitis has several unique features and occurs most commonly in adults 50 to 60 years of age typically presenting with recalcitrant back pain unresponsive to usual symptomatic therapies, elevated inflammatory markers and who may or may not be having fever.[3] The lumbar and thoracic regions are the locations of most infections. Hematogenous infections are most likely to develop in the vascular areas near the subchondral plate region of the vertebral body. These infections are typically monomicrobial and are caused principally by Staphylococci that cause approximately 60% of these infections; however, Gram-negative organisms now play a significant role.[3,4,5] These Gram-negative organisms are most commonly Enterobacteriaceae species, particularly *E. coli* and *Klebsiella pneumoniae*, and most likely originate within the urinary tract or intra-abdominal cavity.[5] *Mycobacterium tuberculosis* and *Coccidioidesimmitis/posadasii* also are known to cause

infections in the spine. Skin and respiratory tract infections are other sources of infection known to lead to vertebral infections. While infections of the spine can involve the vertebrae in 1% to 2% of older children with osteomyelitis, they more commonly involve the disk space of the lumbar vertebrae in children less than 5 years of age.

Contiguous-spread disease has several important differences compared with *hematogeous osteomyelitis*. Although *S. aureus* is still the most common organism isolated, polymicrobial infections, including with Gram-negative bacilli, occur frequently. *Pseudomonas aeruginosa*, streptococcus, *E. coli*, *Staphylococcus epidermidis*, and anaerobes can be isolated.

When anaerobes are grown from cultures, they usually are found in association with other organisms, including aerobic bacteria. Predisposing factors in patients who have anaerobic osteomyelitis include vascular disease, bites, contiguous infections, peripheral neuropathy, hematogenous spread, and trauma. Osteochondritis resulting from puncture injuries to the foot is associated with Gram-negative infection often times caused by *P. aeruginosa*. *S. aureus* is also a significant pathogen in these patients. The anaerobic infections in association with diabetes mellitus almost always involve the foot and are mixed. *Bacteroides fragilis* and *Bacteroides melaninogenicus* comprise the majority of anaerobic isolates.

Infectious Arthritis

Infectious or septic arthritis is an inflammatory reaction within the joint space. Septic arthritis is one of the most common causes of new cases of arthritis. The incidence of proven or likely septic arthritis is 4 to 10 cases per 100,000 patient-years.[6] The incidence of septic arthritis increases to 70 cases per 100,000 patient-years among patients that have rheumatoid arthritis.[7]

Neonates may have infectious arthritis because of a broad range of organisms, with *S. aureus*, group B Streptococcus, and Gram-negative organisms being most common. *S. aureus* and *Streptococcus pyogenes* are the most common pathogens in children younger than 5 years of age. *Hemophilus influenzae* type b (Hib) which used to be the most common pathogen in these children has essentially been eliminated by immunization with the conjugate Hib vaccine. Pneumococcal arthritis is also decreasing in incidence as a result of conjugate pneumococcal vaccine administration to infants. If the child has not been fully vaccinated or is immunocompromised, *H. influenzae* type b may be a cause.

Some organisms, such as *Neisseria gonorrhoeae*, are especially likely to infect a joint during bacteremia. Gonococcal arthritis is a common manifestation of disseminated gonococcal infection occurring in 42% to 85% of such patients.[8] Gonococcal arthritis is now uncommon in North America and Europe although it remains an important concern in developing countries.

Within the adult population, *S. aureus* is responsible for 37% to 65% of nongonococcal bacterial arthritis.[8] Streptococcal infections are the second most common followed by Gram-negative organisms. Among the latter, *E. coli* is the most common; however, *P. aeruginosa* is the most frequent organism in intravenous drug abusers.

Although rare, osteomyelitis and infectious arthritis can be caused by fungi and in the case of arthritis by viruses such as varicella-zoster, rubella or parvovirus.[9] Arthritis is rarely caused by Salmonella, Corynebacteria, Brucella, *Neisseria meningitidis*, *Mycoplasma pneumoniae* or *Ureaplasmaurealyticum*. Penetrating injury of the joint can result in an infection due to Pasteurella in dog bites, Capnocytophaga in human bites and Pantoea when the injury is induced by a thorn.

ETIOLOGY

Osteomyelitis

The most common method of classifying osteomyelitis is based on the mode of acquisition of the bone infection. Disease that results from spread through the bloodstream is termed *hematogeous osteomyelitis*, while that reaching the bone from an adjoining soft tissue infection is termed *contiguous osteomyelitis*. Patients with peripheral vascular disease are at risk for the development of contiguous osteomyelitis, and they present unique management features. Osteomyelitis that results from direct inoculation, such as from trauma, puncture wounds, or surgery, generally is also classified as inoculation osteomyelitis.

Osteomyelitis also can be classified based on the duration of the disease. Acute osteomyelitis describes infections of recent onset, usually several days to 1 week, whereas chronic infections are those of a longer duration. Some authors describe chronic infections as those with symptoms for more than 1 month before therapy, whereas other authors define chronic infections as relapse of an initial infection. *hematogeous osteomyelitis* almost always involves one bone whereas contiguous osteomyelitis can present in multiple bones, especially when vascular insufficiency is an underlying risk factor.

Infectious Arthritis

Infectious arthritis can occur from many different types of microorganisms. Most infecting organisms produce an infection in a single joint, termed *monoarticular infection*; however, infections also can involve two or more joints. As with osteomyelitis, joint infections also can be classified according to the mechanisms by which the infecting organism reaches the joint. Infectious arthritis can result by spread from an adjacent bone infection, direct contamination of the joint space, or hematogenous dissemination. Hematogenous spread of the disease comprises the majority of infections; spread from osteomyelitis and direct inoculation is much less frequent. Septic arthritis is most prevalent in children and the elderly. Approximately, one-third of people with septic arthritis are children younger than 2 years of age.[8]

Unlike children, adults often have significant systemic diseases that predispose them to infectious arthritis, such as diabetes mellitus, immunosuppressive states (eg, cancer or liver disease), or preexisting arthritis. Risk factors associated with adult infectious arthritis (more than one factor may be present) are systemic corticosteroid use, preexisting arthritis, arthrocentesis, distant infection, diabetes mellitus, trauma, and other diseases. Intravenous drug abusers and individuals with intravascular infections such as endocarditis also are prone to develop septic arthritis.

PATHOPHYSIOLOGY

Osteomyelitis

Hematogenous Osteomyelitis

Hematogeous osteomyelitis is typically a disease of the growing bone and most cases occur in patients younger than 16 years of age. Less commonly, these infections occur in adults. **Table 118-1** summarizes the primary characteristics of osteomyelitis.

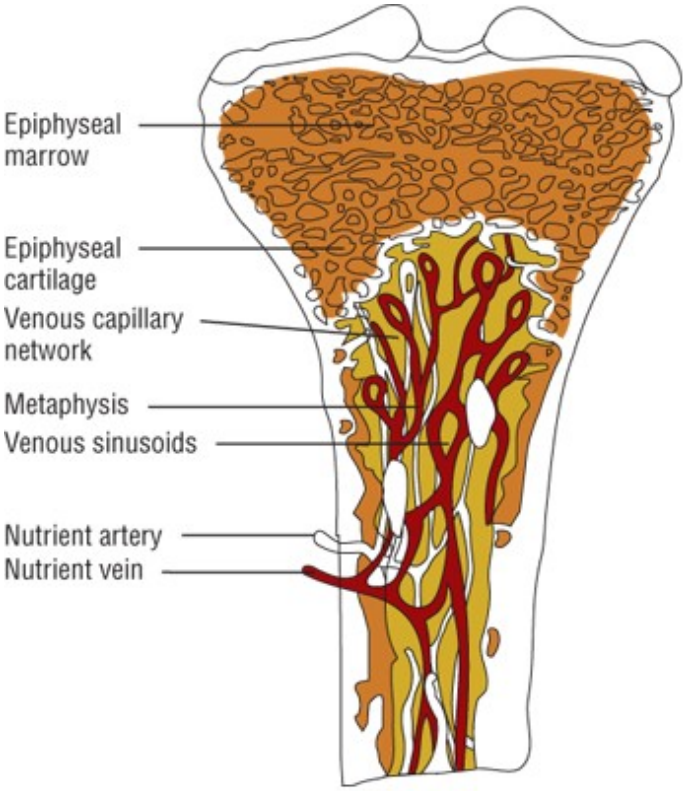
TABLE 118-1 Types of Osteomyelitis, Age Distribution, Common Sites, and Risk Factors

Type of Osteomyelitis	Typical Age (years)	Site(s) Involved	Risk Factors
Hematogenous	<1	Long bones and joints	Prematurity, umbilical or other central venous catheter or venous cut-down, respiratory distress syndrome, and perinatal asphyxia
	1-20	Long bones (femur, tibia, and humerus)	Infection (pharyngitis, cellulitis, and respiratory infections), trauma, and sickle cell disease
	Older than 50	Vertebrae	Diabetes mellitus, blunt trauma to spine, and urinary tract infection
Contiguous	Older than 50	Femur, tibia, and mandible	Hip fractures and open fractures
Puncture	<18	Foot	Puncture injury to foot
Vascular insufficiency	Older than 50	Feet and toes	Diabetes mellitus, peripheral vascular disease, and pressure sores

Unique features of the anatomy and vascular supply of long bones appear to predispose them to become infected.[2] The hematogenous infections begin within the metaphyses (**Fig. 118-1**) as the nutrient arteries of the long bones divide within the medullary canal of the bone into small arterioles. These end in hairpin turns near the growth plate and flow into veins, of much wider diameter, that drain the medullary cavity.[1] The infection is initiated within the bend of the arterioles where there is considerable slowing of blood flow in the hairpin capillary loops. This sludging of blood flow allows bacteria present within the bloodstream to settle and initiate an inflammatory response. They have access to the bone by gaps in the endothelium and the absence of a basement membrane. In addition to these structural features, phagocytosis is less active within the metaphysis. After the bacteria settle in the bone, avascular necrosis can occur from occlusion of the nutrient vessels and release of bacterial enzymes. Once the infection is initiated, exudate begins to form within the bone marrow and the fluid accumulates under increased pressure. The age of the patient largely determines the next stage in the pathophysiology.

FIGURE 118-1

Cross-section of normal bone.



Neonatal infections commonly involve multiple bones. The vascular supply of long bones in neonates has unique anatomic characteristics that affect their clinical presentation. Bridging blood vessels go across the epiphyseal plate from the metaphysis into the epiphysis thus enabling an infection that started within the metaphyseal area to spread easily to involve the epiphyses and then break into the joint. Therefore, in infants, not only can the infection spread under the periosteum or break through the periosteum and the shaft as in older children, but the infection also can spread directly through the bridging blood vessels to involve the joint.

In children older than 12 to 18 months, *hematogeous osteomyelitis* typically involves a single bone and has a predilection for involvement of the long bones, such as the femur, tibia, humerus, and fibula. The infection that started in the metaphysis of a long bone is prevented from spreading into the epiphysis and the adjacent joint space because of the epiphyseal growth plate which acts as a physical barrier; however, the exudate often dissects from the medulla through the soft cortex to the subperiosteal space as the periosteum in these children is loosely attached to the underlying cortex. The periosteum is thick and not easily ruptured thus containing the pus in the subperiosteal space, sometimes forming a subperiosteal abscess. If there is significant damage to the periosteum, the pus can decompress into a soft tissue abscess. The cortex obtains most of its blood supply from the periosteum and a subperiosteal abscess can impair the blood flow to the outer portion of the cortical bone resulting in a devitalized piece of dead bone termed a *sequestrum*. The elevated periosteum remains viable because its blood supply, derived from the overlying muscle, is unaffected. The raised periosteum will continue to produce bone; however, this new bone is now separated from the cortex

because the periosteum has been raised from the infection. This new bone that is deposited under the periosteum is termed *involucrum*. In addition to these anatomic and functional features, there is some evidence that trauma is associated with developing an infection in specific bones. Children who develop *hematogeous osteomyelitis* may report some type of trauma before the onset of their symptoms and animal data indicate that traumatized bone is more likely to become infected than normal bone.

In adults, the periosteum is tightly bound to the cortex which is thick. These anatomic features generally cause the infections to remain intramedullary. As expected, subperiosteal abscess formation is less common in this population. The infection can spread to subperiosteal structures through the Haversian and Volkmann canals.

Osteomyelitis of the vertebrae is also acquired hematogenously and occurs most frequently in patients older than 50 years of age.[10,11] Vertebral disease in young children usually involve the disk space and the two vertebral facets adjoining it because of the nature of the vascular supply of the vertebrae at that age. This entity is known as diskitis. Vertebral osteomyelitis involving the body of the vertebra can be seen in children older than 8 years of age.

Chronic osteomyelitis is more likely to occur if large segments of bone become avascular and necrotic. This results in a piece of devitalized bone to which antimicrobial delivery is impaired. As a result, this infection is prone to exacerbations and may lead to weakening of that bone or to the formation of draining sinuses to the skin.

Direct Inoculation Osteomyelitis

This category of osteomyelitis includes infections caused by direct entrance of organisms from a source outside the body. Penetrating wounds (eg, trauma), open fractures, and various invasive orthopedic procedures can result in direct inoculation of organisms into the bone. More than 80% of cases of postoperative osteomyelitis are known to occur following open reduction of fractures. Specifically, these infections occur most commonly after internal fixation of a hip fracture or femoral or tibial shaft fracture. Inoculation osteomyelitis can also occur as a result of penetrating foreign bodies most commonly nail puncture injuries to the foot.

Contiguous Spread Osteomyelitis

Osteomyelitis secondary to spread from an adjacent soft tissue infection is called contiguous osteomyelitis. It can result from pressure ulcers or from adjacent soft tissue infections and most often involves the distal extremities. Less commonly, infections can spread from infected teeth to involve the mandible or occurs secondary to sinus infections by spreading through the mucosal lining of the sinuses into the vascular system surrounding the bone.

In contrast to *hematogeous osteomyelitis*, which occurs most commonly in children, contiguous-spread osteomyelitis occurs most commonly in patients older than age 50, most likely because of predisposing factors, such as hip fractures or vascular disease, are more common in this age group.

Patients with osteomyelitis in association with severe vascular insufficiency are extremely difficult to manage.[12] As anticipated, most of these patients have diabetes mellitus or severe atherosclerosis, and they develop their infections by contiguous spread. Generally, these patients are between the ages of 50 and 70 years. Frequently, patients with vascular disease develop osteomyelitis in their toes and fingers, and there is usually an adjacent area of infection, such as cellulitis or dermal ulcers. Importantly, infections in these patients are almost always polymicrobial and often include staphylococcus and streptococcus or the combination of staphylococcus, streptococcus, and Enterobacteriaceae. Enterococci and anaerobic organisms also can be involved.

Infectious Arthritis

Infectious arthritis usually is acquired by hematogenous spread. The synovial tissue is highly vascular and does not have a basement membrane, so organisms in the blood can easily reach the synovial fluid. **Table 118-2** summarizes the characteristics of acute infectious arthritis.

TABLE 118-2 Characteristics of Acute Infectious Arthritis

Feature	Finding
Peak incidence	Children younger than 16 years
	Adults older than 50 years
Clinical findings	Fever of 38-40°C (100.4-104°F) in children; painful swollen joint in the absence of trauma
	Physical examination: Effusion, restriction of joint motion, tenderness, redness, and warmth of joint
Most commonly affected joints	Knee, hip, ankle, elbow, wrist, and shoulder
Laboratory findings	
Erythrocyte sedimentation rate	Elevated in 90% of cases
	Elevated in 30%-60% of cases
White blood cell count	Seen in two thirds of patients
Left shift	Positive in 40% of cases
Blood culture	
Needle aspiration of joint	Gram-stain diagnostic in 30%-50% of cases. Synovial fluid cultures are positive in 60%-80% of cases. Synovial fluid differential reveals 90% polymorphonuclear leukocytes. Synovial fluid glucose decreased relative to serum glucose. Lactic acid levels elevated in nongonococcal infectious arthritis, but not in gonococcal infectious arthritis

Preexisting abnormal joint architecture, joint trauma, and surgery are risk factors because chronic inflammation or trauma makes the joint more susceptible to infection. Individuals with rheumatoid arthritis can be prone to bacterial infection because of an inherent phagocytic defect, as well as concomitant corticosteroid therapy.

Organisms can gain access to the joint from a deep-penetrating wound injury, intra-articular steroid injections, arthroscopy, prosthetic joint surgery, and spread to the joint from a contiguous focus of osteomyelitis. After bacteria gain access to the joint, the organisms begin to multiply and produce a purulent exudate within the joint. If this joint effusion is present beyond 7 days, chronic, and sometimes irreversible, damage can occur to the bone and joint as a result of proteolytic enzymes and pressure necrosis. Purulent effusions can promote cartilage destruction by increasing leukocyte enzyme activity. In conjunction with the development of the effusion, almost all patients will develop a hot, swollen, painful joint.

CLINICAL PRESENTATION

Osteomyelitis

The clinical presentation of acute *hematogeous osteomyelitis* is summarized in **Table 118-3**. Although neonatal *hematogeous osteomyelitis* can spread rapidly to involve the joint, often there are few associated systemic symptoms.[13] A joint effusion is present in 60% to 70% of neonatal infections. Decreased limb motion or edema over the affected area may be the only signs from which to suspect the diagnosis. While it is sometimes acute in onset, the disease is often insidious in children.

TABLE 118-3 Clinical Presentation of Hematogenous Osteomyelitis

Signs and symptoms
Significant tenderness of the affected area, pain, swelling, fever, chills, decreased motion, and malaise
Laboratory tests
Elevated erythrocyte sedimentation rate, C-reactive protein, and white blood cell count
50% of patients will have positive blood cultures
Diagnostic studies
Bone changes observed on radiographs 10-14 days after the onset of infection. Magnetic resonance imaging and technetium scans positive as early as 1 day after the onset of infection

Vertebral osteomyelitis produces nonspecific symptoms, such as constant back pain, fever or night sweats, and weight loss.[14] The pain typically is present at rest and increases in severity with movement. Serious neurologic complications can occur if the infection extends and compresses the spinal cord.

The presentation of osteomyelitis after surgery or trauma depends on the precipitating cause. If the

infection follows surgery or bone trauma, the symptoms usually are noted within 1 month. The most frequent symptom is pain in the area of infection. Less commonly, patients also can develop a fever and elevated WBC count.

With contiguous-spread osteomyelitis there is often an area of localized tenderness, warmth, edema, and erythema over the infected site. Patients with significant vascular insufficiency usually have local symptoms, such as pain, swelling, and redness. Less commonly, they also can have fever and elevated WBC count.

Infectious Arthritis

Patients with nongonococcal bacterial arthritis almost always present with a fever, and 50% of patients have an elevated WBC count (see Table 118-2). The average initial synovial WBC count is 10 × 10^3/mm^3 (10 × 10^9/L) or greater in nongonococcal bacterial disease. Nongonococcal bacterial arthritis is almost always monoarticular. The knee is the most commonly involved joint, but infections also can occur in the shoulder, wrist, hip, ankle, interphalangeal joints, and elbow joints. Usually, the initial focus of infection that acted as the portal of entry can be identified. Common routes for bacterial entrance include infections of the respiratory tract, skin, and urinary tract or previous bacteremia; often no specific source can be identified. Blood cultures are important in these patients because they can be positive in 50% of patients.

The most frequent initial sign of disseminated gonococcal infections is the triad of dermatitis, tenosynovitis (inflammation and swelling of a tendon) and migratory polyarthralgia or polyarthritis. Women are more prone to develop disseminated gonococcal infections than men by a ratio of 4:1. The second and third trimesters of pregnancy and the time of menses appear to be the times of greatest risk for developing gonococcal bacteremia, hypothesized to be associated with mucosal vascularity. Common joints involved include the knee, wrist, elbow, and ankle. Presentation varies slightly depending on whether or not the woman is pregnant. In non-pregnant women, duration of symptoms are longer, presence of joint effusion is more likely, and white blood cells are more often present within the synovial fluid.[15]

Another type of infectious arthritis occurs following prosthetic joint surgery. The most common symptom is pain. Local signs of inflammation and fever are common in acute infections while chronic infections present in a more subtle fashion, typically with pain alone and often loosening of the prosthesis. With these infections, the C-reactive protein usually is elevated, although a leukocytosis often is absent. Infections that result from postoperative contamination usually become apparent within 1 year of surgery.

Radiologic and Laboratory Tests

Osteomyelitis

2 The evaluation of a patient who may have osteomyelitis has several unusual aspects. Radiographs of the involved area should be obtained to rule out other processes such as a fracture; bone changes

characteristic of osteomyelitis appear late and are not typically seen until at least 10 to 14 days after the onset of the infection as more than 50% of the bone matrix must be decalcified before the lesions can be detected radiologically. Magnetic resonance imaging (MRI) is the most sensitive and commonly used diagnostic imaging modality and offers the advantage of better anatomic definition, especially of abscesses or joint effusions. Radionuclide bone scanning (technetium/gallium) computed tomographic scanning or positive emission tomography scanning is useful in identifying the focus of osteomyelitis in patients unable to have an MRI.[16]

Despite the seriousness of osteomyelitis, often there are few laboratory abnormalities. The erythrocyte sedimentation rate (ESR), C-reactive protein, and WBC count may be the only laboratory abnormalities. The degree of abnormality of these laboratory findings does not correlate with the disease outcome; however, these inflammatory markers are useful for monitoring therapy. C-reactive protein is generally the more sensitive marker of response to therapy and often increases and decreases before the ESR.

When a clinical assessment of osteomyelitis is suspected, it is important to establish a bacteriologic diagnosis by culture of the infected bone and blood. Accurate culture information is especially important as a guide for treatment of osteomyelitis in this era of increasing antimicrobial resistance. Bone aspiration or bone biopsy are valuable in determining an accurate bacteriologic diagnosis. In addition, they help determine whether or not there is an abscess present. If an abscess is identified, it must be drained and the pus cultured, and a Gram stain performed. Aspirates of subperiosteal pus or metaphyseal fluid yield a pathogen in 70% of cases. Cultures should be done for both aerobic and anaerobic bacteria. A Gram stain of the aspirate can be useful in initiating appropriate empirical antibiotic therapy.

If a specimen is obtained from a previously undrained or unopened wound abscess, the pathogen usually can be identified. In chronic osteomyelitis, however, identification can be more difficult. Open wounds and draining sinuses frequently are contaminated with other organisms and thus provide inaccurate culture information.[17] They cannot be relied on to reflect the pathogen unless consecutive deep sinus tract cultures reveal the same pathogens.[18] Cultures of loculated pus aspirates in the area of orthopedic devices removed from infected bone can be trusted, however, to identify the infecting organism. The preferable time to obtain culture material in a patient with a chronic draining sinus is at the time of open surgical debridement.

In addition to performing cultures from the involved bone, it also is important to obtain cultures from any site believed to be the primary source of a bacteremia. Blood cultures should be obtained. Approximately 50% of patients with *hematogeous osteomyelitis* will have positive blood cultures and may obviate the need for bone aspiration in these patients.

Infectious Arthritis

3 Radiographs of infected joints often reveal distension of the joint capsule with soft tissue swelling in the adjacent space. Magnetic resonance imaging can be helpful in identifying an infected joint, especially the shoulder and hip. In patients who have developed an infected prosthetic joint,

loosening of the prosthesis can be seen radiographically.

When evaluating the possibility of a patient having infectious arthritis, immediate joint aspiration with analysis of the synovial fluid is extremely important. The presence of purulent fluid usually indicates the presence of a septic joint. The synovial fluid WBC count is usually 50 × 10^3-200 × 10^3/mm^3 (50 × 10^9-200 × 10^9/L) when an infection is present. As with osteomyelitis, most patients will have an elevated C-reactive protein concentration and ESR. However, serum WBC, ESR, and C-reactive protein may not be useful acutely in septic arthritis.[19]Approximately half the patients with an infected joint have a low synovial glucose level, usually less than 40 mg/dL (2.2 mmol/L). Gram stains of joint fluid demonstrate bacteria in 50% of patients with septic arthritis; however, such stains are positive in only 25% of patients with gonococcal arthritis. Synovial fluid cultures usually are positive in patients with nongonococcal infections. Both blood and joint fluid should be cultured aerobically and anaerobically in a patient suspected of having an infected joint. Blood cultures are positive in one-half of patients with nongonococcal infections but in only 20% of those with gonococcal infections. Pharyngeal, rectal, cervical, or urethral smears and cultures, as well as cultures of cutaneous lesions, should be performed if a disseminated gonococcal infection is considered. Nucleic acid based assays should also be used for the diagnosis of genital gonococcal infection.

TREATMENT

Desired Outcome(s)

Osteomyelitis

The goals of treatment are resolution of the infection and prevention of long-term sequelae. The ultimate outcome of osteomyelitis depends on the acute or chronic nature of the disease and how rapidly appropriate therapy including surgical drainage where appropriate is initiated. Patients with acute osteomyelitis have the best prognosis. Cure rates exceeding 80% can be expected for patients with acute osteomyelitis who have surgery when indicated and receive appropriate antibiotics for 4 to 6 weeks. When the growth plate is involved in children, discrepancies in the growth of bones or angular bone deformities can result.

In contrast, patients with chronic osteomyelitis have a much poorer prognosis. Dead bone and other necrotic material from the infection act as a bacterial reservoir and make the infection very difficult to eliminate. Adequate surgical debridement to remove all the dead bone and necrotic material, combined with prolonged administration of antibiotics, provides the best chance to obtain a cure.[20] The inability to remove all the dead bone can allow residual infection and require suppressive antibiotics to control the infection.

Infectious Arthritis

While many patients who develop infectious arthritis recover with no long-term sequelae, 50% are left with decreased joint function or mobility. Gonococcal arthritis usually resolves rapidly with antibiotics and has fewer sequelae. Individuals at greatest risk for long-term sequelae are those who

have symptoms present for more than 7 days before starting therapy and those with infections occurring within the hip joint and infections caused by Gram-negative organisms. Common long-term residual effects following infectious arthritis are limited joint motion and persistent pain.

During the initial phase of the infection, weight bearing, such as walking on the joint should be avoided. Passive range-of-motion exercises should be initiated when the pain begins to subside to maintain joint mobility. Approximately one-third of patients with bacterial arthritis have a poor joint outcome, such as severe functional deterioration. Poor joint outcomes are associated with older patients, those with preexisting joint disease, and patients with an infected joint containing synthetic material.

General Approach to Treatment

Osteomyelitis

4 Following completion of the steps needed to determine the infecting organism, the most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time. It is important to stress that early antibiotic therapy can mitigate the need for surgery, subsequent sepsis, chronic infection, disruption of longitudinal bone growth and angular deformity of the bone.[21] A delay in treatment can allow bone necrosis to occur and make eradication of the infection much more difficult. In these patients with chronic osteomyelitis, exacerbations of the infection can result if all necrotic tissue is not removed surgically and all microorganisms eliminated. Chronic suppressive antimicrobial therapy and adjunctive treatment with hyperbaric oxygen or antibiotic-impregnated implants during surgery also has been used.

If a patient with *hematogeous osteomyelitis* does not respond by having a decrease in fever, local swelling, redness, and pain following the initiation of adequate antibiotic therapy, the patient should undergo surgical debridement of the infected area. It is important to emphasize the priority of starting antibiotics immediately after the cultures have been obtained.

Infectious Arthritis

Patients with infectious arthritis are typically admitted to the hospital to obtain synovial fluid and blood cultures and initiate antimicrobial therapy. Attempt to decrease bacterial burden in the joint space is obtained by performing either open or arthroscopic debridement. Empiric antibiotics are started as soon as culture specimens are collected. As with osteomyelitis, it is important to stress early initiation of antibiotic therapy to avoid complications such as avascular necrosis, limb-length discrepancy, and pathologic fractures.[22]

In patients with prosthetic joint devices, it is imperative that orthopedic surgeons work alongside infectious disease practitioners to determine the best course of action.[23] The gold standard treatment method includes resection of the implant, placement of temporary antibiotic-impregnated cement spacer, and delayed component re-implantation. Although it may be decided to retain the

implant in certain cases for which patients will receive irrigation and debridement in addition to antibiotic therapy, or antibiotic therapy alone in patients unable to tolerate surgical procedures.[24]

Pharmacologic Therapy

Osteomyelitis

Antibiotic Selection

A critical component in the management of osteomyelitis is the selection of appropriate antibiotics. Empiric therapy must be selected on the basis of the most likely infecting organism while the results of culture and susceptibility data are pending. Once culture and susceptibility results are obtained the antimicrobial therapy should be tailored. **Table 118-4** summarizes empiric therapy recommendations.

TABLE 118-4 Empiric Treatment of Osteomyelitis

Patient Subtype	Likely Infecting Organism	Antibiotic[a]	Recommendation Grades[b]
Newborn	*Staphylococcus aureus*, group B *Streptococci, Escherichia coli*	Nafcillin or oxacillin 50-150 mg/kg/day IV plus cefotaxime 100-200 mg/kg/day IV	B-3
Children 5 years of age or younger	1. If vaccinated for *Haemophilus influenzae* type b: *S. aureus* or Streptococci 2. If not vaccinated against *H. influenzae* type b	1. Nafcillin or oxacillin 150-200 mg/kg/day IV orcefazolin 100 mg/kg/day IV 2. Cefuroxime 150 mg/kg/day IV	B-3 B-3
Children older than 5 years of age	*S. aureus*	Nafcillin or oxacillin 150-200 mg/kg/day IV or cefazolin 100 mg/kg/day IV	A-3
Adults	*S. aureus*	Nafcillin or oxacillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours	A-3
IV drug abusers	*Pseudomonas*	Ciprofloxacin 750 mg orally twice daily or ceftazidime or cefepime 2 g IV every 8 hours	B-3
Postoperative or posttrauma patients	Gram-positive and Gram-negative organisms	Nafcillin or oxacillin 2 g IV every 4 hours plus ceftazidime or cefepime 2 g IV every 8 hours or	B-3

Patient Subtype	Likely Infecting Organism	Antibiotic[a]	Recommendation Grades[b]
		ticarcillin–clavulanate 3.1 g IV every 4 hours	
Patients with vascular insufficiency	Gram-positive and Gram-negative organisms	Nafcillin or oxacillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours plus ceftazidime or cefepime 2 g IV every 8 hours	B-3
	If anaerobes suspected	Cefotetan 2 g IV every 12 hours or clindamycin 900 mg IV every 8 hours plus ceftazidime or cefepime 2 g IV every 8 hours	C-3

IV, intravenous.

[a]Dosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.

[b]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from more than one properly randomized, controlled studies or multiple time series; or dramatic results from uncontrolled experiments. 2 = Evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

With staphylococcus being the most common bacteria in osteomyelitis, resistance patterns must be considered when deciding on an empiric agent. For communities showing low evidence of resistant strains of *S. aureus*, nafcillin is the drug of choice.[25]Although cefazolin or cephalexin are often chosen to treat susceptible strains due to ease of dosing compared to nafcillin. Clindamycin can be used in less severe cases.[25,26] If 10% or more of the surrounding community *S. aureus* isolates are methicillin resistant, then an agent active against MRSA should be selected. Vancomycin is the drug of choice in this case.[25,26] If the patient is severely ill, then both vancomycin and nafcillin should be used for empiric treatment, as nafcillin is superior for the treatment of methicillin susceptible *S. aureus*.[25]

In the setting of vertebral osteomyelitis, empiric therapy should be initiated in conjunction with culture if the patient is hemodynamically unstable, septic or experiencing neurologic compromise; otherwise, it is recommended empiric therapy be held 1 to 2 weeks while awaiting culture results.[3]

Antibiotic Bone Concentration

5 Antibiotics used in the management of acute osteomyelitis generally are given in high doses (adjusted for weight, renal function, hepatic function, or both) so that adequate antimicrobial concentrations are reached within the infected bone and joint.[27] **Table 118-5** summarizes antibiotics doses that have been successful in the treatment of osteomyelitis.

TABLE 118-5 Antimicrobial Agents for the Treatment of Osteomyelitis

Antimicrobial	Dose[a]	Comments
Amoxicillin	Adult: 500-875 mg orally every 8 hours[21]	
Amoxicillin/Clavulanate	Adult: 875/125 mg orally every 8 hours[21]	
Ampicillin	Adult: 2 g IV every 4 hours[21]	May add IV aminoglycoside for treatment of *Enterococcus* spp[21]
	Children: 150-200 mg/kg/day in 4 equal doses (max 8-12 g daily)[29]	VO:For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]
	VO:12 g IV every 24 hours, continuous, or in 6 divided doses[3]	
Ampicillin/Sulbactam	Adult: 1.5-3 g IV every 6 hours[21]	
Anti-staphylococcal (cloxacillin, flucloxacillin, dicloxacillin, nafcillin, oxacillin)	Adult: Nafcillin or oxacillin 1-2 g IV every 4-6 hours[21,28]	
	Children: ≤200 mg/kg/day in 4 equal doses (max dose 8-12 g daily)[29]	VO: 6 week duration[3]
	VO: Nafcillin or oxacillin 1.5-2 g IV every 4-6 hours or continuous infusion[3]	
Aztreonam	VO: 2g IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered. Use only for severe penicillin allergy and quinolone-resistant strains[3]
Cefepime	Adult: 2 g IV every 24 hours[21,28]	Add IV ciprofloxacin for treatment of *P. aeruginosa*[28]
	VO: 2 g IV every 8-12 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered. For Enterobacteriaceae, 2 g IV every 12 hours[3]

Antimicrobial	Dose[a]	Comments
Cefotetan	Adult: 2 g IV every 12 hours[28]	
Ceftazidime	Adult: 2 g IV every 8-12 hours[21] VO: 2 g IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered[3]
Ceftriaxone	Adult:1-2 g IV every 24 hours[21,28] VO: 2 g IV every 24 hours[3]	VO: 6 week duration. For *Salmonella*, 6-8 week duration[3]
Chloramphenicol	Children: 75 mg/kg/day in 3 equal doses (max dose 2-4 g daily)[29]	To be used if safer agents are not available or affordable[29]
Ciprofloxacin	Adult: 400 IV every 8-12 hours[21,28] or 500-750 mg PO every 12 hours[21,23] VO: 500-750 mg orally every 12 hours, or 400 mg IV every 8 hours[3] Adult: 600 mg IV every 6 hours[21,28] or 300-600 mg orally every 6 hours[21,23]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered. For *Salmonella*, 6-8 week duration[3]
Clindamycin	Children: ≥40 mg/kg/day in 4 equal doses (max dose 3 g daily)[29] VO: 600-900 mg IV every 8 hours, or 300-450 mg orally twice daily[3]	VO: 6 week duration, not recommended for MRSA. Recommended as second line for sensitive staphylococcal infection[3]
Daptomycin	Adult: 4-6 mg/kg IV every 24 hours[21] VO: 6-8 mg/kg IV every	VO: 6 week duration. For enterococcus, 6 mg/kg IV every 24 hours plus 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]

Antimicrobial	Dose[a]	Comments
	24 hours[3]	
Doripenem	VO: 500 mg IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered[3]
Doxycycline	Adult: 100 mg orally twice daily[23]	VO: Can be used in addition to rifampin for brucellar infection
Ertapenem	VO: 1 g IV every 24 hours[3]	VO: 6 week duration[3]
First Generation Cephalosporin (Cefazolin, Cephalexin)	Adult: Cefazolin 1-1.5 g IV every 6 hours[28] or 1-2 g IV every 6-8 hours[21] Cephalexin 500 mg orally every 6 hours[21] Children: ≥150 mg/kg/day in 4 equal doses (max dose 2-4 g daily)[29]	VO: 6 week duration[3]
Fusidic acid	VO: Cefazolin 1-2 g IV every 8 hours[3] Adult: 500 mg orally three times daily[23]	
Imipenem/cilastatin	Adult: 1 g IV every 8 hours[28]	Add IV aminoglycoside for treatment of *P. aeruginosa*[28]
Levofloxacin	Adult: 500-750 mg IV once daily[21,28] or 750 mg PO once daily[23] or 500 mg orally twice daily[23] VO: 500-750 mg orally once daily[3]	Add IV rifampin for treatment of MRSA[28] VO: Add rifampin 600 mg orally daily for all staphylococcus strains, duration 6 weeks of combination therapy[3]
Linezolid	Adult: 600 mg IV or orally every 12 hours[21,23,28] Children: 30 mg/kg/day in 3 equal doses (max	VO: 6 week duration. For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]

Antimicrobial	Dose[a]	Comments
	dose 1.2 g for no more than 28 days)[29]	
Meropenem	VO: 600 mg IV or orally every 12 hours[3] Adult: 1 g IV every 8 hours[21] VO: 1 g IV every 8 hours[3]	VO: 6 week duration. Double coverage for *P. aeruginosa* may be considered[3]
Antimicrobial	Dose	Comments
Metronidazole	Adult: 500 mg IV every 6-8 hours[21,28] or 500 mg orally three to four times a day[23] VO: 500 mg orally three to four times daily[3]	VO:F *Bacteroides* species and other susceptible anaerobes[3]
Minocycline	Adult: 200 mg orally initially, then 100 mg daily[28] or 100 mg PO twice daily[23]	
Moxifloxacin	Adult: 400 mg orally once daily[23] VO: 400 mg orally once daily[3]	VO: For Enterobacteriaceae and other susceptible aerobic Gram-negative organisms. Not recommended for staphylococcal infection[3]
Penicillin G	Adult: 2-4 million units IV every 4 hours[28] or 10-20 million units IV continuous every 24 hours[21] VO:20-24 million units IV every 24 hours, continuously, or in 6 divided doses[3]	VO: For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis[3]
Piperacillin/Tazobactam	Adult: 3.375 g IV every 6 hours[28]	Add IV ciprofloxacin for treatment of *P. aeruginosa*[28]

Antimicrobial	Dose[a]	Comments
Rifampin	Adult: 600 mg IV every 12 hours[28] or 600-900 mg orally every 24 hours[21,23] or 300-450 mg orally twice daily[23]	Only to be used in combination with another antimicrobial
Ticarcillin/Clavulanate	Adult: 3.1 g IV every 4 hours[28]	
Trimethoprim-Sulfamethoxazole	Adult: 1 double-strength tablet orally every 12 hours[28] or 1 double-strength tablet orally three times a day[23] VO: 1-2 double-strength tablets orally twice daily[3]	VO: Second line agent for Enterobacteriaceae and other susceptible aerobic Gram-negative organisms. May need to monitor sulfamethoxazole levels[3]
Vancomycin	Adult: 1 g IV every 12 hours[28] or 15 mg/kg IV every 12 hours[21] Children: ≤40 mg/kg/day in 4 equal doses[29] VO: 15-20 mg/kg IV every 12 hours[3]	Adjust based on patient and pharmacokinetic parameters. Target trough of 15-20 mcg per milliliter[29] VO: Consider loading dose for MRSA and enterococcus, 6 week duration. For enterococcus, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis. For enterococcus, use only if patient is penicillin allergic or bacteria is penicillin resistant[3]

IV, intravenous;MRSA, methicillin susceptible *staphylococcus aureus*;VO, vertebral osteomyelitis.

[a]Dosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.

Oral Antibiotic Therapy

6 Criteria for the use of oral outpatient antibiotic therapy for osteomyelitis includes all of the following:

- Confirmed osteomyelitis
- Initial clinical response to parenteral antibiotics

- Suitable oral agent available
- Adherence ensured

Suitable candidates are children with good clinical response to intravenous therapy and adults without diabetes mellitus or peripheral vascular disease.

The use of oral antibiotics is well studied in children.[30] Typically, injectable antibiotics are used initially and then switched to oral antibiotics when there was a decrease in the signs of inflammation and the ESR or when the patient was afebrile for 3 days. If pus was obtained on the initial needle aspirate, or if a reduction in fever, local swelling, and tenderness did not occur despite adequate rest, immobilization, and intensive antibiotic therapy, the patients underwent surgical drainage. The patients enrolled in oral antibiotic trials generally had disease of recent onset, identification of a specific infecting organism, enforced adherence, and surgery as indicated. In patients who meet these criteria, oral antibiotics appear to offer a great advantage in the treatment of osteomyelitis. Patients not meeting these criteria may have a higher risk of developing chronic osteomyelitis if oral therapy is inappropriate or not strictly adhered to. When oral antibiotics are used, the total duration of oral and injectable therapy is usually at least 4 weeks. Limited retrospective data in adults indicated that parenteral therapy for less than 4 weeks followed by oral therapy may be effective.[31]

Duration of Antibiotic Therapy

7 Following debridement, bone takes 3 to 4 weeks to revascularize thus the basis of treatment duration.[32] The specific duration of antibiotic therapy needed in the management of osteomyelitis is usually 4 to 6 weeks.[33] Failure rates approaching 20% have been observed in children treated with parenteral antibiotics for 3 weeks or less. One analysis in children with *hematogeous osteomyelitis* recommended 20 days of antibiotic therapy after initial parenteral therapy as long as the C-reactive protein level normalized within 7 to 10 days.[34] Although these data were largely evaluated in children, this duration of therapy recommendation is also used in adults. Treatment failures may be due to the presence of infected necrotic bone or infected hardware (wires, plates, screws, and rods) that could not be removed.[35]Improvement in the patient's clinical signs and symptoms and normalization of the C-reactive protein level or ESR are important parameters to assess therapy.[36] If signs or symptoms are still present at 6 weeks, therapy should be extended. In some cases of chronic osteomyelitis, lifelong suppressive therapy might be the most appropriate option.[37]

Duration of antibiotic administration for vertebral osteomyelitis may vary depending on the infecting organism. With Gram-negative bacteria a longer duration (greater than or equal to 8 weeks) is associated with less rates of recurrence compared to shorter durations (4-6 weeks).[5] One study compared 6 weeks versus 12 weeks duration in patients with pyogenic vertebral osteomyelitis and found the shorter duration to be non-inferior.[38] However, many factors remained left for questioning and it is uncertain whether or not it is safe to use a shorter duration for patients with extensive bone destruction or abscesses.[38,39] The IDSA guidelines recommend a minimum of 6 weeks of parenteral therapy or highly bioavailable oral therapy.[3]

Clinical Controversy...

Vertebral osteomyelitis—The exact duration of antimicrobial therapy for a patient with vertebral osteomyelitis is unknown. Many factors play a role in determining the severity of the infection and risk of recurrence. Longer courses might be needed in patients with Gram negative infections or infections complicated by abscesses.

Special Populations

Osteomyelitis in the intravenous drug user has unique features.[40] More than 50% of such infections involve the vertebral column and less than 20% of infections are located in either the sternoarticular or pelvic girdle. Infections are much less frequent within the extremities. They also have an unusual spectrum of organisms with Gram-negative organisms being responsible for 88% of infections. *P.aeruginosa*, either singly or in combination with other organisms, is cultured in 78% of all such infections. *Klebsiella, Enterobacter*, and *Serratia* species also can be found but less commonly. In addition, staphylococcal and streptococcal organisms are sometimes cultured.

Patients with sickle cell anemia and related hemoglobinopathies also represent a unique population in that two-thirds of bone infections in these patients are caused by *Salmonella* species, while the rest are usually caused by staphylococci and other Gram negative organisms.[41] Bowel infarctions from the sickle cell disease can facilitate the entry of salmonellae from the colon into the bloodstream with resultant hematogenous spread to the bone. Osteomyelitis in patients with sickle cell disease may occur in any bone, but it most commonly involves the medullary cavity of long or tubular bones. Because of the difficulty in separating bone pain during a sickle cell crisis from that of an infection, osteomyelitis can be relatively advanced in these patients by the time the diagnosis is made.

Infectious Arthritis

Antibiotic Selection

8 The three most important therapeutic maneuvers in the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest. Smears of the synovial fluid can be useful to select appropriate antibiotic therapy initially.[8] If bacteria are not observed on the Gram stain in a patient who has a purulent joint effusion, antibiotics still should be initiated because of the low sensitivity of the Gram stain. A delay in initiating antibiotics significantly increases the likelihood for long-term complications. The specific antibiotic selected depends on the most likely infecting organism. When staphylococcal infection is suspected, rifampin is often added to the anti-staphylococcal or anti-MRSA agent, especially in the setting of prosthetic hardware.[42]

Antibiotic Joint Space Concentration

The antibiotics selected usually are administered parenterally to achieve sufficient concentrations within the synovial fluid, and thus intra-articular antibiotic injections are unnecessary.

In prosthetic joint infections, antimicrobial cement spacers are often used to aide in delivery of the antimicrobial to the site of infection. The most common antimicrobials used include vancomycin and aminoglycosides, tobramycin and gentamicin.[43,44]However, the doses of each agent are widely variable and it is uncertain whether the placement of antimicrobial cement spacers adds outcome benefit to systemic therapy.[43] The thought of antimicrobial cement spacer providing local exposure of the antimicrobial agent without systemic consequences has been questioned.[45] Ameta-analysis reported the incidence of acute kidney injury in patients receiving treatment with antimicrobial cement spacers at 4.8%, incidence range varied from 2% to 17% based on the definition of acute kidney injury used.[43]

Clinical Controversy…

Antimicrobial cement spacers—The use of antimicrobial cement spacers is routine for patients with prosthetic joint infections. The antimicrobial agents used locally may place the patient at risk for systemic adverse reactions with little benefit added to systemic therapy. In addition, the exact dose of the antimicrobials used is unknown.

Similar to osteomyelitis, once the infection is confirmed if initial response to parenteral therapy is achieved, the culture susceptibilities have resulted, and adherence is ensured, then selected oral antibiotics can be used for the treatment of infectious arthritis. Shorter durations of antimicrobial therapy are needed to treat infectious arthritis compared to osteomyelitis. A randomized trial compared 10 days versus 30 days of antimicrobial therapy and found no difference between the groups.[34] The treatment duration may be extended to 20 days if the adjacent bone is affected.[46]

Home Antibiotic Therapy

Because the management of bone and joint infections frequently requires prolonged parenteral antibiotics, newer antibiotic regimens have been used. Administration of antibiotics in the home environment and the use of antibiotics with extended elimination half-lives are commonly used. Although acute osteomyelitis is one of the more common infectious diseases that can be treated with home intravenous antibiotics, not all patients are acceptable candidates for home administration. Patients must be screened to include only those who are receiving a stable treatment program, those who are interested and are motivated in participating, and those who have good venous access, as well as those who have support from family members or neighbors and have home facilities for storage and refrigeration. Patients with adequate vascular access may be able to use a peripheral intravenous catheter; however, a central intravenous catheter may be required if venous access difficulties occur. Certain exclusion criteria also must be considered. Complications of other preexisting diseases, such as diabetic retinopathy, intention tremor, disabling inflammation or degenerative joint disease, coagulopathies, or various neurologic disorders can prevent individuals from receiving home antibiotics. A history of alcoholism or of intravenous drug abuse also is important exclusion criteria. Patients who are fluent in only a foreign language and patients who are illiterate or hard of hearing may have to be excluded if a qualified guardian is unavailable. In addition to meeting these initial screening criteria, patients must successfully complete a thorough training program before hospital discharge. Aseptic technique, proper catheter care, and correct

administration techniques must be documented. Once a patient is receiving therapy in the home environment, continued monitoring of their antimicrobial therapy and drug levels when indicated is important. It is vital to ensure compliance with the antimicrobial regimen. Catheter-related complications are common in patients receiving prolonged courses of parenteral antibiotics.

In addition, the specific antibiotic regimen characteristics must be considered when evaluating a patient for home antibiotics. Some important features are microbiologic culture and susceptibility data, the number of required daily antimicrobial doses, antibiotic stability data, and requirements for unique monitoring for the specific antimicrobial regimen, such as serum creatinine and drug level monitoring with aminoglycosides or vancomycin. Although an organism can be susceptible to several antimicrobial agents, one antibiotic can provide practical benefits over other agents.

PERSONALIZED PHARMACOTHERAPY

Individualized therapy is important in the treatment of osteomyelitis and infectious arthritis. Patient quality of life can be significantly diminished if long-term sequelae develop, such as impaired joint motion or draining sinus tracts, or if amputation is required. Patient demographics, infection characteristics (eg, infecting organism and its susceptibility patterns), treatment cost, and quality-of-life issues all play a major role in evaluating individualized treatment alternatives (oral therapy or home antibiotic treatment) rather than requiring patients to remain hospitalized to receive 4 to 6 weeks of parenteral antibiotics. In addition, adverse events commonly occur with prolonged outpatient parenteral antibiotic therapy. One study in 45 children noted that 85.7% of patients receiving vancomycin had adverse drug events and 42.9% of patients required the drug be discontinued.[47] This analysis also noted that cefazolin had the lowest rate of adverse drug events in this population. Monitoring is important to ensure that personalized therapy is effective to both cure the infection as well as minimize the risk for complications.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

9 Patients with bone and joint infections must be monitored closely. **Table 118-6** summarizes a pharmaceutical care monitoring protocol. An assessment of a therapy's success or failure is based on the patient's clinical findings and laboratory values. The clinical signs of inflammation, such as swelling, tenderness, pain, redness, and fever, should resolve with appropriate therapy. Initially, the clinical signs are assessed daily until improvement and then periodically thereafter. Elevations in WBC count also should decline gradually. The ESR usually is determined weekly. Elevations in the C-reactive protein or ESR may not return to normal until after several weeks of therapy. The WBC count usually is obtained once or twice per week until it returns to the normal range. If by the end of the 4- to 6-week antibiotic course the clinical findings of osteomyelitis are no longer present and the C-reactive protein and ESR are within normal limits, the patient can be considered a clinical cure. Patients can relapse, however, after initially appearing to be cured. No relapse for 1 year generally is considered a complete cure.

TABLE 118-6 Monitoring Protocol

Parameter	Frequency	Notes
Culture and susceptibility	At initiation of treatment	
White blood cell count	One time per week until within normal range	
C-reactive protein or erythrocyte sedimentation rate	Weekly	May not decrease to normal range until several weeks of therapy
Clinical signs of inflammation (redness, pain, swelling, tenderness, and fever)	Daily during initiation of therapy	
Adherence of outpatient therapy	Reinforce before starting oral therapy and with each healthcare visit	Adherence is critical if treatment is to be successful
Complete blood count	Weekly	Certain antimicrobial agents may cause blood dyscrasias when used for long term therapy (eg, linezolid, trimethoprim/sulfamethoxazole)

If a patient fails to resolve the clinical signs and symptoms of inflammation after appropriate empirical antibiotics, suspicion for an abscess should be raised and imaging by MRI and surgical debridement may be needed. In addition, the patient might have a resistant or an atypical infecting organism that may require a modification of the antibiotic therapy. It is especially important to identify the infecting organism and its susceptibility pattern. Follow-up cultures at subsequent debridements can be useful to assess the antibiotic therapy.

Despite apparently adequate surgery and antibiotics, some patients can fail therapy and have recurrent relapses in their infection.[39] This scenario is more common in those with chronic osteomyelitis. These patients can require long-term oral suppressive antimicrobial therapy to keep the infection under control.

Chapter 119: Sepsis and Septic Shock

S. Lena Kang-Birken

INTRODUCTION

KEY CONCEPTS

- 1 Gram-negative organisms are isolated in 50% to 62% of patients with severe sepsis or septic shock, followed by gram-positive bacteria in 37% to 47%, anaerobic organisms in 5%, and fungi in 8% to 19%.
- 2 Candidemia is a major cause of morbidity and mortality. *Candida albicans* remains the most common pathogen (45.6%); however, non–*albicans Candida* species collectively is more frequently isolated (54.4%).
- 3 Sepsis presents a complex pathophysiology, characterized by the activation of multiple overlapping and interacting cascades leading to systemic inflammation, a procoagulant state, and decreased fibrinolysis.
- 4 Mortality rates with sepsis are higher for older patients with preexisting disease, intensive care unit (ICU) care, and multiple organ failure.
- 5 Prompt initiation of one or more parenteral antibiotics within 1 hour of recognition of septic shock and severe sepsis without septic shock is required and the regimen should be assessed daily for potential de-escalation.
- 6 A significant volume of fluid leaks from the vasculature occurs with sepsis, and initial fluid resuscitation with large volumes of fluid is required. Crystalloid solutions are generally recommended for fluid resuscitation because of the absence of any clear benefit with colloids solutions in addition to the lower cost of crystalloids.
- 7 Norepinephrine is the preferred vasopressor to correct hypotension in septic shock, and epinephrine should be considered the first alternative to patients intolerant to norepinephrine.
- 8 Implementation of protocolized, quantitative resuscitation bundle within 6 hours of

recognition of sepsis-induced hypoperfusion has been shown to decrease the mortality rates as well as the ICU length of stay.

- 9 A blood glucose level less than 180 mg/dL (10 mmol/L) is recommended for the majority of critically ill patients to reduce morbidity and mortality without the detrimental effects associated with hypoglycemia.

- 10 IV hydrocortisone is recommended for adult patients with septic shock whose blood pressure is unresponsive to fluids and vasopressors.

Sepsis and severe sepsis continue to pose major healthcare burden. The Nationwide Inpatient Sample years 2003 to 2009 reported hospitalizations with sepsis claims including septicemia sepsis, severe sepsis, and septic shock increased from 359 per 100,000 US residents to 535 per 100,000, a 49% increase.[1] Despite aggressive medical care and advances, overall in-hospital deaths remains at 15% to 40%, with over one-third of patients discharged to a long-term care facility.[2] Given the public health and financial burden, there is a vital need for clinicians to comprehend the pathophysiology and the optimal management approaches for acutely ill patients with severe sepsis or septic shock.

DEFINITIONS

Periods of bacteremia, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock, or multiple-organ dysfunction syndrome (MODS) often overlap, and they signify an important continuum of progressive physiologic decline (**Fig. 119-1**). *Severe sepsis* refers to patients with an acute organ dysfunction, such as acute renal failure or respiratory failure. Sepsis-induced hypotension is defined as a systolic blood pressure less than 90 mm Hg or mean arterial pressure (MAP) less than 70 mm Hg (<9.3 kPa) **(Table 119-1)**.[3] *Septic shock* refers to sepsis patients with sepsis-induced hypotension that is refractory to adequate fluid resuscitation, thus requiring vasopressor administration. Sepsis-induced tissue hypoperfusion is defined as infection-induced hypotension, elevated lactate, or oliguria.[3,4]

TABLE 119-1 Definitions Related to Sepsis

Condition	Definition
Bacteremia (fungemia)	Presence of viable bacteria (fungi) in the bloodstream
Infection	Inflammatory response to invasion of normally sterile host tissue by the microorganisms
SIRS	Systemic inflammatory response to a variety of clinical insults, which can be infectious or noninfectious. The response is manifested by two or more of the following conditions: temperature >38°C (>100.4°F) or <36°C (<96.8°F); HR >90 beats/min; RR >20 breaths/min or $PaCO_2$<32 mm Hg (<4.3 kPa); WBC >12,000 cells/mm^3 (>12 × 10^9/L), <4,000 cells/mm^3 (<4 × 10^9/L), or >10% (>0.10) immature (band) forms
Sepsis	SIRS secondary to suspected or documented infection Additional criteria include general variables (altered mental status, positive fluid balance

Condition	Definition
	of >20 mL/kg over 24 hours, hyperglycemia >120 mg/dL [>6.7 mmol/L]); inflammatory variables (plasma C-reactive protein/procalcitonin >2 SD above normal value); hemodynamic variables (arterial hypotension <90mm Hg (<12.0 kPa) or MAP <70 mm Hg (<9.3 kPa), elevated mixed venous oxygen saturation of >70% (>0.70); CI >3.5 L/min (>0.058 L/s); organ-dysfunction variables (arterial hypoxemia; acute oliguria of <0.5ml/kg/hr or 45 ml/hr for at least 2 hr, creatinine increase >0.5 mg/dL (>0.44 µmol/L), coagulation abnormalities, paralytic ileus, platelets <100,000 /mm^3 (<100 × 10^9/L), bilirubin >4 mg/dL (>68 µmol/L); tissue-perfusion variable (hyperlactatemia >1 mmol/L, decreased capillary refill)
Severe sepsis	Sepsis associated with one or more organ dysfunctions, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include but not limited to arterial hypoxemia (PaO_2/FiO_2<300) lactic acidosis, oliguria, increase in creatinine, coagulation abnormalities (INR>1.5), and elevated bilirubin
Septic shock	Sepsis with persistent hypotension despite fluid resuscitation (intravenous fluid of 30 mL/kg) or hyperlactatemia >1 mmol/L

CI, cardiac index; HR, heart rate; INR, international normalized ratio; RR, respiratory rate; SD, standard deviation; SIRS, systemic inflammatory response syndrome; T, temperature; WBC, white blood cell (count).

INFECTION SITES AND PATHOGENS

Predisposing factors of septic shock include age, nonwhite ethnic origin in North Americans, comorbid diseases especially chronic obstructive pulmonary disease, malignancy, immunodeficiency or immunocompromised state, chronic organ failure, alcohol dependence, and genetic factors.[1,5,6] Male gender has been associated with higher incidence of sepsis and severe sepsis in the past. However, the difference between the genders appears to be diminishing.[1,2]

The primary sites of microbiologically documented infections that lead to sepsis are the respiratory tract (39%-50%), intra-abdominal space (8%-16%), and urinary tract (5%-37%).[1,2,7,8,9]

Gram-Positive Bacterial Sepsis

1 In international studies, gram-negative organisms were isolated in 50% to 62% of patients with severe sepsis or septic shock, gram-positive bacteria in 37% to 47%, anaerobic organisms in 5%, and fungi in 8% to 19%.[7,9] The most common gram-positive organisms are *Staphylococcus aureus, Streptococcus pneumoniae*, coagulase-negative staphylococci, and *Enterococcus* species.[8,9,10,11] *S. aureus* bacteremia is associated with an overall mortality rate ranging between 10% and 30%.[12] Factors related to a higher mortality include older age, shock, preexisting renal failure, and the presence of a rapidly fatal underlying disease. *Staphylococcus epidermidis* is most often related to

infected intravascular devices, artificial heart valves and stents, and the use of IV and intra-arterial catheters. Enterococci are isolated most commonly isolated from blood cultures following a prolonged hospitalization and treatment with broad-spectrum cephalosporins.

Gram-Negative Bacterial Sepsis

Escherichia coli (8%-30%), *Klebsiella* species (8%-23%), and *Pseudomonas aeruginosa* (7%-18%) are the most commonly isolated gram-negative microorganisms in sepsis.[8,9,10,11,13,14] Other common gram-negative pathogens include *Serratia* species, *Enterobacter* species, and *Proteus* species. *P. aeruginosa* and *Acinetobacter* species are more likely to be associated with prior antibiotic exposure.[13]

A greater proportion of patients with gram-negative bacteremia develop sepsis, and also more likely to produce septic shock in comparison to gram-positive organisms, 50% versus 25%, respectively.[8,9,11] Specifically, *P. aeruginosa* sepsis has been associated with a higher mortality rate.[9,13] Mortality increased significantly with increasing severity of sepsis (3.5% for sepsis, 9.9% in severe sepsis, and 28,6% in septic shock).[14] Furthermore, severity of any underlying conditions is another major factor associated with the outcome of gram-negative sepsis. Patients with rapidly fatal conditions, such as acute leukemia, aplastic anemia, cirrhosis, and human immunodeficiency virus (HIV) have a significantly worse prognosis than those patients with nonfatal underlying conditions such as diabetes mellitus and chronic renal insufficiency.[2]

Anaerobic and Miscellaneous Bacterial Sepsis

Anaerobic bacteria such as *Bacteroides fragilis* and *Clostridium* species are usually considered low-risk organisms for the development of sepsis. If present, anaerobes are often found together with other pathogenic bacteria that are commonly found in sepsis. Polymicrobial infections accounted for 5% to 39% of sepsis.[1,9,10,11,13] Mortality rates associated with polymicrobial infections are similar to sepsis caused by a single organism. Although some clinicians believe the particular combination of organisms present in polymicrobial sepsis can provide clues to the source of infection, no clear source for the infection can be identified in up to 25% of cases.

Fungal Sepsis

3 Candidemia is among the most common fungal etiologic agents of bloodstream infections. Although *Candida albicans* was the most commonly isolated fungus from blood cultures (45.6%), collectively, non-*albicans Candida* species were more frequently isolated (54.4%).[10,11,15,16,17] Non-*albicans Candida* species include *C. glabrata* (26%), *C. parapsilosis* (15.7%), *C. tropicalis* (8.1%), and *C. krusei* (2.5%). Other fungi identified as causes of sepsis are *Cryptococcus*, *Coccidioides*, *Fusarium*, and *Aspergillus*.[10] Traditionally, risk factors for fungal infection include abdominal surgery, poorly controlled diabetes mellitus, prolonged granulocytopenia, broad-spectrum antibiotic treatment, corticosteroid treatment, prolonged hospitalization, central venous catheter, total parenteral nutrition, hematologic malignancy, and chronic indwelling bladder (Foley) catheter. A large

retrospective analysis also reported patients with candidemia and severe sepsis and septic shock were more likely to have been admitted from nursing homes or transferred from outside hospitals.[17] Recent exposure to azoles is an important risk factor for infection with fluconazole-resistant *Candida* spp.[18] There is a close correlation between antibacterial drug exposure and bloodstream infection with *C. glabrata* and fluconazole-resistant *Candida* isolates.[18]

A multicenter analysis of patients with septic shock due to candidemia between 2009 and 2011 reported overall 30-day mortality rate of 54%. A higher in-hospital mortality was reported (61%) among patients with healthcare-associated candidemia.[16] The highest mortality rate of 52.9% was observed in patients with *C. krusei* candidemia; *C. parapsilosis* candidemia was associated with the lowest 12-week mortality rate (23.7%).

PATHOPHYSIOLOGY

Sepsis is the result of complex interactions among the invading pathogen, the host immune system, and the inflammatory responses. The inflammatory response leads to damage to host tissue, and the anti-inflammatory response causes leukocytes to activate. Once the balance to control the local inflammatory process and to eradicate the invading pathogens is lost, systemic inflammatory response occurs, converting the infection to sepsis, severe sepsis, or septic shock.

Cellular Components for Initiating the Inflammatory Process

The pathophysiologic focus of gram-negative sepsis has been on the lipopolysaccharide component of the gram-negative bacterial cell wall. Commonly referred to as endotoxin, this substance is unique to the outer membrane of the gram-negative cell wall and is generally released with bacterial lysis. Lipid A, the innermost region of the lipopolysaccharide, is highly immunoreactive and is considered responsible for most of the toxic effects. Although lipid A can affect tissues directly, its predominant effect is to activate macrophages and trigger inflammatory cascades critical in the progression to sepsis and septic shock.[19] Endotoxin forms a complex with an endogenous protein called a lipopolysaccharide-binding protein, which then engages the CD14 receptor on the surface of a macrophage. Subsequently, cytokine mediators are activated and released by the macrophages.

In gram-positive sepsis, the exotoxin peptidoglycan on the cell wall surface appears to exhibit proinflammatory activity. Although it competes with lipid A for similar binding sites on CD14, the potency of peptidoglycan is less than that of endotoxin.[19] However, an important feature of gram-positive bacteria such as *S. aureus* and *Streptococcus pyogenes* is the production of potent exotoxins, some of which have been associated with septic shock.

Pro- and Anti-inflammatory Mediators

A complex interaction between proinflammatory and anti-inflammatory mediators plays a major role in the pathogenesis of sepsis. In general, proinflammatory reactions are directed at eliminating invading pathogens and the anti-inflammatory reactions are important for limiting local and systemic

tissue injury. The key proinflammatory mediators are tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), and interleukin-6 (IL-6), which are released by activated macrophages.[19,20,21] Other mediators that may be important for the pathogenesis of sepsis are interleukin-8 (IL-8), platelet-activating factor (PAF), leukotrienes, and thromboxane A_2.

The TNF-α levels in plasma can be increased in patients with a variety of diseases and in many healthy people. However, there is a correlation of plasma TNF-α levels with the severity of sepsis. It is highly elevated early in the inflammatory response in most patients with sepsis.[20,21] The TNF-α release leads to activation of other cytokines (IL-1 and IL-6) associated with cellular damage. In addition, TNF-α stimulates the release of cyclooxygenase-derived arachidonic acid metabolites (thromboxane A_2 and prostaglandins) that contribute to vascular endothelial damage. Higher levels of IL-6 and IL-8 have been reported in patients with septic shock than those with SIRS.

The significant anti-inflammatory mediators include interleukin-1 receptor antagonist (IL-1RA), IL-4, and IL-10.[19,20,22] These anti-inflammatory cytokines inhibit the production of the proinflammatory cytokines and down regulate some inflammatory cells. Levels of IL-10 and IL-1RA are higher in septic shock than in sepsis, and higher levels are found among nonsurviving patients than in survivors.[20,21,22]

The activation and secretion of pro- and anti-inflammatory mediators in septic shock occur as a simultaneous immune response as early as the first 24 hours of diagnosis, but the balance between pro- and anti-inflammatory mechanisms determines the degree of inflammation, ranging from local antibacterial activity to systemic tissue toxicity, organ failure, or death.[20,21]

Cascade of Sepsis

3 The cascade leading to development of sepsis is complex and multifactorial, involving causative pathogen (virulence and organism load) and host characteristics (comorbidities and immunosuppression) triggering various mediators and cell lines. Endothelial cells produce a variety of cytokines that mediate a primary mechanism of injury in sepsis. When injured, endothelial cells allow circulating cells such as granulocytes and plasma constituents to enter inflamed tissues, which can result in organ damage.

The microcirculation is affected by sepsis-induced inflammation. The arterioles become less responsive to either vasoconstrictors or vasodilators. The capillaries are less perfused even at the early phases of septic shock, and there is neutrophil infiltration and protein leakage into the venules.[23]

The inflammatory process in sepsis is also directly linked to the coagulation system. Proinflammatory mechanisms that promote sepsis are also procoagulant and antifibrinolytic, whereas fibrinolytic mechanisms can be anti-inflammatory.[24] A key endogenous substance involved in inflammation of sepsis is activated protein C, which enhances fibrinolysis and inhibits inflammation. Levels of protein C are reduced in patients with sepsis.[24]

COMPLICATIONS

Septic shock is the most ominous complication associated with sepsis. Of the patients who presented to the emergency department with sepsis 3.6% progressed to septic shock within 4 hours, and 8.4% progressed to septic shock between 4 and 48 hours.[25] The predictors for progression to septic shock included female gender, nonpersistent hypotension, band neutrophils of at least 10% in blood, lactate of at least 4.0 mmol/L, and past medical of coronary artery disease.[25] Septic shock may lead to several complications including disseminated intravascular coagulation (DIC), acute respiratory distress syndrome (ARDS), and multiple organ failure. The organs that failed most frequently in patients with severe sepsis were kidneys (49%), lungs (48%), and heart (42%).[2] The less frequent complications are hematologic failure (18%), metabolic failure (17%), neurologic failure (11%), and hepatic failure (5%).[2] Mortality occurs in approximately half of the patients with septic shock.

Disseminated Intravascular Coagulation

DIC is the inappropriate activation of the clotting cascade that causes formation of microthrombi, resulting in consumption of coagulation factors, organ dysfunction, and bleeding. Sepsis remains the most common cause of DIC, and the incidence of DIC increases as the severity of sepsis increases. In sepsis alone, the incidence was 16% in comparison to 38% in septic shock.[26,27] DIC occurs in up to 50% of patients with gram-negative sepsis, but it is also common in patients with gram-positive sepsis.

DIC begins with the activation and production of the proinflammatory cytokines, such as TNF, IL-1, and IL-6, which appear to be the principal mediators, along with endotoxin. The combination of excessive fibrin formation, compromised fibrin removal from a depressed fibrinolytic system, and endothelial injury result in microvascular thrombosis and DIC.[27]

Complications of DIC vary and depend on the target organ affected and the severity of the coagulopathy. DIC can produce acute renal failure, hemorrhagic necrosis of the gastrointestinal (GI) mucosa, liver failure, acute pancreatitis, ARDS, and pulmonary failure. Furthermore, as the procoagulant state appears to be the key in the pathogenesis of MODS, coagulation dysfunction and MODS often coexist in sepsis.

Acute Respiratory Distress Syndrome

Pulmonary dysfunction, the most common organ dysfunction in sepsis, usually precedes other organs, and it can even initiate the development of SIRS with resultant MODS. Activated neutrophils and platelets adhere to the pulmonary capillary endothelium, initiating multiple inflammatory cascades with a release of a variety of toxic substances. There is diffuse pulmonary endothelial cell injury, increased capillary permeability, and alveolar epithelial cell injury. Consequently, interstitial pulmonary edema occurs that gradually progresses to alveolar flooding and collapse. The end result is loss of functional alveolar volume, impaired pulmonary compliance, and profound hypoxemia.

Coagulation is locally upregulated in the injured lung, whereas fibrinolytic activity is depressed. These

abnormalities occur concurrently and favor alveolar fibrin deposition, leading to local inflammation, macrophage migration, and increased vascular permeability. Anticoagulant interventions that block the extrinsic coagulation pathway can protect against the development of pulmonary fibrin deposition as well as lung dysfunction and acute inflammation.[27] Overall, fibrin deposition in the injured lung and abnormalities of coagulation and fibrinolysis are integral to the pathogenesis of ARDS.

Hemodynamic Effects

The hallmark of the hemodynamic effect of sepsis is the hyperdynamic state characterized by high cardiac output and an abnormally low systemic vascular resistance (SVR).[23,28] TNF-α and endotoxin directly depress cardiovascular function. Endotoxin depresses left ventricular (LV) function independent of changes in LV volume or vascular resistance. Myocardial dysfunction is common in severe sepsis and septic shock, affecting 64% of patients, and involves LV in more than half of the patients.[28]

Persistent hypotension raises concern for the balance of oxygen delivery (DO_2) to the tissues and oxygen consumption (VO_2) by the tissues. Sepsis results in a distributive shock characterized by inappropriately increased blood flow to particular tissues at the expense of other tissues, which is independent of specific tissue oxygen needs. This perfusion defect is accentuated by an increased precapillary atrioventricular shunt. If perfusion decreases, oxygen extraction increases, and the arteriovenous oxygen gradient widens. Cellular DO_2 is decreased, but VO_2 remains unaffected. When increased oxygen demand occurs without increased blood flow, the increased VO_2 is compensated by increased oxygen extraction. If perfusion decreases sufficiently in the face of high metabolic demands, then the reserve DO_2 can be exceeded, and tissue ischemia results. Significant tissue ischemia leads to organ dysfunction and failure. Therefore, systemic DO_2 relative to VO_2 should be optimized by increasing oxygen delivery or decreasing oxygen consumption in a hypermetabolic patient.

Acute Renal Failure

Early acute kidney injury occurs in 42% to 64% of adult patients with sepsis and septic shock.[29] Without normal urine output, fluid overload in extravascular space including the lungs develops, leading to impairment of pulmonary gas exchange and severe hypoxemia. Consequently, compromised oxygen delivery exacerbates peripheral ischemia and organ damage. Adequate renal perfusion and a trial of loop diuretics should be initiated promptly in oliguric or anuric patients with MODS along with dialysis to facilitate volume and electrolytes.

CLINICAL PRESENTATION

The clinical features of sepsis vary significantly depending on multiple factors including the patient's underlying health status, site and severity of infection, and time course of sepsis before therapy. **Table 119-2** lists some of the common clinical features of sepsis. The initial clinical presentation can

be referred to as signs and symptoms of early sepsis, defined as the first 6 hours. They are typically fever, chills, and change in mental status. Hypothermia can occur with a systemic infection, and this is often associated with a poor prognosis.[30] In patients with sepsis caused by gram-negative bacilli, hyperventilation can occur even before fever and chills, and it can lead to respiratory alkalosis as the earliest metabolic change.

TABLE 119-2 Signs and Symptoms Associated with Sepsis

Early Sepsis	Late Sepsis
Fever or hypothermia	Lactic acidosis
Rigors, chills	Oliguria
Tachycardia	Leukopenia
Tachypnea	DIC
Nausea, vomiting	Myocardial depression
Hyperglycemia	Pulmonary edema
Myalgia	Hypotension (shock)
Lethargy, malaise	Hypoglycemia
Proteinuria	Azotemia
Hypoxia	Thrombocytopenia
Leukocytosis	ARDS
Hyperbilirubinemia	GI hemorrhage
Delirium	Coma

ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.

Progression of uncontrolled sepsis leads to clinical evidence of organ system dysfunction as represented by the signs and symptoms attributed to late sepsis. With the exception of rapidly progressing cases as in meningococcemia, *P aeruginosa*, or *Aeromonas* infection, the onset of shock is somewhat delayed and usually follows a period of several hours of hemodynamic instability. Oliguria often follows hypotension. Increased glycolysis with impaired clearance of the resulting lactate by the liver and kidneys and tissue hypoxia because of hypoperfusion result in elevated lactate levels, contributing to metabolic acidosis. Altered glucose metabolism, including impaired gluconeogenesis and excessive insulin release, is evidenced by either hyperglycemia or hypoglycemia.

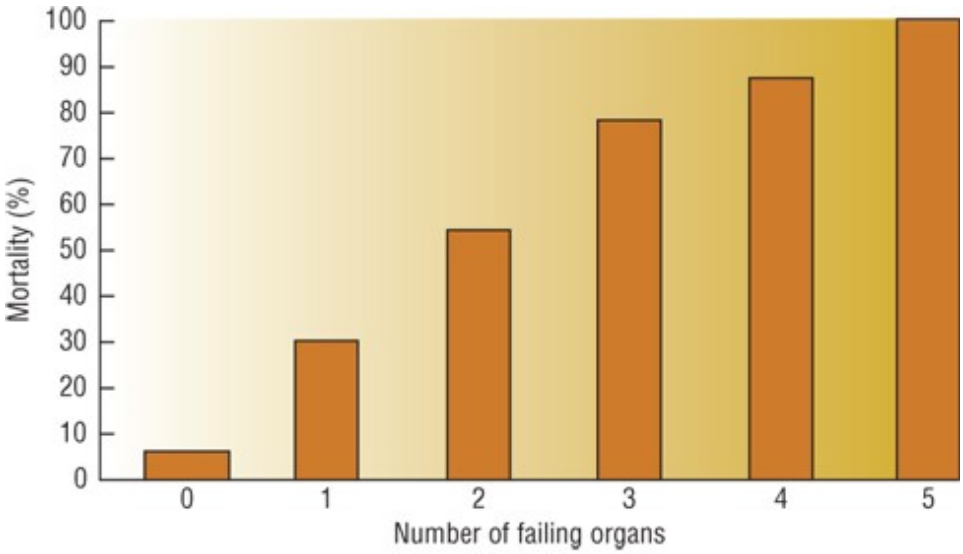
PROGNOSIS

4 As the patient progresses from SIRS to sepsis, severe sepsis, or septic shock, mortality increases in a stepwise fashion. Mortality rates are higher for patients with advanced age, preexisting disease, including chronic obstructive pulmonary disease, neoplasm, and HIV disease, intensive care unit (ICU) care, more failed organs, positive blood cultures, and *Pseudomonas* species infection.[1,2,12] The highest mortality was seen in patients with intra-abdominal infection secondary to ischemic bowel

(75%) whereas the source associated with the lowest hospital mortality was obstructive uropathy-associated urinary tract infection (26%).[7] Mortality from severe sepsis and MODS is most closely related to the number of dysfunctioning organs. As the number of failing organs increased from two to five, mortality increased from 29% to 65% (**Fig. 119-2**).[2] Duration of organ dysfunction can also affect the overall mortality rate.

FIGURE 119-2

Mortality related to the number of failing organs.



An elevated lactate concentration of more than 4 mmol/L in the presence of SIRS significantly increases ICU admission rates, and persistent elevations in lactate for more than 24 hours are associated with an increased mortality rate. Furthermore, 28-day mortality rate was the highest (44.8%) among patients with septic shock and hyperlactatemia more than 2.5 mmol/L, followed by hyperlactatemia without vasopressor need (35.3%), and no hyperlactemia with vasopressor need (27.7%). Hyperlactemia increased the risk of 28-day mortality independent of vasopressor need (odds ratio 3.0, 95% confidence interval 2.1-4.1 for lactate of >4 mmol/L).[31]

Diagnosis and Identification of Pathogen

The presence of clinical features suggesting sepsis should prompt further evaluation of the patient. In addition to obtaining a careful history of any underlying conditions and recent travel, injury, animal exposure, infection, or use of antibiotics, a complete physical examination should be performed to determine the source of the infection.

A collection of specimens should be sent for culture prior to initiating any antimicrobial therapy. Minimally two sets of blood cultures (both aerobic and anaerobic bottles) should be collected without temporal separation between the sets.[3,32] With suspected catheter-related infection, a pair of

blood cultures should be drawn through every lumen of each vascular access device.[32] In severe community-acquired pneumonia, blood cultures and respiratory secretions must be obtained. Urinary antigen detection of *Legionella* sero group 1 is recommended during outbreaks. To document a soft tissue infection, a Gram stain and bacterial culture of any obvious wound exudates should be performed. A needle aspiration of a closed infection such as cellulitis or abscess may be needed for stain and bacterial culture. In abdominal infections, fluid collections identified by imaging studies should be aspirated for Gram stains and aerobic and anaerobic cultures. Development of accurate and rapid identification tests has demonstrated positive impact on prescribing appropriate therapy in bloodstream infections such as methicillin-resistant *Staphylococcus aureus* (MRSA) and *Candida* spp.[3,33,34] The surviving sepsis guidelines recommend the use of 1,3 β-D-glucan assay in case of invasive candidiasis.[3]

A lumbar puncture is indicated with mental alteration, severe headache, or a seizure, assuming that there are no focal cranial lesions identified by computed tomography (CT) scan. Further tests may be indicated to assess any systemic organ dysfunction caused by severe sepsis. The laboratory tests should include hemoglobin, white blood cell (WBC) count with differential, platelet count, complete chemistry profile, coagulation parameters, serum lactate, and arterial blood gases. The potential role of biomarkers such as procalcitonin (PCT) levels or C-reactive protein for diagnosis of infection in patients with severe sepsis remain undefined as there is no definitive way to discriminate the acute inflammatory pattern of sepsis from other generalized inflammation.[3]

TREATMENT

In 2012, a "surviving sepsis" campaign guideline for management of severe sepsis and septic shock updated the earlier publication of an international effort to increase awareness and improve outcome in severe sepsis.[3,35] The primary goals of therapy for patients with sepsis are (a) timely diagnosis and identification of the pathogen, (b) rapid elimination of the source of infection medically and/or surgically, (c) early initiation of aggressive antimicrobial therapy, (d) interruption of pathogenic sequence leading to septic shock, and (e) avoidance of organ failure. Supportive care such as stress ulcer prophylaxis and nutritional support is important to prevent complications during the stay in the ICU. **Table 119-3** describes the summary of the surviving sepsis campaign treatment recommendations.

TABLE 119-3 Evidence-based Treatment Recommendations for Sepsis and Septic Shock

Recommendations	Recommendation Grades[a]
Initial Resuscitation (First 6 Hours)	
Quantitative resuscitation of patients with sepsis-induced tissue hypoperfusion,	
CVP 8-12 mm Hg (1.1-1.6 kPa), MAP ≥65 mm Hg (≥8.6 kPa), urine output > 0.5 mL/kg/hr, $SCVO_2$ ≥70% (≥0.70)	1C
Antibiotic Therapy	

Recommendations	Recommendation Grades[a]
IV broad-spectrum antibiotic within 1 hour of diagnosis of septic shock and severe sepsis against likely bacterial/fungal pathogens	1B
Reassess antibiotic therapy daily with microbiology and clinical data to narrow coverage (de-escalation)	1B
Combination empirical therapy for neutropenic patients with severe sepsis and patients with difficult-to-treat, multidrug-resistant bacterial pathogens such as *Acinetobacter* and *Pseudomonas* spp. for no more than 3-5 days and then de-escalate	2B
Fluid Therapy	
Crystalloids as the initial fluid of choice	1B
Minimum of 30 mL/kg of crystalloids for initial fluid challenge, but more rapid and greater amount may be needed	1C
Albumin when patients require substantial amounts of crystalloids	2C
Vasopressors	
Initiate vasopressor therapy to maintain MAP ≥65 mm Hg (≥8.6 kPa)	1C
Norepinephrine as the first choice vasopressor	1B
Epinephrine when an additional agent is needed to maintain adequate blood pressure	2B
Dopamine as an alternative vasopressor to norepinephrine in selective patients with low risk of tachyarrhythmia and bradycardia	2C
Inotropic Therapy	
Use dobutamine up to 20 mcg/kg/min or added to vasopressor when cardiac output remains low or ongoing signs of hypoperfusion despite adequate MAP	1C
Glucose Control	
Use insulin dosing protocol in ICU patients when 2 consecutive blood glucose levels are >180 mg/dL (>10 mmol/L), targeting an upper blood glucose <180 mg/dL (≤10 mmol/L)	1A
Steroids	
IV hydrocortisone 200 mg per day for septic shock only when hypotension remains poorly responsive to adequate fluid resuscitation and vasopressors	2C
Hydrocortisone should be tapered when vasopressors are no longer required	2D
Deep Vein Thrombosis Prophylaxis	
Use daily low-molecular-weight heparin and intermittent pneumatic compression device whenever possible	1B
If creatinine clearance is <30 mL/min (<0.5 mL/s), use unfractionated heparin or dalteparin	1A, 1A
If heparin is contraindicated, use mechanical prophylactic treatment	2C

Recommendations	Recommendation Grades[a]
Stress Ulcer Prophylaxis	
Stress ulcer prophylaxis should be given to patients who have bleeding risk factors	1B
Proton pump inhibitors are preferred over H2 receptor blockers	2C

CVP, central venous pressure; MAP, mean arterial pressure.

[a]Grades of Recommendation, Assessment, Development, and Evaluation (GRADE) system: a structured system for rating quality of evidence and grading strength of recommendation in clinical practice. Quality of evidence: high (grade A), moderate (grade B), low (grade C), or very low (grade D). Strength of recommendation: strong (grade 1) or weak (grade 2).

Adapted from Dellinger RP, Levy MM, Rhodes A, et al. Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med 2013;41:580-637.

Elimination of the Source of Infection

After the source of infection is identified, prompt efforts to eradicate that source should be made.[3] With an infected intravascular catheter, the catheter should be removed and cultured. Urinary tract catheters should be removed if association with sepsis is suspected. Suspicion of soft tissue (cellulitis or wound infection) or bone involvement should lead to aggressive debridement of the affected area. Evidence of an abscess or sepsis associated with any intraabdominal pathology should prompt surgical intervention.

Antimicrobial Therapy

5 The Surviving Sepsis Campaign guidelines recommended starting IV administration of one or more antibiotics within 1 hour of recognition of septic shock and severe sepsis without septic shock.[3] Early administration (within 1 hour vs 6 hours of diagnosis) of broad-spectrum antibiotics was independently associated with lower hospital mortality in patients with severe sepsis and septic shock, regardless of the number of organ failure.[36,37] Delays in the initiation of effective antimicrobial therapy especially after the onset of hypotension were significant predictors of mortality.[38] In addition to the timing of the empiric antibiotic, administration of appropriate antibiotic, especially for multidrug-resistant bacteria has a great impact in reducing mortality.[14,39,40] Inappropriate initial antimicrobial therapy occurred in about 20% of patients with septic shock, and was associated with a fivefold reduction in survival in comparison to those who received appropriate therapy (52.0% vs 10.3%, respectively).[11] Therefore, early administration of appropriate antimicrobial therapy is critical in the treatment of severe sepsis and septic shock.

Pharmacokinetics of Antimicrobial Agents in Critically Ill Patients

Pathophysiologic changes in sepsis can affect drug distribution, and adjusted dosing regimens are required in critically ill patients with sepsis.[41] Initially, high creatinine clearance can be seen in patients with normal serum creatinine because of increased renal preload. Volume of distribution can increase because of fluid accumulation from leaky capillaries and/or altered protein binding. Consequently, some antimicrobial agents, especially for hydrophilic antimicrobials including aminoglycosides, β-lactams, carbapenems, and vancomycin can result in lower peak serum concentrations with usual doses.[42] However, as sepsis progresses, organ perfusion decreases because of significant myocardial depression and leads to multiple organ dysfunction. Consequently, clearance of antimicrobial agents is decreased, prolonging the elimination half-life and accumulation of metabolites. Hence, in addition to selecting the most appropriate antimicrobial agents, a clinician must ensure effective antibiotic usage, such as proper dosing, interval of administration, optimal duration of treatment, monitoring of drug levels when appropriate, and avoidance of unwanted drug interactions. The lack of adherence to these requirements can lead to suboptimal or excessive tissue concentrations that can promote antibiotic resistance, toxicity, and inadequate efficacy despite appropriate antibiotic selection.

Selection of Antimicrobial Agents

The selection of an empiric regimen should be based on the suspected site of infection, the most likely pathogens, acquisition of the organism from the community or hospital, the patient's immune status, recent exposure to antibiotics within past 3 months, and the antibiotic susceptibility and resistance profile for the institution. All patients should be treated initially with parenteral antibiotics for optimal drug concentrations within the first hour of recognition of severe sepsis after appropriate cultures have been taken.[3] Empiric therapy for an immunocompromised patient should be broad enough to cover likely pathogens and penetrate adequately into the presumed infection site. Once the pathogen and its susceptibility pattern are known, the antimicrobial regimen should be modified accordingly.

Table 119-4 lists antimicrobial regimens that can be used empirically based on the possible source of infection. In the nonneutropenic patient with a urinary tract infection, ceftriaxone or a fluoroquinolone is generally recommended. When there is increased risk of *P. aeruginosa* in sepsis or hospital-acquired infections, an antipseudomonal antibiotic, such as ceftazidime is recommended.[43]

TABLE 119-4 Empiric Antimicrobial Regimens in Sepsis

Infection (Site or Type)	Antimicrobial Regimen	
	Community-Acquired	**Hospital-Acquired**
Urinary tract	Ceftriaxone or ciprofloxacin/levofloxacin	Ciprofloxacin/levofloxacin or ceftriaxone or ceftazidime
Respiratory tract	Levofloxacin[a]/moxifloxacin or ceftriaxone + clarithromycin/azithromycin	Piperacillin/tazobactam or ceftazidime or cefipime + levofloxacin/ciprofloxacin or aminoglycoside carbapenem[b]

Infection (Site or Type)	Antimicrobial Regimen		
	Community-Acquired	Hospital-Acquired	
Intraabdominal	Ertapenem or ciprofloxacin/levofloxacin + metronidazole	Piperacillin/tazobactam or carbapenem[b]
