Patients with T_{3b} and T_4 disease have a very high risk of recurrence and are usually not candidates for radical prostatectomy because of extensive local spread of disease, although it may be possible for some individuals.[32] 4 ADT with a LHRH agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone. Recent evidence suggests that androgen ablation should be instituted at diagnosis rather than waiting for symptomatic disease or progression to occur. In a randomized clinical trial of 500 men with locally advanced prostate cancer who were randomized to either immediate initiation of androgen ablation (either orchiectomy or androgen ablation) or deferred hormonal therapy, patients who received immediate therapy had a median actuarial cause-specific survival duration of 7.5 years for immediate treatment as compared with 5.8 years for deferred treatment.[37]

5 ADT, with orchiectomy, an LHRH agonist alone, an LHRH agonist plus an antiandrogen (combined androgen blockade), or an LHRH with docetaxel without prednisone for six cycles (for patients with visceral metastases and/or four or more bone metastases sites beyond the pelvis or sacrum) can be used to provide palliation for patients with advanced (stage D_2) prostate cancer.

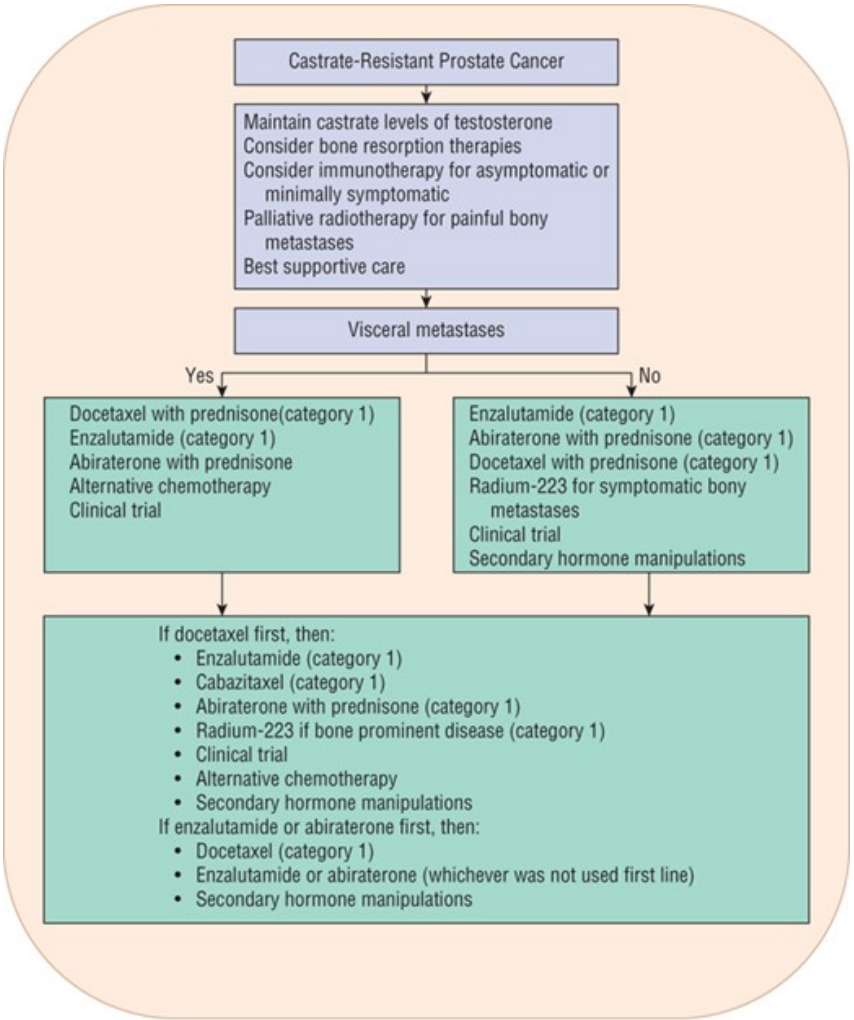
Patients who develop metastatic disease often have tumor progression and develop castration-resistant prostate cancer.[32] This may be described clinically by a rising PSA while on optimal ADT, or the development of symptoms, typically related to bone metastases, including bone pain and fractures. Patients with metastatic disease may be continued on ADT and denosumab ([RANK] ligand inhibitor) or an IV bisphosphonate is added in patients with bone metastases. Importantly, further therapy is determined by the presence of symptomatic disease or whether the metastatic progression is manifested as only a rising PSA.

For clinically asymptomatic patients with a rising PSA, sipuleucel-T is recommended as first-line treatment. Prior to the introduction of sipuleucel-T, standard therapy was a secondary hormonal manipulation, including the addition or withdrawal of antiandrogen therapy.

For those with symptomatic or disease involving internal organs, such as the liver, treatment with docetaxel is recommended as first-line therapy. For patients with symptomatic visceral disease who have a rising PSA enzalutamide or abiraterone acetate are also recommended. Other first-line treatment options following docetaxel chemotherapy include cabazitaxel, a microtubule inhibitor, in combination with prednisone, docetaxel rechallenge, a clinical trial, or mitoxantrone[32] (**Fig. 131-3**).

FIGURE 131-3

Treatment of castrate-resistant prostate cancer.



Nonpharmacologic Therapy

Observation

Observation is often referred to as expectant management, active surveillance or watchful waiting. Observation involves monitoring the course of disease and initiating treatment if the cancer progresses. It is estimated that only about 10% of men who are eligible for observation choose this option.[34] A PSA and DRE are performed every 6 months, with a repeat biopsy at any sign of disease progression. The advantages of observation are avoiding the adverse effects associated with definitive therapies such as radiation and radical prostatectomy, and minimizing the risk of unnecessary therapies. The major disadvantage of observation is the risk that the cancer progresses and requires a more intensive therapy.

Orchiectomy

Bilateral orchiectomy, or removal of the testes, is a form of ADT that rapidly reduces circulating androgens to castrate levels (less than 50 ng/dL [1.7 nmol/L]).[22] However, many patients are not surgical candidates because of advanced age, and other patients find this procedure psychologically unacceptable.[26] Orchiectomy is the preferred initial treatment in patients with impending spinal cord compression or ureteral obstruction.

Radiation

The two commonly used methods for radiation therapy are external beam radiotherapy and brachytherapy.[32] In external beam radiotherapy, doses of 70 to 75 Gy (7,000-7,500 rad) are delivered in 35 to 41 fractions in patients with low-grade

prostate cancer and 75 to 80 Gy (7,500-8,000 rad) for those with intermediate- or high-grade prostate cancer. Brachytherapy involves the permanent implantation of radioactive beads of 145 Gy (14,500 rad) ^{125}iodine or 124 Gy (12,400 rad) of ^{103}palladium and is generally reserved for individuals with low-risk cancers. Radiation therapy may also be given after surgery in patients with localized disease. Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence.[16] Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.[26] Because radiation and prostatectomy have significant and immediate mortality when compared with observation alone, many patients elect to postpone therapy until symptoms develop.

Radical Prostatectomy

Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year.

Pharmacologic Therapy

Drug Treatments of First Choice

Luteinizing Hormone-Releasing Hormone Agonists

LHRH agonists are a reversible method of androgen ablation and are as effective as orchiectomy in treating prostate cancer.[38] Currently available LHRH agonists include leuprolide, leuprolide depot, leuprolide implant, triptorelin depot, triptorelin implant, and goserelin acetate implant. Leuprolide acetate is administered once daily, while leuprolide depot and goserelin acetate implant can be administered either once monthly, once every 12 weeks, or once every 16 weeks (leuprolide depot, every 4 months) (Table 131-6). The leuprolide depot formulation contains leuprolide acetate in coated pellets. The dose is administered intramuscularly, and the coating dissolves at different rates to allow sustained leuprolide levels throughout the dosing interval. Goserelin acetate implant contains goserelin acetate dispersed in a plastic matrix of D, L-lactic, and glycolic acid copolymer and is administered subcutaneously. Hydrolysis of the copolymer material provides continuous release of goserelin over the dosing period. A leuprolide implant is a mini-osmotic pump that delivers 120 mcg of leuprolide daily for 12 months. After 12 months the implant is removed, and a different implant can be placed. Triptorelin LA is administered as an intramuscular injection of 11.25 mg every 84 days. Triptorelin depot is 3.75 mg once every 28 days.

Several randomized trials have demonstrated that leuprolide, goserelin, and triptorelin are effective agents when used alone in patients with advanced prostate cancer.[30] Response rates around 80% have been reported, with a lower incidence of adverse effects as compared with estrogens.[30] The currently available LHRH agonists or the dosage formulations have not been directly compared in clinical trials, but a meta-analysis showed no significant differences in efficacy or toxicity between leuprolide, goserelin, and orchiectomy.[39] Triptorelin is a more recent addition that is generally considered to be equally effective. Therefore the choice between the three agents is usually made based on cost and patient and physician preference for a dosing schedule.

The most common adverse effects reported with LHRH agonist therapy include a disease flare during the first week of therapy, hot flashes, erectile impotence, decreased libido, and injection-site reactions.[30] The disease flare is caused by an initial induction of LH and FSH by the LHRH agonist leading to an initial phase of increased testosterone production, and manifests clinically as either increased bone pain or increased urinary symptoms.[30] This flare reaction usually resolves after 2 weeks and has a similar onset and duration pattern for the depot LHRH products.[40,41] Tumor flare can be minimized by initiating an antiandrogen prior to the administration of the LHRH agonist and continuing for 2 to 4 weeks.[31]

LHRH agonist monotherapy can be used as initial therapy, with response rates similar to those for orchiectomy. The incidence of cardiovascular-related adverse effects is lower with LHRH therapy than with estrogen administration. Patients should be counseled to expect worsening symptoms during the first week of therapy. Appropriate pain and symptom management is required during this period, and a short course of concomitant antiandrogen therapy may need to be

considered prior to initiating the LHRH agonist. Caution should be exercised if initiating LHRH agonist therapy in patients with widely metastatic disease involving the spinal cord or having the potential for ureteral obstruction because irreversible complications may occur.

Another potentially serious complication of ADT is a decrease in bone mineral density leading to an increased risk for osteoporosis, osteopenia, and skeletal fractures. During initial therapy, bone mineral density of the hip and spine decreases by 2% to 3%.[42] Additionally, ADT has been associated with a 21% to 45% relative increase in fracture risk.[43,44,45] Therefore, most clinicians recommend that men starting long-term ADT should have a baseline bone mineral density and be initiated on a calcium and vitamin D supplement.[31,32]

In addition, an antiresorptive agent, either zoledronic acid or denosumab should be considered. A meta-analysis combined data from three identically designed double-blind randomized controlled trials that compared the efficacy and safety of denosumab at a dose of 120 mg with that of zoledronic acid at a dose of 4 mg administered IV.[46] Almost 6,000 patients with breast and prostate cancer and multiple myeloma were included in the meta-analysis. Denosumab reduced the risk of first skeletal-related event (SRE) by 17% (hazard ratio 0.83, 95% CI: 0.76-0.90, $P < 0.001$ for both noninferiority and superiority tests) as compared with zoledronic acid and the median time to first SRE was 27.66 (24.21 to not estimable) months for denosumab versus 19.45 (18.53-21.42) months for zoledronic acid. The benefits were consistent across tumor types evaluated and the incidence of adverse effects was not significantly different between the denosumab and zoledronic acid groups.

ADT has also been associated with a higher incidence of metabolic effects. In a landmark population-based trial, patients treated with an ADT and a gonadotropin-releasing hormone (GnRH) agonist had a greater risk of new-onset diabetes, coronary artery disease, and myocardial infarctions.[47] However, it is not clear whether ADT increases the risk of cardiovascular death. A published meta-analysis of eight trials with 4,141 patients treated with ADT evaluated prostate cancer specific mortality and all-cause mortality.[48] The trials included patients with nonmetastatic disease who were treated with immediate predominantly GnRH-agonist–based ADT versus no immediate ADT (control group). The incidence of cardiovascular deaths was 11.0% (95% CI: 8.3%-14.5%) in the ADT group versus 11.2% (95% CI: 8.3%-15.0%) in the control group. The risk of cardiovascular death for ADT versus control was not significantly different (RR 0.93, 95% CI: 0.79-1.10, P=0.41) and these results suggest that ADT does not lead to increased cardiovascular mortality.[32] Patients receiving ADT should be screened for cardiovascular disease and diabetes and appropriate interventions to prevent and treat these complications should be initiated.[32]

Gonadotropin-Releasing Hormone Antagonists

An alternative to LHRH agonists is the approved GnRH antagonist, degarelix. Degarelix works by binding reversibly to GnRH receptors in the pituitary gland, reducing the production of testosterone to castrate levels. The major advantage of degarelix over LHRH agonists is the rapidity at which it reduces testosterone levels. Castration levels are achieved in 7 days or less with degarelix, as compared with 28 days with leuprolide. Tumor flare does not occur and antiandrogens are not required.

In a trial of 610 men with advanced prostate cancer, degarelix was shown to be equivalent to leuprolide in lowering testosterone levels for up to 1 year. Degarelix is available as a 40 mg/mL and a 20 mg/mL vial for subcutaneous injection, and the starting dose is 240 mg followed by 80 mg every 28 days. The starting dose should be divided into two 120 mg injections.[49] Degarelix has not been studied in combination with antiandrogens, and routine use of the combination is not recommended.

The most frequently reported adverse reactions were injection site reactions, including pain (28%), erythema (17%), swelling (6%), induration (4%), and nodules (3%). Most were transient and mild to moderate, leading to discontinuation in less than 1% of study subjects. Other adverse effects included elevations in liver function tests, which occurred in about 10% of study subjects. Osteoporosis may develop, and calcium and vitamin D supplementation should be considered.[49]

Antiandrogens

Four antiandrogens, flutamide, bicalutamide, nilutamide, and enzalutamide, are currently available (**Table 131-6**).[53,54,55,56,57,58,59,60,61,62,63,64] Cyproterone is another agent with antiandrogen activity, but it is not available in the United States. Antiandrogens have been used as monotherapy in previously untreated patients, but a recent meta-analysis showed that monotherapy with antiandrogens is less effective than LHRH agonists.[41] Therefore, for advanced prostate cancer, flutamide, bicalutamide, and nilutamide are indicated only in combination with androgen-ablation therapy. Flutamide and bicalutamide are indicated in combination with an LHRH agonist, and nilutamide is indicated in combination with orchiectomy.[50] Antiandrogens can reduce the symptoms from the flare phenomenon associated with LHRH agonist therapy.[31] The Food and Drug Administration (FDA) recently approved the newest androgen-receptor inhibitor, enzalutamide. Enzalutamide, also known as MDV3100, is currently approved as a single agent for patients with metastatic castrate-resistant prostate cancer.[51] As with the other antiandrogens, enzalutamide does not lower androgen levels but inhibits androgen-receptor signaling by competitively inhibiting the binding of androgens without stimulation of the androgen receptor. Enzalutamide may have an advantage over the currently available antiandrogen agents in that it inhibits nuclear translocation of the androgen receptor, DNA binding, and coactivator recruitment. It also has a greater affinity for the androgen receptor and has shown activity in patients resistant to other antiandrogens. Initially approved in docetaxel failure only, the PREVAIL study demonstrated enzalutamide may be used in the first line setting to delay the initiation of chemotherapy.[52]

TABLE 131-6 Hormonal Therapies for Prostate Cancer[53,54,55,56,57,58,59,60,61,62,63,64]

Drug (Brand Name)	Usual Dose	Toxicities	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
Antiandrogens						
Flutamide (Eulexin)	750 mg/day	Gynecomastia Hot flashes Gastrointestinal disturbances (diarrhea) Loss of libido LFT abnormalities Breast tenderness Methemoglobinemia	Contraindicated in patients with hepatic impairment No dosage adjustment necessary in chronic renal impairment	Serum transaminases should be monitored prior to start of therapy and monthly for first 4 months, then periodically thereafter Monitor for tumor reduction, testosterone/estrogen, and phosphatase serum levels	Substrate of CYP1A2 and CYP3A4	Administered orally in three divided doses; capsule may be opened into applesauce, pudding, or other soft foods
Bicalutamide (Casodex)	50 mg/day (up to 150 mg/day—unlabeled use)	Gynecomastia Hot flashes Gastrointestinal disturbances (diarrhea) Decrease libido LFT abnormalities Breast tenderness	Discontinue if ALT >2 times upper limit of normal or patient develops jaundice	Serum transaminases should be monitored prior to start of therapy and monthly for first 4 months, then periodically thereafter Periodic monitoring of CBC, EKG, echocardiograms, serum testosterone, luteinizing hormone, and PSA	Inhibits CYP3A4 May increase concentration of vitamin K antagonists	May be taken with or without food
Nilutamide (Nilandron)	300 mg/day for first month then 150 mg/day	Gynecomastia Hot flashes Gastrointestinal	Contraindicated in patients with hepatic impairment	Serum transaminases should be monitored prior to start of therapy and monthly for first 4	Substrate of CYP2C19 and weak inhibitor of CYP2C19	May be taken with or without food

Drug (Brand Name)	Usual Dose	Toxicities	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
		Disturbances (constipation) LFT abnormalities Breast tenderness Visual disturbances (impaired dark adaptation) Alcohol intolerance Interstitial pneumonitis	Discontinue if ALT >2 times upper limit of normal or patient develops jaundice	months, then periodically thereafter Chest x-ray at baseline and consideration of pulmonary function testing (at baseline)		
Enzalutamide (Xtandi)	160 mg/day	Gastrointestinal disturbances (diarrhea) Musculoskeletal disorders (back pain, arthralgias, muscle pain, weakness) Asthenia Peripheral edema CNS (headache, dizziness) Seizures LFT abnormalities	No adjustment necessary for renal or hepatic impairment	Complete blood counts baseline and periodically LFTs baseline and periodically	Strong CYP3A4 and moderate CYP2C9 and CYP2C19 inducer; avoid CYP3A4, CYP2C9 and CYP2C19 sensitive substrates. CYP2C8 substrate, avoid strong inducers and inhibitors of CYP2C8 If vitamin K antagonists necessary, conduct additional INR monitoring	May be taken with or without food
Androgen Synthesis Inhibitor						
Abiraterone acetate (Zytiga)	1,000 mg/day + prednisone 5 mg BID	Gastrointestinal disturbances (diarrhea) Edema Hypokalemia Hypophosphatemia LFT abnormalities Hypertriglyceridemia	250 mg daily for Child Pugh Class B; avoid use in Child Pugh Class C Withhold treatment if LFTs >5 times the ULN or bilirubin >3 ULN	Serum transaminases should be monitored prior to start of therapy, every 2 weeks for 3 months, then monthly thereafter Monitor for signs and symptoms of adrenocorticoid insufficiency; monthly for hypertension, hypokalemia, and fluid	Substrate of CYP3A4. Use with caution with CYP3A4 inhibitors and inducers. Inhibits CYP1A2, CYP2C19, CYP2C8,	Administer on an empty stomach, at least 1 hour before and 2 hours after food

Drug (Brand Name)	Usual Dose	Toxicities	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
				retention	CYP2C9, CYP2D6, CYP3A4, and P-glycoprotein Use sensitive substrates with caution	
Luteinizing-Hormone Agonists						
Leuprolide (Lupron)	7.5 mg IM every month 22.5 mg IM every 3 months 30 mg IM every 4 months 45 mg IM every 6 months	Hot flashes Decreased libido Gynecomastia Osteoporosis Fatigue Weight gain	No adjustment necessary for renal or hepatic impairment	Serum testosterone ~4 weeks after initiation, PSA, blood glucose, and $HgbA_{1c}$ prior to initiation and periodically thereafter	May diminish the effects of antidiabetic agents	Vary injection site
Goserelin (Zoladex)	3.6 mg SQ implant every month 10.8 mg SQ implant every 3 months	Hot flashes Decreased libido Gynecomastia Osteoporosis Fatigue Weight gain	No adjustment necessary for renal or hepatic impairment	Monitor bone mineral density, serum calcium, and cholesterol/lipids	May diminish the effects of antidiabetic agents	Vary injection site
Triptorelin (Trelstar)	3.75 mg IM every month 11.25 mg IM every 3 months 22.5 mg IM every 6 months	Hot flashes Decreased libido Gynecomastia Osteoporosis Fatigue Weight gain	No adjustment necessary for renal or hepatic impairment	Monitor serum testosterone levels and prostate specific antigen	May diminish the effects of antidiabetic agents	Vary injection site
Gonadotropin-Releasing Hormone Antagonists						
Degarelix (Firmagon)	240 mg SQ loading dose 80 mg SQ every 28	Hot flashes Decreased libido Gynecomastia	Use with caution with CL_{cr} <50 mL/min (<0.83 mL/s)	Prostate-specific antigen periodically, serum testosterone monthly until castration achieved then every other	Use with caution with agents that may increase QTC interval	Vary injection site

Drug (Brand Name)	Usual Dose	Toxicities	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
	days (following 28 days after loading dose)	Osteoporosis Fatigue Weight gain	Do not use in patients with severe hepatic impairment	month, LFTs at baseline in addition to serum electrolytes and bone mineral density		

ALT, alanine aminotransferase; BID, twice daily; CBC, complete blood count; CL_{cr}, creatinine clearance; CNS, central nervous system; CYP, cytochrome P450; EKG, electrocardiogram; $HgbA_{1c}$, hemoglobin A1c; IM, intramuscular injection; INR, international normalized ratio; LFT, liver function test; PSA, prostate-specific antigen; SQ, subcutaneous injection; ULN, upper limit of normal.

The most common antiandrogen-related adverse effects are listed in **Table 131-7**. In the only randomized comparison of bicalutamide plus an LHRH agonist versus flutamide plus an LHRH agonist, diarrhea was more common in flutamide-treated patients. The adverse effects of enzalutamide are similar to those of the other antiandrogens, but enzalutamide does have an increased risk of seizures.

TABLE 131-7 Chemotherapy and Immunotherapy for Prostate Cancer[62,63,64]

Drug (Brand Name)	Usual Dose	Toxicities	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
Antimicrotubule Agents						
Docetaxel (Taxotere)	75 mg/m^2 IV every 3 weeks	Fluid retention, alopecia, mucositis, myelosuppression, hypersensitivity	Aspartate transaminase/alanine transaminase >1.5 times the upper limit of normal and alkaline phosphatase >2.5 times the upper limit of normal do not administer	CBC with differential, LFTs, bilirubin, alkaline phosphatase, renal function Monitor for hypersensitivity reactions	Avoid concomitant use of CYP3A4 inhibitors	Administer IV infusion over 1 hour. Premedication with corticosteroids for 3 days beginning the day before
Cabazitaxel (Jevtana)	25 mg/m^2 IV every 3 weeks	Fluid retention, constipation, mucositis, myelosuppression, hypersensitivity	Discontinue if ALT >2 times upper limit of normal or patient develops jaundice	CBC weekly during first cycle, then prior to each treatment. Monitor for hypersensitivity	Avoid concomitant use of CYP3A4 inducers and inhibitors	Administer IV infusion over 1 hour
Immunotherapy						
Sipuleucel-T (Provenge)	Each injection contains >50 million autologous CD54+ cells (obtained through leukapheresis) activated with PAP-GM-CSF.	Hypersensitivity, chills, fatigue, fever, headache, myalgias	No dosage adjustment necessary for renal or hepatic dysfunction	No specific laboratory monitoring recommended	Immunosuppressants may decrease the therapeutic effects of sipuleucel-T	Administer IV infusion over 1 hour. Observe patient for 30 minutes after the completion of the infusion. Premedicate with acetaminophen

Drug (Brand Name)	Usual Dose	Toxicities	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
	Dose is given ~ every 2 weeks for 3 total doses					and an antihistamine 30 minutes prior to administration

ALT, alanine aminotransferase; CBC, complete blood count; CYP, cytochrome P450; LFT, liver function test; PAP-GM-CSF, prostatic acid phosphatase granulocyte-macrophage colony-stimulating factor.

Combined Androgen Blockade

Although up to 80% of patients with advanced prostate cancer will respond to initial hormonal manipulation, almost all patients will progress within 2 to 4 years after initiating therapy.[26] Two mechanisms have been proposed to explain this tumor resistance. The tumor could be heterogeneously composed of cells that are hormone-dependent and hormone-independent, or the tumor could be stimulated by extratesticular androgens that are converted intracellularly to DHT. The rationale for combination hormonal therapy is to interfere with multiple hormonal pathways to completely eliminate androgen action. In clinical trials, combination hormonal therapy, sometimes also referred to as maximal androgen deprivation or total androgen blockade, or *combined androgen blockade* (CAB), has been used. The combination of LHRH agonists or orchiectomy with antiandrogens is the most extensively studied CAB approach.

A systematic review of six meta-analyses concluded that the best evidence for CAB came from the largest meta-analysis, conducted by the Prostate Cancer Trialists Collaborative Group including 8,725 patients from 27 trials.[65] That analysis found no difference in overall survival between CAB and castration alone at 2 or 5 years, but a subgroup analysis showed that CAB with nonsteroidal antiandrogens, including flutamide, bicalutamide or nilutamide was associated with a statistically significant improvement in 5-year survival over castration alone (27.6% vs 24.7%, P=0.005). As expected, antiandrogens increased toxicity over placebo.

Although some clinicians consider CAB to be the initial hormonal therapy of choice for newly diagnosed patients, the clinician must weigh the costs of combined therapy against the modest survival benefit.[65] It is appropriate to use either LHRH agonist monotherapy or CAB as initial therapy for metastatic prostate cancer. CAB may be most beneficial in patients with minimal disease and prevents tumor flare, particularly in those with advanced metastatic disease. All other patients may be started on LHRH monotherapy, and an antiandrogen may be added after several months if androgen ablation is incomplete.

It is not clear when to start hormonal-deprivation therapy in patients with advanced prostate cancer.[30] The original recommendation to start therapy when symptoms appeared was based on the Veterans Administration Cooperative Urologic Research Group (VACURG) trials, in which no overall survival difference was demonstrated in patients who either started diethylstilbestrol (DES) initially or crossed over to active treatment when symptoms appeared; the excess mortality was attributed to estrogen administration.[66] Because LHRH agonists and antiandrogens are viable therapies with less cardiovascular toxicity, it is not clear whether delaying therapy is justified with these agents. Reanalysis of the original VACURG data[67] and recent combined ADT trials[66] demonstrate a survival advantage for young, good-performance-status, minimal-disease patients treated initially with hormonal therapy, suggesting that early intervention before symptoms appear may be appropriate.[67]

Alternative Drug Treatments

Secondary or salvage therapies for patients who progress after their initial therapy depend on what was used for initial management.[32] For patients initially diagnosed with localized prostate cancer, radiotherapy can be used in the case of failed radical prostatectomy. Alternatively, androgen ablation can be used in patients who progress after either radiation therapy or radical prostatectomy.

Secondary Hormonal Manipulations

In patients treated initially with one hormonal modality, secondary hormonal manipulations may be attempted. This may include adding an antiandrogen to a patient with incomplete suppression of testosterone secretion with an LHRH agonist. In patients that have progression while receiving CAB, withdrawing antiandrogens, or using agents that inhibit androgen synthesis may be attempted. For patients who initially received an LHRH agonist alone, castration testosterone levels should be documented. Patients with inadequate testosterone suppression (greater than 20 ng/dL [0.7 nmol/L]) can be treated by adding an antiandrogen or performing an orchiectomy. If castration testosterone levels have been achieved, the patient is considered to have androgen-independent disease, and palliative androgen-independent salvage therapy can be used.

6 Antiandrogen withdrawal, for patients having progressive disease while receiving CAB with an LHRH agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor have been documented that cause antiandrogens to act like receptor agonists.

If the patient initially received CAB with an LHRH agonist and an antiandrogen, then androgen withdrawal is the first salvage manipulation.[32] Objective and subjective responses have been noted following the discontinuation of flutamide,[68] bicalutamide,[69] or nilutamide[70] in patients receiving these agents as part of combined androgen ablation with an LHRH agonist. Mutations in the androgen receptor have been demonstrated that allow antiandrogens such as flutamide, bicalutamide, and nilutamide (or their metabolites) to become agonists and activate the androgen receptor.[71] Patient responses to androgen withdrawal manifest as significant PSA reductions and improved clinical symptoms. Androgen withdrawal responses lasting 3 to 14 months have been observed in up to 35% of patients, and responses appear to be most closely related to longer androgen exposure times. Incomplete cross-resistance has been noted in some patients who received bicalutamide after they had progressed while receiving flutamide.[72] The addition of an agent that blocks adrenal androgen synthesis, such as aminoglutethimide, at the time that androgens are withdrawn may produce a better response than androgen withdrawal alone.[71] Because of the potential for response immediately after antiandrogen withdrawal, a sufficient observation and assessment period (usually 4-6 weeks) is usually required before a patient can be enrolled on a clinical trial evaluating a new agent or therapy for advanced prostate cancer.

Androgen synthesis inhibitors, such as aminoglutethimide or ketoconazole, can provide symptomatic relief for a short time in about 50% of patients with progressive disease despite previous androgen-ablation therapy.[32] Adverse effects during aminoglutethimide therapy occur in about 50% of patients.[32] Central nervous system effects that include lethargy, ataxia, and dizziness are the major adverse reactions. A generalized morbilliform, pruritic rash has been reported in up to 30% of patients treated. The rash is usually self-limiting and resolves within 5 to 8 days with continued therapy. Adverse effects from ketoconazole include gastrointestinal intolerance, transient rises in liver and renal function tests, and hypoadrenalism. Ketoconazole is combined with replacement doses of hydrocortisone to prevent symptomatic hypoadrenalism.[32]

Abiraterone is the newest androgen synthesis inhibitor that targets cytochrome P450 (CYP)17A1, which results in a decrease in circulating levels of testosterone.[73] Abiraterone is indicated in patients with metastatic castration-resistant prostate cancer, either before or after docetaxel-based chemotherapy. The initial approval was based on the results of a phase III study of patients previously treated with a docetaxel-containing regimen. The combination of abiraterone and prednisone increased median overall survival by 3.9 months in comparison to placebo. Hypertension, hypokalemia, and edema may occur due to hypoadrenalism. Abiraterone is available as the prodrug, abiraterone acetate, and should be taken on an empty stomach as food increases bioavailability by up to 10-fold. Monitoring of liver function tests is recommended at baseline, every 2 weeks for the first 3 months, and then monthly thereafter. Since abiraterone is an inhibitor of CYP2D6, medication profiles should be reviewed for potential drug interactions prior to initiation of abiraterone therapy.[73]

Chemotherapy

Chemotherapy with docetaxel and prednisone improves survival in patients with castrate-refractory prostate cancer and is considered first-line therapy for these patients. Docetaxel 75 mg/m^2 every 3 weeks combined with prednisone 5 mg twice a day improves survival in hormone-refractory metastatic prostate cancer.[74] The most common adverse events with this

regimen are nausea, alopecia, and bone marrow suppression. Other adverse effects of docetaxel include fluid retention and peripheral neuropathy. Docetaxel is metabolized in the liver; patients with hepatic impairment may not be eligible for treatment with docetaxel because of an increased risk for toxicity (see Table 131-7).

Cabazitaxel is a taxane with demonstrated activity in docetaxel resistant cell lines and animal models of human cancer.[75] Cabazitaxel has lower affinity for P-glycoprotein multidrug resistance transporter than docetaxel, which may explain why cabazitaxel is active in the setting of docetaxel resistance. In patients previously treated with docetaxel and prednisone, treatment with cabazitaxel 25 mg/m^2 every 3 weeks with prednisone 10 mg daily significantly improved progression-free survival and overall survival as compared to mitoxantrone and prednisone. Neutropenia, febrile neutropenia, neuropathy, and diarrhea are the most significant toxicities. Hypersensitivity reactions may occur and premedication with an antihistamine, a corticosteroid, and an H_2 antagonist is recommended. Cabazitaxel is extensively metabolized in the liver and should be avoided in patients with hepatic dysfunction (see Table 131-7). Mitoxantrone plus prednisone has not demonstrated a survival improvement after failure of docetaxel, but remains a palliative therapeutic option, specifically in men who are not candidates for cabazitaxel or radium-223 therapy.[32]

Immunotherapy

Sipuleucel-T is a novel autologous cellular immunotherapy that was FDA-approved in April 2010 for the treatment of asymptomatic or minimally symptomatic metastatic hormone-refractory prostate cancer.[76] Alternative treatment options for this patient population are secondary hormonal therapy, including antiandrogen therapy, withdrawal of antiandrogen therapy, ketoconazole, abiraterone acetate, enzalutamide, steroids, estrogen, or enrollment on a clinical trial, although none of these options has been shown to improve overall survival. No clinical trials have compared sipuleucel-T to secondary hormonal therapies. Patients treated with sipuleucel-T undergo leukapheresis on day 1 to collect peripheral blood mononuclear cells, the cellular fraction that includes immune effector cells. These cells are incubated with a prostatic acid phosphatase (PAP)–granulocyte-macrophage colony-stimulating factor (GM-CSF) fusion protein; PAP is the specific tumor antigen, and GM-CSF is the immune cell activator. The cellular product is then infused IV into the patient on day 3 or 4, providing an autologous infusion of activated cells. Each course of sipuleucel-T consists of three infusions of activated cells, given every 2 weeks. In the pivotal trial, sipuleucel-T prolonged median survival by 4.1 months and reduced the risk of death by 22% (HR 0.78, 95% CI: 0.61-0.98, *P*=0.03).[76] Adverse effects related to sipuleucel-T were generally mild and nearly all patients were able to receive the entire course (ie, 3 infusions). A course of sipuleucel-T costs about $93,000, and some insurers have questioned the value of the therapy.

Nuclear Medicine

Radium-223, an alpha emitter, can be administered to target specific bone metastases with alpha particles in patients with metastatic, castrate-resistant prostate cancer. Radium-223 administered every 4 weeks improved overall survival by 2.8 months in patients who had received, were not eligible for, or had declined docetaxel therapy. Improvements in skeletal pain, pain-related outcomes, and quality of life were also significant. Opioid needs were decreased in patients who received radium-223 (36% vs 50%). The most common side effects of radium-223 include nausea, diarrhea, vomiting, peripheral edema, and bone marrow suppression .[77] Radium-223 is a category 1 recommendation and may be used in first-, second-, or third-line therapy in patients with metastatic castrate resistant prostate cancer with symptomatic primary bone metastases. Radium-223 has not been approved for use with concomitant chemotherapy.

Clinical Controversy…

The use of sipuleucel-T is controversial. The treatment is indicated for minimally symptomatic prostate cancer and has not been compared to standard second-line hormonal interventions.

PERSONALIZED PHARMACOTHERAPY

Prevention strategies for prostate cancer, specifically whether to undergo PSA screening for early detection or whether to start chemoprevention with finasteride or dutasteride in an effort to prevent prostate cancer, are highly personalized decisions and depend on an individual patient weighing the risks and benefits of either strategy. This is a major change

from previous recommendations, which uniformly recommended screening regardless of age, health status or patient preference.

Prostate cancer therapy is personalized based on clinical factors, including stage of cancer, life expectancy of the patient, and a patient's fitness for surgical interventions (see Table 131-5). Agents used in the treatment of prostate cancer are often personalized with dose adjustments for organ dysfunction of other clinical characteristics (see Table 131-7). Although there are no current selection strategies where individuals with a specific mutation receive a specific therapy, this remains an important area of research.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of prostate cancer depends on the stage of the cancer.[32] When definitive, curative therapy is attempted, objective parameters to assess tumor response include assessment of the primary tumor size, evaluation of involved lymph nodes, and the response of tumor markers such as PSA to treatment. Following definitive therapy, the PSA level is checked every 6 months for the first 5 years, then annually. Local recurrence in the absence of a rising PSA may occur, so a DRE is also performed. In the metastatic setting, chemotherapy and novel hormonal manipulations have been shown to prolong overall survival. In addition, clinical benefit responses can be documented by evaluating performance status changes, weight changes, quality of life, and analgesic requirements, in addition to the PSA or DRE at 3-month intervals.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ADT	androgen-deprivation therapy
AUA	American Urologic Association
BPH	benign prostatic hyperplasia
CAB	combined androgen blockade
CI	confidence interval
CYP	cytochrome P450
DES	diethylstilbestrol
DHT	dihydrotestosterone
DRE	digital rectal examination
ERSPC	European Randomized Study of Screening for Prostate Cancer
FDA	Food and Drug Administration
FSH	follicle-stimulating hormone
GM-CSF	granulocyte-macrophage colony-stimulating factor
GnRH	gonadotropin-releasing hormone
LH	luteinizing hormone
LHRH	luteinizing hormone–releasing hormone
PAP	prostatic acid phosphatase
PCPT	Prostate Cancer Prevention Trial
PLCO	Prostate, Lung, Colon, and Ovarian Screening (study)
PSA	prostate-specific antigen
RANK	receptor activator of nuclear factor k B
REDUCE	Reduction by Dutasteride of Prostate Cancer Events
RR	Relative risk
SELECT	Selenium and Vitamin E Cancer Prevention Trial
SRE	skeletal-related event
TNM	tumor, node, metastases

USPSTF United States Preventative Services Task Force

VACURG Veterans Administration Cooperative Urologic Research Group

Chapter 132: Lymphomas

FIGURE 132-1

Alexandre Chan; Jolynn Sessions

INTRODUCTION

KEY CONCEPTS

- 1 With all stages and risk-groups of Hodgkin lymphoma, restaging PET-CT following about 8 to 12 weeks of chemotherapy will further guide the patient-specific treatment plan.
- 2 Patients with early stage Hodgkin lymphoma should be treated with combination chemotherapy with or without involved-site radiation.
- 3 Combination chemotherapy with doxorubicin (Adriamycin®), bleomycin, vinblastine, and dacarbazine (ABVD) is the primary treatment for patients with advanced-stage Hodgkin lymphoma. Patients with advanced unfavorable disease may be treated with more aggressive regimens, but are associated with a higher risk of secondary malignancies.
- 4 Some patients with Hodgkin lymphoma will be refractory to initial therapy or will have a recurrence following a complete remission. Response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. High-dose chemotherapy and autologous hematopoietic stem cell transplantation (HSCT) should be considered in patients with refractory or relapsed disease.
- 5 The current classification system for non-Hodgkin lymphoma (NHL) is the World Health Organization (WHO) classification system, which is based on the principle that NHLs can be classified into specific disease entities, defined by a combination of morphology, immunophenotype, genetic features, and clinical features.
- 6 As compared with Hodgkin lymphoma, the clinical presentation of NHL is more variable because of disease heterogeneity and more frequent extranodal involvement.

- 7 The Ann Arbor staging system correlates poorly with prognosis in NHL because the disease does not spread through contiguous lymph nodes and often involves extranodal sites.

- 8 Several prognostic models have been developed to estimate prognosis in patients with NHL. The International Prognostic Index (IPI) score is a well-established model for patients with aggressive NHL. The Follicular Lymphoma International Prognostic Index (FLIPI) is a similar model used for patients with follicular and other indolent lymphomas.

- 9 The clinical behavior and degree of aggressiveness can be used to categorize NHL into indolent and aggressive lymphomas. Patients with an indolent lymphoma usually have a relatively long survival, with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, few if any of these patients are cured of their disease. In contrast, aggressive lymphomas are rapidly growing tumors and patients have a short survival if appropriate therapy is not initiated. Most patients with aggressive lymphomas respond to intensive chemotherapy and many are cured of their disease.

- 10 Patients with localized follicular lymphoma can be cured with radiation therapy alone. Advanced follicular lymphoma is not curable, and many treatment options are available, including watchful waiting, extended-field radiation therapy, single-agent alkylating agents, anthracycline-containing combination chemotherapy, anti-CD20 monoclonal antibodies, fludarabine, lenalidomide, idelalisib, and high-dose chemotherapy with HSCT.

- 11 Patients with localized aggressive lymphomas can be cured with several cycles of R-CHOP (rituximab, cyclophosphamide, doxorubicin [hydroxydaunorubicin], vincristine [Oncovin®], prednisone) chemotherapy and involved-field irradiation. Patients with bulky stage II, stage III, or stage IV aggressive lymphomas can be cured of their disease with R-CHOP chemotherapy.

- 12 Conventional-dose salvage therapy can induce responses in patients with aggressive lymphomas who relapse, but long-term survival and cure are uncommon. Some patients with aggressive lymphoma who relapse and respond to salvage therapy can be cured with high-dose chemotherapy and autologous HSCT.

Lymphomas are a heterogeneous group of malignancies that arise from malignant transformation of immune cells that reside predominantly in lymphoid tissues. They most commonly present as a solid tumor, but can sometimes present as circulating tumor cells in peripheral blood. The differing histology of lymphoma cells has led to classification of Hodgkin lymphoma (Reed–Sternberg cells) or non-Hodgkin lymphoma (NHL) (B- or T-cell lymphocyte markers). NHLs are further classified into distinct clinical entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features. Chemotherapy is the mainstay of treatment in patients with lymphoma, especially those with widespread disease. Overall cure rates are high for many subtypes of lymphomas, even when patients present with advanced disease.

HODGKIN LYMPHOMA

Hodgkin lymphoma is one of the most curable forms of cancer. Although initial reports of Hodgkin lymphoma demonstrated the disease to be uniformly fatal, an impressive 80% of patients can be cured today with recommended treatments.[1] Some of the keys to the success of the treatments for Hodgkin lymphoma include: (1) use of multidrug chemotherapy regimens with differing mechanisms of action and toxicities, and (2) treatment with full doses of chemotherapy and on schedule whenever possible. It is also common to use radiation therapy in the treatment schema. However, the success of treatment has not been without cost. The treatment programs are intense, technically demanding, and associated with considerable acute toxicity and long-term complications. The long-term effects, particularly secondary malignancies, account for a higher cumulative mortality than Hodgkin lymphoma 15 to 20 years after treatment. Long-term toxicities with standard chemotherapy regimens have been more fully documented in recent years and are shaping future therapies.[3,4,5]

Hodgkin lymphoma is named after Thomas Hodgkin, who first described seven cases of a mysterious disease of the lymph system in 1832. Although Hodgkin lymphoma was not the first cancer to be described, it was one of the first cancers to have methodical investigational treatments that ultimately lead to successful outcomes.[5]

Since many factors influence prognosis of patients with Hodgkin lymphoma, treatment plans must be personalized for each patient. The staging for Hodgkin lymphoma differs from other cancers, and uses the Ann Arbor Staging Classification where the "A" refers to the absence of B-symptoms, and "B" refers to the presence of B-symptoms. Beyond the stage of the disease, certain factors have been associated with a poor prognosis (unfavorable risk). Several research groups have defined these unfavorable factors, and the International Prognostic Score (IPS) is used clinically to predict an individual's risk of recurrence.

Epidemiology and Etiology

Hodgkin lymphoma represents less than 1% of all known cancers in the United States. It is estimated that 8,500 new cases of Hodgkin lymphoma will be diagnosed in the United States in 2016, and there will be 1,150 deaths associated with Hodgkin lymphoma during this same period.[6] Hodgkin lymphoma occurs slightly more frequently in males than in females. It exhibits bimodal distribution in industrialized countries; the first peak occurs in young adults and the second smaller peak occurs after age 50.[3,5] The 5-year overall survival for all stages of Hodgkin lymphoma is about 85%.[7] Death as a consequence of recurrent Hodgkin lymphoma is less than those from all other causes 15 years after treatment.[8]

The etiology of Hodgkin lymphoma is currently unknown, but laboratory and epidemiologic evidence support infectious exposure as a potential cause.[3,5] Studies suggest an increased risk of Hodgkin lymphoma in patients who have been infected with the Epstein-Barr's virus (EBV); and many patients experience EBV activation even before the onset of Hodgkin lymphoma. EBV is found in about 40% of all classical Hodgkin lymphoma cases, and it is frequently observed in cases of mixed cellularity and lymphocyte-depleted Hodgkin lymphoma.[9] Reed–Sternberg cells (large, bilobate, multinuclear cells looking like "owl eyes"), the malignant cells in Hodgkin lymphoma, are linked to EBV. Individuals who are immunosuppressed, such as patients with congenital immunosuppression, solid-organ transplant

recipients, and human immunodeficiency virus (HIV)-infection, are also at much higher risk to develop Hodgkin lymphoma. Although the risk of developing Hodgkin lymphoma is up to 25-fold greater in patients with HIV, the CD4 level may be very low or within the normal range at diagnosis. Almost all cases of Hodgkin lymphoma (HL) in HIV-infected individuals are EBV positive, and are most commonly the lymphocyte-deplete subtype of HL. Hodgkin lymphoma is not an AIDS-defining illness.

Genetic factors are also associated with an increased risk of Hodgkin lymphoma. The strongest evidence comes from identical twin studies, which show that the unaffected identical twin has almost a 100-fold increase in risk.[10]

Pathophysiology

Hodgkin lymphoma is a clonal malignant lymphoid disease of transformed B-lymphocytes. The malignant cell in Hodgkin lymphoma is known as the Reed–Sternberg cell named after Dorothy Reed and Carl Sternberg, who were credited with the first definitive microscopic description of Hodgkin lymphoma.[2,3] Procedures to isolate and analyze Reed–Sternberg cells remain a challenge to pathologists because of the relatively small percentage (1%-2%) of Reed–Sternberg cells in an inflammatory microenvironment typically found in the Hodgkin lymphoma mass.[9] Fortunately, new laboratory techniques have led to significant progress in identifying the origin of the Reed–Sternberg cell. Single-cell polymerase chain reaction and DNA microarray analyses indicate that nearly all classic Hodgkin lymphoma cases and all nodular lymphocyte-predominant Hodgkin lymphomas (NLPHLs) have immunoglobulin gene rearrangements, which indicates a germinal center or post-germinal center B-cell origin.[9,11] Interestingly, nearly all Reed–Sternberg cells of classical Hodgkin lymphoma fail to express B-cell specific cell surface proteins.

B-cell transcriptional processes are disrupted during malignant transformation, which prevents B-cell surface marker expression and production of immunoglobulin messenger ribonucleic acid. The normal cellular consequence of failure to express immunoglobulin is apoptosis, but because of alterations in the normal apoptotic pathways, cell survival and proliferation are favored. Reed–Sternberg cells overexpress nuclear factor-κ B, which is associated with cell proliferation and antiapoptotic signals. Infections with viral and bacterial pathogens upregulate nuclear factor-κ B and consequently are hypothesized to be involved with the etiology of Hodgkin lymphoma.[3,9,11] This hypothesis is supported by the presence of EBV in many Hodgkin lymphoma tumors, but it is important to note that not all tumors are associated with EBV. Another signaling pathway, Janus kinase–signal transduction and transcription (JAK–STAT), has also been found to be active in Hodgkin lymphoma.[3,9] As molecular techniques continue to improve, our understanding of the pathophysiology of Hodgkin lymphoma will also improve.

The histopathologic classification of Hodgkin lymphoma has undergone numerous changes over the past three decades. The current classification system is the 2016 World Health Organization (WHO) classification (**Table 132-1**).[12] This classification divides Hodgkin lymphoma into two major groups: classical Hodgkin lymphoma and NLPHL, which constitute about 95% and 5% of cases, respectively. Classic Hodgkin lymphoma is further divided into four subtypes: nodular sclerosis, mixed cellularity,

lymphocyte-depleted, and lymphocyte-rich. The subtypes in these classifications are based on characteristics of the Reed–Sternberg cell, the surrounding cells, and the tissue. Nodular sclerosis has features that make it distinct from the other three subtypes, which represent a continuum of background cellularity, with lymphocyte-predominance being the most cellular and lymphocyte-depletion being the least cellular. Typical immunophenotype for classical Hodgkin lymphoma includes $CD15^+$, $CD30^+$, $PAX\text{-}5^+$ (weak), $CD3^-$, $CD20^-$, $CD45^-$, $CD79a^-$. NLPHL is separated because of its distinct immunophenotype: $CD15^-$, $CD20^+$, $CD30^-$, and $CD45^+$ (the opposite of classical Hodgkin lymphoma). With the introduction of extensive staging, sophisticated radiotherapy, and effective combination chemotherapy, the prognostic value of these subtypes is becoming less clear. The true value of understanding these subtypes is likely tied to the pathogenesis of the disease and its potential prevention in the future.

TABLE 132-1 WHO Classification of the Mature B-Cell, T-Cell, and NK-Cell Neoplasms (2016)

B Cell	NK cells	Hodgkin Lymphoma
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma	T-cell prolymphocytic leukemia	
B-cell prolymphocytic leukemia	T-cell granular lymphocytic leukemia	
Lymphoplasmacytic lymphoma	Aggressive NK cell leukemia	
Splenic marginal zone B-cell lymphoma (± villous lymphocytes)	Adult T-cell leukemia/lymphoma (HTLV-I+)	Nodular lymphocyte-predominant Hodgkin lymphoma
Hairy cell leukemia	Extranodal NK/T-cell lymphoma, nasal type	Classical Hodgkin lymphoma
Plasma cell myeloma/plasmacytoma	Enteropathy-associated T-cell lymphoma	Nodular sclerosis classical Hodgkin lymphoma
Extranodal marginal zone B-cell lymphoma of MALT type	Hepatosplenic $\gamma\ \delta$ T-cell lymphoma	Lymphocyte-rich classical Hodgkin lymphoma
Mantle cell lymphoma	Subcutaneous panniculitis-like T-cell lymphoma	Mixed cellularity classical Hodgkin lymphoma
Follicular lymphoma	**Mycosis fungoides/Sézary syndrome**	Lymphocyte-depleted classical Hodgkin lymphoma
Nodal marginal zone B-cell lymphoma (± monocytoid B cells)	Anaplastic large cell lymphoma, primary cutaneous type	
Diffuse large B-cell lymphoma (DLBCL)	**Peripheral T-cell lymphoma, not otherwise specified (NOS)**	
Germinal center B-cell type	**Angioimmunoblastic T-cell**	
Activated B-cell type		

B Cell	NK cells	Hodgkin Lymphoma
	lymphoma	
Burkitt's lymphoma	**Anaplastic large cell lymphoma, primary systemic type**	

HTLV, human T-cell lymphotropic virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer; WHO, World Health Organization.

Note: Not all subtypes are listed. **Malignancies in bold occur in at least 1% of patients.**

Clinical Presentation

CLINICAL PRESENTATION Hodgkin Lymphoma General

- Most patients with Hodgkin lymphoma have lymph node involvement in the supradiaphragmatic and mediastinal areas.

Symptoms

- About 25% of all patients present with fever, night sweats, and weight loss (ie, B symptoms), and up to 50% of patients with advanced disease.
- Fatigue, malaise, and pruritus.

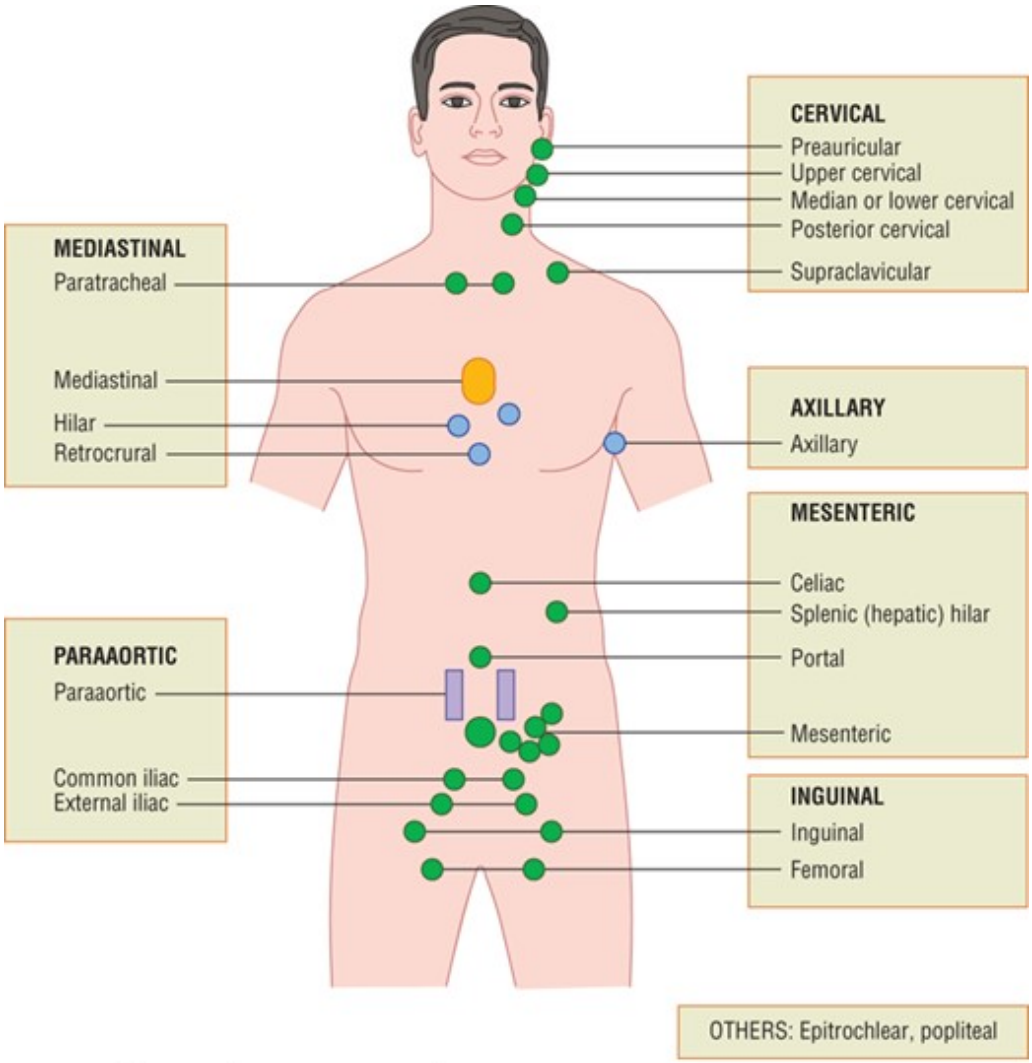
Signs

- Enlarged lymph node, which may present as painless and rubbery.

Most patients with Hodgkin lymphoma present with a painless, rubbery, enlarged lymph node in the supradiaphragmatic area and commonly have mediastinal nodal involvement. Lymphadenopathy may come and go, but persistence of lymphadenopathy more than 2 months warrants evaluation. Hodgkin lymphoma is occasionally diagnosed in an asymptomatic patient who has a mediastinal mass found with chest radiography or another imaging procedure. Asymptomatic adenopathy of the inguinal and axillary regions may be present at diagnosis but is less common (**Fig. 132-1**).[3,5] Patients can also present with constitutional symptoms (B symptoms) before the discovery of lymph node enlargement, and these symptoms include fever greater than 38°C (100.4°F), drenching night sweats, and weight loss greater than 10% within 6 months of diagnosis. At diagnosis, these symptoms may appear in about 25% of all patients and up to 50% of patients with advanced disease. Patients may also experience other nonspecific symptoms including pruritus, fatigue, and development of pain after alcohol consumption at sites where nodes are involved.[5] Extranodal manifestations, such as bowel and hepatic involvements, are much less common in Hodgkin lymphoma than NHL.[3]

FIGURE 132-1

Areas of lymph nodes used in the staging of Hodgkin and non-Hodgkin lymphoma. Each rectangle corresponds to a nodal area.



Diagnosis, Staging, and Prognostic Factors

Diagnostic and staging procedures are based on recommendations made at the Ann Arbor and Cotswolds conferences and new scientific advances, as described in the National Comprehensive Cancer Network (NCCN) guideline.[1] The diagnosis and pathologic classification of Hodgkin lymphoma can only be made by review of a biopsy (preferably an excisional biopsy) of the enlarged node by an expert hematopathologist.

In addition to a careful physical examination, routine laboratory tests including a complete blood count, complete metabolic panel to assess renal and hepatic function, lactate dehydrogenase (LDH), and erythrocyte sedimentation rate (ESR) will be helpful in treatment planning and aid in prognosis. Pregnancy test and HIV status should be assessed. Computed tomography (CT) scans of the chest,

abdomen, and pelvis are routinely performed. Furthermore, positron emission tomography (PET) plays an important role in the initial staging of Hodgkin lymphoma, as it has shown high sensitivity and specificity in the staging of the disease.[13] The use of integrated PET-CT has further improved the staging of Hodgkin lymphoma given that it can provide more sensitive and specific imaging as compared with each imaging alone. The NCCN guideline recommends diagnostic CT and integrated PET-CT scan (preferred) for initial staging.[1] Bone marrow biopsy is now only recommended in patients with cytopenias and a negative PET.

Staging can be based on clinical or pathologic findings. The clinical stage is based on all noninvasive procedures (history, physical examination, laboratory tests, and radiologic findings), whereas the pathologic stage is based on the biopsy findings of strategic sites (bone marrow, spleen, and abdominal nodes). Patients with extranodal disease (bone marrow, bone, or Waldeyer ring) contiguous to involved nodes are classified with the subscript "E" in the Cotswolds staging system.

The Ann Arbor staging classification, which was developed at the 1970 Ann Arbor conference, has proven to be a good schema. At the Cotswolds meeting in 1989, the Ann Arbor classification was modified to incorporate new diagnostic techniques (eg, CT and magnetic resonance imaging), and the understanding that prognosis is associated with the bulk of the disease and the number of involved nodal sites (**Table 132-2**).[5] After careful staging, about one-half of patients have localized disease (stages I, II, and II_E) and the remainder have advanced disease (stage III or IV). About 10% to 15% present with metastatic disease (stage IV). It is important to note that Hodgkin lymphoma appears to follow a predictable pattern of nodal spread that is not seen with the NHLs.[3,14]

TABLE 132-2 The Ann Arbor Staging Classification of Hodgkin Lymphoma

Stage I	Involvement of a single lymph node region or structure (I) or of a single extralymphatic organ or site (I_E)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (II_E). The number of nodal regions involved should be indicated by a subscript (eg, II_2)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of an extralymphatic organ or site (III_E) or by involvement of the spleen (IIIS) or both ($IIIS_E$). III_1: with or without splenic, hilar, celiac, or portal node involvement. III_2: with paraaortic, iliac, or mesenteric node involvement
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement A—No symptoms B—Fever, night sweats, weight loss (>10%) X—Bulky disease >One-third the width of the mediastinum

>10 cm maximal dimension of nodal mass

E—Involvement of extralymphatic tissue on one side of the diaphragm by limited direct extension from an adjacent, involved lymph node region

S—Involvement of the spleen

CS—Clinical stage

PS—Pathologic stage

Patient prognosis is predominately driven by age and amount of disease. Patients older than ages 65 to 70 have a lower cure rate than younger patients. The difference in cure rates may be related to the higher incidence of comorbid diseases and decreased organ function in older patients, which impairs their ability to tolerate intensive chemotherapy. Stage is a dominant factor in predicting survival; patients with limited-stage disease (stages I to II) have a 90% to 95% cure rate, while those with advanced disease (stages III to IV) have only a 60% to 80% cure rate.[3,5]

Seven adverse prognostic factors with similar impact on survival (each factor reduced survival by 7%-8% per year) have been identified through an international collaborative effort. These factors can be combined to generate an IPS that can be used to predict progression-free and overall survival (**Table 132-3**).[15]

TABLE 132-3 The International Prognostic Factors Project Score for Advanced Hodgkin Lymphoma

Risk Factors
Serum albumin (<4 g/dL [<40 g/L])
Hemoglobin (<10.5 g/dL [<105 g/L; 6.52 mmol/L])
Male gender
Stage IV disease
Age (≥45 years)
White blood cell (WBC) count (≥15,000 cells/mm^3 [≥15 × 10^9/L])
Lymphocytopenia (<600 cells/mm^3 [<0.6 × 10^9/L] or <8% of WBC count)

Number of Factors	Freedom from Progression[a]	Overall Survival[a]
0	84 ± 4	89 ± 2
1	77 ± 3	90 ± 2
2	67 ± 2	81 ± 2
3	60 ± 3	78 ± 3
4	51 ± 4	61 ± 4
≥5	42 ± 5	56 ± 5

[a]Percentage of patients at 5 years.

TREATMENT

Hodgkin Lymphoma

Desired Outcomes

The current goal in the treatment of Hodgkin lymphoma is to maximize curability while minimizing short- and long-term treatment-related complications. According to the Surveillance, Epidemiology, and End Results (SEER) database, the 5-year age-adjusted relative survival is greater than 80%.[7] Therefore, the initial treatment goal for all stages of Hodgkin lymphoma should be cure.

General Approach to Treatment

Combination chemotherapy is the primary treatment modality for most patients with Hodgkin lymphoma. In general, patients of all stages are initially treated with combination chemotherapy for about 8 to 12 weeks (depending on the regimen), and then restaged with PET-CT. Three combination chemotherapy regimens are primarily used for the initial treatment of classical Hodgkin lymphoma: ABVD, Stanford V, and some version of BEACOPP (bleomycin, etoposide, doxorubicin (Adriamycin®), cyclophosphamide, vincristine (Oncovin®), procarbazine, and prednisone). Depending on the initial radiographic response from the restaging, further chemotherapy with or without radiation is planned. For patients with refractory or recurrent disease, salvage therapy consists of multi-agent chemotherapy with or without high-dose chemotherapy and autologous hematopoietic stem cell transplantation (HSCT).[1,3,5]

Radiation is often an integral part of the treatment plan. Selected patients with early stage disease (usually nodular lymphocyte-predominant histology) can receive radiation as the only treatment modality, whereas most other patients with early stage disease may receive chemotherapy and radiation depending on the initial bulk of disease and the response to chemotherapy alone. Although radiation is a local therapy, many patients with advanced disease will also receive radiation therapy to residual or bulky disease sites after chemotherapy. Many different radiation techniques targeting different radiation fields have been used over the last few decades, including involved-field radiation (IFRT), extended-field radiation, subtotal nodal irradiation, and total nodal irradiation. The major concern with radiation therapy is its long-term effects, particularly on organs at risk, such as cardiovascular disease and secondary malignancies that commonly occur in the lung, breast, gastrointestinal tract and connective tissue.[16] Involved-site radiation therapy (ISRT) and involved-node radiation therapy are now being used as alternatives to the classic IFRT, and both define a smaller field than IFRT. ISRT targets the nodal sites and extranodal extensions that were involved at diagnosis but is intended to spare adjacent uninvolved organs when lymphadenopathy regresses after chemotherapy and ISRT. Additional techniques help to refine the volume of radiation delivered to the intended sites such as 4D-CT simulation planning, intensity modulated radiation therapy, image-guided RT, and respiratory gating.[17,18,19]

Although multiple treatment modalities are used to treat Hodgkin lymphoma, surgery has a limited role regardless of stage. Surgery is important for an accurate diagnosis via excisional biopsy, and on certain other occasions, such as placement of a central line. The following sections will review treatment of early stage favorable disease, early stage unfavorable disease, advanced-stage favorable disease, advanced-stage unfavorable disease, and salvage therapy.

Chemotherapy Regimens

Prior to the 1960s, the outcome for patients with Hodgkin lymphoma was dismal. Treatment with single-agent therapies or broad radiation fields provided excessive toxicities and few durable responses with advanced disease. The mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) regimen was introduced in the early 1960s and was the initial combination chemotherapy regimen shown to cure advanced Hodgkin lymphoma (**Table 132-4**). This was a tremendous advance in oncology at that time. MOPP chemotherapy was a mainstay of treatment for patients with stages III and IV advanced Hodgkin lymphoma for years to come. However, investigators later learned that MOPP is associated with high rates of sterility and secondary malignancies. The young population of Hodgkin survivors would live long enough to endure these consequences. The research focus was then shifted to maintain the high cure rates obtained with MOPP while decrease the long-term toxicities.

TABLE 132-4 Combination Chemotherapy Regimens for Hodgkin Lymphoma

Drug	Dosage (mg/m^2)	Route	Days
MOPP			
Mechlorethamine	6	IV	1, 8
Vincristine	1.4	IV	1, 8
Procarbazine	100	Oral	1-14
Prednisone	40	Oral	1-14
Repeat every 21 days			
ABVD			
Doxorubicin (Adriamycin®)	25	IV	1, 15
Bleomycin	10	IV	1, 15
Vinblastine	6	IV	1, 15
Dacarbazine	375	IV	1, 15
Repeat every 28 days			
MOPP/ABVD			
Alternating months of MOPP and ABVD			
MOPP/ABV hybrid			
Mechlorethamine	6	IV	1
Vincristine	1.4	IV	1

Drug	Dosage (mg/m^2)	Route	Days
Procarbazine	100	Oral	1-7
Prednisone	40	Oral	1-14
Doxorubicin	35	IV	8
Bleomycin	10	IV	8
Vinblastine	6	IV	8
Repeat every 28 days			
Stanford V			
Doxorubicin	25	IV	Weeks 1, 3, 5, 7, 9, 11
Vinblastine	6	IV	Weeks 1, 3, 5, 7, 9, 11
Mechlorethamine	6	IV	Weeks 1, 5, 9
Etoposide	60	IV	Weeks 3, 7, 11
Vincristine	1.4[a]	IV	Weeks 2, 4, 6, 8, 10, 12
Bleomycin	5	IV	Weeks 2, 4, 6, 8
Prednisone	40	Oral	Every other day for 12 weeks; begin tapering at week 10
One course (12 weeks)			
BEACOPP (standard-dose)			
Bleomycin	10	IV	8
Etoposide	100	IV	1-3
Adriamycin (doxorubicin)	25	IV	1
Cyclophosphamide	650	IV	1
Oncovin® (vincristine)	1.4[a]	IV	8
Procarbazine	100	Oral	1-7
Prednisone	40	Oral	1-14
Repeat every 21 days			
BEACOPP (escalated-dose)			
Bleomycin	10	IV	8
Etoposide	200	IV	1-3
Adriamycin (doxorubicin)	35	IV	1
Cyclophosphamide	1250	IV	1
Oncovin® (vincristine)	1.4[a]	IV	8
Procarbazine	100	Oral	1-7
Prednisone	40	Oral	1-14
Granulocyte colony-stimulating factor		Subcutaneously	8+

Drug	Dosage (mg/m^2)	Route	Days
Repeat every 21 days			

[a]Vincristine dose capped at 2 mg.

The development of ABVD by Bonnadonna and colleagues at the Milan Cancer Institute about a decade later represents the next important step in the evolution of therapy for Hodgkin lymphoma (see Table 132-4).[20] ABVD was initially shown to be effective in treating MOPP failures and was later compared directly to MOPP in advanced disease, where it produced an 82% complete response rate, as compared to a 67% complete response rate with MOPP. Improved failure-free survival was demonstrated with ABVD, but no significant differences in 5-year overall survival were noted.[21] Because ABVD was less toxic and provided similar or better outcomes than MOPP, it eventually replaced MOPP as the standard regimen for advanced-stage Hodgkin lymphoma.

In the early 1980s, the Goldie–Coldman hypothesis proposed that chemotherapy resistance was related to spontaneous mutation rates and the development of resistant clones. To test that hypothesis, researchers designed several clinical trials to evaluate the efficacy of alternating non–cross-resistant drug combinations in patients with Hodgkin lymphoma.[22] The initial approach adopted by investigators was to alternate or combine the MOPP and ABVD regimens. When MOPP and ABVD (or doxorubicin [Adriamycin®], bleomycin, vinblastine [ABV]) are combined in a monthly cycle, it is referred to as a hybrid regimen. Besides a potential benefit in efficacy, another potential benefit of alternating or hybrid regimens is the decreased risk of long-term toxicities. In the alternating MOPP/ABVD regimen, the cumulative doses of procarbazine and mechlorethamine are reduced by 50%, and the cumulative doxorubicin dose is reduced by 50%. In the hybrid regimen, the cumulative doxorubicin dose is reduced by 33%, and the cumulative bleomycin dose is reduced by 50%.

Several clinical trials have been performed to evaluate the efficacy of alternating or hybrid MOPP/ABVD regimens. The results of these trials show that alternating and hybrid regimens are superior to MOPP but not to ABVD.[22,23] Another approach evaluated by researchers was the administration of sequential cycles of MOPP and ABVD (MOPP/ABVD). Results of an intergroup trial showed sequential MOPP and ABVD to be inferior to the MOPP/ABV hybrid regimen in terms of response and survival.[23] In yet another randomized comparison trial of the MOPP/ABV hybrid regimen and ABVD, the complete remission rate, failure-free survival, and overall survival were similar between the two regimens.[24] The latter trial was closed prematurely because of an increased number of treatment-related deaths and secondary malignancies in the patients who received the MOPP/ABV hybrid regimen.

More aggressive regimens, such as Stanford V and BEACOPP, have been evaluated as alternatives to MOPP or ABVD. It is important to note that radiation therapy is an integral part of the Stanford V regimen for all patients. The Stanford V regimen generated considerable interest based on the results of phase II trials.[25] Stanford V, ABVD, and an MOPP/ABV hybrid-like regimen (mechlorethamine,

vincristine, procarbazine, prednisone, epidoxorubicin, bleomycin, vinblastine, lomustine, doxorubicin, and vindesine [MOPPEBVCAD]) were then compared in a randomized trial to determine the best regimen to support a reduced radiotherapy program.[26] Five-year failure-free and progression-free survival were significantly worse for the Stanford V regimen as compared to the other two regimens. However, no significant differences in overall response rate or 5-year overall or failure-free survival were observed between Stanford V and ABVD in a published randomized trial of patients with advanced Hodgkin lymphoma (E2496).[29] Investigators have speculated that differences in the application of radiotherapy may explain the divergent results in the randomized trials. More pulmonary toxicity occurred in the ABVD group, but other toxicities occurred more frequently in the Stanford V group.

The German Hodgkin Study Group (GHSG) developed the BEACOPP regimens based on the principles of dose density, dose intensity, and mathematical modeling. BEACOPP uses similar drugs as in the cyclophosphamide, vincristine, procarbazine, and prednisone (COPP)/ABVD regimen, but rearranges the drugs in a shorter 3-week cycle. Several different versions of BEACOPP have been developed: standard-dose BEACOPP, escalated-dose BEACOPP, and dose-dense BEACOPP (BEACOPP-14). Granulocyte colony-stimulating factor support is required for the escalated-dose BEACOPP and BEACOPP-14 regimens.

It is important to note that the initial evidence for these regimens focused on patients with advanced or metastatic disease as described in this section, but subsequent trials have focused on the use of these regimens in early stage disease.

Restaging during Therapy and Risk-adaptive Therapy

1 With all stages and risk-groups of Hodgkin lymphoma, it is current practice to treat with chemotherapy for 8 to 12 weeks and then obtain a restaging PET-CT.[1] This scan is assessed on a PET 5-point scale, also known as Deauville Criteria. Score 1 indicates no uptake, and can be called a complete response, or no measurable disease (**Table 132-5**).[30] For all stages of Hodgkin lymphoma, further treatment is based on the restaging PET/CT results such that residual uptake at the end of chemotherapy would likely indicate the need for ISRT. If a Deauville score of 5 exists after completion of chemotherapy, then a biopsy of the involved area is indicated. Based on these current guidelines, every patient's treatment plan is personalized based on the response to treatment.

TABLE 132-5 PET 5-Point Scale or Deauville Criteria

Score	PET/CT Scan Result
1	No uptake
2	Uptake ≤ mediastinum
3	Uptake > mediastinum but ≤ liver
4	Uptake moderately higher than liver
5	Uptake markedly higher than liver and/or new lesions
X	New areas of uptake unlikely to be related to lymphoma

Data from Barrington SF, Mikhaeel NG, Kostakoglu L, et al. Role of imaging in the staging and response assessment of Lymphoma: consensus of the International Conference on Malignant Lymphomas Imaging Working Group. *J Clin Oncol* 2014;32:3048-3058.

Classical Hodgkin Lymphoma

Hodgkin lymphoma can initially be divided into two broad classifications: classical Hodgkin lymphoma and NLPHL. Although classical Hodgkin lymphoma can be further divided into pathologic subtypes, the treatments are based on risk factors and presence of bulky disease regardless of the subtype of classical Hodgkin lymphoma.

Treatment of Early Stage Favorable Disease

Patients with early stage favorable disease have stage IA or IIA disease and no adverse risk factors (B-symptoms, extranodal disease, bulky disease, three or more sites of nodal involvement, or an ESR of >50 mm/h [>13.9 µm/s]). Extended-field radiation was previously considered to be the treatment of choice for stages IA and IIA disease. Although most patients were cured of their disease, the radiation is associated with long-term toxicities due to large radiation fields such as heart disease, pulmonary dysfunction, and secondary malignancies.[5,16]

Combined modality therapy (chemotherapy and radiation therapy) has replaced radiation therapy alone in patients with early stage favorable disease. With combined modality therapy, both a shorter duration of chemotherapy and newer, more focused radiation techniques (ISRT, others) are used in an attempt to decrease the long-term toxicities of both.

Clinical trials comparing radiation alone to radiation plus chemotherapy show lower relapse rates in patients treated with combined modality therapy (radiation and chemotherapy), but no change in overall survival because of the availability of effective salvage therapy. Ongoing trials focus on questions such as the optimal number of chemotherapy cycles, the volume of radiation that must be used to obtain optimal patient outcomes, and the role of PET scanning to individualize therapy. Long-term results of clinical trials also suggest that as few as two cycles of Stanford V or ABVD chemotherapy followed by IFRT is sufficient in favorable, early stage disease patients.[27,28] Different combination chemotherapy regimens have been used in these studies, and no one regimen is clearly superior to another.

Clinical trials have also investigated the use of chemotherapy alone to treat low-risk early stage Hodgkin lymphoma. Long-term results of clinical trials show a lower rate of disease control versus combined modality therapy. Selected patients can be treated with chemotherapy alone if they achieve a complete response following two cycles of chemotherapy, with a total treatment of four cycles of chemotherapy.

Clinical Controversy…

Some clinicians believe that radiation therapy can and should be excluded altogether for some patients, especially young patients who are at higher risk of reproductive and secondary malignancy

concerns.

The current NCCN guideline recommends that patients with early stage favorable disease be treated with two cycles of ABVD plus ISRT or two to four cycles of the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, and prednisone), followed by a restaging PET-CT scan. Depending on the response to the initial chemotherapy, consolidative ISRT is recommended if anything less than a complete response is achieved.[1] With this approach, 5-year progression-free and overall survival rates of more than 90% can be achieved in early stage favorable disease.

Treatment of Early Stage Unfavorable Disease

Patients with early stage disease who have certain features associated with a poor prognosis (B symptoms, extranodal disease, bulky disease, three or more sites of nodal involvement, or an ESR >50 mm/h [>13.9 μm/s]) are defined as having unfavorable disease. Different research groups or clinical trials have different definitions for unfavorable disease (**Table 132-6**). Current guidelines recommend combined modality therapy (combination chemotherapy and ISRT) to reduce the relapse rate and avoid the toxicity associated with extended-field radiation.[1]

TABLE 132-6 Examples of "Unfavorable Risk Factors" for Early-stage Hodgkin Lymphoma

Risk Factor	NCCN	GHSG	EORTC	NCIC
Age			≥50	≥40
ESR and B-symptoms	>50 mm/h (>13.9 μm/s) or any B symptoms	>50 mm/h (>13.9 μm/s) if A; >30 mm/h (>8.3 μm/s) if B symptoms	>50 mm/h (>13.9 μm/s) if A; >30 mm/h (>8.3 μm/s) if B symptoms	>50 mm/h (>13.9 μm/s) or any B symptoms
Mediastinal mass	MMR > 0.33 or >10 cm	MMR > 0.33	MTR > 0.35	MMR > 0.33 or >10 cm
Number of Nodal Sites	>3	>2*	>3*	>3
Other		Any extranodal lesion		Histology: mixed cellularity or lymphocyte deplete

EORTC, European Organization for the Research and Treatment of Cancer; GHSG, German Hodgkin Study Group; MMR, mediastinal mass ratio—maximum width of mass/maximum intrathoracic diameter; MTR, Mediastinal thoracic ratio—maximum width of mediastinal mass/intrathoracic diameter at T5-6; NCCN, National Comprehensive Cancer Network, USA; NCIC, National Cancer Institute, Canada.

*Definitions of lymph node regions differ.

Randomized trials show that combined modality therapy reduces the relapse rate in patients with early stage unfavorable disease. Different chemotherapy regimens and number of chemotherapy

cycles have been compared in clinical trials. In most studies involving early-stage unfavorable disease, ABVD is the comparator arm. ABVD plus 30 Gy [3,000 rad] ISRT remains the standard of care for patients with early stage unfavorable disease, but the Stanford V regimen plus radiation or BEACOPP for two cycles followed by ABVD for two cycles are both alternatives in select patients.[1] The Stanford V regimen has been studied in several single arm trials[31,32] and comparative trials versus ABVD[29,33] report overall response rates in the 90% range and 5-year overall survival from 88% to 94%. All of these trials included radiation therapy as part of the treatment schema. The GHSG studied the use of a more aggressive regimen of escalated-dose BEACOPP for two cycles followed by ABVD for two cycles versus ABVD for four cycles. Both treatment arms received 30 Gy [3,000 rad] of IFRT. Patients treated with BEACOPP had longer progression-free survival but similar 5-year overall survival as compared with ABVD.[34] BEACOPP is associated with more toxicities than ABVD in early stage unfavorable Hodgkin lymphoma.[35]

2 In summary, most patients with early stage disease will be treated with two to four cycles of ABVD chemotherapy and involved-site radiation. The number of cycles initially administered is based on the classification of favorable versus unfavorable disease. Restaging with a PET-CT after 4 to 12 weeks of chemotherapy further guides the need for more chemotherapy or radiation (ISRT), but most patients with unfavorable disease will require radiation. Clinical trials have demonstrated the utility of PET scans as biomarkers to individualize therapy and minimize the amount of therapy necessary for cure.[13] Although ABVD is the preferred initial regimen (NCCN category 1 recommendation), evidence supports the use of Stanford V in favorable and unfavorable early stage patients and escalated BEACOPP-ABVD in unfavorable early stage patients.[1] Despite excellent results from treatment with ABVD and radiation, about 5% of patients do not respond to initial treatment and another 15% of patients will relapse following an initial response.

Treatment of Advanced-Stage Disease

Advanced-stage disease consists of stages III and IV disease. In some studies, stage IIB with a large mediastinal mass or extranodal disease is also considered advanced-stage disease (see Table 132-2). By definition, patients with stages III and IV disease have tumors on both sides of the diaphragm, which almost always precludes the use of radiation alone as a therapeutic modality. Intensive combination chemotherapy is the mainstay of treatment, although some patients will benefit from radiation following chemotherapy. The prognosis of advanced-stage disease is excellent with 5-year overall survival rates ranging from 56% to 90%. Most patients obtain a complete response from their initial treatment. Prognostic factors have been identified and standardized to predict an individual's prognosis, according to the IPS (see Table 132-3).[15]

Patients with advanced-stage Hodgkin lymphoma can be classified into two groups based on the number of prognostic factors present from the IPS (see Table 132-3). Advanced-stage patients with three or fewer poor prognostic factors are considered to have favorable disease and have about a 60% likelihood of being failure-free at 5 years with traditional combination chemotherapy. Advanced-stage patients with four or more poor prognostic factors are considered to have unfavorable disease and a less than 50% likelihood of being failure-free at 5 years with traditional

combination chemotherapy. Cures are possible in patients with high-risk disease, but long-term disease control is a more realistic goal for most patients.

Combination Chemotherapy in Advanced-Stage Disease

Doxorubicin (Adriamycin®), bleomycin, vinblastine, and dacarbazine for (ABVD) decades has continued to be the standard initial regimens utilized for advanced Hodgkin lymphoma in many cancer programs. As discussed in the **Chemotherapy Regimens** section, many multinational, randomized large trials have demonstrated ABVD's sustained positive outcomes and lower toxicity profile as compared to other regimens.

The activity of the Stanford V regimen with ISRT in advanced Hodgkin lymphoma has been demonstrated in prospective trials. In a phase III intergroup trial (E2496) comparing ABVD to Stanford V with radiation therapy in either arm, no significant differences in the 5-year overall or failure-free survival were observed.[29]

The BEACOPP regimens were designed to provide a more aggressive treatment for advanced disease. Several randomized trials have compared BEACOPP to other regimens.[5,36] The GHSG conducted a large randomized comparison of COPP/ABVD (alternating), BEACOPP, or an escalated-dose BEACOPP regimen (HD9 trial).[36] Escalated-dose BEACOPP was the most active regimen in this study, with 10-year freedom from treatment failure at 82% and overall survival at 86%, but this regimen was also associated with more toxicities including secondary leukemias, and was particularly toxic in the elderly.[37,38] In the HD2000 study, patients with advanced Hodgkin lymphoma were randomized to receive six cycles of ABVD, four cycles of escalated-dose BEACOPP with two cycles of standard-dose BEACOPP, or a third chemotherapy regimen that is not a current standard of care.[39] BEACOPP was superior to ABVD for 5-year failure-free survival (78% vs 65%, $P = 0.036$) and progression-free survival (81% vs 68%, $P = 0.038$), but 5-year overall survival was not significantly different between ABVD and BEACOPP. It appears that BEACOPP may be superior to ABVD in patients with high-risk advanced Hodgkin lymphoma (IPS ≥3). Higher rates of neutropenia and severe infections were observed with BEACOPP as compared with ABVD. The HD2000 trial also demonstrated a higher risk of secondary malignancy in the BEACOPP versus ABVD arm (6.7 vs 0.9, $P = 0.027$) at 10 years.[40] Finally, GHSG has conducted several trials to evaluate the optimal number and intensity of BEACOPP. The HD12 and HD15 trials are two examples of this research.[41,42] The results of these studies suggest that escalated-dose BEACOPP is superior to ABVD in the treatment of advanced Hodgkin lymphoma, but at the cost of more treatment-related toxicity.

National Comprehensive Cancer Network currently recommends that patients with advanced disease be treated with ABVD, Stanford V or escalated-dose BEACOPP. NCCN further recommends that Stanford V may be considered in patients with IPS less than 3 and escalated-dose BEACOPP may be considered in patients less than 60 years old with an IPS of greater than or equal to 4.[1] As with earlier stage disease, combination chemotherapy should be administered for 4 to 18 weeks, depending on the regimen chosen, followed by a restaging PET scan. Based on the residual Deauville score, additional chemotherapy and/or radiation may be administered.

Summary for Advanced-Stage Hodgkin Lymphoma

3 In summary, there are several approaches to the initial treatment of stages III and IV Hodgkin lymphoma. A standard treatment of advanced-stage favorable Hodgkin lymphoma is to administer two cycles of ABVD chemotherapy followed by a restaging PET-CT. If minimal disease is found (Deauville score 1-3), 4 additional courses of ABVD should be given (total of 6 cycles). If residual disease is suspected (Deauville score 4-5), a switch to escalated-BEACOPP for 4 cycles should be considered. If the Stanford V regimen is selected for initial therapy, then the full 12 weeks of planned chemotherapy would be given before the restaging PET-CT. Escalated-dose BEACOPP for 6 cycles should be considered for patients with unfavorable disease. This risk-adapted approach should result in 70% to more than 90% of patients achieving a complete remission and 60% to 80% of patients being cured of their disease. No further treatment is needed for patients who achieve a complete remission (Deauville 1-2) with chemotherapy alone. Patients who achieve a partial remission (Deauville 3-5) should be considered for consolidative radiation to residual sites of disease. As with all stages and risk-groups of HL, if a Deauville score of 5 remains after completion of initial chemotherapy, a biopsy is recommended to determine if refractory disease is present.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma has been described as more indolent in nature, and has a better prognosis as compared with classical Hodgkin lymphoma. The use of radiation alone for stages I and II NLPHL patients who choose to omit chemotherapy or who cannot tolerate chemotherapy does not appear to adversely affect survival.[1] The disadvantage of radiation therapy alone as compared with combination chemotherapy plus radiation is the higher relapse rate. Patients who relapse after radiation alone (20%-25%) can be successfully salvaged with chemotherapy. If the decision is made to use radiation alone, ISRT is the preferred method. Patients with advanced-stage disease can be treated with combined chemotherapy and radiation therapy. Historically, MOPP and MOPP/ABVD have been used, but these regimens have fallen out of favor much like classical Hodgkin lymphoma. ABVD is frequently used in these patients due to the available evidence to support its use for classical Hodgkin lymphoma, although other regimens, such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), and CVP (cyclophosphamide, vincristine, and prednisone), have been studied. No randomized clinical trials of different chemotherapy regimens have been conducted in NLPHL. NLPHL reliably expresses CD20, and therefore rituximab has demonstrated efficacy in both newly diagnosed and progressive NLPHL. Several phase II trials have reported overall response rates of 90% to 100% with single agent rituximab.[43,44] Current NCCN guidelines recommend that patients with stage IA or IIA non-bulky disease preferentially be treated with ISRT alone. In very select patients with stage IA disease that was completely resected with the excisional biopsy, observation may be an option. Patients with IB, IIB, or advanced disease should receive chemotherapy with or without rituximab, with or without ISRT.[1]

Treatment of Refractory or Relapsed Disease

4 Refractory disease is defined as disease that persists following initial therapy, including any

response less than a complete response. Relapsed disease suggests tumor recurrence following attainment of a complete response. Patients who experience relapsed disease less than 12 months after the completion of therapy have a poor prognosis. The goal of second-line or salvage therapy is still cure. With the increasing use of chemotherapy with or without radiation, regardless of disease extent, the rate of primary refractory disease is decreasing. Many therapeutic options are available for treatment of refractory or relapsed disease, so each patient's treatment should be personalized. The highest survival and cure rates are reported for patients with chemosensitive disease who are medically able to undergo high-dose therapy and autologous HSCT.[45,46] Since most patients are initially treated with ABVD, doxorubicin should be avoided in salvage chemotherapy regimens if the cumulative dose has reached between 300 and 400 mg/m^2, particularly in those patients who have received mediastinal radiotherapy, because of the higher risk of cardiotoxicity.

The response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. Patients who relapse after radiation therapy alone have a good chance of being cured with combination chemotherapy, although fewer patients are being treated with radiation alone. High response rates (60%-87%) have been reported with salvage chemotherapy regimens.[3,5] Other patient groups who have a favorable prognosis following salvage therapy include patients who experience a local recurrence in a nonirradiated location and those who relapse more than 1 year after completion of their initial chemotherapy. Patients who experience late relapses can be cured with retreatment with the same chemotherapy regimen, treatment with a different, potentially non–cross-resistant regimen, or high-dose chemotherapy and autologous HSCT.

Patients who have an early relapse (<1 year after treatment) generally respond poorly to standard-dose salvage chemotherapy. High-dose chemotherapy and autologous HSCT is more effective, but also produces a higher risk of treatment-related mortality. Therefore, the choice of salvage treatment should consider the patient's tolerance for a particular set of chemotherapeutic agents and treatment approach (standard-dose chemotherapy vs high-dose chemotherapy and autologous HSCT).[46]

High-dose therapy should be considered in patients who relapse within 12 months of initial remission and in those who are refractory to first-line chemotherapy.[46] Although no single preparative regimen has been shown to be superior to another, most regimens do not include total-body irradiation because of its potential pulmonary toxicity. Most patients are already at higher risk for pulmonary toxicity because of previous exposure to one or more of the following: bleomycin, thoracic radiation, and nitrosoureas.

Brentuximab vedotin is an antibody-drug conjugate (ADC) comprising an anti-CD30 antibody conjugated by a protease cleavable linker to a potent antimicrotubule agent, monomethyl auristatin E (MMAE). After binding of the ADC to CD30 on the cell surface, the ADC-CD30 complex is internalized. This leads to the release of MMAE via proteolytic cleavage in the lysosomal compartment. Tubulin binding by MMAE disrupts the microtubule network, which can lead to apoptotic death of the cancer cells.[47] In a pivotal multicenter phase II study of 102 patients with relapsed or refractory Hodgkin lymphoma after HSCT, objective responses and complete remissions were observed in 75% and 34% of patients treated with brentuximab vedotin, respectively.

Brentuximab vedotin has also been evaluated as posttransplant consolidation therapy in a phase III trial in 329 patients undergoing autologous HSCT. All patients had a high risk of relapse, defined as disease refractory to initial therapy or relapsed disease less than 12 months from completion of initial therapy with extranodal disease. Patients randomized to receive 16 cycles of brentuximab had significantly longer median progression-free survival (42.9 vs 24.1 months) as compared with placebo.[48] Common toxicities associated with brentuximab vedotin include neuropathy, neutropenia, nausea, and fatigue.[49] Based on these results, the FDA has approved brentuximab vedotin (Adcetris®) for the treatment of classical Hodgkin lymphoma after failure of autologous HSCT or after failure of at least two prior multi-agent chemotherapy regimens in patients who are not candidates for autologous HSCT, and also for patients with classical Hodgkin lymphoma at high risk of relapse or progression as consolidation therapy after autologous HSCT.

Many single-agent and combination regimens can be used as salvage therapy. In this setting, the goal of therapy is disease control, and cures are unlikely. Gemcitabine, vinorelbine, and pegylated liposomal doxorubicin (GVD), ifosfamide, carboplatin, and etoposide (ICE) and ifosfamide, gemcitabine and vinorelbine are examples of chemotherapy regimens that include drugs with different mechanisms of action and toxicity profiles than regimens used earlier in therapy. Bendamustine, lenalidomide, and everolimus have all shown activity in patients with refractory or relapsed Hodgkin lymphoma.

Checkpoint inhibitors, specifically PD1 inhibitors (programmed death 1 pathway) are being studied in refractory Hodgkin lymphoma. Promising results are emerging from phase II trails that involve patients that are heavily pretreated. One trial with single-agent nivolumab reports an objective response rate of 87% with 17% being complete responses. The rate of progression-free survival at 24 weeks is cited at 86%.[49a]

Long-Term Complications

A variety of acute and chronic toxicities may occur as a result of treatment for Hodgkin lymphoma. Long-term complications of radiation therapy, chemotherapy, and combined modality therapy have become more evident as the curability and long-term survival of Hodgkin lymphoma patients has improved.[1,3,5,16] Gonadal dysfunction (including sterility and hypothyroidism), secondary malignancies, and cardiopulmonary diseases have become important considerations in the treatment of this malignancy. Almost all men and up to 50% of premenopausal women treated with six cycles of regimens containing alkylating agents become sterile. This appears to be a dose-related phenomenon. For men, even a single dose of nitrogen mustard or chlorambucil can cause sterility, so if fertility is a major concern, ABVD is the best alternative.[50]

The risk of secondary malignancies is increased about threefold in long-term survivors of Hodgkin lymphoma. The risk of developing leukemia carries the highest increase in risk and is seen with radiotherapy, chemotherapy, and chemoradiotherapy. Solid tumors, including breast cancers, gastrointestinal cancers, and lung cancers, are also likely to develop more than 10 years after the completion of treatment. A recently published British cohort study suggested that unlike radiotherapy, which may increase the occurrence of cancer at almost all anatomic sites,

chemotherapy is associated with an increased risk of leukemia, NHL, and lung cancer.[51] However, studies that evaluate the risk of secondary malignancies (and other complications) must be interpreted cautiously because many factors probably contribute to the development of secondary malignancies. In addition, much of the long-term complication data are derived from patients who were treated with older regimens and extensive field radiotherapy, which are no longer commonly used in clinical practice. As the field of cancer survivorship continues to grow, more specific recommendations for long-term follow-up are developed. Regular mammograms and breast MRI are recommended starting 10 years following the completion of therapy or at age 40 (whichever is earlier) for females. Patients are at increased risk of lung cancer if they have a smoking history, chest irradiation, and/or alkylating agent exposure. These patients should be considered for low-dose screening chest CT. For cardiovascular monitoring, annual blood pressure monitoring and aggressive management of cardiovascular risk factors are strongly encouraged. Hypothyroidism is reported in about 50% of long-term survivors who received irradiation to this area. Thyroid function tests should be performed annually. Monitoring and follow-up should be personalized and patient-specific, after assessing a patient's risks for long-term complications.[1]

NON-HODGKIN LYMPHOMA

The NHLs are a heterogeneous group of lymphoproliferative disorders that affect individuals from early childhood to late adulthood. Advances in molecular biology techniques and our understanding of the human immune system have led to major progress in understanding the pathogenesis and treatment of the lymphomas. NHLs are classified into distinct clinical entities that are defined by a combination of morphology, immunophenotype, genetic features, and clinical features. These differences influence the natural history, and approach and response to treatment. The use of extensive combination chemotherapeutic regimens shows dramatic improvement in survival and cure in patients with a disease that was once considered incurable. The 5-year survival rate for patients with NHL has increased from 48% to 71% over the past 25 years, and the mortality rate actually *declined* from 1997 to 2004.[6,7] Further improvement in survival is anticipated with the continued expansion of our therapeutic armamentarium, including high-dose chemotherapy and biologic therapy.

Epidemiology and Etiology

Non-Hodgkin lymphoma is the fifth most common cause of newly diagnosed cancer in the United States and accounts for about 4% of all cancers. An estimated 72,580 new cases will be diagnosed in 2016, and it is estimated that 19,020 people will die from NHL during this same period.[6] Although the average age of patients at the time of diagnosis is about 67 years, NHL can occur at any age. The incidence rate generally increases with age, and is higher in men than in women and in whites than in blacks.[5] The age-adjusted incidence rate of NHL increased by more than 80% in the United States since the early 1970s, from about 11 cases per 100,000 in 1975 to about 20 cases per 100,000 in 2011 and 2012.[7] The incidence of NHL increased by 3% to 4% from 1975 to 1991, but appears to have stabilized since reaching its peak in 1994. The increased incidence of NHL over the past three decades is second only to melanoma and has been referred to as an epidemic of NHL. Although the

increase has been noted particularly among the elderly and patients with acquired immune deficiency syndrome (AIDS), much of it cannot be explained by known risk factors.

The etiology of NHL is unknown, although several genetic diseases, environmental agents, and infectious agents are associated with the development of NHL.[52,53] An increased incidence of NHL is seen in many congenital and acquired immunodeficiency states, supporting the role of immune dysregulation in the etiology of NHL.[53] Patients with congenital immunodeficiency disorders such as Wiskott-Aldrich's syndrome and ataxia telangiectasia, acquired immunodeficiency disorders such as AIDS, and those receiving chronic pharmacologic immunosuppression in the setting of solid-organ transplantation are predisposed to the development of NHL. Autoimmune diseases (Hashimoto's thyroiditis and Sjögren's syndrome) cause chronic inflammation in the mucosa-associated lymphoid tissue (MALT), which predisposes patients to subsequent lymphoid malignancies. Other autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, are also associated with the development of NHL, but the use of immunosuppressive agents in these diseases makes the pathologic cause less clear.

Certain infections are associated with the development of lymphoma.[52] EBV was discovered in cell lines from tumors of patients with African (endemic) Burkitt lymphoma, and EBV DNA is associated with nearly all cases of endemic Burkitt lymphoma. However, EBV is associated with sporadic Burkitt lymphoma in 15% to 85% of cases. EBV is also associated with posttransplant lymphoproliferative disorders and some lymphomas in patients with AIDS or congenital immunodeficiencies. The human T-cell lymphotropic virus type 1 was the first human retrovirus associated with a malignancy. Infection with human T-cell lymphotropic virus type 1, especially in early childhood, is strongly associated with an aggressive form of T-cell lymphoma, known as adult T-cell leukemia/lymphoma. Human T-cell lymphotropic virus type 1 is endemic in parts of southern Japan, Africa, South America, and the Caribbean. In endemic areas, more than 50% of all NHL cases are adult T-cell leukemia/lymphoma. A third virus associated with NHL is human herpes virus 8 (also referred as Kaposi sarcoma–associated herpesvirus [KSHV]). This virus was originally isolated from Kaposi sarcoma lesions in AIDS patients. Gastric infection with *Helicobacter pylori*, a gram-negative bacteria that leads to chronic gastritis, is associated with gastric MALT lymphomas. Finally, hepatitis C virus has been associated with splenic and nodal marginal zone lymphomas.

A number of physical agents are also associated with the development of NHL.[53] Exposure to herbicides, particularly phenoxyl herbicides, is associated with the development of NHL. These observations may explain why certain occupations, such as farmers, forestry workers, and agricultural workers, are associated with a higher risk of NHL. Exposure to lawn-care pesticides is also increasing in the general population. A higher risk of NHL is also associated with exposure to other chemical solvents and dyes, exposure to radiation from nuclear explosions, and high intake of meats and dietary fats. Smoking or alcohol consumption is not strongly associated with an increased risk of NHL.

Molecular Abnormalities

Chromosomal translocations have become a hallmark of many lymphoid malignancies.[54,55] The

presence of these specific translocations can be helpful in the diagnosis and classification of lymphoid malignancies. The mechanisms leading to the translocations are unknown, but they usually involve the antigen receptor loci. In contrast to most myeloid and some lymphoid leukemias, NHLs usually place a structurally intact cellular protooncogene under the regulatory influence of highly expressed immunoglobulin or T-cell receptor genes, leading to effects on cell growth, cellular differentiation, or apoptosis. The most common chromosomal translocations involve t(8;14), t(14;18), and t(11;14); each translocation involves the immunoglobulin heavy-chain gene locus on chromosome 14 at 14q32. The translocation t(8;14) that involves c-*MYC*, a well-characterized oncogene clearly associated with malignancy, is implicated in nearly all cases of Burkitt lymphoma. The translocation t(14;18) that involves *BCL*-2, one of several putative B-cell lymphoma-associated oncogenes, is found in about 90% of cases of follicular B-cell lymphomas. The translocation t(11;14) that involves *BCL*-1 is found in about 70% of patients with mantle cell lymphoma (MCL). Another putative B-cell lymphoma-associated oncogene, *BCL*-6, is found in about one-third of diffuse large B-cell lymphomas (DLBCLs).

Although mutations in the *p53* tumor suppressor gene have been recognized in many human neoplasms, such mutations have not been consistently found in patients with lymphoma, which suggests that it may occur late in malignant evolution.

Because of their role in the pathogenesis of lymphoma, oncogenes are attractive molecular targets for the development of new and novel therapies.[56]

Pathology and Classification

Non-Hodgkin lymphomas are neoplasms derived from the monoclonal proliferation of malignant B or T lymphocytes and their precursors. About 85% to 90% of NHLs in the United States are of B-cell origin.[53] Proliferation of malignant cells results in the replacement of the normal cells and architecture of lymph nodes or bone marrow with a relatively uniform population of lymphoid cells. The classification of NHLs has evolved over the past five decades, as advances in immunology and genetics have allowed scientists to recognize a number of previously unrecognized subtypes of NHLs (**Table 132-7**).[57,58] The current classification schemes characterize the NHLs according to the cell of origin (B cell vs T cell), clinical features, and morphologic features. Additional immunohistochemical markers, cytogenetic features, and genotypic characteristics may help to further classify NHL into subtypes.

TABLE 132-7 Evolution in the Classification of Non-Hodgkin Lymphomas

Time	Classification System	Basis for Classification
1950s–1960s	Rappaport	Morphology
1970s–1980s	Luke–Collins	Morphology and immunophenotype
1970s–1980s	Kiel	Morphology and immunophenotype
1980s–1990s	International Working Formulation	Morphology and clinical behavior
1990s	REAL	Disease entities
2001	WHO	Disease entities

REAL, revised European–American Classification of Lymphoid Neoplasms developed by the International Lymphoma Study Group; WHO, World Health Organization.

Morphology

The macroscopic and microscopic appearance of the involved tissue remains one of the most important factors in the diagnosis and classification of NHLs.[57,58] In the 1950s, Rappaport et al. proposed a morphologic classification of malignant lymphomas based on two features: that the malignant cell would disrupt the nodal architecture in a *nodular* or *diffuse* manner, and that lymphomas of histiocytic origin existed. The Rappaport classification gained rapid acceptance in the United States because of its precision, simplicity, and prognostic significance. Application of the system divided NHLs into those with large (ie, incorrectly called "histiocytes") or small cells, with or without a nodular (ie, follicular) growth pattern.

Immunology

In the 1970s, it became apparent that NHLs were tumors of the immune system and were derived from B or T lymphocytes. With the availability of techniques using antibodies to antigens on the surface of lymphoid cells (ie, immunophenotype) and cytochemical assays, expert pathologists independently developed new classification schemes for NHL in the 1970s and 1980s.[57,58] The Kiel classification was based primarily on the work of Lennert in Germany and became widely used in Europe. In North America, the Lukes and Collins classification scheme was used briefly, but was soon superseded by the Working Formulation. Like the Rappaport classification, divisions within the Working Formulation were based largely on cell size (large [histiocytic] vs small [lymphocytic]), cell shape (round vs not round), and growth pattern (follicular [nodular] vs diffuse). Both the Kiel and Working Formulation classification schemes considered the histologic grade of the tumor, but only the Working Formulation considered actual survival curves of patients with the various subtypes of NHL. *Low-grade* indicated longer median survival (ie, indolent) whereas *intermediate-grade* and *high-grade* indicated shorter median survival (ie, aggressive). In the 1980s and early 1990s, the Working Formulation became the most widely used classification scheme in North America. It was based on the premise that NHL was a single disease with a range of histologic grades and clinical aggressiveness.

Disease Entities

In the 1980s and early 1990s, rapid advances in immunology and genetics allowed scientists to recognize a number of previously unrecognized subtypes of NHLs. Cytogenetic and molecular genetic analyses identified the presence of many chromosomal translocations, oncogenes, and their gene products in patients with NHL (see Molecular Abnormalities earlier in this Chapter). In addition, diseases that would have been lumped together as low-grade or intermediate/high grade in the Working Formulation showed marked differences in survival, which prompted scientists to reevaluate lymphoma classification schemes.

Information from these studies allowed scientists to further classify B-cell lymphomas as malignant

expansions of cells from the germinal center, mantle zone, or marginal zone of normal lymph nodes.[57,59] Germinal centers are complex structures that form in the spleen and lymph nodes in response to antigenic challenge. In addition to B cells, germinal centers contain antigen-presenting cells and helper T cells that cooperate in mediating the B-cell changes that result in a more potent secondary immune response. Malignant transformation often occurs or is initiated in germinal center B cells. Follicular, Burkitt, and most large cell lymphomas are believed to be tumors of germinal center B cells. Three histologically distinct microenvironments have been described within the germinal center: a mantle zone surrounding interior, dark, and light zones. The mantle zone contains small resting B cells that have not been exposed to antigens (naïve). Tumors of cells from the mantle zone are usually clinically indolent and histologically low grade. Antigen-triggered activation of the densely packed B cells of the dark zone causes cells to proliferate and subjects genomic DNA to somatic hypermutation. Surviving clones from within the dark zone then enter the light zone where proliferation slows and affinity selection occurs. During affinity selection, only cells with surface immunoglobulin receptors with high affinity for the antigen survive. Antigen-specific B cells generated in the germinal center reaction leave the follicle and reappear in the outer mantle zone, to form a marginal zone. Marginal zones are particularly prominent in mesenteric lymph nodes, Peyer's patches, and the spleen. These post-germinal center B cells include memory B cells of the marginal zone and plasma cells. Marginal cell B-cell lymphomas tend to be indolent and may be either extranodal or nodal; extranodal marginal cell B-cell lymphomas are also referred to as MALT lymphomas.

T-cell lymphomas can be classified on the basis of antigen expression as either precursor (thymic) or mature (peripheral) in origin. These classifications clinically translate to precursor lymphoblastic lymphomas or to a heterogeneous group of peripheral T-cell lymphomas. Tumors of natural killer or natural killer-like T cells are uncommon.

The International Lymphoma Study Group, an informal group of 19 hematopathologists from the United States, Europe, and Asia, adopted a new approach to lymphoma classification in 1993. Because it represented a revision of current or prior European and American lymphoma classifications, it was called the Revised European-American Classification of Lymphoid Neoplasms (REAL). The REAL classification system is based on the principle that a classification is a list of "real" disease entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features.[57,58] The relative importance of each of these criteria for both definition and diagnosis differs among different diseases. Morphology is always important, and some diseases are primarily defined by morphology alone (eg, follicular lymphoma), although immunophenotype can be helpful in difficult cases. Some diseases have a specific immunophenotype (eg, MCL, small lymphocytic lymphoma) that is virtually diagnostic of that disease. A specific genetic abnormality is important in some lymphomas—t(11;14) in MCL, t(8;14) in Burkitt lymphoma, and t(14;18) in follicular lymphoma—whereas other lymphomas lack specific genetic abnormalities (eg, MALT lymphoma, DLBCL). Finally, other lymphomas consider clinical features (eg, extranodal vs nodal presentation in marginal zone lymphoma and peripheral T-cell lymphoma).

Since 1995, members of the European and American Hematopathology societies have worked to develop a new WHO classification of hematologic malignancies. The final classification was published

in 2001, and revised in 2008 and 2016.[12,57,58] The WHO classification uses an updated version of the REAL classification and expands the principles of the REAL classification to the classification of myeloid and lymphoid malignancies.

5 The 2016 WHO classification categorizes lymphoid malignancies into two major categories: B-cell lymphomas and T-cell (and natural killer cell) lymphomas (see Table 132-1).[12,57,58] B-cell lymphomas represent about 85% to 90% of all NHLs. Lymphomas within each category can be divided into malignancies of precursor or mature cells. Hodgkin lymphoma and multiple myeloma are now recognized as mature B-cell neoplasms. The WHO classification uses the term *grade* to refer to histologic parameters such as cell and nuclear size, density of chromatin, and proliferation fraction, and the term *aggressiveness* to denote clinical behavior of a tumor. This classification scheme includes both lymphomas and lymphoid leukemias because there is no distinction between the solid and circulating forms of these diseases. The WHO classification includes several previously unrecognized types of lymphomas, and new entities not specifically recognized in the Working Formulation account for about 20% to 25% of the cases.

The WHO classification has broad clinical implications. The WHO Clinical Advisory Committee has agreed that clinical groupings of lymphoid neoplasms into prognostic categories are neither necessary nor desirable because such arbitrary groupings are of no practical value and may be misleading.[60]

Clinical Presentation

CLINICAL PRESENTATION Non-Hodgkin Lymphoma General

- Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal.

Symptoms

- About 40% of patients present with fever, night sweats, and weight loss (ie, B symptoms).
- Fatigue, malaise, and pruritus.

Signs

- More than two-thirds of patients present with peripheral lymphadenopathy.

Laboratory Tests

- A complete blood count, tests of renal and liver function, and serum electrolytes should be obtained.
- Serum β_2-microglobulin and LDH levels may be useful as prognostic factors and for monitoring response to therapy.

Other Diagnostic Tests

- Varies depending on sites of involvement.

6 Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal. Sites of involvement and dissemination of the malignant cells can sometimes be predicted based on the cell of origin and the tendency of tumors to frequently disseminate to areas where the normal counterparts of the lymphoma cells are located. For example, B-cell lymphomas involve areas of the lymphoid system normally populated by B-lymphocytes such as lymph nodes, spleen, and bone marrow. T-cell lymphomas commonly disseminate to various extranodal sites such as the skin and lungs.[55]

Most patients present with peripheral lymphadenopathy. The lymphadenopathy may be either localized or generalized, and the involved nodes are often painless, rubbery, and discrete, and usually located in the cervical and supraclavicular regions as in Hodgkin lymphoma (see Fig. 132-1). Rapid and progressive lymphadenopathy is more characteristic of aggressive lymphomas. Waxing and waning of lymph nodes, including their complete disappearance and reappearance, is more characteristic of indolent lymphomas. Massive lymphadenopathy can sometimes lead to organ dysfunction. For example, patients with NHL may present with acute renal failure from retroperitoneal adenopathy causing ureteral obstruction or from metabolic abnormalities such as hyperuricemia with uric acid nephropathy.

About 40% of patients with NHL present with fever (temperature >38°C [100.4°F]), weight loss (unexplained weight loss of 10% of body weight over the past 6 months), or night sweats (drenching night sweats). If one or more of these symptoms is present, the patient is noted to have B symptoms, and a B is added to the stage of disease (discussed in the Diagnosis, Staging, and Prognostic Factors section under Hodgkin Lymphoma earlier in this Chapter). B symptoms are more commonly observed in patients with aggressive NHLs.

Patients with Hodgkin lymphoma rarely present with extranodal (ie, extralymphatic) disease, but 10% to 35% of patients with NHL have primary extranodal disease at the time of diagnosis. The frequency of extranodal presentation varies dramatically among different subtypes. The most common extranodal sites are the gastrointestinal tract followed by the skin. The liver or spleen may be enlarged in patients with generalized adenopathy. Patients with mesenteric or gastrointestinal involvement may present with signs and symptoms of nausea, vomiting, obstruction, abdominal pain, a palpable abdominal mass, or gastrointestinal bleeding. Patients with bone marrow involvement may have symptoms related to anemia, neutropenia, or thrombocytopenia. Other sites of extranodal disease include the testes and bone. The incidence of solitary brain lymphoma is increasing, especially in patients with AIDS.

Diagnosis, Staging, and Prognostic Factors

As with Hodgkin lymphoma, the diagnosis of NHL must be established by pathologic review of tissue obtained by biopsy.[55,61] The preferred procedure is an excisional biopsy, where the entire involved lymph node is removed for review by an experienced hematopathologist. This procedure should be done carefully to prevent distortional artifact of the architecture, which could lead to an inaccurate

diagnosis. Needle biopsy of the node can sometimes provide adequate tissue for pathologic diagnosis, if an excisional biopsy cannot be performed. When adenopathy is not present, diagnosis may be established by biopsy of cutaneous lesions, bone marrow biopsy and aspiration in patients with unexplained myelosuppression, liver biopsy in patients with hepatomegaly or elevated liver function tests, or biopsy of involved extranodal organs such as bone, Waldeyer's ring, lung, and testis.

After the diagnosis is established, further work-up is required to determine the extent of involvement.[55,61] Clinical staging always begins with a thorough history and physical examination. Patients should be questioned about the presence or absence and extent of fever, night sweats, and weight loss. A detailed history of lymphadenopathy should also be obtained, including when and where the lymph nodes were first noted, and their rate of growth. A complete physical examination is performed to assess the extent of disease involvement, with special attention given to all nodal areas (see Fig. 132-1). All patients should have a complete blood count, serum chemistries including liver and renal profiles, a chest radiograph, and bone marrow aspiration and biopsy. The likelihood of bone marrow involvement varies among the different histologic types of lymphoma (**Table 132-8**). Lumbar puncture to evaluate the cerebrospinal fluid is recommended in patients who have histologic types of lymphoma that often spread to the CNS.

TABLE 132-8 Clinical Characteristics of Patients with Common Types of Non-Hodgkin Lymphomas

Disease	Median Age (Years)	Frequency in Children	% Male	Stage I/II vs III/IV (%)	B Symptoms (%)	BM Involvement (%)	GI Tract Involvement (%)	% Surviving 5 years
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma	65	Rare	53	9 vs 91	33	72	3	51
Mantle cell lymphoma	63	Rare	74	20 vs 80	28	64	9	27
Extranodal marginal zone B-cell lymphoma of MALT type	60	Rare	48	67 vs 33	19	14	50	74
Follicular lymphoma	59	Rare	42	33 vs 67	28	42	4	72
Diffuse large B-cell lymphoma	64	≈25% of childhood NHL	55	54 vs 46	33	16	18	46
Burkitt lymphoma	31	≈30% of childhood NHL	89	62 vs 38	22	33	11	45

Disease	Median Age (Years)	Frequency in Children	% Male	Stage I/II vs III/IV (%)	B Symptoms (%)	BM Involvement (%)	GI Tract Involvement (%)	% Surviving 5 years
Precursor T-cell lymphoblastic lymphoma	28	≈40% of childhood NHL	64	11 vs 89	21	50	4	26
Anaplastic large T-/null cell lymphoma	34	Common	69	51 vs 49	53	13	9	77
Peripheral T-cell non-Hodgkin lymphoma	61	≈5% of childhood NHL	55	20 vs 80	50	36	15	25

BM, bone marrow; GI, gastrointestinal; MALT, mucosa-associated lymphoid tissue; NHL, non-Hodgkin lymphoma.

Imaging studies are usually important in the staging work-up. CT scanning can identify both nodal and extranodal sites of disease, and has largely replaced lymphangiography for the evaluation of retroperitoneal lymphadenopathy. The abdominal and pelvic CT scan can identify mesenteric and retrocrural node involvement. CT scans can also detect tumor involvement of organs, including the kidneys, ovary, spleen, and liver. PET is currently not used routinely for staging of NHL.[61,62] Magnetic resonance imaging is of limited usefulness in the staging of NHL. Gallium scans are sometimes used as part of the staging work-up. Other tests, such as liver-spleen scan, bone scan, upper gastrointestinal series, and IV pyelogram, are sometimes useful in patients with organ symptomatology or serum chemistry abnormalities.

Although staging laparotomy was widely used in the late 1960s and 1970s as part of the staging work-up in patients with lymphoma, it is rarely used today because of technical improvements in imaging studies and the morbidity and potential mortality associated with the procedure.

The Ann Arbor staging classification developed for the clinical staging of Hodgkin lymphoma is also used to stage patients with NHL (see Table 132-2). After completion of the staging work-up, most patients will be found to have advanced disease (stages III and IV). The frequency of localized disease at the time of diagnosis varies depending on the histologic type of lymphoma (see Table 132-8). Stage is a more important prognostic factor in Hodgkin lymphoma than in NHL.

7 The Ann Arbor system emphasizes the distribution of nodal disease sites because Hodgkin lymphoma usually spreads through contiguous lymph nodes and does not involve extranodal sites. But NHL is a disease with tremendous heterogeneity that does not spread through contiguous lymph

nodes and that often involves extranodal sites. As a result of these clinical differences between Hodgkin lymphoma and NHL, Ann Arbor stage correlates poorly with prognosis.

8 This lack of accuracy with the Ann Arbor staging system in NHL has led to several international projects to develop prognostic models for the most common types of NHLs—DLBCLs and follicular lymphomas. The International Non-Hodgkin Lymphoma Prognostic Factors Project was based on more than 2,000 patients with diffuse aggressive lymphomas treated with an anthracycline-containing combination chemotherapy regimen in the United States, Europe, and Canada.[63] The Project identified five risk factors that correlated with low complete response rate to chemotherapy and poor survival: age older than 60 years, reduced performance status more than or equal to 2, abnormal serum LDH levels, two or more extranodal sites of disease, and advanced tumor stage (Ann Arbor stage III or IV) (**Table 132-9**). In patients older than or equal to 60 years old, three risk factors correlated with low complete response rate to chemotherapy and poor survival: reduced performance status, abnormal serum LDH levels, and Ann Arbor stage. It is unclear whether the effect of serum LDH level is related to a tumor or a host event. LDH likely measures cellular catabolism (the enzyme is released from injured cells), or the product of tumor burden and proliferation. Because each of the factors has about the same impact (eg, relative risk) on prognosis, the number of adverse risk factors is summed to provide the IPI. Patients could, therefore, have a score of 0 to 5. For patients older than or equal to 60 years old, a simplified IPI score can be developed based on Ann Arbor stage, serum LDH level, and performance status.

TABLE 132-9 Risk Factors and Survival According to the International Non-Hodgkin Lymphoma Prognostic Factors Project

All Patients	Patients ≤60 Years of Age
Age >60 years	Abnormal LDH level
Abnormal LDH level	Performance status ≥2
Performance status ≥2	Ann Arbor stage III or IV
Ann Arbor stage III or IV	
Extranodal involvement ≥2 sites	

LDH, lactic dehydrogenase.

Data from reference 67.

As prognosis improves as a result of more effective therapy, it is important to reevaluate prognostic factors. The IPI was based on patients treated from 1982 to 1987 with anthracycline-based combination chemotherapy; none of the patients received rituximab. In a reexamination of the IPI in a cohort of patients treated with rituximab-containing chemotherapy, Sehn et al. found that the IPI remained predictive, but it only identified two, rather than four, risk groups.[64] When the number of risk factors is redistributed, three risk groups are identified that correlate with prognosis. This revised IPI score may more accurately predict prognosis in patients treated with rituximab-containing combination chemotherapy, but needs to be validated in a larger group of patients.

Although the IPI is often used to predict prognosis in patients with other NHL subtypes, the IPI has

several shortcomings when applied to patients with indolent lymphomas. Because only patients with diffuse aggressive lymphomas were used to develop the IPI system, some important prognostic factors may have been missed. Furthermore, the IPI system has limited discriminating power in follicular lymphoma because only about 10% of patients are categorized as high-risk in the IPI system. To address these concerns, an international cooperative study was designed to develop a prognostic model similar to the IPI in patients with follicular lymphoma. The results of that study, which was based on more than 4,000 patients with follicular lymphoma diagnosed between 1985 and 1992, were recently published.[65] Five factors were identified that correlated with poor survival: age older than 60 years, advanced tumor stage (Ann Arbor stage III or IV), low hemoglobin level (<12 g/dL [<120 g/L; <7.45 mmol/L]), five or more nodal sites of disease (see Fig. 132-1), and an abnormal serum LDH level. Analogous to the IPI, the number of adverse risk factors is summed to provide the Follicular Lymphoma International Prognostic Index (FLIPI). Three prognostic groups were identified: low-risk (0-1 factors), intermediate-risk (2 factors), and high-risk (≥3 factors). FLIPI appeared to have higher discriminating power among groups as compared with the IPI system. **Table 132-10** shows the correlation between the FLIPI score and overall survival. The survival data from FLIPI, however, may not reflect current treatment results because none of the patients in the cohort used to derive the FLIPI were treated with rituximab. In an updated prognostic model (FLIPI-2) derived from patients with newly diagnosed follicular lymphoma treated with rituximab-containing chemoimmunotherapy regimens, age older than 60 years, low hemoglobin level (<12 g/dL [<120 g/L; <7.45 mmol/L]), longest diameter of the largest lymph node more than 6 cm, abnormal β_2-microglobulin levels and bone marrow involvement were identified as adverse risk factors. FLIPI-2 was highly predictive of treatment outcomes and separated patients into three distinct risk groups: low-risk (0 factors), intermediate-risk (1 or 2 factors), and high-risk (≥3 factors). Three-year progression-free survival was 91%, 69%, and 51% and overall survival was 99%, 96%, and 84% in low-, intermediate-, and high-risk patients, respectively.[66]

TABLE 132-10 Risk Factors and Survival According to the Follicular Lymphoma International Prognostic Index

All Patients	
Age >60 years	
Ann Arbor stage III or IV	
Number of nodal sites ≥5	
Abnormal lactate dehydrogenase level	
Hemoglobin <12 g/dL (<120 g/L; <7.45 mmol/L)	
Risk Group (% of Patients)	**Number of Risk Factors**
Low (36)	0–1
Intermediate (37)	2
High (27)	≥3

Although IPI and FLIPI are clinically useful tools to estimate prognosis, the factors used to calculate these scores probably represent clinical surrogates for the biologic heterogeneity among NHLs and many researchers are interested in determining the prognostic importance of certain phenotypic and

molecular characteristics of NHLs. For example, molecular markers of apoptosis, cell-cycle regulation, cell lineage, and cell proliferation are being evaluated as potentially clinically useful prognostic factors.[67]

Gene expression profiling with microarrays may also correlate with survival. Using gene expression profiling, investigators identified at least two molecularly distinct forms of DLBCLs based on gene expression patterns indicative of different stages of B-cell differentiation: germinal center B-cell–like (GCB) and activated B-cell–like (ABC).[67,68] The GCB subtype of DLBCL probably arises from normal germinal center B-cells while the ABC subtype may arise from post-germinal center B-cells. Many oncogenic pathways are different for the GCB and ABC subtypes, and these differences may lead to the development of targeted therapies for each subtype.[59,67] Patients with the germinal center B-cell profile had significantly better overall survival independent of IPI score after treatment with cyclophosphamide, doxorubicin [hydroxydaunorubicin], vincristine (Oncovin®), prednisone (CHOP) or CHOP-like chemotherapy. In a recently published study of patients with DLBCL treated with either CHOP or rituximab and CHOP (R-CHOP), Lenz et al. identified several gene expressions signatures that predicted survival in both CHOP and R-CHOP cohorts: GCB, stromal-1, and stromal-2.[69] The GCB and stromal-1 signatures were associated with a favorable prognosis while the stromal-2 signature was associated with an unfavorable prognosis. The stromal-1 signature reflects extracellular matrix deposition and histiocytic infiltration whereas the stromal-2 signature reflects tumor blood vessel density. It is speculated that DLBCLs that express the stromal-2 signature may respond to antiangiogenic agents.

Another recently identified molecular subtype is double-hit DLBCL, defined as the existence of both MYC gene arrangement and t(14;18) BCL2 translocation.[70] In one pathologic study that used immunohistochemical scoring, patients with high expression of both BCL2 and MYC protein had the worst prognosis. Double-hit NHL is associated with significantly lower complete response rate, shorter overall survival and shorter progression-free survival.[71] The NCCN guideline suggests that patients with double-hit lymphoma usually have a very poor prognosis, with a median overall survival that is 4 to 6 months even with highly aggressive chemotherapy. Some lymphoma experts suggest that patients with double-hit NHL should be treated with regimens that are more dose-intensive.[67]

Two molecularly distinct profiles of follicular lymphoma also have been identified; the first included genes encoding for T-cell markers and genes highly expressed in macrophages, and the second included genes that are preferentially expressed in macrophages, dendritic cells, or both.[72] Patients with the first molecular signature had a more favorable outcome than those with the second signature. These results suggest that molecular classification of tumors on the basis of gene expression may allow identification of clinically significant subtypes of cancer.

TREATMENT

Non-Hodgkin Lymphoma

Desired Outcomes

The primary goals in the treatment of NHL are to relieve symptoms, cure the patient of the disease whenever possible, and minimize the risk of serious toxicities. The treatment strategy depends on many factors, including the patient's age, concomitant disease, disease type, stage of disease, site of disease, and patient preference.

General Approach

9 Historically, both the clinical behavior and degree of aggressiveness are often used to describe NHLs. Indolent lymphomas, which make up about 25% to 40% of all NHLs, are characterized by their slow-growth behavior. Patients with an indolent lymphoma usually have a relatively long survival (measured in years), with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, there is no convincing evidence of a survival plateau, which indicates that patients are rarely cured of their disease. In contrast, aggressive lymphomas, which make up about 60% to 75% of all NHLs, are characterized by rapid growth rate and short survival (measured in weeks to months), if appropriate therapy is not initiated. Despite their more aggressive nature, many patients with aggressive lymphomas who respond to chemotherapy can experience prolonged disease-free survival and some are cured of their disease. Therefore, the terminology for the NHLs represents a paradox, where "indolent" is bad and "aggressive" is good in terms of the likelihood for cure.

Therapeutic approaches to NHL include radiation therapy, chemotherapy, and biologic agents. The role of radiation therapy in the treatment of NHL differs from its role in the treatment of Hodgkin lymphoma. Although the disease responds to radiation therapy, only a small percentage of patients with NHL present with truly localized disease that can be treated with local or regional radiation therapy. Radiation therapy is used more commonly in advanced disease, primarily as a palliative measure to control local bulky disease.

Effective chemotherapy for NHL ranges from single-agent therapy in indolent lymphomas to aggressive, complex chemotherapy regimens in aggressive lymphomas. The most active agents used in the treatment of NHL include the alkylating agents (eg, cyclophosphamide, chlorambucil), bleomycin, doxorubicin, purine analogs, etoposide, methotrexate, vincristine, and corticosteroids (eg, prednisone, dexamethasone). The most aggressive chemotherapy approaches are dose-dense chemotherapy or high-dose chemotherapy followed by autologous or allogeneic HSCT.

B-cell lymphomas have served as a model for immunotherapy with monoclonal antibodies for more than 20 years, beginning with the successful use of custom-made monoclonal antibodies targeted against the idiotype present on the patient's cancer cells.[73,74] These encouraging results lead to the development of monoclonal antibodies against a more generic target, a molecule on the surface of B cells that would be present on tumor cells. One potential target, the CD20 molecule, is present only on cells in the B-lymphocyte lineage. It is expressed on the surface of both normal and malignant B cells, but not on other normal tissues. Rituximab (Rituxan®) is a chimeric monoclonal antibody directed at the CD20 molecule. Its antitumor activity is mediated through complement-dependent cytotoxicity, antibody-dependent cytotoxicity, and induction of apoptosis.[74] With the availability of monoclonal antibodies and radioimmunoconjugates for the therapy of lymphoma, nearly all patients

with NHL will receive one or more biologic agents during the course of their disease.

Objective response to therapy for NHL should be defined according to the International Workshop to Standardize Response Criteria for Non-Hodgkin Lymphoma, which was recently updated to incorporate the results of newer tests to monitor response such as PET, immunohistochemistry, and flow cytometry.[62] The revised guidelines describe criteria for response (eg, complete response, partial response, and stable disease) and survival (eg, overall, disease-free, event-free, and progression-free).

Appropriate therapy for NHL depends on the patient's age, histologic type, stage of disease, site of disease, and presence of adverse prognostic factors (as measured by IPI or FLIPI score), and patient preferences. In general, treatment of lymphoma can be divided into limited disease and advanced disease. Limited disease includes those patients with localized disease (Ann Arbor stages I and II). Advanced disease is defined as all Ann Arbor stage III or IV patients, and also frequently includes Ann Arbor stage II patients with poor prognostic features (see Tables 132-6 and 132-7).[63,65]

The following section discusses the clinical characteristics and therapy of the most common disease entities.

Follicular Lymphomas

The combined group of follicular lymphomas makes up the second most common histologic type of NHL in the United States, comprising about 20% of all NHLs worldwide and up to 70% of indolent lymphomas reported in American and European clinical trials.[75] The WHO classification includes criteria for grading follicular lymphoma based on the number of centroblasts per high-power field: grade 1 to 2 (0-15 centroblasts/high-power field) and grade 3 (>15 centroblasts/high-power field).[12] The clinical behavior and treatment outcome of grades 1 and 2 follicular lymphoma are similar, and they are usually treated as indolent lymphomas. In contrast, grade 3 follicular lymphoma is synonymous with what is often referred to as follicular large cell lymphoma and is usually treated as an aggressive lymphoma.

Follicular lymphomas tend to occur in older adults, with a slight female predominance (see Table 132-6). Most patients have advanced disease at diagnosis, but about 25% to 33% of patients have localized disease (clinical stage I or II) at diagnosis.[76] Extranodal disease, bulky disease, and B symptoms are uncommon features at diagnosis. Most patients with follicular lymphoma have the chromosomal translocation t(14;18) at the time of diagnosis.

The clinical course is generally indolent, with median survivals of 8 to 10 years. But the natural history of follicular lymphoma can be unpredictable. Spontaneous regression of objective disease has been noted in as many as 20% to 30% of patients.[77] There is also a high conversion rate of follicular lymphoma to a more aggressive histology over time that steadily increases after diagnosis and reaches about 30% at 10 years.[78] At autopsy, most patients with follicular lymphoma have some evidence of DLBCL. Patients with transformed indolent lymphoma should be treated in the same way as patients with an aggressive lymphoma.

Most patients have dramatic responses to initial therapy, and their disease course is characterized by

multiple relapses, with responses to salvage therapy becoming progressively shorter after every relapse, eventually leading to death from disease-related causes. This pattern of constant relapses over time without evidence of a survival plateau and the failure of randomized controlled trials to show a survival benefit with aggressive chemotherapy led to the conclusion that therapy does not prolong overall survival and patients are not cured of their disease. However, several recently published studies suggest that the use of biologic agents, particularly rituximab, has changed the natural history of the follicular lymphoma. In a study of patients enrolled in Southwest Oncology Group (SWOG) trials over a period of more than 20 years, patients treated with CHOP and a monoclonal antibody had a significantly longer 4-year overall survival than those treated with CHOP alone (91% vs 69%).[79] Similar results were reported in patients treated over a 30-year period at the M.D. Anderson Cancer Center.[80] That study also showed an apparent plateau in the failure-free survival curve.

Certain subsets of patients with follicular lymphoma have a much better or worse prognosis. Some studies suggest that the natural history of follicular large cell lymphoma (ie, grade 3 follicular lymphoma) is similar to that of other aggressive lymphomas and that treatment with intensive combination chemotherapy regimens may result in long-term disease-free survival, including a possible plateau in the survival curve.[75] The recent development of the FLIPI prognostic model should help clinicians to identify patients in different prognostic groups based on disease characteristics at the time of diagnosis.[65] Patients who are predicted to have a poor prognosis (ie, high-risk) could then be offered aggressive or experimental therapy, while those who are predicted to have a good prognosis (ie, low-risk) would be treated with standard therapy, avoiding unnecessary toxicity.

Treatment of Localized Disease (Stages I and II)

Radiation therapy is the standard treatment for early stage follicular lymphoma. Involved-field, extended-field, and total nodal irradiation have been used. Carefully staged patients with either stage I or contiguous stage II disease treated with radiation therapy alone can achieve disease-free survival rates of 40% to 50% and overall survival rates of 60% to 70% at 10 years.[75] Late relapses are uncommon; only 10% of patients who reached 10 years without relapse subsequently experienced a recurrence.

Chemotherapy is not usually given in most patients with localized follicular lymphoma, but it may be helpful in some patients with high-risk stage II disease (eg, multiple sites of involvement or bulky disease).[81]

10 About 40% to 60% of patients with clinical stage I or II follicular lymphoma are cured of their disease with radiation therapy alone.[61] Most centers use radiation at a dose of 30 to 40 Gy (3,000-4,000 rad) to either involved (ie, local) or regional fields, which would consist of irradiation to the involved nodal region plus one additional uninvolved region on each side of the involved nodes. Extended-field irradiation is not usually used because of the absence of a survival benefit and possible increased risk of secondary malignancies. In addition, previous use of extended-field irradiation compromises the ability of that patient to receive subsequent chemotherapy. The current

NCCN guideline states that locoregional radiation therapy is preferred for most patients with early stage follicular lymphoma.[61] Immunotherapy (ie, rituximab) with or without chemotherapy is also listed as an option.

Treatment of Advanced Disease (Stages II Bulky, III, and IV)

The management of stages II Bulky, III, and IV indolent lymphomas remains controversial because until recently, no therapeutic approaches had been shown to prolong overall survival despite the high complete remission rates to initial therapy. However, the results of recently published studies suggest that the initial use of biologic therapy such as rituximab is associated with longer overall survival.[79,80] More than 80% of patients with stage III or IV follicular lymphoma are alive at 5 years, and the median survival ranges between 7 and 10 years.

Therapeutic options for these patients are diverse and include watchful waiting, radiation therapy, single-agent chemotherapy, combination chemotherapy, biologic therapy, radioimmunotherapy, and combined-modality therapy.[61] Although complete remission can be achieved in 50% to 80% of patients with various treatments, the median time to relapse is usually only 18 to 36 months. About 20% of patients who have a complete response remain in remission for longer than 10 years. After relapse, patients are retreated, and high remission rates can be achieved. Unfortunately, response rates and duration of response both decrease with each retreatment.

Several different approaches can be used to treat follicular lymphoma. Carefully selected patients may receive no initial therapy followed by single-agent chemotherapy, rituximab, or radiation therapy when treatment is needed. Candidates for the conservative approach are usually older, asymptomatic, and have minimal tumor burden. Patients with symptoms, extensive extranodal involvement, bulky disease, cytopenia due to bone marrow involvement, or impaired end-organ function at the time of diagnosis are not candidates for conservative treatment. Alternatively, patients can be treated aggressively with combination chemotherapy, with or without rituximab early in the disease course. Both conservative and aggressive approaches are listed as possible options in the current NCCN guideline, but the guideline recommends that initial therapy should include rituximab unless contraindicated.[61] Patients who respond to induction therapy may receive maintenance therapy with single-agent rituximab.

At the time of relapse, many of the same treatment options are available, and the following factors must be considered: age, symptomatic status of the patient, tumor burden, rate of regrowth (based on previous assessment of active disease sites), presence or absence of characteristics suggesting transformation or biologic progression, prior therapy, degree and duration of response to prior therapy, availability of clinical trials, and patient preferences.[61]

Watch-and-Wait

Because there are no convincing data that standard treatment approaches have improved survival, some clinicians have adopted a “watch-and-wait” approach for asymptomatic patients where therapy is delayed until the patient experiences systemic symptoms or disease progression such as rapidly

progressive or bulky adenopathy, anemia, thrombocytopenia, or disease in threatening sites such as the orbit or spinal cord.[81,82] The median time until treatment is required is 3 to 5 years, and about 20% of patients do not require therapy for up to 10 years. The 10-year survival is 73%, which is not significantly different from patients who received therapy at the time of diagnosis. In a randomized study of asymptomatic patients with indolent lymphomas (mostly follicular), patients who underwent watchful waiting had similar cause-specific and overall survival as compared with those who received immediate chlorambucil.[82] With a median length of follow-up of 16 years, about 17% of patients who were randomized to the watchful waiting group died of other causes without receiving chemotherapy and an additional 9% are alive and have not yet had chemotherapy. Due to the frequent use of rituximab in current clinical practice, a recent study has evaluated whether the use of the "watch-and-wait" approach is more effective than the use of rituximab to delay the need for chemotherapy or radiotherapy in patients with advanced-stage, low-tumor-burden follicular lymphoma. Immediate treatment with rituximab significantly delays disease progression and the time until chemotherapy or radiotherapy compared with a watchful waiting approach.[83] However, an overall survival advantage has not been demonstrated with this approach.

As described above, patients with follicular lymphoma who are followed without therapy sometimes have spontaneous regressions that can be complete while the disease in other patients can convert to a more aggressive histology. If the watchful waiting approach is chosen, the patient should be evaluated at least every 3 to 6 months for 5 years and then annually, so that intervention can occur before serious problems occur.[61]

Clinical Controversy...

Watch-and-wait is a common approach for managing asymptomatic, indolent follicular lymphomas. Although it is demonstrated that early initiation of induction and maintenance rituximab in this group of patients improves quality of life, it has not been demonstrated to improve overall survival. Some experts suggest that future studies should evaluate whether early induction with rituximab would have an impact on second line therapy.

Chemotherapy

Oral alkylating agents, given either alone or combined with prednisone, have been the mainstay of treatment for follicular lymphoma. More intensive chemotherapy has not been shown to improve patient outcome. In a randomized trial of oral chlorambucil, oral cyclophosphamide, or CVP in patients with indolent lymphoma, no significant difference in overall survival or freedom-from-relapse between the three groups was observed.[77] The dosage of single-agent chlorambucil or cyclophosphamide is usually adjusted to maintain a platelet count above 100,000 cells/mm^3 (100×10^9/L) and a white blood cell count above 3,000 cells/mm^3 (3×10^9/L). Although single-agent alkylating agents have a high initial complete remission rate, the time required to achieve a complete response is slow (median time is 9-12 months). Complete responses occur more rapidly with combination chemotherapy, particularly with doxorubicin-containing regimens. Many clinicians will therefore give CHOP or CHOP-like chemotherapy when a rapid response is necessary. The development of the CHOP regimen is described in more detail in the Aggressive Lymphomas section

later in this Chapter. **Table 132-11** shows the CHOP regimen that is widely used in the treatment of NHL. In those who achieve a complete response, the duration of response is relatively short (about 2.5 years). Maintenance therapy with chemotherapy provides no additional benefit. After the "best" response is achieved, many experts will discontinue therapy and observe.

TABLE 132-11 CHOP Regimen

Drug	Dose	Route	Treatment Days
Cyclophosphamide	750 mg/m^2	IV	1
Doxorubicin	50 mg/m^2	IV	1
Vincristine	1.4 mg/m^2	IV	1
Prednisone	100 mg	Oral	1–5

One cycle is 21 days

Another name for doxorubicin is hydroxydaunorubicin.

[a]Vincristine dose is typically capped at 2 mg.

Both single-agent alkylating agents and CVP are well tolerated by most patients. The advantages of oral chlorambucil are no hair loss, little or no nausea, and minimal myelosuppression. Because of its mild side effects profile, oral chlorambucil is usually recommended for older patients who are minimally symptomatic or who have other comorbidities. There are some concerns with the risk of secondary acute leukemia in patients receiving continuous exposure to alkylating agents.

Anti-CD20 Monoclonal Antibodies

The approval of rituximab is arguably the most important recent development in the treatment of NHL. Its initial approval in 1997 was based on an open-label multicenter study that enrolled 166 patients with relapsed or recurrent indolent lymphoma.[84] Rituximab, given IV at a dose of 375 mg/m^2 weekly for 4 weeks, resulted in an overall response of 48% (complete response: 6%, partial response: 42%). Median time to progression for responders was 13.2 months and median duration of response was 11.6 months. Other studies of single-agent rituximab in patients with relapsed or refractory indolent NHL have reported overall response rates of 40% to 60% and complete response rates of 5% to 10%.[85]

Based on the activity of rituximab in relapsed or refractory patients, it is currently being used as first-line therapy, either alone or in combination with chemotherapy.[73,85,86] When given as a single agent to patients with previously untreated indolent NHL, the overall response rate is 60% to 70% and the complete response rate is 20% to 30%. It is interesting to note that many of these patients remain in molecular remission (ie, polymerase chain reaction–negative) at 12 months. Single-agent rituximab is listed as an acceptable option for first-line therapy of follicular lymphoma, particularly for patients who cannot tolerate more intensive chemotherapy regimens.[61]

The rationale for the use of rituximab in combination with conventional agents is based on clinical

activity of both agents/regimens, non–cross-resistant mechanisms of action, nonoverlapping toxicities, and synergistic antitumor activity in vitro. Many clinical trials have evaluated the use of rituximab in combination with other chemotherapy agents. In a phase II trial of six courses of R-CHOP, the overall and complete response rate in 40 patients with previously untreated or relapsed indolent lymphoma was 95% and 55%, respectively.[87] More than 70% of patients were progression-free after 4 years of follow-up. In an updated analysis, median time-to-progression was reached at 82 months.[88] Based on these encouraging results, several randomized controlled trials have evaluated rituximab in combination with various chemotherapy regimens in first-line therapy for follicular or other indolent lymphomas.[73] In the R-CHOP versus CHOP trial, patients who were randomized to receive R-CHOP as initial therapy had significantly higher overall response rates (96% vs 90%), reduced risk for treatment failure (relative risk 0.4), and longer time-to-treatment failure and overall survival.[89] In another randomized trial of R-CHOP versus CHOP in relapsed or resistant follicular lymphoma, patients treated with R-CHOP had higher overall and complete response rates (85% vs 72% and 30% vs 16%, respectively) and lower risk of treatment failure (hazard ratio [HR] 0.65), but no significant difference in overall survival was observed.[90] Similar results were reported when rituximab was added to other combination regimens.[73,74] In a meta-analysis of all randomized controlled trials, patients with indolent lymphoma treated with rituximab and chemotherapy had a significantly higher overall response rate and reduced risk of treatment failure (HR 0.62) and death (HR 0.65).[91] Rituximab is FDA-approved for first-line therapy for follicular lymphoma in combination with CVP chemotherapy. R-CHOP is listed as an acceptable option for first-line therapy of follicular lymphoma (category 1).[61]

Rituximab and CHOP chemotherapy can be combined in many different ways. In the R-CHOP regimen developed by Czuczman et al., two doses of rituximab are given before the start of CHOP therapy; two more doses are given in the middle of the six cycles of CHOP; and two additional doses are given at the end of CHOP therapy.[87] However, in most NHL protocols and in clinical practice, rituximab is given on day 1 of CHOP chemotherapy. In some protocols, rituximab is given on the day before chemotherapy (ie, day 0) or rituximab is given on day 1 and the other drugs are given on day 3.

In patients who respond to rituximab, either alone or combined with chemotherapy, maintenance therapy with single-agent rituximab is often given to prolong the duration of remission. Rituximab is FDA approved as single-agent maintenance therapy in patients achieving a complete or partial response following induction chemotherapy. The FDA approval was based on a randomized controlled trial in previously untreated patients with advanced-stage follicular lymphoma treated with maintenance rituximab after CVP chemotherapy.[92] Three-year progression-free survival was significantly longer in the maintenance rituximab group as compared with the observation group (65% vs 22%).[83] In another recently published randomized controlled trial, patients responding to first-line chemotherapy in combination with rituximab (such as R-CVP, R-CHOP or rituximab, fludarabine, cyclophosphamide, and mitoxantrone [R-FCM]) were randomized to receive rituximab maintenance (12 infusions of 375 mg/m^2 given IV, once every 8 weeks) or no maintenance.[93] After a median follow-up of 24 months, rituximab maintenance significantly improved progression-free survival compared to observation (75% vs 58%). Interestingly, induction therapy with R-CHOP or

R-FCM was associated with improved progression-free survival, which suggests that R-CVP was not beneficial in this study. Longer follow-up is needed to evaluate the effect of rituximab maintenance on overall survival.

Although the use of maintenance rituximab improves progression-free survival, no overall survival benefit has been observed in randomized controlled trials. Similar findings were observed in a prospective observational study of more than 2,700 patients with newly diagnosed follicular lymphoma treated in the United States from 2004 to 2007, patients who have received maintenance rituximab after induction chemotherapy were found to have significantly longer progression-free survival and time to next treatment after 5 years of follow-up.[94] And maintenance rituximab is expensive and may be associated with adverse effects, including an increased risk of grades 3 or 4 infections. The NCCN guideline lists maintenance therapy with rituximab (one dose every 8 weeks for up to 2 years) as an option following first-line therapy for patients initially presenting with high tumor burden.[61]

Rituximab maintenance following second-line therapy has also been evaluated in patients with relapsed or refractory disease. Two randomized trials have demonstrated a progression-free survival advantage with rituximab maintenance over observation for patients treated with induction chemotherapy.[95,96] In a recently published trial of patients with relapsed or resistant follicular lymphoma responding to CHOP or R-CHOP induction, maintenance rituximab significantly improved median progression-free survival as compared with observation alone (3.7 years vs 1.3 years). The 5-year overall survival, however, was not significantly different between the study arms (74% vs 64%).[96] It is also important to note that patients who develop progression of disease during or within 6 months of first-line maintenance rituximab will likely experience little, if any, benefit from maintenance therapy in the second-line setting. The NCCN guideline recommends optional maintenance therapy with rituximab (one dose every 12 weeks for 2 years) for patients who are in remission after second-line therapy.[61]

Most of the adverse effects of rituximab are infusion-related, particularly after the first infusion, and consist of fever, chills, respiratory symptoms, fatigue, headache, pruritus, and angioedema. Premedication with oral acetaminophen 650 mg and diphenhydramine 50 mg is usually given 30 minutes before rituximab infusion. The package insert recommends a step-up infusion rate of rituximab to decrease the risk of infusion-related infusion. Duration of infusions, however, may take up to 5 hours. Studies have demonstrated that rapid infusion of rituximab (infused over 90 minutes) is feasible in patients who tolerate their first cycle of rituximab without increasing the risk of infusion-related reactions.[97,98] The FDA has approved rapid infusions of rituximab, but they are not recommended in patients with clinically significant cardiovascular disease and high circulating lymphocyte counts (>5,000 cells/mm^3 [5×10^9/L]). Reactivation of hepatitis B has been reported in patients receiving chemotherapy, either alone or combined with rituximab.[99] Hepatitis B testing is recommended in patients who are considering rituximab therapy.[61]

In addition to rituximab, other anti-CD20 antibodies are currently under research development.[74] Ofatumumab, a fully human antibody against CD20, is currently approved for treatment of refractory chronic lymphocytic leukemia. It binds to two sites on the CD20 molecule, which brings the antibody

closer to the cell membrane and increases complement-dependent cytotoxicity.[100] Ofatumumab is being evaluated in randomized controlled trials against rituximab-based regimens for treatment of both indolent and aggressive lymphomas.

Bendamustine

Bendamustine is an alkylating agent with structural similarities to both alkylating agents and purine analogs. The mechanism of action of bendamustine appears to be different from other alkylating agents and it does not show cross-resistance to other alkylating agents. When used as a single agent, bendamustine shows antitumor activity in relapsed or refractory indolent lymphomas. Overall and complete response rates of 70% to 80% and 30% to 35% have been reported, respectively, in phase II trials.[101] Two randomized, non-inferiority studies have demonstrated that bendamustine and rituximab (BR) is noninferior to R-CHOP for indolent lymphomas. In a Phase III randomized non-inferiority study enrolling Stages 3 and 4 indolent lymphoma (with slightly over half follicular lymphoma patients), patients received either BR or R-CHOP. At a median follow-up of 45 months, median progression-free survival was longer in the BR group than in the R-CHOP group. In the subgroup analysis of patients with follicular lymphoma subtype, a significant benefit for progression-free survival was observed with BR versus R-CHOP.[102] In another study, BR was demonstrated to be noninferior to standard therapies (R-CHOP or R-CVP) for both overall (97% vs 91%) and complete response (31% vs 25%).[103] Both studies also reported that BR was associated with fewer infectious episodes and fewer hematological toxicities such as grade 3 to 4 leukopenia and neutropenia. BR was also associated with less peripheral neuropathy and alopecia.[102,103] However, dermatological toxicities, drug-related hypersensitivities and vomiting were more common with BR. Based on these results, BR, R-CHOP, and R-CVP are all listed as first-line therapy of follicular lymphoma (category 1).[61]

Clinical Controversy…

Bendamustine and rituximab is associated with fewer serious adverse events as compared to R-CHOP as first-line therapy for follicular lymphoma. With the increased use of bendamustine-based treatment as first-line therapy for follicular lymphoma in the rituximab era, it is unknown whether maintenance rituximab as consolidation would confer any clinical benefit in this group of patients.

Fludarabine

Fludarabine phosphate shows encouraging results in previously untreated and relapsed advanced follicular lymphoma. The mechanism of action is not well understood, but it is accumulated in lymphocytes and are resistant to adenosine deaminase. In patients with relapsed or refractory indolent lymphoma, single-agent fludarabine has an overall response rate of almost 50% and a complete response rate of 10% to 15%. Response rates are higher in previously untreated patients, with overall and complete response rates of 70% and almost 40%, respectively. The median time to progression is less than 6 months for relapsed disease and more than 12 months for previously untreated patients. Combination regimens with fludarabine have also being investigated. Fludarabine, mitoxantrone, and dexamethasone (FND), given with or without rituximab, are examples

of fludarabine-containing regimens that show encouraging results in patients with indolent lymphoma.[104]

Fludarabine does not usually cause nausea and vomiting or hair loss, but it is associated with cumulative and prolonged myelosuppression and profound immunosuppression, which increases the risk of opportunistic infections, such as fungal infections, *Pneumocystis jiroveci* pneumonia, and viral infections. Because the use of fludarabine-based regimens may impair stem cell mobilization and collection, some experts avoid fludarabine-based regimens for patients who are potential candidates for autologous HSCT.

Radioimmunotherapy

^{90}Y-ibritumomab tiuxetan (Zevalin®) is an anti-CD20 radioimmunoconjugate which is currently available for patients with indolent NHLs.[105] It is a mouse antibody linked to yttrium-90 $^{(90Y)}$, a radioisotope. Another anti-CD20 radioimmunoconjugate, ^{131}I-tositumomab (Bexxar®), was recently discontinued by the manufacturer because of limited use. Indolent lymphomas are known to be responsive to radiation therapy (ie, radiosensitive), and the rationale of radioimmunotherapy is that the antibody will act as a guided missile to deliver its payload (ie, radiation) to its target (ie, lymphoma cells that express the CD20 antigen). The specificity of the monoclonal antibody allows delivery of the radiation selectively to the tumor (and adjacent normal tissues).

^{90}Y-ibritumomab tiuxetan has shown activity in relapsed and refractory patients with indolent or transformed lymphomas.[105] In patients who respond to radioimmunotherapy, the duration of remission can be more than several years. Although radioimmunotherapy is usually reserved for second-line therapy of follicular lymphoma, some clinicians consider radioimmunotherapy earlier in the disease course. In a phase II study, patients with previously untreated follicular lymphoma were treated with six cycles of CHOP chemotherapy followed 4 to 8 weeks later by ^{131}I-tositumomab.[106] The overall response rate to the entire treatment regimen was 91%, including 69% complete remissions, and the 5-year progression-free survival is estimated to be 67%. Similar results were reported in a phase II trial of ^{131}I-tositumomab given without induction CHOP chemotherapy in previously untreated patients with advanced-stage follicular lymphoma.[107] Durable responses have also been reported with ^{131}I-tositumomab and CVP.[108]

Radioimmunotherapy is generally well-tolerated. The major acute toxicities with both radioimmunoconjugates are infusion-related reactions and myelosuppression.[131] The primary concern with radioimmunotherapy is the development of treatment-related myelodysplastic syndrome or acute myelogenous leukemia.[109]

The decision to use radioimmunotherapy must be made carefully because of the complexity, risks, and costs of the treatment regimen. Because of safety concerns related to delivery of radiation to bone marrow, candidates for radioimmunotherapy usually have limited bone marrow involvement and adequate absolute neutrophil and platelet counts. Although medical oncologists usually select patients for therapy, the radioimmunotherapy regimen must be administered at a radiation oncology or nuclear medicine facility.

Lenalidomide

Lenalidomide is an immunomodulating agent which is currently indicated for the treatment of multiple myeloma and myelodysplastic syndromes. There is emerging data suggesting that it has activity in indolent NHL. In a phase II study of lenalidomide and rituximab in previously untreated follicular lymphoma patients, the overall response rate was 98% and the 2-year progression-free survival was 89%.[110] The combination has also been evaluated in the treatment of both patients with previously untreated and relapsed/refractory indolent lymphomas. In another phase II trial of patients with relapsed/refractory indolent NHL, single-agent lenalidomide induced an overall response rate of 27% within the subgroup of patients with follicular lymphoma, with a median progression-free survival for all patients of 4.4 months.[111] Toxicities that are commonly observed with lenalidomide include neutropenia, fatigue and thrombosis. A number of studies are currently evaluating its role as frontline therapy for indolent lymphoma.

Idelalisib

Idelalisib is an oral inhibitor of phosphatidylinositol 3-kinase-delta (PI3K delta) which was approved for the treatment of relapsed and refractory FL. PI3K delta mediates B-cell receptor signaling and microenvironmental support signals that promote the growth and survival of malignant B lymphocytes. In a phase II study, patients with relapsed or refractory indolent NHL were given idelalisib 150 mg twice daily until disease progression. The overall response rate was 57%, with a median duration of response of 12.5 months. Common side effects of idelalisib include neutropenia, transaminitis, diarrhea, and pneumonia.[112] The current NCCN guideline lists idelalisib as an option for second-line therapy for patients with relapsed or refractory follicular lymphoma.[61]

Hematopoietic Stem Cell Transplantation

High-dose chemotherapy, followed by autologous or allogeneic HSCT, is another option for patients with relapsed follicular lymphoma.[113,114] In patients who are transplanted at the time of initial treatment failure, 5-year event-free survival is about 40% to 50%. Although the rate of recurrence is lower after allogeneic HSCT as compared with autologous HSCT, that benefit is offset by increased treatment-related mortality after allogeneic HSCT. The presence of a survival plateau after allogeneic HSCT suggests that some patients may be cured of their disease.

A recent study has evaluated the role of HSCT in relapsed/refractory follicular lymphoma following disease relapse after prior rituximab-based therapy. Allogeneic HSCT was associated with increased risk of death on analysis. Autologous HSCT, on the other hand, was associated with a 3-year overall survival rates at 87%.[115] The current NCCN guideline lists the use of autologous HSCT as an appropriate consolidative therapy for patients achieving second or third remission.[61]

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphomas are the most common lymphoma in the International NHL

Classification Project, accounting for about 30% of all NHLs.[116] DLBCLs are characterized by the presence of large cells, which are similar in size to or larger than tissue macrophages and usually more than twice the size of normal lymphocytes. The median age at the time of diagnosis is in the seventh decade, but DLBCL can affect individuals of all ages, from children to the elderly. Patients often present with a rapidly enlarging symptomatic mass, with B symptoms in about 30% to 40% of cases.[116] About 30% to 40% of patients with DLBCL present with extranodal disease; common sites include the head and neck, gastrointestinal tract, skin, bone, testis, and CNS. DLBCL is the most common type of diffuse aggressive lymphomas, which are characterized by an aggressive clinical behavior that leads to death within weeks to months if the tumor is not treated. Diffuse aggressive lymphomas are also sensitive to many chemotherapeutic agents, and some patients treated with chemotherapy can be cured of their disease.

Several factors have been shown to correlate with response to chemotherapy and survival in patients with aggressive lymphoma. Because the IPI was originally developed based on patients with aggressive lymphoma, IPI score correlates with prognosis (see Table 132-9).[63] As described above, the revised IPI score may more accurately predict prognosis in patients receiving rituximab-containing combination chemotherapy.[64]

Therapy of DLBCL is based on the Ann Arbor stage, IPI (or revised IPI) score, and other prognostic factors.[116] About one-half of patients present with localized (stage I or II) disease. However, many patients present with large bulky masses (ie, larger than 10 cm), and patients with bulky stage II disease are treated with the same approach used for patients with advanced disease (stage III or IV).

Treatment of Localized Disease (Stages I and II)

Before 1980, radiation therapy was the primary treatment for patients with localized DLBCL. Five-year disease-free survival with radiation therapy alone was about 50% and 20% in patients with stage I and stage II disease, respectively.[116] Randomized trials in the 1980s showed that radiation therapy followed by chemotherapy resulted in significantly longer disease-free and overall survival as compared with radiation therapy alone. Other studies reported excellent results with a short course of chemotherapy (three cycles) followed by involved-field radiotherapy or six to eight cycles of CHOP chemotherapy, with or without consolidation radiotherapy. With either of these approaches, 5-year progression-free survival was more than 90% for patients with stage I disease and about 70% for patients with stage II disease.[116]

Because the most effective approach was not clear, the SWOG performed a randomized trial that compared three cycles of CHOP and involved-field radiotherapy or six cycles of CHOP in patients with stage I and nonbulky stage II aggressive lymphoma.[61] Patients treated with three cycles of CHOP plus radiotherapy had significantly better 5-year progression-free (77% vs 64%) and overall (82% vs 72%) survival than did patients treated with CHOP alone. The incidence of life-threatening toxicity was higher in patients who received CHOP alone. But with longer follow-up, more patients who received abbreviated chemotherapy experienced late relapses and the differences in progression-free or overall survival were no longer significant between the two arms. Further subgroup analysis of that trial identified several prognostic factors that led to the development of the stage-modified IPI score.

Four adverse risk factors comprise the score: nonbulky stage II disease (bulky stage II disease is considered advanced disease), age older than 60 years, elevated LDH levels, or performance status more than or equal to 2.

The stage-modified IPI score is often used to identify patients with localized aggressive NHL who may have a poor prognosis. Based on the results of this trial, the current standard for therapy of most patients with localized nonbulky aggressive lymphoma without any adverse risk factors is three to four cycles of R-CHOP followed by locoregional radiation therapy (30-40 Gy [3,000-4,000 rad]).[116] Five-year median survival in this favorable group of patients exceeds 90%.

Five-year median survival is reduced to about 70% in patients with at least one adverse risk factor in the stage-modified IPI score. Patients in this high-risk subgroup may benefit from more aggressive chemotherapy (six cycles of R-CHOP) followed by locoregional radiation therapy.[61]

Treatment of Advanced Disease (Bulky Stage II, Stages III and IV)

It has been known since the late 1970s that intensive combination chemotherapy can cure some patients with disseminated DLBCL.[116] Initial studies with cyclophosphamide, vincristine (Oncovin®), and prednisone or prednisolone (COP; same as CVP) produced a plateau on the survival curve of just 10%, with a median survival of less than 1 year. Based on the activity of single-agent doxorubicin, McKelvey et al. developed the CHOP regimen (see Table 132-9).[117] A few years later, a SWOG study showed that CHOP was more active than COP, and CHOP chemotherapy rapidly became the treatment of choice for patients with aggressive lymphomas.[118] Studies in larger numbers of patients showed that about 50% of patients had a complete remission to CHOP chemotherapy, and 50% to 75% of the patients who had a complete response (about one-third of all patients) experienced long-term disease-free survival and cure of their disease.

In an effort to improve these results, many investigators used several general approaches to develop second- and third-generation regimens in the 1980s.[116] Results of phase II trials suggested that these second- and third-generation regimens were more active than CHOP, with slightly higher complete response rates and improved disease-free survival rates. However, they were also more difficult to administer, more toxic, and more expensive. Based on these results, many oncologists adopted one of these second- or third-generation combination regimens as their standard regimen for patients with advanced aggressive lymphomas.

Many randomized studies have compared different combination regimens in patients with aggressive lymphoma. Although the results of these studies show that no one regimen is clearly superior to another, they demonstrate the superiority of anthracycline-containing regimens over those that do not contain an anthracycline. In the largest and most widely quoted study, the SWOG initiated a randomized trial in 1986 that compared CHOP to three of the most commonly used third-generation regimens in nearly 900 patients with bulky stage II, stage III, or stage IV aggressive NHL. At the time of the initial publication (median follow-up: 35 months), no differences in disease-free and overall survival were observed between the four groups.[119] Furthermore, no significant differences in disease-free or overall survival were observed in any subgroup of patients. But the risk of treatment-

related mortality was higher in patients receiving one of the third-generation regimens. Extended follow-up of that trial shows that about 35% of patients who participated in that trial are probably cured of their disease, regardless of the initial combination chemotherapy regimen. Interestingly, the overall survival is about 10% higher than the disease-free survival, which probably reflects the effectiveness of salvage high-dose chemotherapy with autologous HSCT (see the Treatment of Refractory or Relapsed Disease section later in this Chapter).

Based on the lack of survival benefit with the newer combination chemotherapy regimens, the less complicated and less expensive CHOP regimen was considered as the treatment of choice for most patients with DLBCL and other aggressive NHLs for many years. Even with CHOP chemotherapy, however, less than 50% of patients with DLBCL were cured of their disease and most patients who relapse after an initial response do so in the first 2 years. New treatment approaches were clearly needed.

Several studies attempted to improve treatment results by increasing chemotherapy dose (ie, dose-intensity), shortening the interval between chemotherapy cycles (ie, dose-density), or both. Because of the increased risk of severe neutropenia, these approaches require growth factor support. Although results of these studies have not consistently shown improved survival, encouraging results from several recently published studies suggest that these approaches be evaluated in future randomized trials.[120]

Based on the encouraging results of R-CHOP in indolent lymphomas, several studies evaluated this combination in aggressive lymphomas. The first randomized controlled trial that established the efficacy of R-CHOP in advanced-stage DLBCL showed that R-CHOP significantly increased complete response rates and overall survival in elderly (≥60 years old) patients as compared with CHOP alone (discussed in the Treatment of Elderly Patients with Advanced Disease section later in this Chapter).[121,122] Although the results of that study established R-CHOP as standard therapy in older patients, the role of R-CHOP in the treatment of younger patients was not clear. That issue was recently addressed in the MabThera International Trial, which enrolled younger (18-60 years old) patients with good-prognosis DLBCL.[123] Patients randomized to receive rituximab plus CHOP-like chemotherapy had significantly higher complete response rates (86% vs 68%) and longer 3-year event-free and overall survival (79% vs 59% [HR 0.44] and 93% vs 84% [HR 0.40], respectively). Furthermore, in a population-based study conducted in British Columbia, institution of a policy recommending R-CHOP for all patients with newly diagnosed advanced-stage DLBCL resulted in significant improvements in progression-free and overall survival.[124] Based on these trial results, rituximab received FDA approval for first-line treatment in combination with CHOP or CHOP-like chemotherapy and R-CHOP is recommended for all patients with advanced-stage DLBCL in the current NCCN guideline.[61]

Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory. High-risk groups generally include all patients older than 60 years and those with an IPI score of 3 or more (or an age-adjusted IPI score of ≥2). Because progression-free survival is only about 50% in these high-risk patients treated with R-CHOP,[64,125] other more aggressive treatments, preferably as part of a clinical trial, should be considered in these patients. Examples of more

aggressive approaches include dose-intense or dose-dense chemotherapy with growth factor support, usually combined with rituximab, or high-dose chemotherapy with autologous HSCT.[116,126]

One approach is to give high-dose chemotherapy with autologous HSCT as intensive consolidation in high-risk patients with DLBCL who achieve a remission with standard chemotherapy.[121] A recent published study suggested that this approach improves progression-free survival among patients with high-intermediate-risk or high-risk disease who had a response to CHOP-based chemotherapy.[126]

11 In summary, all patients with bulky stage II, stage III, or stage IV disease should be treated with R-CHOP or rituximab and CHOP-like chemotherapy until a complete response is achieved (usually four cycles).[65] Clinicians are encouraged to adopt the revised response criteria proposed by the International Working Group.[66] In patients who have a positive pretreatment PET scan, PET scanning can be useful in response assessment. A rapid response to chemotherapy (ie, a complete response achieved in the first three treatment cycles) is associated with a more durable remission compared with patients requiring longer treatment cycles. Two or more cycles of chemotherapy should be given following attainment of a complete response (total of six to eight cycles). The use of long-term maintenance therapy following a complete response has not been shown to improve survival. Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory and alternative treatment approaches, preferably as part of a clinical trial, should be considered in these patients. High-dose chemotherapy with autologous HSCT should be considered in high-risk patients who respond to standard chemotherapy and are candidates for autologous HSCT.[65]

Treatment of Elderly Patients with Advanced Disease

More than one-half of patients with NHL are older than 60 years of age at diagnosis, and about one-third are older than age 70 years. The International Non-Hodgkin Lymphoma Prognostic Factors Project showed that patients older than 60 years of age had a significantly lower complete response rate and overall survival.[63] The reasons for the poorer outcome in elderly patients are not clear. Older patients do not tolerate intensive chemotherapy as well as younger patients, and some studies report that older patients have a higher risk of treatment-related mortality. As a result, many clinicians treat elderly patients with reduced dose or less-aggressive chemotherapy regimens. In general, these less-intensive regimens have used anthracyclines with less cardiotoxicity than doxorubicin, have substituted mitoxantrone for doxorubicin, or have used short-duration weekly therapy.[116]

Over the past few years, several nonrandomized and randomized trials have evaluated different treatment approaches in older patients with aggressive NHL.[116] The results of these studies suggest that carefully selected elderly patients with good performance status and without significant comorbidities can tolerate aggressive anthracycline-containing regimens as well as younger patients. These patients should be treated initially with full-dose R-CHOP or similar regimens; dosages can be reduced later if severe toxicity occurs. Hematopoietic growth factors may allow elderly patients to maintain dose intensity.

The combination therapy, R-CHOP, has replaced CHOP as standard treatment for elderly patients

with aggressive lymphoma, based on the results of the Groupe d'Etude des Lymphomes de l'Adulte (GELA) study.[121,122] In that study of 399 elderly patients with DLBCL, patients who were randomized to receive R-CHOP had a significantly higher complete response rate (76% vs 63%) and longer event-free and overall survival as compared with those who received CHOP. After 10 years of follow-up, progression-free survival was significantly longer among those who received R-CHOP than CHOP (36.5% vs 20.1%).[122] A higher risk of death or development of secondary cancer was not observed with the addition of rituximab to CHOP after 10 years of follow-up. In another randomized controlled trial conducted primarily in the United States (Eastern Cooperative Oncology Group 4494), elderly (≥60 years old) patients who received rituximab, either as induction or maintenance with CHOP chemotherapy, had significantly longer failure-free survival as compared with those not given rituximab during their treatment course.[126] Maintenance therapy with single-agent rituximab did not provide any additional benefit in patients who received R-CHOP as induction therapy. It is important to note that rituximab is given differently in the two studies. In the GELA study, rituximab is given on day 1 (the same day that cyclophosphamide, doxorubicin, and vincristine are administered) with each cycle of CHOP chemotherapy.[121,122] In the Eastern Cooperative Oncology Group 4494 study,[127] R-CHOP was modeled after the regimen developed by Czuczman et al.: two doses of rituximab are given before cycle 1, and one dose is given before cycles 3, 5, and 7 (if administered).[87] In most NHL protocols and in clinical practice, rituximab is given on day 1 of CHOP chemotherapy.

Dose-dense chemotherapy, where the interval between cycles is shortened from 3 to 2 weeks, has been evaluated. Before the rituximab era, patients who were randomized to receive biweekly CHOP (CHOP-14) had significantly longer 5-year event-free and overall survival than patients who received standard CHOP every 21 days (CHOP-21).[128] All patients in the CHOP-14 group received prophylactic growth factors starting from day 4. Toxicity was similar between the two groups. In the next study, the same group of investigators evaluated the addition of rituximab (CHOP-14 vs R-CHOP-14) and the number of treatment cycles (six vs eight cycles).[129] Patients who received rituximab did better than those who did not, but eight cycles were not better than six cycles. The addition of rituximab to the CHOP-14 regimen resulted in significantly longer 3-year event-free and overall survival (67% vs 47% and 78% vs 68%, respectively). In the rituximab era, however, data suggested that R-CHOP-21 remains the standard treatment regimen when compared to R-CHOP-14 for treatment of DLBCL. Two recently published randomized studies confirmed that R-CHOP-14 is not superior to R-CHOP-21 for previously untreated DLBCL patients.[130,131] The NCCN guideline does not recommend dose-dense R-CHOP (R-CHOP-14) as first-line therapy for DLBCL.[61]

Treatment of Refractory or Relapsed Disease

12 Although many patients with aggressive NHL experience long-term survival and cure with intensive chemotherapy, about 10% to 20% of patients fail to achieve a complete remission and about 20% to 30% of patients who do achieve a complete remission will subsequently relapse. Therefore, about 30% to 40% of all patients with aggressive NHL will require salvage therapy at some point during their disease course. Response to salvage therapy depends on the initial responsiveness of the tumor to chemotherapy. Patients who achieve an initial complete remission and then relapse generally have a better response to salvage therapy than those who are primarily or partially resistant

to chemotherapy.

Many conventional-dose salvage chemotherapy regimens have been used in patients with relapsed or refractory NHL. Many patients who respond to salvage therapy (ie, chemosensitive relapse) will then receive high-dose chemotherapy with autologous HSCT. In an effort to avoid cross-resistance, most salvage regimens incorporate drugs not used in the initial therapy. Some of the more commonly used salvage regimens include ICE, dexamethasone, cytarabine, cisplatin (DHAP), etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP), and mesna, ifosfamide, mitoxantrone, etoposide (MINE), gemcitabine, dexamethasone, cisplatin (GDP) and no one regimen appears to be clearly superior to any other regimen.[116,132] With these salvage regimens, about 30% to 50% of patients achieve a complete response, with a median duration of remission of 1 to 2 years. Only about 5% to 10% of patients will have long-term disease-free survival.

Rituximab is sometimes added to these salvage regimens. It is recommended, however, to exclude rituximab in second-line therapy if patient's disease is refractory or if the duration of remission is less than 6 months. One study (CORAL study) has compared two salvage regimens (R-ICE and R-DHAP) that are used for treatment of patients with relapsed or refractory DLBCL, followed by autologous HSCT.[133] No significant difference in 3-year event-free survival or overall survival was observed between R-ICE and R-DHAP. However, patients who had received prior rituximab treatment and experienced early relapse (defined as less than 12 months after diagnosis) had a poor prognosis. This suggests that new treatment strategies are needed in order to improve the response rates of salvage regimens.

To improve the cure rate, many studies have evaluated high-dose chemotherapy with autologous HSCT as intensive consolidation therapy in patients who respond to salvage therapy. In the PARMA study, 215 patients with relapsed aggressive NHL who had a response to DHAP salvage therapy were randomized to receive either high-dose chemotherapy or continued DHAP therapy.[134] Patients who received high-dose chemotherapy had significantly longer 5-year disease-free survival (46% vs 12%) and overall survival (53% vs 32%) than those treated with conventional salvage therapy. Further analysis of that study showed that patients who relapsed within 12 months of their initial diagnosis were less likely to benefit from high-dose chemotherapy than patients who relapsed after 12 months. Based on a review of the available evidence, including the PARMA study, high-dose chemotherapy with autologous HSCT is considered to be the treatment of choice in younger patients with chemotherapy-sensitive relapse.[61] High-dose chemotherapy with autologous HSCT is not recommended in patients with untested or chemotherapy-refractory relapse.

Other Aggressive Lymphomas

Mantle cell lymphoma is found in 6% of cases in the International Lymphoma Classification Project.[76] The chromosomal translocation t(11;14) occurs in most cases of MCL. MCL usually occurs in older adults, particularly in men, and most patients have advanced disease at the time of diagnosis (see Table 132-6). Extranodal involvement is found in about 90% of cases. The course of the disease is moderately aggressive; the median overall survival is about 3 years, with no evidence of a survival plateau.

Both aggressive and less-aggressive chemotherapy regimens have been evaluated in patients with disseminated MCL. One widely used aggressive combination regimen is cyclophosphamide, vincristine, doxorubicin, dexamethasone alternating with methotrexate and cytarabine (hyperCVAD) with or without rituximab. Overall response rates to these regimens is about 90%, with about two-thirds of patients achieving a complete response.[61] Because MCL usually expresses CD20, rituximab, either alone or combined with CHOP and bendamustine, has been used with some success in patients with newly diagnosed and relapsed MCL.[91,102] In a phase III study, BR was compared to R-CHOP for first-line therapy in patients with advanced follicular, indolent and MCL. In the MCL subgroup, progression-free survival was higher with BR compared to R-CHOP, and it is associated with less hematological toxicities.[102]

Despite the high response rates, MCL is not considered curable with standard chemotherapy. Consequently, younger patients who have an initial response to chemotherapy often undergo autologous or allogeneic HSCT as consolidation therapy. The NCCN guideline recommends that patients with advanced-stage MCL be treated initially with rituximab and combination chemotherapy, followed by autologous HSCT as first-line consolidation therapy.[61] Unfortunately, most patients with MCL eventually relapse and are treated with salvage therapy or enrolled in trials of investigational agents, some of which are aimed at molecular targets.

Bortezomib (Velcade®) is currently approved for treatment of patients with MCL that has relapsed after at least one prior therapy based on the results of a phase II study that showed a 33% response rate.[135] In a recently published phase III randomized study, patients with newly diagnosed mantle-cell lymphoma who were ineligible or not considered for HSCT received R-CHOP intravenously on day 1 (with prednisone administered orally on days 1-5) or VR-CAP (R-CHOP regimen, but replacing vincristine with bortezomib). After a median follow-up of 40 months, median progression-free survival was longer in the VR-CAP arm compared to R-CHOP (24.7 vs 14.4 months; $P < 0.001$). Rates of neutropenia and thrombocytopenia were higher in the VR-CAP group.[136]

Ibrutinib is an oral Bruton tyrosine kinase (BTK) inhibitor approved for treatment of relapsed or refractory MCL. In a Phase II study, ibrutinib had demonstrated a high response rate of 67% with a median duration of response of 17.5 months. Most of the patients had received three or more prior therapies.[137] The most common side effects of ibrutinib include diarrhea and fatigue. Bleeding can rarely occur, particularly during the first 6 months of ibrutinib therapy.

Non-Hodgkin Lymphoma in Acquired Immune Deficiency Syndrome

The risk of NHL for patients with AIDS is increased more than 100-fold as compared with the general population.[138,139] AIDS-related lymphoma arises as a consequence of long-term stimulation and proliferation of B lymphocytes from HIV and the reactivation of prior EBV infection as a consequence of HIV-induced immunosuppression. AIDS-related lymphoma usually occurs late in the course of HIV infection and is the cause of death in about 15% of HIV-infected individuals. Although HIV infects T cells, more than 95% of AIDS-related lymphomas are B-cell neoplasms. Most cases of AIDS-related lymphomas are classified as Burkitt or DLBCL.

The clinical presentation is similar to that observed in other immunocompromised states. Most patients with AIDS-related lymphoma present with B symptoms and have advanced-stage (III or IV) disease at the time of diagnosis.[138] Involvement of extranodal sites is common. The clinical course of AIDS-related lymphoma is usually aggressive and has improved with the availability of highly active antiretroviral therapy (HAART). Improved survival has been observed, primarily in patients with DLBCL. Patients with AIDS-related lymphoma treated with intensive therapy have a median survival that is similar to the survival of patients with HIV-negative NHLs.[139] In the post-HAART era, many of the prognostic factors have also changed and only lymphoma-related factors such as the IPI remain as independent predictors of prognosis.

The treatment of patients with AIDS-associated lymphomas is difficult because the immunocompromised state of these patients increases their risk of significant toxicity as a consequence of myelosuppressive therapy. Except for primary CNS lymphoma, AIDS-related lymphoma is never considered truly localized and systemic chemotherapy is indicated. For patients with adequate immune function and without a history of an opportunistic infection, chemotherapy regimens similar to that used for aggressive lymphomas may be used.[61] However, many patients with AIDS-related lymphoma were previously treated with less-intensive regimens because of the increased risk of treatment-related toxicity. In the post-HAART era, however, most clinicians believe that standard doses of chemotherapy can be safely administered to patients who achieve a virologic response to HAART.

The results of treatment with standard chemotherapy regimens have been disappointing, particularly in patients with Burkitt lymphoma. In patients with DLBCL, the complete response rate with combination chemotherapy is about 40% to 50%, with 5-year overall survival rates of about 20% to 30%. Newer approaches, such as the dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (EPOCH) regimen developed at the National Cancer Institute, appear promising. In a recently published pooled analysis that included patients with HIV-associated NHL treated in the R-CHOP or R-EPOCH, patients receiving R-EPOCH achieved an improvement of response and survival when compared against R-CHOP.[140] Treatment-associated deaths were more prominent among patients with very low $CD4^+$ counts.

The role of rituximab in the treatment of AIDS-related DLBCL is not clear. In a randomized trial of CHOP versus R-CHOP, no significant differences in progression-free and overall survival were observed.[141] However, 14% of patients treated with R-CHOP died of treatment-related infection as compared with only 2% of those in the CHOP group. NCCN guidelines suggest omission of rituximab in patients at high risk for serious infectious complications (eg, patients on HAART with persistently low $CD4^+$ count).[61]

The optimal timing for HAART is not clear in patients with AIDS-related lymphoma.[138,139] Current NCCN guidelines recommend the use of HAART and growth factor support along with full-dose chemotherapy regimen.[61] If HAART is given concurrently with chemotherapy, patients should be monitored closely for possible pharmacokinetic interactions between HAART and chemotherapy. Prophylactic antibiotics should be continued during chemotherapy and intrathecal chemotherapy should be administered to prevent CNS relapses.

PERSONALIZED PHARMACOTHERAPY

Molecular testing of the lymphoma cells at the time of diagnosis is an essential part of the diagnostic work-up. Molecular subtypes have been identified that predict for survival. For example, two molecular subtypes of DLBCL have been identified, and the ABC subtype appears to be less responsive to chemotherapy than the GCB subtype. Another molecular subtype associated with poor response is double-hit DLBCL, defined as the existence of both MYC gene arrangement and t(14;18) BCL2 translocation.

In addition to disease stage, several prognostic indices such as IPS, IPI, and FLIPI are used clinically to predict response to therapy and survival in individual patients. The results of these evaluations form the basis for risk-adapted therapy, where the intensity of the recommended therapy is tailored to the risk category of the patient. More intensive therapy is generally recommended for higher risk patients, particularly when long-term survival or cure is the treatment goal.

Age or comorbidities often limit the use of chemotherapy regimens. Patients with poor cardiac function may not be able to receive doxorubicin, an important component of combination regimens used to treat both Hodgkin lymphoma and NHL. Patients with preexisting diabetic neuropathy or who develop peripheral neuropathy during chemotherapy may not be able to receive all of their planned doses of vinca alkaloids, particularly vincristine. Most patients with NHL are elderly and these patients may not tolerate the toxicities of intensive chemotherapy regimens. Dosage adjustments or treatment delays may be required.

Interim PET scans are currently being investigated as a biomarker of early response in patients with advanced-stage Hodgkin lymphoma. If validated, PET scans may allow clinicians to decide which patients should receive treatment intensification and which patients should have their treatment discontinued.

EVALUATION OF THERAPEUTIC OUTCOMES

Hodgkin and NHLs tend to respond well to radiation, chemotherapy, and biologic therapy. The goal of therapy for patients with Hodgkin lymphoma and aggressive NHL is long-term survival and cure. The therapeutic goal in patients with indolent NHLs is less clear because of the indolent nature of the disease and the lack of convincing evidence showing that therapy prolongs survival. Therapeutic responses should be evaluated based on physical examination, radiologic evidence, PET/CT scanning, and other positive findings at baseline. Patients with Hodgkin lymphoma and aggressive NHLs are usually evaluated for response at the end of four cycles of therapy or at the end of treatment if fewer than four cycles of therapy are planned. If patients are treated with chemotherapy alone, two additional cycles of chemotherapy are given after the patient has achieved a complete remission. Recent studies have also shown that early interim PET scans may possess prognostic value in patients with advanced Hodgkin lymphoma. The rapidity of response to therapy in patients with indolent NHL depends on the choice of therapy. Responses occur slowly with therapy with oral alkylating agents, but occur much more rapidly with aggressive therapies such as combination chemotherapy with or without rituximab. If radiation alone is used, then a therapeutic evaluation should occur at the end of

treatment.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ABC	activated B-cell–like
ABV	doxorubicin (Adriamycin®), bleomycin, vinblastine
ABVD	doxorubicin (Adriamycin®), bleomycin, vinblastine, and dacarbazine
ADC	antibody-drug conjugate
AIDS	acquired immune deficiency syndrome
BEACOPP	bleomycin, etoposide, doxorubicin (Adriamycin®), cyclophosphamide, vincristine (Oncovin®), procarbazine, and prednisone
BR	bendamustine and rituximab
BTK	Bruton tyrosine kinase
BVR	bendamustine, rituximab, and bortezomib
CEC	cyclophosphamide, lomustine, vindesine, melphalan, prednisone, epirubicin, vincristine, procarbazine, vinblastine, bleomycin
CHOP	cyclophosphamide, doxorubicin, vincristine (Oncovin®), prednisone
CNS	central nervous system
COP	cyclophosphamide, vincristine (Oncovin®), and prednisone or prednisolone
COPP	cyclophosphamide, vincristine, procarbazine, and prednisone
CT	computed tomography
CVP	cyclophosphamide, vincristine, and prednisone
DHAP	dexamethasone, cytarabine, cisplatin
DLBCL	diffuse large B-cell lymphoma
EBV	Epstein-Barr's virus
EPOCH	etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin
ESHAP	etoposide, methylprednisolone, cytarabine, cisplatin
ESR	erythrocyte sedimentation rate
FDA	Food and Drug Administration
FLIPI	Follicular Lymphoma International Prognostic Index
FN	fludarabine and mitoxantrone
FND	fludarabine, mitoxantrone, and dexamethasone
GCB	germinal center B-cell–like
GDP	gemcitabine, dexamethasone, cisplatin
GELA	Groupe d'Etude des Lymphomes de l'Adulte
GHSG	German Hodgkin Study Group

GVD	gemcitabine, vinorelbine, and pegylated liposomal doxorubicin
HAART	highly active antiretroviral therapy
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HR	hazard ratio
HSCT	hematopoietic stem cell transplantation
hyperCVAD	cyclophosphamide, vincristine, doxorubicin, dexamethasone alternating with methotrexate and cytarabine
ICE	ifosfamide, carboplatin, and etoposide
IFRT	involved-field radiation
IPI	International Prognostic Index
IPS	International Prognostic Score
ISRT	involved-site radiation therapy
JAK–STAT	Janus kinase–signal transduction and transcription
KSHV	Kaposi sarcoma–associated herpesvirus
LDH	lactate dehydrogenase
MALT	mucosa-associated lymphoid tissue
MCL	mantle cell lymphoma
MINE	mesna, ifosfamide, mitoxantrone, etoposide
MMAE	monomethyl auristatin E
MOPP	mechlorethamine, vincristine, procarbazine, and prednisone
MOPPEBVCAD	mechlorethamine, vincristine, procarbazine, prednisone, epidoxorubicin, bleomycin, vinblastine, lomustine, doxorubicin, and vindesine
NCCN	National Comprehensive Cancer Network
NHL	non-Hodgkin lymphoma
NLPHL	nodular lymphocyte-predominant Hodgkin lymphoma
PET	positron emission tomography
R-CHOP	rituximab, cyclophosphamide, doxorubicin, vincristine (Oncovin®), prednisone
R-FCM	rituximab, fludarabine, cyclophosphamide, and mitoxantrone
REAL	revised European-American Classification of Lymphoid Neoplasms
RICE	rituximab, ifosfamide, carboplatin, and etoposide
SEER	surveillance, epidemiology, and end results
SWOG	Southwest Oncology Group
WHO	World Health Organization

Chapter 133: Ovarian Cancer

Judith A. Smith; Elizabeth K. Nugent

INTRODUCTION

KEY CONCEPTS

- 1 Ovarian cancer is denoted "the silent killer" because of the nonspecific signs and symptoms that contribute to the delay in diagnosis. The few patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate of 10% to 30%.

- 2 Ovarian cancer is a sporadic disease with less than 10% of cases of ovarian cancer attributed to heredity. However, a history of two or more first-degree relatives with ovarian cancer increases a woman's risk of developing ovarian cancer by greater than 50%.

- 3 Considerable education efforts have been made to identify patients with the persistence, greater than 2 weeks, of nonspecific presenting symptoms of ovarian cancer including: abdominal pressure/pain, difficulty eating or feeling full quickly, urinary urgency/frequency, change in bowel habits, or unexplained vaginal bleeding.

- 4 CA-125 is a nonspecific antigen used as a tumor marker for diagnosis and monitoring epithelial ovarian carcinoma. If CA-125 is positive at the time of diagnosis, changes in CA-125 levels correlate with disease response and progression.

- 5 Although most patients will achieve a complete response to initial treatment, more than 50% of patients will have recurrence within the first 2 years. If recurrence occurs less than 6 months after completion of chemotherapy, the tumor is defined to be platinum-resistant. The antitumor activity of second-line chemotherapy regimens is similar, and the choice of treatment for recurrent platinum-resistant ovarian cancer depends on residual toxicities, physician preference, and patient convenience. Participation in a clinical trial is also a reasonable option for these patients.

- 6 Ovarian cancer is staged surgically with the International Federation of Gynecology and Obstetrics (FIGO) staging algorithm. Tumor debulking and total abdominal hysterectomy–

bilateral oophorectomy surgery are the primary surgical interventions for ovarian cancer. After the completion of the staging and primary surgical treatment, the current standard of care is six cycles of a taxane/platinum-containing chemotherapy regimen.

- 7 The interperitoneal (IP) route of chemotherapy administration has significantly improved progression-free and overall survival, but patients must be carefully selected.
- 8 A platinum-containing doublet chemotherapy regimen is the standard of care for the first recurrence of platinum-sensitive ovarian cancer.
- 9 Despite recent advances, enrollment in an investigational study is still the primary treatment recommendation for patients with recurrent platinum-resistant ovarian cancer.
- 10 The activity of the new class of the poly(adenosine diphosphate [ADP]-ribose) polymerase (PARP) inhibitors depends on BCRA status or "BRCAness" of the tumor.

Ovarian cancer is a gynecologic cancer that usually arises from disruption or mutations in the epithelium of the ovary. It is associated with the highest mortality among the gynecologic cancers, primarily because most patients present with advanced disease. 1 Ovarian cancer is denoted "the silent killer" because of the nonspecific signs and symptoms that often lead to a delay in diagnosis. Ovarian cancers often metastasize via the lymphatic and blood systems to the liver and/or lungs. Common complications of advanced and progressive ovarian cancer include ascites and small bowel obstruction. The few patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate of 10% to 30%. Primary treatment includes tumor-debulking surgery followed by six cycles of a taxane-platinum chemotherapy regimen. Although 70% of patients achieve an initial complete response to chemotherapy, more than 50% of these patients will have recurrence within the first 2 years from diagnosis.[1]

EPIDEMIOLOGY

It is estimated that 22,280 new cases of ovarian cancer were diagnosed, and 14,240 women died of the disease in 2016 giving an overall mortality rate of 63.9%.[2] Unfortunately, despite clinical advances over the past two decades, the overall mortality rate for ovarian cancer has not changed (**Fig. 133-1**). Ovarian cancer is still associated with the highest mortality rate among the gynecologic cancers and is the fifth leading cause of cancer-related deaths in women. The high mortality rate is related to the insidious onset of nonspecific symptoms and the lack of adequate screening tools, which allows the disease to go undiagnosed until it has progressed beyond the pelvic cavity.

ETIOLOGY

As with many other cancers, the risk of ovarian cancer increases with increasing age. A woman's risk increases from 15.7 to 54 per 100,000 as her age advances from 40 to 79 years, and the median age at diagnosis is 59.[2] Most cases of ovarian cancer are diagnosed during the peri- and postmenopausal phase of women's reproductive life span.

2 Heredity accounts for less than 10% of all ovarian cancer cases. Family history is an important risk factor in the development of ovarian cancer. If one family member has a diagnosis of ovarian cancer, the associated lifetime risk is 9%, but this risk increases to greater than 50% if there are two or more first-degree relatives (eg, her mother and sister) with a diagnosis of ovarian cancer or multiple cases of ovarian and breast cancer within the same family.[1]

BRCA1 and *BRCA2* are the tumor suppressor genes thought to be involved in one or more pathways of DNA damage recognition and repair. The *BRCA1* gene is located on chromosome 17q12–21, and the *BRCA2* gene is located on chromosome 13q12–13. Both *BRCA1* and *BRCA2* mutations are associated with ovarian cancer. However, *BRCA1* is more prevalent, being associated with 90% of inherited and 10% of sporadic cases of ovarian cancer.[3] Patients with *BRCA1*-associated ovarian cancer are usually considerably younger than patients with *BRCA2* mutations, with a mean age of 54 years.[3] Patients usually present with advanced stage at diagnosis, and the *BRCA1*-linked ovarian cancers are more aggressive tumors that typically are serous histology, moderate to high grade. As *BRCA1* and *BRCA2* are thought to be involved in DNA damage or repair, their inactivation/mutations may be associated with an increased resistance of ovarian cancer cells to cytotoxic agents.

Hereditary breast and ovarian cancer syndrome is one of the two different forms of hereditary ovarian cancer that are associated with germline mutations in *BRCA1* and *BRCA2*.[3] The hereditary nonpolyposis colorectal cancer or Lynch syndrome is a familial syndrome with germline mutations causing defects in enzymes involved in DNA mismatch repair, which is associated with up to 12% of hereditary ovarian cancer cases.[3] This syndrome is associated with mutations in DNA mismatch repair genes such as *MSH2, MLH1, PMS1*, and *PMS2* and leads to microsatellite instability.

Hormone exposure, specifically estrogen, and reproductive history are also associated with the risk of developing ovarian cancer. Conditions that increase the total number of ovulations in women's reproductive history, such as nulliparity, early menarche, or late menopause, are associated with an increased risk for epithelial ovarian cancers.[4] Conversely those conditions that limit ovulations are associated with a protective effect. Each time ovulation occurs, the ovarian epithelium is broken, followed by cellular repair. According to the *incessant ovulation hypothesis*, the risk of mutations and, ultimately, cancer increases each time the ovarian epithelium undergoes cell repair.

Finally, ovarian cancer is associated with certain dietary and environmental factors. A diet that is high in galactose, animal fat, and meat may increase the risk of ovarian cancer, whereas a vegetable-rich diet may decrease the risk of ovarian cancer.[5] Although controversial, exogenous factors such as asbestos and talcum powder use in the perineal area are also associated with an increased risk of ovarian cancer.[5]

PATHPHYSIOLOGY

Ovarian carcinomas can be separated into three major entities: epithelial carcinomas, germ cell tumors, and stromal carcinomas. Most ovarian tumors (85%-90%) are derived from the epithelial surface of the ovary.[6] The classification of common epithelial tumors has been developed by the World Health Organization and FIGO.[6] The nomenclature considers cell type, location of the tumor, and the degree of the malignancy, which ranges from benign tumors to tumors of low malignancy to invasive carcinomas. Epithelial tumors classified as low malignancy ("borderline malignancy") are characterized by epithelial papillae with atypical cell clusters, cellular stratification, nuclear atypia, and increased mitotic activity, and have a much better prognosis than those classified as invasive carcinomas. Malignant tumors are characterized by an infiltrative destructive growth pattern with malignant cells growing in a disorganized manner and dissection into stromal planes.

Invasive epithelial adenocarcinomas are characterized by histologic subtype and grade, which measures the degree of cellular differentiation. Although the histologic type of the tumor is not a significant prognostic factor, with the exception of clear cell, the histopathologic grade is an important prognostic factor. Undifferentiated tumors are associated with a poorer prognosis than those lesions that are considered to be well or moderately differentiated. A universal grading system for ovarian cancer was developed that combines mitotic score, nuclear atypia score, and architectural score based on the histologic pattern.[7]

The histologic subtypes of adenocarcinomas include papillary serous, mucinous, endometrioid, clear cell, mixed epithelial, transition-cell, and undifferentiated adenocarcinomas.[1,8] Papillary serous

adenocarcinoma is the most common type of epithelial ovarian cancer and accounts for about 46% of cases. The peak age of diagnosis ranges from 45 to 65 years with 63 years as the median age of diagnosis.[6] Serous carcinomas typically display complex papillary and solid patterns and qualify as high-grade carcinomas. Endometrioid carcinomas are seen in women 40 to 50 years of age and comprise about 8% of ovarian carcinomas, of which about 6% are surface epithelial neoplasms.[8] Endometrioid tumors are usually diagnosed as stage I disease and have a better prognosis than tumors with serous histology. Mucinous carcinomas occur in women between 40 and 70 years of age and account for about 36% of all ovarian cancers. The overall prognosis for mucinous carcinoma is better than for serous carcinoma because most patients present with stage I disease. Clear cell carcinoma comprises about 3% of ovarian carcinomas in women, with a mean age of 57 years. Although clear cell carcinoma is the least common ovarian neoplasm, it is most commonly associated with paraneoplastic-related hypercalcemia.[8]

Germ cell tumors of the ovary, including malignant teratoma and dysgerminomas, are rare, comprising about 2% to 3% of all ovarian cancers in Western countries with an increased incidence in black and Asian women.[6] These tumors are highly curable and affect primarily young women. In contrast to epithelial tumors, about 60% to 70% of germ cell tumors are stage I at diagnosis, which is related to earlier detection and response to symptoms in this younger patient population.[6] Serum markers (human β-chorionic gonadotropin and α-fetoprotein) are helpful to confirm the diagnosis and monitor response to treatment.

Finally, ovarian sex cord-stromal tumors account for 7% of all ovarian cancers and tend to be diagnosed at an early stage.[6] Sex cord-stromal tumors are associated with hormonal effects, such as precocious puberty, amenorrhea, and postmenopausal bleeding. Because these tumors are rare, the optimal treatment of ovarian sex cord-stromal tumors is not clear. The current recommended standard of care is surgery followed by treatment with a platinum-based chemotherapy regimen.

Ovarian cancer is usually confined to the abdominal cavity, but spread can occur to the lung, liver, and, less commonly, the bone or brain. Disease is spread by direct extension, peritoneal seeding, lymphatic dissemination, or bloodborne metastasis. Lymphatic seeding is the most common pathway and frequently causes ascites.

SCREENING AND PREVENTION

Screening

Ovarian cancer is an uncommon disease with no known pre-invasive component, which has made it difficult to screen patients to detect early disease. In addition, the risk factors for developing ovarian cancer are not well understood, which also makes it difficult to identify a high-risk group of individuals. At the present time, there are no effective screening tools for early detection of ovarian cancer. 3 However, considerable education efforts have been made to help identify patients with the persistence (ie, >2 weeks) of nonspecific presenting symptoms of ovarian cancer including: abdominal pressure/pain, difficulty eating or feeling full quickly, urinary urgency/frequency, change in

bowel habits, or unexplained vaginal bleeding.

Pelvic examinations are noninvasive and well accepted and can detect large tumors with a sensitivity of 67% for detecting all tumors.[9] However, because pelvic examinations cannot detect minimal or microscopic disease, they do not usually detect ovarian cancer until it is in an advanced stage. As a result of these limitations, routine pelvic examinations are not an effective screening tool and do not decrease overall mortality.[9]

Transvaginal ultrasound (TVUS) creates an image of the ovary by releasing sound waves. It can be used to evaluate the size and shape and to detect the presence of cystic or solid masses or abdominal fluid. Transvaginal ultrasound can also evaluate blood flow within an ovarian mass. Normal ovarian size cutoff parameters range from 1.25 cm^2 for women 55 to 59 years of age to 1.0 cm^2 for women older than age 65 to 69 years.[17,18] Transvaginal ultrasound is sensitive in identifying ovarian lesions and abnormalities, but its use as a routine screening test is limited by a lack of specificity and an inability to detect peritoneal cancer or cancer in normal-size ovaries.[9]

Serum cancer antigen-125 (CA-125) is a nonspecific inflammatory antigen that can be elevated in numerous conditions associated with inflammation in the abdominal cavity. CA-125 has been extensively studied as a potential tumor marker for ovarian cancer based on the observation that CA-125 levels in a woman without ovarian cancer tend to stay the same or decrease over time, whereas levels associated with malignancy tend to gradually increase over time.[9] However, CA-125 is a nonspecific test that can be elevated in a number of benign conditions, including other gynecologic conditions, such as endometriosis, and many nongynecologic conditions, such as diverticulitis and peptic ulcer disease. Because of these limitations, CA-125 levels are not recommended as a routine screening test for detection of ovarian cancer. Numerous other serologic markers such as carcinoembryonic antigen and lipid-associated sialic acid have been evaluated but cannot be recommended for routine screening for ovarian cancer.

The United States Preventive Services Task Force found fair evidence to support screening with CA-125 or TVUS and concluded that earlier detection would likely have a small effect, at best, on mortality from ovarian cancer.[10] Unfortunately, because of the low prevalence of ovarian cancer and the invasive nature of diagnostic testing after a positive screening test, the United States Preventive Services Task Force also found fair evidence that screening could likely lead to important harms. The United States Preventive Services Task Force concluded that the potential harms outweigh the potential benefits and recommended against any form of routine screening with CA-125 or TVUS for ovarian cancer.

In high-risk women, as defined by family history, most clinicians use a multimodality approach for ovarian cancer screening that includes an annual TVUS in combination with a CA-125 blood test every 6 months. Changes in CA-125 are monitored over time, and changes such as a persistent elevation or consistent increases in CA-125 levels in conjunction with TVUS abnormalities are evaluated further.

Prevention

It is difficult to make recommendations for prevention for the general population because ovarian cancer is a sporadic disease with no established risk factors. Noninvasive measures, such as chemoprevention, have demonstrated some benefit in decreasing the risk of developing ovarian cancer. Ovulation itself is considered a potential insult to the ovarian epithelium, increasing its susceptibility to damage and, ultimately, to cancer. Interventions or reproductive conditions associated with decreasing the number of ovulations, including multiparity, may have a protective effect for the prevention of ovarian cancer. However, the more invasive prevention interventions, such as prophylactic surgery and genetic screening, should be reserved for those women identified to be at high risk based on their heredity for developing ovarian cancer.

Chemoprevention

Although a number of agents have been investigated as chemoprevention of ovarian cancer, including oral contraceptives, aspirin, nonsteroidal anti-inflammatory agents, and retinoids, none of these agents is currently accepted as standard treatment for the prevention of ovarian cancer. Oral contraceptives inhibit ovulation, which reduces the opportunity for potential for damage to the ovarian epithelium. When taken for longer than 10 years, oral contraceptives decrease the relative risk to less than 0.4.[11] Because oral contraceptive use is associated with an increased risk of breast cancer, women with a family history of breast cancer are not candidates for this use of oral contraceptives as chemoprevention of ovarian cancer.[11]

Nonsteroidal anti-inflammatory drugs, aspirin, and acetaminophen also have been suggested for use in the chemoprevention of different cancers, especially hereditary nonpolyposis colon cancer.[12] Although the results of observational studies show that the use of nonsteroidal anti-inflammatory drugs, aspirin, and acetaminophen reduces the risk of ovarian cancer, these findings have not been confirmed in prospective clinical studies. The proposed mechanism of these agents is the anti-inflammatory effect on normal ovulation and inhibition of ovulation.[12]

Prophylactic Surgery

Prophylactic surgical interventions for the prevention of ovarian cancer are reserved for patients with a significant family history or known genetic mutations such as *BRCA1* and should be postponed until after childbearing is completed. The goal is to remove healthy, at-risk organs before any carcinogenic activity is initiated, ultimately reducing the risk of developing cancer. These surgeries include prophylactic oophorectomy or bilateral salpingo-oophorectomy and tubal ligation. These procedures will cause surgical menopause, which can be associated with severe hot flashes, vaginal dryness, sexual dysfunction, and increased risk for development of osteoporosis and heart disease in these women. Because of the potential impact on quality of life and increased health risks, prophylactic surgery is not recommended as a general prevention intervention for the general population.

Although prophylactic surgical interventions are associated with significant reduction in risk of developing ovarian cancer, patients who choose to have a prophylactic oophorectomy/bilateral salpingo-oophorectomy completed need to be informed that complete protection is not guaranteed.[11,13] Although a 67% risk reduction has been shown, a potential 2% to 5% risk of primary

peritoneal cancer remains.[13] Primary peritoneal cancers have identical histology of ovarian tumors with diffuse involvement of peritoneal surfaces. Primary peritoneal cancers can often result from "seeding" during the prophylactic surgery. It is recommended for peritoneal washings to be completed during the prophylactic surgery to check for presence of peritoneal surfaces. If positive, then prophylactic surgery would change to staging and treatment surgery to determine extent of disease and remove any other possible lesions.

Tubal ligation is another procedure that can potentially reduce the risk for developing ovarian cancer. In a case-control study, Narod et al. reported that tubal ligation in *BRCA*-positive women was associated with a 63% reduction in risk of developing ovarian cancer.[14] However, it is not recommended as a sole procedure in prophylaxis. The mechanism for its protective effect is not clear, but it has been proposed that tubal ligation may limit exposure of the ovary to environmental carcinogens.

Genetic Screening

Genetic screening should be considered for those women with a significant family history of ovarian cancer. Patients should be evaluated for the presence of genes such as *BRCA1*, *BRCA2*, or other genes such as those associated with hereditary nonpolyposis colorectal cancer or the hereditary breast ovarian cancer (hereditary breast and ovarian cancer syndrome) syndrome.[14] Prior to genetic screening, appropriate patient/family counseling and genetic counseling should be available to help women prepare and deal with the health and psychosocial implications of the genetic screening results.

CLINICAL PRESENTATION

Patients with early ovarian cancer are often asymptomatic and the ovarian mass is often detected incidentally during their annual pelvic examinations. Patients with ovarian cancer often present with nonspecific, vague symptoms such as abdominal bloating, pressure or pain, indigestion, or change in bowel movements.[1] These symptoms can easily be confused with symptoms of common benign gastrointestinal disorders. Patients will often not seek medical attention until these symptoms become unrelenting and bothersome, which allows the disease to progress undetected. Patients with advanced disease may report symptoms such as pain, abdominal distension, and ascites.[1]

Several groups have partnered together to educate women about early signs and symptoms of ovarian cancer. Goff et al. recently developed a symptom index, based on a comparison of symptoms experienced in patients with ovarian cancer and a matched control group.[15] Symptoms that were correlated with ovarian cancer were persistent or recurrent bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary symptoms (either urgency or frequency). The Gynecologic Cancer Foundation, Society of Gynecologic Oncologists, and American Cancer Society recommend that women who have any of those problems nearly every day for more than 2 weeks should see a gynecologist, especially if the symptoms are new and quite different from her usual state of health. Furthermore, healthcare professionals should keep ovarian cancer in the differential

for women presenting with these persistent symptoms.

CLINICAL PRESENTATION General

- Ovarian cancer is sometimes referred to as “the silent killer” because of the vague nonspecific signs and symptoms that contribute to the delay in diagnosis.

Symptoms

- The patient may complain of abdominal discomfort, nausea, dyspepsia, flatulence, bloating, fullness, early satiety, urinary frequency, change in bowel function (diarrhea or constipation), weight change, and digestive disturbances.

Signs

- Abdominal or pelvic mass may be palpable.
- Lymphadenopathy may be present.
- Vaginal bleeding may be irregular.
- Patient may have signs of ascites (abdominal distension, shifting, and dullness to percussion—may present like “pregnant abdomen”).

Laboratory Tests

- CA-125 may be elevated (normal level is <35 units/mL [kU/L]).
- Abnormalities in liver function tests may suggest hepatic involvement.
- Abnormalities in renal function tests may suggest compression of the renal system by the tumor.

DIAGNOSIS

The diagnostic workup for suspected ovarian cancer includes a careful physical examination including a Papanicolaou (Pap) smear and a pelvic and rectovaginal examination.[3] The presence of a pelvic mass that is unilateral or bilateral, solid, irregular, fixed, or nodular is highly suggestive of ovarian cancer. Unfortunately, by the time a pelvic mass can be palpitated on physical exam, the disease is already advanced beyond the pelvic cavity. A detailed family history should be taken, especially noting the number and pattern of first-degree relatives with malignancies.

A complete blood count, chemistry profile (including liver and renal function tests), and CA-125, carcinoembryonic antigen, and CA19–9 levels should be performed. [4] Although CA-125 is a nonspecific antigen, it is the best current tumor marker for epithelial ovarian carcinoma. A normal CA-125 value is less than 35 units/mL (kU/L). If the CA-125 is elevated at the time of diagnosis, changes in CA-125 levels correlate with tumor burden. Rising CA-125 levels are often associated with

disease progression, but CA-125 can be elevated in various other conditions such as different phases of the menstrual cycle, diverticulitis, endometriosis, as well as other nongynecologic cancers. When a patient presents with an abdominal mass, it is important to rule out other cancers in the abdominal cavity. Carcinoembryonic antigen and CA19–9 are markers for other gastrointestinal cancers and may be helpful in the differential diagnosis.

Other diagnostic tests should include a transvaginal or abdominal ultrasonography, chest radiography, computed tomography, magnetic resonance imaging, or positron emission tomography scan. An upper GI series, IV pyelogram, cystoscopy, proctoscopy, or barium enema is sometimes indicated to confirm diagnosis and extent of disease.

TREATMENT

Ovarian Cancer

Desired Outcomes

The goals of treatment of ovarian cancer depend upon the FIGO stage at diagnosis. While ideally "treatment for cure" is desired, it is important to set realistic expectations for the patient. [5] Most patients will achieve a complete response to the initial multimodality treatment, but over 50% of these patients will present with recurrent disease within the first 2 years after completion of treatment. Although overall survival has not significantly changed for ovarian cancer patients, the progression-free survival has improved, which translates to less time on chemotherapy and overall improvement in quality of life for these patients.

In patients who present with metastatic disease or are not surgical candidates, the goal of treatment is to alleviate symptoms and prolong survival as long as quality of life is acceptable. In the setting of recurrent platinum-resistant ovarian cancer, the treatment goal is also to alleviate symptoms and prolong survival as long as quality of life is acceptable.

General Approach

[5] A multimodality approach that includes comprehensive surgery and chemotherapy is used for the initial treatment of ovarian cancer with curative intent. Although most patients will initially achieve a complete response, more than 50% will recur within the first 2 years.[1,16] A clinical complete response to treatment is defined as no evidence of disease by physical examination or diagnostic tests and a normal CA-125 level.

Chemotherapy regimens for ovarian cancer have evolved over the past several decades. Treatment regimens began with single-agent melphalan followed by single-agent cyclophosphamide. Shortly after cisplatin was introduced into clinical practice, it was added to cyclophosphamide, and this combination was the "standard of care" for more than a decade until the introduction of paclitaxel in the 1980s. Paclitaxel soon replaced cyclophosphamide, and paclitaxel plus cisplatin became the standard of care. Carboplatin was then substituted for cisplatin because of its improved toxicity profile, and paclitaxel plus carboplatin was adopted. During this same period, many researchers have

conducted numerous clinical trials of IP chemotherapy. In 2006, Armstrong and colleagues published the first clinical trial to demonstrate a survival advantage of IP therapy over the standard IV regimen.[17] Long-term follow-up of that trial suggests IP therapy significantly improves overall survival.[18] However, these advances in chemotherapy for the treatment of ovarian cancer have not yet translated into major changes in overall 5-year survival for women diagnosed with advanced ovarian cancer, which remains less than 20%.

Certain subgroups of patients have a better or worse response to chemotherapy. The histologic subtype of the tumor is a prognostic factor; clear cell histology is more likely to be poorly differentiated, faster growing, and have intrinsic drug resistance.[1,6] However, the extent of residual disease, size larger than 1 cm, and tumor grade are better predictors of response to chemotherapy and overall survival.[1]

In general, younger patients have a better performance status and tolerate chemotherapy better than elderly patients. For unknown reasons, white women tend to have a worse prognosis and response to therapy as compared with women of other ethnic backgrounds.[1]

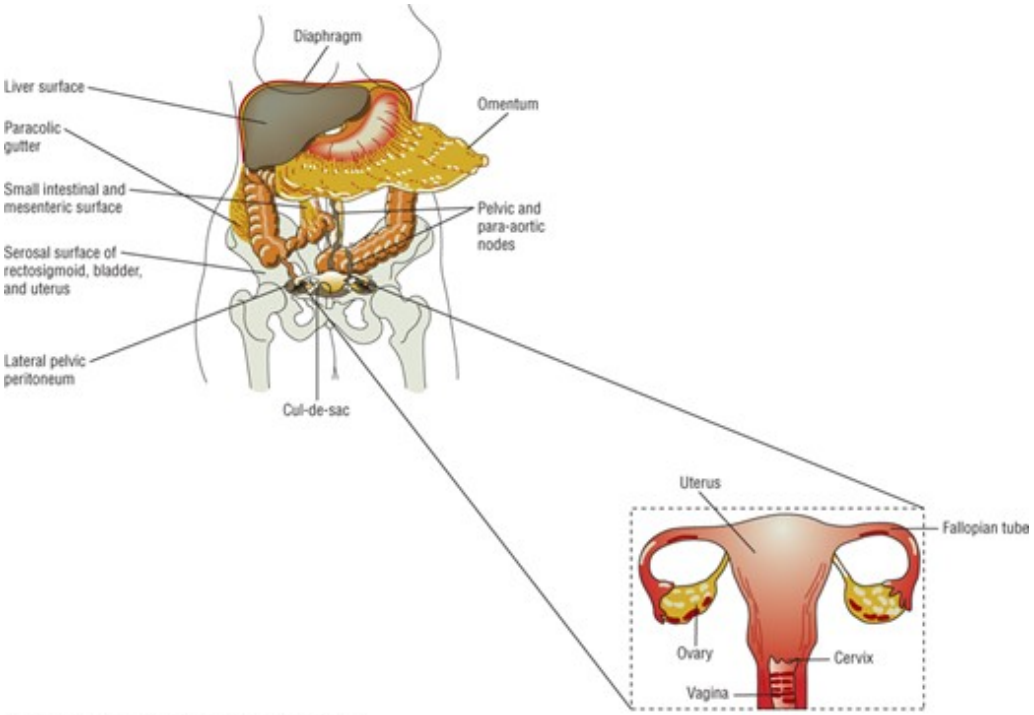
In patients with recurrent ovarian cancer, the goals of treatment are to relieve symptoms such as pain or discomfort from ascites, slow disease progression, and prevent serious complications such as small bowel obstructions.

Surgery

Surgery is the primary treatment intervention for ovarian cancer.[19,20,21] Surgery may be curative for selected patients with limited stage IA disease. Primary surgical treatment includes a total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH/BSO), omentectomy, and lymph node dissection (**Fig. 133-2**).[19,20,21] The primary objective of the surgery is to optimally debulk the tumor to less than 1 cm of residual disease.[42] Long-term follow-up studies confirm that residual disease smaller than 1 cm correlates with higher complete response rates to chemotherapy and longer overall survival as compared to patients with bulky residual disease (>1 cm).[21]

FIGURE 133-2

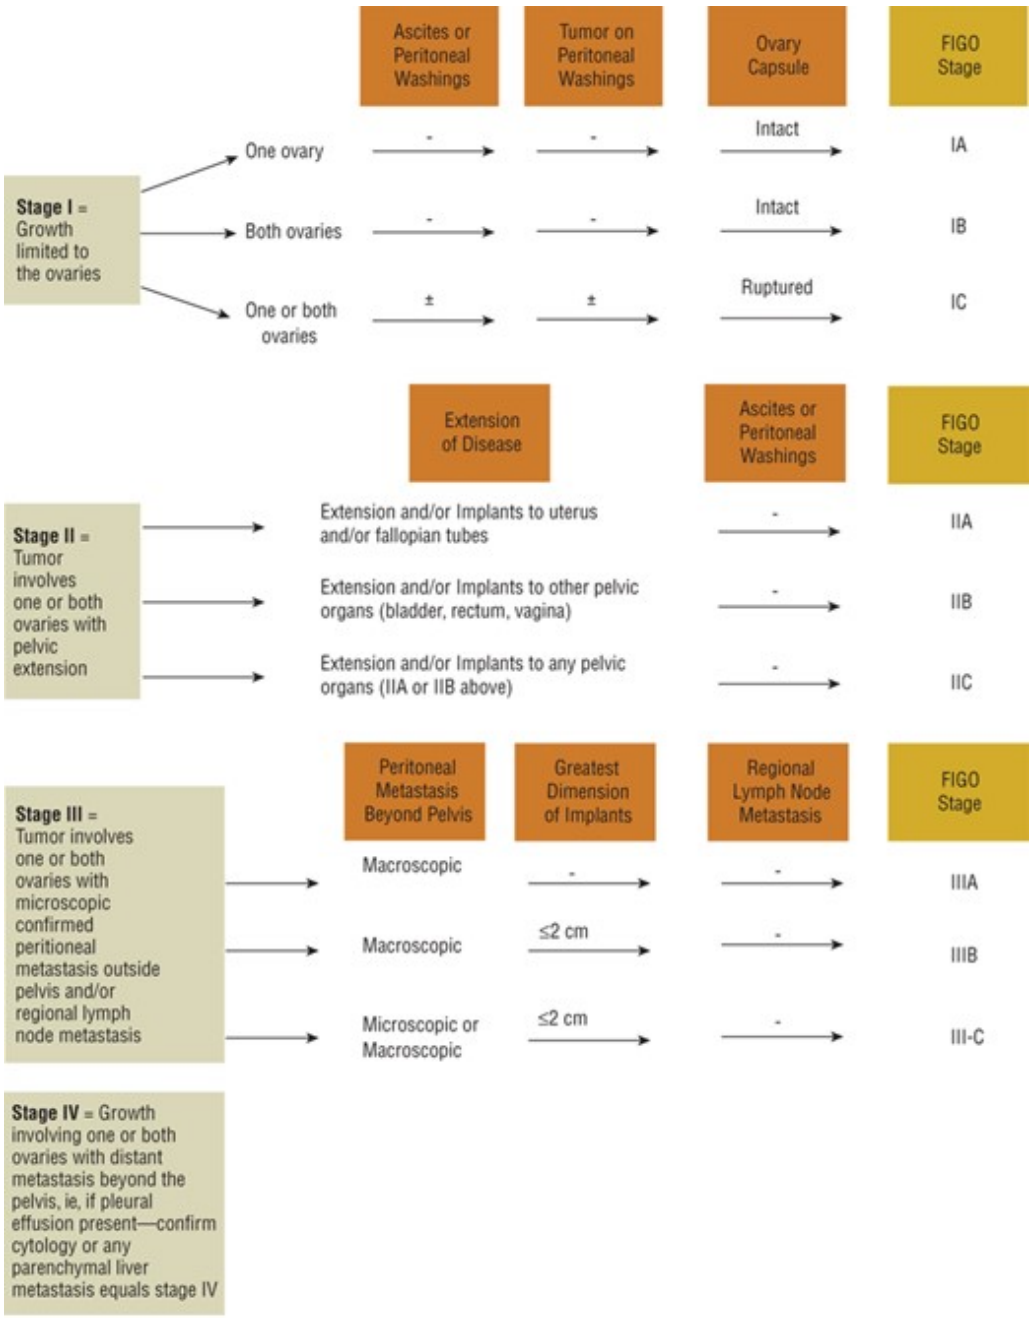
Staging laparotomy for ovarian cancer with diagram of female reproductive tract (uterus, fallopian tubes, ovaries, and vagina). *Dashed line box* outlines what is removed during the total abdominal hysterectomy with bilateral salpingo-oophorectomy.



A comprehensive exploratory laparotomy is vital for the accurate confirmation of diagnosis and staging of ovarian cancer.[19,20] Unlike other cancers that are typically diagnosed by biopsy or laboratory results and clinically staged by results from imaging tests, gynecologic cancers, such as ovarian cancer, are surgically diagnosed and then staged according to the FIGO staging algorithm (**Fig. 133-3**). The FIGO staging system requires a fairly extensive surgery by an experienced gynecologic oncologist. The skill of the surgeon has a significant effect on prognosis, with definitive benefit of a trained gynecologic oncologist performing surgery as compared with a gynecologist or general surgeon.[22] The reasons for this approach include (a) pelvic tumors cannot be readily biopsied without risk of "tumor seeding," which can increase the risk of recurrence, and (b) surgical staging takes into account the presence of microscopic disease in samples obtained by pelvic washing and lymph node dissection and read by a pathologist during the surgical procedure. It is recommended that the initial surgical staging and tumor-debulking surgery be completed by a trained gynecologic oncology surgeon when ovarian cancer is suspected to prevent understaging and to optimize overall outcome.[23]

FIGURE 133-3

International Federation of Gynecology and Obstetrics (FIGO) staging algorithm.



Secondary cytoreduction or interval debulking is when surgery is performed after completion of some or all chemotherapy to remove residual disease. Some protocols include additional cycles of chemotherapy after the surgical procedure. The importance of cytoreduction before, during, or after chemotherapy is still controversial, but it has been recommended to facilitate response to chemotherapy and improve overall survival. Randomized trials of secondary surgical cytoreduction have reported conflicting results. In a recently published study of 550 women with stage III or IV disease treated with primary cytoreductive surgery and three cycles of paclitaxel and cisplatin, patients randomized to receive secondary cytoreductive surgery followed by three more cycles of chemotherapy had similar progression-free survival and overall survival as compared with those randomized to receive three more cycles of chemotherapy alone.[24]

The overall effect of interval debulking is influenced by several factors, including initial response to chemotherapy, the amount of residual disease before and after second-look surgery, and the presence of microscopic residual disease. The results of recent trials suggest that secondary surgical cytoreduction does not prolong survival in patients who are treated with maximal primary cytoreductive surgery followed by appropriate postoperative chemotherapy.

"Second-look surgery" is an elective surgical procedure performed in patients who achieve a clinical complete response after primary chemotherapy to determine if any visible or microscopic disease is present in the peritoneal cavity. The benefit of "second-look laparotomy" to evaluate residual disease after completing chemotherapy remains controversial because it has been difficult to establish any impact on overall survival. It has questionable benefit because about 50% of those with a negative second look still relapsed.[24] If visible or microscopic disease is detected during second look, then the clinician may decide to give additional chemotherapy. But if no visible or microscopic disease is detected during second look, the clinician may decide to observe and monitor the patient. Use of laparoscopic surgical techniques is controversial for initial surgery but is sometimes considered in debulking of recurrent or advanced disease when the intent is palliative rather than curative.[21] In patients with recurrent disease, the goal of debulking surgery is to relieve symptoms associated with complications such as small bowel obstructions and to help improve the patient's quality of life.

Radiation

Radiation has a limited role in the management of ovarian cancer. Use of radiation for treatment of early stage disease has had no benefit or impact on overall survival.[25] Radiation therapy is most beneficial for palliation of symptoms in patients with recurrent pelvic disease, often associated with small bowel obstructions. The two forms of radiation therapy used in ovarian cancer are external beam whole-abdominal irradiation and intraperitoneal isotopes such as phosphorus-32 (^{32}P). Alleviation of symptoms with external beam whole-abdominal irradiation is associated with a significant improvement in the patient's quality of life. The recommended dose ranges from 35 to 45 Gy (3500-4500 rad), depending on the treatment history and ability to tolerate radiation treatments.

First-Line Chemotherapy

The mainstay of ovarian cancer treatment is chemotherapy. It is used as a component of first-line treatment after completion of surgery and is the primary modality of treatment for recurrent ovarian cancer. Systemic chemotherapy with a taxane and platinum regimen following optimal surgical debulking is the standard of care for treatment of epithelial ovarian cancer (**Fig. 133-4**). **Table 133-1** summarizes the chemotherapeutic regimens used as the initial treatment of newly diagnosed epithelial ovarian cancer. More than 60 randomized, controlled clinical trials have evaluated combination chemotherapy regimens for the treatment of advanced ovarian cancer, and a meta-analysis of these trials confirmed the efficacy of platinum and taxane regimens over other regimens.[26]

FIGURE 133-4

Management of newly diagnosed, refractory, and progressive epithelial ovarian cancer. All recommendations are category 2A unless otherwise indicated. (CR, complete response; PD, progression of disease; PR, partial response; TAH/BSO, total abdominal hysterectomy/bilateral salpingo-oophorectomy; USO, unilateral salpingo-oophorectomy.)

TABLE 133-1 Initial Chemotherapeutic Regimens of Epithelial Ovarian Cancer

Drug(s)	Brand Name	Initial Dose(s)/Usual Range	Cycle Frequency

Drug(s)	Brand Name	Initial Dose(s)/Usual Range	Cycle Frequency
Paclitaxel + carboplatin	Taxol/Paraplatin	175 mg/m^2 IV (3-hours infusion) day 1 Dosed to AUC 5-7.5 IV day 1	Every 21 days
Paclitaxel + cisplatin (IV)	Taxol/Platinol	135 mg/m^2 IV (24-h infusion) day 1 75 mg/m^2 IV day 1	Every 21 days
Paclitaxel + cisplatin (IP)	Taxol/Platinol	Day 1: Paclitaxel 135 mg/m^2 IV infused over 24 hours Day 2: Cisplatin 100 mg/m^2 IP infused over 1 hour Day 8: Paclitaxel 60 mg/m^2 IP infused over 1 hour.	Every 21 days
Cisplatin + cyclophosphamide	Platinol/Cytoxan	50-100 mg/m^2 IV day 1 500-1,000 mg/m^2 IV day 1	Every 21-28 days
Docetaxel + carboplatin	Taxotere/Paraplatin	75 mg/m^2 IV day 1	Every 21 days

AUC, area under the curve; IP, interperitoneal.

Historically, single-agent alkylating agents such as melphalan, and later cyclophosphamide, were used for the treatment of advanced ovarian cancer until the introduction of cisplatin in the 1970s. Combination chemotherapy regimens containing cisplatin and cyclophosphamide achieved higher response rates and overall survival than regimens without cisplatin in patients with advanced ovarian cancer.[16] Based on the results of these trials, the combination of cisplatin plus cyclophosphamide remained the standard of care for the treatment of ovarian cancer until the early 1990s.

The next major advance in the therapy of advanced ovarian cancer occurred with the introduction of paclitaxel into chemotherapy regimens. McGuire et al. reported the results of a Gynecologic Oncology Group (GOG)-111 study that found the combination of paclitaxel 135 mg/m^2 over 24 hours and cisplatin 75 mg/m^2 achieved higher response rates and longer survival than did cyclophosphamide 750 mg/m^2 and cisplatin 75 mg/m^2 in patients with newly diagnosed, suboptimally debulked, stages III and IV ovarian cancer.[27] Survival improved significantly in the paclitaxel arm, with an increase in median progression-free survival (18 vs 13 months) and overall survival (38 vs 24 months). Neutropenia, alopecia, and peripheral neuropathy were more severe in the paclitaxel plus cisplatin group. Similar results were reported in a large European-Canadian Intergroup Phase III randomized trial study (OV10) that also confirmed superior response rates with the paclitaxel 135 mg/m^2 over 24 hours with cisplatin 75 mg/m^2 regimen as compared with cyclophosphamide 750 mg/m^2 with cisplatin 75 mg/m^2 regimen.[28] Based on the results of these studies, paclitaxel plus cisplatin was widely adopted and became the accepted standard of care.

The availability of carboplatin led to clinical trials to evaluate whether carboplatin could be

substituted for cisplatin, which would spare patients from the significant neurotoxicity and nephrotoxicity associated with cisplatin. Several prospective randomized comparisons of carboplatin plus paclitaxel versus cisplatin plus paclitaxel in patients with advanced ovarian cancer have been conducted.[29,30,31,32] The results of these trials show that carboplatin plus paclitaxel is equally efficacious and better tolerated than cisplatin and paclitaxel. In the GOG-158 study, 840 previously untreated patients with optimally resected stage III disease (no residual tumor nodule >1 cm) were randomized to carboplatin (area under the curve [AUC] = 7.5) plus paclitaxel 175 mg/m^2 over 3 hours, or cisplatin 75 mg/m^2 plus paclitaxel 135 mg/m^2 over 24 hours administered every 21 days for six cycles.[29,31] The results of that trial showed no difference in progression-free survival between the two treatment arms with a median time-to-progression of 19.4 months in the paclitaxel plus cisplatin arm versus 20.7 months in the paclitaxel plus carboplatin arm. As expected, the incidence of leukopenia, fever, gastrointestinal toxicity, and metabolic toxicity was higher in patients in the cisplatin arm, while patients in the carboplatin arm experienced more thrombocytopenia and pain. Although the incidence of neurotoxicity was similar in the two treatment arms, it was more severe in the paclitaxel plus cisplatin arm. The results of this study showed that the substitution of carboplatin for cisplatin in the regimen does not compromise efficacy and improves tolerability. These findings were confirmed in two other large randomized, controlled studies.[31,32] Based on these results, paclitaxel plus carboplatin became the accepted standard of care.

Other clinical trials have evaluated the use of docetaxel as a substitute for paclitaxel. In the Scottish Randomized Trial in Ovarian Cancer (SCOTROC), Vasey et al. compared carboplatin (AUC = 5) combined with either docetaxel (75 mg/m^2 over 1 hour) or paclitaxel (175 mg/m^2 over 3 hours) administered every 21 days for six cycles as first-line chemotherapy for stages I to IV epithelial ovarian cancer.[33] The results of this study showed that the substitution of docetaxel for paclitaxel does not compromise efficacy and improves tolerability, particularly neurotoxicity. These findings were not confirmed in another randomized, controlled trial. However, based on the results of this study the combination of docetaxel plus carboplatin is considered a reasonable treatment option for patients with advanced ovarian cancer. Six cycles of paclitaxel plus carboplatin following tumor debulking surgery remain the current standard of care for treatment of advanced ovarian cancer.

Although the choice of taxane or platinum agent does not appear to have a major effect on antitumor activity, weekly paclitaxel administration (“dose density”) may be superior to administration every 3 weeks.[34,35,36] In a phase III trial conducted in Japan, Katsumata et al. reported that patients randomized to six cycles of dose-dense weekly paclitaxel plus carboplatin every 3 weeks had longer progression-free survival as compared to the standard paclitaxel plus carboplatin every 3 weeks.[36] Overall survival at 3 years was also significantly longer in patients who received the dose-dense regimen (72% vs 65%, P = 0.03). However, over 42% of the patients who received the dose-dense regimen dropped out of the study before completing six cycles because of treatment-related toxicities. A confirmatory GOG phase III trial is ongoing to confirm these results and address concerns regarding the feasibility of the dose-dense regimen in a larger group of patients as well as the elderly population.

IP chemotherapy was initially employed as palliative care in the management of ascites and uncontrolled intraabdominal tumors. In the late 1970s, IP chemotherapy administration as a primary

treatment intervention was initiated based on the rationale that exposure of the tumor to high drug concentrations would increase tumor drug uptake by passive diffusion and ultimately cancer cell death.[37] The increase in AUC exposure in the peritoneal cavity was demonstrated, but the correlative increase in drug uptake in tumor tissue has yet to be validated in any preclinical or clinical study.

7 IP chemotherapy has demonstrated a benefit in the first-line treatment of patients with optimally debulked advanced-stage ovarian cancer.[38,39,40] In a landmark trial, Armstrong et al. reported the results of the GOG-172 study, which evaluated 415 patients randomized to receive either the combination regimen of paclitaxel 135 mg/m^2 over 24 hours and cisplatin 75 mg/m^2 or a new combination regimen that included paclitaxel 135 mg/m^2 IV infused over 24 hours followed by cisplatin 100 mg/m^2 IP infused over 1 hour on day 2, and then paclitaxel 60 mg/m^2 IP infused over 1 hour on day 8.[17] Both treatment regimens were given once every 21 days for a total of six cycles. Patients randomized to the IP chemotherapy arm had a 5.5-month increase in median progression-free survival and a 15.9-month increase in overall survival.[17] A secondary analysis by Tewari et al. of patients from GOG-172 and GOG-114 IP therapy studies reported a 10.4-month improvement in the median overall survival and 23% decreased risk of death in those patients that had received IP chemotherapy compared to IV chemotherapy.[18] Contributing factors that negatively impacted survival included gross residual disease, clear cell or mucinous histology, and not completing all six cycles of IP chemotherapy.

A potential limitation of IP therapy is significantly more toxicity, including pain, fatigue, myelosuppression, gastrointestinal, metabolic, and neurotoxicity.[17,39,41,42] Despite the potential benefit to improve survival, there has been slow adoption of IP therapy into routine clinical use. Burger et al. completed a cohort study of 823 women with advanced ovarian cancer from six National Comprehensive Cancer Network institutions and found that less than 50% of eligible patients had received IP chemotherapy as part of their primary treatment.[43] The significant increase in systemic toxicity, primarily neurotoxicity, has led to the question of whether IP carboplatin could be substituted for IP cisplatin. Although these platinum agents have demonstrated equal efficacy when administered IV to ovarian cancer patients, it is difficult to extrapolate the IP activity of cisplatin to carboplatin because of the difference in molecular size of cisplatin versus carboplatin and the importance of passive diffusion of drug into the tumor.

Clinical Controversy…

The use of IP chemotherapy as first-line treatment of advanced ovarian cancer has been recommended by the National Comprehensive Cancer Network (NCCN) guidelines. Most clinical trials have used platinum agents given IP until the Gynecologic Oncology Group (GOG)-172 trial that incorporated IP paclitaxel. Many clinicians are concerned about how to manage hypersensitivity reactions to either platinum or taxane agents when administered IP.

The 2015 NCCN guidelines recommend that IP chemotherapy be considered and offered to appropriate patients as first-line treatment of optimally debulked, ≥1 cm residual disease, ovarian cancer.[42] 7 Because of the significant toxicities associated with IP therapy, only carefully selected

patients should receive IP therapy. Ideal candidates for IP therapy are younger patients with good performance status, minimal comorbidities, adequate renal and liver function, and optimally debulked disease without significant bowel resection.[38,41]

In patients who are poor surgical candidates because of comorbidities or bulky tumors, neoadjuvant chemotherapy can be given prior to any surgical interventions.[44] In patients with bulky disease, the goal of neoadjuvant chemotherapy is to reduce tumor burden to make surgery more feasible and optimal tumor debulking more likely. The typical regimen used in neoadjuvant chemotherapy is three cycles of a taxane combined with a platinum agent followed by surgery. After surgery, patients usually receive another three to six cycles, depending on their response to chemotherapy. In patients who are poor candidates for surgery because of comorbidities, the primary intent of neoadjuvant chemotherapy is to relieve symptoms and slow disease progression. In this setting, palliative chemotherapy alone has not been curative for patients with advanced ovarian cancer.[44] If tolerated, these patients will receive the standard taxane plus platinum chemotherapy regimen once every 3 to 4 weeks. Another option for palliative neoadjuvant chemotherapy, especially in elderly patients, is single-agent carboplatin once every 4 weeks.

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy is first-line treatment for patients who are poor surgical candidates or patients with bulky or significant tumor burden.[44] The neoadjuvant chemotherapy regimen typically includes a combination of taxane with platinum agent and is administered every 21 to 28 days as tolerated with intent to reduce tumor burden to point where it potentially could be surgically resected and ideally optimally debulking during surgery.[44] After surgery, patient will receive another three to six cycles depending on response to chemotherapy. The role of neoadjuvant chemotherapy for all patients presenting with advance ovarian cancer is being revisited in ongoing GOG clinical trials.

Consolidation Therapy

If patients do not achieve a clinical complete response after completion of six cycles of taxane-platinum regimen, then consolidation chemotherapy should be considered in an attempt to achieve a complete response (Fig. 133-3). If the patient has a partial response to first-line chemotherapy, as measured by a greater than 50% decline in CA-125 (as compared with the pre-surgery level) or tumor regression, the cancer is still considered sensitive to the regimen. The typical regimens for consolidation chemotherapy are the taxane plus platinum regimen or single-agent therapy with either a taxane or platinum agent.[16] If the patient had a poor response to taxane and platinum, then alternative second-line agents can be considered.[42] Additional cycles of chemotherapy are given until complete response is achieved. Another alternative in the setting of no or minimal measurable disease after completion of primary chemotherapy is to just observe the patient and provide supportive care as indicated until disease progresses, then reinitiate chemotherapy at that time.[42]

Because the initial clinical complete response observed in first-line treatment has not been durable, optimization of first-line therapy is under investigation. Numerous options have been evaluated,

including the use of additional cycles or maintenance chemotherapy and dose intensity.

Maintenance Chemotherapy

Maintenance chemotherapy is similar to consolidation chemotherapy except maintenance chemotherapy is given to those patients who have achieved a clinica complete response. The primary differences between consolidation and maintenance chemotherapy are the types of agents used and duration of therapy. Consolidation therapy usually consists of more aggressive combination regimens, whereas maintenance chemotherapy usually consists of single agents given less frequently (ie, once monthly) to minimize adverse effects. The goal of maintenance chemotherapy is to eliminate any residual microscopic disease that may be present to extend progression-free and overall survival.

Maintenance chemotherapy has gained popularity after the publication of the results of the collaborative Southwest Oncology Group (SWOG) and GOG 178 study that compared single-agent paclitaxel 175 mg/m^2 over 3 hours once every 21 days for three additional cycles versus an additional 12 cycles.[45] Eligible patients had to have been in complete clinical remission after at least five to six cycles of a taxane-platinum regimen. This study was closed after the interim analysis by the SWOG Safety Monitoring Committee because patients receiving the additional 12 cycles had longer progression-free survival than those receiving three cycles of single-agent paclitaxel (28 vs 21 months). After the results were reported, many patients randomized to the three-cycle arm chose to receive nine additional cycles of paclitaxel, which reduced the ability of the trial to show a difference in overall survival.[46] Because this study was closed early and did not demonstrate an overall survival benefit, another randomized, controlled trial through the GOG was initiated to confirm the improvement in progression-free survival and to attempt to determine the impact on overall survival. Until these confirmatory trials are completed, the role of maintenance chemotherapy is controversial in the management of advanced ovarian cancer patients. Maintenance chemotherapy is listed as an option in the 2015 NCCN guidelines (2B recommendation).[42]

Treatment of Recurrent Disease

Although most patients will achieve a complete response to initial treatment, most patients will eventually have recurrence of their disease within the first 2 years. When a patient relapses, the prognostic factors are similar to the factors after initial surgery except that the disease-free interval —defined as the length of time that has lapsed since the completion of chemotherapy—should be considered to determine if the tumor is likely to be drug resistant to agents used in first-line treatment, which included platinum and taxanes. If recurrence occurs less than 6 months after completion of chemotherapy, or if the patient progresses during platinum-based chemotherapy, the tumor is defined as platinum-resistant. Patients with platinum-sensitive disease generally have a better prognosis than platinum-resistant patients.

If the patient has a clinical complete response to first-line chemotherapy and the recurrence occurs more than 6 months after chemotherapy is completed, the tumor is considered platinum-sensitive. 8 In patients with platinum-sensitive ovarian cancer, the standard of care is to treat the first recurrence with a doublet, platinum-containing chemotherapy regimen. **Table 133-2** summarizes

some of the chemotherapeutic regimens used in the treatment of recurrent or refractory ovarian cancer. Because the chemotherapy agents used for second-line treatment of recurrent or refractory platinum-resistant disease have similar response rates that average less than 30%, the selection of the agent depends on multiple factors including the toxicity profile of the agent, physician preference, patient performance status, residual toxicities, and patient convenience (Fig. 133-3). In this setting, the intent of treatment is to prolong survival and alleviate symptoms, not necessarily to achieve another "complete response" to chemotherapy. [9] Because of poor response rates of the available agents, participation in a clinical trial of an investigational agent is often recommended for patients with recurrent platinum-resistant ovarian cancer.

TABLE 133-2 Single-Agent Chemotherapeutic Regimens for Recurrent or Refractory Ovarian Cancer

Drug(s)	Brand Name(s)	Initial Dose(s)/Usual Range	Cycle Frequency
Docetaxel	Taxotere	75 mg/m^2 IV day 1	Every 21 days
Pegylated-liposomal doxorubicin	Doxil	40 mg/m^2 IV day 1	Every 28 days
Gemcitabine	Gemzar	800-1,000 mg/m^2 IV days 1, 8, and 15	Every 28 days
Paclitaxel	Taxol	60-80 mg/m^2 IV (1-h infusion) day 1	Every week
Paclitaxel	Taxol	135-175 mg/m^2 IV day 1	Every 21 days
Carboplatin	Paraplatin	AUC 5 IV day 1	Every 21-28 days
Cisplatin	Platinol	75 mg/m^2 IV day 1	Every 21-28 days
Topotecan	Hycamtin	1.3-1.5 mg/m^2 IV once daily for 5 days	Every 21 days
Topotecan	Hycamtin	4 mg/m^2 IV once a week × 3 weeks, then 1 week off	Every 21 days
Etoposide	Vepesid	50 mg/m^2 orally once daily days 1-10 repeat every 21 days	Every 28 days
Capecitabine	Xeloda	1,800-2,000 mg/m^2 in divided dose twice a day for 2 weeks on, 1 week off	Every 21 days
Altretamine	Hexalen	260 mg/m^2 orally (total daily dose divided in four doses) for 14-21 days	Every 28 days
Tamoxifen	Nolvadex	20 mg orally twice a day	Continuous
Letrozole	Femara	2.5 mg orally once daily	Continuous

AUC, area under the curve.

Platinum-Sensitive Disease

[9] Retreatment with a platinum-containing regimen should be considered in patients with platinum-

sensitive disease. The International Collaborative Ovarian Neoplasm 4 and Arbeitsgemeinschaft Gynaekologische randomized 802 patients with recurrent platinum-sensitive ovarian cancer to either single-agent platinum, a non–taxane-platinum combination, or a taxane plus platinum combination.[47] Patients treated with the paclitaxel plus platinum regimen had significantly longer progression-free (29 vs 24 months) and overall survival (hazard ratio 0.82 [95% CI 0.69- 0.97]) as compared with the other two treatment arms.[47,48] Although the taxane-platinum combination was clearly superior in this European study, it is difficult to extrapolate these results to patients treated in the United States because of differences in first-line treatment. At the time that International Collaborative Ovarian Neoplasm 4 (ICON4) was conducted, the standard of care in Europe for first-line treatment was single-agent carboplatin, so most patients enrolled in this study had no prior exposure to a taxane agent.[47] However, the standard of care in the United States has been a taxane-platinum combination since the early 1990s. Confirmatory data are needed to evaluate whether combination regimens would also be more beneficial in these patients for treatment of recurrent ovarian cancer.

Clinical Controversy…

In patients with recurrent ovarian cancer that is platinum sensitive, some clinicians will recommend retreatment with a chemotherapy regimen including a platinum agent. Other clinicians suggest that the platinum-free interval for these patients should be extended and will recommend that recurrent disease first be treated with a non-platinum regimen (ie, liposomal doxorubicin) and reserve the platinum agent until the next relapse.

The 2015 NCCN guidelines recommend the combination of platinum agent with gemcitabine, liposomal doxorubicin, or paclitaxel for treatment of platinum-sensitive recurrent ovarian cancer (**Table 133-3**).[42] In addition, the combination of gemcitabine plus cisplatin has demonstrated improvement in progression-free survival.[48] Carboplatin alone or any of the second-line agents is recommended for patients with platinum-sensitive disease who are unable to tolerate additional combination chemotherapy regimens because of residual toxicity or poor performance status.[42]

TABLE 133-3 Combination Chemotherapy Regimens for Platinum-Sensitive Recurrent Ovarian Cancer

Drug(s)	Brand Name	Initial Dose(s)/Usual Range	Cycle Frequency
Gemcitabine + carboplatin	Gemzar/Paraplatin	800 mg/m^2 IV day 1 & 8	Every 21 days
Gemcitabine + cisplatin	Gemzar/Platinol	Dosed to AUC 5 IV day 1	Every 21 days
Liposomal doxorubicin + carboplatin	Doxil/Paraplatin	Day 1 & day 8: gemcitabine 800 mg/m^2 & cisplatin 40 mg/m^2	Every 28 days
Cyclophosphamide + bevacizumab	Cytoxan/Avastin	30 mg/m^2 IV over 1-3 h & carboplatin AUC 5 50 mg PO once daily + bevacizumab 15 mg/kg q 3 weeks	Every 28 days

AUC, area under the curve; PO, by mouth.

Platinum-Resistant Disease

Frequently patients present with recurrent drug-resistant disease after initial platinum-based therapy and cytoreductive surgery.[16] Patients who progress on a platinum agent or have no response are considered "platinum-refractory," whereas those patients who have recurrence within 6 months of completing a platinum-containing regimen are considered "platinum-resistant."[42] The 2015 NCCN guidelines list many possible treatment options for recurrent platinum-resistant or refractory ovarian carcinoma.[42] The optimal chemotherapeutic agent or regimen in the treatment of platinum-resistant disease is currently unclear. Ideally, the agent should be active in ovarian cancer and non–cross-resistant with taxanes or platinum agents. Unfortunately, the response rate is low for all of the agents in platinum-refractory or resistant ovarian cancer.[16] Patients should typically be evaluated for response after treatment with at least three cycles of the chemotherapy agent or regimen. Because partial responses are rare, stable disease with relief of symptoms is considered a treatment success. If no response is observed, then an alternative chemotherapy regimen may be selected. Because all the potential agents have similar efficacy, the selection of agents and sequence used for treatment as the patient progresses will vary based on residual toxicity, dosing schedule, patient convenience, and physician preference.

Topotecan, an analog of the plant alkaloid 20(S)-camptothecin, is active in patients with metastatic ovarian cancer and is non–cross-resistant with platinum-based chemotherapy.[16] Preclinical studies suggest that protracted schedules of administration with low doses achieve the greatest antitumor response.[16] Topotecan has demonstrated activity in phase II trials as second-line and salvage therapy in patients who have relapsed after, or progressed during, platinum-based therapy.[49] A randomized phase III trial compared topotecan and paclitaxel in patients with advanced ovarian cancer who had failed one platinum-based regimen.[50] Patients were randomized to receive topotecan 1.5 mg/m^2 per day as a 30-minute infusion for 5 days repeated every 21 days or paclitaxel 175 mg/m^2 as a 3-hour infusion every 21 days. The overall response rate was 21% and 13% for the topotecan- and paclitaxel-treated groups, respectively. The median time-to-progression for topotecan-treated patients (32 weeks) was not significantly different from that for paclitaxel-treated patients (20 weeks). Median survival was 61 weeks in the topotecan-treated group and 43 weeks in the paclitaxel-treated group. Topotecan was well tolerated with minimal nonhematologic toxicities.[49,50]

Pegylated liposomal doxorubicin is one of the primary agents used for second-line therapy of recurrent ovarian cancer.[51,52,53] The drug tends to be better tolerated than topotecan, which is important for heavily pretreated patients with advanced disease. A large, randomized phase III study compared pegylated liposomal doxorubicin 50 mg/m^2 every 4 weeks to topotecan 1.5 mg/m^2 per day for 5 days repeated every 21 days in patients who failed first-line platinum therapy.[53] A total of 474 patients were randomized, 239 to pegylated liposomal doxorubicin and 235 to topotecan. The overall response rates for the pegylated liposomal doxorubicin and topotecan groups were 20% and 17%, respectively. Overall survival tended to favor pegylated liposomal doxorubicin, with a median of 108 weeks versus 71 weeks for topotecan. Differences in toxicity were observed between the arms, with more hematologic toxicity occurring in the topotecan arm and more palmar–plantar erythrodysesthesia (PPE) in the pegylated liposomal doxorubicin arm. However, the incidence of PPE

has decreased in current clinical practice because the standard dose of pegylated liposomal doxorubicin used currently, 40 mg/m^2, is less than the dose that was used in the initial clinical trials and approved by the FDA.[54,55]

Gemcitabine, a novel pyrimidine antimetabolite, is also widely used in the treatment of recurrent platinum-resistant ovarian cancer. Although the overall response rate is only about 13% to 22% with single-agent gemcitabine in patients with platinum-refractory recurrent ovarian cancer, an additional 16% to 50% of patients have stable disease for a median of 7 months.[56] The main toxicities include myelosuppression, fatigue, myalgia, and skin rash. Because of its non-cross-resistant activity and in vivo synergy with platinum agents, gemcitabine is being evaluated in doublet regimens in patients with refractory disease and with carboplatin/taxane regimens in previously untreated patients.[56] The combination of gemcitabine with taxanes has demonstrated response rates from 36% to 90%, which if confirmed, are extremely encouraging.[16]

Other agents that have shown an overall response rate of 10% to 25% in patients with recurrent ovarian cancer include altretamine, etoposide, capecitabine, tamoxifen, letrozole, vinorelbine, and oxaliplatin.[16] Response rates tend to be higher in the platinum-sensitive subgroups. Most of these agents are available in oral formulations, which allows for outpatient administration in the palliative care setting.

Although there are no therapeutic guidelines for the selection of agents for the treatment of recurrent platinum-resistant ovarian cancer, the three most commonly used agents in clinical practice include pegylated liposomal doxorubicin, gemcitabine, and topotecan. These agents have demonstrated efficacy when used as a single agent and in combination with other agents. A phase II GOG study is ongoing to help define the optimal chemotherapy combination for treatment of recurrent or refractory platinum-resistant ovarian cancer. Selection of chemotherapy for treatment of recurrent disease is ultimately based on the patient's residual toxicities, scheduling and convenience, and physician preference.

Additional research continues to identify new agents and new targets for the treatment of ovarian cancer. Because platinum agents and taxanes have been identified as the most active classes of agents for treatment of ovarian cancer, drug development has focused on new platinum derivatives, taxanes and taxane analogs, and agents that exert cytotoxic activity by interacting with DNA directly. Specifically, new cytotoxic agents such as trabectedin, pemetrexed, and epothilones are currently being evaluated in clinical trials.

Biologic and Targeted Agents

Monoclonal antibodies such as bevacizumab and cetuximab and small-molecule tyrosine kinase inhibitors such as sunitinib, gefitinib, or sorafenib, are being evaluated to be incorporated into first line and recurrent treatment regimens for ovarian cancer.[16] Although the biologic agents as single agents have not demonstrated significant activity, the results of several clinical trials show that the addition of agents such as bevacizumab into first line and maintenance regimens improves progression-free survival. However, the impact on overall survival is controversial.

Bevacizumab

Bevacizumab is a recombinant humanized monoclonal antibody that targets vascular endothelial growth factor (VEGF), a key mediator of angiogenesis. In the setting of recurrent disease, single-agent bevacizumab produces a response rate similar to other therapies of 16% to 21%.[57,58] Response rates with combinations of bevacizumab range from 15% to 80%.[57,58,59,60,61] However, these phase II trials have also reported a higher risk of bowel perforation in patients treated with bevacizumab-containing regimens.[57,58] Bevacizumab should therefore not be given to patients who have had recent bowel surgery or a history of significant bowel resections. In an open label phase III study (AURELIA Study) that evaluated the combination of bevacizumab in combination with chemotherapy (pegylated liposomal doxorubicin, weekly paclitaxel, or topotecan), the addition of bevacizumab to chemotherapy had no significant impact on overall survival but did improve median progression-free survival (6.4 vs 3.7 months).[62] Based on this study, bevacizumab was approved for use in combination with pegylated liposomal doxorubicin, weekly paclitaxel, or topotecan for treatment of recurrent ovarian cancer.

Recent efforts have focused on the use of bevacizumab in first-line treatment regimens. Perren et al. conducted an international multi-institutional phase III randomized study (ICON-7) that demonstrated a 7.8-month improvement in overall survival in women who had bevacizumab added to first-line treatment.[63] Based on these encouraging preliminary results, the GOG initiated a confirmatory phase III (GOG-218) study comparing six cycles of standard paclitaxel plus carboplatin to six cycles of the same regimen with bevacizumab to determine whether bevacizumab improves the efficacy of paclitaxel plus carboplatin.[64] A third arm evaluated the benefit of maintenance bevacizumab for an additional 10 months. At the conclusion of the study, no difference in overall survival was observed between the three study arms. However, a four month increase in median progression-free survival was observed in the group that received an additional 10 months of maintenance bevacizumab. Cohn et al. completed a cost utility analysis that incorporated quality of life scores to estimate the cost effectiveness of bevacizumab with paclitaxel/carboplatin for first-line treatment of advanced ovarian cancer.[65] In that analysis, the incremental cost effectiveness ratio of the addition of bevacizumab 15 mg/kg once every three weeks to paclitaxel/carboplatin regimen was $632,571 per progression-free year and $792,380 per quality-adjusted progression-free year. Incorporation of quality of life scores resulted in a less favorable incremental cost effectiveness ratio.

Clinical Controversy…

Although bevacizumab has demonstrated some progression-free survival advantages when used in combination, its effect on overall survival is not clear. Therefore, it is not clear that the benefits justify the high cost of bevacizumab. As a result, health insurance companies do not consistently reimburse providers for bevacizumab when used for the treatment of ovarian cancer.

Poly(Adenosine Diphosphate [ADP]-Ribose) Polymerase Inhibitors

Poly(adenosine diphosphate [ADP]-ribose) polymerase (PARP) has a critical role in the repair of single strand DNA breaks via the base-excision repair pathway. Specifically PARP keeps the low-fidelity

nonhomologous-end-joining DNA repair machinery functioning. PARP inhibition results in double stranded DNA breaks that cannot be repaired in cancer cells with homologous recombinant deficiency such as those with BRCA1/2 mutations. [10] The activity of the new class of the PARP inhibitors depends on BCRA status or "BRCAness" of the tumor.

In 2015, olaparib, the first PARP inhibitor was approved for treatment of recurrent, platinum sensitive BRCA1/2 positive ovarian cancer after failure of at least two prior treatments.[66] The recommended dose for olaparib is 400 mg twice a day with patient monitoring once a month. The common adverse effects associated with olaparib include nausea and vomiting and significant anemia with associated fatigue. Patients often require antiemetics and some require transfusion support. Three other PARP inhibitors, veliparib, rucaparib, and niraparib, are currently in phase II and III trials for treatment of BRCA1/2 positive platinum-sensitive ovarian cancer.[66,67,68] The challenge of combining PARP inhibitors with chemotherapy has been the significant hematological toxicity, primarily anemia, thrombocytopenia and neutropenia.

Other Targeted Agents

Tyrosine kinase inhibitors such as sorafenib, sunitinib, pazopanib, and cediranib inhibit angiogenesis by specifically targeting the VEGF receptor (VEGFR). When given as single agents, tyrosine kinase inhibitors have demonstrated some antitumor activity in ovarian cancer.[69,70] Ongoing trials have focused on combination regimens with cytotoxic agents for first-line treatment and also treatment of recurrent ovarian cancer. Another interesting targeted agent is VEGF Trap (aflibercept), a fusion protein that targets VEGF-A. Aflibercept has been beneficial in the treatment of malignant ascites and is currently being incorporated into first-line regimens. Epidermal growth factor receptor (EGFR) inhibitors such as erlotinib have not demonstrated activity either alone or combined with chemotherapy or bevacizumab for the treatment of ovarian cancer.[71] Newer classes of targeted therapies such as platelet-derived growth factor (PDGF) inhibitors are being investigated in ongoing clinical trials.[72]

PERSONALIZED PHARMACOTHERAPY

Current research efforts are focused on identifying biomarkers which are predictive of response in ovarian cancer. The primary focus has been on response to first-line treatment agents, paclitaxel and platinum and the multidrug resistance (MDR) pathway, specifically ABC-transport protein p-glycoprotein (Pgp).[73]

Epigenetics is a potential source of drug resistance. Epigenetic changes are heritable changes outside of the "traditional" DNA coding sequence. Aberrant DNA methylation and histone acetylation are epigenetic events which can silence tumor suppression genes required for apoptosis or DNA repair and therefore lead to resistance. The acetylation of histones is required for active genes and deacetylation occurs in silenced genes. Histone acetyltransferases (HATs) add acetyl groups and histone deacetylases (HDACs) remove acetyl groups.[74]

Ovarian cancers upregulate a variety of factors involved in DNA repair, angiogenesis, proliferation, and migration; they also downregulate mismatch-repair (MMR), cell adhesion, and apoptotic genes.[74] Tumorigenesis can induce hypermethylation or hypomethylation, which leads to chromosomal instability.[75] Hypermethylation or deacetylation has been shown to silence specific genes such as *hMLH1*, which leads to tumor formation and progression in the ovaries. Deacetylation of p21, a cell cycle regulator, can occur in ovarian carcinomas. Epigenetics may downregulate Apaf-1 and p16 while potentially upregulating MDR1. Finally, resistance to a platinum and taxane regimen may be associated with *hMLH1* methylation.[74]

Genomic information is being gathered to help overcome resistance such as finding amplified or deleted sequences or determining whether single nucleotide polymorphisms (SNPs) are the cause of resistance. Proteomics can also be used to identify mechanisms of resistance by finding over- or underexpressed proteins. These methods could lead to personalized pharmacotherapy if any of these biomarkers are predictive of drug response or resistance.[75]

While most chemotherapy drugs used to treat ovarian cancer are dosed according to body surface area (BSA), carboplatin dosing is personalized based on each individual's renal function with the Calvert formula: carboplatin dose = AUC × (glomerular filtration rate [GFR] + 25).[76] When it was originally developed and validated, measured GFR was used in the Calvert equation. However, the estimated creatinine clearance (CL_{CR}) is now used in clinical practice in place of measured GFR. Despite more than 30 years of clinical use, it is still not clear which equation to use to estimate CL_{CR} and the best method to estimate CL_{CR} in certain patient subgroups. The use of personalized carboplatin dose has reduced potential toxicity such as thrombocytopenia, neuropathy, and nephrotoxicity.[76] Personalized dosing of carboplatin is one of the reasons why it is often the preferred platinum agent over cisplatin for primary treatment for ovarian cancer.[32]

EVALUATION OF THERAPEUTIC OUTCOMES

During chemotherapy patients may experience numerous side effects such as nausea and vomiting, myelosuppression, neuropathy, and changes in organ function. Patients receiving a taxane or platinum chemotherapy regimen should be monitored for signs of hypersensitivity or infusion-related reactions. Patients treated with paclitaxel often experience infusion-related reactions, which have been attributed to the polyethoxylated castor oil (Cremophor) diluent. Premedications including an H_1-blocker, H_2-blocker, and steroid should be administered prior to each chemotherapy administration to prevent hypersensitivity reactions. If a patient has a reaction, increasing the duration of the infusion from 3 to 6 hours may help with infusion-related reactions. For patients with a true taxane allergy, paclitaxel desensitization can be attempted with 24 hours of premedications (H_1-blocker, H_2-blocker, and steroids) followed by paclitaxel given as a titrated infusion (1:1000 → 1:100 → 1:10 → full dose) over 8 hours. With repeated exposure (ie, seven cycles or more) to carboplatin, patients can develop a delayed hypersensitivity reaction. A similar protocol can be used for carboplatin desensitization.

Ovarian cancer patients receive multiple courses of chemotherapy that can have varying effects on

kidney and liver function, often with a delayed onset. Appropriate laboratory tests should be ordered to assess organ function so that chemotherapy doses can be adjusted as indicated. Patients on platinum-containing regimens can often experience electrolyte wasting, so patients should be monitored for electrolyte replacement, IV or oral, as indicated. The use of myeloid growth factors should be considered to prevent treatment delays or dose reductions. Prevention of nausea and vomiting, both acute and delayed, is critical for patients receiving emetogenic chemotherapy regimens.

During initial taxane plus platinum chemotherapy, a CA-125 level should be obtained with each cycle and monitored for at least a 50% reduction in CA-125 after completion of four cycles, which is related to an improved prognosis. Patients who achieve a complete response after completion of first-line treatment should have follow-up once every 3 months, including CA-125, physical examination, pelvic examination, and appropriate diagnostic scans (ie, computed tomography, magnetic resonance imaging, or positron emission tomography), which should be evaluated for presence of disease. In addition to routine follow-up examinations, clinicians should monitor for resolution of any residual chemotherapy-related side effects, including neuropathies, nephrotoxicity, ototoxicity, myelosuppression, and nausea and vomiting.

In the progressive disease or recurrent setting, CA-125 levels can still be used to monitor for response and should be checked with each cycle, although no change in therapy is recommended until after completion of at least three cycles of the second-line chemotherapy. In addition to laboratory monitoring, appropriate diagnostic scans (ie, computed tomography, magnetic resonance imaging, or positron emission tomography) should be done once every three cycles. Patients need to be monitored with each cycle of chemotherapy to evaluate for new or persistent toxicities such as neuropathies, fluid retention, PPE, myelosuppression, and nausea and vomiting. Another precaution to keep in mind for patients with significant ascites, the “dry weight” or an adjusted body weight should be used for dosing chemotherapy.

Most patients with ovarian cancer will eventually progress through all chemotherapy regimens and investigational treatment options, after which the best supportive care measures should be provided to maintain patient comfort and quality of life. A plan to treat common complications of progressive ovarian cancer, including thrombosis, ascites, uncontrollable pain, and small bowel obstruction should be developed. This plan should include an opioid-based pain regimen with both long-acting agents and short-acting opioids for breakthrough or progressive pain; it should also include a bowel regimen to prevent opioid-induced constipation. Nausea can be a problem in women with advanced ovarian cancer when disease progression causes ascites or partial/complete bowel obstruction. Both antiemetic medications and non-pharmacotherapy interventions with nutrition and hydration can be helpful. Management of partial or complete small bowel obstruction focuses on controlling symptoms of pain and nausea. Bowel rest with best supportive care may lead to spontaneous resolution of the small bowel obstruction but most often it is a complication associated with rapidly progressive disease.[77] Palliative surgery may be considered in selected patients to relieve symptoms.

ABBREVIATIONS

AUC	area under the curve
BRCA1	breast cancer activator gene 1
BRCA2	breast cancer activator gene 2
BSA	body surface area
CA-125	cancer antigen 125
CI	confidence index
CL_{cr}	creatinine clearance
EGFR	epidermal growth factor receptor
FDA	Food and Drug Administration
FIGO	International Federation of Gynecology and Obstetrics
GFR	glomerular filtration rate
GI	gastrointestinal
GOG	Gynecologic Oncology Group
HAT	histone acetyltransferase
HDAC	histone deacetylase
HSCT	hematopoietic stem cell transplantation
ICON4	International Collaborative Ovarian Neoplasm 4
IP	intraperitoneal
MDR	multidrug resistance
MMR	mismatch-repair
NCCN	National Comprehensive Cancer Network
^{32}P	phosphorus-32
Pap	Papanicolaou
PARP	poly-ADP-ribose polymerase
PDGF	platelet-derived growth factor
Pgp	p-glycoprotein
PPE	palmar–plantar erythrodysesthesia
QOL	quality of life
SBO	small bowel obstruction
SCOTROC	Scottish Randomized Trial in Ovarian Cancer
SNP	single nucleotide polymorphism
SWOG	Southwest Oncology Group
TAH/BSO	total abdominal hysterectomy/bilateral salpingo oophorectomy
TVUS	transvaginal ultrasound
VEGF	vascular endothelial growth factor
VEGFR	vascular endothelial growth factor receptor

Chapter 134: Acute Leukemias

Amy Hatfield Seung; Alix Dabb

INTRODUCTION

KEY CONCEPTS

- 1 Acute leukemias are the most common malignancies in children and the leading cause of cancer-related death in patients younger than age 20 years.
- 2 Several risk factors correlate with prognosis for acute lymphoblastic leukemia (ALL). Poor prognostic factors include high white blood cell (WBC) count at presentation, very young or very old age at diagnosis, delayed remission induction and presence of certain cytogenetic abnormalities (eg, Philadelphia chromosome positive [Ph^+]).
- 3 For children with ALL, remission induction therapy includes vincristine, a corticosteroid, and asparaginase, with or without an anthracycline. For adults with ALL, vincristine, prednisone, and an anthracycline are given, and asparaginase is sometimes added.
- 4 All patients with ALL require prophylactic therapy to prevent CNS disease because of the high risk of central nervous system (CNS) relapse. The choice for therapy includes a combination of the following: cranial irradiation, intrathecal chemotherapy, or high-dose systemic chemotherapy with drugs that cross the blood-brain barrier.
- 5 Long-term maintenance therapy for 2 to 3 years is essential to eradicate residual leukemia cells and prolong the duration of remission. Maintenance therapy consists of oral methotrexate and mercaptopurine, with or without monthly pulses of vincristine and a corticosteroid.
- 6 Disease-free survival is lower in adults with ALL and has been attributed to greater drug resistance, poor side effect tolerance with subsequent nonadherence, and possibly less-effective therapy. This population is also more likely to have Ph^+ ALL, which is associated with a worse outcome, but the use of tyrosine kinase inhibitors has improved treatment results.
- 7 There are several poor prognostic factors for adult acute myeloid leukemia (AML): older age, organ impairment, presence of extramedullary disease, and presence of certain cytogenetic

and molecular abnormalities.

- 8 Therapy of AML usually includes induction therapy with an anthracycline and cytarabine. Postremission therapy is required in all patients and can include either consolidation chemotherapy with or without maintenance therapy, or hematopoietic stem cell transplantation (HSCT).

- 9 Treatment of acute promyelocytic leukemia (APL) consists of induction therapy, followed by consolidation and maintenance therapy. Induction includes tretinoin and an anthracycline; consolidation therapy consists of two to three cycles of anthracycline-based therapy; maintenance consists of pulse doses of tretinoin, mercaptopurine, and methotrexate for 2 years.

- 10 Hematopoietic growth factors can be safely and effectively used with myelosuppressive chemotherapy for acute leukemias. The benefits may include reduced incidence of serious infections, reduced hospital stays, and fewer treatment delays, but do not include prolonged disease-free survival or overall survival (OS).

The leukemias are heterogeneous hematologic malignancies characterized by unregulated proliferation of the blood-forming cells in the bone marrow. These immature proliferating leukemia cells (blasts) physically "crowd out" or inhibit normal cellular maturation in bone marrow, resulting in anemia, granulocytopenia, including neutropenia, and thrombocytopenia. Leukemic blasts may also infiltrate a variety of tissues such as lymph nodes, skin, liver, spleen, kidney, testes, and the central nervous system (CNS).

Historically, leukemia has been classified based on the cell of origin and cell line maturation, and as acute or chronic based on differences in clinical presentation, rapidity of progression of the untreated disease, and response to therapy. The four major leukemias are acute lymphoblastic (or lymphocytic) leukemia (ALL), acute myeloid (or myelogenous) leukemia (AML), chronic lymphocytic leukemia, and chronic myeloid leukemia. Undifferentiated immature cells that proliferate autonomously characterize acute leukemias. Chronic leukemias also proliferate autonomously, but the cells are more differentiated and mature. Untreated, acute leukemia is fatal within weeks to months.

EPIDEMIOLOGY

It is estimated that 26,540 new cases of acute leukemia—19,950 cases of AML and 6,590 cases of ALL will be diagnosed in the United States in 2016, accounting for 1.57% of the total cancer incidence.[1] The incidence has been relatively stable for two decades. An estimated 11,860 deaths per year, representing about 2% of all cancer deaths, are caused by acute leukemias.[1]

1 Leukemia is the leading cause of cancer-related deaths in persons younger than age 20 years.[2] For males ages 20 to 39, it is now the leading cause of cancer death, but continues to be an uncommon cause of cancer-related death for both genders after age 40 years.[1] Among adults, acute and chronic leukemias occur at equal rates. More than 90% of the cases of acute and chronic leukemia occur in adults. AML accounts for most cases of acute leukemia in adults, and occurs with

increasing frequency in elderly patients. There are about 4.5 cases of AML and 1.5 cases of ALL per 100,000 individuals.[2] The median age at diagnosis of patients with AML is about 67 years, while the peak age for ALL patients is 1 to 4 years.[2] The incidence of AML increases with age from 1.8 per 100,000 in individuals younger than age 65 years to 18.3 per 100,000 in those 65 years or older.[2] Acute leukemia is about 30% more common in males than in females. In the United States, acute leukemia is more common among whites than among blacks, American Indians, and Hispanic ethnicities.[2]

Despite the low incidence, the acute leukemias are the most common malignancy in persons younger than 20 years of age, accounting for 27% of all childhood malignancies.[2] About 80% of children with leukemia have ALL and 15% AML.[2] Conversely, AML represents about 80% of acute leukemias in adults while only 20% of cases are ALL.[1] Childhood ALL is about 30% more common in males than in females, peaks at 1 to 4 years of age, and is almost twice as likely to affect white children as black children.[2] The incidence of childhood AML is highest in the Hispanic population and occurs throughout childhood without any peak age period. Acute leukemia during the first year of life (infant leukemia) slightly favors ALL over AML.[2] Antineoplastic agents including chemotherapy and targeted therapies have dramatically improved the outlook of patients with acute leukemia. More than 85% of children and young adults with acute leukemia achieve an initial complete remission (CR) of their disease. In comparison, 60% to 85% of adults who are 60 years of age or younger, and only 40% to 60% of patients who are older than 60 years of age achieve an initial CR.[3] For persons younger than 19 years of age, the 5-year survival rate is 90% for ALL and about 65% for AML.[2,4] The prognosis of adult acute leukemia is generally worse than that of childhood leukemia, with only 35% to 40% of patients who are 60 years of age or younger and 5% to 15% of patients who are older than 60 years of age becoming long-term survivors.[5]

ETIOLOGY

The exact cause of the acute leukemias is unknown. A multifactorial process involving genetics, environmental and socioeconomic factors, toxins, immunologic status, and viral exposures is likely. **Table 134-1** summarizes the major factors that have been linked to acute leukemias. Infectious and genetic factors have the strongest associations to date.[6,7,8] In pediatric ALL, a number of environmental factors are inconsistently linked to the disease: exposure to ionizing radiation, toxic chemicals, herbicides and pesticides; maternal use of contraceptives, diethylstilbestrol, or cigarettes; parental exposure to drugs (amphetamines, diet pills, and mind-altering medications), diagnostic radiographs, alcohol consumption, coffee and cola consumption, or chemicals before and during pregnancy; and chemical contamination of groundwater.[9,10] A growing body of evidence indicates that high birthweight is a risk for ALL.[6,11] Ionizing radiation and benzene exposure are the only environmental risk factors strongly associated with ALL or AML.[7,8,9] A few studies have reported a possible link between electromagnetic fields of high-voltage power lines and the development of leukemia, but larger studies could not confirm this association. In most patients who develop leukemia, a cause cannot be identified.

TABLE 134-1 Factors Associated with the Development of Acute Leukemia

Drugs	
Alkylating agents	
Anthracyclines	
Epipodophyllotoxins	
Genetic conditions	**Chemicals**
Amegakaryocytic thrombocytopenia	Benzene
Ataxia telangiectasia	Pesticides
Bloom syndrome	Pyrethroid-based shampoo
Diamond-Blackfan anemia	**Radiation**
Down syndrome	Ionizing radiation
Dyskeratosis congenita	**Viruses**
Familial monosomy 7	Epstein-Barr virus
Fanconi anemia	Human T-lymphocyte virus (HTLV-1 and HTLV-2)
Klinefelter syndrome	**Social habits**
Kostmann syndrome	Cigarette smoking
Langerhans cell histiocytosis	Maternal marijuana use
Li Fraumeni syndrome	Maternal ethanol use
Neurofibromatosis type 1	Maternal caffeine consumption
Noonan syndrome	
Shwachman syndrome	
Severe combined immunodeficiency syndrome	
Wiskott-Aldrich syndrome	

Childhood AML is associated with Hispanic ethnicity, prior exposure to alkylating agents or epipodophyllotoxins, and in utero exposure to ionizing radiation.[9] Maternal alcohol consumption, maternal coffee and cola consumption, parental and child organophosphate pesticide exposure, and parental benzene exposure are also associated with childhood AML.[10] AML has been associated with

both low and high birthweight.[11] Adult AML has been associated with prior anthracycline exposure in addition to prior exposure to alkylating agents or epipodophyllotoxins.[7]

PATHOPHYSIOLOGY

A basic understanding of normal hematopoiesis is needed before one can understand the pathogenesis of leukemia. Chapter e86 has a detailed discussion of hematopoiesis. Normal hematopoiesis consists of multiple well-orchestrated steps of cellular development. A pool of pluripotent stem cells undergoes differentiation, proliferation, and maturation, to form the mature blood cells seen in the peripheral circulation. These pluripotent stem cells initially differentiate to form two distinct stem cell pools. The myeloid stem cell gives rise to six types of blood cells (erythrocytes, platelets, monocytes, basophils, neutrophils, and eosinophils). Lymphoid stem cells differentiate to form natural killer cells, B lymphocytes, and T lymphocytes. Leukemia may develop at any stage and within any cell line.

Two features are common to both AML and ALL. First, both arise from a single leukemic cell that expands and acquires additional mutations, culminating in a monoclonal population of leukemia cells. Second, there is a failure to maintain a relative balance between proliferation and differentiation, so that the cells do not differentiate past a particular stage of hematopoiesis. Cells (lymphoblasts or myeloblasts) then proliferate uncontrollably. Proliferation, differentiation, and apoptosis are under genetic control, and leukemia can occur when the balance between these processes is altered.

Acute myeloid leukemia likely arises from a defect in the pluripotent stem cell or a more committed myeloid precursor, resulting in partial differentiation and proliferation of immature precursors of the myeloid blood-forming cells. In older patients, trilineage leukemia occurs suggesting that the cell of origin is probably a stem or very early progenitor cell. In younger patients, a more differentiated progenitor becomes malignant, allowing maturation of some granulocytic and erythroid populations. These two forms of AML exhibit different patterns of resistance to chemotherapy, with resistance more evident in the older adults with AML. ALL is a disease characterized by proliferation of immature lymphoblasts. In this type of acute leukemia, the defect is probably at the level of the lymphopoietic stem cell or a very early lymphoid precursor.

Leukemic cells have growth and/or survival advantages over normal cells, leading to a “crowding out” phenomenon in the bone marrow. This growth advantage is not caused by more rapid proliferation as compared with normal cells. Some studies suggest that it is caused by factors produced by leukemic cells that either inhibit normal cellular proliferation and differentiation, or reduce apoptosis as compared with normal blood cells.

The types of genetic alterations that lead to leukemia have only recently become evident. The genetic defects may include (a) activation of a normally suppressed gene (protooncogene) to create an oncogene that produces a protein product that signals increased proliferation; (b) loss of signals for the blood cell to differentiate; (c) loss of tumor suppressor genes that control normal proliferation; and (d) loss of signals for apoptosis. Most normal cells are programmed to die eventually through

apoptosis, but the appropriate programmed signal is often interrupted in cancer cells, leading to continued survival, replication, and drug resistance. Signal transduction, RNA transcription, cell-cycle control factors, cell differentiation, and programmed cell death may all be affected.

LEUKEMIA CLASSIFICATION

The World Health Organization (WHO), in collaboration with the Society for Hematopathology and the European Association of Haematopathology, published the current classification system for myeloid neoplasms in 2008 (**Table 134-2**).[12] This classification system incorporates not only morphologic findings, but also genetic, immunophenotypic, cytochemical, and clinical features. About 40% to 50% of adult patients with AML have no detectable chromosomal abnormality on standard cytogenetic analysis, but the percent increases with age.[13] The WHO classification attempts to formally incorporate the relationship between AML and myelodysplastic syndrome (MDS), and is being used routinely for children and adults.[12] The WHO classification defines acute leukemias as more than 19% blasts in the marrow or blood. A revision of the WHO classification for myeloid neoplasms is currently ongoing.[3]

TABLE 134-2 World Health Organization Classification of Acute Myeloid Leukemia

Acute myeloid leukemia (AML) with recurrent genetic abnormalities
AML with t(8;21)(q22;q22), (AML1/ETO)
AML with abnormal bone marrow eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22), (CBFβ/MYH11)
Acute promyelocytic leukemia with t(15;17)(q22;q12), (PML/RARα) and variants
AML with 11q23 (MLL) abnormalities
Acute myeloid leukemia with multilineage dysplasia
Following MDS or MDS/MPD disorder
Without antecedent MDS or MDS/MPD, but with dysplasia in at least 50% of cells or two or more lineages
Acute myeloid leukemia and MDS, therapy-related
Alkylating agent/radiation-related type
Topoisomerase II inhibitor-related type (some may be lymphoid)
Others
Acute myeloid leukemia, not otherwise categorized, classify as
Acute myeloid leukemia, minimally differentiated

Acute myeloid leukemia without maturation

Acute myeloid leukemia with maturation

Acute myelomonocytic leukemia

Acute monoblastic/acute monocytic leukemia

Acute erythroid leukemia (erythroid/myeloid and pure erythroleukemia)

Acute megakaryocytic leukemia

Acute basophilic leukemia

Acute panmyelosis with myelofibrosis

Myeloid sarcoma

MDS, myelodysplastic syndrome; MLL, mixed lineage leukemia; MPD, myeloproliferative disease; PML, promyelocytic leukemia; RARα, retinoic acid receptor-α.

Lymphoblast analysis is used to classify ALL. Immunophenotype is determined by flow cytometry that analyzes specific antigens, known as clusters of differentiation (often abbreviated "CD"), present on the surface of hematopoietic cells. Although no leukemia-specific antigens have been identified, the pattern of cell-surface antigen expression reliably distinguishes between lymphoid and myeloid leukemia. The immunophenotype defines the cell of origin. The major phenotypes are mature B-cell, precursor B-cell, and T-cell disease, but the WHO classifies ALL as either B lymphoblastic or T lymphoblastic. About 80% of childhood ALL derives from precursor B cells and about 15% from T cells; the remainder is either mixed lineage or from mature B cells. T-cell ALL is more common in teenage males. In adults, about 75% of ALL is B-cell lineage and 25% of cases are T-cell lineage ALL.

Leukemias may also be described by cytogenetic abnormalities. Chromosome alterations include numerical (hyperdiploidy and hypodiploidy), and structural abnormalities due to exchanges of genetic information within (inversion) or between (translocation) chromosomes. Unique translocations can identify specific subtypes of acute leukemia. Twenty-five percent of children with precursor B-cell ALL have the *ETV6-RUNX1* (formerly *TEL-AML1*) fusion gene generated by the t(12;21)(p13;q22) chromosomal translocation.[6,14] This translocation appears to endow the preleukemia cell with altered self-renewal and survival properties. The most common translocation in adult ALL, occurring in 25% of patients, is the t(9;22) or Philadelphia chromosome positive (Ph^+), which causes fusion of the BCR signaling protein to the ABL nonreceptor tyrosine kinase, resulting in constitutive tyrosine kinase activity. More than 50% of childhood T-cell ALL have activating mutations of the *NOTCH1* gene that encodes for a transmembrane receptor implicated in regulation of T-cell development.[6,14] Acute promyelocytic leukemia (APL) is characterized by a specific translocation between chromosomes 15 and 17: t(15;17). Molecular tests may be used to identify products of specific translocations, such as promyelocytic leukemia (PML) retinoic acid receptor-α (RARα) in APL and *AML1-ETO* and *CBFβ/MYH 11* in other subtypes of AML.

A number of factors may affect the cytogenetics of AML in adults. First, in about 5% of patients, simultaneous blood and marrow samples demonstrate normal cytogenetics versus abnormal cytogenetics, respectively.[15] Second, central cytogenetic analysis is done in multicenter trials because of variability in specimen examination. A small number of patients may have a normal karyotype on standard review, but carry fusion genes, which are identical to those of translocations or inversions. These insertions of very small chromosome segments do not alter chromosome morphology but may affect outcome.

CLINICAL PRESENTATION AND DIAGNOSIS

Common signs and symptoms at presentation result from malignant cells that replace and suppress normal hematopoietic progenitor cells and infiltrate into extramedullary spaces. Many of the signs and symptoms result from low blood cells. Thrombocytopenia can result in bruising, petechiae, and bleeding; low red blood cells can result in fatigue and loss of energy; and low white blood cells (WBCs) can result in signs and symptoms of infection such as fever, chills, and rigors. Patients with ALL may rarely present with small blue-green collections of leukemia cells under the skin called *chloromas*.

In addition to clinical presentation, laboratory and pathology evaluations are required for a definitive diagnosis of leukemia. An abnormal complete blood count is usually the diagnostic test that initiates a leukemia workup. Although leukemic blast cells may be present on the peripheral blood smear, they are not diagnostic of leukemia because there are other causes in which immature blast cells may be present in peripheral blood. The most important diagnostic test is a bone marrow biopsy and aspirate, which is submitted to hematopathology for numerous evaluations, including flow cytometry, cytogenetics, and immunophenotyping. A lumbar puncture is performed to determine if there are blasts in the CNS. A chest radiograph or computed tomography is performed to screen for a mediastinal mass (most common in T-cell disease). The results of these evaluations help to determine the patient's prognosis and therapeutic plan.

CLINICAL PRESENTATION General

- Recent history of vague symptoms such as tiredness, lack of exercise tolerance, weight loss, and "feeling unwell," but in no obvious distress.

Signs and Symptoms

- Common: Patients with anemia present with pallor, malaise, palpitations, and fatigue. Patients with low platelet counts present with bruising, ecchymoses, and petechiae. Temperature is often elevated and may be caused by disease or infection. Patients may have bone pain from a hyperactive bone marrow.

- Other possible symptoms include epistaxis, dyspnea on exertion, seizures, or headache. Splenomegaly, hepatomegaly, and/or lymphadenopathy are common in patients presenting with ALL, but may also have painless testicular enlargement and rarely, small, blue-green collections of leukemia cells under the skin (chloromas). Patients with AML may present with

gum hypertrophy and bleeding.

Laboratory Tests

- Complete blood count with differential. Anemia (43% <7 g/dL [<70 g/L; <4.34 mmol/L]) is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, <20,000 cells/mm^3 [<20 × 10^9/L]) is present in 28% of ALL and 50% of AML cases. Patients can present with leukopenia or leukocytosis; about 20% of patients will present with a WBC count ≥50,000 cells/mm^3 (≥50 × 10^9/L) and 53% of ALL and 20% of AML cases with a WBC <10,000 cells/mm^3 (<10 × 10^9/L). Even patients with elevated counts can be considered functionally neutropenic.
- Uric acid may be elevated because of rapid cellular turnover and is more common in patients presenting with elevated WBC count and with ALL.
- Electrolytes: potassium and phosphate may be elevated with a compensatory decrease in calcium, more common with ALL.
- Coagulation (more common with AML): elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

Other Diagnostic Tests

- Bone marrow aspirate and biopsy: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis. Molecular testing for FMS-like tyrosine kinase 3 (FLT3), nucleophosmin (NPM1), and CCAAT/enhancer binding-protein α (CEBPA), mutations is warranted for suspected AML.
- All children and adults with ALL should have a screening lumbar puncture performed to assess CNS involvement. Screening in patients with AML is not routine and depends on multiple factors at presentation including symptoms, WBC count, and morphology that includes monocytic disease.

ACUTE LYMPHOBLASTIC LEUKEMIA

Risk Classification

Many clinical and biologic features at diagnosis are associated with response to treatment, as measured by the CR rate, duration of remission, and long-term survival. The patient's response to initial therapy is also strongly associated with response to treatment. Identification of these risk factors allows the clinician to better understand the disease and to tailor treatment according to risk of disease recurrence (ie, risk-adapted therapy). For example, if a patient has many clinical and laboratory features that are associated with a favorable response to antineoplastic therapy ("standard risk"), then the clinician may choose to give less-intensive therapy to reduce the risk of long-term adverse effects. Conversely, if a patient is unlikely to respond well to standard therapy (high-risk or

very-high-risk disease), then the clinician may choose to give more intensive antineoplastic therapy. The factors can be grouped as follows: patient characteristics at diagnosis, leukemic cell features at diagnosis, and patient response to initial therapy.

Patient Characteristics

2 The National Cancer Institute (NCI) developed an ALL risk stratification to create a standard for comparison in children.[16] Induction therapy is initially selected based on this classification, which divides children into standard- or high-risk categories based on age and initial WBC count (**Table 134-3a**). Age remains an independent predictor of outcome with children aged 1 to 9 years having the best event-free survival (EFS). This is partly explained by the more frequent occurrence of favorable cytogenetics in this age group.[17] The presence of CNS disease at diagnosis is associated with a higher relapse rate. About 2% of males have testicular disease at diagnosis, but not all cooperative groups classify it as an adverse prognostic factor. Patients with Down syndrome tend to have lower EFS, but this is mostly attributed to higher treatment-related morbidity and mortality.[18]

TABLE 134-3a National Cancer Institute (NCI) Risk Classification for Pediatric Acute Lymphoblastic Leukemia

Risk Group	Standard Risk	High Risk
Age (years)	1- <10	<1 or ≥10
WBC count (× 10^3 cells/mm^3 or × 10^9/L)	<50	≥50
Karyotype	No t(9;22) or t(4;11)	t(9;22) or t(4;11)

WBC, white blood cell.

Race is controversial, with older studies indicating worse outcomes for minorities. Male race and obesity have been associated with worse outcome in cooperative group studies, but not in single-institution studies.[6] Hepatosplenomegaly and mediastinal mass are both associated with worse outcomes.

Leukemic Cell Characteristics

With current therapy, the cell of origin no longer has prognostic significance as therapy has improved. Several chromosomal (cytogenetic) abnormalities are associated with prognosis. Children with ALL have an average of six DNA copy number alterations.[14] Favorable outcomes are associated with three copies of chromosomes 4 and 10, high hyperdiploidy (51-65 chromosomes), and the *ETV6-RUNX1* cryptic translocation, t(12;21).[14] *NOTCH1* and *FBXW7* mutations confer a favorable prognosis for patients with T-cell disease.[14] The Philadelphia chromosome is present in 3% to 5% of children and 25% of adults and is historically associated with a poor prognosis.[19] The mixed lineage leukemia (*MLL*) gene rearrangement (11q23), intrachromosomal amplification of chromosome 21 ($iAMP_{21}$), and hypodiploidy (less than 44 chromosomes) are associated with a poorer prognosis.[20]

Initial Response to Therapy

The strongest prognostic factor for outcome for ALL is response to therapy.[21] Both the rapidity of response and the level of residual disease at the end of induction therapy are associated with long-term outcome. Children with a reduction of bone marrow lymphoblasts within 14 days of initiating antineoplastic therapy (rapid early responders) have a more favorable prognosis. Molecular measurement of subclinical minimal residual disease (MRD) by either flow cytometry or polymerase chain reaction has enabled detection of leukemic cells not visible on morphologic examination to assess treatment response and detect relapse in children and adults.[22] This technique allows detection of 1 leukemia cell in 10,000 normal cells, which is about 100-fold more sensitive than morphologic examination.[22] If MRD is detected at the end of induction therapy, the clinician may decide to give more intensive therapy to decrease the risk of relapse.

The Children's Oncology Group uses a risk- and response-based classification of childhood ALL (**Fig. 134-1**).[23] This classification system uses the NCI risk assignment to initially categorize patients into standard- or high-risk groups (see Table 134-3a). Following induction therapy, risk is reclassified based on the rapidity and completeness of response to therapy, the presence or absence of cytogenetic abnormalities, and CNS involvement (**Table 134-3b**). Patients are then reclassified as low risk, standard risk, high risk, or very-high risk (see Fig. 134-1). Patients who are initially high risk do not have therapy reduced, but may have it intensified to very-high risk as discussed here.

TABLE 134-3b Pediatric Precursor B-Cell Acute Lymphoblastic Leukemia Risk Classification

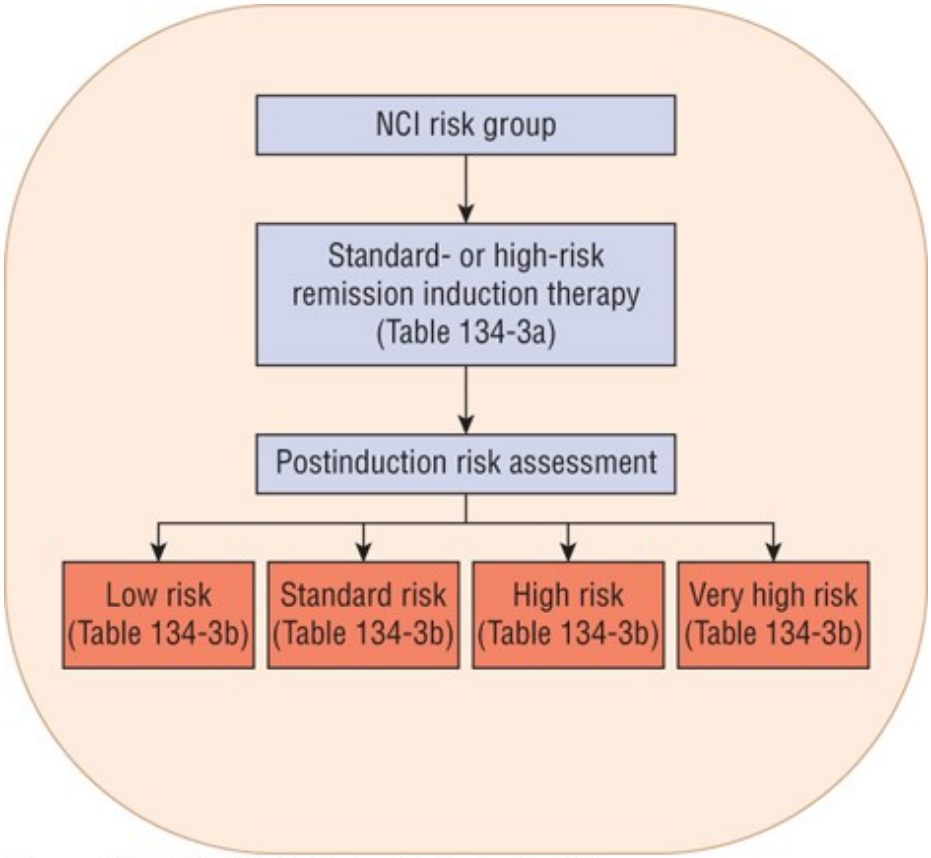
	Low	**Standard**			**High**		**Very High**			
NCI Risk[a]	SR	SR	SR	SR	SR	HR (age <13 y)	SR	HR	HR (age >13 y)	Any
Favorable Genetics	Yes	Yes	No	Yes	No	Any	No	Any	Any	Any
Unfavorable Characteristics	None	None	None	None	None	None	None	None	None	Yes
Day 8 PB MRD	<0.01%	≥0.01%	<1%	Any	≥1%	Any	Any	Any	Any	Any
Day 29 Marrow MRD	<0.01%	<0.01%	<0.01%	>0.01%	<0.01%	<0.01%	>0.01%	>0.01%	<0.01%	Any

HR, high-risk; MRD, minimal residual disease; NCI, National Cancer Institute; PB, peripheral blood; SR, standard-risk.

[a]See Table 134-3a for criteria used to categorize patients into risk categories.

FIGURE 134-1

Pediatric precursor B-cell acute lymphoblastic leukemia risk classification. (NCI, National Cancer Institute.)



Children are classified as low risk and will have therapy reduced if they have trisomy 4 and 10 or the *ETV6-RUNX1* cryptic translocation with less than 0.01% MRD on day 8 peripheral blood and day 29 bone marrow samples. Children with testicular disease, more than 5% blasts in the bone marrow by day 15, MRD greater than or equal to 0.01% at day 29, or who received steroids prior to diagnosis have postinduction therapy intensified and are classified as high risk. Childhood precursor B-ALL with more than five WBCs and blasts present in the cerebrospinal fluid (CSF), Ph^+ disease, hypodiploidy, $iAMP_{21}$, induction failure, or *MLL* gene rearrangement have therapy intensified and are considered very-high risk. Infant ALL, trisomy 21, or childhood T-cell ALL have unique risk classification schemas. Children with T-cell leukemia historically have an inferior response to standard-risk therapy and are automatically categorized as high risk to receive augmented therapy and T-cell targeted therapy. T-cell and mature B-cell disease are favorable phenotypes in adults.[6] Age is inversely associated with prognosis in patients with Ph^+ ALL.[6]

TREATMENT

Acute Lymphoblastic Leukemia

Desired Outcomes

The short-term goal for ALL treatment is to rapidly achieve a complete clinical and hematologic remission. A CR is defined as the disappearance of all physical and bone marrow evidence (normal

cellularity with less than 5% blasts) of leukemia, with restoration of normal hematopoiesis. After a CR is achieved, the goal is to maintain the patient in continuous CR. In general, a child is considered "cured" after being in continuous CR for 5 years.

Successful treatment of ALL was first developed in children. Cure rates in children have risen from less than 10% with treatments used in the 1960s to current rates of about 90.[21] The reason for this improvement lies largely in improved scheduling of existing drugs, as relatively few new drugs have come to the market since the 1960s. Current regimens result in clinical remission in 96% to 99% of children with ALL at the end of induction.[6] MRD is a strong predictor of relapse in ALL. Children with MRD in the bone marrow at the end of induction have a 5-year EFS of 59% versus 88% in children without MRD.[24] Children with low-risk disease have a 5-year EFS of more than 95%.[25] The 5-year EFS for average-risk disease is 90% to 95%.[25] The 5-year EFS is nearly 90% for high-risk childhood B-precursor and T-cell ALL including rapid and slow responders. Children with very-high-risk disease have a 5-year EFS of less than 80%.[25] Response to treatment is determined by intrinsic drug sensitivity and the patient's pharmacogenomics and pharmacodynamics, treatment received, and treatment adherence.

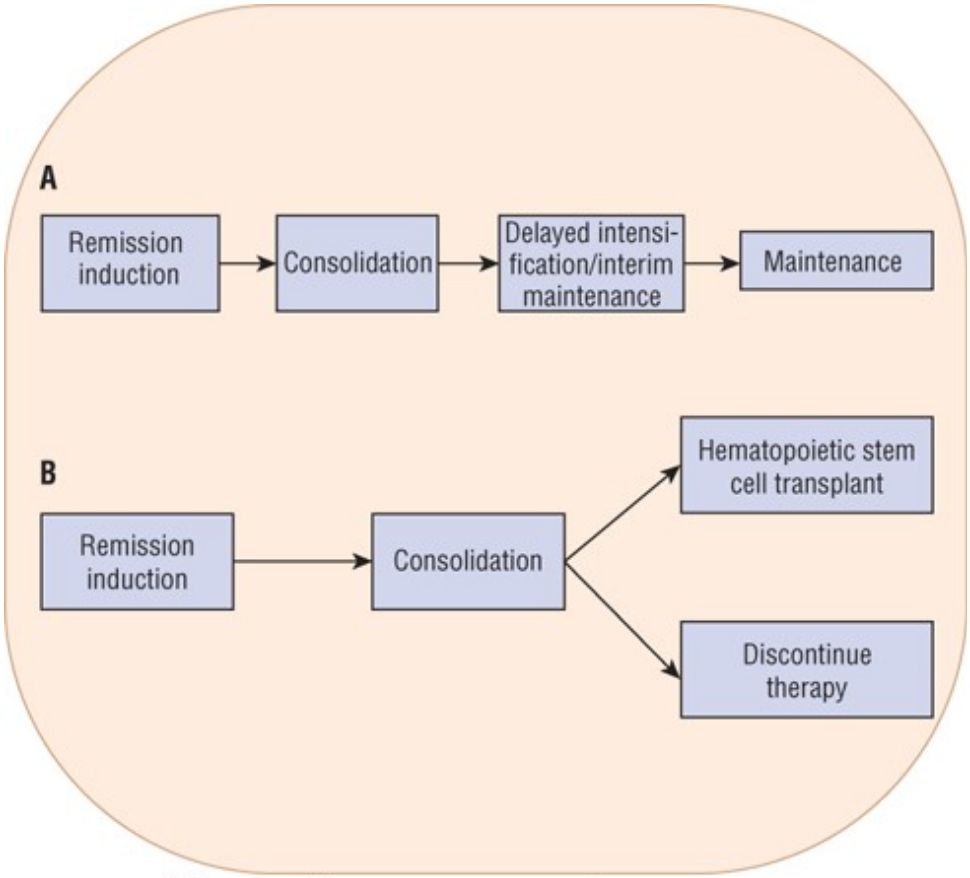
Although treatment results with adult ALL are worse than those with childhood ALL, recent use of aggressive chemotherapy in adult ALL has increased the initial CR rate after induction therapy from 60% to 85%. Long-term EFS in this population, however, remains low (between 30% and 40%) because a higher proportion of adults present with poor-risk disease. CR rates and EFS vary according to a number of poor prognostic factors and certain types of ALL are associated with a very poor outcome.

Treatment Phases

Therapy for childhood ALL is divided into five phases: (a) induction, (b) consolidation therapy, (c) delayed intensification, (d) interim maintenance, and (e) maintenance therapy (**Fig. 134-2**). CNS prophylaxis is a mandatory component of ALL treatment regimens and is administered longitudinally during all phases of treatment. The total duration of treatment is 2 to 3 years.

FIGURE 134-2

Treatment algorithm for (*A*) acute lymphoblastic leukemia and (*B*) acute myeloid leukemia.



Induction

3 The goal of induction is to rapidly induce a complete clinical and hematologic remission. The CR rate is about 98% for standard-risk children treated with vincristine, a glucocorticoid (dexamethasone or prednisone), and pegaspargase.[21] Many treatment protocols include daunorubicin in induction (four-drug induction) for high-risk or very-high-risk ALL. Most children achieve a CR in 4 weeks, which classifies them as rapid early responders. Those who have an M2 (5%-25% blasts) or M3 (more than 25% blasts) marrow on day 15 of induction or have positive MRD at day 29 are classified as slow early responders and receive intensified therapy. Only 2% to 3% of children fail induction therapy and have a 10-year survival rate of 32%.[26]

Prednisone has historically been the primary glucocorticoid used in pediatric ALL regimens.[27] Dexamethasone is now being used in most standard-risk protocols because of its longer duration of action and higher CSF penetration compared to prednisone.[27] When dexamethasone is used in place of prednisone, absolute EFS improves by 5% to 9% and the risk of CNS relapse decreases by 2% to 4%.[27,28] However, dexamethasone increases the risk of side effects such as osteonecrosis, mood alteration, steroid myopathy, hyperglycemia, and infections.[27,28,29] Patients older than 10 years of age are particularly prone to osteonecrosis and receive prednisone instead of dexamethasone to minimize this side effect. Low serum albumin prolongs dexamethasone exposure and may contribute

to increased toxicity.[27] Since patients with Down syndrome have increased infections and mortality with dexamethasone, these patients receive prednisone.[18]

Asparaginase has historically been available in three forms. Asparaginase (no longer manufactured in the United States) and pegaspargase are isolated from *Escherichia coli* while *Erwinia* asparaginase is isolated from *Erwinia chrysanthemi*. A recombinant *E. coli* asparaginase and a pegylated form of recombinant *Erwinia* asparaginase are currently in clinical trials. Pegaspargase is pegylated *E. coli* asparaginase; pegylation prolongs its duration of activity and allows it to be given less frequently. Pegaspargase is used in most protocols and is preferred over asparaginase because of fewer intramuscular injections, decreased antibody formation, and superior response rates. Pegaspargase is also approved for IV administration.[30] The use of prolonged intensive asparaginase treatment compared with shorter treatment increases absolute EFS by 4% to 17%.[31]

Asparaginase products are the antineoplastic agents used in ALL which are most likely to cause hypersensitivity reactions. Depending on the type of asparaginase used and the presence of a coadministered steroid, 8% to 42% of patients may develop hypersensitivity reactions to asparaginase.[32,33] Reactions usually occur during postinduction phases of therapy when asparaginase has not been given for a prolonged period of time.[31] Hypersensitivity reactions to pegaspargase may be delayed in onset (when administered intramuscularly) and prolonged in duration, sometimes requiring hospitalization.[34] *Erwinia* asparaginase is currently only used for patients who are allergic to pegaspargase. Because *Erwinia* asparginase has a short half-life, administration must occur more frequently. A single dose of pegaspargase is replaced by six doses of *Erwinia* asparaginase, given three times per week.[33]

Patients may develop silent inactivation, also known as subclinical hypersensitivity, in which they develop neutralizing antibodies that can rapidly inactivate asparaginase, but without developing a clinical hypersensitivity reaction. Silent inactivation can be detected by therapeutic monitoring of asparaginase activity. If inadequate asparaginase activity is detected, a therapeutic switch from pegaspargase to *Erwinia* asparaginase can be made to optimize activity and outcomes.[35,36] The use of therapeutic drug monitoring to optimize the dosing of asparaginase has also been demonstrated in clinical trials.[37]

Clinical Controversy…

Should therapeutic drug monitoring of asparaginase products be used routinely? With the recent addition of a commercially available asparaginase activity assay, clinicians have the opportunity to use this tool to monitor and optimize asparaginase therapy. Although published data support the use of therapeutic drug monitoring of asparaginase products to optimize pharmacokinetic differences in preparations and detect suboptimal activity levels, this approach is not routinely used. Clinical trials are needed to determine the role for routine therapeutic drug monitoring of asparaginase and any potential impact that this has on outcomes.

Central Nervous System Prophylaxis

Central nervous system prophylaxis is incorporated throughout all phases of therapy. The rationale for CNS prophylaxis is based on two observations. First, many antineoplastic agents do not readily cross the blood-brain barrier. Second, results from early clinical trials of ALL showed that the majority of patients with ALL experienced a CNS relapse.[21] These observations indicate that the CNS is a potential sanctuary for leukemic cells and undetectable leukemic cells are present in the CNS in many patients at the time of diagnosis, while only 3% of children have detectable CNS involvement at diagnosis.[17]

The goal of CNS prophylaxis is to eradicate undetectable leukemic cells from the CNS while minimizing neurotoxicity and late effects. Once CNS relapse has occurred, patients are at increased risk of bone marrow relapse and death from refractory leukemia. Initial trials of childhood ALL in the 1960s established craniospinal irradiation as the standard for prevention of CNS relapse. However, this approach is associated with long-term sequelae including neuropsychological deficits, precocious puberty, osteoporosis, decreased intellect, thyroid dysfunction, brain tumors, short stature, and obesity. Subsequent trials have demonstrated that irradiation may be replaced by frequent administration of intrathecal chemotherapy in children with ALL.[38] Some centers may treat children with CNS disease at diagnosis or very-high-risk disease with cranial radiation.[21]

4 The CNS prophylaxis regimen is selected based on efficacy, toxicity, and risk of CNS disease. Intrathecal chemotherapy, cranial irradiation, dexamethasone, and high-dose IV methotrexate or cytarabine can be used to treat or prevent CNS disease. Current treatment approaches have reduced isolated CNS relapses to less than 5% among children.[39] Risk factors for CNS relapse include male sex, hepatomegaly, T-cell phenotype, CNS2 disease (the presence of leukemic blasts in a CSF sample that contains less than 5 WBC/mm^3 [less than 5 × 10^6/L]), age younger than 2 years or older than 6 years, and a bloody diagnostic lumbar puncture.[6,39] Intrathecal therapy consists of methotrexate and cytarabine, given either alone or in combination. When given together, hydrocortisone is commonly added (triple intrathecal therapy) to decrease the incidence of arachnoiditis. Triple intrathecal therapy is typically reserved for children with refractory CNS disease. For standard-risk ALL, triple intrathecal therapy decreased CNS relapse rates by 30% in comparison to intrathecal methotrexate but had no effect on EFS and worsened overall survival (OS).[39] The doses of intrathecal chemotherapy used for childhood ALL are age-based because of differences in the volume of CSF at various ages. For example, intrathecal methotrexate is dosed as 8 mg if less than 2 years, 10 mg for 2 to 2.99 years, 12 mg for 3 to 8.99 years, and 15 mg for more than or equal to 9 years. Liposomal cytarabine given intrathecally induces CNS remission in 57% of relapsed patients, but is associated with a high incidence of arachnoiditis and other CNS-related adverse effects.[40] Currently its use is limited to refractory or relapsed CNS disease in children.

Patients with T-cell leukemia have an increased incidence of CNS disease and usually receive systemic therapy that penetrates the CNS such as high-dose methotrexate. A WBC count greater than 100,000 cells/mm^3 (100 × 10^9/L) is associated with an increased risk of CNS relapse.[6] Patients with T-cell disease have lower methotrexate polyglutamate accumulation in leukemic blasts and therefore require higher doses of infusional methotrexate (5 g/m^2 compared to 1 g/m^2).[41] Patients with T-cell leukemia may require prophylactic or therapeutic CNS irradiation.[38]

Consolidation Therapy

Consolidation therapy in ALL is started after a CR has been achieved, and refers to continued intensive antineoplastic therapy in an attempt to eradicate clinically undetectable disease in order to secure (consolidate) the remission. Regimens usually incorporate either non–cross-resistant drugs that are different from the induction regimen, or more dose-intensive use of the same drugs.

Randomized trials show that consolidation therapy clearly improves patient outcome in children, but its benefit in adults is less clear.[42] The relative benefit of individual components of treatment regimens is difficult to demonstrate because of the overall complexity of therapy in ALL. Standard consolidation lasts 4 weeks and usually consists of vincristine, mercaptopurine, and intrathecal methotrexate. In children, the intensity of consolidation therapy is based on the child's initial risk classification and response to induction therapy. Children who are slow early responders during induction or have high-risk disease benefit from intensified consolidation that includes the addition of pegaspargase, cyclophosphamide, and low-dose cytarabine to standard therapy.[43] Children with testicular disease usually receive radiation during this phase of therapy if a complete clinical response in the testes is not achieved by the end of induction. Patients with T-cell leukemia also receive nelarabine, a prodrug of ara-G that preferentially accumulates in T lymphoblasts as ara-guanosine triphosphate (GTP), during consolidation and throughout the remainder of their treatment course given the improved EFS when it is added to an intensified therapeutic backbone.[44]

Reinduction (Delayed Intensification and Interim Maintenance)

One or two delayed intensification phases separated by low-intensity interim maintenance cycles can be added to maintain remission and to decrease cumulative toxicity. Delayed intensification usually consists of drugs used during induction and consolidation or agents that lack cross-resistance with those already received such as cyclophosphamide, methotrexate, and limited amounts of doxorubicin. The methotrexate dose is variable; standard-risk children usually receive 1 to 2 g/m^2 while those with T-cell disease usually receive a higher dosage (5 g/m^2). Interim maintenance usually consists of dexamethasone, vincristine, weekly methotrexate, mercaptopurine, and intrathecal methotrexate. Delayed intensification improves EFS for standard-risk children.[41,43] Delayed intensification with dose intensification improved EFS and decreased late relapses for high-risk childhood ALL, but there was no additional benefit for two delayed intensification cycles.[43] Children on the intensified arms of the study received significantly more antimicrobial drugs, blood products, and parenteral nutrition but had no increase in treatment-related mortality.[43] The antimetabolite-based regimens may have a reduced risk of late toxicities, but the more intensive regimens appear to result in better survival for some patients, especially those with higher risk disease.

Maintenance Therapy

5 Maintenance therapy allows long-term drug exposure to slowly dividing cells, allows the immune system time to eradicate leukemia cells, and promotes apoptosis (programmed cell death). The goal

of maintenance therapy is to further eradicate residual leukemic cells and prolong remission duration. Although maintenance therapy is clearly beneficial in childhood ALL, the benefit in adults has only recently been demonstrated.

Maintenance therapy usually consists of daily mercaptopurine and weekly methotrexate for 12-week courses, at doses that produce relatively little myelosuppression, with monthly "pulses" of vincristine and a steroid.[45,46] Based on the results of studies that show a trend toward an increase in late relapse (excluding isolated testicular relapse) among male children treated for 2 years versus 3 years, some centers treat female children for 2 years while males receive maintenance for a total of 3 years of therapy.[17]

Interpatient variability in the pharmacokinetics of oral methotrexate and mercaptopurine may also be an important determinant of the effectiveness and toxicity of maintenance therapy. It is recommended that mercaptopurine be administered in the evening rather than in morning based on data demonstrating improved outcomes.[47] Mercaptopurine cannot be given with milk or milk products because of the presence of xanthine oxidase. Children with an adherence rate less than 95% with mercaptopurine have a 2.7-fold higher risk of suffering a relapse.[48] Factors associated with nonadherence include single-parent household, adolescence, lower socioeconomic status, and Hispanic ethnicity.[49] To account for the interpatient variability, most clinicians will titrate the dose of these agents to achieve adequate myelosuppression.[17] Some protocols overcome bioavailability and poor adherence issues by administering methotrexate IV or intramuscularly. The importance of these pharmacokinetic issues in adults is not well defined.

Philadelphia Chromosome Positive Acute Lymphoblastic Leukemia

Ph^+ ALL has historically been treated as very-high-risk disease.[19] This includes the use of a four-drug induction regimen with the addition of continuous imatinib mesylate, a signal transduction inhibitor that inhibits *BCR-ABL* kinase, throughout all phases of treatment. This targeted therapeutic approach has resulted in a 3-year EFS of 80% in comparison to 35% for historical controls.[50] The results for patients receiving chemotherapy with imatinib were equivalent to those receiving hematopoietic stem cell transplantation (HSCT). Imatinib is currently incorporated into childhood treatment trials for Ph^+ ALL in Europe and the United States. Trials are ongoing with the more potent second generation tyrosine kinase inhibitors, nilotinib and dasatinib, and with ponatinib, which is effective in imatinib-resistant leukemia.[51]

Acute Lymphoblastic Leukemia in Infants

Acute lymphoblastic leukemia and AML in infants younger than 1 year of age account for less than 5% of the reported acute leukemias in childhood, but they are associated with poor outcomes. About 70% to 80% of infants with acute leukemia have t(4;11) involving the *MLL* gene, which is associated with worse outcomes.[52] Infants with ALL are more likely to present with a high WBC count, hepatosplenomegaly, and CNS disease. Age younger than 6 months at diagnosis and poor response to prednisone alone given prior to starting other agents are poor prognostic indicators. Infants with

MLL gene rearrangements are more likely to overexpress FLT3, a tyrosine kinase implicated in leukemogenesis that is associated with a poor prognosis. Current trials are testing the efficacy of FLT3 inhibitors in infants with *MLL* gene rearrangements.[52] Lack of pharmacokinetic data for antineoplastic agents in infants has contributed to toxicity from potential inaccurate dosing of doxorubicin and vincristine. The use of allogeneic HSCT for infants with ALL remains controversial because of a lack of donors, concerns over the long-term toxicity of total body irradiation, excessive mortality in some series, and differing outcomes.[53,54]

Acute Lymphoblastic Leukemia in Down Syndrome

Children with Down syndrome have a markedly increased risk of developing ALL.[55] The clinical presentation of ALL in Down syndrome patients is similar to patients without Down syndrome but there is a lower incidence of high-risk features including T-cell disease, CNS involvement, hepatosplenomegaly, and cytogenetic abnormalities.[18] Therapy for ALL in Down syndrome patients is similar to that of non-Down syndrome patients, with the caveat that anthracycline exposure is limited and methotrexate dosing is reduced and supported with aggressive leucovorin rescue.[18] Children with Down syndrome and ALL have an increased risk of relapse and treatment-related mortality resulting in a decreased OS rate when compared to non-Down syndrome patients with ALL.[56]

Acute Lymphoblastic Leukemia in Adolescents and Young Adults

Although ALL is relatively uncommon in adolescents and young adults (AYA) (15-39 years old), the outcomes are generally worse than for childhood ALL.[57] ALL in AYA has a higher frequency of T-cell immunophenotype and a lower frequency of the t(12;21)(p13;q22) cryptic translocation responsible for hyperdiploidy and the *ETV6-RUNX1* fusion gene; about 5% to 7% of ALL in AYA have Ph^+ disease (higher than children, but lower than older adults).[14,58] A retrospective comparison of 16- to 20-year-old patients treated on pediatric versus adult protocols in the United States resulted in identical CR rates, but the 7-year EFS favored the patients treated on pediatric regimens (64% vs 34%).[58] Patients treated on the pediatric regimens also had a 10% lower CNS relapse rate. The adult regimens studied were more myelosuppressive due to the use of anthracyclines, cyclophosphamide, and cytarabine, while the pediatric regimens intensified steroids, vincristine, and asparaginase and included aggressive CNS-directed therapy and maintenance therapy. The adult regimens had a higher risk of late effects due to higher doses of daunorubicin and use of cyclophosphamide. A current adult intergroup study is using a pediatric regimen for AYA patients and will be able to evaluate some of the other potential reasons for the outcome disparity, such as adherence and psychosocial differences. AYA patients may receive treatment based on an adult or pediatric regimen depending on institutional preferences, but the trend is shifting toward pediatric regimens.

Acute Lymphoblastic Leukemia in Adults

6 Treatment risk stratification for adult patients differs depending on age and Philadelphia chromosome status. The National Comprehensive Cancer Network (NCCN) guidelines recommend different strategies for AYA, adults 40 to 65, and adults older than 65 years with or without poor

performance status.[59] While CR is achieved in 70% to 90% of adults with a four-drug induction regimen containing daunorubicin or doxorubicin, vincristine, an asparaginase formulation, and prednisone, long-term EFS is considerably lower and achieved in only 20% to 40% of patients.[60] Poorer outcomes in adults have been attributed to differences in cytogenetic abnormalities, greater drug resistance, higher risk of treatment-related adverse effects with subsequent nonadherence, and possibly less effective therapy. The value of adding more agents to the basic four-drug induction regimen or higher doses of drugs in the remission induction regimen is not clear. Several different regimens are considered appropriate to use as first-line therapies in adults including the Cancer and Leukemia Group B (CALGB) 8,811 (Larson regimen), Eastern Cooperative Oncology Group (ECOG) 2,993, or Linker regimen.[61] Some studies suggest that high-dose methotrexate and cytarabine alternating with fractionated cyclophosphamide plus vincristine, doxorubicin, and dexamethasone (hyperCVAD) may improve response and survival in adults with ALL.[61] A considerable number of ALL cases occur in patients older than age 65 years, and treatment of this group of patients is an even greater challenge. The response to therapy and durability of response is less than in all other populations. Treatment-related mortality rates during remission induction therapy are also higher in this population.

While the overall incidence of Ph^+ positive disease is 25% in adults, the incidence rises with increasing age to over 40% in adults older than the age of 50 years.[62] Traditionally, treatment outcomes for patients with Ph^+ ALL has been extremely poor with reported OS rates of less than 20% and a 2-year OS of 40% to 50% for those continuing to allogeneic HSCT. As compared with historical control patients treated with standard chemotherapy alone, the addition of *BCR-ABL* tyrosine kinase therapy to chemotherapy is associated with an increased CR and OS.[63,64] No randomized trials have compared imatinib or dasatinib and conventional chemotherapy versus conventional chemotherapy alone. The CR rates seen with tyrosine kinase inhibitors appear to be more durable and allow more patients with Ph^+ disease to proceed to allogeneic HSCT. This approach also appears to be tolerated in elderly patients.[65] For patients older than 65 years of age or for those with a poor performance status, induction regimens may include concurrent chemotherapy with a tyrosine kinase inhibitor, either alone or combined with corticosteroids. Based on these data, the combination of imatinib or dasatinib with concurrent chemotherapy is currently considered as the standard of care for first-line therapy.

Other *BCR-ABL* tyrosine kinase inhibitors, nilotinib, bosutinib, and ponatinib, have also been evaluated in patients with imatinib-resistant Ph^+ leukemias.[61] Responses may be achieved, and they are treatment options in patients with relapsed or refractory Ph^+ ALL. A primary concern with the *BCR-ABL* tyrosine kinase inhibitors is the emergence of resistance, specifically T315I mutations. Ponatinib is the only *BCR-ABL* tyrosine kinase inhibitor available in the United States with known activity against T315I mutations.[66] A patient's specific mutation analysis should be considered in the selection of a specific tyrosine kinase inhibitor in the relapsed or refractory setting.

In adults with B-cell ALL, about 50% have leukemic cells that express CD20. CD20 expression has been associated with decreased CR rates, higher risk of relapse, and shorter OS.[67,68] A phase II study has evaluated hyperCVAD and rituximab versus hyperCVAD alone and reported a higher CR rate (70%

vs 38%) and longer OS (75% vs 47%) in patients treated with hyperCVAD and rituximab.[69] These results support the use of rituximab in patients who have cells that express CD20.

Hematopoietic stem cell transplantation plays an important role in the treatment of adult patients with ALL. For patients with Ph^+ ALL or Ph^- ALL who have a CR after induction therapy, consolidation with allogeneic HSCT should be considered if a human leukocyte antigen (HLA)-matched sibling or matched unrelated donor is available. After HSCT, patients with Ph^+ ALL should continue with standard maintenance therapy that includes a tyrosine kinase inhibitor. For patients with Philadelphia chromosome negative (Ph^-) disease who have MRD after induction therapy an allogeneic HSCT should be considered if a matched donor is available. Allogenic HSCT is preferred over autologous HSCT because of lower disease relapse rates.[70]

Relapsed Acute Lymphoblastic Leukemia

About 20% of children with ALL will relapse, but about 40% will experience long-term OS following relapsed treatment regimens.[21] The most common site for relapse is isolated to the bone marrow, although isolated relapses can occur in the CNS or testicles, in addition to combined sites of involvement.[17] Because marrow relapse usually follows isolated CNS or testicular relapses, patients with isolated extramedullary relapses are treated with localized radiation (cranial or testicular) and aggressive systemic chemotherapy similar to that given to patients with a marrow relapse.[71]

Patients who have completed treatment and remained in remission for longer periods are more likely to achieve remission again. The second CR rate is 78% in children who were in continuous CR for less than 18 months, 78% if the duration of remission was 18 to 36 months, and 93% if the duration of remission was more than 36 months.[72] Three-year OS following bone marrow (28%), CNS (60%), and testicular (60%) relapse is not optimal.[71] Overall, 5-year disease-free survival rates are 27% for second complete remission (CR2) and 15% for third complete remission (CR3).[72]

Clofarabine, a purine antimetabolite, is an option for patients with second or later relapses, but the duration of response is less than 6 months. Nelarabine is an option for relapsed T-cell ALL, especially if the patient had not previously received nelarabine as part of their initial therapy. Other antineoplastic agents that have antileukemic activity in relapsed ALL include liposomal vincristine, moxetumomab pasudotox, inotuzumab ozogamicin, and bortezomib.[73,74]

Blinatumomab received FDA approval in 2014 for relapsed or refractory Ph^- B-cell precursor ALL. As a bi-specific T-cell engager (BiTE), blinatumomab binds to both CD19, an antigen that is present throughout B cell development, and CD3, a T-cell receptor. By linking CD19 and CD3, blinatumomab enables a cascade of events resulting in lysis of CD19 cells.[75] Blintumomab has induced a CR and achieved MRD negativity in adult and pediatric patients with relapsed or refractory ALL. Phase III trials of single-agent blinatumomab are ongoing, as are trials combining blinatumomab with conventional antineoplastic agents. Since blinatumomab has a very short half-life, it must be administered as a continuous infusion for 28 days of a 6-week cycle. Adverse reactions occur in most patients, ranging from mild, reversible symptoms such as fever and rigors to more severe toxicities including

neurotoxicity, infections, and cytokine release syndrome.[76]

Chimeric antigen receptor (CAR) T-cell therapy is a promising therapeutic option for ALL patients without other curative options. This new therapeutic modality involves genetically engineered T cells designed to express CARs directed against CD19, resulting in T cells targeting leukemic cells that express CD19. Clinical trials have reported a CR rate ranging from 70% to 90% in pediatric and adult patients with relapsed or refractory ALL.[77,78,79] Significant adverse effects arising after CAR T-cell therapy include hypogammaglobulinemia, encephalopathy, seizures, and cytokine release syndrome, ranging from mild, flu-like symptoms to multiorgan system failure.

Allogeneic HSCT has traditionally been the treatment of choice for early bone marrow relapse (continuous CR less than 36 months) while children who relapse more than 36 months after completion of initial therapy have traditionally received chemotherapy alone.[42] More recent analyses have shown HSCT to be an advantage to all relapsed children, while some have not shown a benefit.[72] Therefore, the question of who would benefit from HSCT continues to be investigated.

Most patients with relapsed or refractory disease are considered for an allogeneic HSCT with a matched sibling or unrelated donor if they achieve a CR2 following salvage chemotherapy. Most elderly patients are not candidates for standard allogeneic HSCT but are candidates for nonmyeloablative transplant (NMT). Patients who undergo an NMT receive a reduced intensity conditioning regimen. An NMT may produce similar outcomes with less treatment-related morbidity and mortality. The National Marrow Donor Program and the American Society for Blood and Marrow Transplantation have developed guidelines for transplant consultation based on current clinical practice and evidence.[70,80]

Late Effects of Treatment

Certain late effects associated with cranial or craniospinal irradiation and corticosteroids were discussed earlier. The Childhood Cancer Survivor Study tracks the health status of adults treated for childhood cancer between 1970 and 1986 and has yielded invaluable information on how to monitor adult survivors.[81] Leukemia survivors are 3.7 times more likely to develop a severe or life-threatening chronic health condition as compared with healthy siblings, and 2.8 times more likely to report multiple chronic conditions.[81]

Older ALL regimens that incorporated intensive use of topoisomerase II inhibitors (etoposide and teniposide) are associated with unacceptably high risks of development of secondary leukemia.[42] High cumulative doses of anthracyclines used in high-risk or relapsed patients can cause cardiomyopathy. Cranial irradiation is also associated with learning deficits, especially in patients younger than 5 years of age at the time of treatment. Patients who received cranial radiation as children also have higher unemployment rates and lower marital rates among females two decades after diagnosis.[81] The Children's Oncology Group has developed long-term follow-up guidelines for survivors of childhood, adolescent, and young adult cancers.[82]

ACUTE MYELOID LEUKEMIA

Risk Classification

Many clinical and laboratory features at diagnosis are associated with response to treatment, as measured by the CR rate, duration of remission, and long-term survival. Identification of these risk factors may allow the clinician to better understand the disease and to tailor treatment according to risk of disease recurrence. For example, if a patient has many clinical and laboratory features that are associated with a favorable response to chemotherapy ("favorable risk"), then the clinician may choose to give less intensive therapy to reduce the risk of long-term toxic effects. Conversely, if a patient is unlikely to respond well to therapy ("high risk"), then the clinician may choose to give more intensive chemotherapy that may include HSCT.

7 Several prognostic factors have been identified for adults with AML. The most important patient factor is age, with younger patients more likely to achieve a CR than patients older than age 60 years.[3] The lower CR rate in older patients results from an increased frequency of fatal infection and bleeding complications and resistance to conventional chemotherapy. The duration of remission is also shorter in older patients as compared to younger patients. Other patient-specific prognostic factors include concurrent infection and any major organ impairment.[13] Patients with extramedullary disease, CNS involvement, or underlying MDS have a worse prognosis. Other unfavorable prognostic factors in adult AML include: age older than 60 years, multidrug-resistance gene expression, WBC greater than 100,000 cells/mm^3 (>100 × 10^9/L), and therapy-related AML.[13] Age must be evaluated as a continuous variable when looking at prognostic factors. The clinical difference between a patient 61 years old and one 71 years old, is much greater than a 59-year-old and a 61-year-old. Certain cytogenetic abnormalities are also known to worsen the response rate and survival of patients with AML (**Table 134-4**).[13] Chromosome 16 or translocations between chromosome 8 and 21 alter core-binding factor. Core-binding factor is associated with sensitivity to cytarabine.[3,13] In addition, patients who develop a "secondary" leukemia after treatment of another malignancy usually have a very poor response to antileukemic chemotherapy (ie, therapy-related AML). Another factor that needs consideration for any cancer treatment is performance status. A bed-ridden patient with a new diagnosis of AML would not be a good candidate for treatment because of high treatment-related morbidity and mortality. Patients with poor performance status may be offered supportive care.

TABLE 134-4 Risk Category According to Cytogenetic and Molecular Abnormalities Present

	Risk Category		
Disease	***Good-Risk***	***Intermediate-Risk***	***High-Risk***
AML	t(8;21)(q22;q22); inv(16); t(15;17); t(9;11) trisomy 21 Mutated NPM1 without FLT3-ITD Mutated CEBPA	Normal karyotype; trisomy 8; 11q23; del(7q); del(9q); trisomy 22; t(9;11)	Complex karyotype; –5; –7; del(5q); inv(3p) FLT3 ITD

AML, acute myeloid leukemia; CEBPA, CCAAT/enhancer binding-protein α; FLT3-ITD, Fms-like tyrosine kinase 3 internal tandem duplication; NPM1, nucleophosmin.

Cytogenetics may be the most important prognostic factor for a patient newly diagnosed with AML.[3,13] Molecular testing for FLT3-ITD, CEBPA, C-KIT, and *NPM1* is becoming more common in commercial laboratories and referral centers, and should be considered for all newly diagnosed AML patients.[3,13] Patients with core-binding factor with t(8;21)(q22;q22) or inv(16)(p13;q22)/t(16;16)(p13;q22) treated with a cytarabine-based regimen have a relatively favorable prognosis. Adults and children with chromosomal deletions such as 3q[abn(3q)] or 5q[del(5q)], monosomies of chromosome 5 and/or 7(-5/-7) have a poor prognosis with standard chemotherapy for AML, and may benefit from experimental treatments. About 40% of cases have a normal karyotype. Molecular mutations, such as FLT3, *NPM1* (nucleophosmin), C-KIT, and CEBPA (CCAAT/enhancer-binding protein α), can identify subsets of patients with differing outcome who have normal karyotypes. FLT3 is a receptor tyrosine kinase that is mutated in about one-third of patients with AML, including those with normal karyotype, and is associated with higher presenting WBC, decreased duration of CR, and a poorer prognosis. *NPM1* is present in about 30% of patients with AML, even in patients with normal karyotype, and commonly coexists with FLT3, and is associated with a higher CR and reduced relapse risk compared to patients without the mutation.[3,13] C-KIT mutations have been observed in about 20% of patients with core-binding factor AML and are associated with decreased duration of CR and OS.[83] CEBPA is present in about 10% of patients with AML, and is associated with a favorable outcome. The area of cytogenetic and molecular abnormalities is complex and still evolving.

Prognostic factors associated with pediatric AML include response to the first course of remission induction therapy, cytogenetics, and molecular genetics. Poor prognostic factors include monosomy 7, age older than 10 years, black race, internal tandem duplications of FLT3, *MLL* gene rearrangements, and a diagnosis of AML secondary to prior chemotherapy or radiation therapy.[4,84] Conversely, inversion of chromosome 16, trisomy 21, CBF-AML, *PML-RARA*, *NPM1*, biallelic CEBPA, and *RUNX1-RUNX1T1* fusion transcript t(8;21) are associated with a favorable outcome.[4,84]

Acute myeloid leukemia treatment in the future may be based primarily on cytogenetic and molecular classification. Treatment algorithms based on these newer classifications have been proposed, but they are not currently incorporated into the initial remission induction therapy. These tests do provide prognostic information that may be incorporated into subsequent treatment decisions for postremission therapy or relapsed/refractory disease.[15]

TREATMENT

Acute Myeloid Leukemia

Desired Outcomes

The short-term goal of treatment for AML is to rapidly achieve a complete clinical and hematologic remission. In the absence of a CR, a rapid and fatal outcome is inevitable. CR is defined as the disappearance of all clinical and bone marrow evidence (normal cellularity more than 20% with less

than 5% blasts) of leukemia, with restoration of normal hematopoiesis (neutrophils more than or equal to 1,000 cells/mm^3 [more than 1 × 10^9/L] and platelets more than 100,000 cells/mm^3 [more than 100 × 10^9/L]).[85] Partial remission is a significant response to treatment (a decrease of at least 50% of blasts), but evidence of residual disease in the bone marrow remains (5%-25% blasts) and is considered a treatment failure requiring additional therapy. The definition of CR has several categories including not only CR (morphologic CR with restoration of normal hematopoiesis), but also CR with complete remission with incomplete hematological recovery (CRi), cytogenetic CR ([CRc] patient with normal cytogenetics in which cytogenetics were previously abnormal), and molecular CR ([CRm] molecular studies negative).[85] If there is a question of residual leukemia on bone marrow biopsy in adults, a bone marrow aspirate/biopsy should be repeated in 1 week.

After a CR is achieved, the goal is to maintain the patient in continuous CR. The occurrence of leukemic relapse in the bone marrow significantly reduces the likelihood of cure. Most patients who will die from acute leukemia die within the first 6 years; the survival curve (percentage alive vs time) beyond the sixth year after therapy does not continue to decline as rapidly ("survival plateau"), and at this time patients can be considered "cured."

With recent advances in antineoplastic therapy and supportive care, 60% to 80% of all patients with AML achieve a CR, and 20% to 40% become long-term survivors.[3] Overall, the median duration of remission is 1 to 2 years. In patients 60 years of age or older, the CR rate averages around 50%, and the median duration of remission is shorter than 1 year.[3] In contrast to ALL, effective therapies used in AML cause severe and often prolonged myelosuppression. As a result, patients with AML, particularly patients older than 60 years of age, are at greater risk for treatment-related fatal infectious and bleeding complications.

Treatment Phases

Remission Induction

As with ALL, the goal of remission induction for AML is to rapidly induce a CR with associated restoration of normal hematopoiesis. Compared to ALL, however, fewer patients with AML achieve CR. Because the CR rate in AML is related to the intensity of the remission induction regimen, the drugs used in AML are given at doses that uniformly cause severe myelosuppression (except tretinoin). One reason for the lower CR rate in AML as compared to ALL is the inability to give optimal doses of chemotherapy because of marrow toxicity. With continued improvement of supportive care for patients undergoing chemotherapy, more intensive treatment regimens are being given in an effort to reduce the high rate of leukemic relapse and increase the proportion of long-term survivors. Most patients achieve a CR after 1 or 2 courses of chemotherapy. Patients who require additional chemotherapy to achieve a CR have been reported to have a poor prognosis, even if remission is ultimately achieved.

8 The most active single agents in AML are the anthracycline antibiotics (daunorubicin, doxorubicin, and idarubicin), mitoxantrone, and the antimetabolite cytarabine. The standard therapy for the treatment of adult AML has not changed in several decades. The most common regimen ("7+3")

combines daunorubicin administered as a short infusion of 45 to 60 mg/m^2 per day on days 1 to 3, along with cytarabine administered as a continuous 24-hour infusion of 100 to 200 mg/m^2 per day on days 1 to 7.[3,86] The CR rate with the 7+3 regimen is 65% to 75% in patients 18 to 60 years old. Several trials have attempted to improve on conventional 7+3 therapy, but have shown no improvement by (a) increasing cytarabine to 10 days, (b) shortening cytarabine to 5 days, (c) substituting doxorubicin, idarubicin, or mitoxantrone for daunorubicin, (d) adding other agents such as etoposide, thioguanine, or topotecan, or (e) increasing cytarabine to higher doses (2 g/m^2 every 12 hours for 8-12 doses).[3] The most recent change to the standard 7+3 regimen is to increase the daunorubicin dose. Adults younger than 60 years old with AML who were randomized to receive higher daunorubicin dosages (90 mg/m^2 per day on days 1-3) in combination with 7 days of standard-dose cytarabine (100 mg/m^2 per day) had a significantly higher CR rate (71% vs 57%) and longer median OS (23.7 vs 15.7 months) as compared with those who received the standard 7+3 regimen of daunorubicin (45 mg/m^2 per day on days 1-3) and cytarabine.[87]

Idarubicin and mitoxantrone have been evaluated as alternatives to daunorubicin in combination with standard-dose continuous infusion cytarabine. Trials in younger patients reported improved CR rates with these newer anthracyclines (idarubicin) or anthracenediones (mitoxantrone), and one trial reported prolonged survival. Among older adults, the CR rate and OS do not appear to be different among the different anthracyclines or anthracenediones.[3,86] Therefore, the anthracycline of choice for the standard 7+3 regimen is daunorubicin or idarubicin with many centers adopting idarubicin or higher doses of daunorubicin into the induction regimen in younger AML patients.

Based on experimental tumor models that showed a steep dose-response curve for cytarabine, higher cytarabine doses have been evaluated as a means to increase the antileukemic activity of induction therapy. The decision to give high-dose cytarabine in induction may depend on the treatment plan for postremission or consolidation therapy. The Southwest Oncology has evaluated the impact of adding high-dose cytarabine to induction therapy. This strategy does not improve the CR rate or OS, but does improve EFS.[88] A study specifically in younger patients compared conventional dose cytarabine to high-dose cytarabine demonstrated improved OS in patients aged 15 through 45 years of age.[89] A retrospective study conducted by the European Group for Blood and Marrow Transplantation demonstrated that the cytarabine dose administered during induction and/or consolidation did not influence the outcome in patients who ultimately went on to receive allogeneic or autologous HSCT.[90] These data suggest that high doses of cytarabine during induction may not be needed in patients who receive HSCT as postremission therapy. No data are available using more than daunorubicin 60 mg/m^2 or idarubicin 12 mg/m^2. In summary, the role of high-dose cytarabine during induction remains controversial. If used during induction, high-dose cytarabine is more appropriate in younger patients than in elderly patients because of poor tolerance by elderly patients. Additionally, it may be an option in patients unable to tolerate anthracyclines.

Clinical Controversy…

Some studies have reported improved treatment outcomes with high-dose cytarabine (2 g/m^2 every 12 hours for 8-12 doses) given in combination with an anthracycline during induction therapy.

Should high-dose be given for induction therapy? If so, should it be given only to younger patients or those with high-risk AML?

The National Comprehensive Cancer Network (NCCN) has published guidelines for the treatment of AML.[91] The classic 7+3 regimen may be inadequate in adults younger than 60 years of age because the duration of remission is less than that reported in some studies that employed high-dose cytarabine in induction. The NCCN guideline recommends that adults younger than 60 years of age without an antecedent hematologic disorder (ie, no preexisting hematologic malignancy such as MDS) be treated with either the 7+3 regimen or more aggressive chemotherapy including high-dose cytarabine with an anthracycline or anthracenedione. In patients 60 years of age or older with good performance status, the conventional 7+3 regimen should be used or the patient should be enrolled in a clinical trial. The approach in patients with an antecedent hematologic disorder differs, and younger patients (less than 60 years) should be offered available clinical trials or proceed to allogeneic HSCT (provided a suitable donor is available).

Older patients (more than or equal to 60 years) with an antecedent hematologic disorder or those with significant comorbidities unrelated to leukemia should be offered a low-intensity therapy with low-dose subcutaneous cytarabine, a hypomethylating agent such as azacitidine or decitabine, a clinical trial or best supportive care because of the dismal outcomes and toxicity risks associated with conventional chemotherapy. Azacitidine and decitabine are pyrimidine nucleoside analogs of cytidine that inhibit DNA methylation. While each agent has shown promising results versus conventional chemotherapy and best supportive care, the agents have not been compared to each other in trials.[92,93] Azacitidine is usually given 75 mg/m^2/dose IV or subcutaneously for 7 days while decitabine is given 20 mg/m^2/dose IV for 5 days. Cycles are repeated about every 28 days. A minimum of 4 to 6 cycles of therapy must be given before evaluation of response. Azacitidine has resulted in OS rates of 50% as compared to 16% in those treated with usual care (chemotherapy, low-dose cytarabine, or best supportive care).[93] These agents are generally well-tolerated with the most significant adverse effect being myelosuppression. Best supportive care includes use of blood product transfusion support.

All adult patients who present with CNS symptoms or asymptomatic monocytic disease should have a diagnostic lumbar puncture, and, if it is positive, should be treated for disease. Methotrexate or cytarabine should be administered intrathecally twice a week until clearance of leukemic blasts from the CSF, and then weekly for 4 to 6 weeks. Continued secondary prophylaxis is recommended following treatment for CNS disease.[91]

Intensive Postremission Therapy

Although most adults with AML achieve a CR, the duration of remission is short (6-9 months) if no further treatment is given. Relapse is presumably a consequence of the presence of residual, but clinically undetectable, leukemic cells after remission induction therapy. The goal of intensive postremission therapy is to eradicate these residual leukemic cells and to prevent the emergence of drug-resistant disease. The need for postremission therapy is based on postmortem analysis and cell kinetic data suggesting that nearly 10^9 residual leukemic cells remain after effective remission

induction therapy. Strategies evaluated as postremission therapy include (a) low-dose, prolonged maintenance therapy, (b) short-course intensive chemotherapy-alone regimens, and (c) high-dose chemotherapy with or without radiation therapy followed by allogeneic or autologous HSCT.

Chemotherapy

In the treatment of AML, intensive postremission therapy is often referred to as *consolidation therapy*. Results of randomized controlled trials in adults clearly show that intensive postremission therapy following remission induction therapy prolongs survival versus no therapy, although the exact duration of postremission therapy is controversial.[3,5,91]

The intensity of postremission therapy is important. In a large CALGB trial, all patients who achieved a CR after standard 7+3 induction were randomized to receive one of three cytarabine-based consolidation regimens: 100 mg/m^2 per day or 400 mg/m^2 per day as a continuous 24-hour infusion, or 3,000 mg/m^2 every 12 hours on days 1, 3, and 5.[94] For adults younger than age 60 years, the probability of remaining in CR after 4 years was significantly higher in patients who received high-dose cytarabine (25% vs 29% vs 44%, respectively).[94] Elderly patients had lower response rates in all arms and did not benefit from the administration of higher cytarabine doses, probably because they were unable to tolerate the high-dose regimen. Dose-limiting neurotoxicity in the high-dose arm was more common in elderly patients and those patients with impaired kidney function.[94]

It is not clear whether the same agents (cytarabine and an anthracycline) given for remission induction should be used for postremission therapy in higher doses, or whether different agents should be given. If leukemic relapse is caused by a resistant cell line, then the use of different agents that are non–cross-resistant with drugs used in induction might be beneficial.

High-dose cytarabine appears to be an important component of postremission therapy, particularly if it is not used in induction therapy. However, many questions remain, such as the optimal dose (g/m^2), number of doses per cycle, and number of cycles of high-dose cytarabine. Among patients with core-binding factor AML, defined as the presence of either t(8;21) or inv(16), it is clear that multiple cycles are beneficial, generally 3 to 4 cycles. The NCCN guideline recommends 3 to 4 cycles of high-dose cytarabine for adults younger than 60 years of age and with favorable cytogenetics.[91] Patients with intermediate-risk cytogenetics should receive 3 to 4 cycles of high-dose cytarabine, or proceed directly to a matched allogeneic HSCT, while those patients with treatment-related or poor risk disease should continue directly to a matched allogenic HSCT.[91] If a patient is 60 years of age or older, standard-dose cytarabine with or without anthracycline for one to two cycles, a reduced-dose high-dose cytarabine regimen (1-1.5 g/m^2 per day for 4-6 doses) for one to two cycles, continuation of low-intensity therapy such as azacitidine or decitabine, or enrollment in a clinical trial is recommended. Patients with high-risk cytogenetics, underlying MDS, or secondary AML should either be enrolled in a clinical trial or be referred for either a matched sibling or alternative donor allogeneic HSCT.[91]

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic HSCT represents the most aggressive postremission therapy in the management of AML. Much controversy surrounds this treatment approach, specifically the appropriateness, timing, treatment design, and donor selection.

The antileukemic activity of allogeneic HSCT is based on the administration of pretransplant high-dose chemotherapy (or chemoradiotherapy) and the development of a post-transplant immune-based antileukemic response. The immune-based response, referred to as a graft-versus-leukemia (GVL) effect, often accompanies the graft-versus-host disease (GVHD) reaction. The immune-based benefit of allogeneic HSCT has been demonstrated through the observation of consistently lower relapse rates with allogeneic HSCT as compared to autologous or syngeneic HSCT. This potential benefit of allogeneic HSCT can be offset by the risk of post-transplant complications such as GVHD, sinusoidal obstruction syndrome, graft failure, and infections.

Allogeneic HSCT was first evaluated as a treatment modality for AML in refractory patients, but because of initial success in small numbers of patients, it has also been evaluated as intensive postremission therapy in AML patients in first or subsequent remission. Nonrandomized trials of HLA-identical sibling allogeneic HSCT performed in AML patients in first complete remission (CR1) reported 5-year survival rates of 45% to 60% with relapse rates of 10% to 20%.[3,5,86] Transplant-related mortality following HLA-matched sibling allogeneic HSCT ranges from 15% to 25% in most series.[5,86] As clinicians have gained more experience in this intensive form of therapy and been provided with more effective immunosuppressive and antibiotic regimens, transplant-related mortality rates have decreased and survival rates have increased. Bone marrow registry data indicate that long-term survival rates in AML patients who receive a matched sibling allogeneic HSCT while in first remission have increased from about 45% in the early 1980s to about 60% in the mid-1990s.

Allogeneic HSCT from an HLA-matched sibling donor for AML patients in CR1 results in long-term EFS in 43% to 55% of patients. Although the results vary, some of the studies show longer EFS and lower relapse rates with allogeneic HSCT in AML in CR1 as compared to chemotherapy-alone postremission regimens. Overall, single center prospective trials have not shown an OS advantage for allogeneic HSCT in all patients with AML CR1. Meta-analyses of clinical trials evaluating allogeneic HSCT versus other consolidation strategies in CR1 shows that allogeneic HSCT does provide an OS advantage for patients with intermediate- and high-risk AML.[5]

Myeloablative allogeneic HSCT is generally restricted to patients younger than 60 years of age, which limits the number of patients eligible for treatment of a disease that primarily affects older adults. NMT uses reduced intensity preparative regimens and is now being used in AML patients, particularly in older patients and those with comorbid illnesses that would limit their eligibility for conventional allogeneic HSCT. NMT is designed to provide enough immunosuppression in the preparative regimen to allow for engraftment of donor cells, and depends heavily on the development of a GVL effect as a means to treat and prevent relapse of AML. The procedure is well tolerated in a wide age range of patients is associated with low rates of regimen-related toxicity. A larger trial evaluating 264 patients who had received an NMT from matched related and unrelated donors demonstrated a 5-year OS of 33% and disease-free survival of 32%.[95] Because only 30% of patients have an HLA-matched sibling donor, allogeneic HSCT is further restricted as a treatment alternative for AML

patients.[5] Matched unrelated donor HSCT with a phenotypically HLA-matched donor identified from bone marrow registries is also a treatment option in young adults and pediatric AML patients. This approach is associated with long-term EFS rates of 30% to 40%, which are slightly lower than in AML patients undergoing HLA-matched sibling allogeneic HSCT because of a higher risk of treatment-related mortality with the procedure.

The decision to transplant a patient depends a great deal on which prognostic risk group the patient belongs. Among patients with favorable-risk AML, allogeneic HSCT does not result in better outcomes as compared to high-dose cytarabine-based therapy. All patients with high-risk AML, including those with an antecedent hematologic disorder, treatment-related MDS, or induction failure, should undergo evaluation for HSCT. Similarly, patients in CR1 with high-risk cytogenetics and patients in CR2 and beyond should undergo evaluation for allogeneic HSCT.[5,86,91]

Autologous Hematopoietic Stem Cell Transplantation

Compared to allogeneic HSCT, autologous HSCT has the advantage of a lower risk of posttransplant complications because of lack of immunosuppression and GVHD, and more broad applicability because of a lack of donor limitations and fewer age restrictions. Although the preparative regimen still provides antileukemic activity, autologous HSCT is associated with a higher risk of relapse because of a lack of a GVL effect and potential tumor contamination with autologous stem cells. EFS following autologous HSCT for adult AML in CR1 ranges from 40% to 60%, with treatment-related mortality of 5% to 15% and relapse rates of 30% to 50%.[96] Controversies in autologous HSCT include the optimal timing of therapy, the amount of consolidation therapy needed prior to HSCT, the dose of stem cells needed, and the impact of post-transplant therapy.[96]

Clinical Controversy…

Intensive postremission therapy may include an HSCT, but there are many questions concerning the use of HSCT in the treatment of AML. When should a patient receive an HSCT during their postremission therapy? Should a patient receive HSCT during CR1 or later after relapse has occurred? For eligible patients with a matched related (sibling) or unrelated donor, what type of HSCT (allogeneic vs autologous) is preferred?

Comparison of Postremission Therapy Options

Several randomized trials in AML patients in CR1 have compared outcomes following allogeneic HSCT, autologous HSCT, and/or intensive consolidation chemotherapy. In most trials, eligible patients based on age and donor availability received an allogeneic HSCT and the remaining patients were randomized between autologous HSCT and chemotherapy alone. The effect of stem cell source on EFS and OS is controversial. Several comparative trials of bone marrow versus peripheral blood have been completed in patients with hematologic malignancies, and a meta-analysis of nine randomized trials showed a lower relapse rate for those patients receiving peripheral blood stem cells.[97]

Most transplant centers base their decision to transplant on cytogenetic risk category.[3] Patients with

high-risk cytogenetics do poorly with conventional chemotherapy or autologous HSCT (EFS <15%), making allogeneic HSCT the treatment of choice in this population. Patients with favorable-risk cytogenetics should not proceed to transplant in CR1, as neither autologous nor allogeneic HSCT is superior to conventional chemotherapy. The optimal treatment of choice in patients with intermediate-risk cytogenetics is not clear and is based on availability of matched related donor and clinician preference. Many centers consider a relapse probability of 40% to 50% sufficiently high so as to justify the risk of transplant-related mortality. The decision to proceed with HSCT in this group may depend on the results of molecular testing. According to the NCCN guidelines, the decision to proceed to HSCT depends on prognostic risk features including cytogenetics.[91] If the patient has a favorable-risk cytogenetic profile and is younger than age 60 years, then high-dose cytarabine for four cycles or one cycle of high-dose cytarabine-based therapy followed by autologous HSCT is preferred over allogeneic HSCT. If the patient has an unfavorable-risk cytogenetic profile and is younger than 60 years of age, then allogeneic HSCT should be considered early after remission induction. Patients with intermediate-risk cytogenetics should be entered into a clinical trial, but if a clinical trial is not available, either a matched allogeneic HSCT or high-dose cytarabine should be considered. For patients 60 years and older, the NCCN guidelines do not favor a myeloablative HSCT, but NMT is being used more frequently.[5,95] For the AML patient who relapses early after induction therapy, if a sibling or matched unrelated donor is available, then allogeneic HSCT is the primary reinduction therapy because conventional chemotherapy offers little benefit. If the relapse occurs late, then HSCT may be used as postremission consolidation after reinduction therapy.[91]

Acute Myeloid Leukemia in Children

Overall survival rates for pediatric AML are about 60%, which is lower than that for pediatric ALL.[98] About 73% of children with AML are classified as low-risk, based on the presence of certain favorable risk factors, including t(8;21), MRD negativity at the end of induction, or inversion 16, and have an OS of 80%.[99] Children with disease or treatment factors associated with high-risk ALL, such as monosomy 7, 5q deletion, high FLT3-ITD to wild-type allelic ratio, or MRD at the end of induction, have an OS of 35%.[99] Therapy for AML in children includes one to two cycles of induction therapy followed by two to three cycles of consolidation therapy. The number of cycles varies by protocol.[84] Maintenance therapy has no role in pediatric AML (see Fig. 134-2).[4] Induction therapy with cytarabine and an anthracycline is standard. Etoposide is often included in induction but the contribution of this agent to efficacy has been debated.[84] Consolidation therapy relies on the use of high-dose cytarabine in conjunction with an anthracycline and etoposide.[4] The use of intrathecal chemotherapy for CNS prophylaxis is routinely accepted, but the optimal regimen is not known and varies by protocol.[84] Cranial radiation is only used for patients with refractory CNS disease.

Certain patients may be eligible to receive an HSCT as consolidation therapy, instead of continuing chemotherapy. The use of HSCT in CR1 rather than waiting until relapse/CR2 is controversial. Most trials recommend consolidation with chemotherapy for favorable risk patients; the role of HSCT in unfavorable AML may be considered on an individual basis carefully weighing the risks and benefits.

While children younger than 2 years of age at diagnosis are considered high risk, the therapy they

receive is not different than older pediatric AML patients. However, infants with AML generally receive therapy dosed on body weight (per kilogram) rather than body surface area. Children with Down syndrome and AML do not need the same intensive therapy that is given to AML patients without Down syndrome. Recent trials have provided dose reductions and shortened duration of overall therapy to AML patient with Down syndrome without any significant change in outcome.[100]

Relapsed or Refractory Acute Myeloid Leukemia

The most common cause of treatment failure in AML patients receiving chemotherapy alone or undergoing HSCT is relapse. In addition, many patients, particularly elderly patients, have refractory disease as defined by the inability to achieve a CR after two courses of induction therapy. In most cases, the preferred method of treatment for relapsed or refractory disease is HSCT if patients are able to tolerate it. Prolonged EFS is observed in 30% to 40% of patients receiving allogeneic or autologous HSCT in first relapse or CR2. Unfortunately, only a small percentage of relapsed or refractory adult patients will be eligible for HSCT, particularly allogeneic HSCT, because of age and donor restrictions. The role of NMT is also being evaluated in this setting.

The timing of HSCT to treat relapse is controversial. Some studies suggest that outcomes of HLA-matched, related allogeneic HSCT are similar regardless of whether the transplant is performed at the time of early first relapse or in CR2. The difficulty with this approach is identifying a patient in "early relapse," as often the patient will present in a florid relapse. While performing the allogeneic HSCT in first relapse eliminates the need for and toxicity of salvage chemotherapy, the feasibility of this approach is limited by the lead time required to activate a donor search. Patients who relapse following allogeneic HSCT have a poor outcome, with a median survival of about 3 to 4 months. In this setting, treatment options depend on performance status, clinical condition, and the time since allogeneic HSCT. Patients relapsing less than 100 days following allogeneic HSCT are unlikely to respond to current therapies, and salvage attempts are often associated with a high treatment-related mortality. For selected patients relapsing more than 1 year after allogeneic HSCT, a second allogeneic HSCT may be an alternative, but the likelihood of prolonged survival is generally less than 10% with a second transplant. Other strategies being investigated for the treatment of relapse after allogeneic HSCT include immune manipulation to stimulate a GVL effect through donor lymphocyte infusions, and premature discontinuation of calcineurin inhibitors and other immunosuppressants.

If patients with relapsed or refractory disease are not candidates for HSCT, the primary mode of treatment is salvage chemotherapy. The ability to achieve a CR2 with salvage chemotherapy is related to the duration of the first remission. About 50% to 60% of patients who relapse longer than 2 years after induction therapy will achieve a CR2, often with the same induction regimen.[3,86] If a patient relapses 1 to 2 years after induction therapy, the CR2 rate decreases to 40%, and only 10% to 20% of patients who relapse within 6 to 12 months following induction are able to achieve a CR2 with alternate salvage chemotherapy regimens. Long-term survival at 3 years ranges from zero in patients who relapse early to 20% to 25% in those who experience a prolonged duration of initial remission. Based on these data, a risk-adapted approach should be taken when considering treatment options.

Treatment strategies for patients who have relapsed are also categorized according to age and ability

to tolerate intensive therapy. Cytarabine has been administered alone or in combination with various agents, including etoposide, fludarabine, topotecan, clofarabine, and an anthracycline, as treatment of relapsed or refractory AML. Response rates to such salvage regimens range from 30% to 50%, but are often short-lived. Patients who received high-dose cytarabine during remission induction may be less likely to benefit from such a regimen for treatment of relapse, and thus require alternate salvage strategies. Regimens containing purine analogs such as fludarabine or clofarabine are another option.[91] Clofarabine may be given alone or in combination with agents such as cytarabine. While studies have shown CR rates of about 50%, median OS is less than 12 months.[101] Less intensive therapies for relapsed disease include use of low-dose cytarabine or one of the hypomethylating agents, azacitidine or decitabine.

Several classes of agents are being investigated as alternate treatment approaches for relapsed or refractory AML, including multiple targeted approaches for FLT3, NPM1, and C-KIT.[102] Additionally, histone deacetylase inhibitors (panobinostat and vorinostat), farnesyltransferase inhibitors (tipifarnib), monoclonal antibodies, and cell cycle inhibitors (volasertib and rigosertib) are several other classes actively being studied for this challenging indication.[103]

In children with AML, about 5% have refractory disease and 30% experience a relapse.[4] About one-half the children relapse within 1 year of initial diagnosis and have a poor prognosis.[4] Therapy for relapse should include an anthracycline and antimetabolite followed by allogeneic HSCT if a CR2 is achieved. Several new agents are being investigated for use in the relapsed refractory setting including clofarabine, bortezomib, sorafenib, and gemtuzumab ozogamicin.[4,104]

Late Effects of Therapy

Because of the intense therapy received by children with AML, they are at risk for a variety of long-term sequelae. A recent study reported that more than 50% of survivors have growth abnormalities.[105] Other findings include neurocognitive deficits, transfusion-associated hepatitis, endocrine disorders, cataracts, and cardiomyopathy (median cumulative anthracycline dose 335 mg/m^2). The 20-year cumulative risk for a second malignancy is estimated to be 1.8%.

TREATMENT

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia is a subclass of AML that accounts for about 10% of all cases. APL is the most curable of the AML subtypes, but its clinical presentation is associated with a high early death rate secondary to coagulopathy.[106] Most patients are diagnosed between the ages of 15 and 60 years, and the average age is 44 years.[91] Multiple large cooperative group trials have shown that induction regimens produce CR rates exceeding 90%.[107] Five-year EFS rates of 70% to 80% are reported with APL.[107] APL is clinically unique from the other subclasses because of the common occurrence of severe coagulopathy (characterized by disseminated intravascular coagulation) at diagnosis and during induction therapy, which frequently resulted in intracerebral hemorrhage. In APL, differentiation and maturation arrest are caused by alterations in the retinoic acid receptor (RAR)

because of the translocation of chromosomes 15 and 17. The discovery of t(15;17) provides a cytogenetic marker of the disease and is predictive of response to differentiation therapy with tretinoin (commonly referred to as all-*trans* retinoic acid or ATRA). This translocation leads to a fusion protein of the *PML* gene on chromosome 15 and the RARα on chromosome 17.

Prior to the availability of tretinoin in the late 1980s, treatment of APL consisted of the same combination chemotherapy regimens used in the treatment of other subclasses of AML. Such standard regimens produced CR rates of 50% to 60%, but were associated with a high treatment-related mortality rate caused by hemorrhagic complications. The introduction of molecularly targeted therapy with tretinoin allows for high CR rates with a significant reduction in life-threatening bleeding complications. Arsenic trioxide targets the PML moiety, resulting in apoptosis, and appears to be synergistic with tretinoin.

The WBC count at initial presentation is the most important prognostic factor in patients with APL. Risk stratification of patients at diagnosis based on WBC count has improved outcomes. Abnormal creatinine, increased peripheral blast count, and presence of coagulopathy are prognostic factors that predict for early death due to hemorrhage.[107]

Treatment Phases

Induction

Tretinoin, an oral vitamin A analog, is given orally in a dose of 45 mg/m^2 per day, as a single dose or divided into two doses, after a meal. Tretinoin-based regimens achieve CR rates as high as 95% in APL patients within 1 to 3 months. Because tretinoin does not cross the blood-brain barrier, leukemic meningitis should be treated with conventional intrathecal chemotherapy.

Although it is not myelosuppressive, tretinoin therapy is associated with headache, skin and mucous membrane reactions, bone pain, nausea, and the retinoic acid syndrome. When tretinoin is started, rapid onset of differentiation of promyelocytes occurs, which can lead to leukocytosis and retinoic acid syndrome. The retinoic acid syndrome (fever, respiratory distress, interstitial pulmonary infiltrates, pleural effusions, and weight gain) is now referred to as the APL differentiation syndrome or APL hyperleukocytosis syndrome, because it is associated with other treatment modalities in the management of APL. The syndrome is fatal in 5% to 29% of cases. A combination of chemotherapy with tretinoin induction decreases the risk of APL differentiation syndrome, and rapid initiation of dexamethasone 10 mg (0.2 mg/kg per dose in children) twice daily on development of symptoms decreases associated mortality.[108]

A number of clinical trials have evaluated treatment regimens for APL since the discovery of tretinoin.[91,107] These trials show that tretinoin induction therapy, followed by consolidation chemotherapy, produces similar CR rates but decreased relapse and increased EFS and OS as compared to chemotherapy alone for remission induction and consolidation. However, a significant proportion of patients receiving tretinoin in that study relapsed by 4 years, and 25% of patients experienced the APL differentiation syndrome. In an effort to extend the duration of remission and decrease tretinoin-associated toxicity, other trials have evaluated the sequential and concurrent

administration of tretinoin with chemotherapy during induction and consolidation therapy. Additionally, the stratification of therapies based on WBC at diagnosis has been used in trials. A combined analysis of the Programa para el Estudio de la Terapeutica en Hemopatıa Maligna (PETHEMA) 99 and the French APL 2000 trial showed that in patients with WBC less than 10,000/mm^3 (less than 10×10^9/L), the regimen containing tretinoin with idarubicin for induction and tretinoin in consolidation produced similar CR rates with decrease relapse rates, whereas for patients with WBC more than 10,000/mm^3 (more than 10×10^9/L), the induction regimen containing cytarabine resulted in higher CR rates and improved OS rates.[109]

9 Based on these data, the current NCCN guideline for induction therapy for newly diagnosed APL patients includes selection of a regimen based on the WBC count at presentation and ability to tolerate anthracyclines. All of these regimens include tretinoin 45 mg/m^2 per day until a CR is achieved, in combination with an anthracycline (either daunorubicin 50-60 mg/m^2 per dose for 3 or 4 days, or idarubicin 6-12 mg/m^2 per dose every other day for four doses) or tretinoin plus arsenic trioxide for patients unable to tolerate anthracycline therapy.[91] Several of the induction regimens also contain cytarabine 200 mg/m^2 per dose for 7 days; similar CR rates are observed with daunorubicin or idarubicin. APL cells appear to be more sensitive to anthracyclines, possibly because of decreased P-glycoprotein expression. The NCCN guidelines also emphasize the use of one published regimen consistently throughout induction, consolidation, and maintenance phases.[91] Children should also be treated with tretinoin, an anthracycline, and cytarabine with results similar to those achieved in adults.

Another difference in the treatment of APL is the timing of bone marrow biopsy. Assessment of response to treatment of APL is completed at the time of count recovery after induction therapy. A day 10 to 14 day bone marrow biopsy, which is completed for monitoring the effect of induction chemotherapy for other types of AML, is not a long enough time from initiation of therapy because leukemic promyelocytes need more time for differentiation. Assessment of molecular remission should be made after consolidation.

Arsenic trioxide is a compound with demonstrated efficacy in relapsed APL. It has been evaluated as part of remission induction therapy in several studies. The concept of a “chemotherapy-free” regimen in this disease is attractive especially for patients unable to tolerate anthracyclines. A combination of tretinoin with arsenic trioxide for induction therapy resulted in CR of 100% of low/intermediate risk patients.[91]

Consolidation Therapy

Consolidation chemotherapy should be administered to patients with APL because of the high relapse rate. Consolidation therapy usually consists of an idarubicin or daunorubicin-based regimen in combination with tretinoin. Arsenic trioxide has also been evaluated in consolidation therapy.

Postconsolidation Therapy

Unlike other subtypes of AML, maintenance therapy is an important but controversial component of

therapy for APL. Before the advent of tretinoin, nonrandomized trials suggested a benefit of continuous low-dose methotrexate and mercaptopurine in prevention of relapse of APL. Larger prospective randomized trials have demonstrated decreased relapse rates in patients who received maintenance therapy (either tretinoin or combination chemotherapy) and some trials have demonstrated increased EFS and OS.[107] However, other trials have shown little benefit. In a meta-analysis of nine randomized controlled trials of maintenance therapy versus observation in APL in CR1, no statistically significant improvement in OS with maintenance treatment was observed regardless of tretinoin inclusion or maintenance with other therapies. Disease-free survival was improved with maintenance compared to observation, although the difference was not statistically significant. Current recommendations for maintenance therapy in adult APL patients include tretinoin 45 mg/m^2 per day for 15 days every 3 months, in addition to mercaptopurine 100 mg/m^2 orally daily and methotrexate 10 mg/m^2 per week, for 2 years in patients at high risk. The benefit of maintenance therapy may depend on the induction and consolidation regimens given, and thus the NCCN guidelines recommends following the recommendations for maintenance therapy that are used in conjunction with the induction treatment regimen selected.[91]

Relapsed Acute Promyelocytic Leukemia

The incidence of relapsed APL is 10% to 15% overall with rates as high as 20% to 30% in high-risk disease. Most relapses occur in the first 3 years following induction therapy. Arsenic trioxide is the agent of choice for relapsed APL, and this agent serves as a backbone for treatment regimens. Multiple studies have shown CR rates of about 85%.[91,107]

Arsenic trioxide has induced clinical remissions in relapsed APL through its induction of apoptosis and differentiation.[107] The recommended dose is 0.15 mg/kg per day IV until bone marrow remission, not to exceed 60 doses, followed by consolidation beginning 3 to 6 weeks after completion of induction at the same dose for a total of 25 doses over a period up to 5 weeks. Arsenic trioxide therapy is associated with two specific toxicities. First, it can cause the APL differentiation syndrome, similar to that seen with tretinoin. Management is similar: corticosteroids at first signs of pulmonary distress or a rapidly rising WBC count. The second toxicity is a prolongation of the QT_C interval. Consequently, it is important to obtain a baseline 12-lead electrocardiogram prior to starting therapy with arsenic trioxide, and correct any electrolyte abnormalities, including potassium, calcium, and magnesium. Other medications known to prolong the QT_C interval should be avoided, if possible, during arsenic trioxide therapy. The QT_C interval should not exceed 500 milliseconds at baseline, and if it increases to more than 500 milliseconds during therapy, the patient should be reevaluated. Arsenic trioxide should not be restarted until the QT_C is less than 460 milliseconds. Following induction of a CR2 with arsenic trioxide in relapsed patients, postremission therapy with combination arsenic trioxide and chemotherapy can result in molecular remissions and improved EFS, as compared to chemotherapy or arsenic trioxide alone following remission.[107]

It is recommended for patients to proceed to autologous HSCT following hematologic and molecular remission after arsenic therapy. Outcomes with autologous HSCT depend on the disease status of the patient at the time of transplant. Autologous HSCT in CR2 (vs CR1) is associated with a lower OS,

leukemia-free survival, and increased treatment-related mortality. Autologous HSCT have shown increased disease-free survival and OS compared to allogenic HSCT.[91,110]

Patient Monitoring

In comparison to non-APL AML, molecular and cytogenetic testing at the end of remission induction therapy in APL has no prognostic value. Clinicians should not make decisions based on the presence or absence of any genetic abnormalities at this time. Because terminal differentiation of blasts in APL requires more than 40 days, results of a bone marrow biopsy obtained at the end of remission induction can be misleading because insufficient time has elapsed to determine response. Molecular and cytogenetic response assessment should occur after the completion of consolidation treatment.

Detection of residual PML/RARα transcripts in the bone marrow at the end of consolidation therapy is strongly associated with subsequent hematologic relapse. Achievement of PML/RARα-negative status is associated with a higher probability of cure. The use of this molecular technique allows the clinician to assess response to therapy and also detect relapse earlier, which might prevent the development of overt disease recurrence and is associated with improved outcome compared with delaying treatment until overt morphologic relapse.[107] Most experts recommend that APL patients should be routinely evaluated for continuous remission status. Suggested follow-up includes polymerase chain reaction for PML/RARα every 3 to 6 months for 2 years, and then every 6 months for 2 years.[91,107]

ROLE OF HEMATOPOIETIC GROWTH FACTORS IN ACUTE MYELOID LEUKEMIA

10 Hematopoietic growth factors have been evaluated in AML patients to enhance chemotherapy cytotoxicity, shorten the duration of neutropenia, and reduce the incidence and severity of infection following induction and consolidation chemotherapy. Most studies show limited benefit with the use of colony-stimulating factors as “priming” agents administered during remission induction therapy in an effort to recruit leukemia cells into the cycle to enhance susceptibility to cell-cycle–specific chemotherapy agents, leading to increased cell kill. Use of hematopoietic growth factors concurrently during chemotherapy administration is discouraged outside the setting of a clinical trial and is not recommended in the American Society of Clinical Oncology guidelines.[111]

Both filgrastim and sargramostim are FDA approved to prevent neutropenic complications in adult AML patients receiving intensive chemotherapy. Myeloid blast cells have receptors for granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, and there was initial concern that the use of these factors would stimulate regrowth of the myeloid leukemia. Although subsequent studies have addressed these concerns, many clinicians do not initiate filgrastim until an initial remission is achieved.

A number of randomized trials, primarily in elderly patients, consistently demonstrate that filgrastim or sargramostim reduces the duration of neutropenia following AML induction chemotherapy.[111]

While neutropenia can be reduced from 2 to 12 days depending on the trial, results vary in terms of improvements in infectious morbidity and mortality, resource use, and disease response rates. The American Society of Clinical Oncology Guidelines for the Use of White Blood Cell Growth Factors considers the use of hematopoietic growth factors after initial induction therapy reasonable, with the understanding that the effects on length of hospitalization and incidence of severe infection are modest.[111] Patients older than age 55 years appear to derive the greatest benefit, and use is appropriate in this population where more rapid marrow recovery might decrease the duration of hospitalization.[111] A recent review of 19 trials including a total of 5,256 patients showed no difference in the incidence of bacteremias or invasive fungal infections with the use of hematopoietic growth factors.[112] It also concluded that the use of hematopoietic growth factors after consolidation did not affect CR duration, relapse rates or OS. Further pharmacoeconomic data are required in this setting, but the body of evidence supports their use following consolidation therapy in adults. Other controversial issues surrounding hematopoietic growth factor use in AML include which growth factor to use, what dose, which day to start after chemotherapy, how long to continue, and should the marrow be examined for leukemia prior to starting a colony-stimulating factor. All hematopoietic growth factors have been evaluated in patients with AML, including sargramostim, filgrastim, and pegfilgrastim. Although pegfilgrastim is not FDA approved for this indication, research supports its use in this setting. The use of hematopoietic growth factors can also interfere with the interpretation of the day 14 bone marrow examination. Hematopoietic growth factors should be discontinued at least 7 days prior to a bone marrow aspirate and biopsy to avoid interfering with the interpretation of the results (ie, may see immature myeloid forms that would suggest residual disease).

SUPPORTIVE CARE

The most common and significant toxic effect of antileukemic agents is marrow suppression. With the exception of corticosteroids, tretinoin, asparaginase/pegaspargase, and vincristine, antineoplastic agents used to treat acute leukemia cause myelosuppression. During AML remission and postremission therapy, daily monitoring of the complete blood count and the absolute neutrophil count is necessary to determine when red cell and platelet transfusions are needed and when neutropenia is achieved. Less frequent monitoring may be sufficient during ALL induction. Marrow hypoplasia from the myelosuppressive regimens usually reaches its lowest point (nadir) after 1 to 2 weeks of therapy and lasts for another 1 to 2 weeks. During this period of hypoplasia, infectious and bleeding complications are major causes of death in leukemic patients.

As typical signs and symptoms of infection may be absent in the neutropenic host, frequent monitoring of vital signs (especially fever) and daily physical examination are important.[113] Infection control strategies often include routine hand washing; dietary restrictions; reverse isolation and laminar-air flow rooms; fungal, *Pneumocystis*, and bacterial prophylaxis; and the empiric use of broad-spectrum antibiotics when fever occurs (see Chapter 122).[113] *Pneumocystis jiroveci* prophylaxis, usually trimethoprim-sulfamethoxazole, is begun in all adults and children with ALL by the end of induction and continues until 6 months after therapy is discontinued. In contrast to the practice at many institutions, the NCCN guidelines do not recommend prophylactic antimicrobials or gut decontamination during induction or consolidation, and leave the choice to the discretion of the

treating facility based on local infection patterns and concerns.[114] Several groups have analyzed the evidence supporting the use of prophylactic antibacterials. In general, prophylactic antibacterials should be reserved for patients who are expected to have prolonged (more than 7 days) and profound (absolute neutrophil count less than 100 cells/mm^3 [less than 0.100 × 10^9/L]) neutropenia. Based on these criteria, prophylaxis following induction chemotherapy is warranted and postconsolidation therapy is warranted on a case-by-case basis.

In children, prophylactic antibiotics have not proven useful and have resulted in increased resistance. Pediatric ALL patients on standard induction regimens, which generally are minimally myelosuppressive, often have recovered blood counts earlier and do not require very aggressive measures. However, they do require close monitoring of vital signs and blood counts until their counts recover. Pediatric AML patients are usually admitted during periods of neutropenia for close observation and rapid initiation of broad spectrum antimicrobials, but the effectiveness of this non-pharmacologic approach to preventing infections is controversial. Infectious complications, especially fungal, are a major cause of morbidity and mortality, therefore antifungal prophylaxis is strongly recommended.[115] The incidence of viridans streptococci has increased with the intensity of therapy and is most associated with high-dose cytarabine. These infections can lead to meningitis or delayed acute respiratory distress syndrome.

Acute leukemia patients, particularly those patients with an initial elevated WBC count, are at risk for tumor lysis syndrome. Preventive measures include allopurinol or rasburicase, and adequate hydration prior to and during chemotherapy to prevent the development of urate nephropathy from rapid destruction of WBCs. Rasburicase, a recombinant urate-oxidase enzyme produced by genetic modification of *Saccharomyces cerevisiae*, catalyzes the enzymatic oxidation of uric acid into the inactive soluble metabolite, allantoin. In children, rasburicase more rapidly reduces uric acid levels in patients with aggressive malignancies compared to allopurinol, and reduces the need for dialysis.[116] Rasburicase has been evaluated in adults, and some studies in adults show that fixed dosing produces equivalent outcomes to a weight-based, mg/kg dosing strategy. Because of its cost, rasburicase is usually limited to patients with ALL who have a high WBC count or bulky extramedullary disease, aggressive lymphoma, or patients with AML with a high presenting WBC. Most institutions also include an elevated uric acid as part of the criteria for use. Rasburicase has a rapid onset of action and long duration of action; so many institutions also limit its use to a single dose and allow repeat doses as needed. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency. Tumor lysis syndrome may lead not only to hyperuricemia, but also to hyperkalemia, hyperphosphatemia, hypocalcemia and subsequent renal insufficiency.[116]

Hematologic support consists primarily of platelet and packed red blood cell transfusions. Platelet transfusions are often given for peripheral counts below 10,000 cells/mm^3 (10 × 10^9/L) or clinical signs of bleeding. Transfusions of packed red cells may also be indicated for a hemoglobin less than 8 g/dL (80 g/L; 4.96 mmol/L), profound fatigue, shortness of breath, tachycardia, or chest pain. APL can release procoagulants that can cause disseminated intravascular coagulation, necessitating close monitoring and replacement of coagulation factors with cryoprecipitate. Because of the gastrointestinal toxic effects of chemotherapy, parenteral nutrition may be required. Patients are frequently receiving infusions of antibiotics, fluids, hyperalimentation, opioids, and blood products

simultaneously. To provide the total support needed for these patients, a multiple-lumen central venous access device should be considered at the start of therapy.

PERSONALIZED PHARMACOTHERAPY

Treatment of acute leukemia is highly personalized. A risk-adapted approach is used in the treatment of ALL and AML. In ALL, patients are placed into risk categories based on age and disease characteristics. The initial risk category is sometimes changed based on the rapidity and completeness of response to remission induction therapy. The same risk-adapted approach is used in the treatment of AML, but age and cytogenetics are the most important factors in determining the risk category. Molecular mutations are becoming more important in both ALL and AML.

Genetic polymorphisms may affect drug metabolism, receptor expression, drug transportation, drug disposition, and pharmacologic response. These alterations may contribute to acute and chronic toxicity from ALL therapy and to treatment outcome.[6] The most studied polymorphism involves thiopurine metabolism. Cellular thiopurine *S*-methyltransferase (TPMT) inactivates thiopurines such as mercaptopurine and thioguanine. About 10% of the population has intermediate TPMT activity as a result of heterozygous polymorphisms in the gene encoding for TPMT, and 1 in 300 has extremely low activity as a result of homozygous presence of this TPMT polymorphism. Deficiency of TPMT activity can result in excessive myelosuppression from standard doses of thiopurines. Patients with low activity (homozygous mutant TPMT genotype) require 85% to 90% dose reductions.[117] About 50% of the heterozygous patients will require dose reductions. TPMT status can now be determined directly by DNA-based testing, which may become a standard of care in the near future.

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate development of a pharmaceutical care plan for the acute leukemia patient begins with establishing the diagnosis and prognosis for the patient. Long-term therapeutic goals for the patient may include long-term EFS, although palliative care is a possibility in some patients. The desired short-term outcome is the establishment of remission. The return of hematologic values to normal and a repeat bone marrow biopsy that demonstrates no evidence of disease serve as documentation that remission has been achieved. Monitoring guidelines for induction or consolidation are similar (**Table 134-5**). After the appropriate postremission therapy has been completed, the patient may return monthly for 1 year, and then every 3 months, to check hematologic values. If no evidence of disease exists after 5 years from the diagnosis and the patient has been in continuous CR, the patient is considered cured.

TABLE 134-5 Acute Myeloid Leukemia Assessment and Monitoring

Baseline Workup	Monitoring During Therapy	Postremission Monitoring
History and physical examination	Daily physical examination	Routine physical examination at clinic visit
CBC with differential,	CBC with differential, platelets	CBC with differential, platelets
	Serum chemistries (including uric acid,	

Baseline Workup	Monitoring During Therapy	Postremission Monitoring
platelets		
Serum chemistries (creatinine, bilirubin, AST, ALT to assess organ function)		
Coagulation (PT, PTT, D-dimers, fibrinogen)	K^+, Ca^{+2}, PO_4, SCr during tumor lysis syndrome risk period[a])	
Bone marrow biopsy and aspirate with cytogenetics	Coagulation (PT, PTT, D-dimers, fibrinogen [if APL])	
Immunophenotyping and cytochemistry	Bone marrow biopsy and aspirate 7-10 days after end of chemotherapy. Repeat bone marrow biopsy and aspirate upon hematologic recovery to document complete response (with cytogenetics if initially abnormal)	Bone marrow biopsy and aspirate at set intervals to evaluate ongoing remission and if peripheral blood counts are abnormal or if they fail to recover within 5 weeks of treatment
Human leukocyte antigen (HLA) typing		
Cardiac workup (MUGA or echocardiogram; ECG)		PML/RARα monitoring [if APL]
Intravascular access	Temperature curve (initiate antibiotics when febrile)	
Lumbar puncture (if symptomatic or monocytic disease)	Lumbar puncture (with intrathecal chemotherapy) if initial lumbar puncture was positive for leukemia	
Chest radiography		
Height and weight		
Molecular testing for genetic aberrations (FLT3, NPM1, CEBPA)		

ALT, alanine aminotransferase; APL, acute promyelocytic leukemia; AST, aspartate aminotransferase; CBC, complete blood cell count; ECG, electrocardiogram; FLT3, FMS-related tyrosine kinase 3; MUGA, multiple-gated acquisition (blood pool scan); NMP1, nucleophosmin; PML/RARα, promyelocytic-leukemia retinoic acid receptor-α; PT, prothrombin time; PTT, partial thromboplastin time; S_{cr}, serum creatinine.

[a]Risk for tumor lysis syndrome during induction therapy only.

Frequent monitoring of fevers, hematologic and chemistry laboratory values, microbiology reports, and the patient's physical condition are necessary to identify infection, risk of bleeding, and tumor

lysis syndrome early. A coagulation screening panel will identify patients with ongoing disseminated intravascular coagulation, a particular risk with APL.

During therapy, the pharmacist and other healthcare professionals are important providers of patient and caregiver education. Patients should receive information regarding acute and chronic toxicities of the chemotherapy being administered, as well as possible treatments for those toxicities. Healthcare professionals should follow patients throughout therapy for dosing adjustments and toxicities due to antineoplastic therapy. For example, the healthcare team should make sure the patient is receiving corticosteroid and saline eye drops four times daily while the patient is receiving high-dose cytarabine to prevent the ocular toxicity of cytarabine. The pharmacist is an important resource for information regarding antibiotics, antiemetics, nutritional support, hematopoietic growth factors, and other supportive care issues.

Pharmacists should be involved in assessing drug doses and any dose modifications for organ dysfunction or prior toxicity. Pharmacists are often in the best position to recognize the potential risk for medication errors and drug interactions and to help avoid them. Similarly, pharmacists are often able to assess adherence and identify the possibility that patient problems are secondary to drug treatments.

Numerous late sequelae from leukemia therapy have been recognized and should be included in the monitoring plan after therapy is completed. Chapter 140 discusses the long-term consequences of HSCT. Additionally, the Children's Oncology Group Long-Term Follow-Up guidelines provide an additional resource for assessment and monitoring.[82]

Chapter 135: Chronic Leukemias

Patrick J. Kiel; Christopher A. Fausel

INTRODUCTION

KEY CONCEPTS

- 1 Chronic myelogenous leukemia (CML) is defined by the presence of the Philadelphia chromosome (Ph), a translocation between chromosomes 9 and 22. The resulting abnormal fusion protein, p210 *BCR-ABL*, phosphorylates tyrosine kinase residues and is constitutively active, resulting in uncontrolled hematopoietic cell proliferation.
- 2 Without treatment, the disease course of CML is characterized by a progressive increase in white blood cells over a period of years that ultimately transforms to an acute leukemia.
- 3 The commercially available tyrosine kinase inhibitors, imatinib, dasatinib, nilotinib, bosutinib, and ponatinib have demonstrated efficacy in treatment of newly diagnosed CML patients and in patients with either accelerated phase or blast crisis.
- 4 CML monitoring requires assessment of milestones throughout the therapy such as hematologic, cytogenetic, and molecular responses, the ideal of which is a molecular response.
- 5 Allogeneic hematopoietic stem cell transplant (HSCT) is the only known curative treatment option for CML and is reserved for patients with a suitable donor and progression after treatment with tyrosine kinase-based therapy.
- 6 The management of chronic lymphocytic leukemia (CLL) is highly individualized and includes observation in patients with early-stage disease and treatment with targeted therapy, chemotherapy, biologic therapy, or both in patients with more advanced disease.
- 7 Alemtuzumab, ofatumumab, obinutuzumab, and rituximab are monoclonal antibodies that are indicated for the treatment of CLL.
- 8 Regimens such as fludarabine, cyclophosphamide, and rituximab are considered as first-line therapy for patients with CLL who are younger or have more aggressive disease.

- 9 Novel agents such as ibrutinib and idelalisib provide an oral option for the treatment of CLL. Ibrutinib is approved for treatment of patients with 17p-deletion and for patients with relapsed disease who have received at least one prior therapy. Idelalisib may be used in combination with rituximab as first line therapy when concomitant medical conditions preclude the use of systemic chemotherapy.

The chronic leukemias include chronic myeloid leukemia (CML), chronic lymphocytic leukemia (CLL), hairy cell leukemia, and prolymphocytic leukemia. The typical clinical presentation of the chronic leukemias is an indolent course in contrast to patients with acute leukemia who will die of their disease within weeks to months if not treated. This chapter focuses on the two most common types of chronic leukemia, CML, and CLL.

CHRONIC MYELOGENOUS LEUKEMIA

Chronic myelogenous leukemia is a myeloproliferative disease that results from malignant transformation of a subpopulation of pluripotent hematopoietic stem cells. Bone marrow hyperplasia and accumulation of differentiated myeloid cells in the peripheral blood are the initial presenting features of the disease. The terminal stage of CML is characterized by rapid accumulation of blast cells in the bone marrow and suppression of normal hematopoiesis that ultimately leads to death. CML was the first malignant disease identified with a consistent cytogenetic abnormality, namely the Ph that contains the BCR-ABL oncogene. This dominant cytogenetic abnormality has allowed CML to become the template for development of molecular targeted drug therapies.

Epidemiology and Etiology

It is estimated that 8,220 new cases of CML will be diagnosed in the United States in 2016.[1] The median age of diagnosis is 64. The development of CML is not associated with hereditary, familial, geographic, ethnic, or economic status. An increased risk of CML has been noted with ionizing radiation exposure and in atomic bomb survivors from Hiroshima and Nagasaki.[2,3]

Pathophysiology

Chronic myelogenous leukemia was first described in 1845, but extensive research into the genetic and molecular characteristics of the disease began with the discovery of the Ph in 1960 by Nowell and Hungerford.[4] Research in the 1980s identified the molecular changes that occur as a result of the Ph when an oncogenic protein was identified and implicated in the pathophysiology of CML.[4,5]

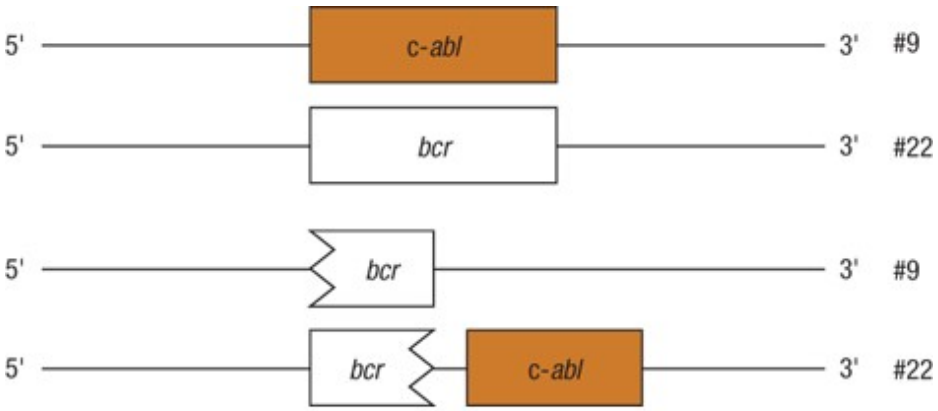
Ph is the first karyotypic abnormality specifically implicated in the pathogenesis of cancer, and its discovery has resulted in extensive research into the molecular biology of CML.[6] This chromosomal abnormality is characteristic of CML and is present in about 95% of patients with the disease.[4,5,6]

1 Ph, identified as a shortened long arm of chromosome 22, is found in granulocyte and erythrocyte progenitors, macrophages, megakaryocytes, and lymphocytes. The Ph is the consequence

of breaks in chromosomes 9 and 22 resulting in a transposition that relocates the 3′ end of *ABL* (Abelson proto-oncogene) from its normal site on chromosome 9 at band 34 to the 5′ end of *BCR* (breakpoint cluster region) on chromosome 22 at band 11 (symbolized as *t*[9;22][q34;q11]).[6,7] This results in the formation of the hybrid *BCR-ABL* fusion gene (**Fig. 135-1**). Through this chromosomal translocation, the *ABL* protooncogene is able to escape the normal genetic controls on its senescence and is activated into a functional oncogene, directing the transcription of an 8.5-kilobase messenger ribonucleic acid (mRNA) molecule. The mRNA is translated into a 210-kDa protein—p210 *BCR-ABL*—that is constitutively (ie, constantly) activated compared to the 145-kDa protein translated by the normal *ABL* gene.[5,6,7] Although p210 *BCR-ABL* is the most common tyrosine kinase found in CML, variations in the breakpoints in the *ABL* gene encode different size proteins. For example, a smaller protein, p190 *BCR-ABL*, is involved in two-thirds of adults with Ph-positive acute lymphoblastic leukemia (ALL), but is rarely found in patients with CML.[6]

FIGURE 135-1

Diagram of the chromosomal translocation that results in the Philadelphia chromosome. *(Reprinted with permission from Fishleder AJ. Oncogenes and cancer: Clinical applications. Cleve Clin J Med 1990;57:721-726. Copyright © 1990 Cleveland Clinic. All rights reserved.)*



Because CML begins with the malignant transformation of a single cell, it is considered a clonal disease. The progeny from this transformed primitive hematopoietic stem cell results in a proliferative advantage over normal hematopoietic cells that displaces normal hematopoiesis. The Ph is found in both myeloid and lymphoid cells, which suggests that the transformed cell of CML is a pluripotent stem cell.[7] This alteration gives the transformed progenitor cell an inheritable growth advantage, leading to the proliferation of a neoplastic, monoclonal population of cells.[8] Disrupted maturation leads to additional divisions by CML progenitor cells before reaching a nonproliferative stage; the resulting number of circulating granulocytes may be many times higher than normal. In the advanced stages of CML, cytopenias may occur in association with fibrotic changes in the bone marrow.

The *BCR-ABL* fusion gene encodes for a constitutively active tyrosine kinase that is involved in both the increased proliferation of the CML clone and the reduction in Fas-mediated apoptosis.

Characterization of the adenosine triphosphate binding site on the *BCR-ABL* tyrosine kinase has provided a target for inhibition of tyrosine kinase activity. The first FDA-approved tyrosine kinase inhibitor (TKI), imatinib mesylate (Gleevec®), was indicated for patients in chronic phase who had failed interferon alfa (IFN-α) or for those with advanced disease. Imatinib received additional FDA approval in 2002 for first-line treatment in newly diagnosed CML. Second-generation TKIs with a higher binding affinity and selectivity for *ABL* kinase are approved as both frontline agents and salvage for patients with resistance or intolerance to imatinib.

Clinical Presentation

The three clinical phases of CML are: chronic phase (CP), accelerated phase (AP), and blast crisis (BC) (**Table 135-1**). Nearly 90% of patients present with CP at the time of diagnosis. Often the diagnosis of CML is found incidentally during routine examination or if a complete blood count is obtained for unrelated reasons because patients are often asymptomatic upon presentation. Signs and symptoms include fatigue, sweating, bone pain, weight loss, abdominal discomfort, and early satiety secondary to splenomegaly. Leukocytosis is the hallmark of CP and the white blood cell count can be as high as 1,000,000 cells/mm^3 (1,000 × 10^9/L), placing patients at risk for complications of leukostasis. Symptoms secondary to leukostasis include acute abdominal pain resulting from splenic infarctions, priapism, retinal hemorrhage, cerebrovascular accidents, confusion, hyperuricemia, and gouty arthritis.[6] Patients can survive several years in CP without treatment.

TABLE 135-1 Criteria for Different Phases of Chronic Myelogenous Leukemia

Chronic Phase	Accelerated Phase	Blast Crisis
• <10% blasts in peripheral blood or bone marrow	• 10%-19% blasts in peripheral blood or bone marrow • Platelets <100,000 cells/mm^3 (<100 × 10^9/L) or >1,000,000 cells/mm^3 (>1,000 × 10^9/L) Additional findings • Cytogenetic evolution • Progressive splenomegaly	• >20% blasts in peripheral blood or bone marrow • Large clusters of blasts on bone marrow biopsy • Presence of extramedullary infiltrates Additional findings • Fever • Malaise • Splenomegaly

Chronic Phase	Accelerated Phase	Blast Crisis

Data from Cortes JE, Talpaz M, O'Brien S, et al. Staging of chronic myeloid leukemia in the imatinib era. Cancer 2006;106:1306-1315.

CLINICAL PRESENTATION Chronic Myelogenous Leukemia[1,6] General

- 90% of patients are diagnosed in CP
- 50% are asymptomatic in CP and often diagnosed following abnormal complete blood count

Signs and Symptoms

- Fatigue
- Left upper quadrant pain
- Abdominal pain or distension
- Weight loss
- Night sweats

Physical Examination

- Splenomegaly
- Hepatomegaly

Laboratory Tests

- Peripheral blood
    - Leukocytosis
    - Thrombocytosis
    - Basophilia
    - Low or undetectable leukocyte alkaline phosphatase
    - Elevated uric acid and lactate dehydrogenase
- Molecular testing
    - Presence of *BCR-ABL* by reverse-transcription polymerase chain reaction (RT-PCR)
- Bone marrow

- Hypercellular
- Fully mature myeloid cells
- Increased megakaryocytes
- <10% blasts in CP

- Cytogenetics
  - Presence of Ph
  - Additional abnormalities

Initial laboratory workup includes complete blood count with differential, complete metabolic panel, and serum uric acid. A bone marrow aspiration and biopsy is required to confirm the diagnosis of CML. The differential diagnosis of CML includes infection, myeloproliferative disorders (ie, polycythemia vera, essential thrombocythemia, myelofibrosis), and chronic myelomonocytic leukemia. Bone marrow is markedly hypercellular (75%-90%) with increased granulocyte/erythroid ratio increased (10-30:1), erythropoiesis increased megakaryocytes normal. Karyotyping (cytogenetic analysis) is required for a diagnosis. The bone marrow aspiration is analyzed with fluorescence in situ hybridization (FISH) to determine the presence of the Ph chromosome. Quantitative RT-PCR is also performed to assess the baseline *BCR-ABL* transcript levels.

AP is characterized by progressive myeloid maturation arrest and loss of efficacy of drug therapy directed to attenuate the increase in white blood cells. Clinical findings of AP include anemia, increasing peripheral blood and bone marrow blasts and basophils, clonal cytogenetic evolution, extramedullary disease sites (bone, breast, CNS, mucosal tissue, lymph nodes, and skin), exacerbation of splenomegaly, and either thrombocytosis or thrombocytopenia. Nonspecific findings such as bone pain, fever, night sweats, and weight loss may occur. The most commonly observed cytogenetic changes with disease progression are an additional Ph chromosome, trisomy 8, and isochromosome 17q. Survival typically will not exceed several months. The World Health Organization (WHO) classification[6] defines AP CML as one or more of the following changes: 10% to 19% of blasts in the peripheral blood or bone marrow, persistent thrombocytopenia less than 100,000 cells/mm^3 (100×10^9/L) (not related to drug therapy), thrombocytosis greater than 1,000,000 cells/mm^3 ($1,000 \times 10^9$/L) despite drug therapy, peripheral basophilia >20%, increasing spleen size and white blood cell count despite drug therapy, bone marrow evidence of progression of the leukemic clone or new cytogenetic abnormalities.

Blast crisis is the terminal stage of disease and clinically resembles acute leukemia where the leukemic clone overwhelmingly dominates the bone marrow at the expense of normal hematopoiesis. The WHO classification defines BC CML as the presence of one or more of the following: greater than 20% blasts in the peripheral blood or bone marrow, extramedullary disease, or large clusters of blasts in the bone marrow.[6] Patients can present occasionally with BC without an apparent AP. One-third of patients present with BC of lymphoid lineage, while two-thirds present with BC of myeloid lineage or undifferentiated like phenotype. The increased proliferative rate in BC

CML is the consequence of a number of factors in addition to *BCR-ABL*, such as the activation of the oncogene signaling pathways and loss of tumor suppressors such as p53. Duration of BC is typically days to weeks before death.

Prognosis

Several models have been proposed for estimating prognosis in patients with CML, but the one proposed by Sokal et al. has become the most widely used.[8] The Sokal algorithm uses spleen size, percentage of circulating blasts, platelet count, and age as prognostic factors for patients in CP. However, this scoring system was developed prior to the advent of TKI therapy and may have limited predictive value in the era of imatinib. The median overall survival for patients diagnosed with CP, AP, and BC CML was reported to be 47 months, 12 to 24 months, and 3 to 6 months, respectively, in the era prior to the introduction of TKIs.[9,10]

TREATMENT

Chronic Myelogenous Leukemia

Desired Outcomes

Without effective treatment, CML disease progression leads inexorably to a fatal outcome within 5 years. The overriding treatment goals for CML include the eradication of the leukemic clone from the bone marrow and maintenance of CP with minimal toxicity from treatment. The only proven therapy to eradicate the malignant clone from the bone marrow is allogeneic hematopoietic stem cell transplantation (HSCT). Both immunotherapy with IFN-α and TKI-based therapies have demonstrated the ability to extend CP beyond the expected period of several years. The introduction of TKI therapy has dramatically changed the clinical course of CML where patients can now expect to maintain disease control for many years.[10] The current standard of practice is to initiate TKI therapy for newly diagnosed CML patients. Long-term follow-up from phase III trials have documented a response in excess of 85% of patients that receive imatinib as primary treatment.[11,12,13] **Table 135-2** shows the effect of various treatment modalities on survival in CP CML.

TABLE 135-2 Effect of Therapy on Survival in Patients with Chronic-Phase Chronic Myelogenous Leukemia

Therapy	5-Year Survival (%)	Median Survival (Months)
Busulfan	30-40	40-50
Hydroxyurea	40-50	50-60
IFN-α	50-70	60-80
IFN-α + ara-C	60-80	NR
Allogeneic transplantation		
Matched sibling	60-80	NR
Matched unrelated	40-70	NR
Imatinib	89	NR

Therapy	5-Year Survival (%)	Median Survival (Months)
Dasatinib	85	NR
Nilotinib	NR	NR
Bosutinib	NR	NR
Omacetaxine	NR	NR
Ponatinib	NR	NR

IFN, interferon; NR, not yet reached.

Clinical response in CML is measured by hematologic, cytogenetic, and molecular indices, all of which have standardized criteria.[6,13] *Hematologic response* is defined as the normalization of peripheral blood counts and is the earliest type of response observed in CML patients. *Cytogenetic responses* are based on the percentage of cells positive for Ph in a bone marrow biopsy. *Complete cytogenetic response* is defined as the elimination of Ph from all cells in the marrow sample whereas *major cytogenetic response* is defined as fewer than 35% Ph-positive cells. Patients who have a major or complete cytogenetic response have an improved survival compared to those who fail to achieve a cytogenetic response.[13]

Because most patients on imatinib achieve a complete cytogenetic response, more sensitive tests to monitor disease status are now used. *Molecular responses* are determined by RT-PCR, which are several logs more sensitive than methods used to measure cytogenetic responses. A *complete molecular response* is the absence of *BCR-ABL* transcripts by RT-PCR. RT-PCR assays should be interpreted carefully because they have varying sensitivities and may show a complete molecular remission even when low levels of *BCR-ABL* transcripts are present.[17] A major molecular response is a greater than 3-log reduction in *BCR-ABL* transcripts by RT-PCR assay. Quantitative RT-PCR should be performed on every patient prior to initiating therapy and throughout therapy to monitor residual disease. Because bone marrow and peripheral blood *BCR-ABL* mRNA levels are correlated, peripheral blood can often be used for this analysis.[12,13]

Conventional Chemotherapy

Conventional cytotoxic chemotherapy is used in CP CML to reduce and temporarily control high peripheral white blood cell (WBC) counts. Historically, the two agents used for leukoreduction are busulfan (Myleran) and hydroxyurea (Hydrea). Busulfan is no longer used because randomized trials have shown that hydroxyurea treatment provides a modest survival advantage, and busulfan has a risk of potentially life-threatening pulmonary fibrosis.[14]

Hydroxyurea rapidly lowers high circulating WBCs in CP CML by inhibiting ribonucleotide reductase, which inhibits DNA synthesis, eliminating cells in the S phase of the cell cycle, and synchronizing cells in the G_1 or pre-DNA synthesis phase. Hydroxyurea is initiated at 40 to 50 mg/kg/day in divided doses until the WBC count falls to about 10,000 cells/mm^3 (10×10^9/L). Hydroxyurea may be discontinued once adequate control of the WBC count is achieved and a TKI has been initiated. Hydroxyurea is not specifically active against Ph and will not change the natural progression of the

disease to BC.

Interferon α

The interferons are a family of glycoproteins involved in many of the functional aspects of the hematopoietic system. Prior to the introduction of imatinib, IFN-*α* was the preferred agent in the treatment of CML. The role of IFN-*α* has since been relegated to patients who fail TKIs and are not candidates for allogeneic HSCT.

3 Use of IFN-*α* in the treatment of CP CML was based on reports that 20% to 50% of patients achieve a major cytogenetic response, which led to prolonged survival.[5,9] In the 10% to 15% of patients achieving a complete cytogenetic response, the median survival was more than 10 years. Patients enrolled on the IFN-*α* arm in the International Randomized Interferon vs STI571 (IRIS) trial had a complete cytogenetic response of 14%, as compared with 76% of patients treated with imatinib.[11] The 2016 National Comprehensive Cancer Network (NCCN) guidelines recommend IFN-*α* only for posttransplant relapse.[12]

IFN-*α* use is also limited by its toxicity profile because it is associated with both short-term constitutional toxicities and potentially dose-limiting long-term toxicities. In the IRIS trial, 26% of patients discontinued IFN-*α* as a result of intolerable side effects.[15] The most predictable early toxicity is a flu-like syndrome characterized by fever, chills, myalgia, headache, and anorexia. These dose-dependent effects may be a result of IFN-*α*–induced leukocytosis and release of inflammatory cytokines. Cardiovascular toxicities (tachycardia, hypotension) are seen in about 15% of patients in the first few weeks. Long-term adverse effects include weight loss, alopecia, neurologic effects (paresthesia, cognitive impairment, and depression), and immune-mediated complications (hemolysis, thrombocytopenia, nephrotic syndrome, systemic lupus erythematosus, and hypothyroidism), which occur in about 5% to 20% of patients.

Despite falling out of clinical favor, IFN-*α* still remains a disease-modifying agent and ongoing clinical trials are investigating the use of imatinib and IFN-*α* in combination for the treatment of CML. Imatinib has been combined with pegylated IFN-α_{2A} in newly diagnosed CP CML yielding improved major molecular response rate at 12 months compared with imatinib 400 mg daily alone (57% vs 38%), but the 12-month complete cytogenetic response rate was similar (66% vs 58%).[15]

Imatinib Mesylate (Gleevec®)

A transformative discovery in cancer therapeutics was the characterization of the adenosine triphosphate binding site on the *BCR-ABL* tyrosine kinase. This specific receptor established a novel drug discovery platform for molecular targeted therapy in CML. Numerous TKIs were in development in the 1990s and STI571 (STI stands for *signal transduction inhibitor*), subsequently named imatinib (Gleevec®), emerged as the drug with the best oral bioavailability and high binding affinity for the *BCR-ABL* tyrosine kinase.[16,17] In 2001, imatinib mesylate received FDA approval for patients in CP CML who had failed IFN-*α* treatment and in patients with AP or BC CML based on phase II studies. In

2002, it received FDA approval for first-line treatment in newly diagnosed CML on the basis of the 2-year follow-up in the IRIS phase III trial.[18]

Imatinib inhibits several other tyrosine kinases including *BCR-ABL*, C-Kit, and platelet-derived growth factor receptor (PDGFR). Imatinib competitively binds to the adenosine triphosphate (ATP)-binding site on *BCR-ABL*, which inhibits the phosphorylation of proteins involved with CML clone proliferation.[16,17,18] **Table 135-3** summarizes the clinical results of imatinib in CML patients in CP, AP, and BC CML. **Table 135-4** summarizes the dosing, food–drug interactions, and drug–drug interactions of TKIs. Early phase I and phase II studies of imatinib, designed to determine maximum tolerated dose and safety, showed higher than expected response rates in all stages of CML.[19]

TABLE 135-3 Cytogenetic and Molecular Response Associated with Tyrosine Kinase Inhibitor Therapy in Chronic Myelogenous Leukemia

Drug (Disease Status)	Daily Dose (mg)	CCyR (%)	MMR	Median Follow-up
Imatinib (CP)	400	82	57%	70 months
	800	90	NR	30 months
Imatinib (AP)	600	43	NR	12 months
	400	11	NR	
Imatinib (BC)	400-800	7.40	NR	—
Dasatinib (CP)	100	83	76%	60 months
Dasatinib (AP)	140	32	NR	15 months
Nilotinib (CP)	600	87	77%	36 months
Nilotinib (AP)	800	16	NR	24 months
Bosutinib (CP–3rd line)	500	24	15%	28.5 months
Bosutinib (CP–1st line)	500	79	59%	12 months
Omacetaxine (CP–2nd line, T315I mutation)	2.5	16	NR	19.1 months
Ponatinib (CP-resistant/intolerant disease)	45	37	NR	10 months
Ponatinib (CP-T315I mutation)	45	66	NR	10 months

AP, accelerated phase; BC, blast crisis; CCyR, complete cytogenetic response; CP, chronic phase; MCyR, major cytogenetic response; MMR, major molecular response; NR, no response.

TABLE 135-4 Dosing of Tyrosine Kinase Inhibitors in Chronic Myelogenous Leukemia

Drug	Brand Name	Dose Range	Food–Drug Interactions	Drug–Drug Interactions
Imatinib	Gleevec	400 mg/day (CP) 600 mg/day (AP/BC) 400 mg/day (moderate hepatic impairment)	Take with food and a large glass of water	CYP3A4 inducers may decrease C_{max} and AUC. CYP3A4 inhibitors may increase C_{max} and AUC. Imatinib inhibits CYP3A4 and

Drug	Brand Name	Dose Range	Food–Drug Interactions	Drug–Drug Interactions
				2D6.
		300 mg/day (severe hepatic impairment)		Package labeling recommendations against using warfarin concurrently.
				CYP3A4 inhibitors may increase dasatinib drug levels.
Dasatinib	Sprycel	100 mg/day (CP) 140 mg/day (AP/BC)	With or without meals; do not crush tablets	CYP3A4 inducers may decrease dasatinib drug levels.
				H_2 antagonists/PPIs decrease dasatinib drug levels.
				Avoid drugs concurrently known to prolong QT interval.
				CYP inducers may decrease nilotinib serum concentrations.
Nilotinib	Tasigna	300 mg BID (CP) 400 mg BID (AP/BC)	Take with water; avoid food 2 hours prior to a dose or 1 hour after	CYP inhibitors may increase nilotinib serum concentrations.
				Nilotinib is an inhibitor of CYP3A4, CYP2C8, CYP2C9, and CYP2D6.
				Nilotinib is an inducer of CYP2B6, CYP2C8, and CYP2C9.
Bosutinib	Bosulif	500 mg/day; may increase to 600 mg/day in patients who do not clinically respond by weeks 8-12	Take with food; PPIs may decrease absorption	Concurrent use with CYP3A or Pgp inhibitors increase bosutinib plasma concentrations.
				Concurrent use with CYP3A inducers reduces bosutinib plasma concentrations.
Ponatinib	Iclusig	45 mg/day (lower dosing may be required as optimal dose is not defined)	With or without food	Concurrent use with CYP3A or Pgp inhibitors increase ponatinib plasma concentrations.

Drug	Brand Name	Dose Range	Food–Drug Interactions	Drug–Drug Interactions
				Concurrent use with CYP3A inducers reduces ponatinib plasma concentrations.

AP, accelerated phase; AUC, area under the curve; BC, blast crisis; BID, twice daily; C_{max}, maximum concentration; CP, chronic phase; CYP, cytochrome P450; Pgp, P-glycoprotein; PPI, proton pump inhibitor.

Chronic Phase

The IRIS study compared imatinib 400 mg orally daily to IFN-α plus low-dose subcutaneous cytarabine in 1,106 patients with newly diagnosed CP CML.[18] After a median follow-up of 19 months, patients who received imatinib achieved a complete hematologic response of 96%, major cytogenetic response of 85%, and complete cytogenetic response of 69%. Six percent of patients had progressed to AP or BC and only 4% discontinued imatinib because of an adverse event. The study was designed to allow crossover to the opposite treatment arm for lack of response or intolerance. After 5 years of follow-up, only 3% of patients randomized initially to receive IFN-α remained on their initial regimen compared with 69% of patients in the imatinib arm. The 5-year follow-up data from the IRIS trial was published in December 2006 and 8-year follow-up data was presented in December 2009.[11,20] Estimated 5-year and 8-year overall survival of the 553 patients who were originally randomized to receive imatinib is 89% and 85%, respectively. At 8 years, estimated event-free survival (EFS) was 81% and freedom-from-progression to AP or BC was 92% and annual rates of progression to AP or BC in years 4 through 8 were 0.9%, 0.5%, 0%, 0%, and 0.4%. Only 55% of patients remained on imatinib therapy at the 8-year time point.[20]

Cytogenetic and molecular responses secondary to imatinib are associated with EFS and risk of progression to AP or BC. Patients who do not achieve a hematologic response by 3 months, cytogenetic response by 6 months, or a major cytogenetic response by 12 months fare significantly worse compared to responders. In addition, patients with a complete cytogenetic response and at least a 3-log reduction in *BCR-ABL* levels via RT-PCR correlated with a 100% survival without disease progression at 18 months. The risk of disease progression according to the Sokal scoring system predicted the rates of disease progression to be 3%, 8%, and 17% in low-risk, intermediate-risk, and high-risk patients, respectively. However, the Sokal score was not associated with disease progression in patients who achieved a complete cytogenetic response.[11]

4 Although most patients attain a complete cytogenetic response on imatinib, very few patients achieve a complete molecular response. In a study of patients enrolled in the IRIS study, Hughes et al. reported that less than 5% of patients on imatinib have undetectable levels of *BCR-ABL* when analyzed by RT-PCR.[21] Recent data suggest that the level of residual disease is predictive of progression-free survival. A 3-log decline in *BCR-ABL* mRNA within 3 months after achieving a complete cytogenetic response is reported to be a predictor of longer progression-free survival.[22]

Careful monitoring of *BCR-ABL* levels by RT-PCR is necessary to guide clinician decision making for therapy modification. The 2016 NCCN guidelines recommend imatinib 400 mg orally daily as one of several options for patients in CP CML (see Table 135-3).[12]

Higher imatinib doses have been evaluated in clinical trials. The European Leukemia Net conducted a randomized phase II trial in high-risk patients defined by the Sokal scoring system to imatinib 400 mg versus 800 mg daily and evaluated the proportion of patients achieving a complete cytogenetic response at 12 months.[23] Patients receiving the higher dose of imatinib achieved a 64% complete cytogenetic response compared to 58% of patients receiving standard dose with a median follow-up period of 12 months (p=0.435). These study results do not justify the routine use of imatinib 800 mg daily as frontline therapy in high-risk patients with CP CML. A phase II trial evaluated imatinib 400 mg daily for 2 weeks, then titrated to 400 mg twice daily in patients with an intermediate-risk Sokal score appeared to have benefit with 88% and 91% of patients achieving a complete cytogenetic response at 12 and 24 months.[24] These data require validation with a phase III clinical trial before a widespread use of a higher dose can become standard of care in CP CML.

Accelerated Phase/Blast Crisis

Response rates for patients with AP or BC CML are lower compared with those in CP CML. A phase II study evaluating imatinib 600 mg daily in patients with AP CML reported complete hematologic and complete cytogenetic response rates of 71% and 19%, respectively.[25] Prior to protocol amendments, patients were able to receive imatinib 400 mg daily, but the rates of hematologic response, cytogenetic response, disease progression, and overall survival were inferior to imatinib 600 mg. The toxicity profile between imatinib 400 mg and 600 mg daily was similar.

Traditional therapy for BC CML has focused on administering cytotoxic chemotherapy in treatment programs similar to acute leukemia induction. Etoposide (VP-16), cytarabine (Ara-C), and carboplatin (VAC-regimen) has demonstrated efficacy in patients with BC CML with a median overall survival of 7 months.[26] Imatinib has demonstrated modest benefit in BC CML. An open-label, nonrandomized trial evaluated imatinib 400 mg daily with dose escalation to 600 mg daily and 400 mg twice daily (for patients not achieving a hematologic response after one month).[27] The primary objectives were to assess hematologic response, complete cytogenetic response, and the return to CP CML. Fifteen percent developed a complete hematologic response, 7.4% achieved a complete cytogenetic response, and 18% achieved a second CP. Imatinib 600 mg was associated with sustained hematologic response. The median overall survival was 6.9 months.

Imatinib Resistance

Despite having high cytogenetic response rates, some patients treated with imatinib will not respond to therapy or will relapse after an initial response.[28] The most prominent mechanism of imatinib resistance is the presence of point mutations in one or more areas on the ABL kinase. More than 100 different mutations have been discovered thus far. Many of these mutations can cause a conformational change in the ATP binding site, which greatly decreases the ability of imatinib to bind and inhibit kinase activity.[13,28] Imatinib binds to *BCR-ABL* by establishing a series of hydrogen bonds

with side chains of amino acids within the kinase domain. Mutations which alter this surface can decrease the affinity of imatinib for *BCR-ABL*, potentially preventing binding entirely. The kinase domain of *BCR-ABL*, which encompasses amino acids 225 to 400, can be subdivided into ATP and imatinib binding site (P loop), the catalytic site where the phosphate from ATP is transferred to the substrate protein, and the activation domain that determines the state of the kinase (open or closed). The imatinib binding site is located in the region of amino acids 300 to 325. Resistance is caused by point mutations in one or more areas on the ABL kinase. The T315I mutation occurs directly within the imatinib binding site and completely disrupts imatinib binding.[13,28] This mutation is important because it confers resistance not only to imatinib but also to second-generation *BCR-ABL* kinase inhibitors.

The other known clinically relevant mechanism of resistance is *BCR-ABL* gene amplification. The *BCR-ABL* gene is overexpressed to such an extent that the typical 400 mg daily dose of imatinib is insufficient to inhibit the activity of the kinase. Reports of clinically significant resistance have been published owing to *BCR-ABL* gene amplification, multiple copies of Ph, or both. The largest series published this far included 66 patients, in whom only 2 patients had confirmed *BCR-ABL* genomic amplification.[28] Other proposed mechanisms of resistance to imatinib include differential binding to α_1-acid glycoprotein in serum, overexpression of P-glycoprotein-induced drug efflux, and clonal evolution to acquisition of additional cytogenetic abnormalities.[12,13,28]

Imatinib Monitoring

Imatinib therapy should be frequently monitored to assess response or disease progression. Recommendations for monitoring include baseline molecular and cytogenetic assessment. Patients with CP CML who have an optimal response have a complete hematologic response within 3 months, partial cytogenetic response within 6 months, complete cytogenetic response within 12 months and major molecular response within 18 months of starting imatinib. *BCR-ABL* transcripts should be evaluated by RT-PCR every 3 months and bone marrow cytogenetics performed at 3 months if RT-PCR is unavailable or 12 months if neither complete cytogenetic response nor major molecular response is achieved. Bone marrow cytogenetics are repeated at 18 months if the patient is not in major molecular response or did not have a complete cytogenetic response at 12 months.[12,13] The loss of hematologic or cytogenetic responses or clonal evolution at any time should be considered a treatment failure warranting a change in therapy. *BCR-ABL* kinase domain mutation analysis is performed for patients who have an inadequate initial response at 3, 12, or 18 months, have any sign of loss of response, or demonstrate disease progression to AP or BC.[12,13]

Adverse Effects and Drug Interactions

Tables 135-4 and **135-5** summarize drug–drug interactions, adverse drug reactions, and monitoring of imatinib. Imatinib-induced myelosuppression is one of the most common adverse events. Moderate-to-severe myelosuppression occurs in about 5% to 10% of patients with CP CML and in 50% to 60% of patients in AP or BC.[11,12,13] The myelosuppression typically occurs within the first 4 weeks of therapy and is more common in patients with advanced disease (ie, high blastic involvement of the bone marrow) and those with a low hemoglobin. Hematopoiesis in patients with

CML depends on the amount of Ph-positive progenitors, although some degree of myelosuppression should be expected when the malignant clone is suppressed. However, imatinib also suppresses normal hematopoiesis, which suggests that myelosuppression associated with imatinib is probably related to effects on the Ph clone and normal hematopoietic cells. When imatinib is initiated, patients should have complete blood counts drawn every 1 to 2 weeks to assess for myelosuppression until they have stabilized.[12] Appropriate initial management of myelosuppression is to interrupt imatinib treatment, not dose reduce, as dose reductions below 300 mg daily do not fully inhibit *BCR-ABL* and may lead to the emergence of imatinib resistance.[12]

Nonhematologic toxicities associated with imatinib include gastrointestinal complications, fluid retention, myalgias and arthralgias, rash, and hepatotoxicity. Drug rash frequently occurs but is usually mild and can be managed with antihistamines or topical steroids. Severe rash, while uncommon, has been reported as an important cause for discontinuation of therapy. Algorithms for desensitization for patients that have experienced serious imatinib-associated rash have been published.[29] Hepatotoxicity can occur with imatinib, and the drug should be withheld if liver function tests exceed five times the upper limits of normal. After the liver function tests normalize, imatinib can be restarted at a reduced dose of not less than 300 mg/day. Imatinib is then dose escalated to the initial dose if liver function tests do not rise during 6 to 12 weeks of treatment. Death as a consequence of liver failure has been reported in a patient receiving large doses of acetaminophen concomitantly with imatinib. It is recommended that patients on imatinib limit their use of acetaminophen to 1,300 mg daily.[12] Other medications that are known to be hepatotoxic should be used with caution while patients are treated with imatinib.

Advanced-Generation Tyrosine Kinase Inhibitors

Dasatinib (Sprycel®) and nilotinib (Tasigna®) are approved second-generation TKIs used for the treatment of CML in patients who are resistant or intolerant to imatinib therapy; both drugs are also approved for first-line treatment of CP CML. Dasatinib is an oral *BCR-ABL* TKI that was FDA approved in 2006 for the treatment of imatinib-resistant CML. Dasatinib is an oral TKI of *BCR-ABL*, the SRC family, C-KIT, EPHA2, and PDGFR. Preclinical data show that dasatinib is 300 times more potent than imatinib and inhibits the growth of imatinib-resistant clones, with the exception of the T315I.[30] Dasatinib received accelerated approval based on hematologic and cytogenetic responses seen in imatinib-resistant or imatinib-intolerant patients.

Dasatinib has been evaluated in patients with imatinib-resistant or intolerant CP, AP, and BC CML. In a phase II trial of 186 patients in CP CML receiving dasatinib 70 mg orally twice daily a hematologic response and major cytogenetic response were noted in 90% and 52% of patients, respectively.[31] Kantarjian et al. evaluated imatinib 400 mg twice daily compared to dasatinib 70 mg twice daily in patients who developed resistance or were intolerant to imatinib 400 mg daily dosing. At 2 years follow-up, patients receiving dasatinib were more likely to achieve a complete hematologic response (93% vs 82%; P=0.034), major cytogenetic response (53% vs 33%; P = 0.023), and an increased estimated progression-free survival at 2 years, which suggests that dasatinib is superior to imatinib dose escalation in disease progression.[32] A trial evaluating different dosing strategies of dasatinib

showed that 100 mg once daily was as efficacious as dasatinib 70 mg twice daily, 50 mg twice daily or 140 mg once daily but with decreased adverse events such as pleural effusions.[33] The standard dose of dasatinib for patients with CP CML is now accepted to be 100 mg daily.

Dasatinib induces responses in patients who are resistant or intolerant to imatinib with advanced disease CML. In a phase II trial of dasatinib 70 mg twice daily in patients with AP CML, 45% achieved a complete hematologic response and 39% achieved a complete cytogenetic response. At 12 months, 66% had progression-free survival and 82% were alive.[34] A phase III trial comparing dasatinib 70 mg twice daily to 140 mg once daily reported similar efficacy at 15 months follow-up, but an improved safety profile that established dasatinib 140 mg once daily as the preferred dosing in AP CML.[35] In patients with BC CML, dasatinib induced a hematologic response in 35% and a major cytogenetic response in 33% of patients. Median overall survival for patients receiving dasatinib in BC CML is 11.8 months.[36]

Dasatinib has been evaluated as first-line therapy in a phase III trial of 519 patients with CP CML.[37] Patients were randomized to dasatinib 100 mg once daily or imatinib 400 mg once daily. The rate of complete cytogenetic response at 5 years was higher with dasatinib as compared with imatinib (83% vs 78%, $P=0.187$). The rate of major molecular response was significantly higher in the dasatinib group (76% vs 64%, $P<0.002$). At the time of analysis, 61% of dasatinib and 63% of imatinib patients remained on study with transformation to AP/BC occurring in 4.6% of dasatinib versus 7.3% of imatinib patients. Five-year overall survival was similar in the two groups (91% dasatinib, 90% imatinib). Adverse effects were similar between the two treatment groups, with the exception that 29% of dasatinib-treated patients developed grade 1 or 2 pleural effusions.

Nilotinib has 20 to 30 times the inhibitory activity of the *BCR-ABL* tyrosine kinase than imatinib, with activity against C-KIT and PDGFR (but not SRC kinases) due to a modification of the methylpiperazinyl structure of imatinib. Nilotinib has inhibitory activity against imatinib-resistant mutants with the exception of T315I. In a phase II trial of 280 patients with imatinib-resistant or intolerant CP CML, 59% of patients treated with nilotinib 400 mg twice daily achieved a major cytogenetic response, with an estimated 4-year progression-free and overall survival of 57% and 78%, respectively.[38] In patients with AP CML treated with nilotinib 400 or 600 mg twice daily, 26% achieved a complete hematologic response and 29% achieved a major cytogenetic response.[39] For first-line treatment of CML, results of a randomized trial in 846 patients comparing nilotinib at two doses (300 or 400 mg twice daily) to imatinib 400 mg once daily have been published.[40] The primary end point of the trial was major molecular response. At 5 years, both nilotinib arms had a significantly higher major molecular response rate at 12 months (77% for nilotinib 300 and 400 mg twice daily) as compared to imatinib (60%, $P<0.0001$ for both comparisons). The nilotinib arms also had a significant improvement in the time-to-progression to the AP or BC, as compared to the imatinib arm. The number of patients discontinued from treatment was similar in all three treatment arms. Nilotinib provides an alternative to dasatinib in patients with imatinib-resistant or intolerant CP or AP CML and is one of several options in initial treatment of CP CML.[12] The phase III trial results for both dasatinib and nilotinib have made them viable alternatives to imatinib for first-line treatment for newly diagnosed CP CML.

Two other TKIs were approved for treatment of CML in 2012, bosutinib and ponatinib. Bosutinib has 15 to 100 times the inhibitory activity of the *BCR-ABL* tyrosine kinase as imatinib with activity against SRC kinases with minimal activity against C-KIT and PDGFR. Among 288 patients previously treated with imatinib, 34% achieved a major cytogenetic response at 24 weeks. Among patients previously treated with imatinib followed by dasatinib or nilotinib, 27% achieved a major cytogenetic response at 24 weeks. Grade 3 or 4 nonhematologic adverse events included diarrhea (9%), rash (9%), and vomiting (3%). Based on this study, the bosutinib dose that was recommended for phase II trials was 500 mg daily. A major cytogenetic response was observed in 32% of patients and a complete cytogenetic response was observed in 24% of patients in the phase II trials.[42]

Bosutinib 500 mg daily was compared to imatinib 400 mg daily in a phase III randomized trial of 502 patients in newly diagnosed CP CML.[43] Although the primary end point of complete cytogenetic response rate at 12 months (70% with bosutinib vs 68% with imatinib) was not significantly different observed, the rate of major molecular response was significantly higher in the bosutinib group (41% vs 27%, $P<0.001$). The incidence of adverse events was similar between the groups with the exception that bosutinib had a higher incidence of diarrhea (68% vs 21%) and imatinib had a higher incidence of edema (38% vs 11%).

Ponatinib is considered a third-generation TKI that contains a novel triple-bond linkage in its chemical structure that avoids the steric hindrance caused by the bulky isoleucine residue at position 315 in T315I *BCR-ABL* binding site cleft, providing clinical activity against this resistance phenotype.[44] In the combined phase I and II trials, 147 patients had a T315I mutated *BCR-ABL* CML in either CP, AP, BC or Ph positive ALL, the maximum tolerated dose of ponatinib was 45 mg with dose-limiting toxicities identified as pancreatitis and myelosuppression.[44,45] Of the 76 patients with CP CML, 72% achieved a complete cytogenetic response and 61% a major molecular response. Of the 45 patients with AP or BC CML, the rate of major hematologic response was 58% and 27%, respectively.[44,45] Hepatotoxicity including reports of liver failure, vascular occlusion, heart failure, and death are also included in the black box warning, several of which occurred within 1 week of starting therapy. The manufacturer recommends specific dose modifications for myelosuppression, hepatotoxicity, and elevated lipase. Due to these toxicities, the FDA requires a Risk Evaluation and Mitigation Strategy (REMS) prescribing program in patients with CML and a T315I mutation or in patients in whom no other TKI therapy is indicated.[46]

Tables 135-4 and 135-5 summarize dosing, drug interactions, adverse drug reactions, and monitoring of advanced-generation TKIs. Edema and plural effusions can be managed by dasatinib drug holiday, diuretics, or short courses of steroids. Nilotinib can be associated with indirect bilirubin elevations in 10% to 15% of patients.[38,39] Nilotinib may prolong the QTc interval (black box warning) and patients should have an electrocardiogram at baseline, at 7 days following initiation of therapy, and periodically thereafter. Based on early clinical trial data, bosutinib appears to have similar rates of adverse events of diarrhea, nausea and vomiting, rash, and abdominal discomfort.[41] Like imatinib, advanced-generation TKIs are metabolized by cytochrome P450 (CYP) 3A4. Clinicians need to be aware of possible drug interactions with inducers and inhibitors of the CYP3A4 pathway such as phenytoin, azole antifungals, or macrolide antibiotics.

TABLE 135-5 Monitoring of Tyrosine Kinase Inhibitors in Chronic Myelogenous Leukemia

Drug	Adverse Reactions	Monitoring Parameters	Comments
Imatinib	Common: • Myelosuppression • Fluid retention (pleural/pericardial effusion, ascites, periorbital, and peripheral edema) • Nausea/vomiting • Rash • Fatigue • Hepatotoxicity • Hypothyroidism • Myalgias Rare but serious: • Congestive heart failure/left ventricular dysfunction • Hemorrhage • Bullous dermatologic reactions	• CBC for myelosuppression • CMP for hepatotoxicity • Consider baseline echocardiogram if preexisting cardiac dysfunction or risk factors for cardiac dysfunction, repeat if experiencing symptoms of cardiac dysfunction • Thyroid-stimulating hormone	Nausea and vomiting improved when drug is administered with food
Dasatinib	Common: • Myelosuppression • Myalgia • Fluid retention • Cardiotoxicity • Rash • Gastrointestinal toxicity	• CBC for myelosuppression • CMP for hypophosphatemia and hepatotoxicity • ECG if risk factors for QTc prolongation • Chest radiograph for signs and symptoms of pleural effusion	Gastrointestinal hemorrhage reported to be fatal; severe pleural effusions requiring thoracentesis; fatal myocardial infarction are reported

Drug	Adverse Reactions	Monitoring Parameters	Comments
	• Hypophosphatemia • Hepatotoxicity Rare but serious: • Pleural effusion • QT prolongation • Congestive heart failure/left ventricular dysfunction • Pulmonary arterial hypertension • Hemorrhage	• Evaluate for signs/symptoms of underlying cardiopulmonary disease for pulmonary arterial hypertension	
Nilotinib	Common: • Myelosuppression • Rash • Gastrointestinal toxicity • Peripheral edema • Liver function abnormalities • Elevated serum lipase/amylase • Electrolyte abnormalities (hypophosphatemia, hypokalemia, hypocalcemia, and hyponatremia) Rare but serious: • Tumor lysis syndrome • Cardiotoxicity (QTc prolongation/sudden	• CBC for myelosuppression • CMP for hypophosphatemia and hepatotoxicity • Serum amylase/lipase • ECG if risk factors for QTc prolongation at baseline, 7 days thereafter and then as clinically indicated	Sudden deaths reported with nilotinib; ventricular repolarization abnormalities may have been contributory

Drug	Adverse Reactions	Monitoring Parameters	Comments
	cardiac death/left ventricular dysfunction)		
Bosutinib	Common: • Myelosuppression • Gastrointestinal toxicity • Fluid retention • Hepatotoxicity • Hypophosphatemia • Rash Rare but serious: • Embryofetal toxicity	• CBC for myelosuppression • CMP for hypophosphatemia and hepatotoxicity • Serum amylase/lipase • ECG if risk factors for QTc prolongation at baseline, 7 days thereafter and then as clinically indicated	Potential for additive risk of hepatotoxicity when given concurrently with letrozole
Ponatinib	Common: • Myelosuppression • Arthralgia • Headache • Fatigue • Fever • Pancreatitis • Elevated lipase • Hypertension • Gastrointestinal toxicity • Dermatologic toxicity • Electrolyte abnormalities • Fluid retention Rare but serious:	• CBC for myelosuppression • Serum lipase • CMP for hepatotoxicity, at baseline for tumor lysis syndrome • Blood pressure as clinically indicated	Deaths reported from hepatotoxicity, thrombosis including myocardial infarction and hemorrhage

Drug	Adverse Reactions	Monitoring Parameters	Comments
	• Arterial thrombosis • Hepatotoxicity • Cardiotoxicity (arrhythmia/congestive heart failure) • Embryofetal toxicity • Hemorrhage • Tumor lysis syndrome • Impaired wound healing/GI perforation		

CBC, complete blood count; CMP, comprehensive metabolic panel; ECG, electrocardiogram; GI, gastrointestinal.

Clinical Controversy…

The controversy of whether to use imatinib or a second-generation TKI therapy as first-line treatment for patients is ongoing. In the first-line setting, a higher proportion of patients treated with nilotinib or dasatinib achieved a major cytogenetic response and *BCR-ABL* transcripts of less than 10% at 3 and 6 months than those on imatinb. The achievement of a major molecular response, especially early in therapy, is associated with long-term disease control. However, the five-year progression-free and overall survival are not significantly different between imatinib and second-generation tyrosine kinase therapy. A generic formulation of imatinib is available that may provide cost savings for payers and patients. The NCCN guidelines currently support that either imatinib, nilotinib, or dasatinib may be used in the first line setting.[12]

Omacetaxine

Omacetaxine was approved by the FDA in October 2012 for treatment of CP or AP CML with resistance or intolerance to two or more TKIs. Omacetaxine is a first-in-class cephalotaxine ester that inhibits protein synthesis independent of direct *BCR-ABL* binding. The putative mechanism is the reduction of *BCR-ABL* oncoproteins and Mcl-1, an anti-apoptotic Bcl-2 family member, via binding to A-site cleft in the peptidyl-transferase center of the large ribosomal subunits. Efficacy with omacetaxine has been demonstrated in two patients groups: CP or AP CML resistant to two or more TKIs and patients previously treated with imatinib harboring the T315I mutation. The former group was evaluated in a combined analysis of two phase II studies for CP and AP CML. Omacetaxine was administered at 1.25 mg/m^2 subcutaneously twice daily for 14 consecutive days every 28 days then for 7 days every 28 days as maintenance.[47] Of the 122 patients enrolled, 81 had CP CML of which

20% achieved a major cytogenetic response, 10% achieved a complete cytogenetic response, with a median overall survival of 34 months.

A phase II trial of omacetaxine was conducted in 62 CP CML patients with a history of the T315I mutation.[48] Patients were treated with the induction regimen as above and transitioned to maintenance when the patient achieved a hematologic response. Hematologic response was achieved in 77%, complete cytogenetic response in 16%, and major cytogenetic response in 23% of patients. The median duration of complete hematologic response was 9.1 months, and major cytogenetic response was 6.6 months. The majority of grade 3/4 toxicities reported in these trials were myelosuppression with occasional reports of myalgias and arthralgias and gastrointestinal toxicity.

Hematopoietic Stem Cell Transplantation

5 Allogeneic HSCT remains the only therapy proven to cure patients with CML, with many patients alive and disease-free decades after transplant. Patients undergoing allogeneic HSCT from a human leukocyte antigen (HLA)-matched sibling donor have 5-year survival rates ranging from 60% to 80% and long-term survival of about 50%.[49,50] In most long-term survivors, the *BCR-ABL* translocation is absent in all diagnostic tests including RT-PCR. Prognostic risk factors associated with survival outcomes include age, phase of disease, and disease duration. Increasing age is associated with poorer prognosis, with higher transplant-related mortality in patients older than age 50 years. Patients with CP who receive allogeneic HSCT have better outcomes than those in AP or BC. The time from diagnosis to transplantation also affects outcomes. Patients who undergo matched-sibling allogeneic HSCT within the first year of diagnosis have a better 5-year survival rate than those who undergo transplantation more than 1 year after their diagnosis (70%-80% vs 50%-60%).[49,50] These data were reported prior to the use of imatinib as first-line therapy for CML.

The major limitation for broad application of HSCT is that fewer than 30% of patients who are transplant-eligible will have an HLA-matched sibling donor. The most practical approach is to use an HLA-matched unrelated donor, if available. Matched unrelated donor HSCT has an overall 5-year survival reported to be 40% to 70%, which approaches overall survival data results reported for matched-sibling donor HSCT.[7,12,49,50] The advent of TKI therapy has resulted in fewer transplants for CML. Data collected to date appear to show that imatinib use prior to transplantation does not negatively affect transplant-related mortality.[51]

Treatment options in patients who relapse after HSCT are limited. Graft-versus-leukemia (GVL) effect, TKIs, omacetaxine, IFN-α, or a clinical trial are reasonable options. The infusion of donor lymphocytes functions as a form of adoptive immunotherapy that can induce a GVL effect. In relapsed CML, donor lymphocytes induce durable responses and these responses strongly correlate with the development of graft-versus-host disease (GVHD).[52] Tumor burden also predicts the likelihood of response to donor lymphocyte infusion in relapsed CML. The optimal method of administering donor lymphocytes remains unclear, but these data suggest it may be possible to partially separate the GVL effect from GVHD.

Imatinib has been used in patients who have residual disease after allogeneic HSCT. Most patients respond to imatinib with complete molecular response of 70%.[53] Use of imatinib or other TKI therapies require further study to determine the magnitude of benefit when applied in the post-HSCT setting.[54] The role of nonmyeloablative transplants in CML is evolving, but preliminary results suggest comparable outcomes to myeloablative transplants. Data from a German registry suggest that 17% of all transplants for CML use a reduced-intensity conditioning regimen.[55]

Personalized Pharmacotherapy

Personalized treatment of CML is mostly directed following initiation of second-line therapy. Mutational analysis of binding sites that confer resistance to TKIs should be evaluated if initial response is inadequate, or the milestones of complete cytogenetic response or major molecular response are lost, or if any signs of disease progression in the form of AP or BC are noted.[12,13] The results of this analysis will guide selection of the appropriate TKI as second-line therapy.[12,13,56] In addition, with the advent of omacetaxine and ponatinib, two agents are now available that are active against the T315I mutation that confers resistance to the rest of the TKIs.

Preliminary data support the role of therapeutic drug monitoring of TKIs in CML. Trough imatinib levels of ≥1 μmol/L have been associated in patients with a higher response than those with <1 μmol/L.[57] Data on nilotinib and dasatinib are more limited. The clinical applicability of therapeutic drug monitoring is still to be determined because the drug assays are not yet commercially available.

Evaluation of Therapeutic Outcomes

Current standard of care is for patients with newly diagnosed CP CML to receive imatinib or one of the second-generation TKIs. The goal of disease monitoring in CML is to differentiate patients who have optimally responded to an initial course of TKI therapy from those at high risk for treatment failure. With imatinib, nilotinib, and dasatinib as appropriate options for frontline therapy for newly diagnosed CP CML, and bosutinib, ponatinib, and omacetaxine approved for salvage therapy, clinicians have a large number of treatment options to consider before allogeneic HSCT. Future research opportunities will focus on how to select second-, third-, and fourth-line therapies and whether combination therapy provides additional long-term benefit.

CHRONIC LYMPHOCYTIC LEUKEMIA

Epidemiology and Etiology

Chronic lymphocytic leukemia is a lymphoproliferative disorder characterized by accumulation of functionally incompetent clonal B lymphocytes.[58] Chronic lymphocytic leukemia is the most common form of leukemia in the United States, but is rare in other countries, such as Japan and China. It is estimated that 18,960 new cases of CLL will be diagnosed in the United States in 2016.[1] Occasional family clusters have been recognized, and first-degree relatives of patients with CLL are at three times the risk of developing a lymphoid malignancy as compared with the general population. Chronic

lymphocytic leukemia is a disease of the elderly, with a median age of 71 years, although 20% to 30% of CLL occurs in patients who are younger than 55 years of age. Male sex, white race, family history, and advanced age are known risk factors for the disease.

Pathophysiology

Chronic lymphocytic leukemia cells are comprised of a neoplastic clone of $CD5^+$ cells, which express low levels of surface-membrane immunoglobulin M (IgM) and immunoglobulin D (IgD) compared to normal peripheral blood B cells. Normal $CD5^+$ B lymphocytes are present in the lymph nodes and in the blood. Neoplastic $CD5^+$ cells accumulate in the lymph nodes and spleen because of the loss of apoptosis by either the overexpression of an oncogene, such as *bcl-1* or *2*, or loss of a tumor suppressor gene, such as *RB1*.[58] The bcl-2 protein is a major regulator of apoptosis or programmed cell death. Evidence is emerging that antigenic stimulation and cytokines drive the proliferation of the CLL cells.

Although CLL lacks a common genetic target as observed in CML, B-cell-receptor signaling has emerged as a driving factor for CLL tumor survival. Bruton's tyrosine kinase (BTK), a member of the Tec family of kinases, is essential for the activation of several constitutively active pathways for CLL cell survival. Bruton's tyrosine kinase leads to activation of the Akt, extracellular signal-regulated kinase (ERK), and nuclear factor kappa light-chain enhancer of active B-cells (NF-κβ) pathways.[59] Additionally, BTK is required for B-cell chemokine-mediated homing and adhesion. Phosphatidylinositol 3-Kinase (PI3K) is a lipid kinas that has a catalytic subunit with four different isoforms: α, β, γ, and δ. When PI3K is activated, it generates phospholipid messengers on the cell membrane that recruit and activate various intracellular enzymes that regulate cell motility, survival, and proliferation.[60] The δ isoform plays a critical role in normal B-cell development, function, and transducing signals from receptors. The PI3Kδ signaling pathway is hyperactive in CLL and other B-cell cancers.

A monoclonal population of B cells with a similar surface antigen phenotype as CLL cells has been recently identified in patients up to several years prior to diagnosis of the disease.[61] This phenomenon, termed monoclonal B-cell lymphocytosis (MBL) appears to predict whether a patient is at risk for developing CLL over time. In a cohort of 77,000 patients enrolled in a cancer screening trial, 45 patients were diagnosed with CLL throughout the duration of the study. Baseline blood samples collected on enrollment of the screening trial were analyzed for the patients who developed CLL. MBL was present in 44 of 45 of the patients by either flow cytometric or molecular analysis (ie, RT-PCR assay) and confirmed in 41 of 45 of these patients by both methods. Samples predated the diagnosis of CLL in a time period ranging from 6 months to 6.4 years. This finding could lead to potentially earlier diagnosis and intervention for CLL.

Cytogenetic abnormalities correlate with disease progression in CLL. About 80% of patients with CLL have a karyotypic abnormality. The chromosomes that are most frequently involved include chromosomes 11, 12, 13, and 17.[62] Additional cytogenetic abnormalities may be acquired during therapy, particularly with deletions of chromosome 17, which have an adverse effect on survival.[63] Somatic point mutations have been identified in a cohort of 91 patients yielding nine mutated genes:

TP53, *ATM*, *MYD88*, *NOTCH1*, *SF3B1*, *ZMYM3*, *MAPK1*, *FBXW7*, and *DDX3X*.[64] These mutations were associated with cell-cycle and DNA repair pathways, intracellular signaling, inflammatory pathways, and RNA splicing and processing. A correlation was identified with *SF3B1* and chromosome 11 deletions providing insight into how these mutations may impact clinical outcomes.

About 4% of patients with CLL will undergo transformation of their disease to an aggressive non-Hodgkin lymphoma (diffuse large B cell), which is termed as *Richter's syndrome*. Richter's syndrome may be triggered by accumulation of additional cytogenetic abnormalities in the malignant clone of lymphocytes or by viral infections, such as Epstein-Barr's virus.[65]

CLINICAL PRESENTATION Chronic Lymphocytic Leukemia Constitutional Symptoms

- Fever, fatigue, weight loss

Physical Examination

- Lymphadenopathy (87%)
- Splenomegaly (54%)
- Hepatomegaly (14%)

Laboratory Tests

Peripheral blood

- Lymphocytosis
- Coombs-positive autoimmune hemolytic anemia
- Hyper- or hypogammaglobulinemia
- Monoclonal gammopathy
- Anemia
- Thrombocytopenia

Bone marrow

- Hypercellular
- Increased mature lymphocytes
- Increased megakaryocytes

Molecular markers

- Cytogenetics (17p-)

- ZAP-70 mutations

Staging and Prognosis

Survival times for patients with CLL are widely variable, with some patients succumbing to disease within 3 years and others living into a second decade from the time of diagnosis. The Rai and the Binet staging systems are commonly used in CLL with the Rai being favored in the United States and the Binet in Europe. The Rai staging system has been combined into a risk classification scheme: low risk (stage 0), intermediate risk (stages I and II), and high risk (stages III and IV) with median survivals of greater than 10 years, 7 years, and 2 to 4 years, respectively.[58,66]

The disease course for CLL varies within each stage such that one patient may have an indolent course with long survival time, while another patient may have more aggressive disease and a relatively short survival time. The Rai and Binet staging systems incompletely predict for individual patients who may experience more rapid disease progression. Patients with Richter's syndrome will have a rapidly advancing disease course that mimics diffuse large B-cell non-Hodgkin lymphoma. However, successful treatment of the diffuse large B-cell non-Hodgkin lymphoma with combination chemotherapy will not eradicate the underlying clone of CLL cells and patients will ultimately relapse.[65]

Biomarkers, such as CD38 expression and ζ-associated protein 70 (ZAP-70) expression, have been explored as prognostic factors for CLL. CD38 is a cell-surface antigen that is associated with early progression, significantly shorter overall survival, and a poor response to fludarabine.[58,67,68] ZAP-70 is an intracellular protein with tyrosine kinase activity. Once considered as simply a surrogate marker for the unmutated variable region of the immunoglobulin heavy chain gene (IGHV), elevated ZAP-70 expression appears to predict for rapid CLL disease progression and independently correlates with prognosis.[66,68]

Cytogenetic changes such as deletion of the short arm of chromosome 17 (17p-), which corresponds to p53 silencing, can be biomarkers of poor response to therapy. A prospective study showed that newly diagnosed patients with 17p- had a median time-to-progression following first-line therapy with either fludarabine or fludarabine and cyclophosphamide of 10 to 12 months.[63] Patients with chromosomal abnormalities of 11, 12, 13, and 17 have reported median survivals of 133 months, 114 months, 79 months, and 32 months, respectively.[62]

TREATMENT

Chronic Lymphocytic Leukemia

Desired Outcomes

6 The primary goals of treatment for CLL are to achieve and maintain remission duration with minimal treatment-related toxicity. The management of patients with CLL is highly individualized with some patients receiving therapy on diagnosis, while other patients with early-stage disease are

managed expectantly. Indications for starting treatment include disease-related symptoms (fatigue, night sweats, weight loss, and fever), threatened end-organ function, bulky disease, doubling of lymphocyte doubling time in less than 6 months, progressive anemia, and platelet count less than 100,000/mm^3 (100 × 10^9/L).[70,71] Consideration of initial treatment options is based on several factors including patient age, disease stage, and high-risk prognostic factors, such as deletion 17p- or 11q.

Most stage 0 patients do not require treatment and can be managed with observation. In patients with stage I disease, treatment is controversial. A consistent survival benefit from early therapy has not been reported in asymptomatic patients.[70,71] Cytotoxic chemotherapy in early stage CLL is usually reserved for patients who have disease characteristics consistent with a more aggressive course, such as short lymphocyte doubling times and presence of biologic markers such as ZAP-70 or high-risk cytogenetics. In stages II through IV disease, treatment is required, with the goal of achieving a partial or complete remission. **Table 135-6** shows the regimens used to treat newly diagnosed and previously treated CLL.[69,70,71]

TABLE 135-6 Treatment for Newly Diagnosed and Previously Treated Chronic Lymphocytic Leukemia

Treatment	Overall Response (%)	Complete Response (%)
Chlorambucil		
Untreated	37	4
Fludarabine alone		
Untreated	60-80	20-30
Previously treated	13-59	3-37
Fludarabine + cyclophosphamide		
Untreated	80-90	25-40
Previously treated	60-70	10-15
Rituximab alone		
Untreated	50-60	10-20
Previously treated	80-90	20-40
Fludarabine + rituximab		
Untreated	80-100	30-50
Previously treated	80-90	20-40
Fludarabine + cyclophosphamide + rituximab		
Untreated	95	70
Previously treated	73	25
Alemtuzumab alone		
Untreated	80-90	20-30
Previously treated	30-50	0-20
Alemtuzumab + fludarabine		
Previously treated	83	17-30
Bendamustine + rituximab		

Treatment	Overall Response (%)	Complete Response (%)
Untreated	97	38
Previously treated	60	9
Ofatumumab + chlorambucil		
Untreated	82	12
Obinutuzumab		
Previously treated	30-62	0-5
Obinutuzumab + chlorambucil		
Untreated	78	20
Ibrutinib		
Previously treated	71	5
Idelalisib + rituximab		
Previously treated	81	0

Cytotoxic Chemotherapy

Orally administered alkylating agents such as chlorambucil and cyclophosphamide, given either alone or with corticosteroids, historically have been used as primary treatment for CLL. Results from a meta-analysis involving 2,048 patients from six randomized controlled studies evaluated low-dose alkylating agents in CLL.[72] That analysis showed that delayed treatment with alkylating agents in asymptomatic patients did not adversely affect 10-year survival. More importantly, if only deaths caused by CLL were considered, significantly longer survival was observed when treatment was deferred. Chlorambucil continues to be used in elderly, symptomatic patients as initial treatment for CLL, but its use is based on a small number of studies with no demonstrable survival advantage.[71,72] Commonly used dosing schedules for chlorambucil are intermittent pulse dosing of 15 to 40 mg/m^2 orally every 28 days or daily doses of 4 to 8 mg/m^2/day.[71] The dose of chlorambucil is often titrated to circumvent myelosuppression.

Cyclophosphamide produces a similar response rate as chlorambucil (overall response rate: 40%-60%; complete response: 4%) and can be used in patients who cannot tolerate chlorambucil or in whom response is not optimal. Some patients who do not respond to chlorambucil will respond to single-agent cyclophosphamide. Cyclophosphamide is typically given orally at a daily dose of 1 to 3 mg/kg. Oral cyclophosphamide is less commonly used than chlorambucil because of the risk of hemorrhagic cystitis and bladder cancer with prolonged treatment.

Fludarabine-based therapy is a common initial treatment in CLL. It is particularly useful in younger patients and in those patients who can tolerate immunosuppressive chemotherapy. Fludarabine, along with the other purine analogs, 2-chlorodeoxyadenosine (cladribine) and 2-deoxycoformycin (pentostatin), are highly active in CLL, with fludarabine being the most widely studied agent in the class in the treatment of CLL.[70,71,72,73] Most patients receive fludarabine 25 to 30 mg/m^2 IV daily for 5 days when used as a single agent. Cladribine and pentostatin have similar activity, although

head-to-head trials comparing these three nucleosides have not been conducted.[73,74,75]

Fludarabine was initially studied in CLL patients who were refractory to chlorambucil. Several trials reported overall response rates to fludarabine in previously treated patients ranging from 13% to 59% and complete response rates of 3% to 37%.[74,75,76,77] Fludarabine has higher overall response and complete remission rates than alkylating-based therapies in the frontline setting. In one of the randomized studies that compared fludarabine to chlorambucil in chemotherapy-naïve patients, fludarabine-treated patients had a higher complete remission rate as compared with chlorambucil (20% vs 5%).[75] However, the higher complete remission rate did not translate into a significant difference in overall survival and patients treated with fludarabine had a higher rate of severe neutropenia and infection. The study allowed chlorambucil failures to cross over to fludarabine, which may have hampered the ability to show a survival advantage in the fludarabine arm. A recent review of younger patients enrolled in a large phase III trial showed that 33% of patients receiving fludarabine or fludarabine-based therapy had infectious complications.[76] An increase in *Pneumocystis* infections was not observed, but a 6% increase in herpes and varicella zoster infection was documented. Dose reductions occurred frequently as a result of the infectious episodes. Based on the increased risk of infectious complications, some practitioners recommend antiviral and antibacterial prophylaxis with treatment.[72,76,77]

Bendamustine is an alkylating agent that contains a purine-derivative benzimidazole ring in its chemical structure that yields a compound that is non–cross-resistant with other alkylating agents. Bendamustine induces cell death via single and double-stranded cross-links.[78] The efficacy of bendamustine was established as first-line agent in Binet stage B or C CLL in a phase III trial that randomized 319 patients to bendamustine or chlorambucil.[79,80] Complete response rates of 31% versus 2% and an overall response rate for 68% versus 31% were observed for bendamustine and chlorambucil, respectively. The median progression-free survival was 21.2 versus 8.8 months favoring bendamustine ($P<0.0001$). The median overall survival was not reached in the bendamustine group and was 78.8 months in the chlorambucil group. Adverse events reported for bendamustine include hematologic toxicity in about 25% of patients, and gastrointestinal and cutaneous toxicity.

Biologic Therapy

Monoclonal antibodies, such as rituximab and alemtuzumab, are increasingly being used in the treatment of CLL. Rituximab is a chimeric monoclonal antibody that targets the CD20 antigen expressed on B lymphocytes. Rituximab was initially approved for patients with indolent non-Hodgkin lymphoma and later for aggressive non-Hodgkin lymphoma. Rituximab received FDA approval for the treatment of CD20-positive CLL in 2010. CLL cells have less prominent CD20 expression on their surface as compared to non-Hodgkin lymphoma, which may explain the lower clinical response. Efficacy with rituximab as a single agent in CLL is moderate with a 58% overall response rate reported with 9% complete responses.[70,71] Subsequent studies have used higher rituximab doses (up to 500 mg/m^2 per cycle) when given in combination with other agents.

7 Alemtuzumab is a monoclonal antibody that targets the CD52 antigen found on both B and T

lymphocytes (**Fig. 135-2**). This agent was initially FDA approved in 2001 for the treatment of patients with CLL who had been treated with alkylating agents and had failed fludarabine therapy and is now approved as a single agent for both frontline and salvage treatment of CLL. Alemtuzumab is titrated to a maintenance dose of 30 mg IV or subcutaneously given 3 times a week for 12 weeks. As a single agent, alemtuzumab has produced response rates from 33% to 53% in patients with refractory disease, but complete responses are infrequent.[81,82,83]

Results from a randomized phase III trial comparing alemtuzumab to chlorambucil in chemotherapy-naïve patients with symptomatic CLL showed higher complete response rates with alemtuzumab than with chlorambucil, 24% versus 2%, respectively.[81] These differences in response rate translated into a significant difference in progression-free survival (hazard ratio, 0.58; 95% confidence interval, 0.43-0.77, $P<0.0001$).

Infusion-related reactions are one of the most frequently reported toxicities with alemtuzumab. The reactions experienced with IV administration include fever, rigors, and hypotension.[82] Alemtuzumab is associated with serious, potentially life-threatening toxicities, including pancytopenia, infusion reactions, and opportunistic infections. Because of alemtuzumab's profound immunosuppression, the 2015 NCCN guidelines recommend antibacterial and antiviral prophylaxis to prevent *Cytomegalovirus* reactivation and *Pneumocystis* infections.[71] Prophylaxis with trimethoprim-sulfamethoxazole and famciclovir or valacyclovir is recommended with the use of alemtuzumab.[71,82] Alemtuzumab is FDA-approved for IV administration, although the use of subcutaneous alemtuzumab has been evaluated to reduce the frequency of these reactions. In a study by Lundin et al. 41 patients received

30 mg of subcutaneous alemtuzumab three times a week for 12 weeks, which yielded a response rate of 87%.[83] Major adverse event were grades 1 and 2 skin reactions in 90% of patients; fever, rigors, and hypotension were infrequent. About 10% of patients had reactivation of *Cytomegalovirus* and required ganciclovir treatment. Similar to IV administration, antiviral and antibacterial prophylaxis is warranted when alemtuzumab is given via the subcutaneous route.[83]

Ofatumumab is a fully human monoclonal antibody to CD20 that was approved as single-agent therapy in 2009 for patients with CLL that is refractory to fludarabine and alemtuzumab. Ofatumumab is administered as an IV infusion with an initial dose of 300 mg then four weekly doses followed by four monthly doses of 2,000 mg. An overall response rate of 58% in patients with fludarabine and alemtuzumab refractory disease and 47% in bulky fludarabine refractory disease was reported.[84] Median time-to-progression was 5.7 and 5.9 months and median overall survival 13.7 and 15.4 months in the fludarabine, alemtuzumab refractory patients and bulky fludarabine refractory disease patients, respectively. Adverse events reported in greater than 10% of patients included infection and neutropenia. Infusion-related events were reported in about 60% of patients, 40% during the first infusion, and 25% with the second infusion. Serious toxicities such as fatal infections, progressive multifocal leukoencephalopathy, and hepatitis B reactivation have been reported.

The efficacy of first-line ofatumumab was studied in a phase III trial of 447 patients with previously untreated CLL.[85] Median progression-free survival was significantly longer in the ofatumumab and chlorambucil group versus the chlorambucil alone group (22.4 vs 13.1 months). Grade III toxicity including neutropenia and infusion-related events were reported more frequently in the combination arm although the overall infection rate was similar in both treatment arms. These results led to the approval of ofatumumab in combination with chlorambucil in previously untreated CLL for whom fludarabine-based therapy is considered inappropriate.

Combination Therapy

The single-agent activity of fludarabine has led to incorporation of fludarabine in combination regimens in patients with CLL. The most widely studied combination is fludarabine with cyclophosphamide, which produces complete response rates between 25% and 40% in treatment-naïve patients as compared with 20% to 30% for single-agent fludarabine.[70,71,72,73,74,75] Although improved response rates and progression-free survival have been reported with fludarabine and cyclophosphamide combinations compared with fludarabine alone, no benefit in overall survival has been observed.

8 The combination of fludarabine and rituximab has promising activity. In vitro studies suggest that rituximab is synergistic with fludarabine and cyclophosphamide and has led investigators to evaluate this combination in clinical trials. Results from an uncontrolled trial of fludarabine, cyclophosphamide, and rituximab (FCR) reported a complete remission rate of 70% in previously untreated CLL patients.[86] FCR has documented a complete remission rate of 25% in previous treated patients. Results of two phase III trials comparing FCR with fludarabine and cyclophosphamide documented a progression-free survival benefit (30 vs 20 months) in patients treated with FCR in patients with refractory disease and an overall survival benefit (87.2% vs 82.5%) in patients with newly diagnosed

disease.[87,88] The results of these phase III trials led to FDA approval of rituximab with fludarabine and cyclophosphamide in CLL.

Bendamustine and rituximab (BR) have been combined in two phase II studies in patients with CLL, in the frontline and relapsed setting.[89,90] In the frontline setting, 117 patients were treated with bendamustine 90 mg/m^2 days 1 and 2 and rituximab 375 mg/m^2 IV on day 0 for cycle 1 and then 500 mg/m^2 IV on day 1 for subsequent cycles.[89] Overall, 88% of patients had a clinical response with 23% being complete responses. The median EFS was 34 months with 90% of patients reported being alive at the median follow-up time point of 27 months. Patients with 17p- responded less well, with a 37.5% overall response rate. Grade 3/4 myelosuppression was observed in about 20% of patients. BR is currently being compared to FCR in previously untreated fit patients with CLL. An interim analysis showed overall response rates of 97.8% for both regimens, but the FCR group had a higher complete response rate (47.4% vs 38.1%, P=0.031) and 2-year progression-free survival (85% vs 78.2%, P=0.041).[90] The advantages of FCR need to be balanced by a higher risk of severe adverse events, in particular neutropenia (81.7% vs 56.8%; P<0.001) and infections (39% vs 25.4%; P<0.001) associated with FCR. Based on these results no firm recommendations of FCR or BR can be made in the first-line setting. The risks and benefits of FCR and BR should be discussed with the patient because no overall survival advantage has been reported.

In the relapsed setting, BR was administered as above with the exception of a lower bendamustine dose of 70 mg/m^2 in 78 patients who had received a median of two prior treatments.[91] The overall response rate was 59%, with 9% of patients having a complete response. With a median follow-up of 24 months, the EFS was 14.7 months with a median overall survival of 34 months. About 25% of patients experienced grade 3/4 myelosuppression with three treatment-related deaths related to infection.

Obinutuzumab is a glycoengineered type II anti-CD20 monoclonal antibody that does not induce translocation of CD20 monoclonal antibody complexes or complement-dependent cytotoxicity, but rather stimulates direct cell death via actin reorganization and homotypic adehesion.[91] Obinutuzumab was FDA approved in 2013 in combination with chorlambucil in patients with previously untreated CLL. A Phase III trial randomized 781 patients to one of three groups: 1) chlorambucil 0.5 mg/kg on days 1 to 15; 2) obinutuzumab 1,000 mg on days 1, 8, 15, of cycle 1 and day 1 on cycles 2 through 6 plus chlorambucil; 3) rituximab 375 mg/m^2 on day 1 of cycle 1 then 500 mg/m^2 on day 1 of cycles 2 through 6 plus chlorambucil. Progression-free survival was increased with obinutuzumab and chlorambucil (26.7 months) compared to rituximab and chlorambucil (16.3 months) or chlorambucil (11.1 months).[92] Overall survival favored obinutuzumab and chlorambucil compared to chlorambucil monotherapy (hazard ratio 0.41; 95% CI 0.23-0.74; P=0.002). Treatment with obinutuzumab and chlorambucil versus rituximab and chlorambucil resulted in longer progression-free survival (hazard ratio 0.39; 95% CI 0.31-0.49; P<0.001) and higher rates of complete response (70% vs 20.7%). Infusion-related reactions and neutropenia were more common with the obinutuzumab group than rituximab, but the risk of infection was similar.

Targeted Therapy

Ibrutinib is an orally administered compound that covalently binds to the cysteine-481 amino acid of the BTK enzyme and inhibits signaling of ERK, NF-κB, and cytosine phosphate-guanine mediated tumor cell proliferation and migration.[59] Ibrutinib was FDA approved in 2014 for the treatment of CLL. In the phase Ib/II trial, 85 patients with relapsed or refractory CLL received ibrutinib at 420 mg or 840 mg by mouth daily.[59] The overall response rate was 71% for both groups with a partial response observed in 20% and 15%, respectively. In a phase III trial, ibrutinib was compared to ofatumumab in patients with relapsed or refractory CLL with a primary endpoint of progression-free survival.[93] Median progression-free survival in the ibrutinib groups was not reached as compared to 8.1 months in the ofatumumab group (hazard ratio 0.22, 95% CI 0.15-0.32; $P<0.001$). The overall response rate was significantly higher in the ibrutinib group at 42.6% versus 4.1% with ofatumumab ($P<0.001$). Overall survival at 12 months also favored ibrutinib, 90% versus 81%. The response rate among patients with a 17p-deletion was 68%, including one complete response, highlighting the ability of ibruitnib to overcome resistance associated with purine analogues and alkylating agents. The most frequent nonhematologic adverse events were diarrhea, fatigue, fever, and nausea. A toxicity unique to ibrutinib is lymphocytosis (69%) secondary to tumor cell mobilization to the peripheral blood. This lymphocytosis is not an indicator of disease progression and ibrutinib should be continued at the standard dose.

Idelalisib is a small-molecule inhibitor of PI3Kδ and interferes with the PI3Kδ-AKT signaling pathway leading to increased apoptosis.[60] Idelalisib 150 mg taken orally twice a day plus rituximab was compared to rituximab plus placebo in a randomized phase III trial in patients with relapsed CLL who had comorbidities that precluded them from being treated with standard chemotherapy.[60] Patients may not have been eligible for systemic chemotherapy for the following reasons: severe neutropenia or thrombocytopenia, an estimated glomular filtration rate of less than 60 mL/min/1.73 m^2, or a score of 6 or more on the Cumulative Illness Rating Scale. The primary endpoint of progression-free survival was not reached in the idelalisib group compared to 5.5 months in the rituximab monotherapy group ($P<0.001$). The overall response rate also favored the idelalisib group, 81% versus 13% ($P<0.001$) as did the 12 months overall survival, 92% versus 80% ($P=0.02$). Black box warnings include hepatic dysfunction, severe diarrhea, colitis, intestinal perforation, and pneumonitis. Patients should have complete blood counts and hepatic function monitored prior to initiation and throughout treatment.

It should be noted that both ibrutinib and idelalisib are metabolized by cytochrome P450 (CYP) 3A4. Therefore, clinicians need to be aware of possible drug interactions with inducers and inhibitors of the CYP3A4 pathway such as phenytoin, azole antifungals, or macrolide antibiotics.

Clinical Controversy…

Certain molecular and cellular markers have been identified that may predict CLL disease progression. ZAP-70 expression, CD38 expression, IGHV mutations, and 17p- are associated with a more aggressive clinical course of CLL. Controversy surrounds whether or not treatment should be based on these biologic markers alone. 17p- is the most consistent poor prognostic marker and results in a loss of the tumor suppressor gene, p53. Consensus guidelines delineate treatment options for patients based on the presence of 17p-. If a patient has 17p- more aggressive regimens that contain

immunotherapy and purine analogs (eg, fludarabine, cyclophosphamide, and rituximab) are potential first-line treatments. Given that ibrutinib is active against CLL with 17p- it is also a potential first line treatment option. Head-to-head comparisons of ibrutinib versus chemoimmunotherpay in the first line setting are lacking and require further evaluation.[71]

Hematopoietic Stem Cell Transplantation

The experience with the use of HSCT in CLL is limited. Patients treated with allogeneic HSCT achieve higher remission rates and appear to have a longer disease-free survival, but is associated with high treatment-related mortality, which approaches 40%. Contrary to the high mortality reported in most studies, a randomized phase II study of high-risk CLL patients comparing allogeneic and autologous HSCT reported 100-day mortality of 4% in both arms. After 6 years of follow-up, no difference in overall survival (58% autologous and 55% allogeneic) was observed.[93] This low early mortality must be interpreted carefully, given that only 25 carefully selected patients received allogeneic HSCT as compared with 137 who received autologous HSCT. T-cell depletion was performed on the allogeneic grafts, which may reduce 100-day mortality at the cost of increased relapse, infectious complications, or posttransplant lymphoproliferative disorders as a consequence of reduced GVL effect.[94]

Although allogeneic HSCT may offer the potential of cure in CLL, the advanced age of most patients, limited donor availability, and the high treatment-related mortality precludes the routine application in the management of this disease. Allogeneic HSCT is a more viable option for younger patients with aggressive disease. Older patients who are not candidates for full-intensity allogeneic HSCT may be candidates for nonmyeloablative allogeneic HSCT.

Immunotherapy

The use of immunotherapy in CLL had been considered as a potential treatment strategy because of the presence of tumor specific antigens such as CD19. The modification of autologous T cells expressing an anti-CD19 chimeric antigen receptor (CART19) has been explored in patients with refractory CLL.[95] Autologous T cells are collected via leukapheresis and treated with a self-inactivating lentiviral vector to express the CD19 specific chimeric antigen receptor concurrently with the costimulatory CD137 signaling domain. Modified cells are kept for about two weeks for expansion and then harvested for infusion. Patients receive a preparative regimen of standard CLL-directed chemotherapy with the goal of lymphodepleting the patients and enhancing the proliferation of the infused T-cells. A cell dose of about 3×10^8 autologous transduced-T cells is administered within several days of completion of chemotherapy.

In the largest single-center experience, 45 highly refractory CLL patients have been treated with this approach.[95] Overall response rate was reported to be 45% with small numbers of patients having documented persistence of the genetically-modified T-cell population lasting beyond 3 years. Toxicity with the procedure is notable for the expected toxicities of the chemotherapy preparative treatment, cytokine release syndrome, hypogammaglobinemia and B-cell aplasia. Cytokine release syndrome is believed to be an interleukin-6 mediated event characterized by escalating fevers (>40°C), myalgias, nausea, vomiting and diarrhea. Severe cases of cytokine release syndrome can progress to

hypotension, capillary leak, and hypoxia requiring critical care level support.

Personalized Pharmacotherapy

Molecular biomarkers are important as predictors for disease time to progression, decision making for initiation of treatment, and prognosis. The most important are cytogenetic abnormalities such as deletion 17p- and 11q, which are associated with more aggressive disease that is less responsive to treatment. Unmutated status of the immunoglobulin heavy chain variable gene locus and overexpression of ZAP-70 and CD38 expression are also predictive of poor prognosis.

The 2015 NCCN guidelines recommend treatment options based on the presence of deletion 17p- or 11q, age older or younger than 70 years, and first- and second-line regimens.[71] Preferred first-line therapy options for patients younger than 70 years without poor-risk cytogenetics or significant comorbidities are aggressive chemoimmunotherapy regimens such as bendamustine, rituximab; fludarabine, cyclophosphamide, rituximab; fludarabine, rituximab; and pentostatin, cyclophosphamide, and rituximab. In patients who are older than 70 years without poor-risk cytogenetics preferred chemotherapy options include: obinutuzumab, chlorambucil; ofatumumab, chlorambucil; rituximab, chlorambucil; or bendamustine, rituximab. In frail patients or those with significant comorbidities and unable to tolerate purine analogs preference of first line therapy may include: obinutuzumab, chlorambucil; ofatumumab, chlorambucil; or rituximab, chlorambucil. The current standard of care for relapsed or refractory CLL is ibrutinib monotherapy and idelalisib plus rituximab.[70,71] For patients who have poor-risk cytogenetics such as 17p- deletion, first-line therapy options consist primarily of more aggressive chemoimmunotherapy treatment options (FCR; fludarabine and rituximab; high-dose methylprednisolone and rituximab) or targeted therapy with ibrutinib. Preferred second-line regimens include ibrutinib or idelalisib plus rituximab regardless of age or comorbidities.[70,71]

Evaluation of Therapeutic Outcomes

Chronic lymphocytic leukemia is an incurable disease and the goal of therapy is to optimize remission duration while minimizing the burden of treatment-related adverse effects. Supportive care for patients undergoing active treatment for CLL is crucial for ensuring a successful outcome. Patients may become hypogammaglobinemic as a consequence of disease progression or treatment will need routine monitoring of serum IgG. If the serum IgG falls below 500 mg/dL (5 g/L), then monthly replacement doses of 300 to 500 mg/kg of IV immune globulin is warranted. Antibiotic prophylaxis for patients receiving fludarabine-based regimens or chemoimmunotherapy should be considered for herpes virus and *Pneumocystis*. Patients who are treated with alemtuzumab will require monitoring for cytomegalovirus (CMV) antigen every 1 to 2 weeks while on therapy and for 2 months after or be given prophylaxis with valganciclovir.

Chapter 136: Multiple Myeloma

Kamakshi V. Rao; Amy M. Pick

INTRODUCTION

KEY CONCEPTS

- 1 Multiple myeloma (MM) is a cancer that develops in plasma cells, leading to excessive production of a monoclonal immunoglobulin.
- 2 Most patients have skeletal involvement at the time of diagnosis with associated bone pain and fractures. Anemia, hypercalcemia, and renal failure may also be present. A bone marrow biopsy with 10% or more plasma cells and a M-protein spike on plasma or urine electrophoresis confirms the diagnosis.
- 3 Cytogenetics may play an important role when selecting the appropriate initial therapy for patients with a new MM diagnosis and tools such as the Mayo Stratification for Myeloma and Risk-adapted Therapy (mSMART) approach are available.
- 4 Induction treatment is based on patients' eligibility for autologous stem cell transplantation. Novel agents such as thalidomide, lenalidomide, pomalidomide, bortezomib, and carfilzomib have gained popularity over traditional chemotherapy because of higher response rates and survival. The increased response rate is at the expense of significant grade 3 and 4 toxicity, which can include myelosuppression, venous thromboembolism (VTE), and neuropathy depending on the regimen used.
- 5 Thalidomide, lenalidomide, and pomalidomide are immunomodulatory agents that have antiangiogenic and anti-inflammatory activity. Thalidomide's dose limiting toxicity is neuropathy. Lenalidomide is less neurotoxic, but can cause significant myelosuppression. Pomalidomide, the newest of this class, is currently only used in relapsed/refractory MM.
- 6 The proteasome inhibitors, bortezomib and carfilzomib, are highly active in the treatment of MM, particularly those with high-risk cytogenetics.
- 7 Autologous hematopoietic stem cell transplantation (HSCT) is used after induction in

patients with reasonably good performance status to maximize complete remissions and prolong survival. Combining autologous HSCT with allogeneic HSCT is investigational and should be performed within a clinical trial.

- 8 Maintenance therapies may be used in both transplant-eligible and ineligible patients. Current regimens typically include lenalidomide or bortezomib with the intent of increasing response rates and progression-free survival.

- 9 Bisphosphonates are used to treat bone disease associated with MM, which results in decreased pain and skeletal-related events and improved quality of life.

- 10 Salvage therapy for patients with relapsed or refractory MM can include any of the prior listed therapies and depends on patient's performance status, risk category, and prior treatments used for induction.

1 Multiple myeloma (MM) is a malignancy of plasma cells or immunoglobulin-producing B lymphocytes.[1,2] The cancer is characterized by clonal proliferation and accumulation of a monoclonal immunoglobulin secreted from the plasma cell that can be measured in the plasma or urine. Patients with MM often have osteolytic bone lesions at the time of diagnosis, which is probably related to various bone-mobilizing cytokines secreted from the MM clone and bone marrow stromal cells. Other clinical manifestations include end-organ damage such as renal insufficiency, hypercalcemia, and anemia. The treatment of MM often consists of two or three drug combinations incorporating a proteasome inhibitor and immunomodulator. These regimens have improved response rates and outcomes compared to conventional chemotherapeutic agents. Although therapy is not currently curative, MM continues to be a remarkable example of bench-to-bedside translation in new drug development.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, it was estimated that 30,330 cases of MM were diagnosed in 2016, with 12,650 deaths.[3] It is a disease that affects older adults with a median age of 69 years at diagnosis.[4] MM occurs more frequently in men and African Americans. Familial clusters of MM have been reported with emerging evidence suggesting a genetic predisposition toward the disease.[5]

Certain environmental factors have been implicated with MM. Radiation exposure has been historically linked to the development of MM with atomic bomb survivors having a five times higher risk of MM than nonexposed controls. Data suggest that low levels of radiation may also be a risk factor. MM has been associated with exposure to various chemicals including pesticides, aromatic hydrocarbons, and petroleum products used in farming, cleaning works, mining, and other occupational groups working with these chemicals. Alcohol and tobacco use have not been strongly associated with an increased risk of MM and the association of MM with an infectious etiology has been inconclusive.[6]

Although the pathogenesis of MM has not been fully elucidated, multiple genetic mutations have

been identified and our understanding of these cellular events has improved. Decades of research and improved scientific techniques have enabled closer examination of the changes that occur during the development of normal and abnormal B cells.

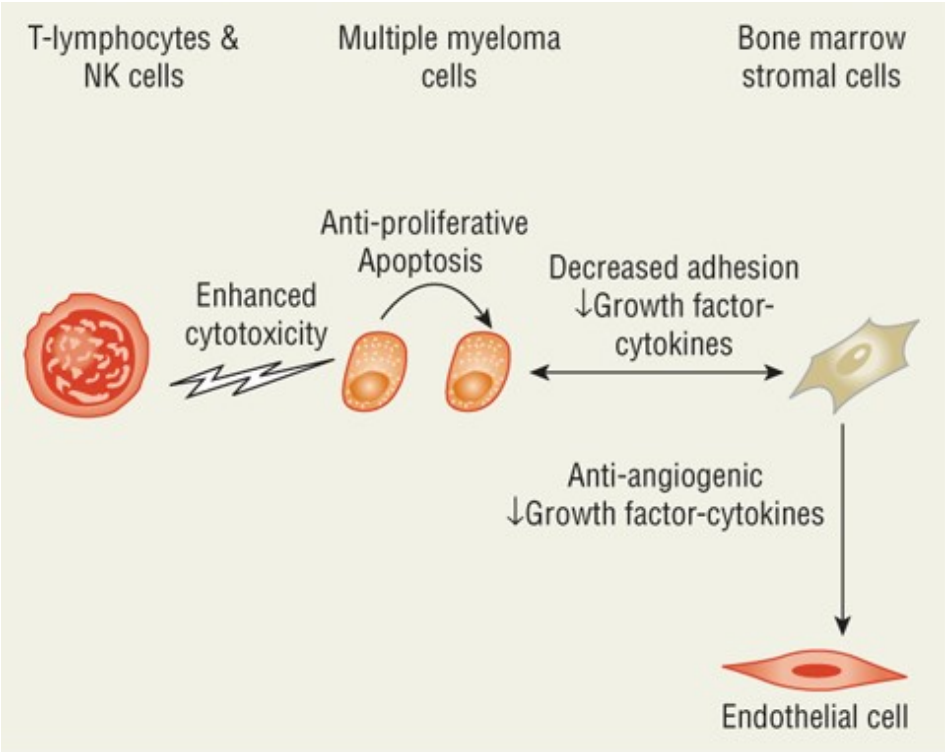
PATHOPHYSIOLOGY

MM is a genetically heterogeneous disease that is characterized by abnormal clonal plasma cell infiltration in the bone marrow. Monoclonal gammopathy of undetermined significance (MGUS) and smoldering MM may precede active MM. MGUS is associated with monoclonal immunoglobulin in the blood (≤ 3 g/dL [≤ 30 g/L]) without clinical manifestations of the complications of MM (eg, end-organ damage).[7,8] The conversion rate of MGUS to MM is about 1% per year. The molecular changes associated with the conversion of MGUS to MM are not clear, but genome-wide studies have identified several candidate genes associated with disease progression.[2,8,9] Smoldering MM is an advanced premalignant stage that is clinically distinct from MGUS with criteria including high monoclonal immunoglobulin in the blood (≥ 3 g/dL [≥ 30 g/L]) without clinical manifestations of the complications of MM. Although patients with smoldering MM have asymptomatic disease, the risk of progression to MM is about 10% per year for the first 5 years after diagnosis, about 3% per year for the next 5 years, and about 1% per year for the next 10 years.[10,11] Certain cytogenetic characteristics appear to be associated with a higher risk of transformation to active MM including a translocation of 4 and 14.[10] Multiple genetic changes may occur over time leading to more symptomatic disease. Numerous genetic mutations are associated with transformation, with one report of four patients who transformed from smoldering MM to MM acquiring an average of 433 mutations.[9] The molecular mechanisms leading to these mutations remain to be fully elucidated.

MM is characterized by the accumulation of malignant plasma cells in the bone marrow. Both MM and normal plasma cells are produced from differentiated B cells after antigen stimulation. Normal plasma cells will die within days to weeks after differentiation, whereas MM plasma cells are immortalized.[1,6] The malignant plasma cell is involved in the unregulated production of a monoclonal antibody referred to as *M protein*. MM cells are seldom seen in large quantities in the peripheral blood because of their close interaction with bone marrow stromal cells. MM cells are supported by a nurturing bone marrow microenvironment which promotes the further expansion of myeloma clones. Molecules such as interleukin-6 (IL-6), vascular endothelial growth factor (VEGF), insulin-like growth factor 1 (IGF-1), and the transcriptional regulator nuclear factor kappa B (NF-*κB*) are part of the microenvironment and stimulate clonal growth, disease progression, and promote resistance to therapy.[9] The disruption of the microenvironment is an important strategy for therapy.[12] **Figure 136-1** shows several of the factors involved in disease pathogenesis and progression and potential mechanisms of action of thalidomide, lenalidomide, pomalidomide, bortezomib, and carfilzomib.

FIGURE 136-1

Proposed mechanisms of action of immunomodulatory drugs.



CLINICAL PRESENTATION

The clinical manifestations are related to the effects of the myeloma cell on the bone microenvironment and the unregulated production of the M protein. Most patients with MM present with complaints of bone pain and fatigue at diagnosis.[6] Initial laboratory evaluation often reveals hypercalcemia, renal insufficiency, anemia, and other abnormalities including β_2-microglobulin that measures tumor burden. Skeletal evaluation shows gross abnormalities in most patients. Bone scans show abnormalities that often include lytic lesions, osteoporosis, and fractures. This group of findings (hyper**c**alcemia, **r**enal insufficiency, **a**nemia, and **b**one lesions) is often referred by the acronym *CRAB* and suggests end-organ damage.[6,7] A confirmed diagnosis is defined by a bone marrow biopsy with 10% or more plasma cells and an M-protein spike on plasma or urine electrophoresis.[7,13] Both the National Comprehensive Cancer Network (NCCN) and International Myeloma Working Group (IMWG) have described criteria to diagnose MM.[13,14]

Following the diagnosis of MM, further workup involves analyzing the isotype of M protein. Serum protein electrophoresis and serum and urine immunofixation identify the M-protein isotype being secreted. In a minority of patients, M protein may not be detected in the plasma but found in the urine, requiring the urine to be examined as part of a complete diagnostic workup. About 60% of patients have intact monoclonal immunoglobulin G (IgG), 20% have monoclonal IgA, and the remaining 20% secrete only monoclonal light chains. Antibodies are composed of two light chains where antigen binds and two heavy chains. Light-chain immunoglobulins, called Bence Jones proteins, can be secreted by the MM clone and excreted in the urine due to their low molecular

weight. Bence Jones proteins are primarily responsible for MM-associated renal failure.[1,6] Serum-free light chains (SFC) may also be measured and these results may provide valuable information on the likelihood of disease progression.[15]

CLINICAL PRESENTATION Multiple Myeloma General Criteria

- 80% of patients present with symptomatic disease

Signs and Symptoms

- Bone pain (fractures, lytic lesions)
- Fatigue (anemia)
- Infection (reduced polyclonal response)
- Neurologic symptoms (nerve compression)
- Polyuria (hypercalcemia)
- Nausea and vomiting (hypercalcemia)

Laboratory Parameters

- Elevated M protein
- Plasma electrophoresis
- Urine electrophoresis
- Immunofixation
- Elevated serum creatinine
- Hypercalcemia
- Low hemoglobin
- Low albumin
- Elevated β_2-microglobulin
- Elevated C-reactive protein

Bone Marrow

- More than or equal to 10% plasma cells

Cytogenetics

- Chromosome 13 deletion
- Translocations of t(4;14), t(11;14) and t(14;16)
- Del (17p)
- Chromosome 1 amplification

Most patients have bone involvement at the time of diagnosis.[6,7] The effects of MM on the bone result from the abnormal production of cytokines, including IL-1, IL-6, tumor necrosis factor-α (TNF-α), and the receptor for activation of NF-κB ligand (RANK-L). Bone involvement is the net effect of the activation of osteoclasts and inhibition of osteoblastogenesis.[16] This leads to bone destruction and resorption predisposing one to pathologic fractures and lytic lesions. Patients with MM are frequently anemic due to infiltration of the bone marrow with the MM clone and poor erythropoietin response. Patients can have clinically important hypercalcemia, which results from calcium mobilization due to bone resorption. Renal failure can occur as a result of high protein load from the monoclonal protein secretion as well as dehydration.

STAGING AND PROGNOSTIC FACTORS

Two clinical staging systems for MM have been developed. The newer International Staging System (ISS) uses serum β_2-microglobulin and albumin concentrations to stage patients.[17] These two routine laboratory tests predict survival in patients treated with either conventional treatment or autologous hematopoietic stem cell transplantation (HSCT). It does not consider cytogenetics or molecular markers. An older staging system, Durie-Salmon, may also be used. It uses hemoglobin, serum calcium, bone involvement, and M protein to categorize patients into one of three stages.[13] The Durie-Salmon system has variable accuracy in patients undergoing HSCT and with newer novel therapies.[6] **Table 136-1** describes the ISS and median survival times for each stage.

TABLE 136-1 The International Staging System for Multiple Myeloma

Stage	Characteristics	Median Survival (mo)
I	Serum β_2-microglobulin <3.5 µg/mL (mg/L) Serum albumin ≥3.5 g/dL (≥35 g/L)	62
II	Not stage I or stage III	44
III	Serum β_2-microglobulin ≥5.5 µg/mL (mg/L)	29

3 Certain cytogenetic abnormalities have been identified as important prognostic factors. Shortened overall survival has been demonstrated in patients with chromosomal 13 deletion (del 13), translocation of 4 and 14 (t(4;14)), and deletion of 17p (del (17p)).[6,13] Recent data suggest that the translocation of 11 and 14 may be associated with increased survival. The Mayo Clinic developed a

risk-adapted approach, known as the mSMART (Mayo Stratification for Myeloma and Risk-adapted Therapy), that categorizes patients into three risk groups based on cytogenetics and gene expression profiling: high, intermediate, and standard risk.[18] Therapeutic options and treatment length is then provided for each risk group. Additional prognostic factors generally represent the underlying pathologic changes associated with MM, including proinflammatory biomarkers (elevated C-reactive protein), tumor load (increased β_2-microglobulin), and dysregulated cellular growth (labeling index and marrow microvessel density).

TREATMENT

Desired Outcomes

The primary goal in the treatment of MM is to prolong the patient's survival and improve quality of life. The different phases of treatment also have specific goals. The goal of induction therapy in newly diagnosed MM patients is to obtain at least a major response.[6,7] Induction therapy is followed by various treatment phases including transplant, consolidation, and maintenance therapy. The goals of these subsequent phases are to further improve response rates. With the integration of novel agents into therapy, progression-free survival and overall survival have steadily improved, and responses have increased in frequency, depth, and duration. Unfortunately, there is no convincing evidence that patients are cured of their disease.

General Approach

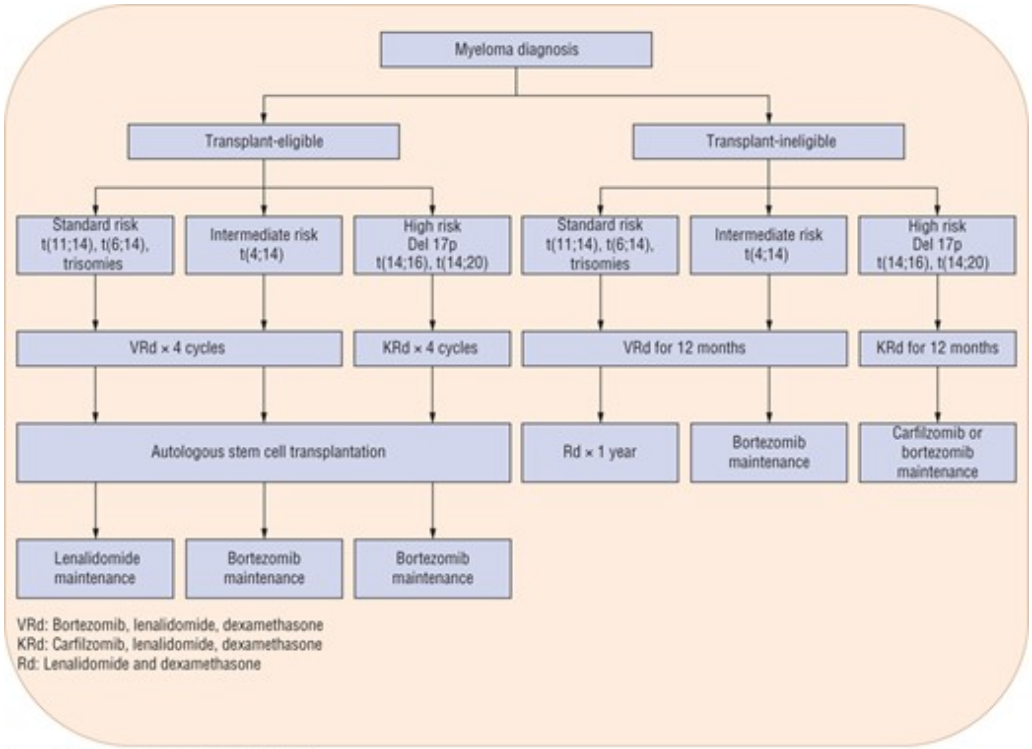
The decision to initiate treatment depends on whether the patient is experiencing symptoms of the disease. Watchful waiting is the most common practice for patients with smoldering MM and is currently recommended by the NCCN guidelines.[13] However, this treatment paradigm is evolving with the availability of novel agents. Several small published studies suggest that early treatment with novel agents in patients with high-risk smoldering MM may improve overall survival and delay time to progression.[9] The challenge remains identifying patients with high-risk smoldering MM and developing criteria to assess a treatment response.[9]

4 Initial management of symptomatic MM (refer to "Clinical Presentation") depends on whether patients are candidates for autologous HSCT (**Fig. 136-2**). Transplant consideration factors include patient age, renal function, performance status, and comorbidities. The determination of transplant eligibility guides further treatment decisions. All patients with symptomatic MM are treated with initial induction therapy, with the selected regimen based on transplant eligibility. Therapies that may compromise stem cell reserve are avoided in transplant-eligible patients and the selected regimen will often be composed of various novel agents. Doublet or triplet combination regimens such as dexamethasone combined with bortezomib and lenalidomide or thalidomide have become common.

FIGURE 136-2

Risk adapted treatment of multiple myeloma based on eligibility for hematopoietic stem cell transplantation.

Adapted from Mayo Clinic mSMART classification.



Induction therapy is usually continued until the desired response is achieved. Patients who are candidates for autologous HSCT will often receive two to four cycles of therapy and then will proceed to hematopoietic stem cell collection. Most patients undergo autologous HSCT immediately following collection, but some patients may decide to delay the transplant until first relapse. Patients who are not candidates for autologous HSCT usually receive several cycles of consolidation therapy, although the optimal duration of therapy after desired response is achieved is unknown. Single-agent maintenance therapy may be given in both transplant-eligible and ineligible patients. The use of guidelines may assist the clinician with drug therapy selection. Clinicians may be guided by the NCCN and IMWG Guidelines and mSMART treatment recommendations, which are discussed later in the "Initial Therapy" section.

The IMWG has developed uniform response criteria for MM.[19] Clinical response to therapy is generally defined by a reduction in M protein in the blood and urine. Numerous response types have been defined and the depth-of-response correlates with improved outcomes. A complete response (CR) is defined as elimination of the M protein as measured by immunofixation and plasma cells (≤5%) in the bone marrow. A CR is desirable because it is associated with improved overall survival.[20] A stringent complete response (sCR) is a CR with normal free light chain and absence of clonal cells in bone marrow. Lesser responses include partial response (PR), near complete response (nCR), and very good partial response (VGPR). These lesser responses are important because they may also correlate with improved survival. **Table 136-2** describes the most common types of responses that are used clinically.[13]

TABLE 136-2 Definition of Clinical Response in Multiple Myeloma

Type of Response	Definition[a]
PR	• ≥50% decrease in serum M protein • Reduction in 24-hour urine light chain by ≥90%
VGPR	• Serum and urine M protein detected on immunofixation but not electrophoresis
CR	• Negative immunofixation on serum and urine • No soft tissue plasmacytomas
sCR	• <5% plasma cells in the bone marrow • CR definition • Normal free light chain ratio • Absence of clonal cells in the bone marrow

CR, complete remission; PR, partial response; sCR, stringent complete response; VGPR, very good partial remission.

Pharmacotherapy of Multiple Myeloma

The current treatment of MM is based on novel agents from two classes of drugs, the immunomodulators and proteasome inhibitors. A three-drug regimen is commonly used in the treatment of MM and often incorporates dexamethasone and a drug from each class. The optimal regimen is not clear because of the lack of head-to-head comparative trials.[6,7] Several highly active combination regimens are available. These regimens have improved response rates and survival with acceptable but different toxicity profiles compared to conventional regimens previously used in MM. **Tables 136-3** and **136-4** show dosing and monitoring parameters for the newer agents used in the treatment of MM. Dose reductions in elderly patients and in patients with adverse events are often required.[13,20]

TABLE 136-3 Dosing of Novel Agents in Multiple Myeloma

Drug (Brand Name)	Initial Dose	Usual Dose	Special Population
Thalidomide (Thalidomide®)	50-100 mg/day	200 mg/day	Start low in elderly adults; increase dose every 1-3 weeks
Lenalidomide (Revlimid®)	10-25 mg/day Days 1-21 (28-day cycle) Days 1-28 (35 day cycle)	25 mg/day	Adjust dose in renal impairment: 30-60 mL/min (0.5-1.0 mL/s) (10 mg every 24 h) <30 mL/min (<0.5 mL/s) (15 mg every 48 h) <30 mL/min (<0.5 mL/s) (dialysis) (5 mg every 24 h)
Bortezomib (Velcade®)	1.3 mg/m^2 Days 1, 4, 8, and 11 Every 21 days		Reduce initial dose in hepatic impairment (serum bilirubin >1.5 × ULN) to 0.7 mg/m^2
Carfilzomib (Kyprolis®)	20/m^2 given on days 1, 2, 8, 9, 15, and 16 of a 28-day cycle	27 mg/m^2	
Pomalidomide (Pomalyst®)	4 mg/day for 21 days (28-day cycle)		

ULN, upper limit of the normal range.

TABLE 136-4 Adverse Reactions and Monitoring Parameters for Novel Agents in Multiple Myeloma

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Thalidomide	Neuropathy, sedations, constipation, VTE, rash, neutropenia, teratogenicity	Neurologic examination, active bowel sounds, CBC, STEPS Program	Evening dose to ↓ sedation Laxatives VTE prophylaxis
Lenalidomide	Myelosuppression, rash	CBC, renal function, REMS	Adjust dose in renal impairment VTE prophylaxis
Pomalidomide	Myelosuppression, rash, VTE, teratogenicity	CBC, REMS	

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Bortezomib	Myelosuppression, neuropathy, infection gastrointestinal	CBC, neurologic examination	VZV prophylaxis Hydration to reduce risk of renal toxicity and TLS
Carfilzomib	Myelosuppression, infection	CBC, fluid status, serum chemistries	Dexamethasone premedication for infusion reactions VZV prophylaxis

CBC, complete blood count; STEPS, System for Thalidomide Education and Prescribing Safety; REMS, Risk Evaluation and Mitigation Strategy; TLS, tumor lysis syndrome; VTE, venous thromboembolism; VZV, varicella zoster.

Conventional Chemotherapy

Conventional chemotherapy incorporating a corticosteroid was once the mainstay for the treatment of MM. Today, these conventional drugs may be combined with a novel agent to improve overall survival. Two of the common conventional chemotherapy regimens used historically to treat MM were melphalan plus prednisone (MP) and vincristine, doxorubicin, and dexamethasone (VAD).[6,21] The two drug regimen MP is no longer preferred because of inferior overall survival compared with newer regimens and is now often combined with a novel agent.[6,7,20] Melphalan is only recommended in the transplant-ineligible patients because of the adverse effects it has on stem cell mobilization and subsequent autologous HSCT.[6] Melphalan has also been associated with the development of myelodysplastic syndromes which is why the use of VAD chemotherapy as initial treatment became more common.[22] VAD has also been replaced with novel therapies.[13]

Corticosteroids are the cornerstone in MM therapy. Dexamethasone has been used alone as initial therapy and is believed to account for most of the antimyeloma activity of VAD (**Table 136-5**). High-dose dexamethasone is associated with a higher rate of infection and central nervous system toxicity compared to MP which led investigators to conclude that high-dose dexamethasone should be used with caution as initial therapy, particularly in older patients.[23] In current regimens, newer agents (thalidomide, bortezomib, lenalidomide, carfilzomib) are combined with dexamethasone or the MP backbone to maximize initial response rates.[6,7,24] Doxorubicin or liposomal doxorubicin are also combined with various novel agents to improve response rates.

TABLE 136-5 Initial Therapies for Multiple Myeloma

	Type of Response (%)		
Regimen	OR	CR	CR/nCR/ VgPR
Melphalan + prednisone	40-50		5-10
Dexamethasone	40-50		

Regimen	Type of Response (%) OR	CR	CR/nCR/ VgPR
Thalidomide	34-40		
Thalidomide + dexamethasone	50-70	5-10	20-30
Melphalan, prednisone, and thalidomide	50-80	5-25	20-50
VAD chemotherapy	50-60		
Doxorubicin combinations + thalidomide	70-90		40-50
Single autoHSCT	80-90		40-50
Tandem autoHSCT	80-90		30-50
AutoHSCT followed by RI-alloHSCT	80-90		60
Bortezomib	40-50		12
Bortezomib + dexamethasone	80-90		20-30
Bortezomib + chemotherapy	80-98	10–30	43
Bortezomib + thalidomide + dexamethasone	85-95	20–35	50-60
Bortezomib + lenalidomide + dexamethasone	100		50-74
Lenalidomide + LD dexamethasone	70		40
Lenalidomide + high-dose dexamethasone	80		50
Clarithromycin + lenalidomide + dexamethasone	93	43	68
Lenalidomide + chemotherapy	80	15-25	
Carfilzomib + Lenalidomide + LD dexamethasone	98	42 (sCR)	81

alloHSCT, allogeneic hematopoietic stem cell transplantation; autoHSCT, autologous hematopoietic stem cell transplantation; CR, complete response; LD, low dose; OR, overall response (at least partial response); RI, reduced intensity; sCR, stringent complete response; VAD, vincristine, doxorubicin, and dexamethasone.

Immunomodulatory Drugs (IMiD)

Thalidomide (Thalomid®)

Thalidomide was first used clinically in Europe in the late 1950s as a sedative and antiemetic but its use was largely abandoned when teratogenicity was reported. Its immunomodulatory effects became evident in the treatment of Hansen disease (leprosy), and it continues to be used for this rare indication. These clinical benefits are thought to be related to the anti-TNF activity of thalidomide. Recognizing that TNF may be involved in the pathophysiology of MM led researchers to study thalidomide as a treatment for refractory MM in 1999. The observation that thalidomide had activity against myeloma rejuvenated it as an important therapeutic agent.[6]

5 Thalidomide and other IMiDs have complex immune effects and appear to block several pathways that are involved in disease progression in MM.[6,7,25] While not fully understood, IMiDs

have anti-angiogenic and anti-inflammatory properties which may directly or indirectly affect the myeloma cell. IMiDs decrease the production of cytokines and growth factors such as IL-6, TNF-*α,* and VEGF which are believed to have a role in the pathogenesis of the disease. IMiDs may also inhibit nuclear factor-*κB* (NF-*κB*) activation, either directly or indirectly via TNF, which results in increased apoptosis of the MM clone.[6] Further discussion of NF-*κB* can be found in the proteasome inhibitors treatment section. Thalidomide and other IMiDs induce IL-2 mediated T-cell proliferation including natural killer cell activity. Figure 136-1 shows the proposed effects of thalidomide on the myeloma cell.

Thalidomide activity has been demonstrated in numerous trials. Initially, single-agent thalidomide was evaluated in refractory MM and produced overall response rates (including minor responses) in about 30% of patients.[26] Although minor and partial responses were the most common types of responses, these end points were associated with improved survival.[27]

With the activity of thalidomide in refractory MM established, subsequent studies evaluated its activity in newly diagnosed transplant-eligible and -ineligible patients. These studies evaluated thalidomide in combination with other therapies, including dexamethasone, bortezomib, and chemotherapy. PR rates with thalidomide monotherapy in untreated patients were about 30% to 40%.[6] When dexamethasone was added to thalidomide in untreated patients, response rates (≥ PR) increased to about 70% to 80%.[28] In vitro results suggest there may be synergism and reversal of resistance when used in combination.[6] The higher response rate with the combination of thalidomide plus dexamethasone has made this an attractive combination for initial therapy. The addition of bortezomib to the combination of thalidomide and dexamethasone (VTD) has been investigated in transplant-eligible patients. The triple drug regimen was associated with higher overall response rates (CR, vCR, and VGPR) compared to the combination of thalidomide and dexamethasone (TD) following first and second HSCT.[13,29] For this reason, the combination of thalidomide, bortezomib, and dexamethasone is a first-line option for transplant-eligible patients. Clinicians should recognize the higher rate of venous thromboembolism (VTE) with this combination (15%-20%) and consider VTE prophylaxis when used in patients with MM.[6,13]

The addition of thalidomide to chemotherapy also increases response rates (**Table 136-5**). Three randomized controlled trials evaluated the addition of thalidomide to MP in newly diagnosed MM.[30,31,32] Two of the three trials showed improvement in progression-free survival and overall survival with melphalan, prednisone, and thalidomide (MPT) compared with MP. The other trial demonstrated only an improvement in progression-free survival but not overall survival. Based on these results, MPT is an option for transplant-ineligible patients including older patients with MM.[13] Clinicians should be aware that the increased response rate of MPT is at the expense of higher rates of grades 3 and 4 toxicity, particularly VTE, peripheral neuropathy, and infection.[31,32]

Thalidomide dose correlates with response and toxicity. When thalidomide is combined with chemotherapy, thalidomide doses of 100 mg/day are associated with high CR rates.[30] Neuropathy is one of the important dose-limiting toxicities and may correlate with cumulative thalidomide doses. Thalidomide-induced neuropathy is usually, but not always, reversible and is associated with

demyelinating changes in peripheral neurons. About 10% to 20% of patients are unable to tolerate thalidomide with neuropathy being the toxicity most often associated with discontinuation of therapy.[6,32]

Other common toxicities associated with thalidomide include constipation, sedation, fatigue, and rash. Although these toxicities can be problematic, they rarely require discontinuation of thalidomide treatment and can be therapeutically managed. Stimulant laxatives can be used to prevent severe constipation. The severity of constipation and sedation declines over time in many patients.[33]

The rate of VTE with single-agent thalidomide is relatively low (< 5%) and may not exceed the baseline incidence for MM patients. For this reason, VTE prophylaxis is not recommended in patients receiving single-agent thalidomide.[33] When thalidomide is combined with dexamethasone or chemotherapy, the risk of thrombosis is elevated, with rates reported between 10% and 30%.[30,31,32] The underlying mechanism for thrombosis in these patients is unknown, however, appears to be multifactorial. The American Society of Clinical Oncology (ASCO) and the IMWG have guidelines for VTE prevention. The ASCO guidelines suggest that patients should receive prophylactic aspirin or low molecular weight heparin (LMWH), depending on VTE risk.[34] The IMWG guidelines include therapeutic doses of warfarin, fixed-dose warfarin, LMWH, or aspirin depending on the patient's risk for VTE.[35] A randomized trial has compared the use of fixed-dose warfarin (1.25 mg/day), aspirin (100 mg/day), or LMWH (enoxaparin 40 mg/day) in MM patients receiving thalidomide combinations. Fixed-dose warfarin and aspirin showed similar efficacy to LMWH based on a composite measure of VTE and cardiac events. However, when only grade 3 to 4 VTEs were evaluated, aspirin prophylaxis was similar to LMWH, but fixed-dose warfarin was inferior.[36] The evidence suggests low-dose aspirin is effective prophylaxis, but should be reserved for patients in whom LMWH is not feasible and in whom there is a low-to-moderate risk of developing VTE.[36]

Lenalidomide (Revlimid®)

5 Lenalidomide is a potent thalidomide analog and shares a similar mechanism of action to other IMiDs by targeting the microenvironment. Lenalidomide is commonly used, due to an improved toxicity profile compared with thalidomide. In phase I studies, patients with relapsed, refractory MM were found to have a maximum tolerated dose of lenalidomide of 25 mg/day, with this dose being the most commonly used dose in subsequent phase II and III studies.[37] Lenalidomide is typically used in combination with low-dose dexamethasone or MP in the treatment of MM. The drug may be used in transplant-eligible or -ineligible patients, but clinicians should be aware that multiple cycles of lenalidomide therapy may impair stem cells, possibly affecting stem cell collection.[13]

Lenalidomide was FDA approved in 2006 for the treatment of relapsed or refractory MM based on the results of two randomized controlled trials. In both trials, patients were randomized to receive a combination of either lenalidomide (25 mg/day on days 1- 21 of a 28-day cycle) and high-dose dexamethasone or an identical lenalidomide placebo and high-dose dexamethasone. In one trial, patients receiving lenalidomide and dexamethasone group had overall response and CR rates of 61% and 14%, respectively, compared with 20% and 0.6% in the dexamethasone alone group (P<0.001).[38]

These improved response rates translated into longer median overall survival time in the lenalidomide and dexamethasone group (29.6 vs 20.5 months). Similar results were reported in the second trial (**Table 136-5**).[39] Lenalidomide subsequently received FDA approval for the treatment of newly diagnosed patient with MM. In this setting, the doublet of lenalidomide and dexamethasone was compared with dexamethasone alone. The trial was halted when a planned interim analysis showed the combination to be more active than dexamethasone alone, with increased progression-free survival and overall response rate in the combination arm.[13]

The most appropriate dosing of dexamethasone with lenalidomide has also been evaluated. An open-label noninferiority phase III trial addressed this question in untreated patients with MM.[40] Patients were randomized to lenalidomide plus high-dose dexamethasone (40 mg on days 1-4, 9-12, and 17-20 of each 28 day cycle) compared with lenalidomide plus low-dose dexamethasone (40 mg/week). The trial reported a superior 2-year overall survival rate in the lenalidomide plus low-dose dexamethasone group (87% vs 75%) and found that lenalidomide with low-dose dexamethasone was associated with higher overall survival and less toxicity than lenalidomide with high-dose dexamethasone. This trial was halted after a second interim analysis and patients were allowed to cross-over to the low-dose arm.[40] Results showed that the lenalidomide plus high-dose dexamethasone arm had a 26% incidence of VTE compared to a 12% rate in those randomized to the lenalidomide plus low-dose dexamethasone arm.[40] The improved survival in the low-dose dexamethasone arm is likely related to lower mortality from adverse events, particularly VTE. Deaths in the high-dose dexamethasone group usually occurred in the first 4 months and in elderly patients. The low risk of VTE in the lenalidomide plus low-dose dexamethasone arm may allow for VTE prophylaxis with low-dose aspirin, LWMH, or warfarin as needed.[40] Lenalidomide plus dexamethasone is considered a category 1 NCCN recommendation for the initial treatment of MM patients regardless of transplant eligibility (see Fig. 136-2).[13]

Lenalidomide is also commonly added to bortezomib-based regimens and chemotherapy. The triplet of bortezomib, lenalidomide, and dexamethasone has demonstrated activity in newly diagnosed and refractory or relapsed MM. It is an option for transplant-eligible MM patients, with ongoing studies to determine its role in this setting (see Fig. 136-2).[13] The triplet regimen of melphalan, prednisone, and lenalidomide (MPL) has been studied in transplant-ineligible patients. In a recent study, MPL was compared to MPT in newly diagnosed patients with MM. No differences in survival and response rates were observed, but MPT was associated with more grade 3 or higher overall toxicity (73% vs 58%; P=0.007).[41] Along with MPT, MPL is recognized by the NCCN as a first-line option for transplant-ineligible patients.[13]

Lenalidomide is considered less toxic than thalidomide. Lenalidomide causes less neurotoxicity, somnolence, and constipation but more myelosuppression than thalidomide.[6] When used as part of combination therapy, the risk of VTE with lenalidomide is similar to that observed with thalidomide, and VTE prophylaxis is recommended.[3,34] Multiple cycles of lenalidomide impair stem cell mobilization.[13,24] IMWG recommends that transplant-eligible patients receiving lenalidomide have stem cells collected within the first four cycles of therapy.[13]

Pomalidomide (Pomalyst®)

5 Pomalidomide is the newest IMiD used in the treatment of myeloma. It is FDA approved in relapsed MM in patients who have received at least two prior therapies including lenalidomide and bortezomib. A phase II trial showed that the combination of pomalidomide with dexamethasone produced a good overall response rate (35%) in heavily pretreated relapsed and refractory MM.[13] The toxicity profile was reasonable and consisted mainly of manageable myelosuppression. Pomalidomide has also been evaluated in phase III trials. An open-label phase III trial compared pomalidomide and low-dose dexamethasone to pomalidomide and high-dose dexamethasone in relapsed or refractory MM. The primary endpoint of progression-free survival was longer in the low-dose dexamethasone arm compared with the high-dose dexamethasone combination (4 vs 1.9 months).[42] Thus, the combination of pomalidomide and dexamethasone is an option for relapsed and refractory MM.

Proteasome Inhibitors

Bortezomib (Velcade®)

Bortezomib was the first drug in the class of proteasome inhibitors. It is approved in newly diagnosed and relapsed or refractory MM. The mechanism of action is complex and involves inhibiting the proteasome and NF-*κB* activation. The proteasome is a protease complex responsible for degrading cytosolic proteins that are conjugated to ubiquitin. Ubiquitin is an 8.5-kD polypeptide that tags various proteins for destruction.[43] By reversibly binding to the chymotrypsin site in the catalytic core of the 26S proteasome, bortezomib inhibits the degradation of these targeted proteins.

As discussed earlier, NF-*κB* activity is increased in MM. In the cytosol, NF-*κB* is bound to and is inhibited by I*κB*. The proteasome degrades I*κB*. When the proteasome is inhibited with bortezomib, cytosolic concentrations of I*κB* remain high, and NF-*κB* is retained in the cytosol as an inactive complex. The resulting inhibition of the NF-*κB* signal leads to a reduction in cytokine production and growth inhibition of the MM clone. Other proteins involved in cell-cycle regulation and apoptotic signaling that may be affected by bortezomib include p53, JNK proteins, and caspase 3.[6,43]

Bortezomib was initially approved in 2003 under the FDA's accelerated approval process for relapsed or refractory MM in patients who had failed at least two prior therapies. The approval was based on a phase II trial in which refractory MM received 1.3 mg/m^2 of bortezomib twice weekly for 2 weeks followed by 1 week of rest. Patients received up to 8 cycles. The overall response rate was 35% (includes minor responses) with seven (3.6%) patients achieving a CR.[44] Subsequently, a large phase III study (Assessment of Proteasome Inhibition for Extending Remissions [APEX] trial) demonstrated that bortezomib had superior activity compared with high-dose dexamethasone in relapsed MM.[45] Bortezomib-treated patients had higher complete and partial response rates (38% vs 18%), longer median time-to-progression (6.2 vs 3.5 months), and improved 1-year overall survival (80% vs 66%) compared with patients receiving dexamethasone. The differences in each of these end points were statistically significant.[45] The results from this study led to expanded FDA approval in 2005 to include

patients who had relapsed after one therapy.

Combination therapy with bortezomib has shown promising results in relapsed MM. The combination of bortezomib and corticosteroids has reported CR and nCR rates ranging between 5% and 15%.[46] Bortezomib is often part of a three-drug combination and, in addition to dexamethasone, may include doxorubicin, melphalan, thalidomide, or lenalidomide. These regimens have reported CR and nCR rates of 10% to 50% in relapsed MM.[6,13,46]

Numerous studies have investigated bortezomib in newly diagnosed patients in both transplant-eligible and -ineligible patients (**Table 136-5**). The inclusion of bortezomib in three- or four-drug combinations produces CR and nCR rates of about 19% to 52% in newly diagnosed MM.[6] Commonly used regimens in the treatment of transplant-eligible patients include bortezomib-cyclophosphamide-dexamethasone, bortezomib-thalidomide-dexamethasone, and bortezomib-lenalidomide-dexamethasone.[13] Bortezomib is also part of a regimen known as MPB (melphalan, prednisone, and bortezomib) used in the treatment of transplant-ineligible patients. The most pivotal trial leading to FDA approval as front-line therapy was the VISTA (Velcade as Initial Standard Therapy in multiple myeloma) trial in which MPB was compared with MP. The overall response and CR rates, time-to-progression, and overall survival were significantly better in the MPB group.[13] An update of this study reported a continued survival benefit after 5 years of follow-up.[47] The NCCN guidelines recognize MPB as an option for transplant-ineligible patients.[13] A meta-analysis of phase III trials suggests that MPB may achieve better response rates, including higher CR and more rapid response than MPT. However, no overall survival and progression-free survival differences were demonstrated.[13] Bortezomib-based therapies may also be preferred in patients with higher risk disease. For example, bortezomib may be able to overcome certain cytogenetic abnormalities, including the t(4;14) translocation.[48]

Bortezomib can cause significant toxicity. The most common adverse effects are mild-to-moderate fatigue and gastrointestinal toxicities. Neuropathy occurs frequently and is the most common cause of discontinuation of therapy. Other important toxicities include thrombocytopenia, fever, neutropenia, and infection. An increased risk of shingles has been reported in bortezomib-treated patients, and the NCCN guidelines recommend that herpes zoster prophylaxis be considered.[13] Bortezomib-based therapy is an attractive option for those patients with renal dysfunction since renal dose modifications are not required. Unlike melphalan and lenalidomide, bortezomib does not affect stem cell mobilization.

Neurotoxicity is a concern with bortezomib. The neurotoxicity may be decreased with modifying the route of administration and dosing schedule of bortezomib. In a phase III trial in relapsed MM, therapeutic equivalence was found between intravenous and subcutaneous routes of administration.[49] In addition, subcutaneous administration offers the potential advantage of administration in patients without IV access, convenience and improved safety profile, particularly less peripheral neuropathy. Dose schedules have also been modified to decrease toxicity-related treatment delays. Once-weekly bortezomib has been compared with twice-weekly dosing with similar overall response rates demonstrated (93% vs 88%), respectively.[13] The once-weekly schedule was

associated with a reduced incidence of serious neuropathy and fewer dose reductions.[50]

Carfilzomib (Kyprolis®)

Carfilzomib is a second-generation, irreversible proteasome inhibitor approved for patients with relapsed and refractory disease. Its mechanism, higher selectivity for the chymotryptic site of the 20S proteasome, and toxicity profile are distinct compared to bortezomib.[51] The dosing schedule is also different than bortezomib. Carfilzomib is more potent, yet tolerable, with two consecutive daily doses. Collectively, clinical trials have generally adopted the administration schedule of days 1, 2, 8, 9, 15, and 16 of a 28-day cycles with carfilzomib, starting at 20 mg/m^2 IV over 2 to 10 minutes on the first cycle/week and increasing to 27 mg/m^2 or more afterward depending on tolerability.[13,51]

Carfilzomib may be used as a single-agent as well as in combination therapy. The single-agent activity of carfilzomib is based on an open-label phase II study of 266 patients with relapsed and refractory MM who had received a median of five previous therapies.[52] Patients received carfilzomib 20 mg/m^2 IV over 2 to 10 minutes twice weekly on 2 consecutive days with dexamethasone premedication for 3 of 4 weeks in cycle 1 and then 27 mg/m^2 in subsequent cycles until disease progression, unacceptable toxicity, or completion of a maximum of 12 cycles. The primary endpoint of overall response rate (≥PR) was 23.7%, and the median duration of response was 7.8 months (95% confidence interval [CI] 5.6-9.2 months). In patients who were refractory or intolerant to both bortezomib and lenalidomide, 37% obtained clinical benefit. In patients refractory to both bortezomib and lenalidomide, the overall response rate (≥PR) was 15.4%. Moreover, unfavorable cytogenetic characteristics did not appear to adversely impact response rates. The median overall survival was 15.6 months compared with the median of 9 months typically seen in this setting.[52]

The activity of carfilzomib in combination regimens as first-line treatment is impressive. Two phase II trials have evaluated carfilzomib in combination with lenalidomide and low-dose dexamethasone and an additional trial has examined carfilzomib with cyclophosphamide and dexamethasone. The overall response rate (VGPR or higher) reported in these trials ranges from 74% to 88%.[13,53] The responses were rapid and increased in depth with additional cycles of therapy. The three-drug regimen containing lenalidomide did not adversely affect stem cell collection, but was associated with peripheral neuropathy, which was predominately grade 1 or 2 and observed in 23% of patients.[53] More data are required before carfilzomib-containing regimens are recommended for first-line therapy. The Endurance trial is currently comparing bortezomib-lenalidomide-dexamethasone versus carfilzomib-lenalidomide-dexamethasone.

Numerous trials of carfilzomib in relapsed myeloma are ongoing. The results from a recent interim analysis showed that the addition of carfilzomib to a lenalidomide-dexamethasone backbone improved progression-free survival (26.3 vs 17.6 months) and health-related qualify of life without any change in adverse effects.[51] Additional trials are examining the role of carfilzomib monotherapy compared with other regimens.

The most mature safety data for carfilzomib come from the compiled results of four phase II

studies.[54] The most frequently reported adverse events included fatigue (55%), anemia (47%), nausea (45%), thrombocytopenia (36%), dyspnea (35%), diarrhea (33%), and pyrexia (30%). The most common grade 3 or greater adverse events were thrombocytopenia (23%), anemia (22%), lymphopenia (18%), pneumonia (11%), and neutropenia (10%). Most of these events were manageable. Peripheral neuropathy appears to be minimal with grade 3 or higher neuropathy reported in less than 1% in clinical trials.

Ixazomib (Ninlaro®)

Ixazomib is the first oral proteasome inhibitor approved for the treatment of MM. It is a once-weekly medication that may be used as second-line therapy in combination with lenalidomide and dexamethasone. The approval is based on the TOURMALINE-MM1 trial which showed the addition of ixazomib to lenalidomide and dexamethasone extended progression-free survival in patients with relapsed or refractory MM compared with lenalidomide and dexamethasone alone (20.6 vs 14.7 months; HR 0.742; *P*=0.012). The safety profile was similar to the individual agents and included neutropenia, anemia, thrombocytopenia, pneumonia, diarrhea, cutaneous rash, and peripheral neuropathy. The approval of ixazomib is exciting because it allows for an orally administered triple-drug combination in the management of MM. Current studies are examining the role of ixazomib in other MM settings including induction and maintenance therapy.[55]

Monoclonal Antibodies

Two monoclonal antibodies have been recently FDA approved for the treatment of relapsed and refractory MM. Daratumumab (Darzalex®) is an IgG1-κ fully human monoclonal antibody that targets CD38, a glycoprotein highly expressed on MM cells. Accelerated FDA approval was granted after two open-label phase II trials of daratumumab showed single-agent activity (overall response rates of 29% and 36%).[57] Elotuzumab (Empliciti®) is another monoclonal antibody that is directed against signaling lymphocyte activation molecule family 7 (SLAMF7). Elotuzumab was evaluated in a phase III trial in combination with lenalidomide and dexamethasone.[57] The elotuzumab combination demonstrated improved progression-free survival and a higher overall response rate compared to lenalidomide.

Panobinostat (Farydak®)

Inhibitors of histone deacetylase enzymes such as panobinostat and vorinostat have shown activity in MM.[13] Panobinostat was evaluated in a recent phase III trial. Patients with refractory or relapsed MM who had received prior therapy with an IMiD and bortezomib were randomized to receive bortezomib, dexamethasone, and panobinostat or bortezomib, dexamethasone, and placebo.[56] The trial enrolled 768 patients and the primary endpoint of progression-free survival was statistically improved by 3.91 months (11.99 vs 8.08 months). No overall survival data were reported. There were serious adverse effects noted including thrombocytopenia, diarrhea, fatigue, and peripheral neuropathy. This trial led to the FDA approval of panobinostat in combination with bortezomib and dexamethasone in patients with refractory or relapsed MM.

Drugs in Development

There are numerous drugs in development for MM that target the MM microenvironment. Combination therapy incorporating traditional chemotherapeutic agents such as bendamustine are currently in clinical trials.[13] In addition, therapies that activate the immune system are also being explored. ImMucin is a 21-mer cancer vaccine that has demonstrated activity in a phase I/II trial.[58] The vaccine targets the mucin 1, cell surface associated (MUC1) glycoprotein domain, which increases the bodies T cells and antibody response. The trial administered ImMucin along with human granulocyte-macrophage colony-stimulating factor to 15 MUC-1 positive patients with MM and found the vaccine to be well tolerated with 11 patients having stable disease or improvement. For this reason, ImMucin was granted orphan drug designation by the FDA for the treatment of MM.

Initial Therapy

Initial therapy is guided by the NCCN, IMWG, and mSMART recommendations.[13,18,35] These recommendations are based on transplant eligibility (see Fig. 136-2). In patients ineligible for autologous HSCT, thalidomide, lenalidomide, or bortezomib is often added to MP.[13,18,20,21,50] Bortezomib-containing regimens (ie, MPB) may be particularly useful in MM patients with high-risk cytogenetics (t(4;14), 17p-). Lenalidomide plus low-dose dexamethasonse is also an option. The preferred combination is currently unclear and will require randomized controlled comparisons of these combinations. Carfilzomib-based therapy has an important role in heavily pretreated refractory MM and is being evaluated in ongoing phase III trials as induction therapy for newly diagnosed MM patients.

If autologous HSCT is planned after induction therapy, melphalan should be avoided, and thalidomide, bortezomib, or lenalidomide can be added to dexamethasone or VAD-like chemotherapy.[13,20,21,50] The NCCN guidelines list several induction therapy options (see Fig. 136-2). Because there is no standard induction regimen, clinicians can select from a wide range of possible induction regimens.[13] Many clinicians recommend lenalidomide or bortezomib and dexamethasone as two-drug induction regimens or bortezomib, dexamethasone, and either cyclophosphamide, doxorubicin, or lenalidomide as three-drug regimens for patients who are autologous HSCT candidates.[20,21,50]

Some clinicians may choose therapies based on risk using the mSMART model.[18] Bortezomib-containing induction regimens are often utilized in patients with high-risk cytogenetics which is reflected in the mSMART model (see Fig. 136-2).[18] In this approach, high-risk patients receive the combination of bortezomib, lenalidomide, and dexamethasone as induction therapy. Intermediate- and standard-risk patients receive the combination of bortezomib, cyclophosphamide, and dexamethasone or lenalidomide and low-dose dexamethasone. These regimens are continued in transplant-eligible patients for four cycles then followed by transplant, but transplant can be delayed depending on patient preference. Transplant-ineligible patients will receive therapy for about 1 year and then possibly maintenance therapy.[18]

Clinical Controversy…

Novel agents, such as thalidomide, bortezomib, and lenalidomide, are routinely used in combination with dexamethasone or chemotherapy as induction therapy. There is no standard induction therapy, and decisions are made based on physician preference and individual characteristics of the patient. Some experts recommend a risk-adapted approach that tailors the treatment based on cytogenetics and gene expression profiling.

Autologous Hematopoietic Stem Cell Transplantation

Although MM is a chemosensitive tumor with significant response rates after treatment with conventional chemotherapy, response durations have been short. In an attempt to improve outcomes with chemotherapy, high-dose chemotherapy regimens with autologous stem cell support have been used after initial induction therapy. The intent of the induction therapy before transplant is to reduce tumor burden. With newer treatment regimens being used for induction, higher rates of quality responses (CR, VGPR, nCR) can be obtained. Recent data suggest that obtaining quality responses during induction improves the outcomes associated with autologous HSCT.[59]

7 Two pivotal, randomized, controlled trials have evaluated the role of high-dose chemotherapy followed by autologous HSCT. In these trials, previously untreated patients were randomized to induction therapy alone versus the same induction therapy followed by high-dose chemotherapy and autologous HSCT. In 1996, the Intergroupe Francophone du Myelome (IFM) reported results of a trial demonstrating a survival advantage for high-dose chemotherapy with autologous HSCT compared with conventional chemotherapy.[60] Since then, six other trials have compared autologous HSCT to conventional chemotherapy.[61,62,63,64] Four of the six trials showed improved progression-free survival, while three showed an increase in overall survival associated with the autologous transplant arms. It is worth noting that only one of these trials used newer myeloma induction regimens. The other trials used induction regimens that are rarely used in the modern era of therapy. Palumbo et al. evaluated an induction regimen of lenalidomide and dexamethasone followed by either chemotherapy (melphalan/prednisone/lenalidomide) or tandem melphalan-based autologous transplants.[64] Results of this trial showed a progression-free survival and overall survival benefit for the autologous transplant arm. Based on all available data, guidelines from the American Society of Blood and Marrow Transplantation (ASBMT) support high-dose chemotherapy and autologous HSCT as a level A recommendation.[65]

Induction regimens containing at least one of the novel agents may make a significant difference in response and survival outcomes after autologous HSCT.[66] A randomized phase III trial performed by the French group compared the combination of bortezomib and dexamethasone to VAD as induction before autologous HSCT.[67] Patients were randomized to one of four treatment arms, which included either bortezomib plus dexamethasone or VAD as induction therapy. All arms underwent autologous HSCT with melphalan preparation (200 mg/m^2). Postinduction CR and nCR rates were 15% in the bortezomib-containing arms compared to 6% in those receiving VAD. Progression-free survival was superior in the patients in whom autologous HSCT was preceded by bortezomib plus dexamethasone induction. Two other studies that used bortezomib-based induction before autologous HSCT showed similar benefit.[66]

The optimal timing of autologous HSCT (early vs late) in MM was investigated in three trials. In a landmark trial, patients were randomized to early (within 12 months of diagnosis, n = 91) or late transplantation (>12 months after diagnosis, n = 94), and no significant difference in 5-year overall survival was observed between the groups.[68] Event-free survival, however, was significantly longer in the early transplantation group (39 months vs 13 months). In an analysis that factors in the time without symptoms, treatment, or treatment toxicity (TWisTT), patients receiving early transplantation had a longer time in a state associated with a good quality of life (27.8 vs 22.3 months). The results of this study supported early autologous HSCT because of its effects on event-free survival and quality of life. Since then, two retrospective studies comparing early versus delayed autologous HSCT have been published.[69,70] These studies included MM patients who received either lenalidomide or thalidomide-based induction regimen, or another novel-therapy based induction regimens. Both trials demonstrated similar time-to-progression and overall survival in the early (within 12 months) and delayed transplant groups. The results of these two retrospective evaluations may support the idea that, in the setting of novel therapy, delaying transplant may be feasible, but the lack of rigorous, prospective, randomized data prevents the uniform recommendation to delay transplant. Enrollment in clinical trials is highly recommended for most patients when evaluating the appropriate timing of stem cell transplantation in MM.[13]

A specialized form of autologous HSCT, tandem transplantation, involves the use of two separate autologous HSCT procedures separated by a rest period of several months. It was theorized that this more intensive approach would lead to improvements in therapeutic outcomes. Since the initial evaluation showing a benefit to the tandem transplant approach, a number of trials have investigated this approach to therapy. Two large meta-analyses evaluated single versus tandem autologous HSCT in the setting of MM.[71,72] Combined, these meta-analyses included nine individual trials in their evaluations. Both analyses concluded that the use of tandem autologous HSCT was associated with an improvement in response rate but did not result in improvements in event-free survival or overall survival. Further, it was noted that the improvement in response rates may have come at the expense of a significant increase in transplant-associated mortality with the use of tandem transplantation.

The primary conclusion from the current data on autologous HSCT as consolidation therapy in MM is that it should be used in younger patients with good performance status. Before transplant, all patients should receive induction therapy to reduce tumor burden. Because of higher transplant-related mortality, a second autologous HSCT is not currently recommended for patients with a diagnosis of MM. There is controversy surrounding the potential value of upfront autologous HSCT in an era of novel induction therapy. Some experts recommend a risk-adapted approach to treatment that included autologous HSCT in the algorithm. For example, the Mayo Clinic offers autologous HSCT to transplant-eligible intermediate- and high-risk patients after bortezomib-based induction therapy. Standard-risk patients are given the option of autologous HSCT followed by maintenance therapy or induction followed by maintenance therapy.[18]

Maintenance Therapy

8 Even with the advances in induction therapy and autologous HSCT, most patients eventually progress within 3 to 5 years, suggesting that effective maintenance therapy is needed to control or

delay disease progression. The International Myeloma Working Group has published a consensus document on maintenance therapy in MM.[73]

Historically, variable efficacy and high toxicities have been reported with interferon-α (IFN-α) and dexamethasone maintenance, and neither drug can be recommended outside of a clinical trial.[23] IFN-α at one time was considered to be the maintenance drug of choice after autologous HSCT based on data from a randomized trial showing superior progression-free survival and overall survival following autologous HSCT.[74] A meta-analysis supports the benefit of IFN-α maintenance, but the benefit is limited by high toxicity and intolerance.[75] A randomized trial conducted by the Southwest Oncology Group evaluated the benefit of prednisone maintenance therapy in 125 patients.[76] Patients who received high-dose steroids had significantly longer progression-free survival and overall survival at the expense of high toxicity. Although IFN-α or corticosteroid maintenance has not been widely adopted because of toxicity profile, these therapies served as proof of principle for maintenance therapy and led to trials evaluating thalidomide, lenalidomide, and bortezomib in this setting.

Thalidomide has been studied as maintenance after autologous HSCT. Six trials have evaluated the role of thalidomide maintenance therapy.[21] In all six trials, treatment with thalidomide was associated with improvements in overall response rate, progression-free survival, and event-free survival. Overall survival was improved in three of the six trials.[21] Toxicity assessments showed that patients receiving thalidomide experienced significantly higher rates of clinically significant toxicities, leading to discontinuation of maintenance therapy in a large number of patients. Of note, three of these studies found that in patients who relapsed after transplant, survival after relapse was shorter if they had received prior thalidomide therapy. Additionally, follow up from the MRC Myeloma IX trial demonstrated that in patients with adverse-risk cytogenetics, use of maintenance thalidomide resulted in shorter overall survival.[77]

Overall, the evidence demonstrates that thalidomide maintenance significantly reduces disease progression and prolongs event-free survival, but the effect on overall survival is unclear. The toxicities associated with thalidomide also make it a less than optimal choice in the maintenance setting.

Lenalidomide has largely replaced thalidomide as maintenance therapy because of its more favorable toxicity profile. Two pivotal, randomized phase III trials have investigated the use of lenalidomide maintenance after autologous HSCT.[78] In the CALGB 100104 study, 460 patients with myeloma underwent autologous HSCT, after which subjects were randomized to receive placebo or lenalidomide maintenance. Interim analysis of the data showed significant improvement in time-to-progression in the lenalidomide arm, which led to the study being unblinded. Upon unblinding, 86 of 128 patients receiving placebo crossed over to active treatment with lenalidomide. Despite this large crossover, time-to-progression and overall survival were still improved in the lenalidomide group. In the IFM-2005 trial, patients after autologous HSCT received two cycles of lenalidomide consolidation, followed by randomization to either further lenalidomide maintenance or placebo. In this trial, lenalidomide treatment was associated with an improvement in progression-free survival, but overall survival was similar between groups.[79,80] One unique adverse effect noted in these trials was second

primary malignancy, including solid tumors, hematologic malignancies, and non-melanoma skin cancers, associated with lenalidomide treatment. In both trials, these second malignancies occurred at significantly higher rate compared to placebo or control arms. Based on the data, the FDA issued a safety announcement to be added to the warning section of the lenalidomide drug labeling, detailing this increased risk. Given the risk, some practitioners have advocated limiting the use of maintenance lenalidomide to 2 years after transplant in order to minimize risk.[78]

Bortezomib maintenance after autologous HSCT has been evaluated in three separate studies.[20,21] Unfortunately, there is significant variability in the regimens used in these studies, and most included bortezomib in both the induction and maintenance setting, making it difficult to clearly define the clinical benefit of bortezomib in the maintenance setting. In the largest of these trials, 827 patients with newly diagnosed myeloma were randomized to receive induction therapy with vincristine/doxorubicin/dexamethasone (VAD) or bortezomib/doxorubicin/dexamethasone (PAD) followed by autologous HSCT.[81] Maintenance for the VAD group consisted of thalidomide, while maintenance for the PAD group consisted of bortezomib. After 2 years of maintenance, CR rates and progression-free survival were improved in the PAD group. Twelve months after randomization, progression-free survival and overall survival were improved for the PAD arm. Although data supports the activity of bortezomib, the exact role, dose, schedule, and duration of therapy remains unclear.

Given the available data, NCCN and ASBMT do not recommend the use of dexamethasone or IFN-α in the maintenance setting.[13,65] Both thalidomide and lenalidomide are recommended maintenance agents by both NCCN and ASBMT (category 1, grade A). ASBMT guidelines note that in most cases, lenalidomide is the preferred agent. Bortezomib is also a feasible maintenance option, though data are limited. NCCN lists bortezomib as a maintenance option with a category 2A recommendation. ASBMT guidelines identify bortezomib as a grade D recommendation for maintenance therapy, with potential utility in those with cytogenetic high risk disease. The decision to use any of these agents in the maintenance setting must include careful consideration of the benefits and risks.

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic HSCT uses a stem cell source other than the patient and is therefore a transplant across immunologic barriers. Unlike autologous HSCT, which is simply a method of increasing the dose intensity of chemotherapy, allogeneic HSCT is a form of immune therapy. The interest in allogeneic transplantation for MM exists from the notion of using a disease-free stem cell source which may potentially offer longer disease control and possible cure. The major posttransplant complications associated with allogeneic transplant are acute and chronic graft-versus-host disease (GVHD). GVHD may be accompanied by graft-versus-myeloma effect. The graft-versus-myeloma effect, which is mediated by antitumor effector cells from the GVHD reaction, reduces relapse risk and may offer the patient the best chance for long-term disease-free survival.[82]

Myeloablative allogeneic HSCT has traditionally been associated with a high rate of morbidity and mortality, between 20 and 50%.[83] Historically, allogeneic transplant has been used after patients have received and progressed after an autologous HSCT. Several trials have compared tandem autologous

transplants to autologous followed by allogeneic stem cell transplant, although there is wide variability in trial design patient selection, and protocols for the prevention and treatment of GVHD).[65] In all trials to date, there have been no consistent findings of improvements in overall survival or progression-free survival. Meta-analyses have shown that the use of allogeneic HSCT may confer a higher CR rate, but this comes at the cost of a higher rate of transplant-related mortality.[84,85]

Allogeneic HSCT may have a role in the management of patients with high risk disease. Ongoing clinical trials are evaluating the role of allogeneic HSCT in patients with MM who have high risk cytogenetic characteristics, who are likely to either respond poorly to upfront therapy or who relapse quickly after upfront therapy or autologous HSCT. There is increasing interest in the use of reduced intensity conditioning regimens. With the current available data, upfront myeloablative allogeneic HSCT is not routinely recommended.

Supportive Care

Bone-Modifying Agents

9 Along with anti-MM therapy, supportive care measures are aggressively used to stabilize skeletal abnormalities. Patients with MM have a high rate of bone involvement of their disease. The mechanism of MM-associated bone disease is thought to be mediated through a number of pathways, including IL-6, IL-1, and TNF-α, but the most targeted pathway is that involving receptor activator factor kappa B ligand (RANK-L) and osteoprotegerin (OPG).[16] In normal bone, RANK-L and OPG are both produced by osteoblasts. RANK-L binds to RANK receptors on osteoclasts, to stimulate bone resorption, and to OPG, a "decoy receptor," to inhibit bone resorption and stimulate bone formation. A balance between RANK-L and OPG is the basis for normal bone remodeling. In MM, an imbalance in normal bone homeostasis leads to increased osteoclast activity and the formation of osteolytic bone lesions which can lead to clinically significant skeletal-related events, including fracture, hypercalcemia, and bone pain.

Bone-modifying agents are frequently used in the treatment of bone-related complications associated with MM. Bisphosphonates are the most studied and used of these agents. Bisphosphonates bind to crystalline calcium in the bone, and are then phagocytized by osteoclasts, leading to osteoclast apoptosis.[86,87] In addition to osteoclast inhibition, bisphosphonates may also promote apoptosis in MM cells. This effect may result from the inhibition of the mevalonic acid pathway, which produces several molecules required for growth of the MM clone.[88] In addition, other potential antimyeloma effects of bisphosphonates may include modifying the cytokine microenvironment, inhibiting the adhesion of MM cells to bone marrow matrix cells, and inhibiting angiogenesis.[89] Although it is possible that bisphosphonates have an antimyeloma effect, there is little direct clinical evidence to support this activity.

The use of bisphosphonates in MM is based on the results of several large, randomized, controlled trials. In the first published study of pamidronate in myeloma, the drug was compared with placebo in a group of MM patients undergoing their first or second course of chemotherapy.[90] Several clinical

end points were found to be positively impacted by pamidronate therapy. The investigators reported that patients in the pamidronate group had a lower risk of skeletal-related events, lower pain scores, and improved quality of life. Importantly, a survival advantage was observed in the pamidronate-treated patients who had already received one or more courses of antimyeloma chemotherapy. This finding of improved survival in subgroup analysis is part of the circumstantial evidence to propose an antimyeloma effect for the bisphosphonates.

In 2003, the long-term follow-up results of a trial comparing zoledronic acid to pamidronate were published.[91] This trial included a total of 1,648 patients, although only 194 of these patients had a diagnosis of MM. Patients were randomized to receive zoledronic acid 8 mg (reduced to 4 mg), zoledronic acid 4 mg, or pamidronate 90 mg every 4 weeks for 24 months. With 25 months of follow-up, results showed that zoledronic acid reduced the proportion of patients overall with skeletal-related events, and decreased skeletal morbidity. These findings were less pronounced in the MM subgroup, where time to first skeletal-related event was similar amongst the groups.

Other randomized, controlled trials have been conducted, and the results of these trials were pooled in a recent systematic review.[92] Twenty randomized trials were included, which accounted for 6,692 MM patients. The risk of vertebral fractures and pain was significantly lower in the bisphosphonate-treated patients, and there was no difference between zoledronic acid or pamidronate. Given that the aggregate data in the systematic review agreed with the large controlled studies described earlier, the effect on vertebral fractures and pain are well-supported benefits of bisphosphonate therapy. An overall survival benefit associated with bisphosphonate use in MM patients remains unclear, but this meta-analysis reported that zoledronic acid improved overall survival compared with placebo.

Of interest, a study sponsored by the Myeloma Research Council was published in 2010, comparing zoledronic acid to clodronate in 1,960 patients with newly diagnosed MM. The results of this trial demonstrated a 16% reduction in mortality associated with zoledronic acid. Median overall survival was also significantly extended in the zoledronic acid arm. These results have provided further interest in the potential that bisphosphonate therapy may have some direct anti-myeloma activity, although the mechanism of this activity is largely unknown.[93]

Pamidronate and zoledronic acid, the two most commonly used bisphosphonates in MM, are usually well tolerated. Flu-like symptoms can occur after the administration of bisphosphonates. Acute renal impairment can occur with both agents and is related to both infusion time and dose. For zoledronic acid, the risk of acute renal impairment is higher with the 8 mg dose (vs 4 mg) and when the duration of infusion is 5 minutes (vs 15 minutes). Patients with moderate renal impairment (creatinine clearance: 30-60 mL/min [0.5-1.0 mL/s]) should have their dose of zoledronic acid adjusted downward by 25% (3 mg). This recommendation is included in the zoledronic acid package insert and is based on a greater renal toxicity in patients with preexisting renal impairment.[94] Randomized studies suggest that renal effects are similar between pamidronate and zoledronic acid, and patients on bisphosphonate therapy should have serum creatinine measured at baseline and then periodically thereafter.[95]

Osteonecrosis of the jaw (ONJ) is characterized by an area of exposed necrotic bone and often affects the mandible and the maxilla, but it can also affect the soft palate. Treatment of ONJ involves surgical

debridement and antimicrobial therapy and is often suboptimal.[96] The development of ONJ may be related to dental disease and tooth extraction and appears to be more common with IV bisphosphonates compared with oral, and more common with zoledronic acid than with pamidronate. The incidence of ONJ is unknown but may be as high as 10% in MM patients receiving zoledronic acid for extended periods of time. A strong recommendation on a preferred bisphosphonate based on ONJ incidence is likely not warranted. A recent meta-analysis found no difference between the bisphosphonate used and the risk of ONJ.[92]

Recommendations for the treatment of MM-related bone disease were published by the International Myeloma Working Group in 2013.[97] These guidelines recommend that bisphosphonate therapy be initiated in patients with or without bone lesions at diagnosis, and should continue for 1 to 2 years. After 2 years, patients who have achieved a CR or VGPR may consider discontinuing therapy because of the increased risk of ONJ. In addition to recommendations regarding bisphosphonate therapy, this publication also provides guidance for nonpharmacologic interventions to optimize bone health, including radiation, surgery, and kyphoplasty or vertebroplasty.

More recently, a new class of bone-modifying agents has emerged. Denosumab is a first-in class monoclonal antibody directed towards RANK-L. By binding to RANK-L, denosumab prevents binding of RANK-L to RANK, reducing osteoclast activity and allowing bone formation and osteoblast function to predominate. A phase III trial evaluated the efficacy and safety of denosumab compared to zoledronic acid in patients with MM and other cancers.[98] Initial results from this study showed denosumab to be noninferior to zoledronic acid in delaying time to first skeletal-related event. Rates of overall survival, disease progression, and ONJ were similar between groups. Of note, renal adverse effects occurred at a higher rate with zoledronic acid. Denosumab does not require dose adjustments for those with impaired renal function. In a subset analysis of patients with MM, the hazard ratio for death was 2.26 for patients receiving zoledronic acid. While the exact reason for this increase in mortality associated with denosumab is unknown, it is not recommended to routinely use denosumab in place of a bisphosphonate for patients with MM.

Clinical Controversy...

Although bisphosphonates are indicated in MM patients with bone disease, controversies surrounding the selection of the best agent and duration of therapy remain. Because of the risk of ONJ in MM patients, a cautious approach on bisphosphonate use is prudent. Some experts recommend that the duration of bisphosphonate therapy should be limited to 2 years. The preference of pamidronate over zoledronic acid is also controversial given that ONJ has also been reported with pamidronate, and the higher risk of ONJ with zoledronic acid is based on observational studies rather than head-to-head randomized comparisons.

Relapsed or Refractory Disease

10 A variety of factors must be considered when determining the most appropriate therapy for an individual who suffers relapses, including the type and duration of previous therapies, whether the patient received a transplant, presence or absence of adverse prognostic factors, toxicity of prior

therapies (eg, peripheral neuropathy), organ dysfunction (eg, renal impairment), and how much time has elapsed from initial response to relapse.[13,20,21] The same drugs used to treat MM initially can also be used as salvage therapy in patients who have relapsed. Patients who suffer relapse more than 6 months after initial induction therapy may have same induction therapy repeated.[13] The treatment of patients with relapsed or refractory MM can be with active agents in combination or single agents used sequentially. With the growing number of highly active agents, combination salvage therapy has become predominant. The NCCN has five category 1 recommendations and lists many other additional regimens.[13] Bortezomib is widely used in relapsed and refractory MM. One reason is that bortezomib has activity in patients with high-risk cytogenetics and high-risk patients are more likely to suffer relapse and require salvage therapy. Bortezomib may be used as a single agent or in combination therapy. The addition of dexamethasone, liposomal doxorubicin, panobinostat, lenalidomide, or thalidomide to patients who progress on single-agent bortezomib has been shown to improved response.[50] Interestingly, prior use of IMiDs or high-dose chemotherapy does not appear to affect bortezomib activity in relapsed MM. A phase III trial reported that bortezomib with or without dexamethasone had activity in relapsed or refractory disease despite prior thalidomide therapy or autologous HSCT.[99] Several IMiD combination regimens may also be used in relapsed and refractory MM. Lenalidomide is the IMiD most commonly utilized and has received a category 1 recommendation in relapsed or refractory patients when combined with dexamethasone alone or in combination with carfilzomib and dexamethasone.[13,50]

Treatment decisions for individual patients with relapsed disease may potentially be improved by taking into account patient-specific information such as the type of previous therapies, adverse cytogenetics, and end-organ dysfunction. For example, in patients with relapsed MM, combined bortezomib and liposomal doxorubicin has shown improved time-to-progression compared with bortezomib alone, including in patients who had received prior anthracyclines, lenalidomide, and thalidomide.[50] In contrast, treatment with lenalidomide and dexamethasone resulted in a significantly shorter time-to-progression in patients who had previously been treated with thalidomide compared with thalidomide-naïve patients.[38,39] Despite clear progress, most salvage therapies produce less than a 50% response rate, and new drugs and drug combinations are needed.

Questions remain on the optimal timing for autologous HSCT. For patients who are eligible for autologous HSCT and did not receive transplant as part of initial therapy, it is appropriate to offer autologous HSCT at first relapse. It is important to emphasize that although higher quality of life was realized when autologous HSCT was used as consolidation therapy, there was no difference in overall survival based on timing of transplant. The use of salvage autologous HSCT in patients who received a prior autologous HSCT seemed to be most beneficial in patients who had a response of greater than 24 months after initial autologous HSCT.[100] In patients with relapsed or refractory MM, autologous HSCT followed by nonmyeloablative allogeneic HSCT has potential benefit but at the expense of increased transplant-related mortality requiring treatment only be performed as part of a clinical protocol.

PERSONALIZED PHARMACOTHERAPY

Therapy for MM is personalized based on staging (eg, ISS), cytogenetics, gene expression profiling, performance status of the patient, age of the patient, and preexisting risk for drug toxicity. Personalized therapy has been driven by the explosion of new treatment options in MM and a better understanding of the MM biology and therapeutic targets. As described previously, the Mayo Clinic recommends a risk-adapted approach that tailors therapy based on risk category (eg, high, intermediate, or standard).

The use of a risk-adapted approach is reasonable in newly diagnosed patients (see Fig. 136-2). MM is currently not curable, and the disease will evolve as the disease progresses, which will require evaluation of biomarkers at times of relapse and progression to tailor therapy in each stage of the disease.

In addition to molecular characteristics of the tumor, a number of patient-related factors guide personalized treatment. For example, older patients with poor performance status would not be candidates for autologous HSCT. Patients with preexisting severe peripheral neuropathy would be less likely to receive thalidomide or bortezomib because of neurotoxicity. Patients with risk factors for VTE would be more likely to receive bortezomib-containing combinations because the risk of VTE is lower compared with thalidomide or lenalidomide combinations. Patients with preexisting renal failure may be less likely to receive lenalidomide because it requires dose adjustment based on renal function. With personalized therapy, patients will have the opportunity to benefit from the use of novel agents.

EVALUATION OF THERAPEUTIC OUTCOMES

As MM is currently an incurable disease, the goals of therapy are to prolong survival and to improve quality of life. Patients with asymptomatic MM are usually followed and not treated. Asymptomatic patients are assessed every 3 to 6 months for disease progression, which would then warrant therapy. Assessment involves measurement of M protein in blood and urine and laboratory tests that include complete blood count, serum creatinine, and calcium. Patients are treated as the disease produces symptoms. Disease response is defined by a decline in M protein. After completion of the initial course of therapy and once a response is obtained, patients should be monitored every 3 months. Bone surveys are performed yearly or as required because of changes in symptoms. Various other tests, including bone marrow biopsy, magnetic resonance imaging, and positron emission tomography, or computed tomography scan, are performed on an as-needed basis to evaluate disease status.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ASBMT	American Society of Bone Marrow Transplant
ASCO	American Society of Clinical Oncology
CI	confidence interval
CR	complete remission

I*κB*	inhibitory factor kappa B
IFN	interferon
IGF-1	insulin-like growth factor
IL	interleukin
IL-6	interleukin-6
IMiD	immunomodulatory drug
HSCT	hematopoietic stem cell transplantation
IFM	Intergroupe Francophone du Myelome
IgG	intact monoclonal immunoglobulin
ImiD	immunomodulatory drug
IMWG	International Myeloma Working Group
ISS	International Staging System
LMWH	low-molecular-weight heparin
MGUS	monoclonal gammopathy of undetermined significance
MM	multiple myeloma
MP	melphalan plus prednisone
MPB	melphalan, prednisone, and bortezomib
MPL	melphalan, prednisone, and lenalidomide
MPT	melphalan, prednisone, and thalidomide
mSMART	Mayo Stratification for Myeloma and Risk-adapted therapy
MUC-1	mucin-1
NCCN	National Comprehensive Cancer Network
NF-*κB*	nuclear factor kappa B
nCR	near complete response
ONJ	osteonecrosis of the jaw
OPG	osteoprotegerin
PAD	bortezomib/doxorubicin/dexamethasone
PR	partial response
RANK	receptor activator of nuclear factor-*κ*B
RANK-L	receptor for activation of NF-*κB* ligand
SFC	Serum free light chains
TNF-*α*	tumor necrosis factor-*α*
VAD	vincristine, doxorubicin, and dexamethasone
VEGF	vascular endothelial growth factor
VGPR	very good partial response
VTE	venous thromboembolism

Chapter e137: Myelodysplastic Syndromes

FIGURE e137-1

Kristen B. McCullough; Julianna A. Merten

INTRODUCTION

KEY CONCEPTS

- 1 Myelodysplastic syndromes (MDS) primarily affect elderly adults, with median age at diagnosis of 76 years.
- 2 MDS are associated with environmental, occupational, and therapeutic exposures to chemicals or radiation.
- 3 The clonal population of cells manifested as MDS results from enhanced self-renewal of a hematopoietic stem cell or acquisition of self-renewal in a progenitor cell, increased proliferative capacity in the abnormal clone, impaired cell differentiation, evasion of immune regulation, and antiapoptotic mechanisms in the disease-sustaining cell.
- 4 Most patients with MDS present with fatigue and lethargy or symptoms related to anemia-induced tissue hypoxia.
- 5 The prognosis of patients with MDS is variable. Overall survival time ranges from a few months to several years and is most accurately estimated with the International Prognostic Scoring System —Revised (IPSS-R).
- 6 The primary goal of therapy is hematologic improvement for lower-risk patients and alteration in the natural course of the disease for higher-risk patients. Palliation of symptoms and improvement in quality of life are goals of therapy for all patients.
- 7 Current guidelines recommend erythropoietin (EPO) or darbepoetin with or without filgrastim for management of anemia in patients with lower-risk MDS.
- 8 Hypomethylating agents are appropriate for patients with lower-risk MDS with clinically significant neutropenia or thrombocytopenia, patients with anemia who are unlikely to respond to or have not

responded to a trial of EPO or immunosuppressive therapy.

- 9 Antithymocyte globulin is appropriate treatment for patients with lower risk, HLA DR15 positive expressing MDS who have symptomatic anemia that is unlikely to respond to erythropoietic agents.
- 10 Lenalidomide is recommended for initial treatment of lower-risk 5q- syndrome accompanied by symptomatic anemia.
- 11 Allogeneic hematopoietic stem cell transplantation offers potentially curative therapy to patients with MDS who have a donor and are healthy enough for the procedure.

Myelodysplastic syndromes (MDS) are myeloid clonal, heterogeneous, stem cell disorders characterized by predominantly hypercellular bone marrows, anemia, thrombocytopenia, leukopenia, and an inherent predisposition toward evolution to acute myeloid leukemia (AML).[1,2] The diagnostic hallmark for MDS is the presence of bone marrow dysplasia in at least 10% of cells of a single myeloid lineage.[1] The clinical course of patients with MDS varies from a slowly progressing indolent disease to more aggressive disease characterized by excess bone marrow blasts and rapid progression to AML in up to 30% of cases.[3,4]

Our understanding of the molecular genetics behind MDS has advanced in recent years, but few targeted treatments have been approved in MDS. Aberrations in epigenetic regulator genes, spliceosome component pathways, DNA damage response genes, and genes regulating transcription factors have redefined the molecular landscape in MDS and several additional chromosomal abnormalities have been incorporated into prognostic models predicting survival and leukemic transformation.[5,6] Between 2004 and 2006, three medications (azacitidine, decitabine, and lenalidomide) were approved by the FDA for the treatment of MDS with both azacitidine and lenalidomide improving survival in MDS.[7,8] Despite progress in disease classification, identification of over 40 recurrently mutated genes, improvement in risk stratification, and development of new treatment options in the past two decades, the ability to provide patient specific, targeted therapy remains elusive.

EPIDEMIOLOGY

1 MDS primarily affect elderly adults, with a median age at diagnosis of 76 years and a slight male predominance, with an estimated male-to-female ratio of about 1.75 to 1.[9,10] An estimated 3 to 12 cases of MDS are diagnosed per 100,000 persons per year. The risk of MDS increases with age; in patients older than 65 to 70 years, an estimated 27 to 75 new cases occur per 100,000 persons per year.[10,11,12] The Surveillance, Epidemiology and End Results (SEER) Program estimates about 19,600 new cases of MDS are diagnosed in the United States each year.[10] Recent reports suggest that the incidence of MDS has been grossly underestimated, with analyses of Medicare claims databases indicating it could be as high as 45,000 per year.[12,13] Many experts predict that the incidence of MDS will increase as the population of the United States ages and clinicians become more aware of MDS.[9]

ETIOLOGY

2 The exact cause of MDS is unknown and is probably multifactorial. MDS have been associated with environmental, occupational, and therapeutic exposures to chemicals or radiation.[14,15] Environmental

exposure to agricultural chemicals has been associated with an increased risk of developing MDS.[14] MDS have also been linked in a dose-dependent relationship to ionizing radiation in atomic bomb survivors in Japan and have been reported in workers in the Chernobyl nuclear accident.[15,16] Occupational exposures to hair dyes, cereal dusts, exhaust gases, diesel fuel, and industrial solvents (including benzene and toluene) have been associated with development of MDS.[14,15] Individuals with a family history of a hematologic malignancy are at increased risk for developing MDS.[14,15] Modifiable risk factors for MDS include smoking and obesity.[17] Recent data suggest that chronic immune stimulation or therapy to manage infectious and autoimmune diseases increases the risk for development of MDS.[18]

About 10% to 15% of all cases of MDS are attributed to radiation, chemotherapy, or both and are termed *therapy-related MDS* (t-MDS).[19,20] Acute myeloid leukemia and MDS that arise after chemotherapy or radiation therapy for a primary neoplasm are considered together as therapy-related myeloid neoplasms (TR-MNs). Intensive chemotherapy regimens and improved survival after cancer treatment contribute to an increased incidence of TR-MNs, with a risk 4.7-fold higher than the general population.[20,21,22,23] As therapeutic modalities for different malignancies change over time, so has the risk for TR-MNs. An increased risk for TR-MNs has been observed in non-Hodgkin lymphoma patients, a decreased risk in multiple myeloma and ovarian cancer patients, and a newly observed risk in sarcoma, cervical, prostate, esophageal, endometrial, and possibly anal cancers.[23] The cancers with the highest standardized incidence ratio for development of TR-MNs include soft tissue and osteosarcoma, Hodgkin lymphoma, small cell lung cancer, and multiple myeloma.[23] t-MDS have an increased likelihood of progression to AML and a poorer prognosis than de novo MDS.[20] Chromosomal abnormalities are found in about 90% of t-MDS compared with 50% to 60% of de novo MDS.[24,25,26]

The risk for developing t-MDS increases with age, higher doses of chemotherapy or radiation, longer duration of exposure, and exposure to both chemotherapy and radiation.[24] Several chemotherapeutic agents have been associated with t-MDS (**Table e137-1**). The contribution of a specific agent is difficult to assess because patients are usually exposed to multiple agents, often in combination with radiation. The most frequently reported classes of chemotherapeutic agents associated with t-MDS are alkylating agents and topoisomerase II inhibitors.[19,24,26]

TABLE e137-1 Therapies Associated with Therapy-Related Myelodysplastic Syndrome

Alkylating Agents	Topoisomerase II Inhibitors	Miscellaneous
Busulfan	Dactinomycin	Azathioprine
Carmustine	Daunorubicin	Carboplatin
Chlorambucil	Doxorubicin	Cladribine
Cyclophosphamide	Epirubicin	Cisplatin
Dacarbazine	Etoposide	Docetaxel
Ifosfamide	Idarubicin	Fludarabine
Lomustine	Mitoxantrone	Iodine-131 tositumomab
Mechlorethamine	Teniposide	Mercaptopurine
Melphalan		Methotrexate
Mitomycin		Mycophenolate
Procarbazine		Paclitaxel

Alkylating Agents	Topoisomerase II Inhibitors	Miscellaneous
Temozolomide		Vinblastine
Thiotepa		Vincristine
		Vindesine
		Yttrium-90 ibritumomab tiuxetan
		Radiation therapy

Data from Czader and Orazi.[19] *and Bueso-Ramos and Kanagal-Shamanna.*[22]

The role of alkylating agents in the development of t-MDS is well established in patients with cancer and those receiving high cumulative doses of alkylating agents for autoimmune disorders such as rheumatoid arthritis.[19,26] The latency period between exposure to alkylating agents and the development of t-MDS is about 4 to 7 years.[19] Characteristic chromosomal abnormalities in t-MDS associated with alkylating agents include deletions on chromosome 5 and chromosome 7.[19]

Topoisomerase II inhibitors, including the epipodophyllotoxins (etoposide and teniposide), anthracyclines (daunorubicin, doxorubicin, epirubicin, idarubicin), and the anthracenedione mitoxantrone, are also associated with t-MDS. t-MDS associated with topoisomerase II inhibitors typically occur a median of 2 to 3 years after exposure, and patients are more likely to present with AML at diagnosis.[19] Chromosomal abnormalities often found in patients with t-MDS associated with topoisomerase II inhibitors include balanced translocations involving the *MLL* gene 11q23 and 21q22.[19]

Radioimmunoconjugates, including ibritumomab tiuxetan and iodine-131 tositumomab, are monoclonal antibodies linked to radioactive isotopes. Radiation is delivered to the antibody-bound targeted cell and to neighboring cells through a "cross-fire" effect. TR-MNs are reported to occur in 5% to 10% of patients exposed to iodine-131 tositumomab and in 1% to 5% of patients exposed to ibritumomab tiuxetan.[27,28,29,30,31] About 8% of patients receiving myeloablative doses of ibritumomab tiuxetan as part of conditioning regimen before hematopoietic stem cell transplantation (HSCT) developed TR-MNs, similar to the rate in patients receiving myeloablative chemotherapy-based conditioning regimens.[32] Both agents are used to treat non-Hodgkin lymphoma, a patient population likely to receive other therapies associated with t-MDS, including alkylating agents, anthracyclines, and radiation. Therefore, it is difficult to determine the additional risk for TR-MNs due solely to exposure to one of these agents.[27,29,31]

Granulocyte colony-stimulating factor (G-CSF) use during treatment of solid tumors and lymphoma in adults has been associated with an increased risk for t-MDS.[33] A systematic review of 25 randomized controlled trials comparing patients receiving filgrastim or lenograstim with placebo found an absolute risk increase of 0.41% for development of TR-MNs associated with use of a colony-stimulating factor.[33] The absolute risk of death was 3.4% lower in the group of patients randomized to a hematopoietic growth factor; the benefit was attributed to lower cancer-related mortality because of greater chemotherapy dose intensity. This systematic review indicates the administration of hematopoietic growth factors to prevent complications associated with febrile neutropenia outweighs the increased TR-MNs risk.[21] The risk of development of t-MDS may also be higher in patients with congenital neutropenia and aplastic anemia treated with long-term G-CSF.[19,34,35]

Patients undergoing autologous HSCT are at increased risk for development of t-MDS. Conditioning regimens given before HSCT usually include high doses of alkylating agents or etoposide, often in

combination with total-body irradiation. As many as 8% to 20% of patients with non-Hodgkin lymphoma treated with autologous HSCT will be diagnosed with t-MDS within 10 years of transplantation.[36,37,38] Risk factors for development of t-MDS after autologous HSCT include antecedent conventional chemotherapy, prior radiation therapy, low stem cell dose, older age at time of transplant, and use of total-body irradiation in the conditioning regimen.[36,37,39]

PATHOPHYSIOLOGY

Knowledge of normal hematopoiesis is needed to understand the pathophysiology of MDS (see Chapter e86 for a more detailed description of hematopoiesis). Progressive bone marrow failure is characteristic of patients with MDS and is the result of ineffective hematopoiesis. In addition to peripheral blood cytopenias, the terminally differentiated cells that are produced may have functional defects. Neutrophils may have reduced bactericidal and fungicidal activity despite a normal quantity of neutrophils.[40] Platelets may be normal in quantity but have impaired activation, secretion, and aggregation.[41] The diverse pathophysiology underlying MDS causes the heterogeneity in clinical presentation, pattern of disease progression, and response to therapy and has not been fully elucidated.[42] A multistep model for the pathogenesis of MDS has been proposed, and it is likely that the disease can arise via multiple different pathways.[1,14,42] The clonal population of cells manifested as MDS results from enhanced self-renewal of a hematopoietic stem cell or acquisition of self-renewal in a progenitor cell, increased proliferative capacity in the abnormal clone, impaired cell differentiation, evasion of immune regulation, and antiapoptotic mechanisms in the disease-sustaining cell.[42] The abnormal clone proliferates or evades apoptosis because of genomic instability and abnormalities in cytokines and the bone marrow stroma.[1,42] These changes create a dysplastic, clonal population of cells in a milieu unable to support normal hematopoiesis.

Bone Marrow Microenvironment

The myelodysplastic clone is associated with cellular dysfunction, including excess secretion of cytokines, defective differentiation, genomic instability, and reduced response to regulatory cytokines.[1] In contrast to the peripheral blood cytopenias characteristic of MDS, bone marrow cells often have a paradoxically high rate of cellular division and are generally normocellular or hypercellular for age.[43] Apoptosis, or programmed cell death, also is increased, leading to futile cycling of precursor cells and impaired production of mature peripheral blood cells.[14] Overproduction of proapoptotic and inflammatory cytokines and vascular endothelial growth factor may contribute to this process.[42] Bone marrow stromal cells from MDS patients show decreased ability to support normal hematopoietic cell function.[14]

Patients with MDS frequently have evidence of immune dysregulation, such as impaired immune surveillance and autoimmune reactions.[1] Cytopenias can be related to an autoimmune T-cell–mediated response. A subset of MDS patients characterized by younger age, refractory anemia of short duration, a hypocellular bone marrow, trisomy 8 as the sole cytogenetic abnormality, and expression of human leukocyte antigen (HLA) haplotype DR15 have a high likelihood of response to immunosuppressive therapy.[14,42] Cyclosporine and antithymocyte globulin may induce durable responses in this subgroup of patients, confirming the role of immune dysregulation.[1] Whether B cells and T cells are a part of the MDS clonal population or a secondary reaction after the development of the malignant clone is unclear.[14]

Genomic Instability

In the multistep model for development of MDS, one or more transformations occur that confer a growth advantage to the dysplastic cell, leading to the emergence of a clonal population.[42] No single inciting genetic alteration for the diagnosis of MDS has been identified.[44] Chromosomal abnormalities, most often genomic losses and gains, are detected by cytogenetic analysis in less than 50% of patients with de novo MDS and remain one of the strongest determinants of prognosis.[43,45] Multiple cytogenetic abnormalities that correlate with the clinical course of MDS were incorporated in the original International Prognostic Scoring System (IPSS) classification and prognostic assessment, including 5q or 20q deletions and chromosome 7 abnormalities.[3] The International Prognostic Scoring System–Revised [IPSS-R] includes several additional cytogenetic abnormalities, including trisomy 8 or 19, 12p or 11q deletions, and double abnormalities, that correlate with the clinical course of MDS.[6] Deletions on chromosome 5q occur in up to 12% of patients and are of particular interest because multiple genes involved in hematopoiesis are located there.[25] Additionally, MDS with 5q deletions as the sole genetic aberration are recognized as a distinct subtype of MDS with a favorable prognosis and a high likelihood of response to lenalidomide.[25,46]

Somatic mutations, identified by whole genome sequencing, are indicators of clonal hematopoiesis, a pathophysiologic driver of MDS.[47,48] These mutations are too minute for traditional metaphase cytogenetics, but preliminary analysis has demonstrated independent prognostic value for MDS.[5,45,49] Large MDS population studies identified at least one somatic mutation in over 90% of patients.[47,48] Unfortunately, several mutations lack specificity for MDS with overlap between myeloproliferative disorders, aplastic anemia, and chronic lymphocytic leukemia.[45] Thus, emerging data have the potential to shape the prognostic landscape for MDS and enhance practitioner ability to select effective therapy.[49] For instance, *TET2*, a tumor suppressor gene and one of the most frequently occurring somatic mutations in patients with a normal karyotype, occurs in 22% to 26% of MDS patients. A mutation in *TET2* is thought to contribute to leukemogenesis by altering passive DNA methylation and has been identified as a favorable prognostic factor, with improved response to azacitidine.[50] Several other genes have been correlated with adverse clinical features including bone marrow blast proportion and severe thrombocytopenia (*RUNX1, NRAS, TP53*), but no targeted pharmacotherapy is available for patients with MDS and those genetic aberrations and testing for these mutations remains investigational.[45,51]

Epigenetics

Several of the somatic mutations that contribute to MDS pathogenesis, regulate the expression of genes central to the neoplastic process. The term *epigenetics* refers to mechanisms that regulate the expression of DNA without affecting its sequence. Epigenetic changes, including DNA methylation (*TET2, DNMT3*) and histone modification (*ASXL1, EZH2*) among many others have been identified in numerous malignancies but are of particular importance in the context of MDS.[45,52]

DNA methylation is the best described and most common epigenetic marker. In the mammalian genome, only cytosine located 5′ to a guanosine (CpG) can be methylated (CpG pair). Clusters of CpG pairs, known as *CpG islands*, are near the promoter regions for many genes. These regions are unmethylated in normal cells, allowing for standard DNA expression to occur.[53] Increased methylation (hypermethylation) of *CpG* islands occurs via DNA methyltransferases and is associated with aberrant gene silencing, which may lead to further genetic instability and dysfunction of the cell cycle. Demethylation (hypomethylation), regulated by *TET2*, may lead to reexpression of previously silenced genes.[52,54] Hypermethylation and gene silencing have been identified in patients with MDS, and azacitidine and decitabine reverse this process.[54,55]

Histone modification is another significant epigenetic marker in MDS.[53] Histones coil with DNA to form tightly wound complexes called chromatin. Posttranslational modifications of histones, by acetylation, methylation and ubiquination, can alter the structure of chromatin creating opportunities for gene suppression or expression, depending on the structural change of the chromatin.[53] *ASXL1*, an epigenetic regulator of chromatin modification, has been identified as the third most commonly mutated gene in MDS, occurring in 15% to 25% of MDS patients and independently associated with worse overall survival.[53] Histone hypoacetylation has been documented in malignant cells and several histone deacetylase inhibitors have been studied in patients with MDS as monotherapy, in combination with hypomethylating agents, or with low-dose cytarabine in an attempt to promote histone acetylation and expression of previously suppressed tumor suppressor genes.[56,57,58,59]

CLASSIFICATION AND PROGNOSIS

Several classification systems and models for predicting risk in MDS have been developed. The French-American-British (FAB) classification established subgroups of MDS based on morphology of bone marrow aspirates and peripheral blood blast percentage. The FAB classification system was replaced in 2008 by the WHO classification system, which also incorporates whether dysplasia or cytopenias affect a single cell lineage or multiple myeloid cell lines and cytogenetics (**Table e137-2**).[60] A revision of the WHO classification was published in 2016 with changes to simplify classification and define the role of molecular genetic testing.[43]

TABLE e137-2 World Health Organization Classification of Myelodysplastic Syndromes

Classification	Blood	Bone Marrow
RCUD: RA; RN; RT	Unicytopenia or bicytopenia	Unilineage dysplasia: ≥10% of the cells in one myeloid lineage
	No or rare blasts (<1%)	<5% blasts
		<15% ringed sideroblasts
RARS	Anemia	≥15% ringed sideroblasts
	No blasts	Erythroid dysplasia only
	Cytopenia(s)	<5% blasts
RCMD	No or rare blasts (<1%)	Dysplasia in ≥10% of cells in ≥2 myeloid cell lines
	No Auer rods	<5% blasts
	Monocytes <1,000 cells/mm^3 (<1 × 10^9/L)	+15% ringed sideroblasts
		No Auer rods
RAEB-1	Cytopenia(s)	Unilineage or multilineage dysplasia
	<5% blasts	5%-9% blasts

Classification	Blood	Bone Marrow
RAEB-2	No Auer rods Monocytes <1,000 cells/mm^3 (<1 × 10^9/L) Cytopenia(s) 5%-19% blasts ±Auer rods Monocytes <1,000 cells/mm^3 (<1 × 10^9/L)	Unilineage or multilineage dysplasia ± Auer rods
MDS-U	Cytopenias <1% blasts	Unequivocal dysplasia in <10% of cells in one or more myeloid lineage when accompanied by a cytogenetic abnormality considered as presumptive evidence for a diagnosis of MDS <5% blasts
Myelodysplastic syndrome associated with isolated deletion of 5q	Anemia Usually normal or increased platelet count No or rare blasts (<1%)	Normal to increased megakaryocytes with hypolobated nuclei <5% blasts No Auer rods Isolated del(5q) cytogenetic abnormality
Childhood myelodysplastic syndrome (provisional entity: RCC)	Cytopenia(s) <2% blasts	<5% blasts Dysplasia in ≥10% of cells in ≥2 myeloid cell lines

MDS-U, Myelodysplastic syndrome, unclassified; RA, refractory anemia; RAEB-1, refractory anemia with excess blasts-1; RAEB-2, refractory anemia with excess blasts-2; RARS, refractory anemia with ringed sideroblasts; RCC, refractory cytopenia of childhood; RCMD, refractory cytopenia with multilineage dysplasia; RCUD, refractory cytopenia with unilineage dysplasia; RN, refractory neutropenia; RT, refractory thrombocytopenia.

Data from Vardiman et al.[60]

Models to predict overall survival and risk of transformation to AML continue to be developed and refined as new information about the genetic basis of MDS evolves. Based on an observational study of mostly untreated MDS patients, the IPSS was developed to identify factors that would predict progression of MDS.[3] Multivariate analyses identified four prognostic factors: cytogenetic abnormalities, percentage of bone marrow blasts, age, and number of cytopenias. Using these four factors, researchers were able to stratify patients into four risk groups that correlated with overall survival, which ranged from a few months to

several years (**Table e137-3**).

TABLE e137-3 International Prognostic Scoring System for Myelodysplastic Syndromes

	Score Value				
Prognostic Variable	**0**	**0.5**	**1**	**1.5**	**2**
Bone marrow blasts (%)	5	5-10	—	11-20	21-30
Karyotype	Good	Intermediate	Poor		
Cytopenia	0 or 1	2 or 3			

Cytopenia: Absolute neutrophil count <1,800 cells/mm^3 (<1.8 × 10^9/L)

Hemoglobin <10 g/dL (<100 g/L; 6.21 mmol/L)

Platelet count <100,000 cells/mm^3 (<100 × 10^9/L)

Karyotype: Good: normal, isolated 5q deletion, isolated 20q deletion, Y

Intermediate: any other abnormalities

Poor: trisomy 7, complex or >3

Score	**Risk Group**	**Median Survival (years)**
0	Low	5.7
0.5-1	Intermediate-1	3.5
1.5-2.0	Intermediate-2	1.2
≥2.5	High	0.4

Data from Greenberg et al.[3]

The IPSS-R was developed after analysis of more than 7,000 patients whose disease had not been treated with disease-altering therapy (**Table e137-4**).[6] This model differs from the IPSS in identifying five risk categories by incorporating different categories for marrow blast percentage value and depth of cytopenias, expanding the cytogenetic risk groups from three to five groups and including a number of less common cytogenetic abnormalities. Patient age, performance status, and serum ferritin and lactate dehydrogenase levels were additional significant predictors for survival but not for AML transformation. Recent reports have demonstrated that recurrent somatic gene mutations predict prognosis independent of the IPSS score, and their incorporation into a risk classification scheme does enhance the model.[5,44] About half of patients with MDS have normal cytogenetics. After the full spectrum of somatic mutations in MDS has been defined, optimal prognostic scoring systems will need to include relevant molecular features. The IPSS-R has demonstrated predictive value in patients with t-MDS and patients receiving disease modifying therapy.[51]

TABLE e137-4 International Prognostic Scoring System—Revised for Myelodysplastic Syndromes

Prognostic Variable	**0**	**0.5**	**1**	**1.5**	**2**	**3**	**4**
Cytogenetics[a]	Very good		Good		Intermediate	Poor	Very poor
Bone marrow blast (%)	≤2		>2-<5		5-10	>10	

Prognostic Variable	0	0.5	1	1.5	2	3	4
Hemoglobin (g/dL)	≥10 (≥100 g/L; ≥6.21 mmol/L)		8-<10 (80-<100 g/L; 4.97-<6.21 mmol/L)	<8 (<80 g/L; <4.97 mmol/L)			
Platelets (cells/mm^3)	≥100,000 (≥100 × 10^9/L)	50,000-<100,000 (50-<100 × 10^9/L)	<50,000 (<50 × 10^9/L)				
Absolute neutrophil count (cells/mm^3)	≥800 (≥0.8 × 10^9/L)	<800 (<0.8 × 10^9/L)					

[a]Karyotype: Very good: Y, del(11q).

Good: normal, del(5q), del(12p), del(20q), double including del(5q).

Intermediate: del(7q), +8, +19, i(17q), any other single or double independent clones.

Poor: 7, inv(3)/t(3q)/del(3q), double, including 7/del(7q); complex: three abnormalities.

Very poor: Complex: >3 abnormalities.

Score	Risk Group	Median Survival (years)
≤1.5	Very low	8.8
>1.5-3	Low	5.3
>3-4.5	Intermediate	3
>4.5-6	High	1.6
>6	Very high	0.8

Data from Greenberg et al.[6]

Currently, the FAB classification may be found in drug indication languages approved by regulatory agencies and some clinical trial inclusion or evaluation criteria.[62] The WHO criteria are used by pathologists to describe MDS and in both clinical trial and off-study management of patients with MDS. The IPSS is reflected in drug labeling, published clinical trials and some trials currently enrolling patients.[43] Recognizing other systems have value, the NCCN guidelines prefer the IPSS-R because of more accurate risk stratification compared with other models.[51]

CLINICAL PRESENTATION Myelodysplastic Syndromes General

- Patients with MDS may develop isolated anemia (hemoglobin less than 11 g/dL [less than 110 g/L; less than 6.83 mmol/L]), neutropenia (less than 1,500 cells/mm^3 [less than 1.5 × 10^9/L]), or thrombocytopenia (less than 100,000 cells/mm^3 [less than 100 × 10^9/L]) or multiple peripheral cytopenias.
- Patients may be asymptomatic, with cytopenia(s) discovered on complete blood count with differential.

Symptoms

- If symptomatic, the patient may report fatigue, lethargy, malaise, palpitations, dyspnea on exertion, exercise intolerance or other symptoms associated with hypoxia secondary to anemia.
- Patients may have symptoms of infection, including cough or dysuria.
- Patients may present with complaints of easy bruising or bleeding.

Signs

- Pallor, tachycardia, or tachypnea related to anemia.
- Fever, chills, rigors caused by infection and immune dysfunction.
- Petechiae, bruising, epistaxis, gingival bleeding, excessive vaginal bleeding, bruising, or hematuria caused by thrombocytopenia.

Laboratory Tests

- Complete blood count with differential.
- Anemia often is macrocytic or normocytic with a low reticulocyte index.
- Serum vitamin B_{12}, red blood cell (RBC) folate and copper levels.
- Testing for the human immunodeficiency virus (HIV).
- Serum thyroid-stimulating hormone.
- Serum EPO level.
- Serum ferritin, iron, and total iron-binding capacity.

Other Diagnostic Tests

- Bone marrow biopsy and aspirate: Morphologic examination, cytochemical staining, immunophenotyping, and cytogenetics (chromosome analysis).

Criteria for Diagnosis

- Stable cytopenia for at least 6 months (2 months if accompanied by a specific karyotype associated with MDS or bilineage dysplasia).
- Exclusion of other causes of cytopenia or dysplasia.
- One of the following:
    1. Dysplasia (more than 10% in one or more of three major bone marrow lineages)
    2. Blast cell count of 5% to 19% (0.05-0.19)
    3. Specific MDS-associated karyotype (eg, del(5q), del(20q), +8, or del(7q))

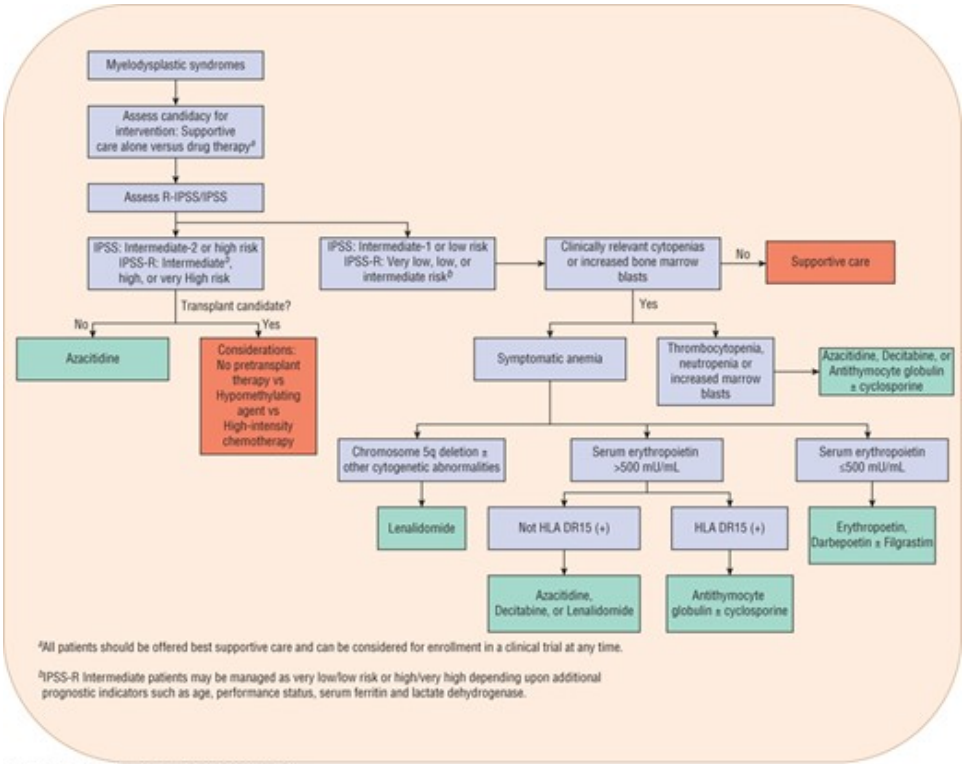
Oncology.[51]

TREATMENT

Treatment of MDS has rapidly evolved during the past two decades following discoveries in disease biology, introduction of new methods for predicting the natural history of the disease and response to a given therapy, and development of new treatment strategies (**Fig. e137-1**).

FIGURE e137-1

Myelodysplastic syndromes treatment algorithm. (HSCT, hematopoietic stem cell transplant; IPSS, International Prognostic Scoring System.)



Desired Outcomes

6 The goals of treatment vary with disease-specific factors, including the type of MDS; cytogenetics; risk of progression to AML and death; rate of disease progression; and patient factors, including age, organ function, performance status, and presence of symptoms related to myelodysplasia. The primary goal of therapy is hematologic improvement for lower-risk patients (IPSS low-, intermediate-1-risk or IPSS-R low, very low, and intermediate) and alteration in the natural course of the disease for higher-risk patients (IPSS intermediate-2 and high-risk or IPSS-R intermediate, high, and very high).[51] Additional therapeutic goals for all risk groups include symptom palliation and quality-of-life improvement. Lower-intensity treatment with a DNA hypomethylating agent or immunosuppressive therapy may improve overall survival, provide symptom palliation, and enhance quality of life without significant toxicity, in selected patients.[7,43,51] The only curative therapy for MDS is allogeneic HSCT, but most patients lack a suitable donor, are not healthy enough to undergo this intensive therapy, or may not be referred for HSCT because of advanced biologic age despite

adequate health and organ function.[63]

General Approach

Therapy for MDS is determined by symptoms, risk stratification for progression to AML or death, patient age and comorbidities, likelihood of response to a given therapy and its effects on quality-of-life, and patients' treatment preferences.[64] Patients with extensive, life-limiting comorbidities or who are asymptomatic at diagnosis may warrant supportive care alone.[64,65] Since lower-risk patients have a better prognosis, less toxic therapies are used to manage MDS, including EPO, darbepoetin, lenalidomide, or DNA hypomethylating agents. Patients with higher IPSS risk MDS have a poorer prognosis and may be candidates for allogeneic HSCT; patients who are not HSCT candidates may benefit from a DNA hypomethylating agent.[7,51] Utilization of known genetic and laboratory factors, such as deletion 5q and erythropoietin (EPO) level can also assist with selection of appropriate therapy. However, some biomarkers, such as mutations in *TET2* or *ASXL1* for predicting DNA hypomethylating agent response, are not widely available or are expensive and thus not used in community oncology setting to determine therapy and are typically reserved for clinical trials.[45,50] Clinicians should recognize that the clinical course of MDS is not stable. MDS may progress, or comorbidities or symptoms may change, either of which may necessitate an adjustment in treatment strategy. Therapy for MDS is generally palliative, and enrollment in a suitable clinical trial is always a viable approach.[51,64]

Careful interpretation is necessary when comparing the results of clinical trials in MDS because baseline patient characteristics, prognostic scores, and response criteria vary widely. Described previously, the clinical course and prognosis are affected by patient-specific characteristics.[3,65] Examples of different response criteria used include changes in hemoglobin, changes in RBC transfusion requirements, or effects on quality of life.[66] The use of RBC transfusion requirement as a primary end point is especially problematic because decisions concerning RBC transfusion needs are highly individualized and may not be consistent among clinicians. Additionally, the relationship between changes in hemoglobin or decreases in RBC transfusion requirements and improved quality of life is not clear. Some treatments for MDS can cause significant adverse effects, resulting in hospitalization or increased clinic visits, and may negatively impact quality of life regardless of their positive effects on hematologic parameters. The impact of treatment on quality of life is an important consideration when selecting therapy and should be assessed regularly with the use of validated instruments.

Supportive Care

All patients with MDS should receive supportive care, including clinical monitoring, psychosocial support, and quality-of-life assessment.[51] The National Comprehensive Cancer Network (NCCN) guidelines recommend that patients with symptomatic anemia should receive leukoreduced RBC transfusions, and those with bleeding caused by thrombocytopenia or platelet counts below 10,000 cells/mm^3 (10×10^9/L) should receive platelet transfusions.[51] Hematopoietic growth factor support should be considered in patients with refractory, symptomatic cytopenias. Patients with evidence of infection should have an appropriate diagnostic evaluation based on history and physical examination followed by appropriate antimicrobial therapy. Routine antimicrobial or hematopoietic growth factor prophylaxis is not recommended in the absence of repeated infections. Iron chelation may be considered in lower-risk patients and candidates for allogeneic HSCT who have received more than 20 to 30 RBC transfusions and are expected to continue to require transfusions, although there are no controlled prospective data indicating

clinical benefit from iron chelation in MDS.[43,51]

Infection

Patients with MDS may be neutropenic or have functional defects in neutrophils, predisposing them to infection.[40] In MDS, the most frequently isolated organisms are bacteria, and the most common sites of infection are the lungs, urinary tract, and bloodstream.[67] Patients with evidence of infection should have appropriate diagnostic evaluation based on history and physical examination and then appropriate antimicrobial therapy. Neutropenic patients with evidence of infection or fever of unknown origin should receive empiric broad-spectrum, IV antibiotics.[68]

Hematopoietic Growth Factors

Filgrastim (G-CSF) and sargramostim (granulocyte-macrophage colony-stimulating factor [GM-CSF]) are colony-stimulating factors that stimulate white blood cell production and may increase circulating neutrophils in 70% to 90% of patients, which may decrease risk of infection.[69] These agents have not been shown to be beneficial as chronic monotherapy because they do not reliably prevent infection and have no impact on survival.[69] G-CSF or GM-CSF should only be administered temporarily as monotherapy in the rare neutropenic MDS patient who develops recurrent severe infections.[1,64]

EPO is a protein produced by the kidney in response to hypoxia that stimulates proliferation and differentiation of erythroid cells. Anemic patients with MDS may have either a lower than expected endogenous serum EPO level relative to the degree of anemia present or an elevated EPO level. The mechanism of action of recombinant erythropoiesis-stimulating agents (ESAs) in MDS is not clear, but exogenous EPO may stimulate a normal clone of cells that is unresponsive to low endogenous levels of EPO, stimulate a dysplastic clone to differentiate that is less responsive to endogenous EPO, or induce apoptosis. An immunomodulatory effect of EPO, G-CSF, or GM-CSF has been proposed.

7 Current guidelines recommend use of ESAs for management of anemia in patients with MDS.[51,65,70] Unlike some solid tumors,[71] no detrimental effects on overall survival or progression to leukemia have been noted in patients with MDS. Treatment with ESAs alone results in hematologic improvement and transfusion independence in low- and intermediate-1 IPSS risk patients. Two meta-analyses have evaluated the efficacy of ESAs in MDS. The first analysis, which included 2,106 patients from 59 studies reported between 1990 and 2005, found a hemoglobin response of about 30% based on the definition of hemoglobin response in the original publication.[72] A subsequent meta-analysis only included studies from 1990 to 2006 that reported results by International Working Group (IWG) criteria[66] to define erythroid response (an increase in hemoglobin of 2 g/dL [20 g/L; 1.24 mmol/L] or transfusion independence). This report included 30 studies with 925 patients with MDS and found an overall erythroid response rate of 58% in patients receiving ESAs.[73] The latter report also suggests that EPO and darbepoetin can be used interchangeably for the management of MDS based on similar response rates achieved. The higher response rate compared with the previous meta-analysis likely reflects inclusion of a higher proportion of patients most likely to respond to ESAs. Patients with lower-risk MDS who have a serum EPO level less than 500 mU/mL (500 IU/L) and a history of receiving fewer than 2 units of RBC transfusions per month have the best chance at responding to ESAs.[51,64,65] The doses required to achieve a response in MDS are higher than those used to treat renal causes of anemia, with EPO doses in the range from 40,000 to 60,000 units subcutaneously two to three times per week.[51] Darbepoetin doses ranging from 100 to 300 mcg subcutaneously weekly or every other

week have also been used for MDS management.[64,73] Doses should be titrated up or down, as clinically indicated, to achieve a hemoglobin level of 10 to 12 g/dL (100-120 g/L; 6.21-7.45 mmol/L).[51] Additionally, patients should receive at least 8 weeks of therapy before doses are adjusted or before patients are considered nonresponders because response to ESAs in MDS can be delayed.[51,64] The median response duration for ESAs in MDS is 1 to 2 years, and the ESA should be discontinued if there is no benefit or the response wanes.[64]

Several trials report that the addition of G-CSF to ESAs improves hematologic response. A large phase III, randomized controlled trial of ESAs in MDS with long-term follow-up compared EPO with or without G-CSF to best supportive care in 110 patients.[74] At 4 months, 34% of patients receiving EPO had an erythroid response by IWG 2006 criteria compared with 5.8% of patients receiving placebo. A total of 47% of patients had a major erythroid response when EPO doses were escalated or filgrastim was added. Patients with RARS were most likely to respond to the addition of filgrastim. No difference in overall survival or leukemic evolution was observed between patients receiving EPO compared with best supportive care after a median follow-up period of 5.8 years, but the study was not prospectively powered to determine differences in these outcomes. A subsequent phase II study treated 99 patients with darbepoetin alfa 500 mcg every 2 weeks subcutaneously for 12 weeks; nonresponders at 12 weeks continued the same darbepoetin regimen with the addition of filgrastim 300 mcg twice weekly for an additional 12 weeks.[75] At 12 weeks, 48% of patients had a response according to IWG 2006 criteria, improving to 56% at 24 weeks after 40 of the nonresponders had filgrastim added to darbepoetin. A meta-analysis of 15 published trials was performed to compare the erythroid response in patients who received EPO as a single agent with those who received EPO plus G-CSF or GM-CSF.[76] The overall erythroid response was 49%, 50.6%, and 64.5% for patients who received standard EPO (30,000-40,000 units/wk), standard EPO plus G-CSF or GM-CSF, or high-dose EPO (60,000-80,000 units/wk), respectively. The authors concluded that higher doses of single agent EPO are more effective than standard doses alone or in combination with G-CSF or GM-CSF. However, a significantly higher proportion of transfusion-dependent patients were enrolled in the trials of combination therapy compared with the other two treatment groups that could have negatively impacted the outcomes.

Some, but not all, studies have shown that patients who respond to ESAs have improvements in quality of life.[74,75] Although EPO, with or without G-CSF, does not improve overall survival, it does not shorten overall survival or time-to-development of leukemia and may decrease the need for RBC transfusions and improve quality of life. ESA therapy is well tolerated, and the NCCN recommends a trial in lower risk patients who have a serum EPO level less than 500 mU/mL (500 IU/L) and a limited transfusion history to target a hemoglobin of 10 to 12 g/dL (100-120 g/L; 6.21-7.45 mmol/L).[51]

Thrombopoietin is a hormone synthesized in the liver and secreted into the systemic circulation, where it binds to thrombopoietin receptors on stem cells, progenitor cells, and platelets, resulting in increased platelet production. Romiplostim and eltrombopag are novel drugs that stimulate the thrombopoietin receptor similarly to endogenous thrombopoietin. Both agents are FDA-approved for patients with chronic idiopathic thrombocytopenic purpura and eltrombopag is also labeled for used in chronic hepatitis C-associated thrombocytopenia and severe aplastic anemia. A randomized, placebo-controlled trial evaluating romiplostim to manage thrombocytopenia in MDS was stopped early in 2011 because of data safety monitoring committee concerns regarding the potential for transient increases in blast cell counts and the risk for progression to AML; 6% of romiplostim patients developed progression to AML compared with 2.4% of placebo patients.[77] A warning about the risk for progression from MDS to AML, potential for an increase in blast percentage without progression to AML, and a limitation of use noting romiplostim is not

indicated for use in MDS were subsequently included in the romiplostim label. Only 56 of a planned 250 patients completed the 58 week study; longer follow-up shows no difference in the risk for progression to AML or overall survival. The design of the study limits the ability to detect a true risk for progression to AML to romiplostim.[77] The primary outcome of the study of clinically significant bleeding events was not different between the arms, but 37.5% of romiplostim patients had a platelet response at 4 weeks, compared with 3.6% of patients.[77] Romiplostim has also been studied in combination with azacitidine, decitabine and lenalidomide in three separate randomized phase II studies to determine feasibility to prevent clinically significant thrombocytopenia caused by these agents. Unfortunately, the studies included small numbers of patients and were unable to demonstrate a difference in the primary endpoint of clinically significant thrombocytopenic events.[77] Preliminary data with eltrombopag monotherapy or in combination with azacitidine has not indicated an increased risk for progression to AML or worsening overall survival.[77] Clinical trials are currently underway to evaluate the use of eltrombopag monotherapy and in combination with decitabine or lenalidomide (registered at *www.clinicaltrials.gov* NCT00961054, NCT01772420 NCT02010645). The most recent NCCN guidelines did not provide recommendations on the use of thrombopoietin-stimulating agents in patients with MDS.[51] Patients should only receive thrombopoietin-stimulating agents under the auspices of a clinical trial until further knowledge is gained about the risk of accelerating the progression to AML and the benefit in patients with MDS.

Transfusion

Patients generally receive RBC transfusions when they develop signs or symptoms of anemia, including tachycardia, fatigue, or dyspnea, which generally occur when hemoglobin drops below 8 to 10 g/dL (80-100 g/L; 4.97-6.21 mmol/L).[51,78,79] Some clinicians use a transfusion threshold of 10 g/dL (100 g/L; 6.21 mmol/L) in patients with significant cardiovascular disease.[80] Platelet transfusion is generally reserved for patients with evidence of bleeding to avoid alloimmunization from repeated platelet transfusions, which leads to refractoriness to donor platelets.[79,80]

Iron Overload

RBC transfusions are associated with shortened leukemia-free and overall survival times in MDS.[81,82] It is unclear if this reflects disease severity or is a direct result of iron toxicity.[1,83] Retrospective data indicate MDS patients receiving RBC transfusions are at higher risk for infections, cardiac, hepatic, and endocrine dysfunction compared with nontransfused MDS patients or the general population without MDS.[12,81,84] It is likely that anemia contributes to development of heart failure and neutropenia to infections, therefore the role of excess iron is unclear.[85] Prospective clinical trials in MDS demonstrate that iron chelation is able to decrease markers of iron overload.[86,87,88,89,90] Six studies including over 700 patients with MDS receiving deferasirox for iron overload suggest improvement in hematologic parameters related to chelation with an increase in hemoglobin level ranging from 6% to 45%, an increase in platelet count from 13% to 61%, and in neutrophil count from 3% to 76%.[91] Eight observational studies have assessed the relationship between iron chelation and overall survival in about 1,500 patients with low-risk and intermediate-1 risk patients with MDS.[92] A meta-analysis reported an improvement in overall survival of 61.2 months, with 7 of 8 studies reporting improvement in overall survival.[92] It is possible that patients who had a better prognosis were more likely to receive iron chelation, which would explain the association between improved survival time and iron chelation. Preliminary results of a cohort of Medicare beneficiaries with MDS indicate longer duration of deferasirox use correlated with improved overall survival times, but deferasirox was not found to

be associated with altered risk of heart failure or endocrine or renal disease.[93] It is hypothesized that iron chelation may lower infection risk, improve the outcome of allogeneic HSCT, and delay leukemic transformation in patients with MDS.[83] A prospective, randomized trial comparing deferasirox with placebo in low- and intermediate-1-risk MDS patients with transfusional iron overload with a primary outcome of event-free survival is ongoing (registered at *www.clinicaltrials.gov*; NCT00940602).

The potential toxicity, expense, and benefits of iron chelation should be carefully considered before initiating therapy.[94] Deferasirox and deferoxamine are FDA-approved for use in patients with chronic iron overload caused by RBC transfusions. Deferiprone is FDA-approved for patients with transfusional iron overload secondary to thalassemia when current chelation therapy is inadequate. The prescribing information for deferiprone has a black box warning regarding agranulocytosis, which may lead to serious infection and death. The prescribing information for deferasirox has a black box warning describing renal and hepatic impairment and GI hemorrhage; fatalities were reported. These reactions were more frequently observed in patients with advanced age, high-risk MDS, underlying renal or hepatic impairment, or thrombocytopenia (less than 50,000 cells/mm^3 [less than 50 × 10^9/L]). Diarrhea may complicate therapy with deferasirox and recommendations for management have been published.[23]

Clinical Controversy…

Initiation of iron chelation in patients with MDS is controversial because prospective, controlled trials of iron chelation with clinical outcomes have not been completed.[43] It is unclear if iron chelation will impact the natural history of MDS or reverse end-organ damage associated with iron overload. Iron chelation is expensive and may have adverse effects including renal dysfunction and GI intolerance. Despite a lack of prospective, controlled data, more than 10 clinical practice guidelines have been published regarding iron chelation in MDS.[85] These guidelines differ on whether or not to initiate chelation and at what threshold; which agent, dose, and duration to use; and how to monitor for the efficacy and toxicity of iron chelation.

Many clinicians suggest iron chelation be initiated after 20 to 30 RBC transfusions are administered or when serum ferritin levels exceed 1,000 to 2,500 ng/mL (1,000-2,500 mcg/L; 2,250-5,620 pmol/L) in patients with lower-risk MDS who have an anticipated survival of at least 1 year or in patients proceeding to allogeneic HSCT.[51,78,80,85,95,96] Patients receiving pharmacotherapy for iron chelation should be monitored for gastrointestinal and ocular toxicity, ototoxicity, renal and hepatic dysfunction, and complete blood counts in addition to markers of iron overload.[96]

Pharmacotherapy

The primary goal of pharmacotherapy of MDS is to change the natural history of MDS. **Table e137-5** lists the responses reported in selected clinical trials of non-HSCT therapies. DNA hypomethylating agents may prolong overall survival, but allogeneic HSCT remains the only curative option for patients. Because most patients with MDS are not candidates for HSCT, less toxic therapeutic modalities are being evaluated in an attempt to improve quality of life and disease-free survival.

TABLE e137-5 Results from Pivotal Trials of Low-Intensity Treatment for Myelodysplastic Syndromes

Medication	Patients (*n*)	Median Age (years)	Percent of Patients by IPSS Risk Category Low Int-1 Int-2 High	Response Criteria	Complete Response (%)	RBC Transfusion Independence (%)	Overall Hematologic Improvement (%)

[a]Evaluated in 39 of 99 patients.

[b]International Prognostic Scoring System (IPSS) not evaluable because of missing cytogenetics in 11%.

[c]Intermediate-2- and high-risk patients.

Immunosuppressive Agents

Immunosuppressive agents that modulate effector T cells, including antithymocyte globulin (ATG), cyclosporine, and corticosteroids have been evaluated in patients with hypoplastic MDS with a disease pathobiology similar to aplastic anemia. The National Institute of Health has developed an algorithm to predict response to immunosuppressive therapy, and criteria include: age younger than 60 years, hypocellular marrow, refractory anemia of short duration, trisomy 8 as the sole cytogenetic abnormality, and HLA DR15 positive expression.[97] ATG, with or without cyclosporine, has been investigated primarily in patients with intermediate-1-risk and low-risk MDS. Treatment with ATG may not be beneficial for all patients because of the potential for infectious complications and serum sickness. Most studies have used equine ATG at a dose of 40 mg/kg/day IV for 4 consecutive days with corticosteroids to prevent serum sickness complications.[97,98] A retrospective evaluation of patients enrolled on clinical trials at the National Institutes of Health demonstrated that the combination of equine ATG and cyclosporine was associated with response to therapy compared with either agent administered alone.[99] Responses generally occur within 4 months, and about one-third of previously transfusion-dependent patients achieve durable transfusion independence.[97,98] Rabbit ATG has also been evaluated in daily doses ranging from 2.5 to 3.75 mg/kg/day administered IV for 4 to 5 consecutive days.[100,101,102] Response rates appear similar and treatment with either horse or rabbit ATG is reasonable.

A survival benefit from therapy with ATG has not been demonstrated, despite clinical trials of various regimens, including both formulations, with or without hematopoietic growth factor support, and cyclosporine or corticosteroids. A phase III randomized controlled trial compared equine ATG and cyclosporine versus best supportive care in all IPSS risk categories.[103] At 6 months, 29% of patients achieved

a hematologic response in the immunosuppressive therapy arm compared with 9% of those receiving best supportive care, but no difference was seen in overall, leukemia-free, or 2-year transformation-free survival. Notably, these patients were not evaluated for HLA DR15, and nearly 25% of patients in each group had undetermined risk, intermediate-2-risk, or high-risk IPSS.[103]

Alemtuzumab is a monoclonal antibody with immunosuppressive activity that has been evaluated in MDS. Initial data in 32 patients demonstrated hematologic improvement in 77% of intermediate-1 risk patients with HLA DR15 positivity.[104] A small cohort of 9 patients validated these results in low risk patients with hypocellular bone marrow and found a 60% response rate.[105] Further evaluation will be needed to determine its role in therapy of MDS.

Immunomodulating Drugs

Thalidomide and lenalidomide are immunomodulating drugs, frequently referred to as *IMiDs*. Thalidomide was discovered to possess anti-inflammatory, antiangiogenic, and antiapoptotic properties, prompting its investigation as a potential treatment of MDS. Initial response rates were encouraging, but few complete responses and high rates of discontinuation because of intolerable side effects have limited thalidomide's use in MDS. Common side effects of thalidomide include fluid retention, peripheral neuropathy, thrombosis, sedation, and constipation.

Lenalidomide is structurally similar to thalidomide but offers a distinct side-effect profile and potentially enhanced therapeutic effects. Lenalidomide is more potent in vitro than thalidomide. Recent evidence has determined that the pleiotropic effects of lenalidomide are due to modulation of the ubiquitination and degradation process. Lenalidomide binds cereblon, a component of the ubiquitin ligase complex and modulates the substrate specificity of the enzyme, and thus the targeted cellular proteins for degradation. Lenalidomide selectively and specifically degrades casein kinase 1A1, a kinase located on chromosome arm 5q. Cells that are haploinsufficient, or deletion 5q, are more susceptible to the degradation process.[106] Compared with thalidomide, lenalidomide causes less fluid retention, peripheral neuropathy, thrombosis, and constipation but more frequently induces neutropenia and thrombocytopenia. Pruritus, rash, diarrhea, and hypothyroidism have been reported with lenalidomide use but seldom require treatment discontinuation. Lenalidomide undergoes substantial renal elimination, and dose reduction in patients with renal insufficiency is recommended to decrease the likelihood of significant bone marrow suppression. Treatment-emergent thrombocytopenia and neutropenia during lenalidomide therapy are associated with response in low-risk MDS patients.[107] Careful consideration is necessary before reducing the dose or holding lenalidomide treatment in low-risk MDS patients who develop myelosuppression.

Lenalidomide has been evaluated in several clinical trials. An uncontrolled trial of lenalidomide in 43 MDS patients reported a 56% overall response rate and 62% rate of transfusion independence. Patients with a clonal deletion of chromosome 5q demonstrated an 83% complete response rate.[108] A subsequent phase II trial of patients with 5q deletion and transfusion-dependent anemia evaluated lenalidomide 10 mg orally once daily. Cytogenetic remission was seen in 45% of patients with 67% achieving transfusion independence.[46] The median time to response was 4 weeks. The results of this pivotal trial led to FDA approval of lenalidomide for treatment of low-risk MDS in patients with a 5q deletion. Nearly 8 years later, long term follow-up of patients enrolled in these phase II patients shows longer survival for those who achieved transfusion independence for at least 8 weeks as compared with non-responders (4.3 years vs 2 years).[109]

Low- and Intermediate-1-Risk Patients

A phase III randomized, placebo-controlled study of lenalidomide in low- and intermediate-1-risk MDS patients with a deletion 5q compared the efficacy and safety of lenalidomide 10 mg daily for 21 of 28 days or 5 mg daily with placebo in transfusion dependent patients with a primary endpoint of transfusion independence for at least 26 consecutive weeks.[110] Transfusion independence was significantly improved in both the lenalidomide 10- and 5-mg groups, 56% and 43%, respectively, versus placebo at 6%. The lenalidomide 10-mg group showed significantly better transfusion independence for patients with baseline EPO levels greater than 500 mU/mL (500 IU/L). Cytogenetic remission was achieved in 50% and 25% of the patients treated with lenalidomide 10 mg and 5 mg, respectively. Overall survival was not significantly different between groups, although this may reflect the crossover of more than 80% of placebo patients beginning at week 16. Patients with either isolated deletion 5q or a single additional cytogenetic abnormality were less likely to progress to AML at 24% and 21%, respectively, versus patients with two or more additional abnormalities; the rate of progression was 47%. Further subset analyses have revealed patients who achieved transfusion independence for greater than 182 days demonstrated an improvement in overall survival for lenalidomide-treated patients at either dose level.[8]

Intermediate-2- and High-Risk Patients

Lenalidomide activity in low-risk MDS patients prompted its evaluation in patients with higher-risk MDS with 5q deletion. A phase II trial of lenalidomide in patients with higher-risk MDS with a 5q deletion and other cytogenetic abnormalities reported responses by IWG 2006 criteria in 13 of 47 patients (27%); significant myelosuppression was reported, and most patients (64%) required hospitalization.[111] Patients with thrombocytopenia or additional cytogenetic complexity progressed rapidly despite lenalidomide therapy.

Lenalidomide has also been studied in a phase II trial of 214 patients with low- and intermediate-1-risk MDS without 5q deletions. Transfusion independence was achieved in 26% of patients who received lenalidomide after a median of 4.8 weeks, and 43% had hematologic improvement by IWG criteria.[112]

Lenalidomide produces high rates of sustained transfusion independence in patients with low- and intermediate-1-risk MDS with 5q deletions. The response rate to lenalidomide is lower in patients with higher-risk MDS and those without a 5q deletion but may still be considered a treatment option for patients who do not respond to initial therapy.[51]

Two trials have reported on the combination of lenalidomide and EPO.[113,114] Evaluation of lenalidomide in 31 patients without deletion 5q and refractory to ESAs demonstrated transfusion independence in 37% of patients. Response was more robust in patients who remained on ESA therapy at 55% versus those on lenalidomide monotherapy at 36%. Median response duration was 24 months.[114] In the second trial, lower-risk MDS patients received lenalidomide 10 or 15 mg daily for 16 weeks; erythroid nonresponders were eligible to receive EPO 40,000 units/wk in addition to lenalidomide. Among 39 patients, 23 patients proceeded to combination therapy, with 6 (26%) achieving erythroid hematologic improvement. In 19 patients without deletion 5q, 4 (21%) showed erythroid hematologic improvement. A randomized, phase III study is currently underway to assess the effects of combination therapy in patients who have failed ESA monotherapy (www.clinicaltrials.gov; NCT00843882).

DNA Hypomethylating Agents

Azacitidine and decitabine are nucleoside analogs structurally similar to cytosine and capable of being incorporated into DNA in place of cytosine. When these agents incorporate into DNA, substitution of carbon for nitrogen at the 5′ position prevents methylation by DNA methyltransferase. As a result, DNA methylation is decreased, and genes previously silenced by aberrant hypermethylation are activated. In vitro studies have confirmed that these agents can promote the reexpression of previously silenced genes.[52] The activity of both agents is concentration and time dependent, and trials are ongoing to evaluate the optimal dose, route, schedule, and duration of therapy.

The median time to response with DNA hypomethylating agents is 3 to 4 months.[43] Long-term follow-up of high-risk MDS patients who responded to azacitidine therapy reported the median time-to-first response was two cycles, and 91% of responding patients achieved their first response within six cycles. The first response was the best response in 52% of patients, but the remaining 48% did not achieve their best response until a median of three additional cycles beyond their first response.[115] Experts recommend continuing therapy until evidence of disease progression or unacceptable toxicity even in patients who only achieve stable disease.[43,65] The primary dose-limiting toxicity of both azacitidine and decitabine is myelosuppression, including leukopenia, granulocytopenia, and thrombocytopenia. Febrile neutropenia and other infectious complications have been reported with azacitidine and decitabine.[116,117] Nausea and vomiting may occur, and antiemetic prophylaxis is recommended. Azacitidine-induced erythema at the site of subcutaneous injection may occur, and can be minimized with the use of hot or cold compresses or topical corticosteroids. Rare hepatotoxicity is reported after either azacitidine or decitabine. Hypomethylating agents should be used cautiously in patients with an estimated glomerular filtration rate of less than or equal to 29 mL/min (0.48 mL/s). Pharmacokinetics of a single cycle in this population do not demonstrate significant variability in area-under-the-plasma-time curve or maximum observed plasma concentration, but cumulative dosing may increase the incidence of grade 3 or 4 myelosuppression, necessitating cycle delays and dose reductions.[118,119]

It remains unclear if the degree of DNA methylation at baseline or the level of demethylation response predicts success and survival after treatment. Shen et al. showed that higher levels of methylation correlated with shorter median overall survival and progression-free survival (PFS) times.[120] The degree of methylation at baseline did not predict response to decitabine. Mutations in *TET2* likely affect the global methylation level, but changes in methylation status as a result of treatment have not yet been evaluated.[121] At this time, methylation levels are not routinely incorporated into clinical decision making for MDS therapy.

Low- and Intermediate-1-Risk Patients

Azacitidine was evaluated in a phase III, multicenter, randomized trial of patients diagnosed with any classification of MDS based on FAB criteria.[117] Patients in lower-risk categories of MDS, including refractory anemia and RARS, were required to meet additional criteria for significant bone marrow dysfunction. A total of 191 patients (median age, 68 years) were randomized to treatment with either supportive care alone or supportive care plus azacitidine 75 mg/m^2 subcutaneously once daily for 7 days, repeated every 28 days. Hematopoietic growth factor support was not permitted. Responses based on Cancer and Leukemia Group B criteria occurred in 60% of patients in the azacitidine group compared with 5% in the supportive care alone group. Almost half (45%) of the patients previously transfusion dependent who received azacitidine became transfusion independent. The rate of progression to AML was significantly lower with azacitidine (15%) compared with supportive care alone (38%), but azacitidine did not significantly improve overall survival. A quality-of-life analysis identified a significant advantage for azacitidine therapy compared with supportive

care alone, including improvements in physical functioning, fatigue, dyspnea, psychosocial distress, and affect.[122]

Decitabine was also evaluated in a multicenter, randomized phase III trial of patients diagnosed with MDS by FAB criteria.[116] Patients were required to have an IPSS risk of intermediate-1 or greater; two-thirds of patients had intermediate-2- or high-risk MDS. A total of 170 patients were randomized to either supportive care alone or supportive care plus treatment with decitabine 15 mg/m^2 by IV infusion every 8 hours for 3 days repeated every 6 weeks. In contrast to the azacitidine trial, hematopoietic growth factor support was allowed. The overall response rate by IWG criteria was 17% in the decitabine group compared with 0% in the supportive care group. Thirteen percent of patients who received decitabine experienced hematologic improvement compared with 7% who received supportive care alone. Time-to-progression to AML or overall survival was not significantly different between groups. The patients with known clonal abnormalities at baseline who underwent follow-up cytogenetic evaluation were noted to have a complete cytogenetic response of 35% with decitabine compared with 10% with supportive care. Decitabine also improved quality-of-life measures, including global health status, fatigue, and dyspnea.

Intermediate-2- and High-Risk Patients

An open-label, randomized, phase III study compared azacitidine with a conventional care regimen (CCR) in patients with higher-risk MDS.[7] Before randomization, treating physicians selected supportive care alone, low-dose cytarabine, or AML-type induction as the CCR for a given patient if randomized to the conventional care arm. Of the 340 patients receiving treatment, 175 received azacitidine, 102 received best supportive care, 44 received low-dose cytarabine, and 19 received AML-type induction. At 2 years, 51% of azacitidine patients were alive compared with 26% of patients who received a CCR, and median overall survival time was prolonged by 9 months. This is the only prospective, randomized controlled study to demonstrate therapy improves overall survival in MDS.

In attempt to better define which patients are most likely to respond to azacitidine, Itzykson et al identified four factors that independently predicted overall survival in a cohort of 282 high- or intermediate-2-risk MDS patients who received azacitidine for a median six cycles in a compassionate use study.[123] Each factor was given a point-based score: performance status greater than or equal to 2 (1 point), intermediate- and poor-risk cytogenetics (1 and 2 points, respectively), presence of circulating blasts (1 point), and RBC transfusion dependency of at least 4 units within 8 weeks (1 point). Median overall survival was not reached in the low-risk (0 point), 15 months in intermediate-risk (1-3 points), and 6.1 months in high-risk (4-5 points) patients. This prognostic scoring system was independently validated in the azacitidine cohort of Fenaux and colleagues.[7]

Decitabine has also been compared with best supportive care in a phase III trial of 233 intermediate- or high-risk MDS patients older than 60 years who were ineligible for intensive chemotherapy.[124] Decitabine was more active than best supportive care, with a complete and partial response rate of 13% and 6%, respectively, versus 0% for best supportive care. Median PFS was significantly improved with decitabine compared with supportive care at 6.6 months versus 3 months, respectively. Progression to AML at 1 year was significantly reduced with decitabine to 22% versus 33% in the best supportive care arm. However, unlike the trial with azacitidine, no overall survival benefit was observed. Decitabine did demonstrate improvement in quality-of-life measures of fatigue and physical functioning.

Clinical Controversy…

Although both azacitidine and decitabine have demonstrated significant improvement in complete response, partial response, and hematologic improvement rates, only azacitidine has demonstrated overall survival benefit for high-risk disease. The lack of survival improvement for decitabine remains controversial because it may reflect suboptimal administration due to dosing interval (4 vs 6 weeks), schedule (3 vs 5 days), and number of cycles received.[148] Currently, the NCCN guidelines do not favor one agent over the alternative in lower risk but give a more favorable rating to azacitidine in high-risk MDS (intermediate-2 or higher).[51]

Despite moderate success with both hypomethylating agents, current data suggest that using decitabine after azacitidine failure is not effective. Bhatnagar and colleagues evaluated 22 MDS or AML patients with disease progression or lack of response to azacitidine who went on to receive decitabine.[125] After a median of two courses, all 22 patients demonstrated disease progression or lack of response to decitabine. Higher-risk MDS patients who fail hypomethylating therapy may require therapeutic intervention with an alternative mechanism of action or as part of a clinical trial.

The pivotal trials for azacitidine and decitabine led to the approval of these agents for the treatment of patients with MDS, but their FDA-approved administration schedules are inconvenient and impossible for many cancer centers whose outpatient clinics are not open extended hours or on weekends, necessitating hospitalization. A more convenient regimen for decitabine (20 mg/m^2 by IV infusion daily for 5 consecutive days every 4 weeks) demonstrated similar response rates and adverse events to the traditional regimen.[126] In early 2010, the FDA granted approval for this alternative dosing regimen. Preliminary results of an oral azacitidine formulation have been positive, particularly in extended dosing strategies of 14 or 21 days, which also correlated with higher achievement of demethylation.[127,128] An ongoing phase III trial of oral azacitidine in lower-risk MDS with significant cytopenias should provide more definitive information on its place in therapy (available at www.clinicaltrials.gov; NCT 01566695). An additional option is oral decitabine combined with deoxyguanosine to protect it from deamination by cytidine deaminase in the liver and GI tract, thereby significantly prolonging the half-life.[129] A phase II study reported a complete response rate of 20% and transfusion independence rate of 32%. Additional phase II studies are ongoing (available at www.clinicaltrials.gov; NCT01261312, NCT02131597). Although a variety of dosing options have been studied, none of these approaches have been directly compared in prospective trials, and further evaluation is required to determine optimal azacitidine and decitabine treatment regimens.

Lack of durable survival benefit with existing therapies and inability to utilize HSCT in many patients has led to attempts at combination therapy with hypomethylating agents. Azacitidine has been combined with lenalidomide in a phase II study of 36 patients with higher-risk MDS who were not candidates for HSCT.[130] The regimen included azacitidine 75 mg/m^2/day for days 1 through 5 and lenalidomide 10 mg daily on days 1 to 21, with cycles repeated every 28 days. The overall response rate was 72% and complete response rate was 44%. The follow-up was short at 11.5 months. A larger data set evaluated azacitidine monotherapy versus azacitidine plus lenalidomide versus azacitidine plus vorinostat, a histone deacetylase inhibitor.[131] Although the population was a mixture of MDS and chronic myelomonocytic leukemia patients, the overall response rate of 33% was similar among treatments. Further studies of combination therapy in varying risk groups and cytogenetics groups are ongoing and the role of combination therapy should be limited to the clinical trial setting.

Intensive Chemotherapy

Patients with higher risk disease, including IPSS intermediate-2- or high-risk MDS or IPSS-R intermediate,

high, or very high MDS may be candidates for intensive chemotherapy with AML-type induction combination chemotherapy regimens, including anthracyclines, cytarabine, fludarabine, and topotecan. AML-type induction therapy is described in detail in Chapter 134. Intensive chemotherapy in MDS patients is often less successful than de novo AML, with complete remission rates of 40% to 60%, a median duration of response of only 10 to 12 months, and a longer period of aplasia.[132] Treatment-related mortality in younger patients with current supportive care measures, including antibiotic and hematopoietic growth factor support, is less than 10%.[7,133] Patients younger than 55 years who have a favorable karyotype and good performance status are most likely to benefit, but this approach cures fewer than 15% of patients.[132,133] Intensive chemotherapy can be used as a bridge to allogeneic HSCT to reduce tumor burden and control disease while a suitable donor is found and a referral is made to a transplant center.

Hematopoietic Stem Cell Transplantation

Allogeneic HSCT offers potentially curative therapy to patients with MDS who have a suitable donor and are healthy enough for the procedure. With a median age of 76 years at diagnosis of MDS, fewer than 5% of patients are referred for allogeneic HSCT.[134] Two large retrospective studies indicate that recipient age alone should not be considered a contraindication to allogeneic HSCT.[135,136] About 30% to 50% of patients with MDS treated with allogeneic HSCT have prolonged disease-free survival.[135,137,138] However, 20% to 50% of patients succumb to treatment-related mortality, and many of the remaining patients relapse. Outcomes vary based on patient comorbidities, time from diagnosis to transplant, FAB subtype of MDS, percentage of bone marrow blasts at the time of HSCT, IPSS risk category, type of conditioning regimen administered before HSCT, and dose and source of stem cells infused.[135] Complications of allogeneic HSCT are described in greater detail in Chapter 140. An HLA-matched allogeneic HSCT is recommended if an appropriate donor is available. An autologous HSCT can be considered in the context of a clinical trial if an allogeneic donor is not available, complete remission is achieved with chemotherapy, and adequate stem cells can be collected.[138]

Because of the high rate of treatment-related mortality in patients with MDS, allogeneic HSCT has not been recommended for lower-risk patients because these patients may have stable disease for several years, and early transplant may shorten overall survival. The International MDS Risk Assessment Workshop conducted a decision analysis based on clinical data from two international registries and a single center to identify the optimal time to recommend allogeneic HSCT for patients who have a donor and meet HSCT eligibility criteria.[139] The analysis showed that patients with low- and intermediate-1 IPSS risk scores should be closely observed and transplanted at the time of disease progression. Patients with intermediate-2 and high IPSS risk scores should be transplanted soon after diagnosis to confer the greatest benefit from allogeneic HSCT.[138] This model was developed in 2003 and included patients younger than 60 years who had undergone HSCT primarily in the 1990s. It did not incorporate treatment with novel agents for MDS, the use of reduced-intensity conditioning (RIC), or all of the known prognostic factors currently available and thus may not be applicable to contemporary patients being evaluated for HSCT.[140] The WPSS may enhance selection of patients likely to derive the most benefit from allogeneic HSCT based on recent retrospective data demonstrating patients with low-risk disease have low rates of treatment-related mortality and relapse and a 5-year overall survival rate of 80%.[141] Another retrospective series by de Witte et al. reported a 4-year overall survival rate of 52% in younger patients with lower-risk refractory anemia after allogeneic HSCT,[142] remarkably similar to the median survival rate for untreated patients with refractory anemia.[3] The decision to proceed to allogeneic HSCT and optimal timing should be weighed carefully at diagnosis and subsequently

at regular intervals for factors that might influence prognosis, such as degree of cytopenias, cytogenetic abnormalities, transfusion requirement, progression to a higher risk category, donor availability, comorbidities, and availability of effective nontransplant therapies.[63,142] Prospective studies comparing allogeneic HSCT with hypomethylating agents or best supportive care are ongoing (available at www.clinicaltrials.gov; NCT01404741 and NCT02016781).

Retrospective comparisons of RIC and myeloablative conditioning regimens before allogeneic HSCT showed inconsistent results with some reporting a lower treatment-related mortality rate but a higher rate of disease relapse with RIC while others reporting no difference.[137,143] Comparison of the results from patients receiving RIC with myeloablative conditioning regimens is difficult because patients treated with RIC regimens tend to be older or have significant comorbid illnesses preventing them from receiving myeloablative conditioning regimens. A prospective, randomized controlled trial (BMT CTN 0901) is underway to compare myeloablative and RIC in patients with MDS undergoing allogeneic HSCT (available at www.clinicaltrials.gov; NCT00682396). A clinical advisory was released May 15, 2014 stating the study suspended enrollment for the clinical study BMT CTN 0901 following preliminary data indicating superiority of myeloablative regimens for allogeneic HSCT patients eligible for the study.[144] Pending full publication of the study results, comorbidities and age remain factors used to select the intensity of the conditioning regimen; myeloablative conditioning is preferred for patients healthy enough to tolerate it.[63]

Clinical Controversy...

Experts disagree on whether patients should proceed to allogeneic HSCT without receiving any prior therapy, after receiving a hypomethylating agent or after intensive induction chemotherapy.[23,49,144] Pretransplant therapy may be useful to reduce the burden of marrow blasts and clonal cells before HSCT, but this therapy may cause additional toxicity making the patient less likely to tolerate HSCT.[23] Observational studies have shown no difference in post-transplant outcomes on the basis of pretransplant management and no prospective, randomized, controlled trials have been completed.[48,121,149]

Treatment Based on Risk Group

All patients with MDS should receive appropriate supportive care and be encouraged to participate in clinical trials to determine the role of different approaches in the management of MDS.[51]

Lower-Risk Patients (IPSS Low, Intermediate-1; IPSS-R Very Low, Low, and Intermediate)

Patients with lower-risk MDS may be managed with supportive care alone; those who are likely to respond to ESAs should be managed with this strategy because it is well tolerated.[51] Patients with endogenous EPO less than 500 mU/mL (500 IU/L) and a low transfusion requirement are most likely to respond to ESAs. Addition of low-dose G-CSF may benefit some patients who do not respond to EPO alone. Most patients eventually stop responding to ESAs and develop an increased need for transfusions; these patients may benefit from more intensive therapy.

8 The NCCN recommends a DNA hypomethylating agent (azacitidine or decitabine) for treatment of lower-risk MDS in patients with clinically significant neutropenia or thrombocytopenia and patients with anemia who are unlikely to respond to or have not responded to a trial of ESAs, and patients who qualified for and failed immunosuppressive therapy.[51] Small numbers of low-risk and intermediate-1-risk (by IPSS) MDS patients were enrolled in the clinical trial that evaluated azacitidine, and further research is needed to

determine its place in therapy for these patients. Responses to hypomethylating agents often require 2 to 4 months of treatment, and the duration of response is generally less than 1 year. Clinical trials of azacitidine and decitabine enrolled different patient populations, used diverse response criteria, and administered therapy for different durations, making it difficult to determine if one agent is superior. A phase III open-label trial to compare decitabine with azacitidine in low- and intermediate-1-risk patients with MDS is underway in the United States (available at www.clinicaltrials.gov; NCT01720225). Either DNA hypomethylating agent is appropriate for lower-risk MDS patients who are transfusion dependent or who are symptomatic despite management with best supportive care.[43,49,51]

9 The current NCCN treatment guideline for MDS recommends immunosuppressive therapy (ATG with or without cyclosporine) for select patients with lower-risk MDS; young patients (60 years old or younger) with a hypocellular marrow, normal cytogenetics, expression of HLA DR15, or paroxysmal nocturnal hemoglobinuria are most likely to respond.[51] The potential benefit of transfusion independence must be considered carefully in the context of complications that can arise from immunosuppressive treatments.

10 Lenalidomide is currently recommended for patients with symptomatic anemia and lower-risk MDS with a 5q deletion.[51] Patients with multiple cytogenetic abnormalities, in addition to a chromosome 5 deletion, may respond to lenalidomide but the response rate is typically lower. Lenalidomide is also effective for some patients with lower-risk MDS without a chromosome 5 deletion and is considered an alternative treatment approach by NCCN.[51,112]

Higher-Risk Patients (IPSS Intermediate-2 or High; IPSS-R Intermediate, High, and Very High)

11 Patients with higher-risk disease who are candidates for intensive therapy should receive an allogeneic HSCT, if possible, because it is the only curative option for MDS.[49,63] Patients may receive intensive chemotherapy with an AML-type induction regimen or a less intensive therapy with a DNA hypomethylating agent to reduce disease during the process of finding a donor and referral to a transplant center. They also may proceed directly to allogeneic HSCT without cytoreduction if they have fewer than 10% bone marrow blasts. Azacitidine should be considered for higher-risk MDS patients who are not eligible for allogeneic HSCT based on the observation that azacitidine prolongs survival in these patients.[7,51]

Although clinical trials are beginning to determine which therapies are effective in patients with different risk categories, none of the therapeutic options have been directly compared in a clinical trial. The optimal management of patients who progress or do not respond to initial therapy is not clear.

PERSONALIZED PHARMACOTHERAPY

Although many different chromosomal and somatic abnormalities have been discovered in MDS, only two are used to personalize pharmacotherapy: deletion 5q- syndrome and HLA DR15 positivity. Patients with an isolated deletion of chromosome 5q and no excess marrow blasts are a distinct WHO category of MDS termed *5q- syndrome*. This subtype of MDS is characterized by severe refractory anemia often requiring frequent RBC transfusions.[145] Patients with 5q- syndrome typically survive longer and have a lower risk for progression to AML than a similar IPSS risk patient. About 50% to 67% of 5q- syndrome patients become transfusion independent with lenalidomide therapy, and 45% to 50% achieve cytogenetic remission.[46,146] The NCCN guidelines recommend these patients receive lenalidomide as primary therapy before alternative treatments.[51]

As discussed earlier (see Immunosuppressive Agents above), patients with HLA DR15 positivity have a superior response to immunosuppressive therapy as first-line management.[99] Patients with HLA DR15 are most likely to respond if they are younger than 60 years, have IPSS risk of intermediate-1 or lower, and have rapid initiation of immunosuppressive therapy on diagnosis.[99] More definitive studies are needed to determine how this knowledge and other recently discovered genetic abnormalities can be incorporated into prognostication and treatment models.

EVALUATION OF THERAPEUTIC OUTCOMES

Standardized response criteria in clinical trials of MDS enable clinicians to evaluate study outcomes, compare results from different trials, and tailor therapy according to patient or disease characteristics.[66] The IWG for MDS guidelines for response criteria in MDS clinical trials categorize patient responses into categories that correlate with quality of life or morbidity.[66,147] Based on these criteria, the four treatment goals are altering the natural history of the disease, cytogenetic response, hematologic improvement, and quality of life. Changes in the WHO classification system and new therapies with novel mechanisms of action, time to response, and likelihood of treatment-related cytopenias have created a need for further refinement of these guidelines.[95] Patients with MDS should have regular follow-up with a history, physical examination, and complete blood counts. The frequency of follow-up varies with the natural history of each patient from weekly to every 6 months.

Chapter e138: Renal Cell Carcinoma

Christine M. Walko; Daniel J. Crona

INTRODUCTION

KEY CONCEPTS

- 1 Renal cell carcinoma (RCC) predominantly occurs later in life, with about 70% of all cases diagnosed between the ages of 55 and 84 years.
- 2 Established risk factors for RCC include smoking, obesity, hypertension, and inherited susceptibility.
- 3 Inactivation of the von Hippel-Lindau tumor suppressor gene is the hallmark of the most common type of RCC, the clear cell histologic subtype.
- 4 More than 50% of RCC cases are diagnosed by incidental findings on routine imaging for unrelated reasons.
- 5 The Memorial Sloan-Kettering Cancer Center Prognostic Factors Model for Survival classifies patients into low-, intermediate-, and high-risk groups based on five clinical factors and can predict survival among both untreated patients and those treated with immunotherapy and/or targeted agents.
- 6 Surgical excision of the primary tumor, either by radical or partial nephrectomy, is the preferred treatment modality for patients with stage I-III RCC, but some patients with stage IV disease may also benefit from surgery.
- 7 Historically, immunotherapy (interleukin [IL]-2 and interferon [IFN]-α) was considered the preferred first-line therapy for metastatic RCC (mRCC) but has largely been replaced by targeted agents because of their improved efficacy and tolerability. Nivolumab is a new immunotherapy option for mRCC patients who have received prior targeted therapy.
- 8 Sunitinib, pazopanib, and axitinib are oral small molecule inhibitors of vascular endothelial growth factor (VEGF) and platelet-derived growth factor and are treatment options as first-line

therapy for mRCC. Bevacizumab and IFN-α is also a first-line option.

- 9 The multikinase inhibitors sorafenib and cabozantinib, and the mammalian target of rapamycin (mTOR) inhibitor everolimus, are the oral agents used as second-line therapy options for mRCC patients who progress on a targeted therapy or cytokine-based therapy first-line regimen.

- 10 Temsirolimus is an IV administered mTOR inhibitor indicated for first-line therapy in patients with high-risk mRCC.

Renal cell carcinoma (RCC) represents about 2% of all adult malignancies and is the most common type of malignancy of the kidney and renal pelvis. Until a decade ago, there were few treatment options, and those that were available had modest activity and were poorly tolerated by patients. However, treatment for the disease has been revolutionized by targeted agents that were developed based on an increased understanding of RCC pathophysiology. Clear cell is the predominant subtype of RCC (up to 75% of all cases), and is the result of inactivation of the von Hippel-Lindau (*VHL*) tumor suppressor gene located on chromosome 3p25. *VHL* inactivation leads to increased production of growth factors, such as vascular endothelial growth factor (VEGF), transforming growth factor (TGF), platelet-derived growth factor (PDGF), and others responsible for angiogenesis and cell growth.[1] Prior to 2005, the primary therapeutic option for patients with advanced or metastatic RCC (mRCC) after nephrectomy was immunotherapy, which induced few durable responses and caused high rates of severe toxicities. However, nine new drugs have been approved as first- or second-line therapy for RCC: sorafenib, sunitinib, temsirolimus, bevacizumab (in combination with interferon-*α* [IFN-*α*]), everolimus, pazopanib, axitinib, nivolumab, and cabozantinib.[2,3,4,5,6,7,8,9] Each drug is an example of targeted therapy against growth factors important in the pathophysiology of RCC and has yielded much needed progress in a disease with few therapeutic options. RCC serves as an example of rational development of targeted agents based on knowledge of tumor biology and molecular signaling pathways for the treatment of other malignancies.

EPIDEMIOLOGY

About 62,000 new cases of kidney and renal pelvis cancer are diagnosed each year in the United States, with two-thirds of these cases occurring in men. More than 13,000 people in the United States will die of kidney cancer each year. Kidney cancer is the seventh most common cancer in men, and the number of new cases diagnosed each year is similar to non-Hodgkin lymphoma and melanoma. In women, kidney cancer is the eighth most common cancer, occurring at a rate similar to the rates for ovarian and pancreatic cancers.[10] The incidence of RCC has increased over the past three decades. The rate has increased more rapidly in blacks than whites and in women than men. In the United States, between 2002 and 2006, the age-adjusted incidence rate in black men was 21.3, white men 19.2, black women 10.3, and white women 9.9 per 100,000 person years.[11] This increase may be related to improved imaging techniques and greater use of these imaging modalities, although the higher prevalence of some risk factors may also explain the increased incidence.

1 Kidney cancer is most commonly diagnosed between the ages of 40 and 70 years, with a peak in the sixth and seventh decades of life. Nearly 70% of all cases of kidney cancer are diagnosed in people between the ages of 55 and 84 years, with less than 3% of all cases diagnosed in patients younger than 34 years.[11]

One of the primary factors influencing overall survival (OS) is the extent of disease spread. When the tumor is confined to the kidney at the time of diagnosis, surgical resection can result in a 5-year OS rate of about 85%. However, that figure falls to 64% when localized spread has occurred beyond the kidney.[12] About 30% of RCC patients will present initially with metastatic disease, and an additional 30% to 50% of RCC patients, initially thought to be curable through nephrectomy, will relapse. The median survival time for patients with mRCC is 10 to 12 months. The 5-year survival rate for these patients is about 23%, and the 10-year survival is only 12.3%.[13] Median OS rates for RCC have improved over the past two decades, which could be attributed to improved screening and early detection of smaller tumors, the use of cytoreductive nephrectomy prior to the use of systemic therapy in advanced disease, and/or the United States Food and Drug Administration (FDA) approval of eight new targeted agents that target angiogenic and oncogenic signaling pathways.

ETIOLOGY

The incidence rates of RCC vary more than 10-fold worldwide, with the highest incidence rates in Western and European countries and the lowest in Asia and Africa, which suggests that lifestyle and environment could be important factors underlying the development of RCC. Established risk factors associated with RCC include smoking, obesity, hypertension, and inherited susceptibilitiy. Additional risk factors that require additional validation include: dietary factors (eg, use of alcohol), occupational exposures (eg, asbestos, cadmium, hydrocarbons, and trichloroethylene [TCE]), reproductive factors (eg, use of oral contraceptives and parity), and the use of analgesics.

2 Smoking remains the most consistently established risk factor and is estimated to be responsible for 20% to 30% and 10% to 20% of RCC diagnoses in men and women, respectively.[14,15] Smoking is associated with a relative risk of 1.54 for men and 1.22 for women with a strong dose-dependent relationship. Heavy smoking, defined as 21 or more cigarettes per day, is associated with an increased relative risk of 2.03 and 1.58 for men and women, respectively. Smoking cessation has been demonstrated to reduce the risk of RCC, with a 15% to 30% decrease in patients who have quit smoking for 10 to 15 years, and a 50% decrease for those who have quit for 30 years or more.[16]

Obesity is also an established risk factor in RCC. Men with a body mass index (BMI) between 22.86 and 27.75 kg/m^2 had a 30% to 70% higher relative risk of RCC development, when compared to men with a BMI less than or equal to 20.75 kg/m^2. And those with a BMI more than or equal to 27.76 kg/m^2 had a 90% increased relative risk of RCC development.[17] A separate analysis reported a relative risk of 2.5 for those with a BMI of 30 kg/m^2 or greater.[18] It is estimated that 30% to 40% of RCC cases may be attributed to obesity, which suggests that increasing rates of obesity in the United States may be partially responsible for the increased incidence of RCC that have been observed over the past three decades.[15] Numerous mechanisms that could explain the link between obesity and

RCC development have been proposed, but none have yet been definitively validated. One plausible hypothesis has linked obesity to increased lipid peroxidation, which can result in carcinogenesis of the proximal renal tubules. Byproducts of the lipid peroxidation pathway have also been shown to result in deoxyribonucleic acid (DNA) adducts in the kidney, leading to oncogene and tumor suppressor gene mutations and eventually malignancy.[19] Adipose tissue, when stimulated, can release numerous substances that regulate energy balance and lipid metabolism. Insulin resistance and compensatory elevated serum insulin levels result in increased levels of circulating insulin-like growth factor-1 (IGF-1), which regulates cell proliferation and can inhibit cellular apoptosis.[18] Finally, the kidneys of obese men and women are more susceptible to carcinogenesis because of higher glomerular filtration rates, renal perfusion, and atrophic scarring of the kidneys.[15]

The risk of RCC development is associated with increased duration and severity of elevated blood pressure. Patients with a diastolic blood pressure (DBP) greater than 90 mm Hg had a relative risk of 2.1 compared with DBP less than 70 mm Hg. A systolic blood pressure (SBP) greater than 150 mm Hg was associated with a relative risk of 1.6 compared with SBP less than 120 mm Hg.[17] The exact pathphysiologic mechanism underlying the causal relationship between hypertension to RCC is yet to be conclusively identified, but it is believed to be related to hypertension-induced renal injury and lipid peroxidation.[15,19] Antihypertensive medications do not appear to be associated with RCC.

A well-defined link between RCC development and an inherited susceptibility has also been described. Although most RCC cases are not associated with hereditary factors and are considered "sporadic," 2% to 3% of RCC cases are secondary to inherited syndromes.[20,21] Heriditary RCC is most commonly the result of an autosomal dominant transmission of the diseased gene from a carrier to the offspring. Initially, one carrier parent has one healthy chromosome and one chromosome with the diseased gene. When this carrier has offspring with a healthy individual with two healthy chromosomes, the offspring each have a 50% chance of also being a carrier. These carriers with one healthy chromosome and one chromosome with the diseased gene are then more sensitive to developing RCC after being exposed to additional somatic mutations that can affect the remaining healthy chromosome. The most common examples of hereditary RCC include von Hippel-Lindau syndrome and Birt-Doge-Dube syndrome.

The analgesic phenacetin has a historical link to RCC. The drug was introduced in 1887 and used until the 1970s, when increased concerns for carcinogenesis resulted in replacement with safer analgesics, such as the major metabolite of phenacetin, acetaminophen. Despite its association with the known carcinogen, acetaminophen has not been associated with an increased risk of RCC development.[15]

SUBTYPES AND PATHOPHYSIOLOGY

RCC arises from the epithelia that lines the renal tubules, and at least 85% of all malignancies arising in the kidney and renal pelvis can be classified as RCC.[21] The renal pelvis is less commonly affected, and only about 12% of the diagnosed kidney cancer cases each year are cancers of the renal pelvis. Other rare malignancies, affecting other parts of the kidney (eg, medullary and collecting duct carcinomas), make up the remaining 3%. The subtypes of RCC include clear cell, papillary (also known

as chromophilic), chromophobic, and oncocytic. Each subtype has a unique genetic pathophysiology that results in a different clinical course and response to therapy.[20]

Clear Cell Subtype: The Role of the von Hippel-Lindau Gene

The most common histological subtype of RCC is clear cell RCC (70%-80% of all cases of RCC).[22,23,24] Clear cell RCC typically affects the proximal tubule of the kidney and is more likely to metastasize than other subtypes. An association between tumors with the clear cell histology and losses in the short arm of chromosome 3 eventually led to the discovery of gene responsible for this histologic subtype, and subsequently *VHL* was mapped to 3p24-25.[25,26,27] Inactivation of this tumor suppressor gene is now recognized as the hallmark of clear cell RCC. The Knudson and Strong two-hit model explains that the sequential inactivation of both copies of the *VHL* leads to the development of clear cell RCC.[27] In patients with sporadic disease, the two copies of *VHL* present in a healthy kidney can be inactivated via loss of chromosome 3p, gene silencing via hypermethylation, missense mutations, and premature truncation or nonsense mutations. Additional mutations can result in a single, unilateral tumor. In patients with hereditary disease, one copy of *VHL* has already been deleted via a germline mutation. Fewer events are then needed to delete the remaining copy of *VHL*, which explains why patients with hereditary disease are more likely to present with multicentric, bilateral tumors.[20,21]

VHL codes for the VHL protein (VHL), which is expressed ubiquitously throughout the body, and is part of the complex that selects substances for ubiquitination and subsequent destruction by the proteasome.[28] Because of this role, VHL regulates cellular response to oxygen. Under normoxic conditions, hypoxia-inducible factor (HIF)-1α is marked for ubiquination. Hydroxylated HIF-1α binds to VHL and is destroyed by the proteasome (**Fig. e138-1**). However, when the cellular environment is hypoxic, HIF-1α is not hydroxylated and does not bind to VHL. The unbound HIF-1α can then initiate transcription of hypoxia-inducible genes in the cell nucleus, which enables the cell to adapt and survive a hypoxic insult (**Fig. e138-2**).[28,29] In the case of clear cell RCC, when *VHL* is mutated or silenced, VHL is unable to bind and target HIF-1α for degradation regardless of the oxygen presence in the environment. As a result, HIF-1α levels increase, and are able to translocate into the nucleus to activate transcription of pro-angiogenic and pro-mitogenic genes, including *VEGF*, *PDGF*, *TGF*, as well as genes that encode for glucose transporters, and erythropoietin (**Fig. e138-3**).[28,29] Six of the eight targeted agents approved by the FDA for the treatment of RCC target these genes, and are discussed later in the chapter.

FIGURE e138-1

The role of von Hippel-Lindau (VHL) protein and hypoxia-inducible factor (HIF): normal oxygen, normal *VHL*. In a normal oxygen environment, HIF is hydroxylated. This enables binding of the VHL protein and subsequent attachment of a polyubiquitin chain, which is a process called ubiquitination. This allows the ubiquitin-tagged HIF to be recognized for destruction by the proteasome. The proteasome acts as a garbage disposal for compounds labeled by the ubiquitination process.

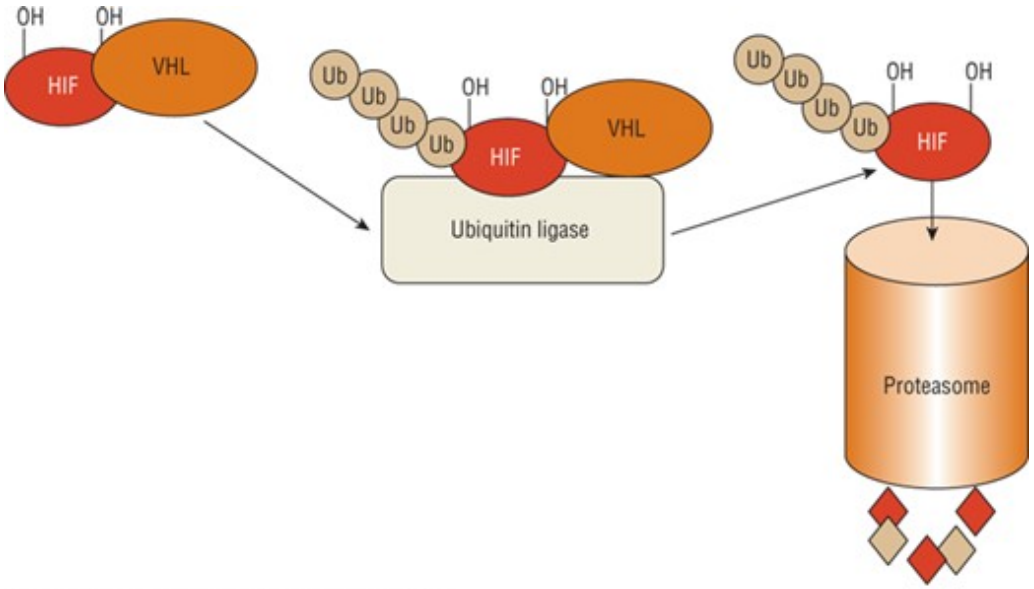

FIGURE e138-2

The role of von Hippel-Lindau (VHL) and hypoxia-inducible factor (HIF)-1α: low oxygen, normal *VHL*. In a low oxygen environment, the cell wants to increase production of substances to promote a switch to anaerobic metabolism, including enzymes involved in glycolysis and glycerol metabolism. In this situation, HIF-1α is not hydroxylated and cannot bind to VHL. HIF-1α is then able to translocate into the nucleus of the cell. In the nucleus, HIF-1α combines with the HIF-β subunit and the p300 transcriptional cofactor on the hypoxia response element (HRE) that promotes the transcription of HIF-1α target genes. More than 100 genes can be activated by this complex and include vascular endothelial growth factor (*VEGF*), platelet-derived growth factor (*PDGF*), transforming growth factor (*TGF*), erythropoietin (*EPO*), and glucose transporter 1 (*GLUT1*).

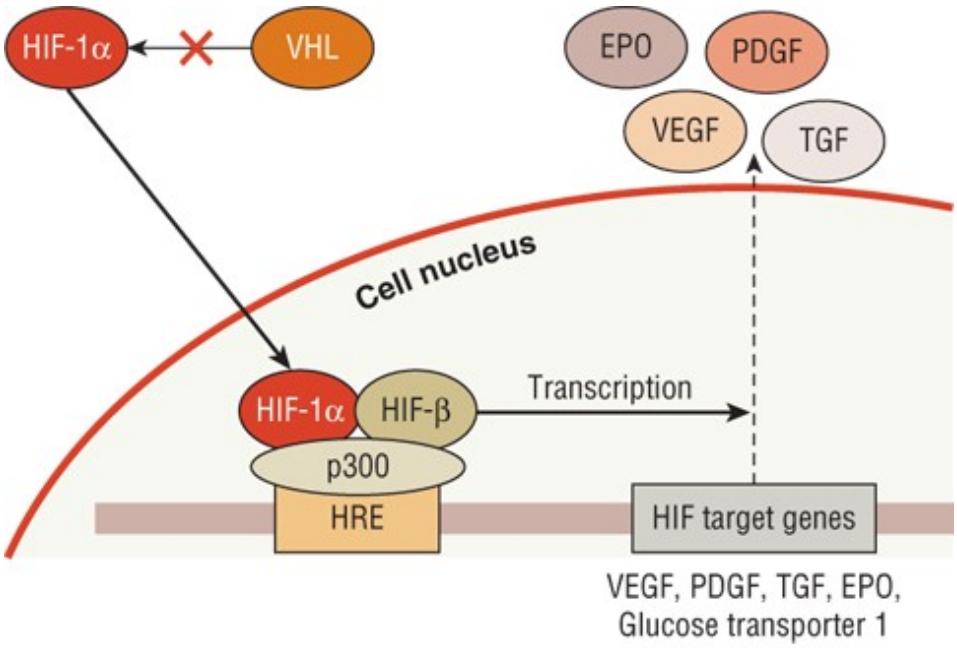

FIGURE e138-3

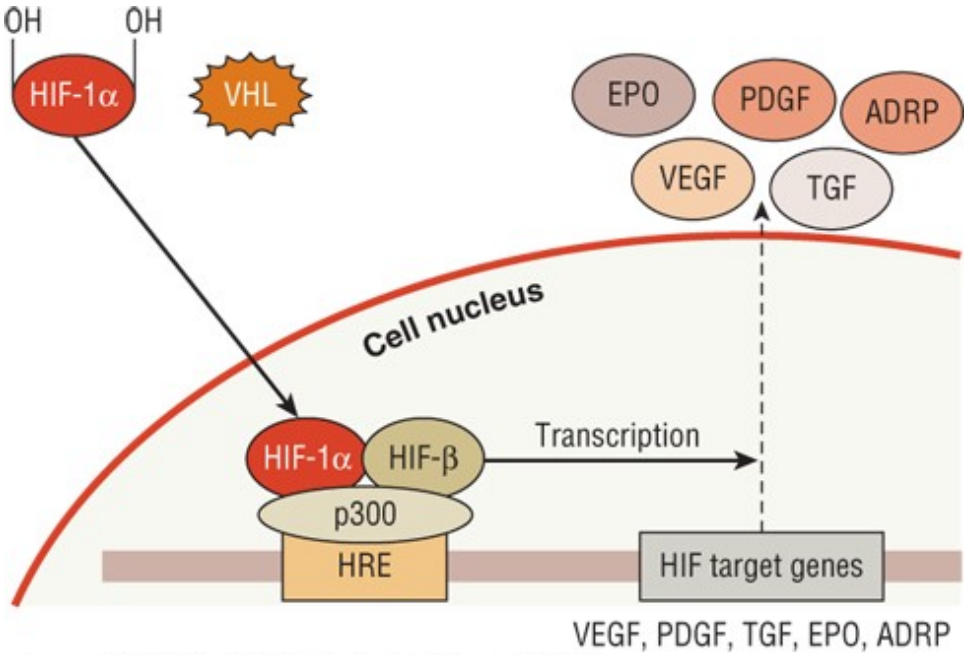
The role of von Hippel-Lindau (VHL) and hypoxia-inducible factor (HIF)-1α: normal oxygen, mutated *VHL*. When the VHL protein is mutated, it is not able to bind to the hydroxylated HIF-1α regardless of the presence of oxygen in the environment. Because HIF-1α is not bound to VHL, it is not destroyed by the proteasome and is thus free to translocate into the nucleus, combine with the HIF-β subunit and the p300 transcriptional cofactor on the HRE, and initiate gene transcription. Because a hypoxic situation is not present, production of these genes involved in angiogenesis, cellular survival, and glucose metabolism can result in an oncogenic process. (ADRP, adipose differentiation-related protein [responsible for neutral lipid accumulation in the cell cytoplasm, resulting in the clear cell appearance]; EPO, erythropoietin; PDGF, platelet-derived growth factor; TGF, transforming growth factor; VEGF, vascular endothelial growth factor).



In addition to VHL, other growth factors and cell adhesion pathways control HIF-1α activity.[28] TGF is a ligand for the epidermal growth factor receptor (EGFR) and, upon binding, activates the phosphatidylinositol 3-kinase (PI3K)/AKT/mammalian target of rapamycin (mTOR) pathway, in addition to other protein kinase pathways. Activation of the mTOR pathway increases production of HIF-1α, which can drive the oncogenic process described earlier.[28,30] The mTOR pathway is another target for RCC treatments, which are discussed later in the chapter.

Papillary Subtypes

Papillary subtypes account for 5% to 10% of RCC cases and occur in the renal proximal tubules. They are most commonly diagnosed when disease is localized, and thus have a more favorable prognosis than the clear cell subtype. Unlike mutations in a single tumor suppressor gene (eg, *VHL*) that predominantly drive the development of clear cell RCC, papillary RCC has been associated with multiple genetic abnormalities. These tumors are further subclassified into types 1 and 2. Papillary type 1 patients are more likely to have multiple, lower grade, bilateral tumors, and have a better prognosis. In contrast, patients with type 2 are more likely to present with singular, higher grade, unilateral tumors, and have a poorer prognosis.[19,21,28]

More than 80% of hereditary papillary type 1 RCC cases are associated with germline activating mutations in the mesenchymal–epithelial transition (*MET*) oncogene, located at chromosome 7q31-34.[31] These mutations are responsible for about 13% of sporadic type 1 disease, but chromosome 7 duplications have been found in 75% of these cases, further supporting the oncogenic role of *MET*.[28] Activation of the c-MET receptor results in increased cell proliferation and motility and decreased cellular apoptosis.[30] Stabilization of HIF can also play a role in the oncogenic potential of the c-MET receptor.[32]

The papillary type 2 subtype occurs in patients with hereditary leiomyomatosis, which initially presents as multiple skin and uterine leiomyomas when patients are in their 20s and 30s, and eventually results in formation of RCC. The associated gene for this subtype is the fumarase hydratase (*FH*) gene, located at chromosome 1q42.3-45. *FH* is a tumor suppressor gene that encodes the enzyme FH responsible for catalyzing fumarate to malate in the Krebs cycle. The gene is predominantly inactivated by loss-of-function mutations, which ultimately results in HIF stabilization and subsequent oncogenesis.[33,34]

Chromophore and Oncocytoma Subtypes

The chromophore and oncocytoma subtypes combined are responsible for 5% to 10% of all RCC cases, and occur in the intercalated cells of the collecting system. Both are associated with a wide variety of chromosomal abnormalities, including deletions and translocations. Oncocytomas are relatively benign and rarely metastasize.[35] Hereditary forms of these subtypes are associated with the Birt-Hogg-Dube syndrome, which is characterized by hair follicle fibrofolliculomas of the face and neck and lung cysts, in addition to RCC, in 15% to 30% of affected individuals. The *BHD* tumor suppressor gene (also known as *FLCN*) is located on the short arm of chromosome 17 and is responsible for encoding the protein folliculin.[19]

CLINICAL PRESENTATION AND DIAGNOSIS

Imaging modalities, such as computed tomography (CT) scans, are widely used in the medical workup of numerous conditions. 4 As a result, at least 50% of new RCC diagnosed are incidental after patients undergo radiographic imaging for reasons unrelated to RCC. This is a sharp increase from 1970, when only 10% of new diagnoses were incidental.[36] Fewer than 10% of patients currently present with the classic triad of flank pain, hematuria, and a palpable abdominal mass. Incidental diagnoses, or those diagnosed in the absence of signs and symptoms historically associated with RCC, are usually smaller in size, lower stage, and more localized than those seen in patients who present with symptoms. In addition to the classic triad, patients commonly present with nonspecific signs and symptoms, including fatigue, weight loss, anemia, hypertension, fever, and lower extremity edema. Bone pain, adenopathy, and pulmonary symptoms are indicators of mRCC spread to the mediastinum or lung parenchyma.[36]

CLINICAL PRESENTATION Symptoms

- Flank pain
- Fatigue
- Absence of symptoms is often seen with early disease

Symptoms of Disease Progression

- Bone pain

- Pulmonary symptoms, including shortness of breath and cough
- Types of symptoms differ depending on location of disease spread

Signs

- Weight loss
- Anemia
- Hypertension
- Fever
- Lower extremity edema
- Hematuria
- Palpable abdominal mass

Sign of Advanced Disease

- Adenopathy

Diagnostic Tests

- Complete blood count
- Serum calcium
- Serum creatinine
- Liver function tests
- Lactate dehydrogenase
- Coagulation profile
- Urinalysis
- Contrast and noncontrast CT or magnetic resonance imaging (MRI) of the chest, abdomen pelvis
- Fine-needle biopsy only in select cases

As noted previously, RCC development can be either sporadic or hereditary. Several differences exist between the two etiologies in terms of development patterns. Sporadic RCC most often presents as a single tumor affecting one kidney in a patient who is at least 60 years of age. These lesions may or may not be cystic in histology, and a family history is usually not reported. In contrast, those with a hereditary etiology more commonly present with numerous cystic tumors that affect both kidneys.

These patients are more likely to be younger than 50 years, and may also have other malignancies (eg, retinal angiomas, hemangioblastomas, and pheochromocytomas) or have a strong family history of RCC.[21,36]

Laboratory evaluation should include a complete blood count, serum calcium, serum creatinine, liver function tests, lactate dehydrogenase, coagulation profile, and urinalysis. Imaging studies, including contrast and noncontrast CT or MRI of the chest, abdomen, and pelvis, are also performed to further characterize the renal tumor, assess involvement of the inferior vena cava, and determine the patient's disease stage. Fine-needle biopsy is used only in rare selected cases.

STAGING AND PROGNOSIS

Factors associated with poor prognosis include positive margins after surgery, evidence of metastatic spread, presence of sarcomatoid architecture, tumor subtype, tumor grade, and tumor stage, with the latter being the most powerful prognostic indicator.[37] The Union Internationale Contre le Cancer/International Union Against Cancer (UICC) and the American Joint Committee for Cancer Staging and End Results Reporting (AJCC) introduced the tumor–nodes–metastasis (TNM) staging system for RCC in 1978. The 7th edition is the most recent, and was published in 2010.[38,39] The AJCC staging classification considers tumor size, number of lymph nodes involved, and the presence or absence of distant metastases. Subdivisions in the tumor (T) classification further describe the structures of the kidney that have been invaded by the tumor, including the adrenal gland, Gerota's fascia (the layer of connective tissue surrounding the kidneys), and perinephric fat that lies between the fascia and renal capsule.[39] **Table e138-1** summarizes the AJCC TNM staging definitions, and **Table e138-2** shows the TNM stage and corresponding 5-year OS rates.

TABLE e138-1 American Joint Committee for Cancer Staging and End Results Reporting Seventh Edition Staging

Primary Tumor (T)	
T_x	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_1	Tumor ≤7 cm in greatest dimension, limited to the kidney
T_{1a}	Tumor ≤4 cm in greatest dimension, limited to the kidney
T_{1b}	Tumor >4 cm but not >7 cm in greatest dimension, limited to the kidney
T_2	Tumor >7 cm in greatest dimension, limited to the kidney
T_{2a}	Tumor >7 cm but ≤10 cm in greatest dimension, limited to the kidney
T_{2b}	Tumor >10 cm in greatest dimension, limited to the kidney
T_3	Tumor extends into major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota's fascia
T_{3a}	Tumor grossly extends into the renal vein or its segmental (muscle containing) branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota's fascia
T_{3b}	Tumor grossly extends into the vena cava below the diaphragm

T_{3c} Tumor grossly extends into vena cava above the diaphragm or invades the wall of the vena cava

T_4 Tumor invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)

Regional Lymph Nodes (N)

N_x Regional lymph nodes cannot be assessed

N_0 No regional lymph node metastasis

N_1 Metastasis in regional lymph node(s)

Distant Metastasis (M)

M_0 No distant metastasis

M_1 Presence of distant metastasis

5 In patients with mRCC, the Memorial Sloan-Kettering Cancer Center (MSKCC) Prognostic Factors

Model for Survival was developed from a retrospective analysis of 670 patients with advanced RCC from 24 different trials at MSKCC between 1975 and 1996. The model identified five factors associated with poor prognosis: Karnofsky performance status, lactate dehydrogenase, hemoglobin, corrected serum calcium, and nephrectomy status (later interchanged with duration of time from diagnosis to initial treatment). Patients with none of the poor prognostic risk factors are considered low risk, one or two factors are intermediate risk, and three or more factors are high risk (**Table e138-3**). In this analysis, 25% of patients were classified as low risk and had a median OS of 20 months, 53% were intermediate risk with a median OS of 10 months, and 22% were high risk with a median OS of 4 months. Three-year OS for the low-, intermediate-, and high-risk groups was 31%, 7%, and 0%, respectively.[40] This model has been validated externally and can be used to predict survival outcomes for patients treated with IFN-based therapy.[41] Another retrospective study in 353 patients with untreated RCC confirmed the MSKCC prognostic model but identified two additional independent prognostic factors: prior radiation and number of metastatic sites (none or one compared with two or more). Low risk was defined as the presence of no or one risk factor, intermediate risk as two risk factors, and high risk as the presence of three or more risk factors. Based on these criteria, 37% of the patients were classified as low risk (median OS, 26 months), 35% as intermediate risk (median OS, 14.4 months), and 28% as high risk (median OS, 7.3 months).[42] In an updated analysis of mRCC patients treated with targeted agents, the MSKCC prognostic model confirmed the importance of hemoglobin, corrected serum calcium, Karnofsky performance status, and time from diagnosis to treatment as prognostic factors for OS. Elevated neutrophil and platelet counts were also independent survival prognostic factors. Of the 586 evaluable patients treated with targeted agents (sunitinib, sorafenib, or bevacizumab), 23% were low risk with an OS that was not reached after a median follow-up of 24.5 months, 51% were intermediate risk with a median OS of 27 months, and 26% were high risk with a median OS of 8.8 months. Corresponding 2-year OS rates for the low-, intermediate-, and high-risk groups were 75%, 53%, and 7%, respectively.[43]

TABLE e138-3 Memorial Sloan-Kettering Cancer Center Poor Prognostic Factors

- KPS < 80%
- Low serum hemoglobin (<13 g/dL [<130 g/L; <8.07 mmol/L] for men and <11.5 g/dL [<115 g/L; <7.14 mmol/L] for women)
- Elevated corrected calcium (>10 mg/dL [>2.50 mmol/L])
- Elevated serum LDH (≥300 U/L [≥5.00 μkat/L] or 1.5 × ULN)
- Absence of prior nephrectomy (has been shown to be a function of duration of time between diagnosis and start of therapy, with >1 year delay being considered a poor prognostic factor)

Expanded criteria in untreated patients include

- Two or more sites of metastatic disease
- Prior radiotherapy

LDH, lactate dehydrogenase; KPS, Karnofsky performance status; ULN, upper limit of normal.

The MSKCC criteria, with minor revisions discussed previously, is currently used in practice to determine optimal therapy for patients, and has been incorporated into the National Comprehensive Cancer Network (NCCN) guidelines.[44] For example, temsirolimus is currently recommended for patients with high-risk disease (ie, based on these poor prognostic factors). Additionally, the criteria are used to determine eligibility or stratification for clinical trials in an effort to further individualize and optimize patient therapy.

Current efforts have focused on the identification of predictive biologic biomarkers for therapy. In contrast to the prognostic factors discussed previously that correlate with survival regardless of intervention, predictive biomarkers correlate with response to a specific therapy. Predictive biomarkers can help clinicians to optimize therapy choices for patients. To date, no predictive biomarkers for mRCC have been clinically validated, but numerous factors are under investigation, including the HIF target carbonic anhydrase IX; angiogenic proteins linked to HIF-associated signaling; and biologic participants in the mTOR signaling pathway, such as phosphorylated-AKT, phosphorylated-S6 kinase, phosphatase and tensin homologue (PTEN), and cytoplasmic p27.[45,46,47,48]

TREATMENT

Surgical excision of the renal tumor remains the primary method of local disease control and is performed in patients with stage I, II, or III disease.[44] In patients with advanced or metastatic disease, treatment options for patients after nephrectomy had historically been limited to immunotherapy approaches with IFN-α, interleukin-2 (IL-2), or both therapies. However, novel multitargeted tyrosine kinase inhibitors (TKIs; sunitinib, sorafenib, pazopanib, axitinib, and cabozantinib), mTOR inhibitors (temsirolimus and everolimus), and the VEGFA inhibitor bevacizumab (in combination with IFN-α) have provided clinicians with additional pharmacotherapeutic options, and have become the cornerstone of treatment for advanced and mRCC.

Desired Outcomes

The goal of therapy for RCC depends on the stage of disease at diagnosis and other patient-specific factors, including age, performance status, and comorbidities. In patients with localized disease confined to the kidney (stages I, II, and III), the initial treatment recommendation is surgical removal with curative intent. In patients with initially localized disease who undergo nephrectomy, 20% to 30% will relapse, with most relapses occurring in the first 2 years after surgery. When patients have developed metastatic disease, the goal of therapy is to control disease burden and prolong survival while maximizing quality of life.[49] Even among mRCC patients, survival outcomes depend on patient-specific factors, including the MSKCC-adapted model for targeted agents and the specific therapy chosen.[43] The selection of each line of therapy and even agents within the same line of therapy should be weighed against the risks and benefits for each individual patient.

Regardless of the first-line and subsequent therapies, optimizing quality of life is always a goal of treatment. Symptoms differ based on disease stage, sites of distant disease, and treatment. Patients

with bone involvement may experience pain in the areas of metastatic disease that can be addressed with the use of bone modifying agents (eg, bisphosphonates or denosumab), palliative radiation therapy, and optimized daily pain medication regimens. Adherence to oral targeted therapies should be emphasized, both in terms of taking the medication regularly as prescribed but also following administration recommendations such as taking medication with or without food and avoiding interacting medications. Treatment-related toxicities should also be aggressively addressed to optimize the benefits of therapy. Hypertension, skin-related effects, and diarrhea are common toxicities of the TKIs that target the three VEGF receptors (VEGFRs), while hypercholesterolemia and hyperglycemia are common toxicities associated with the mTOR inhibitors. Adverse effects can be prevented or mitigated with close monitoring and/or appropriate therapeutic interventions when needed to improve tolerability to these oral agents and to optimize patient quality of life. The subjective nature of many of these treatment-related and disease-related adverse effects can make consistent assessment challenging, but trials incorporating quality-of-life outcomes, using validated patient-reported assessments, will improve our ability to optimize treatment by improving both survival and quality-of-life outcomes for RCC patients.

Surgery

Surgery represents the initial therapy for most patients with RCC regardless of stage. Surgical options include total excision of the entire kidney (radical nephrectomy) and nephron-sparing surgery. The type of surgery performed depends on numerous patient-specific factors including the size and location of the renal tumor, whether multiple tumors are present, and whether the patient has a single kidney or has a concurrent disease with a risk of multiple kidney tumors, such as a known genetic predisposition. Radical nephrectomy involves excision of the entire kidney, Gerota's fascia, and ipsilateral adrenal gland after ligation of the renal vein and artery. Radical nephrectomy is preferred for patients with large tumors (4-7 cm), depending on the location of the tumor. Centrally located tumors are more amenable to complete resection than partial nephrectomy.[44,50] Regardless of the functional capacity of the remaining kidney, radical nephrectomy has been associated with a higher risk for patients developing chronic kidney disease, which explains why nephron-sparing techniques have become increasingly preferred.[51]

The most common nephron-sparing procedure is partial nephrectomy, which has been shown, in appropriately selected patients, to have equivalent outcomes as those seen in patients who received a radical nephrectomy.[52] Partial nephrectomy candidates are those with smaller lesions (usually less than 4 cm) that are located in the cortical region of the kidney. Patients with bilateral tumors and those with already compromised renal function are also candidates for partial nephrectomy. Nephron-sparing surgery usually refers to partial nephrectomy, but it can also be used to describe probe-based thermal ablation procedures such as radiofrequency ablation (RFA) and cryoablation. The long-term efficacy of these two techniques has not yet been established, with some reports suggesting higher local recurrence rates than actual surgical excision.[53] Because RFA and cryoablation can result in localized fibrotic reactions, surgical salvage after relapse can be compromised, and these procedures are typically reserved for patients who are not surgical candidates but still desire aggressive localized therapy. In addition to surgical excision of the tumor,

some surgeons recommend extended lymphadenectomy. The procedure is controversial when lymph node involvement is not apparent, but advocates of the procedure suggest that it can be prognostic because the discovery of positive nodal involvement on lymphadenectomy can predict the presence of distant metastatic disease (even after lymph nodes have been removed).[44,54] Nearly one-third of patients relapse after surgery, but adjuvant targeted or immunotherapy is not currently recommended because neither has yet been shown to improve relapse-free survival in patients who initially present with localized disease (stages I-III). Adjuvant radiation therapy has also not been shown to improve survival, and is not recommended either. As a result, observation is the recommended strategy, with imaging of the chest and abdomen every 4 to 6 months after surgery and then as clinically indicated.[23,44]

Surgery is still used for patients with metastatic disease (stage IV) and may consist of surgical resection of the renal tumor, metastectomy (surgical removal of metastatic sites), or both. Ideal candidates are those who have minimal regional lymphadenopathy, and a solitary site of metastatic disease. Metastatic sites amenable to resection include the lung, bone, brain, and soft tissue.[44,54] The benefits of surgical resection in patients with mRCC treated with IFN-α have been demonstrated in two randomized trials. Patients with mRCC in both studies were randomized to nephrectomy followed by IFN-α or IFN-α alone. In a combined analysis, the median OS was 13.6 months for the nephrectomy followed by IFN-α group as compared with 7.8 months for the IFN-α alone group (hazard ratio [HR] = 0.69; 95% confidence interval [CI] = 0.55-0.87; P=0.002).[55,56,57] Patients with mRCC only involving the lung, good prognostic features, and a performance status of 0 or 1 appear to benefit the most from nephrectomy followed by IFN-α. The exact mechanism underlying the apparent improvement in OS is currently unknown, but it has been hypothesized that nephrectomy may reduce total tumor burden, may increase the time for the tumor to develop, and/or may eliminate the primary source of immunosuppressive cytokines and tumor-producing growth factors. The benefit of newer targeted therapies is also being evaluated in this setting.[23] Finally, palliative nephrectomy may be an option for patients with symptoms related to their primary tumor when removal can provide symptom relief.

Clinical Controversy...

Over the past decade, VEGFR- and mTOR-targeted agents have become the cornerstone of treatment for patients with mRCC, but stage IV disease remains incurable with a 5-year survival of about 23%. Although up to 35% of patients experience progression to mRCC after nephrectomy, particularly in patients with poor prognostic features (eg, locally advanced disease at the time of surgery), none of the therapies approved for the treatment of RCC have yet been shown to be effective in the adjuvant setting. However, based on an increased understanding of the antitumor properties of the approved targeted agents, several trials are currently ongoing to evaluate their ability to prevent progression to mRCC.

Chemotherapy

Traditional cytotoxic therapy has demonstrated minimal efficacy in the treatment of RCC. Numerous agents have been investigated, the most active being gemcitabine, vinblastine, and 5-fluorouracil.

However, response rates of more than 4% to 6% were rarely observed with single agents.[21] Intrinsic resistance to chemotherapy may be partially explained by increased expression of the multidrug resistance gene (*MDR1*), which encodes for the P-glycoprotein (Pgp) transmembrane pump involved in drug efflux. Variable expression of *MDR1* has been found throughout many normal human tissues and in a number of different tumor types. Normal kidney tissue and various renal cell carcinoma subtypes both express high *MDR1* levels.[58,59] RCC tumors expressing high levels of the Pgp have been shown to be resistant to a number of chemotherapeutic agents. Overexpression of other drug transporter proteins, including the multidrug-resistance–associated proteins, may also play a role in the development of resistance. Alterations in glutathione metabolism and proteins involved with regulation of apoptosis, ultimately leading to failure of cells to undergo programmed cell death, are also possible reasons underlying resistance to traditional cytotoxic chemotherapy.[60]

Immunotherapy

Patients with RCC occasionally experience spontaneous regression of their disease, which has led researchers to hypothesize that RCC evokes a host immune response, which provides rationale for studying immunotherapy in RCC.[61] IFN-α and IL-2 have been investigated in numerous trials and combinations of these two agents and were the standard of care for patients with mRCC prior to the targeted therapy era. Low response rates, few durable responses, and high rates of severe toxicities have limited their clinical utility over the past decade. However, clinical trials are ongoing to determine if they have a role in combination regimens. Novel immunotherapies, including the programmed cell death protein 1 inhibitors, such as nivolumab, have also been investigated in mRCC due to the prior clinical efficacy seen in select patients and have shown encouraging improvement in efficacy and safety.

IL-2 (aldesleukin) is a glycoprotein primarily produced by helper T lymphocytes that stimulates the growth of cytotoxic T lymphocytes. IL-2 has been associated with response rates of 6% to 30%. Although the complete response rate is only about 4% to 6%, complete and durable responses can be achieved.[23,62] The FDA-approved dose of IL-2 is 600,000 international units/kg IV over 15 minutes given every 8 hours for a maximum of 14 doses. After this initial treatment, the dose schedule is repeated 9 days later for an additional 14 doses as tolerated. Because of significant IL-2-related toxicities, treatment delays and discontinuations are common. The most common reported toxicities include hypotension, diarrhea, chills, vomiting, dyspnea, and peripheral edema in addition to increases in bilirubin, serum creatinine, and electrolyte abnormalities.[63] Many of these effects are related to capillary leak syndrome. Inpatient administration, intensive monitoring and supportive care are required, and many institutions administer IL-2 in an intensive care setting. Many patients are not candidates for IL-2 therapy because of their age (older than 60 years), comorbidities, organ function, and poor performance status.

IFNs are naturally occurring glycoproteins produced by macrophages and lymphocytes in response to foreign antigens as part of the host immunity. They exert their antitumor effects by activating cytotoxic T and natural killer cells, upregulating cell surface antigens (eg, major histocompatibility classes I and II), and modulating expression of genes related to tumor proliferation.[64,65] A number of

different IFNs have been studied for the treatment of mRCC, including IFN-α, -β, and -γ. The response rates are similar among the different IFNs, but IFN-α is most commonly used to treat RCC.

Although IFN has been used to treat RCC for two decades, it is not approved as monotherapy by the FDA for the treatment of advanced or mRCC. Overall response rates to IFN range from 5% to 20%.[62,64,66] Two randomized trials demonstrated a survival benefit with IFN. In the first trial, IFN-α plus vinblastine was compared with vinblastine alone in 160 patients with advanced RCC. Both groups received vinblastine at 0.1 mg/kg IV every 3 weeks, and the combination group also received IFN-α at a dose of 3 million units subcutaneously or intramuscularly three times a week for the first week and then 18 million units subcutaneously three times a week thereafter. The median OS was significantly improved in the combination group compared with the vinblastine alone group (67.6 vs 37.8 weeks; P=0.005).[67] In the second trial, IFN-α was compared with medroxyprogesterone acetate 300 mg/day in 350 patients with mRCC. IFN-α was dosed at 5 million units for two doses and then increased to 10 million units three times a week for a total of 12 weeks. The median OS was 8.5 months compared with 6 months for IFN-α and medroxyprogesterone, which translated into a 28% reduction in the risk of death in the IFN-α group (P=0.017).[68] Based on these studies, IFN-α remains the comparator for novel treatments in mRCC. IFN-α is also more preferable as a comparator than IL-2 because it is better tolerated and can be self-administered at home. However, more than 90% of patients still experience chills, fever, asthenia, fatigue, headache, diarrhea, and liver function abnormalities, while some patients even develop depression and other neuropsychiatric symptoms.

The focus of clinical research is to improve and build upon the durable responses observed with the older immunotherapies such as IFN-α and IL-2 for a subset of patients, while focusing an immune response to the site of disease in an effort to minimize side effects for all patients receiving immunotherapy. This research has led to discovery and development of immune checkpoint inhibitors, which block cytotoxic T lymphocyte-associated antigen, or programmed cell death protein 1 (PD-1) and its associated ligand, PD-L1. PD-1 is expressed on activated T cells, while PD-L1 is expressed on immune and tumor cells. When PD-L1 is bound to PD-1, the activity of T cells is downregulated. By blocking this interaction, either at the level of the PD-L1 ligand or the PD-1 receptor, PD-1 inhibitors allow T cells to remain activated. Because this interaction occurs in the lymph nodes and at the tumor, adverse effects are limited and more manageable.[69] One of the initial phase I trials with the PD-1 inibitor nivolumab enrolled 34 patients with previously treated advanced RCC. Objective responses were observed in 29% of patients, with a median response duration of 12.9 months and OS was 22.4 months.[70] Due to encouraging results in this and other trials, a large randomized, open-label phase III trial, known as CheckMate 025, compared nivolumab and everolimus in mRCC (n = 821) who had previously received one or two prior therapies with an antiangiogenic agent. Nivolumab was dosed at 3 mg/kg every 2 weeks or everolimus 10 mg daily and continued until disease progression or toxicity. The median OS was 25 months in patients receiving nivolumab compared with 19.6 months in those receiving everolimus (HR = 0.73, P=0.002). The objective response rate was also higher with nivolumab (25% vs 5%, P<0.001). Grade 3 or 4 treatment-related effects occurred in 19% of the nivolumab patients compared to 37% of those treated with everolimus. The most common nivolumab treatment-related effects of any grade were fatigue, nausea, pruritis, diarrhea, decreased appetite and rash.[71] As a result of the CheckMate 025 trial results, nivolumab received approval from the FDA in November 2015 for advanced RCC patients

who have received prior antiangiogenic therapy. While the CheckMate 025 survival data suggests that nivolumab could be a favorable option for RCC patients following progression after VEGF-targeted therapy, additional studies are needed to identify biomarkers that identify which patients may have a more "immune-responsive" disease, and thus are more likely to respond to nivolumab and other check point inhibitor immunotherapies.

Targeted Therapy

8 Since 2005, eight new targeted agents have been approved either as first- or second-line therapy for the treatment of advanced and/or mRCC: sunitinib, sorafenib, pazopanib, axitinib, cabozantinib, bevacizumab (in combination with IFN-α), temsirolimus, and everolimus (**Table e138-4** and **Fig. e138-4**).

TABLE e138-4 Comparison and Dosing of Targeted Agents for Patients with Metastatic RCC

Targeted Agent	Brand Name	Initial Dose	Maintenance Dose	Special Population Dose	Drug Interactions
Tyrosine Kinase and VEGFR Inhibitors					
Sunitinib[6, a]	Sutent	50 mg orally daily × 4 weeks; then off 2 weeks	None	Hemodialysis: no adjustment to starting dose; subsequent doses may be increased up to twofold	CYP3A4 inducers may decrease sunitinib exposure CYP3A4 inhibitors may increase sunitinib exposure
Sorafenib[7, b]	Nexavar	400 mg orally twice daily	None	No data	UGT1A1 and UGT1A9 substrates may have increased exposure when coadministered with sorafenib because of inhibition of glucuronidation Docetaxel and doxorubicin exposure may increase when coadministered with sorafenib CYP3A4 inducers may decrease sorafenib exposure
Pazopanib[5, c]	Votrient	400 mg orally daily	800 mg orally daily	Moderate hepatic impairment, 200 mg orally once a	CYP3A4 inducers may decrease pazopanib exposure

Targeted Agent	Brand Name	Initial Dose	Maintenance Dose	Special Population Dose	Drug Interactions
Tyrosine Kinase and VEGFR Inhibitors					
				day Do not use in severe hepatic impairment	CYP3A4 inhibitors may increase pazopanib exposure
Axitinib[8], *d*	Inlyta	5 mg orally twice daily	Increase every 2 weeks to 7 mg orally twice daily and then 10 mg orally twice daily	Hepatic impairment (Child-Pugh class B), reduce dose by half	CYP3A4/5 inhibitors may increase exposure; reduce dose of axitinib by half if a strong CYP3A4/5 inhibitor is administered CYP3A4/5 inducers may decrease exposure
Monoclonal Antibody and VEGF Inhibitor					
Bevacizumab[3], *e*	Avastin	10 mg/kg IV every 2 weeks	None	No data	No known drug interactions
Mammalian Target of Rapamycin Inhibitors					
Everolimus[4], *f*	Afinitor	10 mg orally daily	None	Hepatic impairment (Child-Pugh class B), reduce dose to 5 mg orally daily	CYP3A4 and Pgp inhibitors may increase exposure CYP3A4 inducers may decrease exposure
Temsirolimus[2], *g*	Torisel	25 mg IV once weekly	None	If mild hepatic impairment, reduce dose to 15 mg IV once weekly Do not use if bilirubin is greater than 1.5 times the ULN	CYP3A4 inhibitors may increase exposure CYP3A4 inducers may decrease exposure

Pgp, P-glycoprotein; RCC, renal cell carcinoma; ULN, upper limit of normal; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

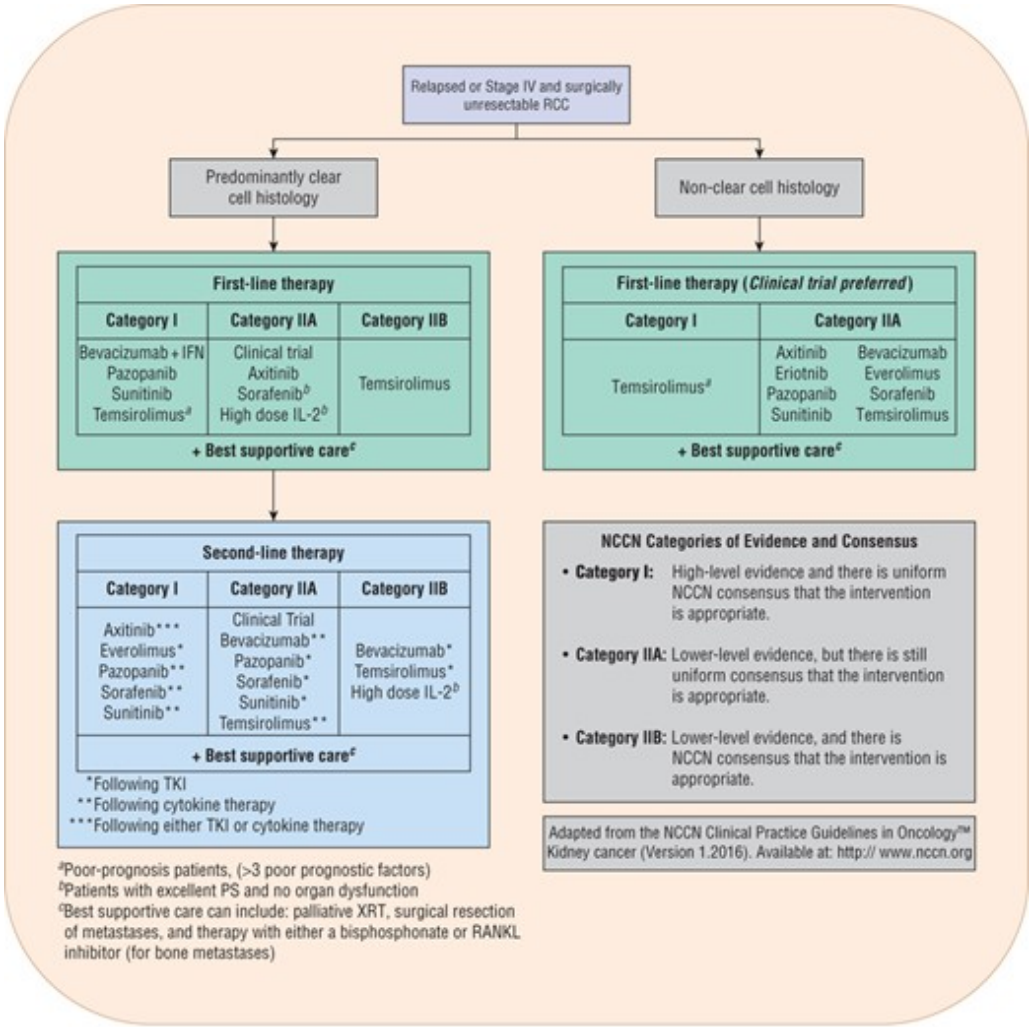
[f]Everolimus (Afinitor) prescribing information: Novartis Pharmaceuticals Corp. East Hanover, NJ. Revised September 2015.

[g]Temsirolimus (Torisel) prescribing information: Wyeth Pharmaceuticals Inc. Philadelphia, PA. Revised February 2015.

NOTE: Cabozantinib and lenvatinib (in combination with everolimus) received U.S. FDA approval in 2016 for the treatment of advanced RCC at an oral dose of 60 mg daily; however, at the time of press, their respective package inserts had not yet been revised to reflect recommendations for dosing modifications.

FIGURE e138-4

First- and second-line therapy recommendations for relapsed or Stage IV and surgically unresectable RCC. Since November 2015, nivolumab, cabozantinib, and lenvatinib (in combination with everolimus) all received approval from the United States FDA for the treatment of advanced RCC, but all three medications have not been incorporated into the guidelines. (IFN, interferon; IL, interleukin; NCCN, National Comprehensive Cancer Network; RANK, receptor activator of nuclear factor-κB; RCC, renal cell carcinoma; XRT, radiation therapy).



Sunitinib

Sunitinib is an orally administered antiangiogenic agent that inhibits multiple tyrosine kinases, including the three VEGFRs and platelet-derived growth factor receptor (PDGFR).[72] Sunitinib is approved for the first-line treatment of mRCC (NCCN guidelines, category I).[44] Its approval was based on results from both a multicenter phase II clinical trial and a randomized, phase III clinical trial that compared sunitinib with IFN-α_{2a} as first-line therapy in 750 patients with clear cell mRCC.[6,73] In the phase III trial, sunitinib was administered in a 6-week cycle at 50 mg orally given daily for 4 weeks followed by 2 weeks without treatment. IFN-α_{2a} was administered subcutaneously three times weekly on nonconsecutive days, with a gradual dose increase from 3 million units to 9 million units over a 3-week period. Sunitinib was found to be superior to IFN-α_{2a}, with a median progression-free survival (PFS) of (11 vs 5 months; $P<0.001$). The improved PFS with sunitinib was observed regardless of baseline characteristics and prognostic factors. Both treatments were generally well tolerated with a low incidence of grade 3 or 4 adverse events. The sunitinib group had higher rates of diarrhea, vomiting, hypertension, hand–foot syndrome, hair discoloration, and myelosuppression than IFN-treated patients. Health-related quality of life was significantly better in the sunitinib group compared with the IFN-α_{2a} group ($P<0.001$). Sunitinib-treated patients also had prolonged OS as

compared with IFN-α_{2a}-treated patients (26 vs 22 months; P=0.05), even though 25 patients in the IFN-α2a group crossed over to the sunitinib group.[3] Sunitinib has been evaluated in three clinical trials as either first- or second-line therapy after progression on cytokine therapy, with response rates ranging from 30% to 45%, which was higher than the response rates observed for cytokines.[6,23,73,74] In addition to the higher response rates, sunitinib was relatively well tolerated, with most adverse events managed through supportive care and/or dose modifications (less than 10% discontinuation due to treatment-related adverse events). As a result, the NCCN guidelines recommend sunitinib for first-line therapy in patients with mRCC who have never received systemic therapy (category 1) and for second-line therapy in patients who have progressed on cytokine (category 1) or TKI (category 2A) therapy.[44]

Sorafenib

Sorafenib is another orally administered antiangiogenic agent that inhibits multiple tyrosine kinases, including the three VEGFRs, PDGFRβ, v-Raf murine sarcoma viral oncogene homolog 1 (Raf-1), v-Raf murine sarcoma viral oncogene homolog B (BRAF), fms-like tyrosine kinase receptor-3 (FLT-3), fibroblast growth factor receptor-1 (FGFR1), and mast/stem cell growth factor receptor (c-Kit). Sorafenib is approved for the second-line treatment of advanced or mRCC after progression on cytokine therapy. The approval was based on a phase III double-blind clinical trial in which 903 patients with advanced or mRCC, who had progressed after previous therapy with IFN-α and/or IL-2, were randomized to treatment with sorafenib or placebo. Study patients received sorafenib 400 mg orally twice daily continuously or placebo twice daily until disease progression or intolerable toxicities. Notably, 48% of patients in the placebo arm crossed over to the sorafenib arm after evidence of progression prior to a planned interim analysis. At the time of interim analysis, a significant PFS advantage was observed in patients treated with sorafenib compared to those treated with placebo (5.5 vs 2.8 months; HR = 0.44; P<0.01).[7] The primary endpoint of the study was OS, and final analyses revealed no OS difference between sorafenib and placebo (17.8 vs 15.2 months; HR = 0.88; P=0.15), but censoring for patients who crossed over showed a significant OS benefit favoring sorafenib therapy (17.8 vs 14.3 months; HR = 0.78; P=0.03).[75] Sorafenib was generally well tolerated with few grade 3 or 4 adverse events, although about 5% of patients reported cardiac infarct or ischemic events.[7] Sorafenib was also studied as first-line therapy for mRCC. In a randomized phase II clinical trial, which compared sorafenib to IFN-α_{2a}, study patients received oral sorafenib 400 mg twice daily or subcutaneous IFN-α_{2a} 9 million units 3 times weekly. Patients were allowed to cross over from the placebo arm to the sorafenib arm, and dose escalations up to 600 mg twice daily were permitted. The primary endpoint of PFS showed no difference between sorafenib and IFN-α therapy. However, patients reported better quality of life with sorafenib compared with IFN-α therapy.[76] As a result, sorafenib is recommended by NCCN as second-line therapy for mRCC after progression on initial systemic cytokine therapy (category 1) or TKI therapy (category 2A) and as first-line therapy only in select patients (category 2A).[44].

Pazopanib

Pazopanib is orally administered TKI that was approved for the treatment of mRCC in 2009.

Pazopanib also inhibits multiple kinase receptors, including the three VEGFRs, PDGFRα and β, FGFRs, c-Kit, IL-2 receptor inducible T-cell kinase (ITK), and leukocyte-specific protein tyrosine kinase (LCK).[77] Pazopanib was evaluated in a phase III double-blind clinical trial in which 435 patients with mRCC were randomized to treatment with pazopanib 800 mg/day or placebo. The study population included 233 treatment-naive and 202 cytokine-pretreated patients. The study showed a significant PFS benefit in patients from the pazopanib arm compared with placebo (9.2 vs 4.2 months; HR = 0.46; $P<0.001$). Subgroup analyses also revealed a PFS benefit in both treatment-naive (11.1 vs 2.8 months; HR = 0.46; $P<0.001$) and cytokine-pretreated (7.4 vs 4.2 months; HR = 0.40; $P<0.001$) patients. Pazopanib was generally well tolerated, with few grade 3 or 4 adverse events.[11] It is an option for the first-line treatment of mRCC (category 1) and as second-line therapy after progression on cytokines (category 1) or TKI (category 2A).[44] A randomized, double-blind, placebo-controlled cross-over trial in patients with mRCC assessing patient preference between pazopanib and sunitinib demonstrated that 70% of patients preferred pazopanib compared with 22% who preferred sunitinib and 8% who had no preference. The most common reasons patients gave for pazopanib preference were improved quality of life and less fatigue.[78] A second phase III noninferiority trial compared the efficacy of these two agents as first-line treatment in 1,110 previously untreated patients with clear cell mRCC. The primary endpoint of the study was achieved as pazopanib was shown to be noninferior to sunitinib in terms of PFS (8.4 vs 9.5 months; HR = 1.05). OS was also similar between the pazopanib and sunitinib arms (28.4 vs 29.3 months; HR = 0.91; $P=0.28$). Patients treated with sunitinib experienced a higher incidence of fatigue (63% vs 55%), hand-foot syndrome (50% vs 29%), and thrombocytopenia (78% vs 41%). Conversely, patients treated with pazopanib had a higher incidence of elevated hepatic enzymes (60% vs 43%). Quality-of-life measures, particularly those related to fatigue or soreness in the hands, feet, mouth, and/or throat, favored pazopanib. Investigators on this phase III trial concluded that pazopanib and sunitinib have similar efficacy in the the first-line setting, but safety and quality-of-life profiles favor pazopanib.[79] Pazopanib has also been prospectively studied as a second-line option in patients previously treated with sunitinib or bevacizumab. This phase II trial showed that 27% of the patients had an objective response to pazopanib, and 49% of the patients experienced stable disease. Median PFS for the entire cohort was 7.5 months, and similar PFS was observed among patients treated with sunitinib versus those treated with bevacizumab. The OS rate for the entire cohort at 24 months was 43%. This trial showed that pazopanib remains an active and viable treatment option for the treatment of mRCC, even after patients have progressed on previous targeted therapy treatment.[80]

Although sunitinib, sorafenib, and pazopanib are all orally administered antiangiogenic multikinase inhibitors, clinical studies have clearly demonstrated that these agents have different efficacy and toxicity profiles (**Tables e138-4** and **e138-5**). Whereas sunitinib and pazopanib have been reported to improve PFS in both first- and second-line treatment settings, sorafenib has demonstrated improved PFS only in the second-line treatment setting. In addition to differences in efficacy, these agents have subtle differences in their adverse effect profiles.[81] Sunitinib and pazopanib are associated with higher rates of hypertension and hair discoloration than sorafenib. Sunitinib is also associated with higher rates of hypothyroidism than sorafenib. Sorafenib is associated with higher rates of gastrointestinal side effects and hand–foot syndrome than sunitinib and pazopanib. It is also important to note that sunitinib is administered intermittently in a 6-week cycle (4 weeks on

treatment, 2 weeks off treatment), but sorafenib and pazopanib are both administered continuously. Both sunitinib and sorafenib appear to have benefit in the subgroup of patients with non–clear cell histology.

TABLE e138-5 Drug Monitoring Recommendations for Targeted Agents Used in Metastatic RCC

Targeted Agent	Adverse Drug Reactions	Monitoring Parameters	Comments
Tyrosine Kinase and VEGFR Inhibitors			
Sunitinib[6, a]	Leukopenia, thrombocytopenia, diarrhea, nausea, vomiting, anorexia, constipation, mucositis, hypertension, hand–foot syndrome, hair discoloration, hypothyroidism, decreased LVEF	Adrenal insufficiency, CBC with platelets, electrolytes, liver function, thyroid function, urinalysis, blood pressure, ECG, for hemorrhagic events, for signs and symptoms of CHF or TLS	Discontinue sunitinib if clinical manifestations of CHF occur. Delay or reduce dose if no clinical manifestations of CHF but EF <50% and >20% below baseline.
Sorafenib[78, b]	Diarrhea, nausea, vomiting, anorexia, fatigue, hand–foot syndrome, desquamating rash, hypertension, fatigue, cardiac ischemia, hemorrhagic events	Electrolytes, blood pressure, liver function tests, ECG for QT interval prolongation in patients with CHF, bradyarrhythmias, or electrolyte abnormalities	Consider discontinuing therapy if clinical manifestations of cardiac ischemia or hemorrhagic event occur.
Pazopanib[5, c]	ALT elevation, leukopenia, thrombocytopenia, diarrhea, nausea, vomiting, hypertension, hair discoloration, QT prolongation, hemorrhage, thromboembolism, hypothyroidism	Hepatic function, electrolytes, thyroid function, urinalysis, ECG, blood pressure	Temporarily discontinue therapy in patients undergoing surgery.
Axitinib[8, d]	Diarrhea, hypertension, fatigue, decreased appetite, nausea, dysphonia, hand–foot syndrome, weight loss, vomiting, asthenia, constipation, hypothyroidism, stomatitis, arthralgia, proteinuria, rash, dry skin, headache, dyspepsia, cough Laboratory abnormalities: anemia,	Blood pressure, for thromboembolism, hemorrhage, GI perforation or fistula, thyroid function, wound healing, RPLS, proteinuria, hepatic impairment, pregnancy	None

Targeted Agent	Adverse Drug Reactions	Monitoring Parameters	Comments
	lymphopenia, thrombocytopenia, hyperkalemia, hyperglycemia, hypocalcemia, decreased bicarbonate, increased lipase, amylase, serum creatinine, ALP, AST, and ALT		
Monoclonal Antibody and VEGF Inhibitor			
Bevacizumab[3,e]	Epistaxis, hemorrhage, delayed wound healing, hypertension, thromboembolic events, proteinuria, GI perforation, dry skin, rhinitis, taste alteration	Blood pressure, urine protein	Do not administer within 4 weeks of surgery
Mammalian Target of Rapamycin Inhibitors			
Everolimus[4,f]	Abdominal pain, asthenia, cough, dehydration, diarrhea, dyspnea, fatigue, infections, pneumonitis, and stomatitis Laboratory abnormalities: anemia, hypercholesterolemia, hypertriglyceridemia, hyperglycemia, lymphopenia, and increased serum creatinine	Blood glucose, serum cholesterol, serum creatinine, triglycerides, liver function tests, chemistry, and hematologic parameters	Avoid live vaccinations and close contact with those who received live vaccines.
Temsirolimus[2,g]	Anorexia, asthenia, edema, hypersensitivity reactions, infections, interstitial lung disease, mucositis, nausea, rash, wound healing complications Laboratory abnormalities: anemia, hyperglycemia, hyperlipidemia, hypertriglyceridemia, hypophosphatemia, leukopenia, lymphopenia, thrombocytopenia, and elevated ALP, aspartate transaminase, and serum creatinine	Blood glucose, serum cholesterol, serum creatinine, triglycerides, liver function tests, chemistry, and hematologic parameters	Avoid live vaccinations and close contact with those who received live vaccines.

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; CHF, congestive heart failure; ECG, electrocardiogram; EF, ejection fraction; GI, gastrointestinal; LVEF, left ventricular ejection fraction; RCC, renal cell carcinoma; RPLS, reversible

posterior leukoencephalopathy syndrome; TLS, tumor lysis syndrome; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

[a]Sunitinib (Sutent) prescribing information: Pfizer, Inc. New York, NY. Revised May 2015.

[b]Sorafenib (Nexavar) prescribing information: Bayer Healthcare Pharmaceuticals, Inc. Wayne, NJ. Revised June 2015.

[c]Pazopanib (Votrient) prescribing information: GlaxoSmithKline, Inc. Research Triangle Park, NC. Revised January 2015.

[d]Axitinib (Inlyta) prescribing information: Pfizer, Inc. New York, NY. Revised August 2014.

[e]Bevacizumab (Avastin) prescribing information: Genentech, Inc. San Francisco, CA. Revised May 2015.

[f]Everolimus (Afinitor) prescribing information: Novartis Pharmaceuticals Corp. East Hanover, NJ. Revised September 2015.

[g]Temsirolimus (Torisel) prescribing information: Wyeth Pharmaceuticals Inc. Philadelphia, PA. Revised February 2015.

NOTE: Cabozantinib received FDA approval in 2016 for the treatment of advanced RCC; however, at the time of press, their respective package inserts had not yet been revised to reflect monitoring recommendations.

Axitinib

Axitinib is a second-generation orally administered TKI approved in January 2012 for the treatment of advanced RCC after progression on one prior systemic therapy. Axitinib is a second-generation, selective inhibitor of all three VEGFRs, and has been shown to be 50 to 450 times more potent than first-generation VEGFR inhibitors (eg, sorafenib and sunitinib). Unlike first-generation agents, axitinib has limited activity beyond VEGFR blockade, potentially reducing off-target toxicities.[82] Axitinib was compared to sorafenib in a randomized, open-label, phase III trial in 723 patients with clear cell RCC who had progressed on a previous first-line regimen of sunitinib, bevacizumab plus IFN, temsirolimus, or cytokine-based therapy. Most of the patients enrolled had previously received either sunitinib-based therapy (54%) or cytokine-based therapy (35%). The AXIS trial was notable because it was the first phase III trial where another targeted therapy was used as the comparator (sorafenib). AXIS achieved its primary endpoint by revealing a PFS benefit in patients treated with axitinib when compated to patients treated with sorafenib (6.7 vs 4.7 months; HR = 0.67; $P < 0.0001$). This benefit was seen in both the patients who received prior therapy with sunitinib and cytokines. Additionally, fewer patients discontinued axitinib because of toxic effects compared with sorafenib (4% vs 8%). The most common adverse effects seen with axitinib were diarrhea, hypertension, fatigue, nausea, and dysphonia, and patients had notably less hand–foot syndrome and alopecia compared with those treated the multikinase inhibitor sorafenib.[8] A second phase III trial was subsequently conducted to

assess the benefit of axitinib as a first-line treatment. This open-label trial randomized treatment-naïve patients to receive either oral axitinib 5 mg twice daily or oral sorafenib 400 mg twice daily. PFS was the primary endpoint of the trial, and there was a trend toward a PFS benefit in patients treated with axitinib when compared to those treated with sorafenib (10.1 vs 6.5 months). Despite the fact that the PFS was not significantly different among the two treatment arms in this trial, there was sufficient evidence of axitinib activity and an acceptable toxicity profile in the first-line setting.[83] Based on the results from these two phase III trials, axitinib is an option for the first-line treatment of mRCC, and as second-line therapy after progression on cytokines and/or a TKI (all category 1).[44]

Cabozantinib

Cabozantinib is the newest orally administered TKI approved for the treatment of advanced RCC after progression on one prior systemic therapy. Cabozantinib tablets first received breakthrough approval from the FDA in August 2015, and then received full approval in April 2016, for the treatment of advanced RCC. Cabozantinib has been shown to potently inhibit VEGFR2, as well as MET, FLT-3, RET, and AXL.[84] A single-arm, open-label phase I trial evaluated the safety and tolerability of cabozantinib in patients with clear cell mRCC. Patients enrolled on this trial were heavily pretreated (median two prior systemic therapies, and 88% of patients had received at least one prior VEGF-pathway inhibitor. Cabozantinib-related toxicities were similar to other approved VEGF-pathway inhibitors, and included fatigue, diarrhea, nausea, proteinuria, decreased appetite, palmar-plantar erythrodysesthesia, and vomiting. Partial response was reported in 28% of patients, median PFS was 12.9 months, and median OS was 15.0 months.[85]

FDA approval was granted to cabozantinib based on interim results from the phase III METEOR trial, which compared oral cabozantinib 60 mg daily versus oral everolimus 10 mg daily. The trial achieved its primary endpoint by showing a significant PFS benefit among the first 375 randomized patients. Cabozantinib reduced the risk of disease progression or death by 42% compared to the everolimus arm (HR = 0.58; $P < 0.0001$). Objective response rates also favored cabozantinib when compared to everolimus (21% compared to 5%; $P < 0.001$). Interim analysis results also showed a trend toward an OS benefit for patients treated with cabozantinib (HR = 0.67; $P=0.005$), but did not cross the significance boundary for the interim analysis. Dose reductions due to adverse events occurred more often in cabozantinib patients than everolimus patients (60% vs 25%), but treatment discontinuation rates were similar between the two arms (9% of the cabozantinib patients vs 10% of the everolimus patients).[9]

Clinical Controversy…

Most patients with advanced or metastatic RCC will receive first-line therapy with a tyrosine kinase inhibitor (TKI) that targets VEGFRs, but disease progression inevitably occurs, and therapy with an alternate VEGFR-targeted agent, PD-1 inhibitor, or mTOR inhibitor will be initiated. Because responses to initial VEGR-targeted therapy are rarely complete or durable, the question of optimal therapy sequencing is important, yet problematic because few head-to-head studies have been conducted to address this issue. Future clinical trials are certainly needed to determine the optimal

sequencing of these distinct agents in the first-line setting and beyond.

Bevacizumab

Bevacizumab is a humanized monoclonal antibody that binds circulating VEGFA and inhibits the ligand from binding to the VEGFRs.[72] Bevacizumab was studied in a phase III double-blind clinical trial in which 649 treatment-naive patients with mRCC were randomized to receive bevacizumab plus IFN-α_{2a} or placebo plus IFN-α_{2a}. Bevacizumab was administered IV at 10 mg/kg every 2 weeks until disease progression or intolerable toxicity; no dose reductions were allowed. IFN-α_{2a} was administered subcutaneously at 9 million units three times weekly with dose reduction to 6 million or 3 million units for treatment-related toxicity.[5] The primary endpoint of the trial was not achieved because OS was not statistically different between the two treatment groups (23.3 vs 21.3 months; P=0.13).[81] However, the secondary endpoints showed a significant benefit with the addition of bevacizumab to IFN-α_{2a}. PFS was longer (10.2 vs 5.4 months; P=0.0001) and objective response rate was higher (31% vs 13%) when bevacizumab was added to IFN-α_{2a}. The most common adverse effects were attributed to IFN-α_2 therapy, and the addition of bevacizumab did not significantly increase toxicity. However, treatment discontinuations due to adverse events occurred more often in the bevacizumab group, with proteinuria, hypertension, and gastrointestinal perforation as the most common causes of discontinuation.[5,86] Bevacizumab plus IFN-α_{2a} was studied in a Cancer and Leukemia Group B phase III clinical trial (CALGB 90206), which compared it with IFN-α_{2a} monotherapy as first-line treatment.[87] The results of this study were similar, with improvements in PFS and objective response rates but no difference in OS. The combination of bevacizumab plus IFN-α_{2a} is an option for the first-line treatment of mRCC (category 1), and bevacizumab monotherapy is also an option as second-line therapy (category 2B).[44] Recently, a randomized phase II trial was conducted in 361 clear cell mRCC patients. The goal of the study was to demonstrate that two-drug regimens were superior to bevacizumab monotherapy. Patients were randomly assigned to receive bevacizumab and temsirolimus, bevacizumab and sorafenib, sorafenib and temsirolimus, or bevacizumab monotherapy. Among the 331 patients eligible for treatment, there was no PFS benefit in any of the two-drug regimens when compared to bevacizumab monotherapy, and adverse events were comparable among all four treatment arms.[88]

Temsirolimus

10 Temsirolimus is an IV administered agent that inhibits mTOR. As discussed previously, mTOR is a downstream component of the PI3K/AKT pathway that ultimately results in HIF regulation.[28,31] Temsirolimus was compared with IFN-α_{2a} or the combination of the two agents in a phase III multicenter trial of 626 treatment-naive patients with higher risk mRCC. About 75% of patients were considered high risk (more than or equal to three poor prognostic risk factors), and 25% were considered intermediate risk (less than or equal to two poor prognostic risk factors), based on the MSKCC risk classification. The IFN-α_{2a} group received 3 million units subcutaneously three times weekly for the first week, 9 million units the second week, and 18 million units thereafter. The temsirolimus group received 25 mg IV once weekly, and the combination group received IFN-α_{2a} at 3

million units subcutaneously three times weekly for the first week and 6 million units subcutaneously three times weekly and temsirolimus 15 mg IV once weekly. The trial was discontinued early after the second interim analysis based on temsirolimus benefit.[4] The trial achieved its primary endpoint as OS was significantly improved in patients who received single-agent temsirolimus compared to those who received IFN-α_{2a} or combination therapy (10.9 vs 7.3 months for IFN-α_{2a} alone and 8.4 months for combination therapy). Median PFS for single agent temsirolimus, single agent IFN-α_{2a}, and combination therapy was 5.5, 3.1, and 4.7 months, respectively. Serious adverse effects were more common in the IFN-α_{2a} groups than in the single agent temsirolimus group, resulting in fewer dose reductions and dose delays for those patients. Patients receiving temsirolimus were more likely to experience hyperlipidemia, hyperglycemia, and hypercholesterolemia, which were expected adverse effects based on mTOR's role in the regulation of glucose and lipid metabolism. The results of this trial support the use of temsirolimus for first-line treatment of high risk patients with poor prognostic features, making it the first therapy specifically approved for this patient population. Historical data on patients with more than or equal to three factors associated with poor prognosis have revealed a median OS of 4 to 8 months, which is consistent with the 7.3 months OS observed in this study.[41,42,89,90] Based on these results, temsirolimus is recommended by NCCN for first-line treatment in patients with mRCC with poor prognosis (category 1) and as an option for select patients of other risk groups (category 2B). It is also recommended as a second-line option in patients who have received prior cytokine therapy (category 2A) and/or prior TKI therapy (category 2B).[44]

Everolimus

Everolimus is an orally administered mTOR inhibitor, which was approved by the FDA in 2009 for patients with advanced RCC who had failed sorafenib or sunitinib therapy. A phase II trial of everolimus in patients with predominantly clear cell histology mRCC, who had received no more than one prior therapy, resulted in a modest number of partial responses or stable disease.[91] Based on these data, a multinational, multicenter, double-blind, phase III trial was conducted. This trial randomized patients who had failed previous sunitinib or sorafenib therapy to everolimus or placebo. Patients randomized to the everolimus treatment arm received oral everolimus 10 mg once daily. Due to food effects associated with everolimus, patients from both treatment arms administered their medication while either fasting or with a light, fat-free meal. The trial was halted after the second interim analysis based on benefit seen in the everolimus group.[4] The trial achieved its primary endpoint when it revealed a PFS benefit for patients treated with everolimus when compared to placebo (4.0 vs 1.9 months; $P<0.0001$). Patients in the everolimus treatment arm had a 26% probability of being progression-free at 6 months compared with 2% in the placebo group. Final analyses revealed similar median OS between the everolimus and placebo arms (14.8 vs 14.4 months; HR, 0.87; $P=0.162$), with 80% of patients in the placebo arm crossed over to everolimus. After adjustment for crossover, OS was 1.9-fold longer in patients treated with everolimus when compared to placebo.[92] Partial responses were rare and were seen in only three patients in the everolimus group and none in the placebo group.[4] Health-related quality of life was assessed with the European Organization for the Research and Treatment of Cancer (EORTC) QLQ-30 and Functional Assessment of Cancer Therapy Kidney Symptom Index—Disease-Related Symptoms (FKSI-DRS)

questionnaires.[93,94] Although the time-to-definitive deterioration of patient-reported outcomes was not different between the two groups, quality of life was sustained during treatment with everolimus relative to placebo as assessed by the EORTC QLQ-C30 and FKSI-DRS questionnaires. All adverse events occurred more frequently in the everolimus group than in the placebo group, but severe adverse effects were uncommon. Elevations in glucose and lipids were seen because of everolimus' ability to inhibit mTOR.[95] Based on these results, the NCCN guidelines recommend everolimus for patients with mRCC who have failed treatment with prior TKI therapy (category 1).[44]

Temsirolimus and everolimus are both mTOR inhibitors, but they have several important differences. First, everolimus is administered orally once daily, whereas temsirolimus is administered as a once weekly IV infusion. Second, while everolimus was studied only in patients with clear cell RCC, the temsirolimus phase III trial enrolled patients with clear cell histology (80%) as well as other RCC histological subtypes (20%). Third, whereas temsirolimus was studied in the first-line setting in patients with poor prognosis based on clinical features, everolimus was studied in the second-line setting in patients who had progressed after sorafenib or sunitinib.

Clinical Controversy…

Since mRCC remains incurable and the long-term efficacy and durability of VEGFR- and mTOR-targeted agents for most patients is limited, combination therapy remains a clinically controversial option for the treatment of these patients. Previous attempts to combine the eight approved agents with one another or with IL-2/IFN-α have not proven to be more efficacious than single agent regimens, but have resulted in increased toxicities and dose reductions. Despite past failures, combination therapy continues to be of interest to researchers. As a result, several early phase trials are underway to explore the efficacy of combinations that include already approved VEGFR-targeted therapies and novel inhibitors of nonangiogenic signaling pathways.[96]

PERSONALIZED PHARMACOTHERAPY

Given the numerous treatment options for advanced and mRCC, the utilization of patient-related factors to guide treatment selection would be beneficial, but no validated predictors of treatment response have been determined. The use of therapeutic drug monitoring for the TKIs and mTOR inhibitors is an attractive option given the numerous factors that can cause variation in drug exposures. For example, differences in first-pass liver metabolism, variation in activation and deactivation pathways, and drug interactions can result in differences in the pharmacokinetics of these agents. Barriers of implementation in current practice are numerous and include a well-defined and validated therapeutic target concentration and availability of reliable analytic assays that can be implemented into clinical practice.[97] However, there is some evidence that this strategy may be possible with sunitinib and everolimus in the future.[95]

A meta-analysis of sunitinib in patients with RCC or gastrointestinal stromal tumors was performed to explore the relationship between exposures of sunitinib and its active metabolite, SU12662, and clinical outcomes. Steady-state area-under-the-curve (AUC) of sunitinib and SU12662 were associated with time-to-progression, OS, and toxicity. Higher AUC was associated with longer

time-to-progression and OS; increased response rate; and increased incidence of fatigue, hypertension, and neutropenia.[98] Moreover, a recent pharmacokinetic-guided sunitinib dosing pilot study was conducted in 42 patients with advanced solid tumors. Patients were treated with oral sunitinib 37.5 mg daily. At days 15 and 29 of treatment, plasma trough levels of sunitinib and N-desethyl sunitinib were measured. If the total trough level was less than 50 ng/mL (mcg/L; less than 125 nmol/L) and the patient did not experience a grade greater than or equal to three adverse events, then sunitinib was escalated by 12.5 mg daily. If the patient suffered from grade greater than or equal to three adverse events, sunitinib was decreased by 12.5 mg daily. A total of 67% of the patients were evaluable for pharmacokinetic assessments, and grade greater than or equal to three adverse events were noted in 24% of the evaluable patients at the starting dose, and in 31% after dose escalation. Total trough levels were below target in 52% of the evaluable patients at the starting dose. Of these, 17% reached target total trough levels after dose escalation. In about 33% of the evaluable patients below the target total trough level at 37.5 mg of sunitinib, the dose could be increased without additional toxicities.[99] While this type of study has not been conducted in a cohort comprised solely of patients with RCC, and still requires additional clinical validation, these types of analyses provide rationale for conducting future prospective dose-targeting trials.

Everolimus is a derivative of sirolimus, an immunosuppressant agent used in the prevention of solid organ transplant rejection. Therapeutic drug monitoring is commonly used in clinical practice to optimize dosing of sirolimus, which suggests that the same may be possible and beneficial with everolimus. In a phase I pharmacodynamic trial in solid tumor patients, plasma trough concentrations of everolimus were correlated with inhibition of mTOR as evidenced by decreased concentrations of downstream mTOR pathway proteins. The linear pharmacokinetics of everolimus also makes pharmacokinetic-directed therapy an attractive and feasible future option.[100]

In summary, current clinical applications for personalized RCC therapies are limited, but properties of the agents currently used for management of the disease make them attractive options for future pharmacogenetic and pharmacodynamic studies.

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of treatment in patients with RCC depends on the extent of disease at the time of diagnosis. Whereas localized RCC has a 5-year survival of about 85%, mRCC has a 5-year survival of less than 23%.[12] The standard of care in patients with localized RCC (stage I-III) is surgical removal with a goal of long-term survival and cure. However, 20% to 30% of patients will relapse within 3 years, and 50% to 60% of these patients will have distant recurrence to the lungs. The NCCN Kidney Cancer Panel recommends that patients undergo a medical history; physical examination; comprehensive metabolic panel (including blood urea nitrogen, serum creatinine, calcium levels, and liver function tests); and abdominal, pelvic, and chest imaging every 6 months for the first 2 years after surgery and annually thereafter.[44] For patients with stage IV and unresectable RCC, the goal of treatment is to control disease burden and prolong survival while maximizing quality of life. Current treatment options depend on RCC histology, comorbidities, patient performance status, and prognosis and include enrollment in a clinical trial; immunotherapy (IFN-α, IL-2, and nivolumab); or

targeted therapy with VEGFR-TKIs (sunitinib, sorafenib, pazopanib, axitinib, and cabozantinib), mTOR inhibitors (everolimus, temsirolimus), or a monoclonal antibody VEGF inhibitor (bevacizumab). If a patient has disease progression on the initial treatment regimen, subsequent treatment from a different medication class should be considered. At each patient visit, adherence to medication regimens must be strongly emphasized, and treatment-related toxicities should be closely monitored and prevented, if possible. Because optimizing quality of life is usually the therapeutic endpoint in mRCC, best supportive care should be given to all patients, which may include palliative radiation, metastasectomy, and bisphosphonates or receptor activator of nuclear factor-κB ligand inhibitors for the treatment of bone metastases.[44]

ABBREVIATIONS

Chapter 139: Melanoma

Cindy L. O'Bryant; Jamie C. Poust

INTRODUCTION

KEY CONCEPTS

- 1 Cutaneous melanoma is an increasingly common malignancy, but it is a cancer that can be cured if detected early. Public education about screening and early detection is one strategy to control the increase in incidence and the mortality associated with cutaneous melanoma.
- 2 Surgical resection can cure patients with early-stage melanoma.
- 3 Adjuvant therapy should be considered in patients with locally advanced disease; recommended options include IFN-α_{2b}, ipilimumab or participation in a clinical trial.
- 4 Single agent chemotherapy offers limited benefit in metastatic melanoma. Combination chemotherapy has not been shown to be superior to single-agent therapy.
- 5 Advances in immunotherapy with ipilimumab, pembrolizumab, and nivolumab have led to long durable responses in some patients with metastatic melanoma and have significantly impacted overall survival.
- 6 The immune-related toxicities associated with immunotherapy can be severe and life-threatening. Consequently, the use of these agents warrants appropriate patient selection, close monitoring and toxicity management by an experienced healthcare team.
- 7 As the biology of melanoma has been further delineated, a growing number of potential targets for drug therapy have been identified. BRAF mutations appear in up to 70% of melanoma patients. The use of BRAF inhibitors with or without MEK inhibitors has been shown to improve overall survival in patients with this mutation.
- 8 Treatment of melanoma is determined by many factors. As the number of treatment options for patients with metastatic melanoma grows, it will be important to consider disease- and patient-related aspects when determining appropriate therapy.

Skin cancer is the most common malignancy worldwide and is associated with chronic ultraviolet (UV) exposure. The two types of skin cancer are nonmelanoma skin cancers (NMSCs) and melanoma. Although NMSCs are the most common malignancy of the skin, cutaneous melanoma accounts for up to 75% of all skin cancer-related deaths. Melanoma cases are increasing globally with the highest rates found in Australia, New Zealand, North America, and Northern Europe. Melanoma is the sixth most common cancer in the United States. The incidence of melanoma has steadily increased in the United States since the 1970s, and for the last decade, has raised an average of 1.4% each year.[1] When detected early, patients generally have a good prognosis. With the rise in the number of melanoma skin cancers and the associated mortality, it is essential to consider issues of care beyond that of disease treatment. Skin cancer prevention and screening have a major impact on public health, and on the success of treatment, for those individuals diagnosed with both NMSC and melanoma. Skin cancers tend to occur more frequently in older individuals with a median age of diagnosis 63 years old.[1] Therefore, as the population continues to age, effective strategies to prevent, detect, and treat individuals with these cancers are necessary. An understanding of the biology of melanoma has led to the development of targeted therapies toward somatic mutations and immunotherapies, which have shown improved outcomes in patients with advanced melanoma.

EPIDEMIOLOGY

In the United States, about one in every 50 individuals will be diagnosed with melanoma in their lifetime. The lifetime risk is greater in men than women, but rates are higher in women before the age of 50. Risk also varies with ethnicity, with the majority of melanoma occurring in non-Hispanic whites.[2,3] In 2016, it is estimated that 76,380 new cases of melanoma would be diagnosed in the United States.[3] Unfortunately, this estimate may not be accurate as many superficial, and in situ melanomas, are managed in facilities that do not routinely report their cases to cancer registries. Childhood and adolescent melanoma account for only 1% of new melanoma cases each year, but is the most common skin cancer in individuals younger than 20 years old. The incidence in this age group is increasing by 2% per year. Adolescents between the age of 15 and 19 years have the highest rates of melanoma (18%) compared to younger children, with the incidence in girls being higher than boys in all age ranges.[4]

The estimated number of individuals expected to die of melanoma in 2016 in the United States is 10,130.[3] Survival rates have gradually increased over the past four decades. The 5- and 10-year relative survival rates are 91% and 89%, respectively, but survival declines to 16% with more advanced disease.[1] Although the overall mortality rate has remained stable, those younger than 50 years of age had a 2.6% decrease from 2007 to 2011 while those over 50 years of age had a 0.6% increase.[3]

A number of patient-specific factors and environmental factors have been identified (**Table 139-1**), and it is likely these factors alone, or in combination, increase the risk of cutaneous melanomas.

TABLE 139-1 Risk Factors for Melanoma

Patient-Specific Risk Factors

Patient-Specific Risk Factors

Adulthood (age older than 15 years)

History of cutaneous melanoma

Dysplastic nevi

High density of common nevi and atypical nevi

Cutaneous melanoma in first-degree relative

Immunodeficiency or immunosuppression

High degree of freckling

Sunburns easily or tans rarely

Blonde or red hair

Blue, green, or gray eyes

Socioeconomic status (higher > lower)

Race (Caucasians > Hispanics > African Americans)

External Risk Factors

Intense intermittent sun exposures

History of sunburn

More than four painful sunburns before age 15 years

Recreational sun exposure

Individual physical characteristics can determine responses to UV radiation. Caucasians with fair-colored hair (red or blond), light-colored eyes (blue or green), high degrees of freckling, and those who have a tendency to burn, and rarely tan with exposure to sunlight, appear to be especially at risk. Both UVB and UVA are known carcinogens and are related to the development of melanoma. Clinical and epidemiologic research shows a higher rate of melanoma in those who have extensive or repeated intense UV and sun exposure.[5] Intermittent intense sun exposure, blistering sunburns, the use of tanning beds, and the time of life when exposed to the sun are critical factors for development of cutaneous melanoma. Individuals with a history of these factors are at highest risk. The risk is lower in individuals who have had chronic sun exposure, without a history of burning, and those with occupational exposure. The risk with sunlight and UV radiation seems to be greatest during childhood and adolescence and is more hazardous than exposure during adult life.

An important risk factor for melanoma is the number and size of melanocytic nevi (pigmented lesions or moles) on the body. The formation of these nevi has been shown to be directly related to

cumulative sun exposure. The relative risk of developing melanoma increases with the number of typical nevi an individual has. A second risk factor is the presence of atypical melanocytic nevi. Atypical nevi may progress from a normal nevus or be dysplastic from the onset. Up to 20% of melanomas develop from atypical nevi. Congenital melanocytic nevi may be present at birth or within the first few months after birth, and the associated risk of melanoma increases with size.

Immunocompromised patients are at an increased risk for development of cutaneous melanoma and these cases have been shown to have a poor prognosis.[6] Immunodeficiency includes individuals with chronic lymphocytic leukemia, Hodgkin lymphoma, and immunosuppression after organ transplant. Acquired immunodeficiency syndrome (AIDS) has been shown to increase the risk of developing cutaneous melanoma and the disease often is more aggressive. A personal history of NMSC or melanoma skin cancers is a risk factor for subsequent melanoma and may be associated with a poor prognosis. Xeroderma pigmentosum is a rare skin disorder associated with an increased risk for melanoma.

A number of genes have been implicated in melanoma development and progression, and molecular profiling studies have identified several distinct molecular subclasses of melanoma. Familial atypical multiple mole syndrome (FAMMS) or dysplastic nevus syndrome is a hereditary disease characterized by a predisposition to develop dysplastic nevi and cutaneous melanoma. It is estimated that up to 12% of cases of melanoma are associated with a family history or hereditary dysplastic nevus syndrome. FAMMS is associated with mutations in the *CDKN2A* gene located at chromosome 9p21. *CDKN2A* encodes two distinct proteins: inhibitor of cyclin-dependent kinase 4 (INK4A or $p16^{INK4a}$) and ARF (alternative reading frame; p14ARF). INK4A regulates cell cycle progression at the G_1/S checkpoint by inhibiting the G_1 cyclin-dependent kinases that phosphorylate and inactivate the retinoblastoma protein. ARF inhibits p53 degradation and loss of ARF inactivates p53. The frequencies of *CDKN2A* mutations vary in melanoma, but are more commonly found in individuals with familial inheritance patterns and are associated with multiple cases of melanoma in a family, young age at diagnosis, multiple primary melanomas among family members, and pancreatic cancer.[7]

ETIOLOGY

Melanoma arises from the melanocytes in the basal layer of the epidermis. DNA damage, most commonly a result of UV radiation, causes cellular mutations which transform the cell, allow uncontrolled proliferation, and lead to the formation of tumors. The identification of these genetic alterations has led to the recognition of molecular subgroups of melanoma, and more focused drug development for treatment. The first insights to the role of genetics were seen with the relationship of *CDKN2A* mutations and FAMMS.

One of the major signaling pathways found to be associated with the development of melanoma is the mitogen-activated protein kinase pathway (MAPK), which mediates receptor tyrosine kinases, resulting in activation of RAS and downstream BRAF. Activating *BRAF* mutations are the most common somatic genetic event in human melanoma, occurring in 25% to 70% of melanoma patients and primarily noted by a single point mutation (V600E). In the V600E mutation, a valine is substituted

for glutamic acid at codon 600. *BRAF* is a somatic mutation and its high prevalence appears to be an epidemiologic link between UV radiation and melanoma. *BRAF* mutations are common in melanomas arising from skin with intermittent sun exposure.[8]

Upstream of BRAF, mutations in *NRAS* and c-*Kit* have also been found as molecular drivers in the development of melanoma. Mutations in *NRAS* are found in 15% to 20% of patients. These tumors are associated with more advanced disease at diagnosis, high growth rates, and shorter survival times than those with *BRAF* mutations.[8] c-*Kit* is a transmembrane receptor tyrosine kinase which, when activated, signals the MAPK andphosphatidyl-inosital-3-OH kinase (PI3K) pathways, resulting in transcription and cell proliferation. Mutations in c-*Kit* are commonly found in acral and mucosal melanomas.[8]

Other genetic alterations involved with the development of melanoma include *MITF* (microphthalmia-associated transcription factor), which is a gene important to the survival of melanocytes. When mutated, *MITF* acts as an oncogene.[9] The melanocortin 1 receptor gene (*MC1R*), is prevalent in individuals with melanoma and signals through the MITF pathway. It is involved in melanin synthesis and is associated with the red hair and fair skin phenotype. Variants in *MCIR* lead to a shift in the production from eumelanin (brown/black pigment) to pheomelanin (red/yellow pigment).[10]

PREVENTION AND DETECTION

1 Skin cancer is recognized as a major health problem in the United States. As a result, in 2014 the US Surgeon General released Call to Action to Prevent Skin Cancer. The Call to Action addresses the following goals to support skin cancer prevention: increase opportunities for sun protection in outdoor settings; provide individuals with the information they need to make informed, healthy choices about UV radiation exposure; promote policies to advance the national goal of preventing skin cancer; reduce harms from indoor tanning; and strengthen research, surveillance, monitoring, and evaluation related to skin cancer prevention.[11] As such, the mainstay of melanoma prevention remains strategies to protect individuals from the harmful effects of the sun (**Table 139-2**). There are three different strategies for melanoma chemoprevention: primary chemoprevention in healthy individuals; secondary chemoprevention to prevent premalignant melanoma precursors from becoming melanoma; and tertiary chemoprevention to prevent melanoma recurrence.

TABLE 139-2 Options for Sun Protection Sunscreens

	Sunscreens	
Behavioral	**Physical Blockers (Reflectants)**	**Chemical Absorbers**
Protective clothing and accessories	Zinc oxide	Ultraviolet B absorbers
Seek shade (avoid peak sun hours)	Talc	Salicylates
Avoid tanning equipment	Titanium dioxide	Cinnamates
	Red petrolatum	Camphor derivatives

	Sunscreens	
Behavioral	**Physical Blockers (Reflectants)**	**Chemical Absorbers**
		Aminobenzoates
		Ultraviolet A absorbers
		Benzopehnone-6
		Dibenzoylmethanes

UV exposure plays a major role in melanoma development and is the most preventable cause of melanoma. For most people, the sun is the most common source of UV exposure and an important environmental factor in the pathogenesis of melanoma. The incidence of melanoma has been associated with latitude and the intensity of solar exposure among susceptible populations. Radiation in the UVB range (280-320 nm) is historically considered to be the critical factor linking sunlight and melanoma, although prolonged exposure to UVA radiation (320-400 nm) is also important.

Education, and reeducation, about the importance of sun protection have the potential to decrease the rising incidence of this disease. Strategies such as sun avoidance, especially during peak hours of sun intensity (10 am-4 pm), and staying in the shade when outdoors, are important education concepts for individuals who are in the sun for prolonged periods or who are at high risk for burning. Skiers and winter sports enthusiasts should be cautioned about exposure to UV radiation because the reflection off snow and high altitude contribute to increased UV exposure. The use of protective clothing to minimize damage to the skin for individuals who spend time in the sun is also an option. Clothing and hats designed to protect an individual from sun exposure, but allow for physical activities, such as water sports and hiking, are widely available. In addition, the use of sunglasses, with both UVA and UVB protection, is important. The use of tanning beds has also been associated with development of melanoma. A recent meta-analysis reported that about 6,000 cases of melanoma may be related to indoor tanning in the United States each year.[12] In 2009, the World Health Organization International Agency for Research on Cancer declared UV light emitted from tanning beds was a human carcinogen.[13] To aid in the prevention of skin cancers here in the United States, the Food and Drug Administration (FDA) reclassified UV tanning devices to class II (moderate-to-high risk) devices.[14] Furthermore, regulations have been put in place to restrict minors' access to indoor tanning in 44 states, including 13 which prohibit the use of indoor tanning for anyone younger than 18 years of age.[11]

The use of sunscreens is another strategy to decrease UV exposure. Historically, people have been educated that the risk of skin cancer can be limited by the use of sunscreens with a sun protection factor (SPF) of 15 or greater. In 2011, the FDA mandated new testing and labeling regulations for sunscreen products. Under these regulations, sunscreens labeled as broad spectrum must protect against both UVA and UVB radiation. A product labeled as broad spectrum with a SPF of 15 or higher when used regularly, as directed, and with other sun protective measure, will help prevent sunburn and reduce the risk of skin cancer. Additionally, the regulations limit the SPF value on sunscreen labels to 50+ because of the lack of evidence to show that products with SPF values greater than 50

provide greater protection.[15]

It is important to counsel patients about the appropriate use of sunscreens to optimize benefits from these products. Sunscreens should be applied 30 minutes before going into the sun and should be reapplied every 2 hours, after swimming, and after perspiring heavily. About 1 oz (30 mL) of sunscreen (a "palmful") should be used to cover the arms, legs, neck, and face of the average adult. Sun protection must be used regularly and not merely limited to times of recreation or anticipated "prolonged" exposure. Times of season changes, when the potential for sun exposure can be perceived as erratic, are possible times for the "first-of-the-season sunburn."

Thickness and stage of the disease are inversely related to melanoma survival. Early detection can play a large part in the secondary and tertiary prevention of melanoma. Many healthcare organizations, and skin cancer groups, recommend monthly self-skin examination (SSE) to serve as a mechanism for recognizing moles or marks on the skin that may be melanoma. Patients with a strong family history should have additional clinical examinations, and in some cases, screening photography to document the size, shape, and location of moles. Both patients and clinicians need to be properly educated in the clinical features of the disease to ensure more appropriate diagnosis. Currently, there are no consistent recommendations for the screening and early detection of melanoma.

PATHOPHYSIOLOGY

Melanomas most often arise within epidermal melanocytes of the skin, although they can also arise from noncutaneous melanocytes. During fetal development, melanocytes migrate over a predictable route to a variety of sites within the body including the skin, uveal tract, meninges, and ectodermal mucosa. Primary melanoma can arise in any area of the body with melanocytes. The skin is the most frequent site of melanoma; cutaneous melanoma constitutes 90% of all melanomas. Primary melanoma can arise in the eye (ocular melanoma), the mucosa, and in some cases, as metastatic disease with unknown primary site.[16]

Melanocytes synthesize melanin to protect various tissues, such as the skin, from UV damage and reach the keratinocytes in the upper layers of the epidermis via dendrites. Tyrosinase is an essential enzyme within melanosomes that synthesizes melanin. They are resistant to severe UV radiation, unlike keratinocytes, and their survival leads to the proliferation of mutated genes.

The pathogenesis of human melanoma involves a series of morphologic stages: melanocytic atypia, atypical melanocytic hyperplasia, radial growth phase in which limited growth and radial expansion of the nevi may occur without metastatic competence, primary melanoma in the vertical growth phase with or without in-transit metastasis, regional lymph node metastatic melanoma, and distant metastatic melanoma. Primary melanoma is characterized by radial growth and limited vertical thickness (less than 0.75 mm). Primary melanoma demonstrates little tendency to metastasize. Melanoma has a potential for metastasis formation with the onset of a vertical growth phase. Therefore, the thickness of a primary melanoma is an important prognostic factor and is used in the staging classification of cutaneous melanoma. Of note, melanomas can skip steps in this

development pathway.

Melanoma cells secrete a variety of growth autocrine and paracrine factors which may facilitate proliferation. As disease progresses, melanoma cells increase production of certain growth factors and cytokines which, in turn, activate cellular growth and survival pathways. Understanding the biology of melanoma has provided potential targets for drug therapy. Pathways, such as MAPK and PI3K/AKT, have been targeted by RAF and MEK inhibitors and mammalian target of rapamycin (mTOR) inhibitors, respectively. As new pathways are identified and as agents that inhibit these pathways are developed, there is growing excitement about the opportunities to impact treatment of melanoma in new and effective ways.

The immune response appears to be more involved in the progression of melanoma than other solid tumors. Spontaneous cancer regressions are rare but are a well-documented phenomenon seen in melanoma and appear to be associated with host immunity.[17] Recombinant cytokines including interleukin-2 (IL-2) and interferons (IFNs) have been used in the treatment of melanoma to stimulate the immune system through T cell activation. Immune checkpoint receptors, such as cytotoxic T lymphocyte antigen 4 (CTLA-4) and programmed death-1 (PD-1), both found on the surface of activated T cells, appear to have an inhibitory effect on the cells. Blocking these receptors is an effective strategy for increasing the T-cell antitumor response. Vaccines against melanoma-associated antigens and the use of adoptive T cell therapy (ACT) and chimeric antigen receptors (CARs) T cell therapy are other immunotherapeutic approaches currently under investigation.[17,18]

HISTOLOGIC SUBTYPES

Cutaneous melanomas are categorized by growth patterns. Four major histologic subtypes, or growth patterns of primary cutaneous melanoma, have been identified: superficial spreading melanoma (SSM), nodular melanoma, lentigo maligna melanoma (LMM), and acral lentiginous melanoma (ALM). Clinical outcomes of the four major melanoma subtypes are similar if the comparison controls for depth of penetration or tumor thickness. Any of the four subtypes can present as an amelanotic variant. Amelanotic melanomas appear to be devoid of clinically apparent pigmentation. Desmoplastic melanoma is a less common subtype found in about 1% of cases. It is frequently seen in older individuals, and its clinical presentation is similar to that seen in NMSCs. If a biopsy of the lesion is not obtained, the disease may be mismanaged.

SSM is the most common morphologic type of cutaneous melanoma, accounting for about 75% of all melanomas and is associated with intense, intermittent sun exposure. Early in lesion development, SSM is flat, growing radially before vertically. SSM evolves slowly, typically over 1 to 5 years. As the lesion progresses it may become raised or ulcerated. The borders are often irregular and asymmetrical as the lesion progresses and may vary in color (blue, black, brown, pink, or other colors). SSMs may occur at any anatomic site on the body, but are more commonly seen on the back in men, and on the legs in women.[19] The average age of a diagnosis of SSM is 50 years old. These lesions can be linked to mutations in *BRAF*.

LMM represents 10% to 20% of melanomas and is commonly found on the head and neck. It is

unique from other histologic subtypes; because of prolonged radial growth phase, it does not have the same propensity to metastasize. LMM arises on chronically sun-exposed sites in older individuals and presents as a freckle-like lesion. LMMs are generally large flat, tan-colored lesions with shades of brown and black. The lesions gradually grow, develop, and begin to change in color.[19] Evolution into invasive melanoma is characterized by nodular development within the flat lesion. Median age at diagnosis is 65 years old. These lesions can be linked to mutations in *KIT*.

Nodular melanoma is the second most common growth pattern of melanoma, occurring in 15% to 30% of patients. Since nodular melanoma is a pure vertical growth phase disease, it is more aggressive and develops more rapidly than other subtypes.[19] Nodular melanomas are dark blue–black and often uniform in color with a shiny surface, although a small percentage of nodular melanomas are amelanotic and have a fleshy appearance. Nodular melanomas are raised and often symmetric. Although they can occur at any age, they typically occur around 50 years of age, and are most common on the trunk, head, and neck. Nodular melanomas are more common in men.

ALM makes up about 5% of melanomas and is not related to UV exposure. It presents as three distinct clinical subtypes: melanoma on the palms of the hands or soles of the feet, subungual melanoma, and mucosal melanoma.[6] Most ALMs are located on the soles of the feet and appear as a large tan or brown stain. The lesions often have irregular convoluted borders and may be masked by thick skin on the feet. Suspicious lesions on the palms or soles of the feet should be evaluated. Subungual melanoma arises in the nail matrix or nail bed. The most common presentation is a brown or black line in the great toe or the thumbnail. Mucosal melanoma is rare but can occur on any mucosal surface. Mucosal melanoma occurs most commonly in the oropharyngeal mucosa followed by the anal and rectal, genital, and urinary mucosa. Unfortunately, mucosal melanoma often does not become clinically apparent until the mass is large or the lesion bleeds. ALM is the most common type of melanoma reported in individuals with a dark complexion (eg, African Americans, Asians, and Hispanics).[19] Similar to LMMs, this subtype is characterized by a protracted radial growth phase and are associated with mutations in *c-KIT*.

Uveal melanoma is currently considered a separate disease from cutaneous melanoma. It is the most common primary intraocular malignancy seen in adults but is an uncommon tumor. Unlike cutaneous melanoma, the frequency and mortality rates of uveal melanoma have remained steady. This melanoma arises from the pigmented epithelium of the choroid. Iris melanoma is a subset of uveal melanoma and tends to have a more benign course. The risk of metastasis varies with the histologic type and size of the tumor as well as the location in the eye and most frequently metastasizes to the liver but can spread to a variety of tissues.[20]

CLINICAL SUBTYPES

With the understanding of the role of genetic alterations in the treatment and outcomes of patients with melanoma, four distinctive clinical subtypes have emerged based on UV exposure and anatomic site. The four subtypes are divided into 1) nonchronic sun damage (non-CSD): melanomas on skin without chronic sun-induced damage; 2) CSD: melanomas on skin with chronic sun-induced damage characterized by the presence of solar elastosis; 3) acral; and 4) mucosal. A genomic analysis revealed

differences in the activation of the MAPK and PI3K between the different clinical subtypes. The data showed *BRAF* mutations predominantly occur in non-CSD and less commonly in the other groups. About 10% to 20% of all the subtypes contain *NRAS* mutations and these mutations occur independent of BRAF.[21,22] Further studies showed *c-KIT* mutations are found in almost 40% of acral and mucosal subtypes, in almost a third of CSD melanomas and not at all in non-CSD melanomas.[21,22] This data further emphasizes the need for continued refinement of tumor classifications in melanoma based on genetic and biological features with the hope this will ultimately lead to more personalized treatment options and improved outcomes for patients.

CLINICAL PRESENTATION

Benign nevi often occur in sun-exposed areas and are typically 4 to 6 mm in diameter (about the size of a pencil eraser), raised or flat, uniform in color and round in shape. Dysplastic nevi, an intermediate between benign nevi and melanoma, tend to be larger than common nevi (greater than 5 mm), appear as flat macules with asymmetry, have a fuzzy or ill-defined shape, and vary in color.

The initial clinical presentation of melanoma is often a cutaneous lesion and depends on the histologic subtype and the stage of development of the lesion. The cardinal clinical feature of a cutaneous melanoma is a pigmented skin lesion which changes over a period of time. Any changes in the skin surrounding a nevus, including redness or swelling, are important clinical signs. Uncommonly, the lesion may become itchy or tender and painful. Friability of the lesion, resulting in bleeding or oozing, is a danger sign. Perhaps, the most important warning sign of danger is the evolution in any characteristic of a lesion. A biopsy of the lesion is critical to establish diagnosis of melanoma. Subsequent pathologic interpretation of the biopsy will help provide information on prognosis and treatment options. An excisional biopsy, with a 1- to 2-mm margin of normal-appearing skin, is recommended for a suspicious lesion and should include a portion of underlying subcutaneous fat for microstaging. For larger lesions, an incisional or punch biopsy can be performed, and should include a core of full-thickness skin and subcutaneous tissue. When excisional biopsies are not appropriate, as with the face or palmar surface of the hands, a full-thickness incisional or punch biopsy is preferred. A shave biopsy is never appropriate because it can underestimate the thickness of the lesion and may not fully remove the lesion. Additionally, scarring may mask the remaining tumor.

CLINICAL PRESENTATION General

- Any lesion that changes in appearance over time

Local Signs and Symptoms

- The clinical features used to describe questionable lesions are highlighted with the mnemonic “ABCDE”
    - (A) Asymmetry: Melanoma lesions are often asymmetric
    - (B) Border: Melanoma lesions have irregular borders

    - (C) Color: Color is often variegated in a melanoma ranging from tan, blue-black, red, purple, or white
    - (D) Diameter: Melanoma lesions are frequently greater than 6 mm
    - (E) Enlargement or evolution: A sudden enlargement or change in lesion is concerning for melanoma
- Other signs of melanoma include a lesion that swells, bleeds, or oozes

Systemic Signs and Symptoms

- Palpable lymph nodes
- Depending on the site of metastasis, shortness of breath, abdominal pain, bone pain, headache, and mental status changes

Laboratory Tests

- In addition to a comprehensive metabolic panel, LDH should be evaluated

Other Diagnostic Tests

- Biopsy and pathology review for staging with molecular testing for BRAF and *c-Kit*
- When applicable, SLNB
- Systemic staging should include chest, abdomen, and pelvic CT scan or CT/PET bone scan, and brain MRI

CT, computed tomography; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET, positron emission tomography; SLNB, sentinel lymph node biopsy.

Evaluation of any individual with a suspected melanoma includes a complete history and total-body skin examination. The focus of the patient history is identifying potential risk factors including family history of melanoma, personal history of skin cancer or nevus excisions, sun exposure, and phenotype. A total dermatologic examination is necessary to determine melanoma risk factors (eg, mole pattern, mole type, or freckling) and for staging. Melanoma commonly spreads to the lymph nodes; therefore, individuals suspicious for advanced disease should be examined for lymphadenopathy. Lactate dehydrogenase (LDH) should be measured as elevated serum levels are an independent predictor of decreased survival.[23] In addition, any other signs or symptoms suggestive of metastatic disease should be completely evaluated.

1 Improved survival rates for melanoma have been attributed to the identification and treatment of disease at an early stage when the disease is limited and has not yet metastasized. It follows that one strategy to improve survival rates would be to increase efforts to identify early-stage melanoma. The cost-effectiveness of massive screening for all adults by a physician has never been demonstrated. However, routine examination of the skin by physicians is recommended for individuals, adults, and

children who are at high risk. The entire cutaneous surface, including the scalp, should be examined.

It has been estimated that about 50% of the initial melanoma lesions found are discovered by self-examination. Therefore, one of the most direct strategies to improve early detection would be a method to increase effective SSE by the individual, the individual's partner, or a caregiver. Identification of early melanoma allows the opportunity to treat lesions when they are early stage and curable, thus lowering the mortality rate of the disease. Healthcare professionals who routinely work with the public, such as community pharmacists, have an opportunity to increase public awareness concerning the benefits and appropriate methods for SSE. Educational pamphlets describing SSE (**Table 139-3**) for the public are widely available through the American Cancer Society, American Academy of Dermatology, and Skin Cancer Foundation. If a newly discovered pigmented lesion is identified, or if a preexisting pigmented lesion changes, the individual should be evaluated by a physician immediately.

TABLE 139-3 Self-Examination of Suspicious Moles

1. Examine your body front and back in the mirror and then the right and left sides with the arms raised
2. Bend the elbows and look carefully at the forearms and upper arms and palms
3. Look at the backs of the legs and feet. Look specifically in the spaces between toes and at the soles of the feet
4. Examine the back of the neck and scalp with the help of a hand-held mirror; part the hair (or use a blow dryer) to lift the hair and give yourself a closer look
5. Check the back and buttocks with a handheld mirror

Derived from publications of the American Academy of Dermatology.

SSE is of special interest in elderly adults. As the population of older adults (greater than or equal to 65 years of age) increases, it is expected that the mortality rate from melanoma also will increase. Barriers to successful SSE in elderly adults, such as failing eyesight, lack of partners, and poor memory, impact older adults in detecting new or changing lesions. These barriers, coupled with the higher incidence of melanoma in men, present challenges and opportunities for healthcare professionals to target education to this growing segment of our population.

STAGING AND PROGNOSTIC FACTORS

The size of a primary melanoma lesion is associated with the likelihood of metastasis. The Breslow tumor thickness of the primary melanoma lesion is commonly used as prognostic factor to determine predicted outcomes.[24] Tumor thickness is quantified to the nearest tenth of a millimeter with an ocular micrometer, measuring from the top of the granular layer of the overlying epidermis to the deepest contiguous invasive melanoma cell. The correlation between tumor thickness and probability

of tumor metastasis is strong but does not include aspects such as tumor satellites, defined rather arbitrarily, as skin involvement within 2 cm of the primary lesion, and vascular invasion. Patients with satellitosis have a worse prognosis than patients with thick primary lesions (tumor thickness greater than 4 mm), and prognosis is more similar to that of patients with nodal metastasis. Mitotic rate, defined as the number of mitosis per square millimeter, is another important prognostic factor for developing metastatic disease. Increasing mitotic rate represents a more aggressive lesion and is associated with a poorer survival rate despite tumor size. The American Joint Committee on Cancer (AJCC) developed a staging system for melanoma which divides patients with localized melanoma into four stages according to microstaging criteria of Breslow, but data from large patient databases demonstrated that the different cut off values for primary thickness may better predict overall survival. Additionally, ulceration of the melanoma and satellite lesions of the primary tumor should be considered when making decisions about therapy. As a result, the AJCC revised the staging system for cutaneous melanoma which was updated in 2009.[23] It is important to carefully examine older clinical trials to determine which staging system was used to determine patient inclusion and exclusion criteria, as results may differ based on these patient criteria. Clinical staging includes microstaging of the primary melanoma with clinical, laboratory and radiologic evaluation. It is used after complete excision of the primary melanoma along with clinical assessment to determine regional and distant metastasis. Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional nodes after partial or complete lymphadenectomy. At this time, it appears that patients with very limited disease (in situ or stage 0) do not require pathologic evaluation of lymph nodes (**Tables 139-4** and **139-5**).[22]

TABLE 139-4 Melanoma Tumor (T), Node (N), Metastasis (M) Classification

T Classification	**Thickness**	**Ulcerative Status**
T_X	Primary tumor cannot be addressed (eg, shave biopsy)	
T_0	No evidence of primary tumor	
T_{is}	Melanoma in situ	
T_1	≤1 mm	A: No ulceration and mitosis $<1/mm^2$ B: With ulceration or mitosis $\geq 1/mm^2$
T_2	1.01-2 mm	A: No ulceration B: With ulceration
T_3	2.01-4 mm	A: No ulceration B: With ulceration
T_4	>4 mm	A: No ulceration B: With ulceration
N Classification	**No. of Metastatic Nodes**	**Nodal Metastatic Mass[a]**
N_X	Regional lymph nodes cannot be assessed	
N_0	No regional lymph nodes	
N_1	1 node	A: Micrometastasis B: Macrometastasis

T Classification	Thickness	Ulcerative Status
N_2	2-3 nodes	A: Micrometastasis B: Macrometastasis C: In-transit metastases or satellite(s) without metastatic nodes
N_3	≥4 metastatic lymph nodes or matted nodes or in-transit metastases or satellite(s) with metastatic node(s)	
M Classification	**Site**	**Serum Lactate Dehydrogenase**
M_X	Distant metastases cannot be assessed	
M_0	No detectable distant metastasis	
M_{1a}	Distant skin, subcutaneous tissue, or nodal metastatic disease	Normal
M_{1b}	Lung metastases	Normal
M_{1c}	All other visceral metastases	Normal
	Any distant metastasis	Elevated

M, metastasis; N, node; T, tumor.

[a]Micrometastases are diagnosed after sentinel or elective lymphadenectomy. Macrometastases are defined as clinically detectable lymph node metastases confirmed by therapeutic lymphadenectomy or when any lymph node metastasis exhibits extracapsular extension.

Data from Balch CM, Gershenwald JE, Soong SJ, et al. Final version of 2009 AJCC melanoma staging and classification. J Clin Oncol 2009;27:6199-6206.

As with other solid tumors, the presence of regional lymph node involvement is a powerful predictor of tumor burden and patient outcome. Sentinel lymph node biopsy (SLNB) is a minimally invasive procedure which determines if a patient is a candidate for a complete lymph node dissection. The rationale for lymphatic mapping and subsequent SLNB is based on the observation that regions of the skin have patterns of lymphatic drainage to specific lymph nodes in the regional lymphatic basin. The sentinel lymph node is believed to be the first node in the lymphatic basin into which the primary melanoma drains. Unlike other solid tumors, melanoma appears to progress in an orderly nodal distribution. SLNB allows for detection of micrometastases as a result of more thorough examination of a single sentinel node than is possible when examining multiple lymph nodes with a lymph node dissection, and may be most useful for melanomas located in ambiguous drainage sites such as the head and neck areas. SLNB is associated with low false-negative rates and low complication rates.[25] Detection of clinically undetectable disease in a lymph node basin not directly adjacent to the primary lesion, may allow for upstaging of patients who initially are believed to have node-negative disease. The American Society of Clinical Oncology and Society of Surgical Oncology joint clinical practice guidelines recommend SLNB for patient with any intermediate-thickness melanoma.[25]

The stage of melanoma, based on tumor thickness, level of tumor invasion, and ulceration, at the time of diagnosis, is one of the primary indicators of the natural history of the disease and contributes to prognosis. Other factors such as tumor growth pattern, or histological subtype, mitotic rate, density of tumor infiltrating lymphocytes (TILs) in the tumor tissue, elevated LDH level, satellite lesions, angiolymphatic invasion, gender, and age also have been reported to influence survival (**Table 139-6**). The location of the primary tumor on the skin is also important as tumors of the extremities have an increased survival compared with those with axial, neck, head, and trunk tumors. In addition, a number of additional prognostic factors have been identified in patients with advanced disease. The number of metastatic sites, disease involvement of the gastrointestinal tract, liver, pleura, or lung, Eastern Cooperative Oncology Group (ECOG) performance status of 1 or greater, male sex, and prior immunotherapy have been associated with poor prognosis.[26]

TREATMENT

Desired Outcomes

Treatment of cutaneous melanoma depends on the stage of disease. Local disease is managed, and often cured, with surgical ablation. Regional disease is treated with surgical resection of the primary lesion and, depending on the risk of recurrence, adjuvant therapy in an effort to eradicate any residual disease and cure the patient. The role of interferon-α (IFN-α) as adjuvant therapy after surgical resection remains controversial. Until recently, metastatic melanoma has been a difficult disease to treat. The treatment goals for metastatic disease are to slow tumor progression, prolong life, relieve acute symptoms, and improve quality of life. With the advent of new immunotherapy and molecular targeted therapy, the management of metastatic melanoma has drastically changed. After more than a decade of ineffective drug development, several new treatment options now exist for the treatment of metastatic melanoma such as CTLA-4 inhibitors, BRAF inhibitors, MEK inhibitors, and PD-1 inhibitors. Molecular targeted agents offer rapid and high response rates with prolonged time to disease progression, while immunotherapy can induce durable responses. These new treatment options have increased survival expectations to an all-time high in the history of melanoma treatment.

Surgery

Patients who present with a suspicious pigmented lesion should undergo a full-thickness excisional

biopsy, if possible. A full-thickness incisional or punch biopsy is preferred, in cases where an excisional biopsy not possible, to provide microstaging and ultimately determine therapy.

2 Localized cutaneous melanoma can often be cured with surgical excision. The cure rates for melanomas smaller than 1 mm are as high as 98%. The extent of the excision margin is important in preventing local recurrence and ultimate survival. For melanoma in situ, excision of the visible lesion or biopsy site with a 0.5 to 1 cm border of clinically normal skin, and a layer of subcutaneous tissue with confirmation of histologically negative peripheral margins, is recommended. The recommended clinical margin for invasive melanoma depends on tumor thickness. Excision with a 1 cm margin of clinically normal skin, and underlying subcutaneous tissue, is recommended for invasive melanomas 1 mm thick or smaller. Current guidelines recommend a 1 to 2 cm margin for melanoma with tumor thickness of 1.01 to 2 mm.[22] Lesions which are 2 to 4 mm thick should be excised with a 2 cm margin. Primary tumors more than 4 mm thick require at least a 2 cm margin, whether a larger margin is beneficial is unclear. Surgical management of lentigo maligna melanoma is problematic as subclinical extension of atypical junctional melanocytic hyperplasia may extend beyond the visible margins. Complete excision of these lesions is important.

When isolated regional lymph nodes are detected via physical examination, in the absence of distant disease, therapeutic lymphadenectomy is recommended. The extent of therapeutic lymph node dissection often is modified according to the anatomic area of the lymphadenopathy. Selective regional lymphadenectomy performed after scintigraphic and dye lymphographic identification of the affected sentinel draining lymph node(s), is the standard of care for melanomas more than 1 mm thick. If the sentinel node is found to have micrometastatic melanoma, regional dissection of the involved nodal basin is performed. If the lesion is 0.75 to 1 mm in thickness with ulceration or is Clark level IV or V, lymphatic mapping with SLNB may be considered based on patient characteristics, such as ulceration of the tumor.[27] The likelihood of detecting metastatic disease in the sentinel lymph node is about 1% in tumors which are smaller than 0.8 mm, but increases to more than 30% in tumors 4 mm thick.[27] Final results, with 10 years of follow-up, from the Multicenter Selective Lymphadenectomy Trial I showed no difference in disease-specific survival when SLNB was compared to the watch and wait approach (remove nodes once palpable).[28] These results support current clinical practice to remove microscopic metastasis before they become problematic. The Multicenter Selective Lymphadenectomy Trial II is currently enrolling patients to assess whether or not a complete lymph node dissection after a positive SLNB improves overall survival. SLNB results are important for accurate staging, therapeutic lymphadenectomy, and to aid in the decision to offer adjuvant treatment.[27]

One of the most important aspects of surgical management of cutaneous melanoma is the role of patient follow-up.[22] Postsurgical follow-up of patients who have had a melanoma excised is essential to monitor for undetected metastatic disease and the development of a second primary cutaneous melanoma or nonmelanoma primary malignancy. Scheduled screening, in addition to routine surgical follow-up, is required for any patient with a melanoma; the recommended frequency and duration depend on the stage of melanoma. The optimal duration of follow-up remains controversial. Most patients who develop recurrent disease do so in the first 5 years after treatment, but late recurrences, more than 10 years after surgery, have been observed. The increased lifetime risk of developing a

second primary melanoma supports lifetime dermatologic surveillance for all patients.

A patient with stage III melanoma commonly has lymph node involvement and in-transit metastases may also occur. In-transit metastasis is the clinical manifestation of tumor which develops in lymphatics between the primary melanoma and the regional lymph node basin.[5] In-transit metastases are more than 2 cm from the original lesion. In-transit metastases are more common in individuals with thick, ulcerated lesions. Surgery is used for management of in-transit lesions, with the goal of complete resection. Unfortunately, subsequent recurrence in the same extremity often occurs after initial resection of in-transit metastasis.

The role of surgery beyond that of cure is less clear, although surgery may offer palliation for patients with isolated metastasis.[27] In these cases, surgery may extend survival time in select patients with metastatic disease. Patients whose metastasis can be completely resected may experience improved quality of life, improved overall survival, and occasionally long-term disease control.[27]

Brain metastasis is a frequent complication of advanced melanoma. About 20% to 50% of patients with stage IV disease develop clinically apparent central nervous system (CNS) involvement. Surgical resection, with or without radiation, has been used in select individuals. More recently, high control rates of brain metastasis have been achieved with focal radiation therapy such as linear accelerator-based stereotactic radiosurgery or gamma-knife technologies.[29] Melanoma in the gastrointestinal tract can lead to bowel obstruction. Appropriate resection or bypass may provide significant relief of symptoms. Despite the lack of controlled clinical trials, the impact on palliative surgery should be evaluated in the context of a patient's comfort and quality of life. The risk of relapse and death after resection of a local, or regional cutaneous melanoma, is the primary determinant for use of adjuvant therapy after primary resection. Adjuvant trials have focused on patients at intermediate or high risk for recurrence.

Adjuvant Therapy

3 Melanoma is considered one of the most immunogenic solid tumors, and it appears to interact with, and respond to, the immune system of the host in which it arises. Spontaneous regressions of melanoma suggest the importance of the immune system in disease modulation. Lymphoid infiltration into the primary melanoma also suggests that immunomodulation may impact the biology of melanoma. Early work has shown that nonspecific immunomodulators, such as levamisole and Bacillus Calmette-Guérin (BCG) for treatment of melanoma, were associated with some regression of the tumor, although many of these responses were limited and short-lived. Because melanoma is generally resistant to traditional treatment modalities such as radiation and chemotherapy, immunotherapy offers an avenue of treatment. In early trials, patients who showed the highest response to immunotherapy had minimal disease burden. The use of adjuvant immunotherapy to treat these patients has been investigated to prevent distant recurrence and improve long term survival.

Interferon

One of the oldest, and most controversial, immunotherapy approaches for the treatment of melanoma is the use of IFNs. The IFNs are a group of proteins with diverse immunomodulatory and antiangiogenic properties. A number of studies evaluated various doses and schedules of recombinant IFN for treatment of metastatic melanoma. Response rates in metastatic melanoma range from 10% to 30%, and overall response rates are about 15% for IFN-α. In clinical trials of IFN therapy for patients with metastatic melanoma, response rates were highest in patients with limited disease. Responses were seen at all sites of disease, but were most frequent in subcutaneous, lymph node, and pulmonary metastasis. The activity of IFN in patients with minimal disease encouraged investigators to evaluate the role of adjuvant IFN. A large, multicenter cooperative group trial (E1684) of adjuvant IFN-α_{2b} versus observation was designed for 287 patients with high-risk (stages IIB and III disease based on the 1997 AJCC staging criteria) melanoma after curative surgical resection. IFN-α_{2b} was given IV as an induction therapy at maximum tolerated doses of 20 million IU/m^2 per dose 5 days per week for 4 weeks; treatment was continued for 48 weeks with subcutaneous IFN-α_{2b} 10 million IU/m^2 per dose 3 times per week. This therapy now is often referred to as *high-dose interferon* (HDI). With a median follow-up period of 6.9 years, patients treated with HDI had significantly longer relapse-free and overall survival compared with patients who were observed after surgical resection (1.72 vs 0.98 years and 3.8 vs 2.8 years, respectively).[30] Both the 5-year relapse-free and overall survival rates were higher with HDI. This data led to the 1995 FDA approval of HDI as standard of care. With longer follow-up (median, 12.6 years), however, the difference in overall survival was no longer significant.[31] Further analysis showed that the greatest reduction in melanoma recurrence occurred during the first few months of treatment. Subgroup analysis of this study indicated that patients with large primary tumors and node-negative disease did not receive the same benefit from therapy, but the small number of patients in this group made it difficult to draw definite conclusions about the role of IFN for adjuvant therapy in this setting.

Pegylated IFN-α_{2b} has also been evaluated in the adjuvant setting with the hope for a better efficicy and toxicity profile. The European Organization for Research and Treatment of Cancer (EORTC) 18991 trial evaluated 1,256 patients with resected stage III melanoma. Patients were randomized to observation or pegylated IFN. Pegylated IFN was given less frequently compared with nonpegylated IFN. Updated results demonstrated an improvement in relapse-free survival, but no difference in overall survival or distant metastasis-free survival.[32] Based on this data, the FDA approved pegylated IFN-α_{2b} as an option for adjuvant treatment.

HDI treatment is associated with multiple toxicities, including flu-like syndrome. Toxicities of IFN therapy in the adjuvant HDI trials were common and severe. About one-third of patients will need a dose modification during induction and only half of the patients are able to complete the year of therapy in an outpatient setting. One strategy for reducing toxicities associated with IFN is to modify the dose and duration. A subsequent ECOG trial (E1690) of low-dose IFN (3 million IU per dose given subcutaneously three times weekly *low-dose interferon* [LDI]) for 24 months compared with the HDI regimen described earlier versus observation did not demonstrate an overall survival advantage of HDI versus observation.[33] At a median follow-up period of 52 months, the 5-year estimated relapse-free survival rates for HDI, LDI, and observation were 44%, 40%, and 35%, respectively. With longer follow-up, however, the difference in relapse-free survival was no longer significant.[33] A

significant overall survival benefit was not seen for HDI or LDI compared with observation, although the investigators speculated that this analysis of survival was affected by the number of patients in the observation arm who received IFN therapy after disease progression.[33]

The use of IFN in the adjuvant setting remains controversial. Although the HDI regimen is used in the United States, the LDI strategy remains standard in many European countries. In a pooled analysis of 713 patients who participated in two randomized controlled trials (E1684 and E1690), HDI was associated with a significant reduction in relapse-free survival compared with observation ($P < 0.006$).[31] No benefit in overall survival was observed in the pooled analysis. The results of nine randomized clinical trials of adjuvant HDI or LDI versus observation in melanoma were included in a systematic review. The systematic review observed a trend toward reduced risk of recurrence of melanoma and of death among the IFN-treated patients in nearly all studies.[34] Because of differences in dose, frequency, and duration of IFN-α treatment in the various trials, the review was not able to compare LDI versus HDI. Furthermore, the wide variability in number of patients enrolled, end points, patient selection, quality, type of therapy, duration of treatment, and follow-up precluded statistical analysis of the pooled results. Although the differences in overall survival have not always been statistically significant, HDI remains the only adjuvant treatment shown to prolong survival in prospective randomized trials. IFN-α_{2b} is approved by the FDA for treatment of patients with primary melanomas larger than 4 mm (stages IIB and IIC) and in patients with melanoma involving regional lymph nodes who are disease-free after lymph node dissection (stage III).

For patients who receive IFN, it is important to effectively prevent and manage treatment-related toxicities. A common syndrome seen with IFN-α therapy is a diverse group of side effects referred to as *constitutional symptoms*, which can include acute symptoms such as fever, chills, myalgia, and fatigue, and can encompass some of the more chronic toxicities such as fatigue, anorexia, and depression.[35] Acetaminophen can be used to prevent or minimize acute dose-related symptoms such as fever, myalgia, and chills. Opiates, such as meperidine, are often required when patients experience severe chills or rigors, most commonly during the initial month of the HDI induction phase. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been used to manage IFN-related myalgia, but may have overlapping side effects with IFN, such as a decrease in renal blood flow. NSAIDs and acetaminophen may mask fevers which occur in patients who experience neutropenia while undergoing therapy. Additionally, NSAIDs may increase the risk of bleeding in the setting of thrombocytopenia caused by IFN. Fatigue is one of the most frequently observed dose-limiting toxicities seen with IFN therapy, occurring in 70% to 100% of patients.[35] IFN-induced fatigue appears to be dose related and may worsen with continued therapy. Pharmacologic (eg, methylphenidate) and nonpharmacologic (eg, exercise, psychosocial techniques, distraction, energy management, and dietary modifications) may improve IFN-related fatiguein patients. Depression is common and should be fully evaluated. Contributing factors such as IFN-induced hypothyroidism or concomitant IFN symptoms (eg, nausea and fatigue) should be evaluated concurrently with depression symptoms to optimize treatment decisions. Antidepressants, such as selective serotonin reuptake inhibitors, have been studied in IFN-induced depression with notable benefit.[35] Anorexia is reported in about 70% of patients receiving adjuvant IFN therapy for melanoma and is thought to be mediated through direct effects on hypothalamic neurons, modification of normal hypothalamic neurotransmitters or

neuropeptides, or effects from stimulation of other cytokines.[35] Taste alterations may contribute to anorexia. Glucocorticoids should not be used for appetite stimulation or as part of an antiemetic therapy as they may adversely impact the immunomodulatory effects of IFN. Other toxicities, such as hematologic or hepatic toxicities, require monitoring and appropriate dose modification.

CTLA-4 Checkpoint Inhibitor

One of the major advances in the treatment of metastatic melanoma has come through targeting specific immune checkpoints. T-cells play a role in cell-mediated immunity and cancer immunotherapy. T-cells are activated when the T-cell receptor (TCR) interacts with its antigen followed by the interaction of CD28 on the T-cell with the co-stimulatory molecule, B7 on antigen presenting cells. To prevent over activation of T-cells receptors, such as CTLA-4, function as a co-inhibitory receptor for the co-stimulatory molecule B7. Crosslinking of CTLA-4 by B7 inhibits T-cell activation, transcription, translation, and transduction. CTLA-4 blockade overcomes this inhibition and results in activation and proliferation of Tcells.[17] Ipilimumab, a monoclonal antibody to CTLA-4, has demonstrated efficacy in the metastatic melanoma setting. More recently, the EORTC 18071 trial evaluated 475 patients treated with high-dose ipilimumab 10 mg/kg IV every 3 weeks × 4 doses, then every 3 months for up to 3 years, compared to placebo in the adjuvant setting. Recurrence-free survival was 26.1 months in patients treated with high-dose ipilimumab compared to 17.1 months in patients treated with a placebo (P = 0.0013).[36] The effect on overall survival remains to be determined.

CTLA-4 antibodies produce several immune-related adverse effects (irAEs) that are distinct and different than adverse events associated with conventional cancer treatments. CTLA-4 antibodies cause autoimmune-irAEs by promoting the activation of self-reactive T cells. The incidence of irAEs is as high as 60%, and up to 20% of patients experience Grade 3 or 4 irAEs.[37] The most common serious irAEs include dermatitis, enterocolitis, hepatitis, and endocrinopathies.[17] These adverse reactions are dose-related and follow a predictable pattern: skin related toxicities occur first after the first dose; colitis follows after the second dose; and hepatitis and endocrinopathies occur last, after third or fourth dose.[38] Most irAEs are reversible with treatment and resolve after 6 to 8 weeks, with the exception of endocrinopathies which may require lifelong hormonal treatment. Close monitoring for irAEs and participation in a risk evaluation and mitigation strategy (REMS) program while on therapy is necessary.[22] It is recommended that patients obtain a comprehensive metabolic panel (with liver function tests), complete blood count, and thyroid function tests at baseline, throughout treatment and for up to 6 months after treatment.[38] Ipilimumab therapy should be held for moderate-to-severe irAEs. High-dose systemic corticosteroids should be initiated for patients who do not improve from withholding therapy or for grade 3 immune-related events. Ipilimumab can be restarted when adverse events improve to grade 0 or 1 and systemic corticosteroid doses have been minimized. In early studies, corticosteroids were discouraged for concern they would blunt the desired immune response. But studies show that the efficacy of ipilimumab is not compromised with steroid use.[39] For patients who are steroid refractory, defined as no response to high dose IV steroids within 48 to 72 hours of initiation, other immunosuppressive agents have been utilized. Agents such as infliximab and mycophenolate can be used for patients who develop steroid refractory colitis and

hepatitis, respectively.[38] Due to its own hepatotoxicity potential, infliximab should be used with caution. Published guidelines for the treatment of irAEs are available.[38] In cases of severe or life-threatening irAEs, permanent discontinuation of therapy is recommended. In clinical studies reported to date, patients who experienced grade 3 or 4 autoimmune toxicities were also the most likely to exhibit tumor regression and increased time-to-relapse in the metastatic setting.[37] The most common adverse effects observed in the EORTC 18071 adjuvant trial were autoimmune colitis and autoimmune hepatitis, consistent with known adverse effects. Autoimmune endocrinopathies occurred at a higher frequency than in the metastatic disease trials. irAE led to the discontinuation of treatment in 52% of patients who were treated with ipilimumab. Of concern, five deaths were attributed to drug-related adverse effects.[36]

Although IFN is approved for the adjuvant setting, many experts continue to question its use given the considerable treatment toxicities and the uncertain overall survival advantage. High-dose ipilimumab provides a new treatment option for patients with high risk disease. Further evaluation is needed to determine its effect on overall survival. Given the significant toxicities associated with high-dose ipilimumab, the decision to treat a patient should be based on careful evaluation of the risk versus benefit. Patients who receive ipilimumab must be carefully monitored for irAEs. The National Comprehensive Cancer Network (NCCN) guidelines for melanoma list IFN-α and ipilimumab as treatment options in the adjuvant setting. Other options include observation, and most importantly, clinical trials.[22]

Clinical Controversy…

The role of ipilimumab in the adjuvant setting for high-risk patients after surgical resection of melanoma needs further investigation. In the adjuvant trial, ipilimumab was dosed at 10 mg/kg while the FDA approved dose in the metastatic setting remains 3 mg/kg. The optimal dose to balance efficacy and toxicity remains unknown.

Treatment of Metastatic Melanoma

Chemotherapy and Biochemotherapy

4 Although many drugs show in vitro activity against melanoma, only a few drugs have consistently shown a response rate greater than 10% in individuals with metastatic melanoma. Most clinical trials of new agents in melanoma measure antitumor activity in terms of response rates, which does not always correlate with survival, and do not evaluate benefit to the patient. Complete responses can be durable in a small number of patients.

Dacarbazine, a cytotoxic drug thought to exert its antitumor effect through alkylation, currently is the most effective chemotherapeutic agent for treatment of melanoma. Dacarbazine remains the only FDA-approved chemotherapeutic agent for treatment of metastatic melanoma in the United States. Prospective controlled clinical trials have observed response rates of 10% to 25%, with an average duration of response of 5 to 7 months.[40] Complete responses are uncommon, with fewer than 5% of patients treated with single-agent dacarbazine sustaining long-term complete responses. The

optimum dose schedule of dacarbazine has never been determined; doses of 250 mg/m^2/day for 5 days or 800 to 1,000 mg/m^2 every 3 weeks are seen in practice. Common adverse effects of dacarbazine therapy include myelosuppression, severe nausea and vomiting, and flu-like symptoms after high doses. Nausea and vomiting can be prevented and managed with available antiemetics and are not a major complication.

Temozolomide is an oral prodrug of the active metabolite of dacarbazine and is less emetogenic than dacarbazine. Temozolomide appears to cross into the CNS and was initially thought to have benefit for patients with CNS metastasis. In a phase III trial of chemotherapy-naïve individuals with metastatic melanoma, temozolomide showed efficacy at least equivalent to that of dacarbazine in terms of objective response rates, time-to-progression, and overall and disease-free survival but appeared to be associated with improvement in some aspects of quality of life.[40]

Other chemotherapeutic agents such as *platinum analogues*, *taxanes*, and *nitrosureas* have been evaluated as single agents in the treatment of metastatic melanoma and have been found to exhibit minimal benefit. Of note, a phase III trial comparing *albumin-bound paclitaxel* with dacarbazine in chemotherapy-naïve melanoma patients reported an increase in progression-free survival and a trend in overall survival in patients receiving albumin-bound paclitaxel. Neuropathy and neutropenia were more common in the albumin-bound paclitaxel arm.[41] At this time, these agents are not routinely used as single-agent therapy for melanoma, but are being incorporated into multidrug strategies against metastatic melanoma.

In an attempt to improve the limited responses seen with single-agent chemotherapy, a variety of combination chemotherapy regimens have been evaluated in both small and large clinical trials. The combination of dacarbazine with other chemotherapy, most commonly cisplatin, increased response rates with minimal survival benefit. The initial reports with the cisplatin, vinblastine, and dacarbazine (CVD) regimen were exciting, with reported response rates greater than 50%, a 4% complete response rate, a median response duration of 9 months, and acceptable toxicities.[42] Subsequent reports showed no difference in response rates or survival.

The Dartmouth regimen is a combination which includes carmustine, dacarbazine, cisplatin, and tamoxifen. Initial reports with this regimen demonstrated high response rates of 20% to 50%, but few patients achieve long-term survival. A controlled clinical trial from the National Cancer Institute of Canada demonstrated no benefit in response or survival from tamoxifen in this combination.[43] Further trials showed no benefit of the Dartmouth regimen compared with single-agent dacarbazine.[40] Of concern, toxicities were higher with the combination study and included bone marrow suppression, nausea, vomiting, and fatigue.

Low overall response rates and toxicity have limited the routine use of chemotherapy alone in the management of metastatic disease. The strategy of a combination of chemotherapy (dacarbazine, platinum agents, or vinca alkaloids) and cytokines (aldesleukin or IFN) often termed *biochemotherapy*, has been a focus of investigation in the management of metastatic melanoma. The primary rationale for this combination is to increase overall activity and perhaps response rates based on preclinical trials which suggest potential synergistic interactions between cytokines and some chemotherapy

agents. As with other treatment strategies in melanoma, results from initial trials suggested higher response rate with biochemotherapy than with either chemotherapy or biotherapy alone. Despite encouraging results with combination chemotherapy and combination biotherapy, the results of clinical studies have not demonstrated a clear advantage with biochemotherapy compared with chemotherapy alone. A meta-analysis of 18 randomized trials of chemotherapy versus biochemotherapy showed that biochemotherapy was associated with a significantly higher response rate in treatment of metastatic melanoma but the higher response rate did not translate into a significant difference in overall survival.[44] Toxicities can be severe and are consistent with the individual agents in the regimen.

Biochemotherapy has also been evaluated in the adjuvant setting. Early published data was encouraging. Recently, results from larger phase III studies comparing biochemotherapy with IFN, as adjuvant therapy in high-risk stage III disease, were published. This trial demonstrated that biochemotherapy significantly improved relapse-free survival, but no difference in overall survival was observed.[45]

The role of chemotherapy and biochemotherapy in metastatic melanoma is limited because of low response rates and a lack of survival benefit. NCCN currently recommends these treatment approaches as second-line or subsequent treatment options for patients with metastatic melanoma.[22]

Immunotherapy

Significant attention has been given to immunotherapy as a treatment modality in metastatic melanoma due to its general resistance to traditional treatment modalities. Although complete response rates seen with biotherapy are relatively low, the responses can be durable. Over the past few years, advances in immunotherapy for the treatment of melanoma have significantly impacted survival in patients with metastatic melanoma.

Interleukin-2

Interleukin-2 is a glycoprotein produced by activated lymphocytes. IL-2 was first identified as a T-cell growth factor, but IL-2 is also a growth factor for a variety of cells, including lymphocytes and natural killer (NK) cells. IL-2 also may be immunosuppressive.

The precise mechanism of cytotoxicity of IL-2 is unknown. In vitro and in vivo, IL-2 stimulates the production and release of many secondary monocyte-derived and T-cell–derived cytokines, including IL-4, IL-5, IL-6, IL-8, tumor necrosis factor (TNF)-α, granulocyte-macrophage colony-stimulating factor, and IFN-γ, which may have direct or indirect antitumor activity. In addition, IL-2 stimulates the cytotoxic activities of NK cells, monocytes, lymphokine-activated killer (LAK) cells, and cytotoxic T lymphocytes (CTLs). IL-2 also appears to activate endothelial cells, which results in increased expression of adhesion molecules.[46]

High-dose aldesleukin was evaluated is a series of trials with objective response rates around 16%. Of significance, 6% of those patients produced a complete response which were durable (median

response, 70 months).[46] Responses were seen at a number of metastatic sites such as the lung, liver, bone, lymph nodes, and subcutaneous tissue. The FDA approved high-dose aldesleukin regimen used for treatment of metastatic melanoma is 600,000 IU/kg per dose every 8 hours for 14 doses maximum in a 5-day period given for two cycles, with a 10- to 14-day rest period between cycles. At these doses, cytokine-induced capillary leak syndrome is a common problem and often is accompanied by significant hypotension, visceral edema, dyspnea, tachycardia, and arrhythmias. Increased permeability of capillary walls allows for a fluid shift from the intravascular space into tissue. As the patient becomes intravascularly dehydrated, hypotension may occur, resulting in reflex tachycardia and arrhythmias. In addition, the decrease in blood volume may result in decreased renal blood flow and urine output, manifesting as increases in blood urea nitrogen, serum creatinine, edema, and weight gain and a decrease in urine output (input greater than output). Visceral edema may result in pulmonary congestion, pleural effusions, and edema. The management of patients receiving high-dose aldesleukin requires extensive supportive care medications, careful monitoring, and staff trained in aspects of critical care such as hypotension management. Constitutional symptoms are a frequent complication of aldesleukin therapy and become more intense as therapy progresses. Additional side effects seen with aldesleukin include pruritus, eosinophilia, bone marrow suppression, increased liver function tests, neurologic disturbances, diarrhea, and nausea

Careful patient selection for aldesleukin therapy is important. Pretreatment factors such as performance status, site of metastasis, and LDH may predict who will respond. Based on reports of long-term responses (greater than 10 years) experienced by some patients, the benefit certainly exceeds the risk for those individuals. Unfortunately, at this time, it is difficult to determine which individuals will respond to aldesleukin therapy because no biologic or immunologic biomarkers have been found to correlate with response. The decision to treat an individual with high-dose aldesleukin should be based on an analysis of an individual patient's risk versus potential benefit. With newer agents now available on the market, and complexity of administration, the role of aldesleukin has diminished.

CTLA-4 Checkpoint Inhibitors

CTLA-4 was the first immune checkpoint inhibitor identified as a target for anticancer therapies and ipilimumab was the first drug in this class of drugs to demonstrate efficacy in metastatic melanoma. Results from phase I and II trials with ipilimumab demonstrate up to 20% response rates in advanced disease.[47] In a phase III trial of 676 HLA-A*0201-positive patients with refractory metastatic melanoma, ipilimumab (3 mg/kg) plus a glycoprotein 100(gp100) peptide vaccine was compared with ipilimumab (3 mg/kg) alone or gp100 alone.[48] The median overall survival time was significantly longer in patients treated with ipilimumab, alone or combined with gp100, as compared with patients treated with gp100 alone (10.0 or 10.1 vs 6.4 months, hazard ratio [HR] 0.66, $P = 0.003$). Another phase III trial compared a higher dose of ipilimumab (10 mg/kg) plus dacarbazine with dacarbazine alone in patients previously untreated for metastatic melanoma.[49] Ipilimumab plus dacarbazine demonstrated significantly longer overall survival (11.2 vs 9.1 months, HR 0.72, $P < 0.001$) and higher survival rates at 1 year (47.3% vs 36.3%), 2 years (28.5% vs 17.9%), and 3 years (20.8% vs 12.2%) than dacarbazine alone. In 2011, ipilimumab, dosed at 3 mg/kg IV every 3 weeks × 4 doses, became the first FDA approved drug for the treatment of unresectable or metastatic melanoma with a survival

benefit. With longer follow-up data, the survival benefit is maintained for patients who had an initial response to ipilimumab. Five-year follow-up data from clinical trials demonstrates survival rates of 13% to 23% with survival durations of 13 to 16 months.[50] It is also important to note that the 3-year survival mark is noteworthy for patients treated with ipilimumab. Up to 85% of the patients who were alive at 3 years were alive at 4 years, suggesting that the 3-year survival mark may be a useful surrogate endpoint.[51] After a period of time, it is felt that the balance between immune response and tumor growth can shift leading to disease relapse after an extended duration of response. Re-treatment can be an option for patients who had an initial clinical benefit and has been shown to re-induce a response; no additional toxicities have been observed with re-induction.[52]

One of the greatest lessons learned from early clinical trials with ipilimumab was the differing kinetics of response and how to evaluate response to treatment. Patients appeared to have no regression of disease for many weeks after treatment initiation. Even more alarming was around 10% of patients initially experienced a significant increase in tumor burden which suggested disease progression. This was then followed by a delayed response to the drug after 12 weeks of therapy; some patients continued to have a steady reduction in tumor burden over time which eventually produced a durable clinical benefit.[53] It is hypothesized that the delayed response is related to the time needed to stimulate the immune system.[50] Due to this phenomenon, the Response Evaluation Criteria in Solid Tumors (RECIST) developed immune-related response criteria (irRC) to evaluate immunotherapies. The most significant additions were the allowance of up to 25% increase in tumor volume and deferral of assessing response until 12 weeks from the start of therapy.[50]

6 The greatest challenge with the use of ipilimumab is management of irAEs. Patients must be thoroughly educated on signs and symptoms of irAEs and when to seek medical attention. Providers should be familiar with the differing type, timing and appropriate management of irAEs (**Table 139-7**). As previously discussed, management of irAEs should follow established treatment guidelines.[38]

TABLE 139-7 Management of Immune-Related Adverse Effects

Organ Toxicity	Signs/Symptoms	Management	Comments
Skin and Mucosa	Pruritus, rash, desquamation, mucositis	Grade 1 or 2 Topical corticosteroids (betamethasone 0.1%) Urea based creams Oral antipruritic as needed (diphenhydramine or hydroxyzine) Grade 3 or 4	Rare cases of toxic epidermal necrosis and Stevens-Johnson syndrome have been reported with ipilimumab

Organ Toxicity	Signs/Symptoms	Management	Comments
Gastrointestinal	Diarrhea, hematochezia, abdominal cramping, nausea and vomiting	Prednisone 1-2 mg/kg/day or equivalent Grade 1 Oral hydration Electrolyte repletion Loperamide Grade 2 Diphenoxylate hydrochloride and atropine Budesonide 9 mg daily Grade 3 or 4 Methylprednisolone 125 mg IV once followed by prednisone 1-2 mg/kg/day or equivalent	Infliximab 5mg/kg IV every 2 weeks may be given if symptoms do not improve with 48-72 hours of high dose steroids. Bowel perforation and obstruction may occur in cases of severe colitis
Hepatic	Transaminitis, jaundice, sclera icterus	Grade 1 or 2 Hold therapy Grade 3 or 4 Prednisone 1-2 mg/kg/day or equivalent	Mycophenylate mofetil 500 mg IV/PO Q12 hours can be used in patients who do not respond to steroids within 48 hours
Neurologic	Muscle weakness, motor neuropathies, sensory neuropathies	Grade 1 Monitor Grade 2 Consider holding therapy Grade 3 or 4 Prednisone 1-2 mg/kg/day or equivalent	Rare case reports of Guillian-Barre' syndrome and myasthenia gravis have been reported with ipilimumab
Endocrine	Headache, weakness, visual changes,	Grade 1 or 2	Potential endocrinopathies include Addison's disease,

Organ Toxicity	Signs/Symptoms	Management	Comments
		Appropriate hormone replacement therapy	
	behavioral changes, electrolyte imbalances	Grade 3 or 4 Methylprednisolone 1-2 mg/kg IV then 1-2 mg/kg/day of oral prednisone or equivalent Grade 1 or 2	pan-hypopituitarism, adrenal crisis and hypophysitis. These effects may be permanent
Ocular	Photophobia, eye dryness, blurred vision	Prednisolone acetate 1% topical Grade 3 or 4 Prednisone 1-2 mg/kg/day or equivalent	Rare cases of episcleritis and uveitis have been reported
Pulmonary	Dyspnea, new or worsened cough, chest pain, hemoptysis	Grade 2 Prednisone 1-2 mg/kg/day or equivalent Grade 3 or 4 Methylprednisolone 1-2 mg/kg IV then 1-2 mg/kg/day of oral prednisone or equivalent	Pneumonitis is more common with pembrolizumab and nivolumab than ipilimumab

*Hold immunotherapy for grade 3 or 4 irAEs. Data from references 53 and 56.

PD-1 and PD-L1 Checkpoint Inhibitors

PD1 protein is an immune checkpoint upregulated on activated T-cells in response to inflammation. Antibodies directed against PD-1 block the binding of program death-ligand 1 (PD-L1) and 2 (PD-L2) to the receptor on tumor cells, thus allowing Tcells to remain stimulated and the immune response to continue.[8] Pembrolizumab (formerly known as lambrolizumab) and nivolumab are two monoclonal antibodies directed against PD-1. These agents have demonstrated response rates of 30% with long term clinical benefit in early phase I trials.[54] Most notably from these trials, PD-1 inhibitors had a more favorable safety profile with significantly fewer irAEs compared to ipilimumab. Additionally, benefits were seen in patients who had been previously treated with ipilimumab with no difference in response rates. The KEYNOTE-001 trial evaluated the efficacy of pembrolizumab in patients who were previously treated with ipilimumab. The trial reported that overall response rate was 26%,

progression-free survival at 24 weeks was 45%, and 1-year overall survival was 58%.[55] Treatment was well tolerated with grade 3 or 4 adverse effects only occurring in 12% of patients. In the randomized controlled trial of patients previously treated with ipilimumab, nivolumab produced higher response rates (32% vs 11%) with fewer irAEs when compared to chemotherapy.[56] An important observation from these studies is the lack of cross resistance between ipilimumab and PD-1 inhibitors. As with ipilimumab, if patients are able to achieve a response to these agents, that response can be maintained for an extended duration. In 2014, the FDA approved both pembrolizumab at 2 mg/kg IV every 3 weeks and nivolumab 3 mg/kg IV every 2 weeks for the treatment of patients with advanced or unresectable melanoma who progressed on previous ipilimumab therapy and, if applicable, a BRAF inhibitor.

6 Like ipilimumab, the response to PD-1 inhibitors is delayed. One notable difference is response to the PD-1 inhibitors may be slightly faster than with ipilimumab. The most common adverse effects of pembrolizumab and nivolumab are fatigue, cough, nausea, pruritis, rash, decreased appetite, constipation, arthralgias and diarrhea.[55,56] The risk of grade 3 or 4 irAEs is significantly lower compared to ipilimumab. The incidence of grade 3 or 4 diarrhea/colitis with PD-1 inhibitors is dramatically lower and occurs in only1% to 2% of patients. A higher incidence of autoimmune pneumonitis (1%-2%) is seen with nivolumab and pembrolizumab compared to ipilimumab.[38] Patients should be counseled to notify a provider if they notice new or worsening cough, chest pain or shortness of breath. Treatment of irAEs follows the same established treatment algorithms as ipilimumab (**Table 139-7**).

First line therapy with PD-1 inhibitors has been evaluated for the treatment of unresectable or metastatic melanoma. In the KEYNOTE-006 trial, pembrolizumab was compared directly to ipilimumab for first line treatment. In this trial, 834 patients with unresectable or metastatic melanoma were randomized to receive 10 mg/kg every 2 weeks or every 3 weeks or ipilimumab 3 mg/kg every 3 weeks for 4 doses. One-year overall survival rates were 75% for the pembrolizumab every 2 weeks (HR 0.63, $P = 0.005$), 68.4% for the pembrolizumab every 3 weeks (HR 0.69, $P = 0.0036$) and 58.2% for ipilimumab.[57] Treatment-related grade 3 or 4 adverse effects were lower in both the pembrolizumab arms. With better efficacy and less toxicity compared to ipilimumab, the FDA has approved pembrolizumab 2 mg/kg IV every 3 weeks as a first line treatment option for metastatic melanoma. Similarly, in a randomized controlled trial, nivolumab produced significantly better 1-year overall survival rates (73% vs 42%, HR 0.42, $P < 0.001$), median progression-free survival (5.1 vs 2.2 months, HR 0.43, $P < 0.001$), and overall response rates (40% vs 14%) when compared to dacarbazine in the first line treatment of *BRAF* wild-type metastatic melanoma.[58] The NCCN Guidelines recommend both pembrolizumab and nivolumab as first-line treatment options for patients with unresectable or metastatic disease.

Combination CTLA-4 and PD-1 Checkpoint Inhibitors

The mechanism of inhibition of CTLA-4 and PD-1 is complementary. A combination of a CTLA-4 inhibitor, which exerts its immune inhibition at the central level in the priming phase of activated T cells, and a PD-1 inhibitor, which acts in the peripheral phase within the tumor microenvironment,

can result in synergistic activity. Impressive survival rates of 90% at 1-year and greater than 80% at 2-years are unprecedented in the treatment of metastatic melanoma in early trials.[37] This combination was studied in 945 previously untreated patients with unresectable stage III or IV melanoma. Patients were randomized to nivolumab alone, nivolumab plus ipilimumab, or ipilimumab alone. The median progression-free survival was 11.5 months with nivolumab plus ipilimumab, compared with 2.9 months with ipilimumab (HR 0.42, $P < 0.001$).[59] One of the most significant concerns of combining two immune checkpoint inhibitors is the safety profile. Grade 3 and 4 treatment-related adverse effects are significantly higher with the combination armcompared to the ipilimumab arm (55% vs 27.3%). The risk of hepatotoxicity was higher in the combination arm. A second trial, CheckMate-069 trial confirmed the benefits of this combination. In this double-blind trial, 142 untreated melanoma patients were randomized to receive ipilimumab 3 mg/kg and nivolumab 1 mg/kg or the same dose of ipilimumab with placebo once every 3 weeks for 4 doses. Ipilimumab was then discontinued and patients received nivolumab or placebo at the same dose every 2 weeks until disease progression or unacceptable toxicity.[60] Objective response rate was 61% for patients receiving the combination versus 11% for patients receiving ipilimumab alone ($P < 0.001$). Complete responses were seen in 22% of the combination arm and none in the ipilimumab arm. Responses were seen regardless of BRAF mutational status. Median progression-free survival was significantly longer in the combination arm (HR 0.40, $P < 0.001$). As with previous studies, the responses appeared to be durable, with 82% of responding patients in the combination arm maintaining their response. The higher response rate with combinations of immune checkpoint inhibitors comes at the cost of greater toxicity. The risk of grade 3 or 4 drug-related adverse reactions was higher in the combination arm (54% vs 24%). As a result of data from these two trials, the FDA granted approval of combination therapy with nivolumab and ipilimumab inpatients with *BRAF* V600 wild-type unresectable or metastatic melanoma. While this combination offers higher response rates, some of which can be durable, judicious monitoring and aggressive management of toxicities are important.

Clinical Controversy…

The combination of ipilimumab and nivolumab leads to higher response rates compared to ipilimumab alone. Autoimmune toxicities with the combination are significantly higher and must be aggressively managed. Future trials are needed to evaluate if ipilimumab and nivolumab produce higher responses compared to nivolumab alone.

With the rapid advances in immunotherapy, the treatment of melanoma with these new therapies offers new hope to patients. Improved survival has been seen with both CTLA-4 and PD-1 inhibition. While pembrolizumab and nivolumab have better efficacy with less toxicity, ipilimumab is still effective and irAEs can be managed. The combination of ipilimumab and nivolumab has significantly higher responses compared to ipilimumab alone, but the risk of irAEs is also significantly higher. The NCCN guidelines list all of these regimens as potential treatment options for metastatic melanoma.

Despite advances in the treatment of melanoma, several questions still surround the use of immunotherapy. First, who is the best treatment candidate for immunotherapy? Some clinicians are hesitant to treat elderly patients with ipilimumab because of concern for toxicity. Similarly, patients

with existing autoimmune conditions have been excluded from treatment with ipilimumab. These unique patient populations require further investigation. Second, what are the biomarkers of response to immunotherapy? Immunologic markers as well as biomarkers have been investigated without success to help identify patients who respond to ipilimumab.[37] Tumors that express PD-L1, regardless of the cancer, have demonstrated higher responses to PD-1/PD-L1 blockade. However, patients with tumors that do not express PD-1/PD-L1 do benefit and should not be excluded from this treatment option. Additionally, it remains unclear as to the best approach for assessing PD-L1 expression, definition of positivity in the assay, and clinical application.[54] Lastly, what is the optimal sequencing of immunotherapeutic agents and with immunotherapy and other therapeutic options? Studies are ongoing looking at sequencing of CTLA-4 inhibitors, PD-L/PD-L1 inhibitors, BRAF/MEK inhibitors, chemotherapy and other investigational agents.

Clinical Controversy…

Treatment with immunotherapy is expensive. The projected cost of combination therapy with ipilimumab and nivolumab is $250,000 the first year of therapy and $150,000 per year thereafter. Further analysis is needed to assess the cost-effectiveness of these therapies and the economic burden on patients and society.

Other Immunotherapy Approaches

Vaccine therapy has been investigated for over a decade in metastatic melanoma. The rationale for vaccination is that antigens expressed on the surface of tumor cells differ from normal cells and vaccines have the ability to induce effective tumor-specific immune responses with less toxicity than conventional chemotherapy or other immunotherapies.

A variety of melanoma vaccines, based on whole tumor cells, peptides, and proteins have been evaluated for treatment of patients with metastatic disease and for intermediate- and high-risk patients after surgical resection of disease and to date none have shown a survival advantage.[17] Occasional clinical responses have been observed in clinical trials of melanoma vaccines, which demonstrate their potential. Vaccines in combination with other biologic therapies have been evaluated. Although tumor responses with some of these combination approaches have been observed in phase I and II trials, none of the vaccine responses or improvement in survival have been confirmed in phase III trials.[17] Clinical trials looking at way to incorporate vaccines into currently approved immunotherapeutic treatments are ongoing.

Oncolytic immunotherapy is currently being investigated for the treatment of metastatic melanoma. Talimogene laherparepvec (T-VEC) is a genetically modified oncolytic immunotherapy derived from herpes simplex-1. T-VEC works by two distinct mechanisms: 1) modification of attenuated HSV-1 to selectively replicate within the tumor environment causing death while sparing other cells and 2) secretion of GM-CSF to attract dendritic cells to the site to start the process of antigen presentation and T cells activation. Activated T cells can then target the cancer cells systemically. In a phase III study, T-VEC demonstrated better response rates (including complete responses) and a trend toward improved survival compared to GM-CSF alone.[61] It was well tolerated with fatigue, chills, and fever

being the most common adverse effect with few severe adverse effects reported. T-VEC was recently FDA approved for the local treatment of unresectable cutaneous, subcutaneous, and nodal lesions in patients with recurrent melanoma after initial surgery. T-VEC is administered intratumorally (injected directly into the tumor) and as such patients with internal visceral disease are not appropriate candidates for treatment. With its favorable toxicity profile, ongoing studies are evaluating T-VEC in combination with other immune-directed treatments.

Targeted Therapy

Protein kinase inhibitors have emerged as standard therapy for malignancies such as renal cell carcinoma, chronic myelogenous leukemia, subsets of lung cancer and gastrointestinal stromal tumors. As our understanding of the biology of melanoma grows, there is increasing interest in targeted therapies against molecular targets involved in the development and progression of melanoma. Several orally administered targeted therapies are FDA approved for treatment of melanoma (**Tables 139-8** and **139-9**).

TABLE 139-8 Dosing of Oral Targeted Therapies

Drug	Brand Name	Dose	Food–Drug Interactions	Drug–Drug Interactions
Trametinib	Mekinist	2 mg Daily Store in the refrigerator (36-46°F)	Administration with a high-fat, high-calorie meal may decrease AUC Take 1 hour before or 2 hours after a meal	Trametinib may enhance the adverse effect of dabrafenib
Cobimetinib	Cotellic	60 mg daily on days 1-21 of 28	Take with or without meal Avoid grapefruit and grapefruit juice	CYP3A4 inducers may decrease cobimetinib drug levels CPY3A4 inhibitors may increase cobimetinib drug levels Vemurafenib may increased drug levels of CYP1A2 and Pg-P substrates
Vemurafenib	Zelboraf	960 mg twice daily A missed dose may be take up to 4 hours prior to the next dose	Take with or without meal Avoid grapefruit and grapefruit juice	CYP3A4 inhibitors may increase vemurafenib drug levels CYP3A4 inducers may decrease vemurafenib drug levels Monitor closely if vemurafenib is use concurrently with other drugs known the prolong QT interval

Drug	Brand Name	Dose	Food–Drug Interactions	Drug–Drug Interactions
Dabrafenib	Tafinlar	150 mg twice daily A missed dose may be take up to 6 hours prior to the next dose	Take 1 hour before or 2 hours after a meal High-fat meals decrease Cmax and AUC Avoid grapefruit and grapefruit juice	Dabrafenib may decrease drug levels of CYP2B6, CYP2C19, CYP2C8, CYP2C9, and CYP3A4 substrates CYP2C8 and CYP3A4 inhibitors may increase dabrafenib drug levels CYP2C8 and CYP3A4 inducers may decrease dabrafenib drug levels Concurrent use with antacids, H2-Antagonists and proton pump inhibitors may decrease dabrafenib concentrations

AUC, area-under-the-curve; CYP, cytochrome P450.

TABLE 139-9 Monitoring of Oral Targeted Therapies

Drug	Adverse Reaction	Monitoring Parameters	Comments
Trametinib	Common: • Hypertension • Skin toxicity (most commonly puritis, acneiform rash, erythema, skin rash) • Hypoalbuminermia • Diarrhea • Stomatitis • Anemia • Lymphedema • Hyperglycemia • Increased liver function tests	• CBC at baseline and periodically for myelosuppression • CMP at baseline and periodically for hepatotoxicity and hyperglycemia • LVEF at baseline, 1 month after therapy initiation, then at 2- to 3-month intervals for cardiomyopathy • Ophthalmological evaluation periodically especially if patients report visual disturbances	• Hospitalization may be required for severe skin toxicities • Intracranial hemorrhage reported to be fatal • The risk of adverse effects increases when trametinib is used in combination with dabrafenib

Drug	Adverse Reaction	Monitoring Parameters	Comments
	• Fever Rare but serious: • Cardiomyopathy • Hemorrhage • Rhabdomyolysis • Interstitial lung disease • Serious febrile events • Retinal detachment • Retinal vein occlusion • Basal cell carcinoma, squamous cell carcinoma or primary melanoma	• Evaluate for signs/symptoms of pulmonary toxicity (eg, cough, dyspnea, hypoxia, pleural effusions, infiltrates) • Blood pressure • Signs and symptoms of bleeding concerning for hemorrhage • Dermatologic exams when used with dabrafenib at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies	
Cobimetinib	Common: • Nausea/vomiting/diarrhea • Hypertension • Photosensitivity • Electrolyte disturbances • Hypoalbuminemia • Lymphocytopenia • Anemia • Increased liver function tests • Increased CPK • Increase in serum creatinine	• CMP at baseline and monthly during treatment for hepatotoxicity, renal dysfunction and electrolyte replacement • CPK at baseline and periodically during treatment for rhabdomyolysis • LVEF at baseline, 1 month after initiation of therapy, and every 3 months for cardiomyopathy • Dermatologic exams at baseline, every 2 months	

Drug	Adverse Reaction	Monitoring Parameters	Comments
	• Fever Rare but serious: • Cardiomyopathy • Hemorrhage (GI and cerebral) • Secondary skin malignancies (cutaneous squamous cell carcinoma or keratoacathoma, basal cell carcinoma or secondary primary melanoma) • Retinal vein occlusion/Retinopathy • Hepatotoxicity • Rhabdomyolysis	during treatment, then 6 months after discontinuationfor secondary skin malignancies • Ophthalmological evaluation periodically especially if patients reports visual disturbances • Signs and symptoms of hemorrhage and rhabdomyolysis	
Vemurafenib	Common • Nausea/vomiting/diarrhea • Skin toxicity (most commonly rash, photosensitivity, pruritus) • Headache • Alopecia • Peripheral edema • Arthralgias/myalgias • Hyperkeratosis • Fever • Decreased appetite Rare but serious:	• CMP at baseline and monthly or as clinically indicated for hepatotoxicity and renal failure • LVEF at baseline, 1 month after initiation of therapy, and every 3months for cardiomyopathy • Dermatologic exams at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies	• Off label indication for *BRAF* V600K mutation

Drug	Adverse Reaction	Monitoring Parameters	Comments
	• Renal failure • Prolonged QT interval • SJS/TEN • Hepatotoxicity • Secondary skin malignancies (squamous cell carcinoma, basal cell carcinoma or keratocanthoma) • Hypersensitivity • Uveitis	• Eye pain, photophobia or vision changes	
Dabrafenib	Common • Nausea/vomiting/diarrhea • Skin rash pruritus • Hyperkeratosis • Fever • Hypophosphatemia • Peripheral edema • Headache • Alopecia • Palmar-plantar erythrodysesthesia • Increased liver function tests • Hyperglycemia • Hemolytic anemia • Arthralgias	• CMP with electrolytes for hypophosphatemia, hyperglycemia, and hepatotoxicity • CBC for myelosuppression • Dermatologic exams at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies • Eye pain, photophobia or vision changes for uvetitis	• The risk of secondary skin malignancies decreases when used in combination with a MEK inhibitor • Assess LEVF when used in combination with a MEK inhibitor • Patients with G6PD deficiency are at risk for hemolytic anemia

Drug	Adverse Reaction	Monitoring Parameters	Comments
	Rare but serious: • Interstitial nephritis • Pancreatitis • Secondary skin malignancies (squamous cell carcinoma, basal cell carcinoma or keratocanthoma) • Uveitis • Hypersensitivity • Hemorrhage • Serious febrile event		

CBC, complete blood count; CMP, comprehensive metabolic panel; CPK, creatine phosphokinase; DVT, deep vein thrombosis; LFT's, liver function tests; LEVF, left ventricular function; PE, pulmonary embolism.

The MAPK and PI3K/AKT pathways are involved in tumor cell growth and differentiation and are activated in melanoma. BRAF is downstream in the MAPK pathway. *BRAF* mutations have been described in melanoma cell lines, and it appears that up to 70% of melanomas exhibit BRAF alteration.[8] In a phase I/II trial, vemurafenib, an orally available inhibitor of mutated BRAF, showed activity in patients with melanoma that had *BRAF* with the V600E mutation. In a phase III trial comparing vemurafenib with dacarbazine in patients with unresectable, previously untreated stage IIIC or IV melanoma with a *BRAF* V600E mutation, vemurafenib significantly improved response rate (48% vs 5%) and overall survival.[62] Patients treated with vemurafenib had longer median progression-free survival (5.3 vs 1.6 months) and a higher overall survival rate at 6 months (84% vs 64%). The median time-to-response was also shorter with vemurafenib than dacarbazine (1.45 vs 2.7 months). Dabrafenib, another oral selective BRAF inhibitor, demonstrated similar activity to vemurafenib in early stage clinical trials in patients with previously untreated *BRAF* V600E mutated melanoma. In a phase III study, dabrafenib 150 mg orally twice daily was compared to dacarbazine in patients with untreated stage IV or unresectable stage III melanoma. Patients in the dabrafenib arm had longer median progression-free survival (5.1 vs 2.7 months, HR 0.30, $P < 0.0001$).[63] A follow-up analysis showed that overall survival at 12 months was 70% with dabrafenib as compared to 63% with dacarbazine.[63] Both vemurafenib and dabrafenib have been studied in melanoma patients with CNS metastasis with some activity. Other drugs targeted toward mutated *BRAF*, such as sorafenib, have not reported encouraging results.

BRAF inhibitors are generally well tolerated (Table 139-9). Skin complications comprising of cutaneous squamous cell carcinoma or keratoacanthoma and photosensitivity reactions, are a major concern with the use of these agents. In clinical trials, the incidence of cutaneous squamous cell carcinoma or keratoacanthoma with vemurafenib is 18% and 6% with dabrafenib.[22] The development of these lesions is thought to result from activation of the MAPK pathway in healthy skin cells lacking *BRAF* alterations. As a result, patients receiving a BRAF inhibitor should have dermatologic evaluations prior to starting therapy, every 2 months while on therapy and for up to 6 months following discontinuation of therapy. Cutaneous complications can be effectively managed by surgical resection, and treatment with the BRAF inhibitor can continue without dose adjustment.[64]

Unfortunately, patients develop resistance to BRAF inhibitors, typically after 5 to 6 months of therapy. Resistance is potentially caused by mutations in *MEK,* dependency on MEK/ERK antiapoptotic signaling, PI3K/AKT pathway involvement, *NRAS* mutation, or MAPK pathway reactivation. The use of MEK inhibitors in combination BRAF inhibitors has been found to delay the development of acquired resistance.[62,64]

7 MEK inhibitors have been studied in the treatment of metastatic melanoma and have shown modest activity as monotherapy. Trametinib is an inhibitor of MEK1/2. Compared with chemotherapy (dacarbazine or paclitaxel) in *BRAF*-mutated patients in a phase II trial, patients treated with trametinib had improved progression-free survival, overall survival, and response rates. These results were confirmed in a phase III trial that compared trametinib to chemotherapy (dacarbazine or paclitaxel). In this trial, median progression-free survival was 4.8 months versus 1.5 months in the trametinib and chemotherapy arms respectively (HR 0.45, $P < 0.001$). Overall survival at 6 months was 81% for trametinib and 67% for chemotherapy (HR 0.54, $P = 0.01$), even with crossover at progression. Common adverse events seen with trametinib were rash, diarrhea, and peripheral edema. Interestingly, secondary skin neoplasms were not observed in this trial.[65]

In addition to delaying drug resistance, the combination of a MEK inhibitor and a BRAF inhibitor has shown efficacy in the treatment of melanoma. The combination of trametinib 2 mg orally once daily and dabrafenib 150 mg orally twice daily received accelerated approval for the treatment in patients with unresectable or metastatic melanoma with *BRAF* mutations based on higher objective response rates compared to either agent alone. Additional trials with this combination compared to a BRAF inhibitors in the same patient population confirmed early findings and led to a full FDA approval. In a clinical trial that compared the combination to dabrafenib alone, patients randomized to the combination had longer median progression-free survival (9.3 vs 8.8 months, HR 0.75, $P = 0.03$), overall survival at 6 months (93% vs 85%, HR 0.63, $P = 0.02$) and higher overall response rates (66% vs 51%) as compared with dabrafenib alone.[66] In another phase III trial, the combination of dabrafenib and trametinib showed significantly longer median overall survival (not reached vs 17.2 months, HR 0.69, $P = 0.005$) and higher overall survival at 12 months (72% vs 65%). Median progression-free survival was also significantly longer (11.4 vs 7.3 months, HR 0.56, $P < 0.001$) and overall response rate was higher (64% vs 51%, $P < 0.001$) in patients treated with the combination.[67] The safety profile with the combination was similar to that observed with either drug given alone, with the notable exception of deceased incidence of skin complications in the combination arms.

Cobimetinib is another inhibitor of MEK1/2 which was recently FDA approved for the treatment of patients with unresectable or metastatic melanoma with a *BRAF* mutation in combination with vemurafenib. The recommended dosing with this regimen is vemurafenib 960 mg orally twice daily on days 1 to 28 and cobimetinib 60 mg orally once daily on days 1 to 21 of a 28 day cycle. In a phase III trial, median progression-free survival was significantly improved with the combined regimen of cobimetinib and vemurafenib versus vemurafenib alone (9.9 vs 6.2 months, HR 0.51, $P < 0.001$). Longer follow-up is needed to evaluate overall survival. Overall response rates were 68% and 45% for the combination and single agent arms, respectively. Adverse events were similar across the two groups and similar to the other MEK and BRAF combination, the number of secondary cutaneous cancer was decreased.[68]

Another agent of interest is imatinib mesylate, an oral agent that inhibits *c-KIT* and platelet-derived growth factor receptor. *c-KIT* is expressed primarily on acral and mucosal melanomas. Imatinib suppressed melanoma cell growth in preclinical studies. In clinical trials with unselected patients, imatinib is not active in metastatic melanoma despite downregulation of phosphorylated *c-KIT*.[22] However, a phase II trial of imatinib in patients with *c-KIT* mutations reported that 23% had a partial response, 30% had stable disease, and progression-free survival was 3.5 months.[8] Reponses in these patients were short similar to what is seen with BRAF inhibitors.

Other important potential molecular targets in the treatment of melanoma include vascular endothelial growth factor (VEGF) and cyclin-dependent kinases. Studies with drugs that inhibit these pathways are currently ongoing. With the success of immunotherapy, combining targeted agents with immunotherapeutic agents is another area of research interest. Reports from a phase I trial combining vemurafenib and ipilimumab showed significant hepatotoxicity, which shows the importance of patient selection to identify the best candidates for combined modality therapy.[69]

Other Approaches

Radiation

The role of radiation in the adjuvant treatment of melanoma is being investigated based on retrospective data that suggests patients treated with therapeutic lymphadenectomy for lymph node field relapse benefit from postoperative radiation to the nodal basins. Overall, these data demonstrate improvement in locoregional control with reasonable toxicity, but with no impact on overall survival. Results of a phase III trial indicated adjuvant radiotherapy reduced the risk of lymph node field relapse in patients who had undergone therapeutic lymphadenectomy for metastatic melanoma in regional lymph nodes.[70] No difference in relapse-free survival was observed. Radiation can be used patients with in-transit metastasis or for extranodal tumor extension. For patients with metastatic melanoma, radiation is palliative to symptomatic areas of disease progression. Adjuvant whole brain radiation after resection of brain lesions is controversial and is currently being investigated.[71]

Limb Perfusion and Limb Infusion

Isolated limb perfusion is a surgical procedure involving regional intravascular delivery of chemotherapy or biotherapy (or both) into an extremity with cutaneous melanoma.[72] When in-transit metastasis occur in extremities, local therapy with isolated limb perfusion or isolated limb infusion has been used. Isolated limb perfusion is a method for escalating the dose of chemotherapeutic drugs to a specific region of the body while limiting the systemic toxicities of the agent. Most perfusions can be performed with drug exposures of less than 2%. The most significant side effect of isolated limb perfusion are regional toxicity because the skin, subcutaneous tissue, and tissue of the extremity receives the same dose and is subjected to the same perfusion conditions as the tumor located within the extremity. After regional perfusions, objective response rates greater than 50% in treated limbs have been reported, with overall response rates possibly as high as 80%. The role of hyperthermia (38.9°C-40°C [102°F-104°F]) with regional isolated perfusion is not clearly defined. Although most clinical trials have used melphalan, it is not known whether the combination of melphalan with other agents may improve results.[73] Agents that have been combined with melphalan include actinomycin D, nitrogen mustard, thiotepa, and cisplatin. Work with biologic response modifiers, such as TNF-α, has been encouraging.[74] A simplified form of isolated limb perfusion, called isolated limb infusion, is a low-flow isolated limb perfusion performed under hypoxic conditions via small-caliber arterial and venous catheters. It has been proposed that the hypoxia that develops during isolated limb infusion may be beneficial with certain cytotoxic agents such as melphalan.

PERSONALIZED PHARMACOTHERAPY

Treatment of cutaneous melanoma is determined by both disease-related and patient-related issues. Treatment recommendations are based on stage of disease. Treatment of localized disease is surgical excision, with the extent of excision based on the tumor size. Wide excision is recommended for in situ melanoma and wide excision with SLNB for stage IA, IB, and II disease.

The role of adjuvant therapy in the management of individuals at high risk for recurrence remains controversial. One controversy is to identify which patients are appropriate candidates for treatment after resection of the primary tumor. Another controversy with adjuvant therapy is the choice of therapy. HDI has the most evidence supporting its use and is FDA approved for this indication. The challenges with this therapy have been discussed and its use has limited worldwide acceptance. Based on positive clinical trial results, ipilimumab is now an acceptable option in the adjuvant setting. Patient selection must be carefully considered given the irAEs. New therapies and combinations must be evaluated to answer the remaining questions about adjuvant therapy in melanoma. The most appropriate option at this time is a clinical trial, if available.

8 Due to the rapid influx of effective therapies, the management of metastatic melanoma has become complex. The NCCN guidelines list a variety of preferred systemic therapies for advanced or metastatic melanoma, including ipilimumab, pembrolizumab, nivolumab, dabrafenib with or without trametinib, vemurafenib with or without cobimetinib, high-dose aldesleukin, and clinical trial. Dacarbazine, temozolomide, combination chemotherapy, or biochemotherapy are also included as treatment options.[22] The choice of drug therapy should be based on *BRAF* mutational status, the

aggressiveness of the disease, and disease-related symptoms. Patients with a more indolent clinical picture may respond better to immunotherapy. Pembrolizumab or nivolumab are now recommended as first line treatment in *BRAF* wild-type melanoma over ipilimumab. Patients with a documented *BRAF* mutation are candidates for treatment with a BRAF inhibitor with or without a MEK inhibitor. These agents may be particularly beneficial in patients with *BRAF* mutations who are symptomatic from their disease because of the rapid response rates that are seen with their use. In patients who harbor the *c-KIT* mutation, imatinib can be offered as first-line therapy.[22] Combination chemotherapy or biochemotherapy should be reserved for patients who do not respond to immunotherapy or targeted therapy upfront. These modalities may be beneficial in stabilizing disease in patients who are *BRAF* wild-type with rapid disease progression. Best supportive care is also an option in some individuals. Data suggest that surgical treatment of metastatic melanoma should be considered in select individuals based on the extent and location of disease and performance status.

In patients who develop brain metastasis, treatment of CNS disease is independent of systemic therapy. Depending on the size and location of metastasis, surgical resection can be offered as the first-line treatment modality in patients with a favorable prognosis. Stereotactic radiosurgery is an acceptable alternative for patients who are unable to undergo resection. Whole-brain radiotherapy is generally reserved for patients with a large volume of metastasis because of the concern of cognitive decline.[75] In many cases, after brain metastasis have been treated, patients can continue with their systemic treatment. The role of targeted treatments and immunotherapy in patients with brain metastasis is ongoing. Early trials with ipilimumab excluded patients with active brain metastasis. Recently, several case reports have described activity in this patient population.[76] An important consideration for treatment of melanoma is the clinical presentation of the disease. As discussed, treatment of melanoma isolated to the limb may be most appropriately treated with regional therapy. Treatment options for metastatic uveal melanoma include strategies for managing hepatic metastasis.

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of patients treated with melanoma depends on the stage of disease at presentation. The prognosis of patients with thin tumors (less than 1 mm in thickness) and localized disease is good with long-term survival in more than 90% of patients. The risk of regional nodal involvement rises with increasing tumor thickness and survival rates decrease in patients with nodal involvement. Long-term survival in patients with distant metastasis is even lower. Therefore, early diagnosis and appropriate treatment of early disease are essential. Patients with suspicious pigmented lesions should be evaluated and the lesion excised whenever possible. Treatment is determined by patient factors and stage of disease.

Clinical practice guidelines published by the NCCN and European Society of Clinical Oncology (ESMO) provide guidance for treatment and follow-up of patients with melanoma.[22,77] Intensive surveillance has the benefit of early detection of recurrent disease, which may lead to better options of surgical resection. Emphasis on evaluation of locoregional areas is important. For patients with in situ melanoma, periodic skin examinations for life are recommended, with frequency determined based on patient risk factors. Local recurrence is associated with aggressive tumor biology and

frequently is a manifestation of an aggressive primary tumor. If a local recurrence occurs after inadequate primary disease management, the patient should undergo a workup based on the lesion thickness of the original melanoma. Patients with nodal recurrence should be evaluated for lymph node metastasis. Patients with systemic recurrence should be evaluated and treated in a fashion similar to patients presenting with systemic disease.

ABBREVIATIONS

AJCC	American Joint Committee on Cancer
ALM	acral lentiginous melanoma
ARF	alternative reading frame
bFGF	basic fibroblast growth factor
CTL	cytotoxic T lymphocyte
CTLA-4	cytotoxic T lymphocyte antigen 4
ECOG	Eastern Cooperative Oncology Group
EORTC	The European Organization for Research and Treatment of Cancer
ESMO	European Society of Clinical Oncology
FDA	Food and Drug Administration
HR	hazard ratio
HDI	high-dose interferon
HLA	human leukocyte antigen
IFN	interferon
IL-2	interleukin-2
irAEs	immune related adverse effects
INK4A	inhibitor of cyclin-dependent kinase 4
LAK	lymphokine-activated killer
LDH	lactate dehydrogenase
LDI	low-dose interferon
LMM	lentigo maligna melanoma
MAPK	mitogen-activated protein kinase pathway
mTOR	mammalian target of rapamycin
NCCN	National Comprehensive Cancer Network
NK	natural killer
NMSC	nonmelanoma skin cancer
NSAID	nonsteroidal antiinflammatory drug
PD-1	programed death receptor 1
PET	positron emission tomography

PI3K	phosphatidyl-inosital-3-OH kinase
SLNB	sentinel lymph node biopsy
SPF	sun protection factor
SSE	skin self-examination
SSM	superficial spreading melanoma
TNF	tumor necrosis factor
TIL	tumor-infiltrating lymphocyte
UV	ultraviolet
UVA	ultraviolet A
UVB	ultraviolet B
VEGF	vascular endothelial growth factor

Chapter 140: Hematopoietic Stem Cell Transplantation

Susanne Liewer; Janelle Perkins

INTRODUCTION

KEY CONCEPTS

- 1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a donor into a recipient, after the administration of chemotherapy with or without radiation. The rationale is to increase tumor cell kill by increasing the dose of chemotherapy. Immune-mediated effects also contribute to the tumor cell kill observed after allogeneic HSCT.

- 2 Hematopoietic stem cells used for transplantation can come from the recipient (autologous) or from a related or unrelated donor (allogeneic). If the related donor is a twin, the transplant is referred to as a syngeneic transplant.

- 3 Human leukocyte antigen (HLA) mismatching of allogeneic donor–recipient pairs at either class I or class II loci increases the risk of graft failure, graft-versus-host disease (GVHD), and worsens survival. The ideal donor is one that is matched at HLA-A,B,C, DRB1, and DQ.

- 4 Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood. Because of the rarity and similarity to other cells, hematopoietic stem cells are difficult to isolate and measure. These stem cells express the CD34 antigen, and measurement of the number of $CD34^+$ cells is a clinically useful measure of the number of hematopoietic stem cells.

- 5 Because of clinical and economic advantages, peripheral blood has replaced bone marrow as the source of hematopoietic stem cells in the autologous and adult allogeneic HSCT setting.

- 6 The purpose of the preparative (or conditioning) regimen in traditional myeloablative transplants is twofold: (a) maximal tumor cell kill and (b) immunosuppression of the recipient to reduce the risk of graft rejection (allogeneic HSCT only).

- 7 Reduced-intensity conditioning regimens (including those that are nonmyeloablative) have been developed in order to reduce early posttransplant morbidity and mortality while maximizing the graft-versus-malignancy (GVM) effect. The advantage to this approach is that patients who would otherwise not be eligible for allogeneic HSCT can now be offered a potentially curative therapy.

- 8 Transplant-related mortality associated with allogeneic HSCT ranges from 10% to 80% depending mostly on age, donor, and disease status. Major causes of death include infection, organ toxicity, and GVHD. The most common cause of death after autologous HSCT is disease relapse; transplant-related mortality is usually less than 5%, depending on the conditioning regimen, age, and disease status.

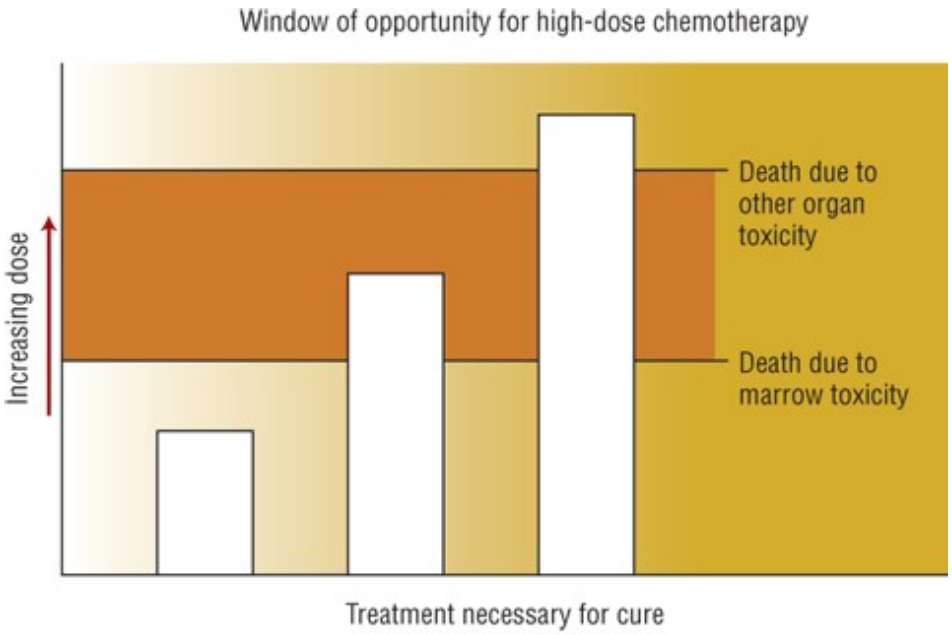
- 9 Patients undergoing allogeneic HSCT are given prophylactic immunosuppressive therapy, which inhibits T-cell activation, proliferation, or both. The most commonly used GVHD prophylaxis regimens are cyclosporine or tacrolimus and methotrexate. Sirolimus or mycophenolate mofetil are often substituted for methotrexate.

- 10 Initial treatment of both acute and chronic GVHD consists of prednisone, either alone or combined with cyclosporine or tacrolimus. Treatment of patients with steroid-refractory GVHD is unsatisfactory.

1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a compatible donor into a recipient, usually after administration of high-dose chemotherapy with or without radiation (called conditioning or preparative regimens). The original rationale for HSCT for treatment of malignant disease is based on studies showing that most anticancer drugs have a steep dose–response relationship and that myelosuppression limits the chemotherapy dosage that can be safely administered. Although standard-dose chemotherapy can prolong survival in many cancer patients, most patients are not cured of their disease with this strategy alone. Infusion of hematopoietic stem cells allows administration of very high doses of chemotherapy (as much as 10-fold higher) by reestablishing hematopoiesis. If tumor cells that are resistant to standard doses are sensitive to higher doses of chemotherapy, then tumor cell kill will be greatly increased, and the likelihood of cure would be higher with HSCT compared with standard dose chemotherapy. However, the chemotherapy dose cannot be escalated indefinitely because of the risk for death caused by nonhematologic toxicity (**Fig. 140-1**).

FIGURE 140-1

Patients represented by the middle column are the best candidates for hematopoietic stem cell transplantation because the technique allows for administration of chemotherapy or radiation in doses that otherwise would be intolerable because of severe myelosuppression.



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

HSCT is an important modality for treatment of a variety of malignant and nonmalignant diseases. More than 18,000 transplants were performed in the United States in 2012, primarily for malignant diseases.[1] The most common malignancies treated with HSCT are multiple myeloma, lymphomas, and leukemias. The number of transplants has grown steadily over the past decade because of an increase in the number of patients receiving alternative donor transplants and an increase in the number of patients older than 60 years undergoing transplantation.

Although HSCT is most commonly used for treatment of malignant diseases, many nonmalignant hematologic disorders, including aplastic anemia, thalassemia, and sickle cell anemia; immunodeficiency disorders; and other genetic disorders are also potentially curable with allogeneic HSCT. Transplantation is also being investigated as a treatment modality for patients with life-threatening autoimmune diseases, such as rheumatoid arthritis, systemic and multiple sclerosis, and systemic lupus erythematosus.

This chapter summarizes the procedures involved in HSCT and the common complications associated with HSCT. More detailed information on HSCT can be found in published reviews and books.[2,3,4,5] Information on HSCT also can be found on several websites, including *http://www.cibmtr.org* (Center for International Blood and Marrow Transplant Research [CIBMTR]) and *https://bethematch.org/* (National Marrow Donor Program [NMDP]).

HISTOCOMPATIBILITY TESTING AND DONOR SELECTION

2 Different types of donors are used in HSCT. The choice of donor depends on the diagnosis and disease status of the recipient as well as his or her age and comorbidities. The role and indications for HSCT are discussed in detail within individual disease chapters of this text. In *autologous* transplants, patients receive their own hematopoietic stem cells, which were collected and stored before

administration of the transplant conditioning regimen. In *syngeneic* transplants, an identical twin serves as the donor. In *allogeneic* transplants, the donor is genetically not identical to the recipient but shares some common cell surface antigens called human leukocyte antigens (HLAs). These antigens are encoded by the major histocompatibility complex (MHC), a cluster of genes located on the sixth chromosome.[6] The MHC contains three distinct regions designated as class I, class II, and class III. Class I and class II genes encode for HLA; products of class III genes have other important roles in the immune system. Class I and class II HLA antigens differ in their tissue distribution, structure, and function. Their primary function is to aid the immune system in recognizing cells or tissues as "self" or "nonself." The genes (and the corresponding antigens they encode for) important in HSCT are the class I antigens, HLA-A, HLA-B, and HLA-C and the class II antigen, HLA-DRB1. Because of the polymorphism of the HLA system, there are many different HLA antigens within each different class of HLA. To reduce the chance of graft rejection and graft-versus-host disease (GVHD), a donor is chosen based on how many of these HLA antigens are the same as those of the recipient. Thus, an ideally matched donor would be a "8/8" match, matching at each of the HLA loci mentioned above.

To identify a suitable allogeneic donor, both the recipient and potential donors are HLA typed (ie, specific HLA antigens are identified); the potential donor who is most closely matched is generally chosen to be the transplant donor. HLA typing is accomplished by DNA-based techniques that use polymerase chain reaction (PCR) amplification of specific HLA genes from genomic DNA. DNA typing methods are categorized by the level of discrimination they provide in defining the sequence of an HLA gene.[6] Low-resolution methods provide limited sequence information about a particular HLA gene and are typically used to identify sibling donors. However, low-resolution techniques cannot distinguish the extremely polymorphic nature of many of the HLA antigens. HLA antigens are characterized by thousands of genetic variations (alleles), and each allele may correspond to a unique HLA molecule. Different alleles can be distinguished only by high-resolution typing techniques; high-resolution methods are used to identify suitable unrelated donors.

3 The degree of HLA mismatching correlates with the risk of graft rejection, GVHD, and survival.[6] Mismatches at HLA-A, HLA-B, HLA-C, and HLA-DRB1 are similarly associated with increased risk of GVHD and mortality.[7] HLA-DQ mismatching is less predictive of negative outcomes suggesting an 8/8 match is as beneficial as a 10/10 match. As the number of mismatches increase, the risk of GVHD and transplant-related mortality also increases. In the search for an allogeneic donor, the patient's siblings are typed first. The odds that any one full sibling will match a patient are one in four. About 30% of Americans have an HLA-identical sibling. In an effort to offer allogeneic HSCT to patients who lack an HLA-identical sibling donor, alternative donors are being used. The most common type of alternative donor is an individual unrelated to the recipient who is fully or closely HLA matched. To facilitate identification of these donors, the NMDP (https://bethematch.org) was started in 1986 with initial funding from a US Navy contract. To date, the NMDP has registered more than 16 million donors in the United States and has facilitated more than 60,000 unrelated donor transplants. Donors outside the United States can also be accessed by the NMDP through agreements with international cooperative registries. About one-third of the allogeneic HSCTs performed worldwide are from unrelated donors.[1] The NMDP currently requires that the recipient be typed by high-resolution methodology at HLA-A,B,C, and DRB1. Although it is the transplant center's responsibility to select

the donor, the NMDP recommends that selected donor and recipient be matched at HLA-A,B,C, and DRB1 by high-resolution typing when possible for bone marrow or peripheral blood HSCT.[8] If more than one suitable HLA-matched unrelated donor is identified, other factors can be used to select the donor, such as younger age, being male or a nulliparous female, and negative cytomegalovirus (CMV) serostatus.

The likelihood of a recipient finding an HLA-matched unrelated donor ranges from one in 100 to one in 1,000,000 depending on the prevalence of the recipient's HLA type, race, and ethnic background. With the current size and racial make-up of the NMDP registry, the matching likelihood is higher for whites than for patients from other racial or ethnic groups. Agreements between NMDP and international registries may improve the likelihood of finding donors for these patients and NMDP has launched a major effort to promote participation among nonwhite volunteers. Another limitation is the time needed to search for a potential donor. While searches are generally done in an expeditious manner, some donor searches may take up to 3 to 4 months, and patients with acute leukemia can relapse while waiting for completion of the search. With improved HLA typing techniques and better supportive care, most reported outcomes with matched unrelated donors are no longer significantly different than those reported with related sibling donors.[9]

Unfortunately, not every patient who could benefit from an allogeneic donor transplant will have a matched related or unrelated donor available. This has sparked interest in evaluating the use of alternative donor options such as umbilical cord blood (discussed in the next section), mismatched unrelated donors or related haploidentical donors.[10] Potentially useful HLA-mismatched unrelated donors are those who are mismatched at one or, at most, two HLA loci. By allowing for minimal mismatching, the chance of finding an unrelated donor increases significantly. Although mismatched unrelated donor transplants are inferior with respect to GVHD, transplant-related mortality and overall survival when compared to matched unrelated donors, these transplants do offer a curative therapeutic option in select populations.[11] Research is being focused on evaluating the relative effect of mismatches at specific loci to determine if some are less detrimental (permissive) than others in order to improve outcomes. In addition, NMDP recommends testing the recipient for donor-specific HLA antibodies as graft failure is more common when the antibodies are present.[6]

Related haploidentical donors are those that are a complete half mismatch to the recipient; the donor and recipient are matched at 3 of 6 or 4 of 8 HLA loci. Donors can be parents, children or siblings of the recipients. Historically, haploidentical allogeneic transplants (Haplo-HSCT) generated poor outcomes related to high rates of graft failure and GVHD. Strategies to reduce the incidence of graft failure and GVHD have included various methods of T-cell depletion including administration of anti-thymocyte globulin (ATG), alemtuzumab, or posttransplant cyclophosphamide.[11,12] The use of high dose post-transplant cyclophosphamide (PTCy) on days 3 and 4 after infusion of stem cells has provided encouraging results. Three observational studies have compared outcomes after Haplo-HSCT and PTCy to traditional matched related and unrelated donor transplants and have shown that GVHD and survival outcomes were similar.[12] Two parallel prospective studies with identical objectives, eligibility criteria and clinical endpoints were conducted with reduced-intensity conditioning regimens in either Haplo-HSCT with PTCy or umbilical cord blood transplant (UCBT).[13] While the trials were not designed for results to be compared directly, patients receiving Haplo-HSCT

had higher rates of engraftment, lower incidence of acute and chronic GVHD and less nonrelapse mortality than reported in the UCBT trial. However, relapse rates were lower after UCBT leading to similar progression-free and overall survival between the two studies. These trials reproduce promising single-center results with Haplo-HSCT or UCBT and suggest that survival rates with these alternative donor sources are comparable to those observed after matched unrelated donors. Based on these results, a phase III study comparing the two alternative stem cell sources is currently underway (BMT-CTN 1101, NCT01597778). Until the results of that trial and other randomized controlled trials are available, choosing an alternative donor in the absence of a HLA-matched sibling or unrelated donor will remain controversial and depends on patient characteristics, physician preference and center experience.

HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells serve as "mother" cells for all blood cells, including erythrocytes, leukocytes, and platelets (see Chapter e86). Stem cells have varying degrees of "stemness." True pluripotent stem cells are capable of replicating indefinitely and can give rise to stem and progenitor cells of all tissues. Multipotent stem cells, such as hematopoietic stem cells, have the capacity for self-renewal and can differentiate into more than one cell type in a particular tissue lineage. Because of their capacity for self-renewal, hematopoietic stem cells are capable of repopulating the recipient's marrow, which has been "emptied" by administration of high-dose chemotherapy, either alone or combined with radiation.

4 Hematopoietic stem cells are rare cells, comprising less than 0.01% of all bone marrow cells. Isolation and quantitative measurement of hematopoietic stem cells are extremely difficult because of their rarity and their similar appearance to other cells. For these reasons, surrogate markers are used to measure the number of stem cells. CD34 is an antigen expressed on hematopoietic stem cells and other early progenitor cells. Determination of the number of cells expressing the CD34 antigen ($CD34^+$ cells), as determined by flow cytometry, has become the standard method of measuring hematopoietic stem cell content.

Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood (UCB). Hematopoietic stem cells from the bone marrow are obtained by multiple aspirations from the anterior and posterior iliac crests while the donor is under general anesthesia. The procedure takes about 1 hour and yields 200 to 1,500 mL, depending on the size of the donor. In allogeneic bone marrow transplantation (BMT), the marrow stem cells are given to the recipient 12 to 24 hours after harvest. In autologous BMT, the marrow is frozen and stored until needed. After intravenous infusion, the marrow stem cells enter the systemic circulation and find their way to the bone marrow cavity, where they reseed and grow in the bone marrow microenvironment. Although the donor experiences local soreness for a few days, the procedure usually is well tolerated, with no delayed complications resulting from the marrow aspiration. The major risk of serving as a marrow donor is the risk of undergoing general anesthesia.

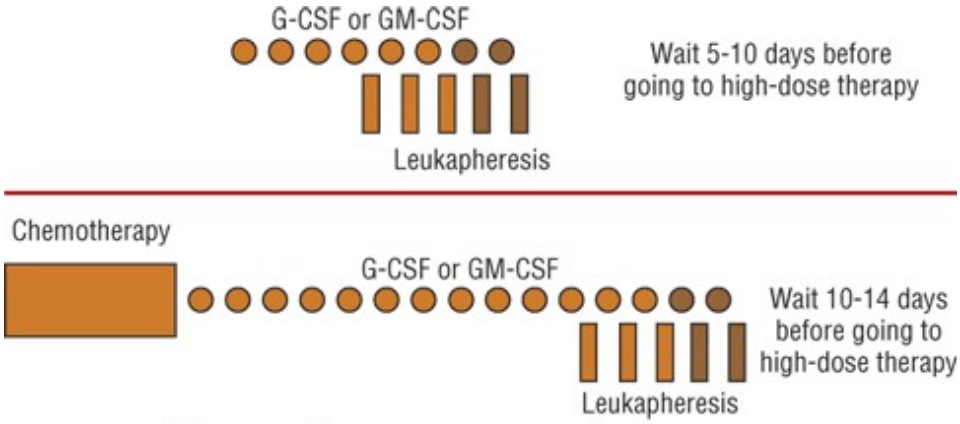
Hematopoietic stem cells in peripheral blood (peripheral blood stem cells [PBSCs]) are found in the mononuclear fraction of white blood cells (lymphocytes and monocytes) and are collected by a

procedure called leukapheresis (or apheresis). This is an outpatient procedure that involves withdrawal of blood from a vein (through a specialized IV catheter), selective removal of mononuclear cells (containing the hematopoietic stem cells) by an apheresis machine, and reinfusion of the unneeded blood components back to the patient. During this process, about 10 to 15 L of blood is processed over several hours during each daily apheresis session. Most of the blood cells are returned to the donor, and each apheresis yields about 200 mL of cells. Leukapheresis is continued daily until a target number of $CD34^+$ cells (which include hematopoietic stem cells) are collected.

The number of hematopoietic stem cells that circulate in peripheral blood normally is too low for apheresis to be technically feasible. Without mobilization techniques, at least six aphereses are usually required to collect a sufficient number of PBSCs. Several methods have been used clinically to "mobilize" hematopoietic stem cells from the bone marrow into peripheral blood for use in autologous transplantation. **Figure 140-2** shows representative schemas for mobilization and collection of PBSCs. The most commonly used mobilization method in both donor populations (healthy donors and autologous donors) is administration of a recombinant hematopoietic growth factor such as granulocyte colony-stimulating factor (G-CSF [filgrastim]) or granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]). Both agents are approved by the Food and Drug Administration (FDA) for this indication, but filgrastim is more commonly used. Head-to-head comparisons report superior outcomes with filgrastim in terms of number of stem cells collected, and posttransplant patient outcomes such as hematopoietic recovery, transfusion and antibiotic support.[14] Chemotherapy followed by a hematopoietic growth factor in the autologous transplant population increases the number of PBSCs to a greater extent than growth factor alone. This approach is more expensive and is associated with more adverse effects, but the number of aphereses is reduced, and the additional chemotherapy may further reduce the tumor burden before transplant. However, these benefits have not translated into improved transplant outcomes so this approach is generally not used.[14] Pegfilgrastim (pegylated filgrastim) has also been evaluated in the mobilization setting, either alone or after chemotherapy (6 and 12 mg doses). Its prolonged half-life of 33 hours allows for single-dose administration, increasing patient convenience. Studies of single agent pegfilgrastim are limited by small numbers and report varying degrees of success.[14] The combination of pegfilgrastim and chemotherapy mobilization has resulted in similar $CD34^+$ cell collections and transplant-related outcomes to chemotherapy and filgrastim mobilization.[14]

FIGURE 140-2

Schema for collection of peripheral blood progenitor cells after hematopoietic growth factor administration (top) or after chemotherapy and hematopoietic growth factor administration (bottom). Symbols with darker shading represent procedures performed only if adequate numbers of $CD34^+$ cells have not been collected. (G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.)



An ongoing area of controversy is the use of biosimilar filgrastim agents during stem cell mobilization. Most of the data to support the use of biosimilars is in the setting of chemotherapy-induced neutropenia. A meta-analysis summarized the results in over 900 subjects that included healthy donors and patients with hematologic malignancies who used biosimilar agents to collect PBSCs. Mobilization with biosimilars resulted in expected $CD34^+$ stem cell yields with similar posttransplant engraftment and side effects to filgrastim, which suggests that biosimilars may be an acceptable option in mobilization.[15] The European Bone Marrow Transplantation Association (EBMT), World Marrow Donor Association (WMDA), as well as American Society for Blood and Marrow Transplantation (ASBMT) recommend that filgrastim biosimilars only be used within the context of a clinical trial until further information is available.[16,17]

Plerixafor is a novel inhibitor of the CXCR4 chemokine receptor that is FDA approved as a mobilizing agent in combination with filgrastim in autologous transplant candidates. Two phase III trials of plerixafor combined with filgrastim reported the combination was associated with higher $CD34^+$ cell yields, fewer apheresis sessions, increased likelihood of achieving $CD34^+$ target yields, and lower graft failure rates compared to single-agent filgrastim.[18,19] Based on the results of these trials, plerixafor is being routinely used to mobilize stem cells in autologous HSCT patients. However, because most patients are able to mobilize efficiently with filgrastim alone and plerixafor is expensive, transplant centers generally use a risk-adapted or preemptive approach to identify which patients are appropriate candidates for plerixafor. One approach is to give plerixafor to patients with certain characteristics that have been associated with a high risk of poor mobilization (ie, risk-adapted approach). These characteristics include older age, diagnosis of non-Hodgkin lymphoma (NHL), extensive chemotherapy history, previous radiation therapy, previous exposure to lenalidomide or purine analogs, previous mobilization failure and low preapheresis circulating peripheral blood $CD34^+$(PBCD34^+) cell counts.[14] However, these characteristics lack sensitivity and specificity in predicting poor mobilization outcomes and thus patients may be either over or under treated.[20] Another approach is often referred to as a preemptive strategy, which identifies poor mobilizers based on PB ("PBCD") $CD34^+$ cell counts on day 4 or 5 of filgrastim administration or on the first apheresis collection. Low numbers of $CD34^+$ cells after filgrastim administration have been associated with mobilization failure. Patients who do not have a minimal number of $CD34^+$ cells

receive plerixafor.[14] Many transplant centers use these preemptive approaches to guide their mobilization strategies thereby limiting plerixafor use to patients at high risk for not obtaining the target $CD34^+$ yield. These algorithms have been reported to improve initial mobilization rates while efficiently managing resources.[14]

In about 20% to 30% of autologous transplant candidates, an optimal number of $CD34^+$ cells will not be obtained after the first attempt with standard mobilization regimens.[14] Several strategies for overcoming the obstacle of poor mobilization have been evaluated, including remobilization with the same or higher doses of the same hematopoietic growth factor, a combination of hematopoietic growth factors (ie, filgrastim and sargramostim), or a combination of chemotherapy and a hematopoietic growth factor. Each of these remobilization strategies has been used with varying success. Unfortunately these strategies are associated with failure rates that exceed 70%.[14] Bone marrow harvest is also an option if other strategies fail.

Current consensus guidelines suggest that plerixafor be used in remobilization regimens for patients failing primary mobilization attempts, regardless of whether it was used in the primary mobilization.[14] When combined with filgrastim, plerixafor is associated with failure rates of less than 30%, which compares favorably with other secondary mobilization strategies but is also more costly, especially if multiple doses of plerixafor are required.[21] The use of plerixafor combined with chemotherapy and filgrastim may a promising strategy, but further data are needed to better understand the appropriate timing and use of this regimen. The selection of a secondary mobilization regimen should be based on patient-specific factors and clinician judgment.

Several studies show that the number of $CD34^+$ cells infused correlates significantly with the rate of neutrophil and platelet recovery after high-dose chemotherapy.[14] Rapid neutrophil recovery usually is observed in patients who receive at least 2×10^6 $CD34^+$ cells/kg (body weight of recipient). More rapid platelet recovery is observed when at least 5×10^6 $CD34^+$ cells/kg is transplanted compared with lower cell doses. As a result, consensus guidelines recommend 2×10^6 $CD34^+$ cells/kg as a minimum number to collect for autologous transplant, with an optimal target of 5×10^6 $CD34^+$ cells/kg.[14] The decision to use a collection yield of less than 2×10^6 $CD34^+$ cells/kg should be limited to those cases in which the potential benefit of a HSCT outweighs the risks of infusing a suboptimal $CD34^+$ cell dose. For patients with multiple myeloma undergoing tandem transplants, cells for both transplants are collected before the first transplant. A minimum of 4×10^6 $CD34^+$ cells/kg is required, and generally the entire cell dose collected is divided into two equal aliquots, one for each transplant.

5 Use of peripheral blood instead of bone marrow as a source of hematopoietic stem cells offers several clinical and economic advantages. For autologous transplant patients the most clinically important advantage is that patients who receive mobilized PBSCs experience more rapid hematopoietic engraftment. Although engraftment of all lineages is more rapid when PBSCs are used, the most significant effect is observed with platelet recovery. Patients who receive mobilized PBSCs experience platelet recovery as much as 2 to 3 weeks earlier and require fewer platelet transfusions than those who receive bone marrow stem cells. As a result, patients usually are discharged earlier from the hospital, so the overall cost of autologous HSCT is reduced with the use

of PBSCs. PBSCs may be less likely to be contaminated with malignant cells compared with marrow stem cells. Finally, because PBSCs are collected from the mononuclear cell fraction, a fraction that also contains immunocompetent cells (eg, natural killer [NK] cells and T lymphocytes), some investigators believe that infusion of PBSCs represents a form of "adoptive immunotherapy." In this model, NK cells and lymphocytes targeted against tumor cells help to kill residual tumor cells. As a result of these clinical and economic advantages, peripheral blood has replaced bone marrow as the source of stem cells in the autologous setting.

Peripheral blood has also become the predominant source of hematopoietic stem cells in adult allogeneic HSCT.[22] About two-thirds of allogeneic HSCTs performed in adults currently come from PBSCs harvested from normal donors receiving filgrastim mobilization. Filgrastim is generally well tolerated in the normal donor population. Short-term effects are similar to those seen in cancer patients receiving filgrastim (eg, bone pain, headache, fever, arthralgias, malaise). Although there are concerns about increased risk of acute myelogenous leukemia (AML) in healthy subjects given filgrastim, no higher risk has been observed thus far.[23] Because of the long latent period of drug-related AML and the very low incidence of AML in the general population, longer follow-up of thousands of healthy donors will be required to definitively rule out an association between filgrastim and AML.

Randomized controlled trials and meta-analyses have shown that the stem cell source can influence posttransplant outcomes in allogeneic HSCT. Traditionally, matched related PBSCT have been associated with a more rapid hematopoietic recovery and required fewer transfusions compared with patients receiving bone marrow.[24] The difference in the rate of engraftment may be related to the threefold higher numbers of $CD34^+$ cells infused in recipients of PBSC transplants. Although increased risk of acute GVHD or transplant-related mortality in patients receiving allogeneic PBSC transplants has not been reported, a higher risk of chronic GVHD has been observed in many retrospective studies and meta-analyses.[24] The Blood and Marrow Transplant Clinical Trials Network (CTN) reported results from a trial that randomized 551 patients to allogeneic PBSC or bone marrow from matched unrelated donors.[25] Two years after transplant, there were no differences in overall survival, relapse, acute GVHD or mortality not related to relapse. However, a higher incidence of chronic GVHD was reported in patients who received PBSC transplants. Two-year survival is an early outcome, and further follow-up will need to be done to determine if these results are maintained over time. The published reports describing the impact of stem cell source on transplant related outcomes has focused primarily on transplants using myeloablative conditioning (discussed below). The CIBMTR reported retrospective data of patients with hematologic malignancies who received reduced intensity unrelated donor transplant with either PBSCs or bone marrow. Time-to-engraftment, risks of acute or chronic GVHD, relapse, non-relapse morality and overall survival were not significantly different between the two groups. Subgroup analysis suggests that GVHD prophylaxis may impact survival in this patient population and warrants further evaluation.[26] Selection of the optimal source of hematopoietic stem cells for an individual patient should be based on the risk of relapse, chronic GVHD, graft failure, and donor preference.

Hematopoietic stem cells found in UCB are an attractive source for several reasons.[27] Because the stem cells are collected from placental blood, there is a very low risk of transmissible infectious

diseases, no risk to the mother or the baby, and the cells are immediately available. UCB initially was obtained from siblings, but now recipients of transplants from unrelated donors account for almost all patients who receive UCB transplants. More than 600,000 UCB grafts are available in more than 100 UCB banks, and more than 30,000 unrelated UCB transplants have been performed worldwide.[27]

Recipients of UCB transplants usually receive a $CD34^+$ cell dose more than 1 log lower than that given to recipients of BMT, and this difference in $CD34^+$ cell dose may explain the delayed engraftment in recipients of UCB transplants. The number of infused total nucleated and $CD34^+$ cells correlates with outcomes after UCB transplantation. The CIBMTR compared outcomes for adults with acute leukemia who were transplanted with unrelated bone marrow or PBSC versus UCB. Overall and leukemia-free survival were similar in all transplant groups. The risk of acute and chronic GVHD was lower in UCB recipients compared with PBSC, and the risk of chronic GVHD was lower in UCB compared with bone marrow. However, transplant-related mortality was higher after UCB as compared with other stem cell sources. These data support the use of UBCs as a source of stem cells when matched PBSCs or bone marrow are not immediately available.[28]

A major limitation of UCB transplants is the small volume of blood collected, usually 60 to 150 mL with resultant low numbers of $CD34^+$ cells. The relatively low numbers of hematopoietic cells may limit its use for larger recipients. This has led to "pooling" 2 or more units of UCB for one recipient (referred to as double cord transplant). The Seattle and Minnesota groups published their experience in more than 500 patients older than 10 years of age who received a matched related donor, matched unrelated donor, mismatched unrelated donor, or double cord transplant. Leukemia-free survival was similar in all groups, but the double cord transplant recipients had a higher risk of transplant-related mortality.[11] The Blood and Marrow Transplant CTN conducted a phase II trial in which a reduced-intensity conditioning regimen was administered with subsequent unrelated double cord transplant.[13] At 1 year posttransplant, the nonrelapse mortality remained high compared to alternative donor sources. Although the role of double cord transplantation has not yet been fully defined, these results suggest that pooled UCB units may provide an option for patients in which no other appropriate donors are available.

Initially, Haplo-HSCT generated poor outcomes related to high rates of graft failure and GVHD.[12] The use of PTCy on days 3 and 4 after infusion of stem cells has provided some encouraging results. Three observational studies have compared outcomes between Haplo-HSCT with PTCy to traditional matched related and unrelated donors and reported similar transplant outcomes. Two parallel prospective studies of reduced intensity conditioning regimens in Haplo-HSCT with PTCy or UCBT reported higher rates of engraftment and lower rates of acute and chronic GVHD and nonrelapse mortality in the Haplo-HSCT group. However, relapse rates were lower after UCBT leading to similar progression-free survival and overall survival between the two studies.[13] Based on these results, a phase III study comparing the two alternative stem cell sources is currently underway.

Clinical Controversy…

For patients that do not have a fully matched related or unrelated donor, the optimal alternative stem cell source, such as umbilical cord blood, mismatched unrelated, or HLA-haploidentical donors, is not

clear. An ongoing phase III trial will directly compare two of these stem cell sources and may provide more definitive recommendations.

APPROACHES TO ERADICATE MALIGNANT CELLS

Conditioning Regimens

6 The purpose of the pretransplant conditioning regimen (also called the preparative regimen) depends on the type of transplant and the indication for its use. In the autologous setting, conditioning is used to eradicate malignant cells.[29] This is also the case in allogeneic HSCT for malignant diseases, but the conditioning regimen also serves a dual purpose to suppress the recipient's immune system to allow for donor cell engraftment. Two types of conditioning regimens are used, myeloablative and reduced intensity. Myeloablative conditioning (MAC) regimens contain very high doses of chemotherapy with or without radiation that would lead to life-threatening or fatal myelosuppression if hematopoietic stem cells were not infused.[30] Patients undergoing autologous HSCT receive only MAC regimens. Reduced-intensity conditioning (RIC) regimens are only used in allogeneic HSCT and consist of lower doses or different types of chemotherapy or lower doses of radiation than used in MAC regimens. RIC regimens were developed after the observation was made that some of the antitumor effect of the allogeneic transplant was mediated by a reaction between the donor's immune system and the recipient's cancer cells. This meant that very high doses of chemotherapy, radiation, or both may not be needed. Because RIC regimens use lower doses of chemotherapy or radiation or less toxic drugs, older patients and those with comorbidities are now able to undergo allogeneic transplant. Both types of regimens are discussed in detail below.

Myeloablative Conditioning Regimens

MAC regimens usually include at least one anticancer drug with a relatively steep dose-response curve and myelosuppression as their dose-limiting toxicity, such as alkylating agents. Cyclophosphamide, melphalan, busulfan, and carmustine are examples of chemotherapy agents commonly used in MAC regimens. Other agents are usually added that have additive or synergistic effects with these alkylating agents in specific types of cancers; other alkylating agents have also been used. **Table 140-1** lists chemotherapeutic agents that are frequently used in MAC regimens as well as the doses used and their dose-limiting toxicity in the transplant setting.

TABLE 140-1 Dose-Limiting Nonhematologic Toxicities for Selected Chemotherapeutic Agents Included in Myeloablative Conditioning Regimens in Hematopoietic Stem Cell Transplantation

Drug	Conventional Dose[a] (mg/m^2)	HSCT Dose (mg/m^2)	Dose-Limiting Toxicity
Busulfan (oral)	2	450	Hepatic
Carboplatin	400	2,000	Hepatic, renal
Carmustine	200	1,200	Pulmonary, hepatic
Cisplatin	100	200	Renal, peripheral neuropathy

Drug	Conventional Dose[a] (mg/m^2)	HSCT Dose (mg/m^2)	Dose-Limiting Toxicity
Cyclophosphamide	1,000	7,500	Cardiomyopathy
Etoposide	300-600	2,400	Mucositis
Ifosfamide	5,000	18,000	Renal
Melphalan	40	225	Mucositis
Thiotepa	20-50	1,125	Mucositis, central nervous system

HSCT, hematopoietic stem cell transplantation.

[a]Doses are approximate and are for drugs used as single agents. When combinations are used, doses may need to be decreased.

Total-body irradiation (TBI) is also used in some pretransplant conditioning regimens. In patients with malignant disease, the rationale of TBI is to eradicate malignant cells located in areas inaccessible to the systemic circulation and thus to the chemotherapeutic agents (eg, CNS and testicles). TBI also has significant immunosuppressive activity. TBI doses for MAC regimens range from 10 to 15 Gy (1,000-1,500 rads or cGy), which is more than twice the lethal myelosuppressive dose of radiation for a normal person. TBI in these doses is typically fractionated (split over several days, once or twice a day) rather than given as a single-dose. Fractionated TBI has an improved therapeutic ratio compared with single-dose administration, that is, destruction of more leukemic cells and marrow stem cells while sparing other normal tissues. The acute toxicities of TBI consist of fever, nausea, vomiting, diarrhea, mucositis, and tender swelling of the parotid gland. Long-term complications of TBI-containing regimens include cataract formation, growth retardation, carcinogenesis, permanent reproductive sterility, and secondary malignancies.

Based on its immunomodulatory and antineoplastic effects, cyclophosphamide (60 mg/kg/day for 2 days) is commonly combined with TBI (CyTBI). Other chemotherapy agents have been used with TBI but there is no evidence to suggest that any of these combinations are more effective than CyTBI.[31] Due to the toxicities seen with high dose TBI, chemotherapy only regimens also have been developed. Many of these regimens contain busulfan due to its activity against a variety of malignancies. Busulfan can either be given IV or orally. The use of IV busulfan-containing regimens has been associated with improved survival compared to TBI containing regimens in patients with myeloid malignancies.[32] At some transplant centers, plasma busulfan concentrations are monitored and doses adjusted as systemic exposure has been shown to correlate with both efficacy and toxicity and use of a preparative regimen with targeted busulfan may improve patient outcomes.[31,33] Busulfan was originally combined with cyclophosphamide (BuCy) but more recently has been combined with fludarabine (BuFlu) to increase regimen tolerability when used in the allogeneic

transplant setting.

Several studies, both prospective and retrospective, have been done evaluating differences between allogeneic transplant MAC regimens.[31,32] In general, there is no definitive data showing the superiority of one regimen over another, such that the choice of regimens before allogeneic HSCT generally is based on the experience of the transplant center, patient characteristics, diagnosis, and disease status.

Conditioning regimens used in autologous HSCT are exclusively myeloablative and generally include at least one alkylating agent with other agents added that may have specific activity against the tumor type being treated.[29,31] TBI usually is not commonly used and is not included in the conditioning regimen in patients who have received prior radiotherapy. MAC regimens used in patients with lymphoma generally include different combinations of cyclophosphamide, carmustine, etoposide, and cytarabine. Rituximab is commonly added in patients with CD20-positive lymphomas, although randomized controlled studies supporting the use of rituximab in this setting are lacking.[29] The Blood and Marrow Transplant CTN conducted a prospective comparative trial randomizing patients with diffuse large B cell lymphoma to receive high-dose chemotherapy with rituximab or iodine-131 tositumomab followed by autologous HSCT.[29] Progression-free survival and overall survival were not significantly different between the two groups, and thus anti-CD20 radiolabeled monoclonal antibodies are not used routinely as part of conditioning for patients with NHL undergoing autologous HSCT. Single-agent melphalan (200 mg/m^2) is the standard conditioning regimen for patients undergoing autologous HSCT for myeloma. The addition of other agents to melphalan has not been proven to be superior to melphalan alone.[29]

Reduced-Intensity Conditioning Regimens

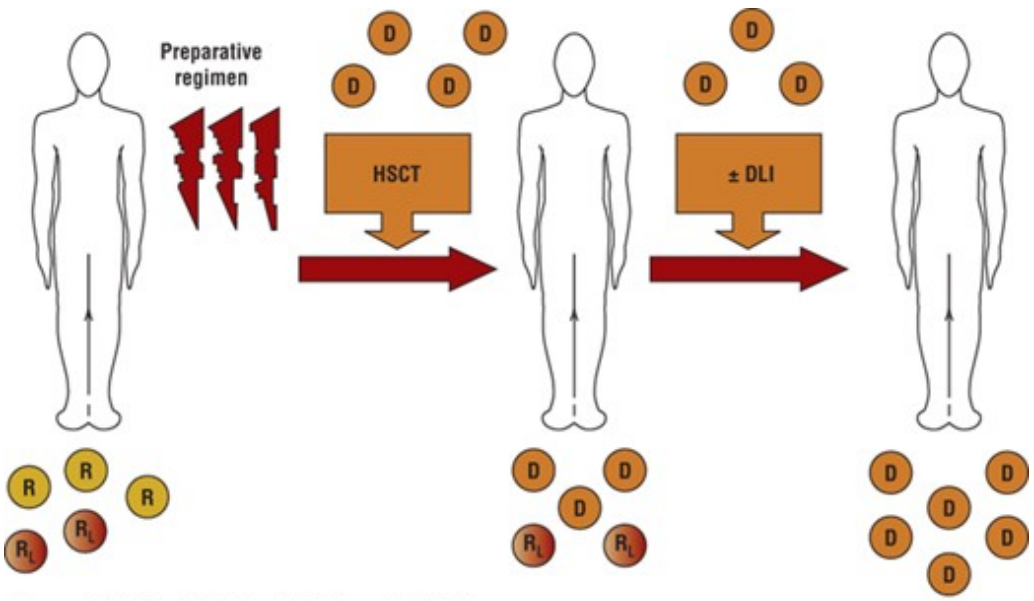
7 Donor T cells contribute to the tumor cell kill and prevention of relapse observed after allogeneic HSCT, an effect referred to as the graft-versus-malignancy (GVM) effect. Evidence for the GVM effect is based on retrospective studies showing that patients who developed GVHD had a lower risk of leukemic relapse than those who did not develop GVHD. However, the overall survival rate was not different because of the increased nonrelapse mortality associated with GVHD. Other anecdotal evidence supporting a T cell-mediated GVM effect includes the increased risk of relapse found with T cell-depleted transplants compared with unmodified transplants and the efficacy of donor lymphocyte infusions (DLIs) in producing responses in patients who have relapsed after allogeneic HSCT.[31]

RIC regimens containing lower doses of chemotherapy or radiation or less toxic agents were developed to take advantage of the GVM effect but with a lower incidence of regimen-related toxicity than that of MAC regimens. Animal data demonstrated that MAC was not required for engraftment of donor cells (the other important role of conditioning in allogeneic HSCT), thus paving the way for the evaluation of RIC in humans.[31] The major advantage of RIC is that potentially curative transplants can be offered to patients who typically would not be considered for allogeneic HSCT because of their unacceptably high risk of transplant-related complications due to increased age or moderately compromised organ function. Use of RIC regimens has steadily increased in patients

aged 50 and older.[1] In addition, because of the lower rate of toxicity, allogeneic HSCT with RIC can be offered to patients who have relapsed after traditional myeloablative autologous or allogeneic transplants, provided they are healthy enough to tolerate a second transplant. Because RIC regimens may not be completely myeloablative, host hematopoiesis can persist and lead to mixed chimerism (blood cells from both donor and recipient are present) (**Fig. 140-3**).[34] Several studies have reported significant correlations between donor T-cell chimerism levels and the risk of graft rejection, GVHD, and relapse. For example, a low percentage of donor T and NK cells present on day 14 has been associated with graft rejection, but high T-cell donor chimerism on day 28 has been associated with acute GVHD. Achievement of full donor chimerism was associated with better GVM effect and longer progression-free survival. These data suggest that monitoring donor chimerism after transplant may allow early interventions to prevent graft rejection or relapse.[34]

FIGURE 140-3

Schema for nonmyeloablative transplantation for hematologic malignancy. Recipients (R) receive a reduced-intensity conditioning regimen and an allogeneic hematopoietic stem cell transplant (HSCT). Initially, mixed chimerism is present with the coexistence of donor (D) cells and recipient-derived normal and leukemia/lymphoma (R_L) cells. Donor-derived T cells mediate a graft-versus-host hematopoietic effect that eradicates residual recipient-derived normal and malignant hematopoietic cells. Donor lymphocyte infusions (DLIs) can be administered to enhance graft-versus-malignancy effects.



A number of RIC regimens that vary in their cytotoxic, myelosuppressive, and immunosuppressive activity have been developed.[31] Most regimens include fludarabine (125-240 mg/m^2) because of its potent immunosuppressive activity, combined with either low-dose TBI (at doses up to 8 Gy [800 rad]) or an alkylating agent, such as cyclophosphamide (2-3.6 g/m^2 or 120-200 mg/kg), busulfan (up to 10 mg/kg), or melphalan (up to 180 mg/m^2). ATG or alemtuzumab is sometimes given for

additional immunosuppression, and other purine analogs (eg, pentostatin or clofarabine) are sometimes used instead of fludarabine. Rituximab has also been included in patients with CD20-positive lymphoid malignancies. Many of these regimens are myeloablative but are defined as RIC because of the reduced doses of chemotherapy.[30]

Some RIC regimens are considered nonmyeloablative because they result in little to no myelosuppression and do not require hematopoietic cell support for recovery of hematopoiesis. Nonmyeloablative regimens are associated with very little regimen-related toxicity but, similar to other RIC regimens, are immunosuppressive enough to result in full engraftment of important donor immune effector cells.[30] Two of the most common nonmyeloablative regimens are fludarabine (25 mg/m^2/day for 3-5 days) combined with cyclophosphamide (60 mg/kg/day × 2 days) or with TBI (less than or equal to 2 Gy [less than or equal to 200 rad]). Although these regimens are clearly nonmyeloablative, the distinction may be more difficult with other regimens as definitions remain somewhat arbitrary.

Progression-free and overall survival varies depending on the specific RIC regimen, disease type and status at the time of transplant, donor type, and patient age and comorbidities. Patients with indolent lymphoid malignancies generally have the lowest relapse rate after RIC transplants; those with advanced myeloid and lymphoid malignancies have higher relapse rates.[35] Several large retrospective registry-based studies have reported the results of RIC regimens.[35] In general, regimen-related toxicity and nonrelapse mortality have been reported to be lower than that of historical or concurrent control participants receiving MAC regimens in nonrandomized comparisons. This is remarkable considering the older age and higher incidence of comorbidities in patients receiving RIC transplants. Of concern, however, has been an increased rate of relapse in patients receiving RIC regimens, resulting in similar overall survival. One randomized trial has been published to date comparing RIC (FluTBI) versus MAC (CyTBI) regimens in patients 18 to 60 years of age with AML in first complete remission.[36] The two groups were well matched for age, cytogenetic abnormalities and donor type. The trial was stopped early due to slow accrual. Overall and progression-free survival were similar between the groups but, because the study was closed early, it likely lacked power to show a difference in the primary endpoints. The Blood and Marrow Transplant CTN performed a large randomized trial comparing RIC versus MAC in patients with AML or MDS. Eligibility criteria included age less than or equal to 65, disease in complete remission and minimal comorbidities. This trial was halted prematurely because a benefit in the MAC arm of the study was observed. The results, when published in a peer-reviewed journal, will assist clinicians in selecting the appropriate choice of regimen for the population represented in the study.[31] For other populations, clinicians will consider patient and disease characteristics as well as donor type when choosing an appropriate conditioning regimen until more evidence is available.

Clinical Controversy…

Although RIC regimens reduce transplant-related mortality, whether this approach results in improved survival compared with MAC regimens is not clear. Direct comparison of the results of RIC versus MAC transplants is difficult because patients undergoing RIC transplants tend to be older and have more comorbidities. Randomized controlled trials addressing these questions are ongoing, and

the results of these studies should better define the role of RIC transplants.

Posttransplant Therapy

Relapse of primary disease remains the most common cause of death for both allogeneic and autologous HSCT patients. As a result, much research has been directed at both preventing and treating posttransplant relapse or progression of disease.[37,38,39,40] The use of therapy posttransplant can be categorized either as "maintenance (or consolidation) therapy" or "salvage therapy." Maintenance/consolidation therapy is used to prevent relapse whereas salvage therapy is given to treat active relapse. Methods of identifying relapsed disease for many transplantable malignant diseases have become quite sensitive, and often disease can be detected at the molecular level (ie, minimal residual disease) and used to direct posttransplant therapy. Several posttransplant therapies have been evaluated both in the maintenance and salvage settings, including immunotherapy, conventional chemotherapy, and targeted therapy. Relapse after autologous transplant can often be treated with standard doses of chemotherapy, a second autologous transplant, or even an allogeneic transplant, depending on the diagnosis, disease status, side effects, response, and duration of response to the first transplant. Treatment options for most patients who relapse after allogeneic HSCT are more limited, and prognosis is generally poor. Disease-specific chemotherapy and immunotherapy can be considered for some patients. A second allogeneic HSCT may be considered but is associated with a mortality rate of up to 45%.[38]

Immunotherapy

The rationale for posttransplant immunotherapy after allogeneic HSCT is based on the GVM effect. To take advantage of the GVM effect in patients who relapse after allogeneic HSCT, immunosuppressive therapy being used for GVHD is withdrawn as quickly as possible without inducing a serious GVHD flare. In rare cases, this is enough to reinduce a remission, but further therapy is usually required. In addition, this is not a viable option in patients with active GVHD. Induction of the GVM effect has been investigated with several immunostimulatory drugs including interleukin-2, cyclosporine, interferon-gamma, and interleukin-1. None of the randomized trials done with these agents showed survival benefit.[40] Other posttransplant immune strategies include DLI and monoclonal antibodies.

Donor Lymphocyte Infusion

Perhaps the most commonly used form of posttransplant immunotherapy is DLI.[41,42] Lymphocytes are collected from the same donor who provided hematopoietic stem cells for the original allogeneic transplant, thus limiting this option to patients with available donors. Response to DLI is disease specific. More than 80% of patients with CML who are in cytogenetic or molecular relapse respond to DLI. The response rate of patients in more advanced phases is about 15% to 30%. Although the time to response is delayed (median, 3-4 months), patients often have a durable molecular remission to DLI. Response rates to DLI of patients with other myeloid malignancies, such as AML and myelodysplasia, are generally lower (25%-30%) than the rates of patients with CML. This may be related to the rapid proliferation of acute leukemia within the often prolonged time to response after DLI. Patients with relapsed AML after HSCT are more likely to achieve a complete response to DLI if

they had a longer remission period after transplant and have some GVHD after the DLI; low tumor burden, remission at the time of DLI, and good-risk cytogenetics have also been shown to be favorable characteristics. Administration of induction chemotherapy or therapeutic agents with novel mechanisms of action (eg, 5-azacitidine, lenalidomide, and bortezomib) before DLI administration may improve the antitumor activity of DLI in patients with AML or other rapidly proliferating malignancies, but this method has not been tested in a randomized study.[38] DLI has been shown to have limited benefit in patients with relapsed acute lymphocytic leukemia (ALL) after transplant.

DLI appears to be effective in patients with multiple myeloma who relapse after allogeneic HSCT, with reported response rates of 40% to 50%. Chemotherapy followed by DLI may induce a GVM effect in patients with relapsed lymphoma. The highest response rates were reported in patients with indolent NHL while more aggressive malignancies had lower response rates.

The most serious complications of DLI are pancytopenia and GVHD, and DLI is not usually given to patients with active GVHD. The cytopenias generally are transient and can be treated with hematopoietic growth factors. Some patients may have a more prolonged course of aplasia with associated risk of infection, bleeding, and anemia and these patients may benefit from another infusion of donor hematopoietic stem cells.

New strategies being evaluated to improve outcomes with DLI include priming the donor with filgrastim, infusion of selected subsets of T-lymphocytes to promote GVM, preemptive use of DLI based on the presence of minimal residual disease or evidence of molecular/cytogenetic relapse, or prophylactic DLI in patients who are at high risk of relapse.[41]

Monoclonal Antibodies

Although earlier studies showed potential benefit of rituximab as maintenance therapy for certain types of NHL patients after autologous HSCT, more recent randomized controlled trials with mature follow up have not consistently demonstrated benefit.[29,40] Therefore, routine use of rituximab maintenance is not recommended. Rituximab may be useful in combination with other active agents for salvage therapy of posttransplant relapse.

Brentuximab vedotin (anti-CD30 antibody conjugated to monomethyl auristatin E, a microtubule-disrupting agent) was evaluated as maintenance therapy in a randomized placebo-controlled study in patients with Hodgkin lymphoma after autologous HSCT.[43] Progression-free survival was significantly improved in patients randomized to brentuximab (hazard ratio 0.57, 95% confidence interval 0.4-0.81). Consistent benefit was seen across all subgroups that were analyzed. The most frequent adverse events in the brentuximab group were peripheral sensory neuropathy and neutropenia. No difference in overall survival was seen, likely because patients receiving placebo were allowed to crossover to brentuximab treatment at the time of progression. These results are encouraging given the generally poor prognosis of patients with relapsed/refractory Hodgkin lymphoma.

Chemotherapy or Targeted Therapy

Tyrosine kinase inhibitors (TKIs), such as imatinib, dasatinib, and nilotinib have been shown to be

effective in the prevention and treatment of relapse after allogeneic HSCT in patients with CML and Philadelphia chromosome–positive (Ph+) ALL.[44] In patients with CML who experience hematologic relapse (presence of leukemic blasts in blood or bone marrow) after allogeneic HSCT, imatinib has been reported to induce complete hematologic responses (disappearance of leukemic blasts) and complete cytogenetic responses (disappearance of cytogenetic markers of disease) in a majority of these patients. Outcomes in patients with Ph+ ALL have also been encouraging. TKIs are also given soon after transplant to prevent relapse.[44,45] Patients with Ph+ ALL and CML without evidence of disease after transplant who are treated with TKIs to prevent relapse appear to have sustained cytogenetic remissions (without evidence of cytogenetic markers of disease). In a study of patients with Ph+ ALL, 50% of patients who had minimal residual disease detected after stem cell transplant had a complete response to TKI therapy.[45] TKIs are generally well tolerated after transplant. Commonly reported side effects include neutropenia, thrombocytopenia, liver function abnormalities, edema, and muscle pain, which may require dosage reductions or discontinuation. Larger comparative studies will be required to clearly define the benefit of TKIs after transplant, as well as the optimal dosing, timing, and duration of therapy.

Based on its activity in AML and MDS, 5-azacitidine is being evaluated in the posttransplant setting to prevent or treat relapse in patients with these diagnoses. Investigators at the MD Anderson Cancer Center performed a dose and schedule finding study with 5-azacitidine maintenance therapy in patients who were in a complete remission after HSCT. The dose-limiting toxicity was thrombocytopenia, and the optimal dose was 32 mg/m^2 given subcutaneously for 5 days for 4 cycles. This study demonstrated that low-dose 5-azacitidine may be administered in this population safely, and it may prolong event-free survival and overall survival, justifying further studies to confirm these preliminary findings.[40,46] 5-azacitidine maintenance therapy has also been associated with a reduction in GVHD and increasing donor chimerism which delayed disease relapse.[39] Retrospective analyses of 5-azacitidine used to treat posttransplant relapse of AML have reported a response rate of 50% to 75% but overall survival remains poor (15%-20% at 2 years) and toxicity is substantial.[47] Improved results have been seen when DLI is given after 5-azacitidine.[39] Other therapies being investigated as maintenance therapy after allogeneic HSCT include panobinostat (deacetylase inhibitor) and the FLT3 tyrosine kinase inhibitors (sorafinib, quizartinib, and midostaurin).[39] Posttransplant therapy is also being evaluated in patients with multiple myeloma. Previous studies showed a potential benefit of thalidomide to prevent relapse after autologous transplant, but its use is limited by neurotoxicity and other bothersome adverse effects. When given after autologous transplant in patients with nonprogressing disease, lenalidomide has been shown to prolong progression-free survival compared with patients receiving placebo.[40] However, a small but significant increased incidence of second primary cancers was reported in the lenalidomide-treated patients. Further study is needed to better define the risk of second malignancies. Patients should be aware of this potential safety issue when discussing treatment with lenalidomide after autologous HSCT. Bortezomib maintenance therapy after autologous HSCT has also been associated with prolonged progression-free survival.[40]

TRANSPLANT-RELATED COMPLICATIONS

8 Although many patients with cancer who are treated with high-dose chemotherapy and autologous or allogeneic HSCT experience long-term survival and cure of their disease, this modality is associated with many serious and potentially life-threatening complications.[29,32] In spite of the availability of improved broad-spectrum anti-infective agents, immunosuppressive drugs, and hematopoietic growth factors which has improved survival over the last four decades, the transplant-related mortality rate after allogeneic HSCT with HLA-matched sibling and unrelated donors is 20% to 30%. The mortality rate is generally lower with the use of RIC regimens but higher when alternative donors are used. Causes of nonrelapse-related death are a result of transplant-related organ toxicity, GVHD, or immunosuppression. The risk of transplant-related mortality after autologous HSCT generally is less than 5%, depending on patient population and conditioning regimen.[29] The mortality rate is lower with autologous transplants because of the lack of GVHD and associated complications of immunosuppression. Transplant-related mortality in autologous HSCT usually is caused by regimen-related toxicity or infection.

Table 140-1 lists the dose-limiting nonhematologic toxicities for several drugs that are commonly included in MAC regimens. These toxicities may be uncommon or rare with administration of conventional doses of specific drugs. When these agents are given in high doses, the toxicities seen with conventional doses (eg, mucositis, enteritis, nausea, vomiting, and hematuria) can be more frequent or severe. Several unusual and severe manifestations of regimen-related toxicities are discussed in this section.

Sinusoidal Obstruction Syndrome

Sinusoidal obstruction syndrome (SOS), formerly known as hepatic venoocclusive disease (VOD), occurs as a result of chemotherapy-induced damage to the sinusoidal endothelial cells of the liver, which leads to release of proinflammatory cytokines and further damage to the endothelium. Gaps develop between the endothelial cells allowing cellular debris to accumulate, causing the sinusoids to narrow and eventually become occluded. In addition, injury to the endothelial cells produces fibrin deposition and clot formation, further narrowing the sinusoids.[48] These histologic changes can lead to obstruction of sinusoidal flow, reduced hepatic venous outflow, portal hypertension, and hepatic failure. Clinical signs of SOS include fluid retention (resulting in sudden weight gain and ascites), hepatomegaly (sometimes painful), and hyperbilirubinemia or jaundice. SOS usually occurs within the first 4 weeks after transplant, and the incidence of SOS ranges from 5% to 20% in most published series. Severe SOS is fatal in 50% to 75% of cases. Factors that have been reported to increase the risk of SOS include use of TBI-containing conditioning regimens (dose dependent), use of sirolimus for the prevention of GVHD, increased systemic exposure to busulfan, oral administration of busulfan, individual variability in cyclophosphamide metabolism, chronic viral hepatitis, and elevated liver function test results before transplant. Pretransplant exposure to gemtuzumab ozogamicin (Mylotarg®) has been implicated in the development of SOS in patients undergoing allogeneic HSCT, especially when given within a few months of transplant.[48]

Prostaglandin E_1, unfractionated low-molecular-weight heparin, and ursodiol have all been studied in prevention of SOS.[32,48] Ursodiol has been found to not only reduce the risk of SOS in patients

undergoing MAC allogeneic transplants but has also been associated with reduced transplant-related mortality and GVHD. Defibrotide, a polydisperse oligonucleotide with fibrinolytic properties, is another agent that has been used successfully in the prophylaxis of SOS. It is being routinely used in some European transplant centers in patients at high risk for SOS.[48]

Treatment of SOS is generally supportive, including fluid and electrolyte management. Hepato- and nephrotoxic drugs should be avoided. Mild-to-moderate disease generally resolves without specific therapy. Recombinant tissue plasminogen activator has been given to patients with severe SOS because of the possible role of the coagulation cascade in the pathogenesis of SOS. Responses have been reported, but patients also experienced a higher risk of bleeding.[48] Mounting evidence supports the use of defibrotide in the treatment of patients with severe SOS, demonstrating improved response rates and lower mortality compared with historical control participants.[48] Defibrotide (Defitelio®) was recently approved by the FDA in 2016 and its role in the treatment of SOS is still being defined.

Pulmonary Complications

Pulmonary complications after HSCT can be categorized as infectious and noninfectious (infectious complications are discussed in Chapter 122). Noninfectious complications can be caused by direct damage to the pulmonary tissue by chemotherapy or radiation used in the conditioning regimen, immune effects of the graft, or other causes not clearly understood. Early complications include diffuse alveolar hemorrhage, periengraftment respiratory distress syndrome, and idiopathic interstitial pneumonitis.[49] Diffuse alveolar hemorrhage is characterized by dyspnea, hypoxia, dry cough, and fever; chest radiography usually shows diffuse infiltrates in an alveolar pattern. Diffuse alveolar hemorrhage is diagnosed by examination of bronchoalveolar lavage fluid via bronchoscopy, which reveals progressively bloodier fluid with each instilled aliquot and negative findings on microbiologic analysis. Although the condition can be life-threatening or fatal, prompt treatment with high doses of corticosteroids is sometimes beneficial.[49]

Periengraftment respiratory distress syndrome is characterized by fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema can occur during neutrophil recovery after HSCT.[49] The incidence of engraftment syndrome is not known because of the lack of uniform diagnostic criteria, although some series report that about 10% of patients who receive autologous HSCT develop the syndrome. This syndrome can progress to life-threatening respiratory failure with or without multiple organ failure. Corticosteroids are effective in some patients.

Idiopathic interstitial pneumonitis (also called idiopathic pneumonia syndrome) is defined as widespread alveolar injury in the absence of active lower respiratory tract infection after HSCT.[50] Patients with idiopathic interstitial pneumonitis are clinically indistinguishable from patients with interstitial pneumonitis related to infection. Idiopathic interstitial pneumonitis is postulated to have a multifactorial etiology, including toxic effects of MAC, immunologic cell-mediated injury, inflammatory cytokine-induced lung damage, and occult pulmonary infections. The risk is similar in recipients of autologous or allogeneic HSCT but appears to be higher in patients who are conditioned with a TBI-containing regimen or who have acute GVHD. A mortality rate as high as 70%

has been reported, and treatment consists of supportive care only as the efficacy of corticosteroids is not well described. Etanercept may be beneficial in some patients with idiopathic interstitial pneumonitis.[51]

Late pulmonary complications cover a wide spectrum of disorders and include both obstructive and restrictive lung diseases.[49,52] The best described of these disorders is bronchiolitis obliterans with or without organizing pneumonia. Although bronchiolitis obliterans is thought to be a result of chronic GVHD affecting the lungs, its pathogenesis has not been completely elucidated. Therapy consists of corticosteroids, which are about 50% effective. Patients with mild-to-moderate airflow impairment appear to have the best response. The survival rate at 5 years from diagnosis of bronchiolitis obliterans is less than 20%.

Graft Failure

Initial engraftment of hematopoietic cells after high-dose chemotherapy conditioning regimens usually occurs in the first 2 to 4 weeks after transplant. Engraftment is evidenced by rising peripheral blood counts and the presence of hematopoietic precursor cells in the marrow. In allogeneic HSCT, the presence of donor cells (ie, chimerism) is confirmed by PCR-based analysis of polymorphic DNA sequences of cells from the bone marrow and peripheral T cells. Full chimerism is defined as greater than 95% of cells of donor origin. In most patients, engraftment is sustained with complete recovery of hematopoiesis.

However, graft failure (loss of bone marrow function with resultant loss in peripheral blood counts) can occur after both allogeneic and autologous HSCT. It can be the result of heavy pretreatment with chemotherapy or radiation therapy (or both); infusion of insufficient numbers of hematopoietic stem cells; viral infection; recurrence of primary hematologic malignancy; drug reaction (eg, to ganciclovir); development of a secondary myelodysplasia; or in the allogeneic setting, an immunologic reaction between the donor and recipient caused by inadequate immunosuppression of the recipient (ie, graft rejection). Two syndromes have been observed. Whereas early graft failure occurs when the rate of hematopoietic recovery is delayed or does not occur at all (primary graft failure or delayed engraftment), late graft failure is characterized by a decline in peripheral blood counts after initial engraftment (secondary graft failure). With widespread use of PBSCs and posttransplant growth factors, primary graft failure is rare after autologous and HLA-matched allogeneic HSCT but is not uncommon after UCBT. Graft failure that occurs after allogeneic HSCT, characterized by regrowth of immunocompetent recipient cells and a simultaneous loss of donor cells, is referred to as *graft rejection*. Graft rejection occurs rarely after HLA-matched allogeneic HSCT. An increased risk of graft rejection has been observed in recipients of hematopoietic stem cells from HLA-mismatched donors, recipients of T cell-depleted marrow, and patients with severe aplastic anemia. In a large retrospective analysis of over 20,000 patients undergoing myeloablative allogeneic HSCT the incidence of primary graft failure was reported was 5.5%.[53] In this analysis, risk factors for primary graft failure included bone marrow (vs peripheral blood) grafts, diagnosis of a myeloproliferative disorder, HLA mismatched transplants, ABO incompatibility, and BuCy conditioning. The long-term prognosis of patients with graft failure is poor. Despite supportive care and treatment with hematopoietic growth factors, death may result from infection or bleeding. In some patients with an

allogeneic donor, a second infusion of stem cells can be attempted.[32]

Hematopoietic growth factors usually are given after transplant to patients who receive autologous HSCT, based on several benefits associated with their use including fewer antibiotic days and decreased length of stay. Decreasing resource utilization after transplant (total antibiotic days and length of stay) can help justify the cost of growth factors in this patient population. Growth factors can be initiated the day of, the day after, or as late as 7 days after the infusion of stem cells and are continued until neutrophil recovery to greater than an arbitrary number of neutrophils (500-1,000 cells/mm^3 [0.5-1.0 × 10^9/L]). Pegfilgrastim appears to be equally efficacious to filgrastim in this setting.

Hematopoietic growth factors also accelerate the rate of neutrophil recovery in patients undergoing allogeneic HSCT. However, filgrastim does not reduce infection rates, antibiotic days or length of stay. The decision to whether or not to use filgrastim must be made by each institution and may be reserved for use in patients who are at risk for a prolonged rate of neutrophil recovery (eg, UCB transplants).

Results of studies with platelet growth factors, such as thrombopoietin and interleukin-11 (IL-11), given posttransplant have been disappointing. Platelet transfusions remain the standard of care in patients with thrombocytopenia below a given threshold (eg, 10,000 cells/mm^3 [10 × 10^9/L]) and in patients with significant bleeding.

Anemia may be problematic in the posttransplant setting, especially in patients receiving allogeneic HSCT. The etiology is unclear and most likely is multifactorial. Although erythropoietin administration may be useful in reducing the need for red blood cell transfusions, its use in cancer patients is associated with an increased risk of adverse events and is limited by FDA warnings and restrictions.

Graft-Versus-Host Disease

GVHD is caused by immunocompetent allogeneic donor T cells reacting against recipient/host antigens on the surface of antigen-presenting cells (APCs). In that setting, donor T cells recognize unmatched major or minor histocompatibility antigens of the host as genetically foreign, become activated, proliferate, and attack recipient tissue, thereby producing the clinical syndrome of GVHD.

Two different clinical syndromes of GVHD (acute and chronic) are recognized, each with two subcategories. Classic acute GVHD occurs within 100 days after transplant or DLI while persistent, recurrent or late-onset acute GVHD occurs beyond 100 days after transplant, withdrawal of immunosuppression or DLI.[54] Both subcategories of acute GVHD occur in the absence of chronic GVHD. Classic chronic GVHD usually occurs after day 100, with only clinical manifestations that can be attributed to chronic GVHD. Chronic GVHD may occur after resolution of acute GVHD or de novo (no prior acute GVHD). Acute and chronic overlap syndrome is a newly defined entity in which features of both acute are chronic GVHD appear together. Chronic GVHD usually develops before resolution of acute GVHD (also called progressive onset). The clinical manifestations of GVHD are distinct. Whereas acute GVHD usually is limited to the gastrointestinal tract, skin, and liver, signs and symptoms of chronic GVHD resemble an autoimmune disorder and can affect many organ systems.

A “hyperacute” form of GVHD may occur in patients with multiple HLA mismatches and in patients who receive T cell–replete transplants without adequate GVHD prophylaxis, especially after MAC regimens.[55] Descriptions of hyperacute GVHD vary but usually include fever, generalized erythroderma, desquamation, and edema. More severe forms with accompanying organ failure have been seen in haploidentical donors. Hyperacute GVHD typically occurs about 1 week after transplant before engraftment of neutrophils. The response rate to first-line therapy appears to be lower in patients with hyperacute GVHD compared with patients who develop GVHD later after transplant, but no difference in survival has been observed.

Acute Graft-Versus-Host Disease

The pathophysiology of acute GVHD has been described as a three-step process.[56] In step 1, the conditioning regimen causes damage to the intestinal mucosa, leading to release of lipopolysaccharides into the systemic circulation. This stimulates secretion of inflammatory cytokines such as IL-1 and tumor necrosis factor-α (TNF-α). These cytokines upregulate MHC gene products and host APCs such as dendritic cells, which play a critical role in this immune response. In step 2, donor T cells are activated, and secretion of other cytokines (IL-2 and interferon-γ) by activated T cells results in recruitment of macrophages and alteration of target cells in the gastrointestinal tract and skin so that they are more susceptible to damage. In step 3, multiple cytotoxic effector cells (T cells and macrophages) are generated and contribute to target tissue injury by secreting more inflammatory cytokines that cause target cell apoptosis. The term “cytokine storm” is sometimes used to describe the critical role of inflammatory cytokines in this process. Three general approaches have been used to prevent GVHD in humans. The first is to reduce host tissue damage with the use of RIC regimens. The second and most widely used approach is to modulate donor T cells by reducing T-cell numbers (T-cell depletion), activation (most immunosuppressive agents), or proliferation (antiproliferative agents). The third approach is to block inflammatory stimulation and effectors (eg, TNF-α inhibition, IL-1 receptor blockade).

The principal target organs in acute GVHD are the skin, liver, and gastrointestinal tract.[56] Acute GVHD is classified into four grades, depending on the number of organs involved and the degree of involvement of each organ (**Table 140-2**). Grade I disease involves only the skin. Grades II through IV involve the skin and the liver, gastrointestinal tract, or both. Acute skin GVHD usually is manifested as a generalized maculopapular rash that initially involves the face, ears, palms, soles, and upper trunk. The skin rash can spread to the rest of the body and, if untreated or refractory to treatment, will progress to bullae formation and desquamation similar to a burn injury. Gastrointestinal GVHD presents as a secretory diarrhea but may progress to abdominal pain or cramping and ileus; hemorrhage may also occur. GVHD of the upper intestinal tract appears as persistent nausea, vomiting, anorexia, and dyspepsia. The diagnosis of gastrointestinal GVHD should be made by biopsy of the intestinal tract (stomach, duodenum, or rectum). Hepatic GVHD usually is asymptomatic, consisting of hyperbilirubinemia and elevated alkaline phosphatase levels; increases in serum transaminases occur less consistently. The diagnosis can be made by biopsy, if possible.

TABLE 140-2 Consensus Grading of Acute Graft-versus-Host Disease

Organ/Extent of Involvement

	Skin	Liver	Intestinal Tract
Stage			
1	Rash on <25% of skin[a]	Bilirubin 2-3 mg/dL (34.2-51.3 µmol/L)[b]	Diarrhea >500 mL/day[c] or persistent nausea[d]
2	Rash on 25%-50% of skin	Bilirubin 3-6 mg/dL (51.3-102.6 µmol/L)	Diarrhea >1,000 mL/day
3	Rash on >50% of skin	Bilirubin 6-15 mg/dL (102.6-256.5 µmol/L)	Diarrhea >1,500 mL/day
4	Generalized erythroderma with bulla formation	Bilirubin >15 mg/dL (>256.5 µmol/L)	Severe abdominal pain with or without ileus
Grade			
0	None	None	None
I	Stage 1-2	None	None
II	Stage 3	or Stage 1	or Stage 1
III	—	Stage 2-3	or Stage 2-4
IV[e]	Stage 4	or Stage 4	—

[a]Use the "rule of nines" to determine body surface area involvement.

[b]Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin has been documented.

[c]Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area.

[d]Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.

[e]Grade IV may include lesser organ involvement but with extreme decrease in performance status.

The overall incidence of moderate-to-severe (grades II-IV) acute GVHD ranges from 20% to more than 80%.[57] Mortality directly attributable to acute GVHD or its treatment occurs in about 20% of patients. The incidence of GVHD is related to the degree of histocompatibility, number of T cells in the graft, donor and recipient age and gender, intensity of the conditioning regimen, source of hematopoietic cells (bone marrow vs peripheral blood), and prophylactic regimen. The most severe acute GVHD is observed in allogeneic HSCT with non-HLA-identical donors. In this setting, the incidence of grades II to IV acute GVHD can exceed 50% despite aggressive GVHD prophylaxis. Severe acute GVHD is a major cause of mortality with the risk of death increasing as the grade of GVHD increases. This risk is further increased if initial therapy is not effective.

Multiorgan acute GVHD and the drugs given to prevent or treat the disease are associated with delayed immunologic recovery and increased susceptibility to infections. Infection is often the primary cause of death in patients with GVHD. Patients with GVHD treated with an immunosuppressive regimen should receive prophylactic antiviral, antibacterial, and antifungal therapy and be monitored routinely for the occurrence of these infections.

Prevention of Acute Graft-Versus-Host Disease

9 Because treatment of established acute GVHD often is unsatisfactory, aggressive preventive measures usually are taken. The most common strategy used to prevent acute GVHD is to block the activation of T cells by administration of immunosuppressive agents.[56,57] Several immunosuppressive agents have been used, including methotrexate (MTX), cyclosporine (CSA), tacrolimus (TAC), sirolimus, mycophenolate mofetil, ATG, corticosteroids, and monoclonal antibodies directed at T cells. **Table 140-3** shows the doses, toxicities, and monitoring of immunosuppressive agents used to prevent or treat GVHD. Most GVHD prophylaxis regimens combine immunosuppressive agents that affect different stages of T-cell activation. The most commonly used GVHD prophylaxis regimens are CSA or TAC and MTX. Another strategy is removing or depleting most T cells from donor bone marrow ex vivo before transplant by physical separation or by treatment with monoclonal antibodies directed at T cells.

TABLE 140-3 Immunosuppression for the Prevention and Treatment of GVHD

Agent	Dose	Drug Monitoring
Prevention		
Tacrolimus[54]	0.02-0.03 mg/kg/day IV beginning 1-3 days before transplant; change to PO when able to tolerate	Check serum levels ~72 hours after start and then 2-3 times/wk until stable (trough serum levels, 5-15 mcg/L [6.2-18.6 nmol/L]); serum creatinine for renal toxicity, CBC for hematologic toxicity, blood pressure for hypertension, and BMP for electrolyte abnormalities
Cyclosporine[54]	3-5 mg/kg/day IV beginning 1-3 days before transplant; change to PO when able to tolerate	Check blood levels ~72 hours after start and then 2-3 times/wk until stable (trough blood levels, 150-450 mcg/L [125-374 nmol/L]); serum creatinine for renal toxicity, CBC for hematologic toxicity, blood pressure for hypertension, and BMP for electrolyte abnormalities
Sirolimus[58]	Loading dose 12 mg PO on day +1 followed by 4 mg PO daily starting on day +2	Check serum levels ~24 hours after start and then 2-3 times/wk until stable (trough serum levels, 3-12 mcg/L [3-13 nmol/L]); serum creatinine for renal toxicity and CBC for hematologic toxicity
Methotrexate[54]	15 mg/m^2 IV on day +1 followed by 10	Monitor for toxicity: mucositis, LFTs for hepatic dysfunction, serum creatinine for renal impairment, fluid retention, and CBC for hematologic toxicity;

Agent	Dose	Drug Monitoring
	mg/m^2 IV on days +3, 6, and 11 *or* 5 mg/m^2 IV on days +1, 3, 6, and 11	methotrexate levels are not routinely monitored unless the patient develops renal dysfunction or third spacing; doses may be omitted if severe mucositis or hepatotoxicity develops
Mycophenolate[60]	15 mg/kg/dose IV twice daily beginning on day 0; change to PO when able to tolerate	Monitor for toxicity: CBC for neutropenia and severe GI symptoms
Pentostatin[64]	1.5 mg/m^2 IV weekly × 4 doses beginning day +8	Monitor for toxicity: BMP for renal impairment and CBC for thrombotic thrombocytopenic purpura
Cyclophosphamide[12]	50 mg/kg/day IV on days +3 and +4	Monitor for toxicity: BMP for renal impairment, LFTs for hepatic toxicity (including SOS), urinalysis for hemorrhagic cystitis, vital signs and possible cardiac workup for pericarditis (only for symptomatic patients)
Rabbit anti-thymocyte globulin (ATG)[67]	2.5-5 mg/kg/day IV beginning 3 days before transplant	Monitor for toxicity: frequent vital signs during infusion for fever, rash, cardiovascular and GI dysfunction, anaphylaxis and serum sickness
Alemtuzumab[65]	10-20 mg/day IV daily beginning 4-5 days before transplant	Monitor for toxicity: fever, chills, infection, and anaphylaxis
Treatment		
Methylprednisolone[a] *or* Prednisone[a,57]	1-2 mg/kg/day	Monitor for toxicity: glucose for hyperglycemia, blood pressure for hypertension, labile mood, bone osteopenia, avascular bone necrosis, impaired wound healing, and adrenal insufficiency
Mycophenolate[57]	1.5-2 g PO daily in divided doses	As above
Sirolimus[57]	1-2 mg/day; then adjust based on levels	As above
Denileukin diftitox[57]	9 mcg/kg on days 1, 3, 5, 15, 17, and 19	Monitor for toxicity: LFTs for hepatic toxicity
Infliximab[57]	10 mg/kg/wk for at least 4 doses	Monitor for toxicity: anaphylaxis (rare)

Agent	Dose	Drug Monitoring
Etanercept[57]	0.4 mg/kg/dose (maximum dose, 25 mg) SC twice weekly for 8 weeks	Monitor for toxicity; generally well tolerated
Rabbit ATG[57]	0.5 mg/kg for first dose followed by 1-1.5 mg/kg for subsequent doses	As above
Pentostatin[57]	1.5 mg/m^2 IV on days 1-3 and 15-17	As above

BMP, basic metabolic panel; CBC, complete blood count; GI, gastrointestinal; LFT, liver function test; PO, orally; SC, subcutaneous; SOS, sinusoidal obstruction syndrome.

[a]Considered 1st line therapy.

Initially, acute GVHD prophylaxis was single agent MTX administered on days 1, 3, 6, and 11 after transplant and then weekly. However, when a short course of MTX was combined with CSA, the two agents showed synergy and a survival benefit. The addition of a third agent, such as prednisone, to the CSA/MTX combination failed to improve overall outcomes. TAC, another calcineurin inhibitor, was shown to have similar results to CSA when combined with a short course of MTX. The combination of a calcineurin inhibitor with MTX remains a standard immunosuppressive regimen used today. Intravenous CSA or TAC is usually started a few days before or on the day of transplant. Patients are converted to oral formulations when they can be tolerated. CSA or TAC typically are given at full doses until days 50 to 100, gradually tapered in the absence of GVHD, and discontinued by day 180. MTX is still given IV on days 1, 3, 6, and 11 after transplant. About 70% of patients are able to receive all four doses of MTX. Elimination of one or more MTX doses may be associated with an increased risk of GVHD. However, toxicities such as severe mucositis, hepatotoxicity or the development of conditions that may prolong MTX systemic exposure (eg, renal failure or third spacing) are common reasons to omit the day 11 dose of MTX. For patients who experience significant toxicity from MTX, monitoring of MTX levels with leucovorin rescue may be warranted.

Despite standard prophylaxis with CSA or TAC and MTX, grade II to IV acute GVHD still occurs in 30% to 50% in matched related donor transplants and 40% to 70% in matched unrelated donor transplants. Because of the gastrointestinal and hematologic toxicities of MTX, and in an effort to improve prevention, other prophylactic regimens have been evaluated. Sirolimus, an mTOR inhibitor, has been successfully used for the prevention of rejection in solid organ transplant patients and has theoretical advantages when used as GVHD prophylaxis. This agent has been reported to promote immune tolerance through generation of regulatory T cells, has antiviral properties (CMV and Epstein-Barr virus), and has antitumor activity against some hematologic malignancies.[58] Several studies have shown encouraging results with sirolimus when combined with a calcineurin inhibitor (TAC or CSA) in the prevention of GVHD, and many clinicians believe that the combination of TAC and sirolimus is less toxic and more efficacious than CSA and sirolimus. A phase III randomized trial was

conducted by the Blood and Marrow CTN that compared TAC and sirolimus with TAC and MTX as GVHD prophylaxis.[59] The primary endpoint, grade II to IV acute GVHD-free survival at day 114, and the incidence of grade II to IV GVHD were similar between the two groups (67% vs 62%, *P*=0.38; 26% vs 34%, *P*=0.48). Neutrophil and platelet engraftment were more rapid in the TAC and sirolimus group by two and three days, respectively. Toxicities were similar between the two groups, except that oropharyngeal mucositis was less severe in the TAC and sirolimus arm. Chronic GVHD, disease relapse and overall survival at 2 years from transplantation were not different between groups. Based on similar long-term outcomes and shorter time-to-engraftment, TAC and sirolimus can be considered as an alternative to TAC and MTX.

Other MTX-sparing strategies have been evaluated for GVHD prophylaxis. Mycophenolate mofetil through its metabolite, mycophenolic acid, inhibits proliferation of lymphocytes and is synergistic with calcineurin inhibitors. Mycophenolate mofetil with TAC was compared with TAC and MTX in recipients of matched related and unrelated donors. The results of two small randomized trials have shown less toxicity with mycophenolate mofetil with similar rates of acute GVHD or overall survival.[60,61]

Single-agent PTCy is another GVHD prophylaxis strategy which does not include a calcineurin inhibitor. Its immunosuppressive activity is related to its antiproliferative effects on rapidly dividing alloreactive T cells. Hematopoietic stem cells have high levels of aldehyde dehydrogenase, thus sparing them from the antiproliferative activity of Cy. In patients receiving MAC with single-agent Cy posttransplant prophylaxis, 43% developed grade II to IV GVHD, and 10% had grade III to IV GVHD. The incidence of chronic GVHD was 10% at 26 months.[62] The use of posttransplant Cy combined with other immunosuppressive agents such as mycophenolate mofetil and a calcineurin inhibitor has shown to be effective immunosuppression for Haplo-HSCT patients.

Other novel agents, such are bortezomib, and pentostatin have shown activity in preventing GVHD. The addition of bortezomib, given on days 1, 4, and 7 after transplant, to standard TAC and MTX in RIC mismatched unrelated donor transplants showed an incidence of grade II to IV GVHD that was comparable to patients who received HLA-matched transplants.[63] Pentostatin 1.5 mg/m^2 weekly for 4 weeks combined with a calcineurin inhibitor and MTX increased the proportion of patients alive without GVHD at day 100 compared with control participants.[64] Although the addition of these novel agents is intriguing, the role of these agents in GVHD prophylaxis is not clear. The Blood and Marrow CTN is conducting a phase II trial evaluating the activity of several novel three-drug GVHD prophylaxis regimens: bortezomib or maraviroc added to TAC and MTX; and PTCy added to TAC and mycophenolate mofetil (BMT-CTN 1203, NCT02208037).

Another strategy to reduce the risk of acute GVHD is to reduce the number of donor T cells in the stem cell donation. In vivo T-cell depletion may be incorporated into conditioning regimens with agents such as ATG or alemtuzumab.[65] Uncontrolled trials of ATG with MAC regimens suggested that ATG could prevent GVHD, but may increase the risk of relapse and graft failure. A Cochrane review of six trials reported that ATG given with MAC regimens did decrease the risk of grade II to IV acute GVHD, but did not significantly improve overall survival, disease relapse or nonrelapse mortality.[66] The role of ATG with RIC transplantation has not been evaluated in a randomized controlled trial. The

CIBMTR has reported that ATG recipients were more likely to have disease relapse, shorter overall and disease-free survival.[67] However, another observational study of European patients receiving RIC regimens reported reduced incidences of acute and chronic GVHD with similar relapse risk, nonrelapse mortality and survival.[68] Results from that study also suggested a dose effect with ATG doses of less than 6 mg/kg associated with improved outcomes. Based on these conflicting data, the use of ATG in RIC transplants should be reserved for clinical trials.

The role of ex vivo T-cell depletion is controversial.[56] Earlier reports of this technique were associated with an increased risk of graft failure, delayed immune reconstitution, leukemic relapse, CMV reactivation, and Epstein-Barr virus–related lymphoproliferative disorders. Most of these studies occurred when bone marrow was the preferred stem cell source. In a comparative analysis of patients who received ex vivo T-cell depletion or the standard calcineurin inhibitor and MTX prophylaxis, T cell–depleted stem cells had lower rates of chronic GVHD. No differences in rates of graft rejection, leukemia relapse, treatment-related mortality, or overall survival rates were reported.[69]

It is difficult to predict which patients will develop acute GVHD. Risk factors are unable to accurately identify patients who will go onto develop GVHD. Biomarkers that could predict the development of GVHD could direct treatment before the patient develops severe disease. An ideal biomarker would be predictive of both disease onset and prognosis, inexpensive, and readily available in order to facilitate real-time clinical decision making. Many biomarkers have been studied including IL-2 receptor alpha, IL-8, peptidase inhibitor-3, regenerating islet-derived 3α (REG 3α), hepatocyte growth factor, serum albumin and microRNAs.[70] Although several biomarkers appear promising, they should not be used outside of a clinical trial.

Treatment of Acute Graft-Versus-Host Disease

10 Patients with mild skin-only acute GVHD (grade I) can be treated with topical corticosteroid preparations and counseled on the appropriate use of sunscreen. If a patient develops grades II to IV GVHD, prophylactic agents are continued, and high-dose corticosteroids in the form of IV methylprednisolone or oral prednisone are given.[56] The usual dosage is 1 to 2 mg/kg/day given in two divided doses; higher dosages have not been shown to be more efficacious. About 25% to 40% of patients with established acute GVHD respond to high-dose corticosteroids. If the patient responds, the corticosteroid dose is tapered gradually over several weeks to months, depending on response. In patients who experience a flare in GVHD during the taper phase, therapy consists of increasing the corticosteroid dose and then tapering more slowly. Oral beclomethasone dipropionate, a topically active corticosteroid, has been shown to reduce the frequency of gastrointestinal GVHD relapses when continued after prednisone taper.[71] Administration of beclomethasone has been associated with a better survival at 200 days and 1 year after transplant. Budesonide, another nonabsorbable corticosteroid, has also been evaluated in uncontrolled studies and may also reduce the need for sustained use of high-dose systemic corticosteroid administration.[71]

GVHD-associated mortality is strongly correlated to response to initial treatment and ranges from

about 25% in patients who had a complete response to about 80% in patients who had no response or progressive disease. Several randomized trials have evaluated other agents combined with methylprednisolone in an effort to improve response to initial therapy for acute GVHD.[56] In a randomized phase II trial, 180 patients were treated with methylprednisolone 2 mg/kg/day combined with etanercept, mycophenolate mofetil, denileukin diftitox, or pentostatin.[72] After 28 days of treatment, efficacy and toxicity data suggested that the use of mycophenolate mofetil plus corticosteroids was the most promising regimen to compare with corticosteroids alone in a definitive phase III trial. This trial was halted early when a futility rule was met at a planned interim analysis. GVHD-free survival 56 days after randomization was not different between the groups. Based on the current published data, the use of glucocorticoid treatment with an additional agent for initial therapy of acute GVHD should only be done within the confines of a clinical trial.[57]

The mortality rate of patients with steroid-refractory GVHD is high. Criteria and indications for initiating secondary therapy for steroid-refractory acute GVHD have not been well defined in the literature. Although different centers may have varying criteria, in general, if the manifestations of acute GVHD in any organ worsen over 3 days of corticosteroid treatment or symptoms do not improve by 5 days, the patient likely will not respond to corticosteroids, and secondary therapy should be considered.[57] There is no standard treatment of patients with steroid-refractory acute GVHD because very few prospective comparative studies have been conducted to assess the efficacy of individual agents. Second-line therapy has consisted of continuation of corticosteroids with the addition of one or more of the following: ATG, mycophenolate mofetil, sirolimus, infliximab, etanercept, denileukin diftitox, alemtuzumab, or pentostatin.[57,73] One approach that has shown benefit as corticosteroid-sparing therapy is extracorporeal photopheresis. During this procedure, the patient's blood is exposed extracorporeally to 8-methoxypsoralen followed by ultraviolet A radiation and then returned to the patient. This process is thought to result in suppression of T-cell reactivity and induction of regulatory T cells. Clinical results have been positive, especially in patients with skin GVHD.[74] The choice of a second-line regimen for acute GVHD should be based on the risk of potential toxicities, interactions with other agents, convenience, and cost.

Clinical Controversy…

Optimal treatment of steroid-refractory GVHD is unclear. Comparative trials are needed to determine a standard approach to this difficult clinical condition.

Chronic Graft-Versus-Host Disease

Chronic GVHD is the major determinant of late transplant-related morbidity and mortality. The pathophysiology of chronic GVHD is poorly understood and likely involves inflammation, cell mediated immunity as well as humoral immunity and fibrosis.[75] The presentation of chronic GVHD is diverse and resembles a variety of autoimmune disorders. The incidence of chronic GVHD is 30% to 70%, and while its clinical manifestations usually present during the first year, it can also develop many years after transplant. Both HLA mismatching and transplantation from unrelated donor transplants help explain the growing incidence of chronic GVHD. The diagnosis of chronic GVHD is often based on clinical presentation, but biopsies of affected organs can help differentiate acute from

chronic GVHD. More recently, the use of biomarkers has been studied in order to facilitate diagnosis and predict treatment response.[75] The risk of chronic GVHD increases with a previous history of acute GVHD, increasing donor and recipient age, patients who receive transplants from HLA-nonidentical donors and in patients who receive PBSC transplants (especially with higher $CD34^+$ cell doses). Unlike acute GVHD, prophylactic immunosuppression does not appear to reduce the incidence or severity of chronic GVHD.

Chronic GVHD resembles autoimmune diseases and can affect any organ or tissue of the body. The most common sites involved are the skin, mouth, liver, and eye, but other sites include the gastrointestinal tract, joints, muscles, and lungs. The National Institutes of Health (NIH) Consensus Development Project developed standardized criteria for the diagnosis of chronic GVHD and proposed a clinical scoring system for the evaluation of patients with chronic GVHD based on the extent of organ damage and degree of functional impairment.[75] The Working Group recommends that the diagnosis of chronic GVHD be made with the presence of at least one diagnostic clinical sign of chronic GVHD (eg, poikiloderma or esophageal web) or a distinctive manifestation (eg, keratoconjunctivitis sicca) confirmed by biopsy or other test (eg, Schirmer test). For patients with overlap syndrome, the NIH Working Group now recommends documenting all specific manifestations (acute and chronic) when establishing a diagnosis.

The clinical scoring system categorizes chronic GVHD into mild, moderate, and severe.[75] Mild chronic GVHD involves only one or two organs or sites (except the lung) with no clinically significant functional impairment. Moderate chronic GVHD involves at least one organ or site with clinically significant but no major disability, three or more organs or sites with no clinically significant functional impairment, or mild lung involvement. Severe chronic GVHD indicates major disability caused by chronic GVHD or at least moderate lung involvement.

Patients with mild skin-only chronic GVHD can be treated with a variety of topical preparations, such as clobetasol, TAC, and pimecrolimus.[76] Other organs such as mouth, eyes and genital tract may also be treated with aggressive local therapy. Initial treatment of patients with more severe or systemic involvement of chronic GVHD consists of prednisone 0.5 to 1 mg/kg/day followed by taper with or without a calcineurin inhibitor. Although calcineurin inhibitors do not conclusively improve outcomes, they are often used to reduce toxicities of prolonged steroid therapy, especially in patients who may be at high risk for prednisone-related complications.[77] Treatment is continued until signs and symptoms of the disease have resolved and then are tapered gradually over an extended period of time. Patients with chronic GVHD may require prolonged immunosuppressive treatment for an average of 2 to 3 years from the initial diagnosis.

In addition to treatment specifically for chronic GVHD, ancillary therapies and supportive care should be recommended to lessen the symptoms of chronic GVHD.[77] Patients should be educated on the use of sunscreens (and avoidance of sun exposure) to reduce skin injury and exacerbation of GVHD skin lesions. Nonsclerotic skin lesions without erosions or ulcerations may respond well to emollients in addition to topical corticosteroids. Patients should be advised to maintain good oral hygiene with routine dental care. Saliva substitutes can be given for dry mouth symptoms, and topical corticosteroid gels can be used for localized and symptomatic oral lesions. Artificial tears or, if

necessary for more severe symptoms, CSA or corticosteroid eye drops are useful for patients with chronic GVHD manifesting as dry eyes or conjunctivitis. Physical therapy is recommended to reduce functional loss as a result of steroid myopathy, joint contractures, and deconditioning.

Patients who do not respond to initial therapy have a very poor prognosis. Indications for secondary treatment include worsening symptoms, involvement of new organs, no improvement of symptoms after 1 month of therapy, inability to decrease steroid dose or significant treatment-related toxicity. Uncontrolled trials have investigated several therapies with varying degrees of success. To date, no consensus has been reached regarding the optimal choice for salvage therapy. When choosing initial salvage therapy, clinicians should consider agents with documented activity and an adequate safety profile as well as agents that are steroid sparing. Agents with reported activity in refractory chronic GVHD include thalidomide, extracorporeal photophoresis, TAC, sirolimus, pentostatin, mycophenolate mofetil, hydroxychloroquine, rituximab, imatinib, and others.[77,78]

Monitoring for long-term drug toxicities and infectious complications is critical during long-term immunosuppression. Infection is the primary cause of death in patients with chronic GVHD, and antimicrobial prophylaxis is an important component of the care of patients being treated for chronic GVHD.[77,78] Patients should receive oral trimethoprim–sulfamethoxazole, penicillin, an antifungal azole agent, and acyclovir to prevent infections commonly seen in immunocompromised patients. Routine monitoring for CMV reactivation should be performed. Some HSCT centers also administer IV immunoglobulin to patients with low serum immunoglobulin G levels. Patients who remain on long-term steroids should be monitored for steroid-induced osteoporosis and diabetes mellitus. Other potential long-term complications of chronic GVHD therapies include hyperlipidemia, cataracts, myelosuppression, elevated blood pressure, and renal dysfunction.

Infection

Patients undergoing high-dose chemotherapy with autologous or allogeneic HSCT are severely immunocompromised and therefore are at high risk for bacterial, fungal, and viral infections.[29,32] Management of these infections is discussed in detail in Chapters 121 and 122.

Late Complications

With the success of HSCT, the number of long-term survivors has grown. Many survivors experience delayed complications of transplantation and treatments used to prevent or treat those complications, including restrictive and obstructive pulmonary disease, bone and joint disease (including osteoporosis and avascular necrosis), cataract formation, endocrine dysfunction (including sterility and thyroid dysfunction), impaired growth and development, infections, cardiovascular disease, chronic renal and hepatic dysfunction, and secondary malignancies.[29,32,79] These effects are more frequent after allogeneic compared with autologous HSCT and among allogeneic HSCT patients, those with chronic GVHD tend to have a higher prevalence of multiple health conditions than those without chronic GVHD.[29,79] Physical recovery tends to occur earlier than psychological or work recovery. Full recovery usually takes several years, and about two-thirds of patients are without major limitations by 5 years. Both allogeneic and autologous transplants are associated with a

several-fold increase in risk of premature death; relative mortality decreased with time but remained significantly elevated even 10 years after transplant. The leading cause of death is relapse of primary disease in both allogeneic and autologous HSCT patients, but allogeneic HSCT patients also continue to die from complications of chronic GVHD, while autologous HSCT patients more frequently succumbed to secondary malignancies.[29,79] Long-term monitoring of HSCT patients is required, both by transplant clinicians and primary care providers who are knowledgeable in the care of these patients, to screen for, prevent and treat late complications when such interventions are available. In 2012, the CIBMTR (in partnership with leading transplant organizations) published posttransplant care recommendations for adult and pediatric autologous and allogeneic HSCT recipients (www.cibmtr.org/posttransplant).

Chapter 141: Assessment of Nutrition Status and Nutrition Requirements

FIGURE 141-1

Katherine Hammond Chessman; Vanessa J. Kumpf

INTRODUCTION

KEY CONCEPTS

- 1 Malnutrition encompasses both overnutrition (obesity) and undernutrition.
- 2 Nutrition screening is distinct from assessment; it should be designed to quickly and consistently identify those with preexisting malnutrition or those at risk for malnutrition.
- 3 A comprehensive nutrition assessment is required to formulate a nutrition care plan for an individual found to be nutritionally-at-risk for nutrition-related poor outcomes.
- 4 A nutrition-focused physical examination and medical, surgical, and dietary history are essential components of a comprehensive nutrition assessment.
- 5 Evaluation of anthropometric measurements (weight, height, and head circumference) should be based on published standards.
- 6 Laboratory assessment of visceral proteins and other nutrition-related parameters must be interpreted in the context of physical findings, medical and surgical history, including acute and chronic inflammation, and clinical status.
- 7 Micronutrient or macronutrient deficiencies or toxicities or risk factors for these deficiencies or toxicities can be identified by a comprehensive nutrition assessment.
- 8 Evidence-based patient-specific goals should be established considering the patient's

clinical condition and the need for maintenance or repletion in adults or continued growth and development in children.

- 9 Validated predictive equations are most often used to determine energy requirements; however, if available, indirect calorimetry is the most accurate bedside method to determine energy requirements.

- 10 Drug–nutrient interactions can affect nutrition status and the response to and adverse effects seen with drug therapy.

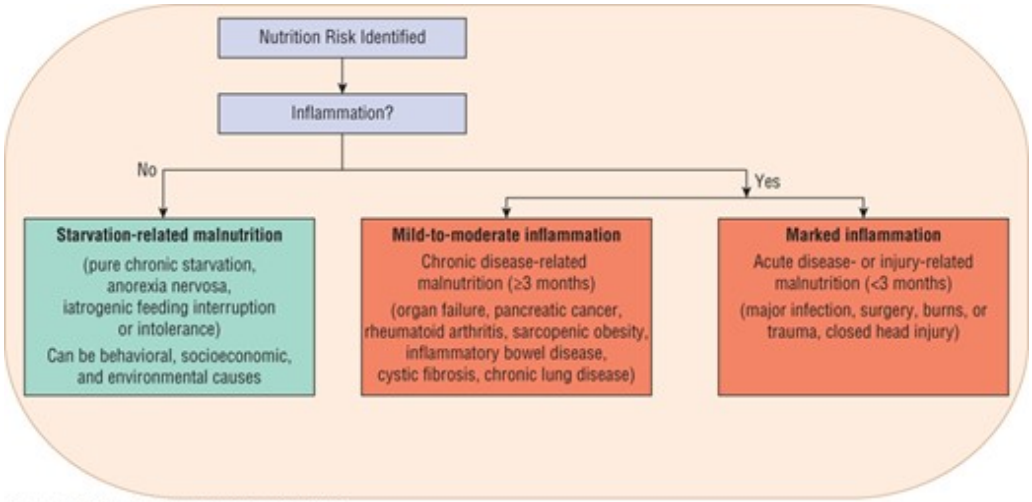
Nutrition care is a vital component of quality patient care and nutrition screening and assessment are integral parts of the nutrition care process. No single clinical or laboratory parameter is an absolute indicator of nutrition status, so information from a number of them must be collected and analyzed. This chapter reviews the tools most commonly used for accurate, relevant, and cost-effective nutrition screening and assessment, including various methods used to determine patient-specific macro- and micronutrient requirements and potential drug–nutrient interactions.

CLASSIFICATION OF NUTRITION DISEASE

1 Malnutrition is a consequence of nutrient imbalance. In general, deficiency states can be categorized as those involving protein and calories or single nutrients such as individual vitamins or trace elements. Starvation-associated malnutrition, marasmus, results from prolonged inadequate intake, absorption, or utilization of protein and energy. It occurs in patients with an inadequate food supply, anorexia nervosa, major depression, and malabsorption syndromes (**Fig. 141-1**). Somatic protein (skeletal muscle) and adipose tissue (subcutaneous fat) wasting occurs, but visceral protein (albumin [ALB] and transferrin [TFN]) production is usually preserved. Weight loss may exceed 10% of usual body weight (UBW; typical weight). Patients with starvation-associated malnutrition commonly have a prototypical wasted appearance.[1,2] Kwashiorkor, a form of starvation-associated malnutrition develops as a consequence of inadequate protein intake and is usually seen in areas where there is famine or limited food supply. In the United States, kwashiorkor has been seen in children and elderly individuals who are abused or neglected. Patients with kwashiorkor may not appear malnourished because of relative adipose tissue sparing, especially with mild undernutrition, but visceral (and to some degree somatic) protein stores are depleted, resulting in severe hypoalbuminemia and edema in more advanced cases. In patients with starvation-related malnutrition, enhancing nutritional intake or bypassing impaired absorption with specialized nutrition support can reverse the condition.[1,2]

FIGURE 141-1

Etiologic basis for malnutrition diagnosis. (*Adapted from references 4 and 35.*)



Malnutrition can also develop as the result of an acute or chronic disease, especially those associated with mild-to-severe inflammation (see Fig. 141-1).[3,4] Patients with severe acute disease or injury (major infections, burns, trauma, and traumatic brain injury) or with chronic inflammatory diseases, organ failure, or cancer can develop disease-related malnutrition because of increased metabolic demands despite seemingly adequate nutrition intake. Individuals with starvation-related malnutrition can develop marked malnutrition when a severe injury or inflammatory process occurs simultaneously. In patients with disease-related, acute or chronic, malnutrition, simply providing nutrients in usual or even increased amounts may not be sufficient to reverse the nutrient imbalance. Regardless of the cause, undernutrition can result in changes in subcellular, cellular, or organ function that increase the individual's risks of morbidity and mortality.

Nutrition assessment can also be used to identify overnutrition: overweight and obese individuals and those at risk of becoming overweight or obese. Obesity is a major global healthcare concern: during 2011 to 2014, approximately 69% of U.S. adults were overweight (defined as a body mass index [BMI] greater than or equal to 25 kg/m^2)[5], and about 36.5% (82 million) were obese (BMI greater than or equal to 30 kg/m^2).[6] Obesity prevalence in 2014 ranged from 21% in Colorado to about 36% in West Virginia, Arkansas, and Mississippi.[7] Additionally, 17% (12.7 million) of all U.S. children and adolescents (age 2-19 years) were obese (BMI greater than or equal to 95th percentile for age on the gender-appropriate BMI-for-age Centers for Disease Control and Prevention's [CDC] 2000 growth chart).[5,6,8] Many more children (approximately 32%) were overweight (BMI greater than or equal to 85th percentile for age).[5] Interestingly, there was no change in obesity prevalence among U.S. adults or children from 2011 to 2014 compared with 2003 to 2004.[6] After a steady increase in obesity prevalence since 1999, this leveling trend is encouraging. The consequences of obesity are numerous and include type 2 diabetes mellitus, cardiovascular disease, hypertension, and stroke (see Chapter 144).

Malnutrition is associated with higher morbidity and mortality rates in many settings. An effective nutrition screening program will consistently identify patients at nutrition-related risk alerting trained clinicians to perform a comprehensive nutrition assessment to accurately characterize baseline nutrition status, estimate nutrition needs, and develop a patient-specific nutrition care plan. Diligent

monitoring of ongoing nutrition status can ensure that nutrition-related goals are being met and improve patient outcomes.

NUTRITION SCREENING

Nutrition screening is distinct from nutrition assessment.[9] It is not practical, cost-effective, or clinically warranted to conduct a comprehensive nutrition assessment on every individual; thus, nutrition screening provides a reliable, systematic method to identify persons for whom a detailed nutrition assessment is needed. A nutrition screen can be used to detect those who are overweight, obese, malnourished, or at risk for malnutrition; predict their health outcomes as a result of nutrition-related factors; and identify those who would benefit from nutritional intervention.

The ideal nutrition screening tool is quick, simple, and noninvasive and can be done by lay and healthcare providers in homes, long-term care facilities, ambulatory care clinics, and hospitals. Since 1995, the Joint Commission has included nutrition screening and assessment in its performance standards for accredited healthcare institutions.[10] Each entity must have a written nutrition screening process and criteria that determine when a more in-depth assessment will be performed. In hospitals, a nutrition screen must be completed within 24 hours of admission on all patients unless the institution's policy excludes certain patient populations. In hospitals, most screens are done by nurses.[11] For patients who are determined to be '*nutritionally-at-risk*' by the screening criteria, a comprehensive nutrition assessment must be completed within 48 to 72 hours. Periodic rescreening should occur at regular intervals determined by the institution and the patient population, usually every 3 to 7 days. Most nutrition assessments are completed by dietitians but may be completed by others including pharmacists with training in nutrition support.[11] For outpatients, nutrition screening should occur ideally at the first visit with a new provider and thereafter as warranted by the patient's condition.

Risk factor identification is the foundation of appropriate nutrition screening. Risk factors for undernutrition include recent unintended weight loss, presence and severity of acute and chronic disease states, drug and or other treatments, and socioeconomic factors that may result in a decreased nutrient intake or altered nutrient absorption, metabolism, or utilization. Risk factors for obesity include a family history of obesity, certain medical diagnoses (eg, polycystic ovary syndrome, Prader-Willi syndrome, and Cushing's syndrome), poor dietary habits, inadequate exercise, and some drug therapies. Various rating and classification systems have been proposed to screen for nutrition risk and guide subsequent interventions.[2,9,12,13,14,15,16,17] The Malnutrition Screening Tool (MST)[16] and the Subjective Global Assessment (SGA) are among the most frequently utilized.[17,18] In general, checklists of varying complexity are used to quantify a person's food and alcohol consumption habits; ability to buy, prepare, and eat food; weight history; diagnoses; medical and surgical procedures; drug therapies; and, history of specialized nutrition support (enteral or parenteral nutrition). Nutrition screening for children is based on the evaluation of growth parameters against the CDC or World Health Organization (WHO) growth charts[8,19] and the presence of medical conditions known to increase nutrition risk. Current estimates of the prevalence of in-hospital malnutrition for pediatric and adult patients, range from 13% to 88% depending on the patient population, disease severity,

and the criteria used to identify its occurrence.[11] In any setting, patients determined to be nutritionally-at-risk should receive a timely comprehensive nutrition assessment to verify nutrition-related risk and to formulate a nutrition care plan with monitoring parameters to ensure that desired outcomes are met.

ASSESSMENT OF NUTRITION STATUS

3 A comprehensive nutrition assessment is the first step in formulating a patient-specific nutrition care plan. Goals of nutrition assessment include identification of the risk factors associated with malnutrition, including disorders resulting from macro- or micronutrient deficiencies (undernutrition), obesity (overnutrition), or impaired nutrient absorption, metabolism or utilization; determination of the risk of nutrition-related complications; estimation of nutrition needs; and establishment of baseline nutrition parameters against which to measure nutrition therapy outcomes. Nutrition assessment should include a nutrition-focused medical, surgical, and dietary history; a nutrition-focused physical examination, including anthropometrics; and laboratory measurements.

Nutrition-Focused History and Physical Examination

4 The nutrition-focused medical, surgical, and dietary history serves to identify factors that predispose to malnutrition (eg, prematurity, chronic diseases, gastrointestinal [GI] dysfunction, alcohol abuse, and acute or chronic inflammation [cancer, surgery, and trauma]), and overnutrition (eg, poor dietary habits, limited exercise, chronic disease, and family history). The clinician should determine any history of weight gain or loss (intended or unintended), anorexia, vomiting, diarrhea, decreased or restrictive food intake, including enteral or parenteral nutrition (**Table 141-1**).

TABLE 141-1 Pertinent Data from a Nutrition-Focused Medical, Surgical, and Dietary History

Nutrition intake and dietary habits
Anorexia
Unusual or absent taste
Dietary intake, including vegetarianism
Specialized diets, including enteral or parenteral nutrition
Supplemental vitamin, mineral, or herbal intake
Food allergies or intolerance
Underlying pathology with nutritional effects
Chronic infections or inflammatory states
Neoplastic diseases

Endocrine disorders

Chronic illness, including pulmonary disease, liver cirrhosis, and kidney failure

Hypermetabolic states, such as trauma, burns, and sepsis

Digestive or absorptive disease, nausea, vomiting, diarrhea, and constipation

Hyperlipidemia

End-organ effects

Weight changes

Skin or hair changes

Exercise intolerance or fatigue

Gastrointestinal tract symptoms such as diarrhea, vomiting, and constipation

Gastrointestinal surgery

Bariatric surgery

Small bowel or colon resection or diversion

Gastrectomy

Miscellaneous

Catabolic medications or therapies, including corticosteroids, immunosuppressive agents, radiation, or chemotherapy

Other medications, including diuretics, laxatives, antipsychotics, or anabolic steroids

Genetic background, including body habitus of parents, siblings, and family

Alcohol or drug abuse

Data from references 1, 2, 9, 12, and 15,16,17,18.

4 The nutrition-focused physical examination should assess each body system for physical findings associated with nutrition-related problems, such as muscle wasting, edema, or loss of subcutaneous fat.[20,21] The presence of findings commonly associated with malnutrition such as alopecia, dermatitis, glossitis, cheilosis, or jaundice should be noted (**Table 141-2**). Additionally, nonspecific indicators of ongoing inflammation or stress (eg, fever and tachycardia) should be documented (**Table 141-3**).

TABLE 141-2 Physical Examination Findings Suggestive of Malnutrition

General

Edema (especially ankle and sacral)

Cachexia or obesity

Ascites

Signs and symptoms of dehydration, including poor skin turgor, sunken eyes, orthostasis, or dry mucous membranes

Muscle wasting or loss of subcutaneous fat

Fever

Tachycardia

Alopecia/dry brittle hair

Skin and mucous membranes

Thin, shiny, dry, or scaly skin

Decubitus ulcers

Ecchymoses or perifollicular petechiae

Poor healing of surgical or traumatic wounds

Pallor or redness of gums or fissures at mouth edge

Glossitis, stomatitis, or cheilosis

Musculoskeletal

Retarded growth or short stature

Bone pain or tenderness or epiphyseal swelling

Muscle mass less than expected for habitus, exercise level

Neurologic

Ataxia, positive Romberg test result,[a] or decreased vibratory or position sense

TABLE 141-3 Assessment of Inflammation

Laboratory Assessment	Clinical Findings	Acute/Chronic Disease States
Decreased		
Albumin	Fever	
		Cancer
Transferrin	Hypothermia	
		Celiac disease
Prealbumin	Infection	
		Cystic fibrosis
Nitrogen balance	Urinary tract	
		Inflammatory bowel disease
Elevated	Pneumonia	
		Organ failure
CRP	Bacteremia	
		Pancreatitis
Glucose	Wound/incision	
		Rheumatologic disorders
% neutrophils	Abscess	
		Rheumatoid arthritis
Decreased or increased	Trauma	
		Systemic lupus erythematosus
WBC	Burns	
Platelets		

CRP, C-reactive protein; WBC, white blood cell count.

Data from reference 4.

The SGA is a representative example of a relatively simple, reproducible, cost-effective, bedside approach to nutrition assessment.[17,18] This screening tool assesses five aspects of the medical and dietary history: weight change in the previous 6 months, dietary changes, GI symptoms, functional capacity of the patient, and disease states known to affect nutrition status. Weight loss of less than 5% of UBW is considered a "small" loss, 5% to 10% loss is "potentially significant," and more than a 10% loss is "definitely significant." Dietary intake is characterized as normal or abnormal, and the duration and degree of abnormal intake are noted. The presence of daily GI symptoms (anorexia, nausea, vomiting, and diarrhea) for longer than 2 weeks is significant. Functional capacity assesses

the patient's energy level and whether the patient is active or bedridden. Finally, disease state impact on metabolic demands (no, low, moderate, or high stress) is documented. Four physical examination findings are rated as normal, mild, moderate, or severe: loss of subcutaneous fat (triceps and chest), muscle wasting (quadriceps and deltoids), edema (ankle and sacral), and ascites. The patient's nutrition status is then rated as adequately nourished, moderately malnourished or suspected of being malnourished, or severely malnourished. Critics of the SGA find it time-consuming and complex.[2] Another example of a simple screening tool, the Mini Nutritional Assessment, has been used extensively in geriatric patients and found to be useful in several care settings.[2,22]

Anthropometric Measurements

5 Anthropometric measurements, which are physical measurements of the size, weight, and proportions of the human body, are important parameters used to assess nutrition status. Common measurements are weight, stature (standing height or recumbent length), head circumference (for children younger than 3 years of age), and waist circumference. Measurements of limb size, such as skinfold thickness, midarm muscle circumference, and wrist circumference, may be useful in selected individuals. Bioelectrical impedance analysis (BIA) is also an anthropometric assessment tool. An individual's body measurements can be compared with normative population standards to identify clinical concerns and may be repeated at various intervals to monitor response to a nutrition care plan. In adults, nutrition-related changes in anthropometric measurements tend to occur slowly; several weeks or more may be required before detectable changes are noted. In infants and young children, changes occur more quickly. Significant acute changes in weight and skinfold thickness usually reflect changes in hydration, which must be considered when interpreting these parameters.

Weight, Stature, and Head Circumference

Body weight is a nonspecific measure of body cell mass, representing skeletal mass, body fat, and the energy-using component lean body mass (LBM). Fat-free mass includes skeletal muscle, bone, connective tissue, organs, and water while fat mass includes the subcutaneous fat beneath the skin and the visceral (internal) fat. Change in weight over time, particularly in the absence of edema, ascites, or voluntary losses, is an important indicator of altered LBM. Actual body weight (ABW) interpretation should include consideration of ideal weight-for-height, referred to as ideal body weight (IBW), UBW (typical weight), fluid status, and age (**Table 141-4**). Patients who are dehydrated will have a decreased ABW but not a loss of LBM. Once rehydrated, these patients must be reweighed to establish a baseline weight for nutrition evaluation. Edema and ascites increase total body water (TBW), thus increasing ABW but not LBM. Because the ABW of patients with severe edema and ascites should not be used for nutrition assessment; practitioners often use an estimated "*dry weight*" to account for this increase in TBW. Both acute and chronic changes in fluid status can affect the ABW; these changes often can be detected by monitoring the patient's daily fluid intake and output. Accurate weight measurement can be difficult in critically ill patients because of their clinical condition and stress-related water retention.

TABLE 141-4 Evaluation of Body Weight and Waist Circumference

Parameter	Interpretation	NHLBI Obesity	Waist Circumference

Classification

ABW compared with IBW	
ABW <69% IBW	Severe malnutrition
ABW 70%-79% IBW	Moderate malnutrition
ABW 80%-89% IBW	Mild malnutrition
ABW 90%-120% IBW	Normal
ABW >120% IBW	Overweight
ABW ≥150% IBW	Obese
ABW ≥200% IBW	Morbidly obese
ABW compared with UBW	
ABW 85%-95% UBW	Mild malnutrition
ABW 75%-84% UBW	Moderate malnutrition
ABW <75% UBW	Severe malnutrition

BMI (kg/m^2)				
Adults				
<16	Severe malnutrition			
16-16.9	Moderate malnutrition			
17-18.9	Mild malnutrition			
19-24.9	Healthy		Disease risk above BMI-related risk[a]—Waist Circumference	
Older Adults			Women ≤89 cm (35 in) Men ≤102 cm (40 in)	Women >89 cm (35 in) Men >102 cm (40 in)
22-30	Healthy			
25-29.9	Overweight		Increased	High
30-40	Moderate obesity			
30-34.9		I	High	Very high
35-39.9		II	Very high	Very high

>40	Severe or morbid obesity	III	Extremely high	Extremely high
Children				
BMI for age <5th percentile	Underweight			
BMI for age 5th-84th percentile	Healthy			
BMI for age 85th-94th percentile	Overweight			
BMI for age ≥95th percentile	Obese			

[a]Increased risk for Type 2 diabetes mellitus, hypertension, and cardiovascular disease.

ABW, actual body weight; BMI, body mass index; IBW, ideal body weight; NHLBI, National Heart, Lung, and Blood Institute; UBW, usual body weight.

Data from references 8, 13, 36, and 38,39,40,41.

The IBW is a population reference standard against which the ABW can be compared. IBW-for-height reference tables are available, and IBW can be calculated using mathematical equations based on gender and height. Using the Hamwi method, IBW is calculated as (48 kg [106 lb] + 2.7 kg [6 lb] × [inches over 5 feet]) for adult men and for adult women as (45 kg [100 lb] + 2.3 [5 lb] × [inches over 5 feet]).[23] Using the Devine equations, IBW is calculated as 50 kg + (2.3 × inches over 60 feet) for adult men and 45.5 kg + (2.3 × inches over 6 feet) for adult women.[24] For both equations, a range of ± 4.5 kg for large or small frame size is used for interpretation purposes. For obese adults, use of an adjusted ABW has been recommended for nutrition-related calculations, where adjusted ABW = ([ABW – IBW] × 0.25-0.5) + IBW.[25,26,27] The use of this adjusted ABW is not evidence-based because most of the metabolic rate equations were formulated using ABW in a mix of obese and non-obese individuals.[25,27,28] The IBW of a child can be calculated as ([height in cm]^2 × 1.65)/1,000. Alternatively, IBW-for-height can be determined by identifying the body weight corresponding to the same growth channel as the child's measured stature on the appropriate CDC or WHO growth chart. Comparison with the 50th percentile weight-for-age has been suggested but can be misleading if the child's height is not also at the 50th percentile.

Change in weight over time can be calculated as a percentage of UBW (see Table 141-4). Use of UBW as a reference point may provide a more accurate reflection of clinically significant weight changes over time. However, unless documented in the medical record, determining UBW depends on patient or family recall, which may be inaccurate. The use of UBW avoids the inherent problems with normative tables and documents comparative changes in body weight. All weight changes should be interpreted relative to time. Unintentional weight loss, especially rapid weight loss (5% of UBW in 1

month or 10% of UBW in 6 months), increases the risk of nutrition-related poor clinical outcomes.[13,14]

Adult stature is determined by both genetics and nutrition. In infants, recumbent length is measured; in older children and adults, a standing height is preferred. If a standing height cannot be measured, the measurement of demispan can be used to estimate height. Demispan is determined in a seated patient by measuring the distance from the sternal notch to the web between the middle and ring fingers along a horizontally outstretched arm with the wrist in neutral rotation and zero extension or flexion. Demispan may more accurately assess stature in elderly adults, especially those with kyphosis or vertebral collapse. After the demispan is measured, height is estimated using the following equations: women: height (cm) = (1.35 × demispan [cm]) + 60.1; men: height (cm) = (1.4 × demispan [cm]) + 57.8.[29] Knee height may also be used to estimate stature and is especially helpful in patients with limb contractures, such as patients with cerebral palsy.[29,30,31] Knee height is measured from just under the heel to the anterior surface of the thigh just proximal to the patella. Using the average of two measurements rounded to the nearest 0.1 cm, height can be estimated using the following equations: women: height (cm) = 84.88 (0.24 × age [years]) + (1.83 × knee height [cm]); men: height (cm) = 64.19 (0.04 × age [years]) + (2.02 × knee height [cm]).[31]

Appropriate growth is the best indicator of adequate nutrition in a child. At each medical encounter, weight, stature, head circumference (until 3 years), and BMI (after 2 years) should be plotted on the WHO (younger than 2 years) or CDC gender- and age-specific growth curves.[8,19] The CDC charts were revised in 2000 from U.S. data only and indicate how U.S. children grow. The WHO charts developed in 2006 are preferred in those younger than 2 years because they include data from infants from six industrialized countries including the United States who were predominantly breastfed for the first 4 months of life and who were receiving some breast milk at 12 months, conditions felt to ensure optimal growth.[19] Specialized charts are also available for assessment of short- and long-term growth of premature infants.[32,33] For premature infants with corrected postnatal age of 40 weeks or more, the WHO growth charts can be used; however, weight-for-age, length-for-age, and head circumference-for-age should be plotted according to corrected postnatal age until 2 years, 3.5 years, and 3 years of age, respectively.

Recommended intervals between measurements in young children are weight, 7 days; length, 4 weeks; height, 8 weeks; and head circumference, 7 days in infants and 4 weeks in children until 3 years of age. Growth velocity can be used to assess growth at intervals too close to plot accurately on a growth chart (**Table 141-5**). In newborns, average weight gain is 10 to 20 g/kg/day (24-35 g/day in term infants; 10-25 g/day in preterm infants). The rate of weight gain declines considerably after 3 months of age; children 6 to 10 years of age gain about 2 to 3 kg/yr. The adolescent 'growth spurt' typically begins at 9 to 10 years in girls and 11 to 12 years in boys. During the 11 to 13 year-old-interval of maximum growth in height, girls will gain about 10 kg (22 lb) while boys gain 15.5 kg (33 lb). Length increases rapidly in infancy (see Table 141-5). In children 6 to 10 years of age, height increases by 2 to 3 in/yr (approximately 5-7.5 cm/yr) and continues until about 16 to 18 years of age in girls and 18 to 20 years of age in boys. Head growth (measured by head circumference), usually 0.5 cm/wk (0.2 in/wk) during the first year of life, can be compromised during periods of critical illness or malnutrition. Rapid head growth, especially at a rate faster than expected, suggests hydrocephalus

and should be further evaluated.

TABLE 141-5 Expected Growth Velocities in Term Infants and Children

Age	Weight (g/day)	Height (cm/mo)[a]
0-3 mo	24-35	2.8-3.4
4-6 mo	15-21	1.7-2.4
7-12 mo	10-13	1.3-1.6
1-3 yr	5-9	0.6-1
4-6 yr	5-6	0.5-0.6
7-10 yr	7-11	0.4-0.5

Example of growth assessment

Age: 2 mo; weight: 3.2 kg; weight at 1 mo of age, 3.1 kg; time since last weight was obtained: 30 days.

Growth velocity = ([3.2 kg–3.1 kg] × 1,000 g/kg)/30 days = 3.3 g/day.

Interpretation: suboptimal growth; comprehensive nutrition assessment needed.

[a]Growth velocity of 1 cm/mo is equivalent to 0.4 in/mo.

Data from references 8 and 19.

Failure to thrive (growth failure) in children has commonly been defined as weight-for-age, length-for-age, BMI-for-age, or weight velocity below the 5th percentile or a weight deceleration crossing two or more major percentiles (major percentiles are defined as 97th, 95th, 90th, 75th, 50th, 25th, 10th, 5th, and 3rd).[34] In children, a significant weight loss is defined as: greater than 2% in 1 week; greater than 5% in 1 month; greater than 7.5% in 3 months; and, greater than 10% in 6 months. Malnutrition can be defined by using z-scores for weight-for-length, BMI-for-age, or length- or height-for age: -1, mild malnutrition -2, moderate malnutrition; and, -3, severe malnutrition.[35] Weight-for-height evaluation is age independent and helps differentiate a stunted child (chronic malnutrition) from a wasted child (acute malnutrition). Short stature can be associated with chronic undernutrition, but short stature in the absence of poor weight gain suggests another etiology, such as growth hormone deficiency or constitutional growth delay.

Body Mass Index

Body mass index can be calculated as either body weight in kilograms divided by height in meters squared (kg/m^2) or body weight in pounds multiplied by 703 divided by height in inches squared (lb/in^2). The 2013 AHA/ACC/TOS joint guideline for management of obesity in adults endorses using BMI as the first step but not the sole criterion, to judge potential health risk.[36] A BMI of 25 kg/m^2 or higher is considered a risk factor for premature death and disability. Health risks increase as the BMI increases; however, individual variation, especially in very muscular persons, can lead to erroneous

classification of nutrition status when BMI alone is used. Thus, BMI should be interpreted based on characteristics such as sex, frame size, race/ethnicity, and age. For example, at the same BMI, a woman tends to have more body fat than a man, and an older adult would have more body fat than a younger one. Also, Asians may have more body fat than whites, especially at lower BMIs, and thus health risks may be associated with lower BMIs in individuals of Asian descent.[37]

In general, a BMI between 18.5 and 24.9 kg/m^2 is indicative of a healthy weight, between 25 kg/m^2 and 29.9 kg/m^2 signifies being overweight, and 30 kg/m^2 or higher indicates obesity (see Table 141-4).[13,36,38] These BMI classifications may not be appropriate for those older than 60 years, where a BMI between 25 kg/m^2 and 30 kg/m^2 is not associated with the same increased nutrition-related risks seen in younger individuals.[39,40] BMI has also been used to assess undernutrition (less than 18.5 kg/m^2 indicates undernutrition), but this relationship is not as well established.[13,38] Children 2 years of age and older are considered overweight if their BMI is at or above the 85th percentile on the age- and gender-specific CDC BMI chart and obese if the BMI is at or above the 95th percentile.[8] Use of these charts at each medical encounter helps to heighten awareness of children whose BMI and family history put them at risk for adult obesity and its associated complications.

Waist Circumference

Waist circumference is a simple measurement used to assess abdominal (visceral) fat. Extra weight around the waist rather than peripheral (subcutaneous) fat confers a greater health risk than extra weight around the hips and thighs. The larger the waist, the greater the risk of obesity-related complications, especially diabetes mellitus, cardiovascular disease, and all-cause mortality.[36,41] Waist circumference is determined by measuring the distance around the smallest area below the rib cage and the top of the iliac crest. Men are at increased risk (beyond the BMI-related risk) if the waist circumference is greater than 40 inches (102 cm); women are at increased risk if the waist circumference is greater than 35 inches (89 cm) (see Table 141-4); and children are at risk if the waist circumference is at the 75th percentile or greater (16-17-year-old girls) or 90th percentile (all others) according to CDC age- and gender-specific standards.[42]

Waist-to-Hip and Waist-to-Height Ratios

The waist-to-hip ratio is determined by dividing the waist circumference by the hip circumference (maximal posterior extension of the buttocks). In adults, a waist-to-hip ratio of greater than 0.9 in men and 0.85 in women is considered an independent risk factor for adverse health consequences.[41] Waist-to-height ratio (both measured in centimeters) has been used to evaluate children at risk for the metabolic syndrome because, unlike waist circumference, it is independent of age and gender. A child with a waist-to-height ratio of more than 0.5 is considered at risk for developing the metabolic syndrome.[43]

Skinfold Thickness and Mid-Arm Muscle Circumference

More than 50% of the body's fat is subcutaneous; thus, changes in subcutaneous fat reflect changes

in total body fat. Skinfold thickness measurement provides an estimate of subcutaneous fat, and mid-arm muscle circumference, which is calculated using the skinfold thickness and mid-arm circumference, estimates skeletal muscle mass. Although simple and noninvasive, these anthropometric measurements are used most commonly in population analysis and long-term monitoring of individuals. Triceps skinfold thickness is used most often, but reference standards also exist for subscapular and suprailiac measurements.[44] Consistent technique in the use of pressure-regulated calipers is essential for reproducibility and reliability in measuring triceps skinfold thickness.[45] Standards do not account for variation in bone size, muscle mass, hydration, or skin compressibility, and they do not consider obesity, ethnicity, illness, and increased age. Results should be interpreted cautiously as these parameters change slowly in adults, often requiring weeks before significant alterations from baseline can be detected. They will change more rapidly in young children.

Bioelectrical Impedance

Bioelectrical impedance is a simple, quick (less than 15 minutes), noninvasive, portable, and relatively inexpensive technique used to measure body composition.[46,47] When a weak, alternating electric current is applied to two appendages (wrist and ankle or both feet), impedance (resistance) to flow is measured as it passes through the body. Current is well conducted by water and electrolyte-rich tissues such as blood and muscle and poorly conducted by fat, bone, and air-filled spaces. Assessment of LBM, TBW, and water distribution can be determined with BIA. Increased TBW decreases impedance; thus, it is important to evaluate hydration along with BIA. Other potential limitations of BIA include variability with electrolyte imbalance and interference by large fat masses, environment, ethnicity, menstrual cycle phase, and underlying medical conditions.[47] Although BIA equations have high validity when used in the population in which they were developed (mostly young healthy adults), BIA calculations are subject to considerable errors if applied to other populations and if conditions are not identical (eg, electrode placement must be identical).[47] The lack of reference standards that reflect variations in individual body size and clinical condition also limits BIA use in clinical practice.[46]

OTHER NUTRITION ASSESSMENT TOOLS

Functional status assessment has been recommended as part of nutrition assessment, but the specific components of this assessment are not well defined. Muscle function is an end-organ response; thus diminished skeletal muscle function can be a useful indicator of malnutrition. Muscle function also recovers more rapidly in response to adequate nutrition support than anthropometric measurements. Simple assessments of functional status include ability to perform activities of daily living, participate in physical and occupational therapy, and wean from the ventilator. Hand-grip strength (forearm muscle dynamometry), respiratory muscle strength, and muscle response to electrical stimulation also have been used. Measuring hand-grip strength is a relatively simple, noninvasive, and inexpensive procedure that correlates well with patient outcome.[48,49] Normative standards supplied by the manufacturer of the dynamometer can be used. Hand grip strength is a proxy for LBM making it a good parameter for assessment of undernutrition. However, conditions that limit hand grip strength

include rheumatoid arthritis, stroke, neuromuscular disease, dementia, and heavy sedation. Ulnar nerve stimulation causes measurable muscle contraction and can be used in most intensive care units to monitor neuromuscular blockade. In malnourished patients, increased fatigue and a slowed muscle relaxation rate are noted; these indices return to normal with refeeding.

Other methods have been used to determine body composition in the research setting, including bioimpedance spectroscopy, dual energy x-ray absorptiometry (DXA), quantitative CT, air displacement plethysmography (BodPod®), three-dimensional photonic scanning, MRI, quantitative MRI, ultrasonography, and positron emission tomography.[47,50,51] These methods are complex and expensive to perform. DXA, best known for its use in measuring bone density, is a promising method for routine clinical practice because it can quantify mineral, fat, and LBM compartments and is available in most hospitals and many outpatient facilities. A central body DXA scanner requires a fair amount of space, and the cost depends on the scanner's complexity. Portable (or peripheral) DXA devices can be used to measure bone density in peripheral bones, such as the wrist, fingers, or heel, and have also been used to assess subcutaneous fat. Portable DXA scanners are much less expensive (about $10,000 compared to $80,000 for a central scanner) and can be used in community screenings. Further research is needed to determine how DXA can be used clinically in nutrition assessment. MRI and CT can measure subcutaneous, intra-abdominal, and regional fat distribution and thus also have the potential to be useful clinically.

Laboratory Assessment

6 Biochemically, LBM can be assessed by measuring the serum concentrations of the visceral proteins, ALB, TFN, and prealbumin (also known as transthyretin). C-reactive protein (CRP) can be useful as a marker of inflammation. Creatinine-height index has historically been calculated to assess LBM but is seldom used now because of the lack of evidence to support its value.

Visceral Proteins

Visceral proteins synthesized by the liver with the greatest relevance for nutrition assessments are serum ALB, TFN, and prealbumin. It is assumed that in undernutrition states, a low serum protein concentration reflects diminished hepatic protein synthetic mass and indirectly reflects the functional protein mass of other organs (heart, lung, kidney, and intestines). Many factors other than nutrition can affect serum concentrations of these proteins including age; abnormal kidney (nephrotic syndrome), GI tract (protein-losing enteropathy) or skin (burns) losses; hydration (dehydration results in hemoconcentration, overhydration in hemodilution); liver function (synthesis); and metabolic stress and inflammation (sepsis, trauma, surgery, and infection). Thus, visceral protein concentrations must be interpreted relative to the individual's overall clinical condition **(Table 141-6)**. The significant influence of inflammation on visceral protein concentrations is now well established; thus these negative acute phase proteins may be considered to reflect the presence of inflammation more than the presence of malnutrition in many circumstances (see Table 141-3). Visceral protein concentrations for nutrition assessment are of greatest value in the presence of uncomplicated starvation and recovery. During severe acute stress (trauma, burns, and sepsis), these proteins are relatively poor markers of nutrition status because the resultant increased vascular permeability can lead to dramatic

fluid shifts and the reprioritizing of liver protein synthesis increases the production of acute-phase reactants such as CRP, ferritin, fibrinogen, and haptoglobin.[52] CRP can be used in these cases to assess the degree of inflammation present: if CRP is elevated, then inflammation is a likely major contributing factor to decreased visceral protein concentrations. Assessing individual patient trends is most useful in these cases.

TABLE 141-6 Visceral Proteins Used for Assessment of Lean Body Mass

Serum Protein	Half-Life (Days)	Function	Factors Resulting in Increased Values	Factors Resulting in Decreased Values
Albumin	18-20	Maintains plasma oncotic pressure; transports small molecules	Dehydration, anabolic steroids, insulin, infection	Fluid overload; edema; kidney dysfunction; nephrotic syndrome; poor dietary intake; impaired digestion; burns; heart failure; cirrhosis; thyroid, adrenal, or pituitary hormones; trauma; sepsis
Transferrin	8-9	Binds Fe in plasma; transports Fe to bone	Fe deficiency, pregnancy, hypoxia, chronic blood loss, estrogens	Chronic infection, cirrhosis, burns, enteropathies, nephrotic syndrome, cortisone, testosterone
Prealbumin	2-3	Binds T_3 and, to a lesser extent, T_4; retinol-binding protein carrier	Kidney dysfunction	Cirrhosis, hepatitis, stress, surgery, inflammation, hyperthyroidism, cystic fibrosis, burns, zinc deficiency

T_3, triiodothyronine; T_4, thyroxine.

Albumin, the most abundant serum protein, is involved in maintenance of colloid oncotic pressure and binding and transport of numerous hormones, anions, drugs, and fatty acids. Although it has been widely used as a marker of chronic malnutrition, it is a relatively insensitive index of protein malnutrition because there is a large amount normally in the body (4-5 g/kg of body weight), it is extensively distributed in the extravascular compartment (60%), and it has a long half-life (18-20 days). However, chronic protein deficiency in the setting of adequate non-protein calorie intake leads to marked hypoalbuminemia because of a net ALB loss from the intravascular and extravascular compartments. Serum ALB concentrations also are affected by moderate-to-severe calorie deficiency and liver, kidney, and GI disease. ALB is a negative acute-phase reactant, and serum concentrations decrease with inflammation, infection, trauma, stress, and burns. Serum ALB concentrations less than 2.5 g/dL (25 g/L) can be expected to exacerbate ascites and peripheral, pulmonary, and GI mucosal edema as a result of decreased colloid oncotic pressure. Hypoalbuminemia also affects the interpretation of serum concentrations of calcium and highly protein bound drugs (eg, phenytoin and valproic acid).

Transferrin is a glycoprotein that binds and transports ferric iron to the liver and reticuloendothelial system for storage. Because it has a shorter half-life (8-9 days) and there is less of it in the body (less than 100 mg/kg of body weight), TFN will decrease in response to protein and energy depletion before the serum ALB concentration decreases. If a direct measure of serum TFN is not available, TFN concentration can be estimated indirectly from measurement of total iron-binding capacity, where TFN (in mg/dL) = (total iron-binding capacity [mcg/dL] × 0.8) – 43. Alternatively, TFN (mg/dL) = 0.7 × total iron-binding capacity (mcg/dL) and TFN (g/L) = 0.039 × total iron-binding capacity (µmol/L). TFN is also a negative acute-phase reactant, and its concentration is decreased in the presence of critical illness and inflammation. Iron stores also affect serum TFN concentrations: in iron deficiency, hepatic TFN synthesis is increased, resulting in increased serum TFN concentrations.

Prealbumin (transthyretin) is the transport protein for thyroxine and a carrier for retinol-binding protein. Prealbumin stores are low (10 mg/kg of body weight), and it has a very short half-life (2-3 days); thus, the serum prealbumin concentration may be reduced quickly after a significant reduction in calorie and protein intake (NPO status) or in patients with severe metabolic stress (trauma, burns). Prealbumin is most useful in monitoring the short-term, acute effects of nutrition support or deficits, as it responds very quickly in both situations. As with ALB and TFN, prealbumin synthesis is decreased in liver disease. Increased prealbumin concentrations may be seen in patients with kidney disease because of impaired excretion.

Clinical Controversy…

Serum visceral proteins (ALB, TFN, and prealbumin) have been used for many years as markers of nutrition status. With the growing recognition of the role that inflammation plays in the development of both acute and chronic malnutrition, the use of these visceral proteins as markers of malnutrition has been challenged. Assessing CRP concomitantly with these traditional visceral protein markers can assist the clinician in assessing their usefulness. However, the role of CRP in nutrition assessment requires further investigation.

Immune Function Tests

Nutrition status affects immune function either directly, via actions on the lymphoid system, or indirectly by altering cellular metabolism or organs that are involved with immune system regulation. Immune function tests most often used in nutrition assessment are the total lymphocyte count and delayed cutaneous hypersensitivity (DCH) reactions. Both tests are simple, readily available, and inexpensive. A lack of specificity, however, limits the usefulness of these tests as nutrition status markers.

Total lymphocyte count reflects the number of circulating T and B lymphocytes. Tissues that generate T cells are very sensitive to malnutrition, undergoing involution resulting in decreased T-cell production and eventually lymphocytopenia. A total lymphocyte count less than 1,500 cells/mm^3 (1.5 × 10^9 cells/L) has been associated with nutrition depletion.[2] Total lymphocyte count is reduced in the presence of infection (eg, human immunodeficiency virus [HIV], other viruses, and tuberculosis), immunosuppressive drugs (eg, corticosteroids, cyclosporine, tacrolimus, sirolimus, chemotherapy, and antilymphocyte globulin), leukemia, and lymphoma.

Delayed cutaneous hypersensitivity is commonly assessed using recall antigens to which the patient was likely previously sensitized, such as mumps and *Candida albicans*. Anergy is associated with severe malnutrition, and response is restored with nutrition repletion. Other immune function tests used in research include lymphocyte surface antigens (CD4, CD8, and the CD4:CD8 ratio), T-lymphocyte responsiveness, and various serum interleukin concentrations. A number of factors affect DCH, including fever, viral illness, recent live-virus vaccination, critical illness, irradiation, immunosuppressive drugs, diabetes mellitus, HIV, cancer, and surgery. Nutrients such as arginine, omega-3 fatty acids, and nucleic acids given in pharmacologic doses may improve immune function (see Chapter 143). Monitoring efficacy of a nutrition care plan that includes these potentially immune-modulating nutrients may include immune function assessment.

SPECIFIC NUTRIENT DEFICIENCIES AND TOXICITIES

7 A comprehensive nutrition assessment should include an evaluation for possible trace element, vitamin, and essential fatty acid deficiencies (EFAD) or toxicities. Because of their key role in metabolic processes (coenzymes and cofactors), a deficiency of any of these nutrients may result in altered metabolism and cell dysfunction. An accurate history to identify symptoms and risk factors for a specific nutrient deficiency or toxicity is critical. A nutrition-focused physical examination and biochemical assessment to confirm a suspected deficiency or toxicity should be done in all nutritionally-at-risk patients. Ideally, biochemical assessment would be based on the nutrient's function (eg, metalloenzyme activity) rather than simply measuring the serum concentration. Unfortunately, few practical methods to assess micronutrient function are available; thus, the nutrient's serum concentration is most often measured **(Table 141-7)**.

Trace Elements

The trace elements that are essential in humans (at least one important role and a range of intakes within which homeostasis is maintained) are zinc, copper, manganese, selenium, chromium, iodine, molybdenum, and iron.[53,54,55,56,57,58] Each trace element is involved in a variety of biologic functions and is necessary for normal metabolism, serving as a coenzyme or playing a role in hormonal metabolism or erythropoiesis. Toxicities can occur with excess intake of some trace elements. With the current interest in complementary medicine, clinicians must ask patients about their use of all dietary supplements (see Table 141-7).

TABLE 141-7 Assessment of Trace Element Status

Trace Element	Signs of Deficiency	Signs of Toxicity	Factors Associated with Altered Plasma Concentrations	Monitoring
Chromium	Impaired glucose/protein utilization, peripheral neuropathy, low RQ, weight loss, increased	Industrial exposure: skin or nasal septum lesions, allergic dermatitis, increased	**Decreased**: long-term inadequate intake	Serum glucose, plasma chromium

Trace Element	Signs of Deficiency	Signs of Toxicity	Factors Associated with Altered Plasma Concentrations	Monitoring
	LDL-C, increased free fatty acid concentrations	incidence of lung cancer	**Increased**: kidney failure	(unreliable)
Copper	Menkes' syndrome: progressive mental deterioration, vomiting, diarrhea, protein-losing enteropathy, hypopigmentation, bone and hair changes Deficiency: neutropenia, hypochromic anemia, pallor, dermatitis, neurological dysfunction, osteoporosis, myopathy, thrombocytopenia, decreased bone mineralization (children)	Wilson's disease: cirrhosis, Kayser-Fleischer rings,[a] kidney dysfunction, neurologic or psychiatric symptoms (tremors, slow speech, inappropriate behavior, personality changes) Mild chronic toxicity: fatigue, anemia, thrombocytopenia Acute toxicity: nausea, vomiting, diarrhea	**Decreased**: high zinc, iron, or vitamin C intake; corticosteroid use **Increased**: infection, rheumatoid arthritis, pregnancy, oral contraceptives, decreased biliary excretion	Serum copper and ceruloplasmin with CRP[b], CBC
Iodine	Hypothyroid goiter, neuromuscular impairment, deaf-mutism, increased embryonic and postnatal mortality, cognitive impairment, impaired fertility, congenital hypothyroidism (severe cases)	Thyrotoxicosis: nodular goiter, weight loss, tachycardia, muscle weakness, warm skin	**Decreased**: long-term inadequate intake	Serum T3,T4,TSH
Iron	Microcytic, hypochromic anemia (weakness, pallor, fatigue), glossitis, headache, dysphasia, nail changes, gastric atrophy, paresthesia, decreased cognitive function	Cirrhosis, cardiomyopathy, pancreatic damage, skin pigmentation changes	**Increased**: blood transfusion **Decreased**: blood loss; long-term iron-free PN	Serum ferritin[c], iron, percent iron saturation, iron binding capacity; CBC
Manganese	Nausea; vomiting; dermatitis; hair color changes; hypocholesterolemia;	Parkinsonian-like symptoms, hyperirritability, hallucinations, libido	**Increased**: decreased biliary excretion, high iron or vitamin C intake	Whole blood manganese, brain MRI

Trace Element	Signs of Deficiency	Signs of Toxicity	Factors Associated with Altered Plasma Concentrations	Monitoring
	growth retardation; defective carbohydrate, lipid, and protein metabolism	disturbances, ataxia, mental confusion, lack of attention, memory loss, weakness, seizures, facial nerve abnormalities, headache, dizziness, dystonia, peripheral neuropathy		
Molybdenum	Tachycardia, tachypnea, altered mental status, visual changes, headache, nausea, vomiting	Gout-like syndrome, increased urinary copper	**Decreased**: low birth weight, excessive GI losses	Urinary hypoxanthine, xanthine, and sulfite oxidase
Selenium	Muscle weakness or pain, cardiomyopathy, skin and hair pigmentation changes, macrocytosis, alopecia and growth retardation in infants	Nausea, vomiting, hair or nail loss, tooth decay, skin lesions, irritability, fatigue, peripheral neuropathy	**Decreased**: malignancy, liver failure, pregnancy, stress, infection **Increased**: reticuloendothelial-neoplasia	Plasma, serum, or whole blood selenium, RBC glutathione peroxidase; CBC
Zinc	Dermatitis (scaly, hyperpigmented skin lesions), stomatitis, glossitis, perioral and periungual ulceration, altered taste and smell, alopecia, diarrhea, apathy, depression, growth retardation, impaired wound healing, anorexia, confusion, immunosuppression, delayed sexual maturation, hypogonadism (decreased sperm count and function)	Acute: diarrhea, vomiting, nausea, dizziness, garlic-smelling breath; death with large IV doses Chronic: immunosuppression, decreased HDL-C, copper deficiency	**Decreased**: infection, burns, stress, hypoalbuminemia, corticosteroids, pregnancy, inflammation **Increased**: tissue injury, hemolysis, contaminated collection tube	Plasma or serum zinc with albumin and CRP, stool or ostomy output

CBC, complete blood count; CRP, C-reactive protein; GI, gastrointestinal; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; MRI, magnetic resonance imaging; PN, parenteral nutrition; RBC, red blood cell; RQ, respiratory quotient; TSH, thyroid stimulating hormone.

[a]Kayser-Fleischer rings are dark rings that appear to encircle the iris of the eye.

[b]If CRP > 4 mg/dL (> 40 mg/L), serum copper concentration will be falsely elevated. Ceruloplasmin increased with inflammation, pregnancy, liver disease, malignancy, and myocardial infarction.

[c] If ferritin low, iron deficiency; if high, inflammation.

Data from references 13, 20, 53, 54, 56,57,58, and 61.

Iron is the most abundant trace element and is an important component of hemoglobin, myoglobin, and cytochrome enzymes; it is also involved in oxygen transport and cellular energy production. Patients with iron-deficiency anemia generally present with fatigue, weakness, and pallor, but they may have other symptoms (see Chapter 100). Inadequate iron intake, malabsorption, and blood loss are the principal causes of iron-deficiency anemia. Iron toxicity (overload) with possible organ damage can occur when chronic iron intake exceeds requirements, such as in patients receiving multiple blood transfusions over an extended period of time (1 unit of packed red blood cells provides 200 mg elemental iron). Iron deficiency or overload is confirmed by assessment of body iron stores, as reflected indirectly by measurement of hemoglobin, serum iron, total iron-binding capacity, and serum ferritin or directly by bone marrow staining or liver biopsy. Direct methods are the most accurate but are invasive and rarely necessary. Because indirect parameters may be altered by acute or chronic illness independent of iron stores, concomitant illness must be considered in their interpretation.[54,56]

Zinc, the second-most abundant trace element, is a cofactor in many enzymatic reactions involved in protein, fat, and carbohydrate metabolism and is involved in the regulation of gene expression, wound healing, and liver regeneration.[54,56,59] Most of the body's zinc (85%) is found in muscle and bone; less than 1% is found in the serum. Excess zinc intake is usually eliminated by the kidneys and GI tract; thus, zinc toxicity is uncommon except in overdoses. Patients at risk for zinc deficiency include those with anorexia, alcohol dependence, excessive bile, intestinal, or urine losses, increased metabolic demands (burns) or after bariatric surgery.[59] Zinc deficiency can develop in 14 days to 3 months with insufficient intake and is characterized by skin lesions (acrodermatitis enteropathica), a moist eczematous dermatitis that is most apparent in the nasolabial folds and around orifices, and other symptoms (see Table 141-7). Recovery is rapid with oral zinc supplementation; severe dermatitis can remit in as little as 4 to 5 days.[58] Zinc deficiency can be documented by the presence of low serum zinc concentrations.[53,59] However, serum zinc concentrations decrease during acute stress states (trauma, burns, and infection) and generally remain depressed until the stress resolves. Hair zinc analysis and urinary zinc excretion can also be used as biomarkers of zinc status.

Copper is a cofactor in oxidative enzymes vital to the function of hematopoietic, vascular, and skeletal tissue, as well as structure and function of the nervous system.[60,61,62] It is a component of

ceruloplasmin and key metalloenzymes involved in iron metabolism (ceruloplasmin), electron transport and energy metabolism (cytochrome oxidase), connective tissue and collagen cross-linking (lysyl oxidase, elastase, and monoamine oxidase), and free radical scavenging (superoxide dismutase), among other functions. Copper is absorbed in the duodenum and excreted through the bile bound to bile salts. Most copper (67%) is found in bone and muscle, and 60% to 95% of serum copper is bound to ceruloplasmin.[62] Signs and symptoms of copper deficiency are listed in Table 141-7 and include anemia, neutropenia, and thrombocytopenia, and neurologic dysfunction. In severe cases, such as in Menkes' syndrome, copper deficiency is further manifested as hypothermia, hair and skin depigmentation, progressive mental deterioration, and growth retardation. Factors predisposing to copper deficiency include generalized malabsorption, protein-losing enteropathy, nephrotic syndrome, and copper-free parenteral nutrition.[60,62] Patients undergoing bariatric surgery are also at risk for developing copper deficiency as early as 2 months after surgery. Resolution typically occurs within 1 to 3 weeks after initiation of copper supplementation (1 mg/day). Copper deficiency is assessed using serum copper concentrations along with CRP and ceruloplasmin, which appear to reflect changes in copper status in both copper-depleted and copper-replete individuals.[61] While they are reliable indicators of severe copper deficiency, serum copper and ceruloplasmin concentrations may not detect marginal copper deficiency because serum concentrations may be altered by a variety of conditions including inflammation (see Table 141-7). Copper concentrations should be monitored routinely in patients receiving long-term parenteral nutrition. While long-term parenteral nutrition supplemented with copper increases the risk of copper toxicity, copper deficiency has been reported as a result of copper-free parenteral nutrition most often because of concern for accumulation with cholestasis and the resulting decrease in biliary elimination.[62] The chronic ingestion of excessive copper or inadequate elimination can result in cirrhosis as seen in Wilson's disease, an autosomal-recessive genetic disorder. Copper concentrations should be monitored every 2 to 6 months in patients receiving long-term parenteral nutrition.

Trivalent chromium is needed for insulin function and maintenance of normal blood glucose concentrations. A low-molecular-weight chromium binding substance, "*the glucose tolerance factor*", may enhance insulin receptor response to insulin.[63] Chromium is stored in the liver, spleen, soft tissues, and bones and excreted by the kidney. Chromium deficiency is characterized by glucose intolerance, increased insulin requirements, and impaired protein utilization. Patients with chromium deficiency also may have increased free fatty acid concentrations and a low respiratory quotient (RQ) (see Table 141-7). Chromium deficiency has only been identified in patients receiving long-term chromium-free parenteral nutrition. Serum chromium concentrations do not accurately reflect total body chromium status, presumably because the biologically active form of chromium is the low-molecular-weight chromium binding substance. Toxicity from trivalent chromium is not a common clinical concern; toxicity has been reported only with contaminated drinking water or industrial exposure. Chromium supplementation as an adjunct to aerobic exercise for weight loss has not been proven effective[64] (see Chapter 142).

Manganese is needed for the proper function of metalloenzymes, including arginase (amino acid metabolism via the urea cycle), pyruvate carboxylase and phosphoenolpyruvate carboxykinase (carbohydrate and cholesterol metabolism), superoxide dismutase (mitochondrial antioxidant), glycosyltransferases (bone formation via proteoglycans), and prolidase (wound healing).[54,56,] Excess

manganese is eliminated mainly in bile. Manganese deficiency has only been reported in association with the ingestion of chemically defined manganese-deficient oral diets. Table 141-7 lists common symptoms associated with manganese deficiency. Manganese toxicity is more concerning and has been described in industrial exposures via inhaled manganese and in patients receiving long-term manganese-supplemented parenteral nutrition in the setting of chronic cholestasis.[65,66,67,68] Manganese can accumulate in brain tissue and the newborn brain may be more susceptible to the effects of manganese toxicity.[66] Increased signal intensity on T1-weighted MRI of the globus pallidus has been found in patients with manganese toxicity. Whole-blood manganese concentrations are used to assess manganese status; serum concentrations do not correlate with either whole blood concentrations or MRI.[67] Clinical toxicity is evidenced primarily by extrapyramidal symptoms mimicking Parkinson's disease, such as headache, dizziness, tremors, ataxia, facial muscle spasms, and other symptoms.[54,65] These symptoms may be preceded by psychiatric symptoms, including irritability, aggressiveness, and hallucinations. In most reported cases, removing manganese from the parenteral nutrition solution resulted in resolution of neurologic symptoms within 6 months with partial or total normalization of the MRI after 1 to 2 years.

Selenium is incorporated into at least 25 enzymes known as selenoproteins, about half of which have a defined metabolic function. Important selenoproteins include selenoprotein P (antioxidant activity), glutathione peroxidase (antioxidant activity), iodothyronine deiodinase (thyroid hormone regulation), thioredoxin reductase (vitamin C), selenoprotein V (spermatogenesis), and selenoprotein S (inflammation and immune response).[54,56,69] Selenoprotein P is the major (60%) circulating form of selenium in serum. A key metabolic function of selenium is its role in the enzymatic cofactor selenocysteine, the 21st amino acid.[56] Prematurity, critical illness, chronic GI losses, and long-term selenium-free parenteral nutrition are associated with low serum selenium concentrations and decreased glutathione peroxidase activity.[54,56,69] The clinical significance of reduced serum selenium concentrations is unclear, but low selenium concentrations may increase susceptibility to physiologic stressors. Although critically ill patients require higher selenium intakes than normal, the optimal intake is unknown. Current recommendations range from 20 to 1,000 mcg/day.[70] Low serum selenium concentrations in critically ill patients correlate with low triiodothyronine (T_3) concentrations.[70] Serum selenium concentrations reflect acute distribution between tissues rather than selenium stores. Selenium deficiency is associated with muscle pain, wasting, and weakness (see Table 141-7), but severe biochemical deficiency is not always accompanied by these symptoms. Fatal cardiomyopathy has been reported in several cases.

Serum, erythrocyte, and whole-blood selenium, serum selenoprotein P, and serum, platelet, and whole-blood glutathione peroxidase activity respond to changes in selenium intake, but the response is heterogeneous.[69] Decreased serum selenium concentrations may indicate selenium deficiency, but reductions have also been observed in patients with malignancies, liver failure, pregnancy, alcoholism, and HIV; in patients receiving statins or corticosteroids; and in smokers. Selenium toxicity (selenosis) generally occurs only in those with long-term exposure to foods grown in selenium-rich soil (eg, U.S. Great Plains area) and may occur when intake exceeds 400 mcg/day for prolonged periods; although, the lowest reported adverse event intake is 850 mcg/day. Selenium toxicity results in hair and nail brittleness and loss, GI disturbance, skin rash, garlic breath odor, fatigue, irritability,

and nervous system abnormalities.

Molybdenum is a cofactor for enzymes involved in catabolism of sulfur-containing amino acids, purines, and pyrimidines (xanthine, aldehyde, and sulfite oxidases).[54,56,71] Molybdenum deficiency is uncommon, but a rare genetic defect that prevents sulfite oxidase synthesis resulting in molybdenum deficiency has been identified. One case of molybdenum deficiency has been reported in a patient receiving long-term molybdenum-free parenteral nutrition who presented with symptoms that included tachycardia, tachypnea, headache, night blindness, nausea, vomiting, central scotomas, lethargy, disorientation, and ultimately coma (see Table 141-7). Symptoms were reversed when molybdenum was added to the parenteral nutrition solution.[72] Factors predisposing to molybdenum deficiency appear to be low birth weight,[73] excessive GI losses, and long-term inadequate intake. Biochemical abnormalities expected in molybdenum deficiency include very low serum and urine uric acid concentrations (low xanthine oxidase activity) and low urine inorganic sulfate concentrations with high urine inorganic sulfite concentrations (low sulfate oxidase activity).[71] Molybdenum toxicity has not been described.

Iodine is found primarily in the thyroid gland (70%-80%). Iodine deficiency may result in goiter formation (see Chapter 75). However, not everyone with an iodine-deficient diet will develop a goiter. Measurement of thyroxine (T_4), T_3, and TSH (thyroid stimulating hormone) can be used to assess iodine status (see Table 141-7). Intravenous iodine supplementation is not necessary except during long-term parenteral nutrition with minimal enteral intake. Iodine needs may be met by consumption of iodized salt or cutaneous iodine absorption from povidone–iodine, a topical antiseptic, used in catheter care. Use of povidone–iodine for this indication has virtually been eliminated with increased chlorhexidine use for catheter care, putting long-term parenteral nutrition patients at higher risk. Iodine excess is rarely a clinical concern when thyroid and kidney functions are normal except in overdoses.

Vitamins

Vitamins act as both catalysts (cofactors) and substrates in essential metabolic reactions. A comprehensive nutrition-focused history and physical examination is the most valuable means of assessing patients for vitamin deficiency or toxicity (**Table 141-8**). A thorough review of vitamins and their complex effects on nutrition and metabolism is beyond the scope of this chapter.[56,57,74,75] Generalized malnutrition is often associated with multiple vitamin deficiencies or increased needs; however, single vitamin deficiencies do occur. Thiamine (B_1) deficiency can result in early symptoms (dry or wet beriberi and GI symptoms) or advanced symptoms (lactic acidosis, Wernicke's encephalopathy, polyneuropathy, ataxia, and mental confusion) due to impaired oxidative and energy metabolism often leading to serious and potentially irreversible neurological damage or death.[56,76] Macrocytic anemia, peripheral neuropathy, and neuropsychiatric sequelae are also caused by vitamin B_{12} (cyanocobalamin) deficiency which can occur after gastric or ileal resection. Vitamin B_{12} deficiency has been reported with increasing frequency in adults, especially with prolonged gastric acid suppression.[77] There is a high prevalence of subclinical vitamin K deficiency in patients with chronic kidney disease, including those on hemodialysis or peritoneal dialysis. Vitamin K

deficiency is a modifiable risk factor for cardiovascular disease and bone fracture in this patient population.[78]

TABLE 141-8 Assessment of Vitamin Status

Vitamin	Signs of Deficiency	Laboratory Assay	Comments
Water-Soluble Vitamins			
Thiamine (B_1)	Early: anorexia, fatigue, depression, impaired memory or concentration Late: paresthesia, nystagmus, GI beriberi (nausea, vomiting, abdominal pain, lactic acidosis), beriberi (heart failure, edema), Wernicke's encephalopathy, Korsakoff's psychosis, peripheral neuropathy	Whole blood or erythrocyte transketolase activation test Blood thiamine pyrophosphate Erythrocyte glutathione reductase activity coefficient	Increased need with hemo- and peritoneal dialysis, alcoholism, malabsorption, hypermetabolism
Riboflavin (B_2)	Mucositis, dermatitis, cheilosis, glossitis, photophobia, corneal vascularization, lacrimation,decreased vision, impaired wound healing and growth, normocytic anemia	Urine riboflavin	
Pantothenic acid	Fatigue, malaise, headache, insomnia, vomiting, abdominal cramps	Serum pantothenic acid	
Niacin	Pellagra: dermatitis, dementia, glossitis, diarrhea, memory loss, headaches	Urine niacin and N_1-methylnicotinamide Erythrocyte NAD and NADP concentrations to determine "niacin number"	Flushing, nausea, and vomiting seen with hyperlipidemia treatment; increased need with hemo- and peritoneal dialysis
Pyridoxine (B_6)	Pellagra, dermatitis, glossitis, cheilosis, distal limb numbness or paresthesia, convulsions, microcytic anemia	Plasma pyridoxal 5-phosphate Urine 4-pyridoxic acid	Sensory neuropathy and seizures with very high doses (>2 g/day)
Folic acid	Macrocytic anemia, diarrhea, glossitis, cheilosis, angular stomatitis, fatigue, difficulty	Serum or plasma folate (acute)	Decreased with increased cellular/tissue turnover (pregnancy, malignancy,

Vitamin	Signs of Deficiency	Laboratory Assay	Comments
	concentrating, irritability, headache, palpitations, shortness of breath, heart failure, tachycardia, postural hypotension, lactic acidosis, neural tube defects, impaired cellular immunity, paranoid behavior	Red blood cell folate (chronic) Serum homocysteine	hemolytic anemia); masks diagnosis of vitamin B_{12} deficiency; decreases risks of neural tube defects
Cyanocobalamin (B_{12})	Pernicious (megaloblastic) anemia, glossitis, spinal cord degeneration, peripheral neuropathy, paresthesias, pancytopenia, personality changes, dementia, depression, psychosis	Serum cobalamin Plasma homocysteine Urine or plasma methylmalonic acid[a] CBC	Decreased absorption in the elderly, distal ileal resection, loss of gastric intrinsic factor due to gastrectomy or long-term gastric acid suppression
Biotin	Dermatitis, depression, lassitude, somnolence	Urine biotin	
Ascorbic acid (C)	Enlargement or keratosis of hair follicles, impaired wound healing, anemia, lethargy, depression, bleeding, ecchymosis, scurvy	Plasma ascorbic acid Leukocyte ascorbate	GI disturbances, hyperoxaluria and kidney stones, excess iron absorption with excess intake; smokers need 35 mg/day more than nonsmokers; rebound scurvy with abrupt discontinuation after long-term high doses
Fat-Soluble Vitamins			
Vitamin A (includes retinol, retinal, retinoic acid, and retinyl esters)	Dermatitis, night blindness, xerophthalmia, Bitot spots,[b] pruritus, follicular hyperkeratosis, excessive deposition of periosteal bone, hair changes, poor growth and wound healing, impaired resistance to infection Irreversible: punctate keratopathy, keratomalacia, corneal perforation	Serum retinol Serum retinol-binding protein Serum retinyl esters (toxicity)	Teratogenic, liver toxicity with excessive intake; alcohol intake, liver disease, hyperlipidemia, and severe protein malnutrition increase susceptibility to adverse effects of high intake; β-carotene supplements recommended only for those at risk of deficiency (fat malabsorption); may reverse corticosteroid-

Vitamin	Signs of Deficiency	Laboratory Assay	Comments
			induced poor wound healing
D	Rickets, osteomalacia, osteoporosis, muscle weakness, poor growth, hypocalcemia, immune dysfunction, cardiomyopathy	Serum 25-hydroxy-vitamin D	Elevated intake causes hypercalcemia, nephrocalcinosis, azotemia, poor growth; decreased in uremia, elderly (especially in winter), fat malabsorption
α-Tocopherol (E)	Hemolysis	Serum α-tocopherol Ratios of serum α-tocopherol to total lipids	Excess intake: hemorrhagic toxicity; increased risk of bleeding with anticoagulants; impaired leukocyte function
K	Bleeding (ecchymosis, petechiae, hematomas)	Prothrombin time INR	Anticoagulant therapy can be affected by supplements or diet

CBC, complete blood count; GI, gastrointestinal; INR, international normalized ratio; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate.

[a]Plasma methylmalonic acid concentrations increase with vitamin B_{12} deficiency.

[b]Bitot spots are spots which are oval, triangular, or irregular in shape and located superficially in the conjunctiva. *Data from references 13, 20, 21, 56, 57, and 75.*

The increasing prevalence of vitamin D deficiency is a worldwide concern, including all ages, genders, and racial/ethnic groups, especially children, elderly adults, individuals with dark skin, invalids and shut-ins, patients on long-term parenteral nutrition, and those living in temperate and higher latitudes.[79,80] Laboratory assessment can confirm the clinical suspicion of a deficiency state. Vitamins D2 (ergocalciferol) and D3 (cholecalciferol) are quickly converted to 25-OH-vitamin D via hydroxylation in the liver. The best marker for vitamin D deficiency is the serum concentration of 25-OH-vitamin D. Reference ranges for U.S. laboratories are typically 20 to 100 ng/mL (50-250 nmol/L) but the optimal range is likely above 30 ng/mL (75 nmol/L) based on the concentration associated with parathyroid hormone (PTH) stimulation and calcium absorption efficiency.[79] The first indication of a deficiency is usually a decrease in circulating serum concentrations of 25-OH-vitamin D. Subsequently, there is a decrease in urinary excretion of vitamin D, which is followed by diminished tissue concentrations. Because 1,25-$(OH)_2$-vitamin D is produced only when needed, not stored, and dependent on kidney function, intact PTH concentration, and calcium and phosphorus supply, it is not a useful marker of vitamin D deficiency (see Table 141-8; see Chapter 44)

Vitamin toxicity can occur, especially with fat-soluble vitamins (A, D, E, and K), which are stored in the

body. Excessive dietary vitamin A intake (hypervitaminosis A) is linked to an increased risk of hip fractures in both men and women.[81,82] Vitamin D toxicity can cause significant hypercalcemia. With the exception of cyanocobalamin, which is stored in the liver, water-soluble vitamins are not stored in the body; consequently, the toxicity risk is minimal unless ingested in very high doses. Recent evidence, however, suggests that even water-soluble vitamins may be associated with adverse events when taken chronically in high doses. Although folic acid administration is definitively associated with a reduction in neural tube defects, its effect on some cardiac outcomes (as a result of its effect on homocysteine concentrations) is not established.[83] The administration of folic acid, vitamin B_6 (pyridoxine), and vitamin B_{12} after coronary artery stenting has been associated with an increased risk of stent restenosis.[84] With Americans' current use of nutrition supplements, clinicians should be alert for signs of hypervitaminosis (see Table 141-8) and inappropriate vitamin use and discuss rational supplement use with all patients.

Essential Fatty Acids

The human body can synthesize all fatty acids except the essential fatty acids, linoleic acid (an omega-6 fatty acid) and α-linolenic acid (an omega-3 fatty acid). Essential fatty acid deficiency (EFAD) can be prevented if approximately 5% of total calories are ingested as these fatty acids.[85,86] EFAD is rare in adults and children but can occur with prolonged use of lipid-free parenteral nutrition, severe fat malabsorption, very low-fat enteral feeding formulations or diets, high medium chain triglyceride-containing diets, and severe malnutrition, especially in stressed patients. Although the time course to develop EFAD is variable, overt EFAD has been shown to occur after 4 weeks of lipid-free parenteral nutrition, and biochemical evidence can occur within 1 week.[86] Because newborns, especially those born prematurely, have limited fat stores, they may develop EFAD more rapidly than adults. Biochemical evidence of EFAD has been noted within 72 hours after birth in preterm infants receiving fat-free intravenous solutions.[87] Symptoms of EFAD include dermatitis (dry, cracked, and scaly skin), alopecia, impaired wound healing, growth failure, thrombocytopenia, and anemia.

Linoleic acid is converted to arachidonic acid (20:4ω-6; a tetraene fatty acid). When linoleic acid is unavailable, oleic acid (18:1ω-9) is the preferred substrate, resulting in production of eicosatrienoic acid (20:3ω-9; a triene fatty acid). Thus, EFAD is associated with decreased tetraene and increased triene production. The usual ratio of trienes to tetraenes is less than 0.4; a ratio of greater than 0.2 indicates subclinical EFAD, but clinical symptoms of EFAD are generally only seen when the ratio is greater than 0.4.[88] EFAD diagnosis is generally made based on risk assessment and clinical findings with confirmation by measuring serum fatty acid concentrations.

Carnitine

Carnitine is a quaternary amine required for transport of long-chain fatty acids into the mitochondria for β-oxidation and energy production. Additionally, acyl compounds that are trapped within cells due to cell membrane impermeability to them can be esterified with carnitine and transported out of the cell, aiding in their elimination (detoxification), especially when the acyl compounds accumulate to inhibitory or toxic concentrations. Carnitine is available from a wide variety of dietary sources

(especially meats) and can be synthesized by the liver and kidneys from lysine and methionine. Hepatic synthesis is decreased in premature infants, and low serum carnitine concentrations and overt carnitine deficiency have been documented in premature infants receiving carnitine-free parenteral nutrition or diets, as well as in those with inborn errors of carnitine metabolism.[89] Other predisposing factors for carnitine deficiency include chronic kidney[90] or liver disease,[89] chronic valproic acid[89] and zidovudine use,[91] and a vegetarian diet. The clinical presentation of carnitine deficiency includes generalized skeletal muscle weakness, hypotonia, failure-to-thrive, fasting hypoglycemia, encephalopathy, and coma.[89]

Although tissue concentrations, especially muscle, are higher than serum concentrations, in clinical practice, carnitine status is most often assessed by measurement of serum total and free carnitine concentrations and acylcarnitine. Serum and urine carnitine concentrations are most helpful in primary carnitine deficiency (an inborn error of metabolism); acylcarnitine concentrations are more helpful in secondary causes of carnitine deficiency. When only total and free concentrations are available, the free is subtracted from the total to give the acylcarnitine concentration.[89]

NUTRIENT REQUIREMENTS

8 Individual nutrient requirements vary with age, gender, size, disease state, and clinical condition. Nutrition status, physical activity, and the need for continued maintenance of adequate nutrition or repletion in those with ongoing metabolic stress or malnutrition dictate the nutrient requirements for an individual. For obese patients, usual nutrition requirements may be altered because of desired weight loss or after bariatric surgery. In children, there is the added consideration of sustaining or reestablishing normal growth and development. Organ function (intestine, kidney, liver, and pancreas) may affect nutrient utilization. Nutrient requirements can be estimated using various methods interpreted in the context of patient-specific factors.

Recommended Dietary Allowances

The recommended daily allowances (RDAs) were first established in 1941, and in 1997, the Food and Nutrition Board introduced a new designation for nutrition reference values: the dietary reference intakes (DRIs).[92] The four DRI categories are estimated average requirements (EARs), RDAs, adequate intakes (AIs), and tolerable upper intake levels (ULs). The nutrient intake that meets the needs of half of the healthy persons in a group (EAR) can be used for planning nutrient intakes for groups. The RDA, the nutrient intake that meets the needs of almost all persons in a designated group, is approximately 2 standard deviations above the EAR for nutrients for which the requirement is well defined and 1.2 times the EAR for other nutrients. To evaluate an individual's daily intake, the RDA is the most appropriate comparator. AI, defined as the average intake for the designated group that appears to sustain a particular nutrition state, growth, or other functional indicator of health, is reserved for nutrients for which no EAR or RDA has been determined. Finally, the UL is the maximum nutrient intake unlikely to pose adverse effects in almost all persons in a designated group.[92]

Dietary reference intakes have been established for six nutrient groups: calcium, phosphorus,

magnesium, vitamin D, and fluoride; folate and other B vitamins; antioxidants (eg, selenium and vitamins C and E); trace elements; macronutrients (eg, protein, fat, carbohydrates, and fiber); and electrolytes and water. Because of the increased prevalence of vitamin D deficiency, calcium and vitamin D recommendations were revised in 2010.[93] The U.S. Department of Agriculture's website includes an Interactive DRI for Healthcare Professionals, which calculates a generally healthy individual's DRI-based nutrition needs.[94]

According to the DRIs, adults and children older than 1 year of age should consume 45% to 65% of their total calories as carbohydrates. Recommended fat intakes vary by age: 1 to 3 years, 30% to 40%; 4 to 18 years, 25% to 35%; and, adults, 20% to 35% of total calories. Infants, especially premature infants, require a higher proportion of calories from fat (approximately 40%-50% of total calories) to ensure normal neurological development. Protein recommendations also vary by age: 1 to 3 years, 5% to 20%; 4 to 18 years, 10% to 30%; and, adults, 10% to 35% of total calories.[85]

Energy

9 Energy requirements of individuals can be estimated using published, validated equations or can be measured directly. The most appropriate method is determined by a variety of factors, including severity of illness and resource availability.

Estimating Energy Expenditure

Daily energy expenditure consists of the basal energy expenditure (BEE), diet-induced thermogenesis (10%), and energy used for physical activity. In sick or injured patients, the BEE is increased because of stress-related hypermetabolism, but the physical activity and the energy needed for metabolism are usually reduced. For example, continuous infusion enteral feeding, often used in critically ill patients, results in minimal diet-induced thermogenesis (5%) when overfeeding is not present.[28] Failure to account for these changes can result in overfeeding.

More than 200 methods for determining an individual's daily energy requirement have been published.[2,28,95,96,97] These methods use population estimates of calories per kilogram of body weight (kcal/kg), equations that estimate energy expenditure (kcal/day or kJ/day; 1 kcal is equivalent to 4.184 kJ), or indirect calorimetry. The simplest method to determine energy requirements is to use population estimates of calories required per kilogram of body weight. This method assumes standard values for health or the energy requirements associated with various disease states or clinical conditions, as well as the additional requirements for repletion of a malnourished individual. Most do not take into consideration age- or gender-related differences in energy needs. No stress or activity modifiers are used with these equations because the effect of the clinical condition (hypermetabolism) has been captured in the calculation. Daily adult requirements by this method can be estimated as shown below:[95,96,97]

1. Healthy, normal nutrition status, minimal illness severity: 20 to 25 kcal ABW/kg/day (84-105 kJ ABW/kg/day).

2. Illness, metabolic stress (BMI less than 30 kg/m^2): 25 to 30 kcal ABW/kg/day (105-126 kJ ABW/kg/day).

3. Illness, metabolic stress (BMI greater than or equal to 30 kg/m^2): 11 to 14 kcal ABW/kg/day (46-59 kJ ABW/kg/day) or 22 to 25 kcal IBW/kg/day (92-105 kJ ABW/kg/day).

4. Major burn injury (greater than or equal to 50% total body surface area) or repletion: greater than or equal to 30 kcal ABW/kg/day (greater than or equal to 126 kJ ABW/kg/day).[98]

When using the ranges in 3 above, as the BMI increases, the number derived using ABW compared to IBW becomes quite disparate. Accuracy is improved by using the ABW recommendation for patients with BMI 30-50 kg/m^2 and the IBW recommendation when the BMI is greater than 50 kg/m^2. When these recommendations are used for patients with a BMI of 30 kg/m^2 or more, the calories provided allow for permissive underfeeding (provision of approximately 80% of estimated or measured energy needs), which decreases infection rates and hospital length of stay.[28] **Table 141-9** shows suggested calorie intakes (kcal/kg) for maintenance and normal growth of healthy infants and children.[85] These maintenance energy requirements are approximately 150% of the basal metabolic rate, with the additional calories provided to support usual activity and growth. For all ages, energy requirements increase with fever, sepsis, major surgery, trauma, burns, and long-term growth failure and in the presence of chronic conditions such as bronchopulmonary dysplasia, congenital heart disease, and cystic fibrosis. Energy needs may decrease with obesity and neurologic disability (eg, cerebral palsy).

TABLE 141-9 Dietary Reference Intakes for Energy and Protein in Healthy Children

Age (Reference age/weight)	Estimated Energy Requirement (kcal/day)[a]		Protein RDA (g/kg/day)[b]
	Boys	Girls	
0-6 mo (3 mo/6 kg)	570	520	1.52[c]
7-12 months (9 mo/9 kg)	743	676	1.5
1-2 yr (24 mo/12 kg)	1,046	992	
1-3 yr (24 mo/12 kg)			1.1
3-8 yr (6 yr/20 kg)	1,742	1,642	
4-8 yr (6 yr/20 kg)			0.95
9-13 yr (11 yr/M: 36 kg; F: 37 kg)	2,279	2,071	0.95
14-18 yr (16 yr/M: 61 kg; F: 54 kg)	3,152	2,368	0.85

F, female; M, male; RDA, recommended dietary allowance.

[a]1 kcal is equal to approximately 4.18 kJ.

[b]Protein requirements in children with moderate to severe stress increase by 50% or more.

[c]Adequate intake.

Data from reference 85.

Numerous equations are available to estimate energy expenditure in adults and children (**Tables 141-10** and **141-11**, respectively).[2,28,95,96,97] The Harris-Benedict equations, derived in 1919 from a study of 239 individuals, are still used by some clinicians for assessing energy requirements in adults. They have the advantage of incorporating the patient's age, height, weight, gender, and clinical condition into the estimation. These equations were derived from oxygen consumption measurements made in normally nourished healthy individuals who were in a fasting and resting state. Although they are commonly referred to as the "BEE equations," they actually estimate resting energy expenditure (REE), the amount of energy expended at rest by a fasting, awake individual in a temperature-controlled environment performing only basal functions such as breathing, circulation, and metabolic processes.

TABLE 141-10 Estimates of Energy Expenditure in Adults[a]

Healthy Adults
Harris-Benedict[b] Equations (kcal/day)
Men: BEE = 66 + (13.75W + 5H [cm]) – (6.8A)
Women: BEE = 655 + (9.6W + 1.8H [cm]) – (4.7A)
DRI Equations (kcal/day)[c]
Men: EER = 662 – 9.53A + (PA × 15.91W) + 539.6H (m)
Women: EER = 354 – 6.91A + (PA × 9.36W) + 726H (m)
PA = 1 if sedentary; 1.12 if low active; 1.27 if active; and 1.45 if very active
Mifflin-St. Jeor Equations (kcal/day)
Men: 10W + 6.25H (cm) – 5A + 5
Women: 10W + 6.25H (cm) – 5A – 161
Critically Ill Adults
Penn State Equations (kcal/day)
Age ≥60 years with BMI ≥30 kg/m^2: Mifflin(0.71) + T_{max}(85) + Ve(64) – 3085
All others: Mifflin(0.96) + T_{max}(167) + Ve(31) – 6212

A, age in years; BEE, basal energy expenditure; BMI, body mass index; DRI, dietary reference intakes; EER, estimated energy requirement; H, height in centimeters or meters, as indicated; PA, physical activity factor; T_{max}, maximum body temperature in the previous 24 hours in degrees centigrade; Ve, minute ventilation in L/min; W, actual body weight in kilograms.

[a]No real consensus exists as to which formula is best in all situations. Many clinicians use more than one equation and calculate a range of acceptable intakes.

[b]The common practice of using an adjusted body weight for obesity in these calculations is not

supported by the original data that used actual body weight in all cases up to a BMI of 56 kg/m^2 in men and 40 kg/m^2 in women.

[c]1 kcal is equal to approximately 4.18 kJ.

Data from references 2, 28, 95, and 96.

TABLE 141-11 Equations to Estimate Energy Expenditure in Children[a,b]

FAO/WHO/UNU 2001 (kcal/day)[b]
0-12 Months
Breastfed
TEE (kcal/day) = –152 + 92.8W
TEE (MJ[c]/day) = –0.635 + 0.388W
Formula fed
TEE (kcal/day) = –29 + 82.6W
TEE (MJ[c]/day) = –0.122 + 0.346W
Boys 1-17 Years
TEE (kcal/day) = 310.2 + 63.3W – 0.263W^2
TEE (MJ[c]/day) = 1,298 + 0.265W – 0.0011W^2
Girls 1-17 Years
TEE (kcal/day) = 263.4 + 65.3W – 0.454W^2
TEE (MJ[c]/day) = 1,102 + 0.273W – 0.0019W^2
DRI Equations (kcal/day)
Birth through 2 years of age
EER = (89W – 100) + GF
GF = 175 kcal if 0-3 months; 56 kcal if 4-6 months; 22 kcal if 7-12 months; 20 kcal if 13-35 months
3-18 years of age
Boys: EER = 88.5 – (61.9A) + PA (26.7W + 903H) + GF
Girls: EER = 135.3 – (30.8A) + PA (10W + 934H) + GF
GF = 20 kcal if 3-8 years; 25 kcal if 9-18 years
PA = 1 if sedentary; 1.13-1.16 if low activity; 1.26-1.31 if normal activity; and 1.42-1.56 if very active

A, age in years; DRI, dietary reference intakes; EER, estimated energy requirement; FAO/WHO/UNU, Food and Agriculture Organization/World Health Organization/United Nations University; GF, growth factor; H, height in meters; PA, physical activity factor; TEE, total energy expenditure; W, actual body weight in kilograms.

[a]No real consensus exists as to which formula is best in all situations. Many clinicians use more than one equation and calculate a range of acceptable intakes.

[b]Additional daily calories are needed for growth; about 2 kcal/g of weight gain desired.

[c]1 kcal is equivalent to approximately 4.18 kJ; 1 MJ = 1,000 kJ.

Data from references 85, 101, and 102.

Because these equations approximate REE, the results have been historically modified by a factor that adjusts for the individual's clinical condition. For example, an individual who is confined to bed may require a calorie intake that is only 20% to 30% above the REE, while a person who has sustained a severe burn injury may require 150% to 200% of the calculated REE. Some clinicians multiply the calculated REE by both a stress factor and an activity factor. Because validation studies have shown that these equations overestimate REE by 6% to 15%, the calculated REE should be multiplied by either a stress factor or an activity factor to avoid further overestimation of the individual's energy needs.[2] It should also be noted that ABW (up to a BMI of 56 kg/m^2 in men and 40 kg/m^2 in women), not IBW or adjusted body weight, was used to generate the original data with these equations and thus should be used for these calculations.[96] Overestimation of energy needs with the Harris-Benedict equations is well documented.[28,96] When compared to indirect calorimetry, the accuracy has been shown to be about 34%.[99] The Mifflin-St. Jeor equations tend to be more accurate in healthy adults than the Harris-Benedict equations (see Table 141-10): the accuracy rate is 80% in patients who are not obese (BMI less than or equal to 30 kg/m^2) and 70% in obese patients (BMI greater than 30 kg/m^2).[28,99]

There is no individual method proven to accurately determine the energy needs of all critically ill patients.[95] The Penn State equations are the most accurate in critically ill adults receiving mechanical ventilation[28] (see Table 141-10), but the accuracy is only about 67% when compared to indirect calorimetry measurements.[99] The Penn State modified appears to be more accurate in older obese patients, with an accuracy of approximately 74% when compared to indirect calorimetry measurements in the same individuals.[99] There is no consensus as to the best equation for critically ill adults who are not mechanically ventilated. The metabolic response to stress in children appears to be different than in critically ill adults; thus, "stress factors" used in adults, shown in **Table 141-12**, are not appropriate for use in estimating energy use in children.[100,101,102]

TABLE 141-12 Stress Factors for Use in Adults

Condition	Factor
No Stress	
Confined to bed	1.2
Out of bed: normal activity	1.3
Catch-up growth	1.5
Mild Stress[a]	
Postoperative recovery: uncomplicated surgery	1-1.15
Trauma: mild (eg, long-bone fracture)	1.2
Moderate Stress[a]	

Condition	Factor
Sepsis (moderate)	1.2-1.4
Trauma: CNS (sedated)	1.3
Trauma: moderate to severe	Children: 1.5
	Adults: 1.3-1.4
Severe Stress[a]	
Sepsis (severe)	Children: 1.6
	Adults: 1.3
Trauma: CNS (severe)	Children: up to 2.0
	Adults: up to 1.3
Burns (proportionate to burned area)[b]	Up to 2.0

CNS, central nervous system.

[a]Assumes decreased activity during periods of stress.

[b]Formulas specifically for estimating energy needs in burned children and adults have been published and are likely to be more accurate. See reference 98.

Data from reference 2.

Clinical Controversy…

Many equations have been published for estimating energy requirements of patients in a variety of settings. Indirect calorimetry is becoming more widely available for use in many patient settings. Whether estimating energy needs using an appropriate validated equation is cost-effective and/or improves outcomes versus measuring the energy requirements using indirect calorimetry is not yet established.

Measuring Energy Expenditure

The most accurate method to determine energy expenditure in clinical practice is to measure it using indirect calorimetry (metabolic gas monitoring), but capital and operational costs limit its availability. Handheld calorimeters have been shown to produce similar results to metabolic carts and may be a viable alternative to the more expensive equipment in both the inpatient and outpatient setting.[103]

Indirect calorimetry methodology is based on pulmonary gas exchange: when a substrate (carbohydrate, fat, or protein) is oxidized, heat is produced, oxygen is consumed, and carbon dioxide is expired in a constant amount depending on the substrate being oxidized. More carbon dioxide is produced when a gram of glucose is metabolized than either a gram of protein or a gram of fat. Indirect calorimetry is a noninvasive procedure in which oxygen consumption (VO_2, mL/min) and carbon dioxide production (VCO_2, mL/min) are measured, and the measured resting energy expenditure (MREE; kcal/day) is calculated using the abbreviated Weir equation as MREE = ([3.94 VO_2

+ 1.11 VCO_2] + [2.17 uN_2]) × 1.44.[99,104,105] The urinary nitrogen component (uN_2) is often omitted when calculating energy expenditure because it accounts for less than 4% of the energy expenditure in critically ill patients, and its omission results in only a 1% to 2% calculation error.[28,105] Excluding the nitrogen component obviates the need for a 24-hour urine collection, which can be difficult in many patients and delay the measurement in others.

The MREE represents the total energy expended during the time period over which the measurements were taken extrapolated to a 24-hour period to approximate daily energy requirements. MREE reflects changes in energy requirements resulting from diseases or clinical conditions, but it does not include energy required for repletion of a malnourished individual or growth in a child. The energy intake required for these functions is accounted for by multiplying MREE by a metabolic or activity factor: mechanically ventilated, critically ill, 1; critically ill, no mechanical ventilation, 1 to 1.1; adult acute, not critically ill, 1.1 to 1.4, depending on activity; adult needing repletion or a child, 1.3 to 2; adult outpatient, 1.1 to 2, depending on activity; and adult depletion (weight loss), less than 1.[104,105]

Indirect calorimetry also can be used to determine the patient's RQ, calculated as VCO_2/VO_2, which reflects substrate oxidation and characterizes substrate utilization. RQ values for nutrient substrates are fat, 0.7; carbohydrate, 1; protein, 0.8; and mixed substrate (fat, carbohydrate, and protein), 0.85. RQ values greater than 1 represent either lipogenesis or hyperventilation; less than 0.7 may indicate a ketogenic diet, fat gluconeogenesis, or ethanol oxidation. Values outside the physiologic range of 0.67 to 1.3 suggest an invalid test. Clinically, the RQ is used to determine if a patient is being overfed, which is likely if the RQ value is greater than 1.

Indirect calorimetry is a respiratory measurement that does not reflect metabolism in all clinical situations. Indirect calorimetry overestimates REE for patients with hyperventilation, metabolic acidosis, overfeeding, and if there are air leaks anywhere in the ventilator circuit. Underestimation of REE is likely with hypoventilation, metabolic alkalosis, underfeeding, and gluconeogenesis. Mechanically ventilated patients are technically easier to study because the indirect calorimeter can be integrated into the ventilator circuit. However, the patient must be at complete rest for 1 hour, must not receive bolus feedings either by feeding tube or orally for 4 hours, should have no changes in substrate delivery for 12 hours, and must be on a fraction of inspired O_2 of less than 0.6 with a positive end-expiratory pressure less than 5 cm H_2O (approximately 0.5 kPa) to ensure an accurate steady-state reading. Unfortunately, many of the patients in whom indirect calorimetry would be most useful will not meet these requirements. Indirect calorimetry should be considered in any patient in whom uncertainty in estimating energy requirements needs to be minimized, such as adults and children who are severely malnourished (BMI less than 18.5 kg/m^2) or obese (BMI greater than 30 kg/m^2), who have unexplained high partial arterial pressure of carbon dioxide ($PaCO_2$) concentrations or minute ventilation, spinal cord injuries, who experience weight loss despite apparently receiving adequate protein and energy intakes, critically ill surgery patients receiving parenteral nutrition, and patients unable to be weaned from the ventilator.[28,104,105]

Protein

Daily protein requirements are based on age, gender, nutrition status, disease state, and clinical condition. Table 141-9 lists the RDAs for protein for children; for individuals older than 18 years of age, the RDA is 0.8 g/kg/day, which is significantly less than most Americans typically consume.[85] In adults older than 60 years of age, protein needs are increased to 1.5 g/kg/day to reduce the loss of LBM that occurs with aging, and 1.5 to 2 g/kg/day or more may be needed in states of metabolic stress (infection, trauma, and surgery).[85,97,106] Protein requirements are also higher in pregnant and lactating women (1.1 g/kg/day or 6-10 g protein per day above the usual RDA).[85]

Protein metabolism depends on both kidney and liver function. Critical illness results in a hypercatabolic state in which there is both increased protein synthesis and degradation. The goal of protein administration is to minimize catabolism by maximizing protein synthesis. Consequently, protein requirements are increased to 1.2 to 2 g/kg/day in critically ill patients. For obese critically ill patients, protein needs are 2 g/kg IBW or more if the BMI is between 30 and 40 kg/m^2 and 2.5 g/kg IBW or more if the BMI is greater than 40 kg/m^2.[95] Adults with significant total body surface area burns have protein requirements as high as 2.5 to 3 g/kg ABW/day. In children with significant burns, between 20% and 25% of their total calorie needs should be provided as protein.[98] Soft tissue defects and large stool or ileostomy losses also increase protein requirements. Liver failure typically results in the need for protein restriction (0.5 g/kg/day) unless a hypercatabolic state is also present, which will increase requirements to 1.5 g/kg/day. Protein needs in patients with kidney failure are variable and affected by the various renal replacement therapies available. The application of these protein intake guidelines requires both clinical judgment and frequent monitoring of kidney and liver function, serum chemistries, clinical condition, and nutrition outcomes.

Nitrogen is found only in protein and at a relatively constant ratio of 1 g nitrogen per 6.25 g of protein. This ratio may vary somewhat for enteral and parenteral feeding formulations, depending on the biologic value of the protein source. The adequacy of protein intake can be assessed clinically by a nitrogen balance study—measuring urinary nitrogen excretion and comparing it with nitrogen intake. Nitrogen balance indirectly reflects protein use or the protein catabolic rate, which increases with hypercatabolism. As the stress level increases, a concomitant increase in protein catabolism results in an increase in urinary nitrogen excretion. The amount of urine urea nitrogen (UUN) measured in a 24-hour urine collection in healthy individuals, accounts for 80% to 90% of the total urine nitrogen (TUN) excreted. Nitrogen output (g/day) can be approximated as 24-hour UUN + 4, where 4 is a factor representing usual skin, fecal, and respiratory nitrogen losses. At higher UUN values (30 g nitrogen or more), then the use of a factor of + 6 may yield a more accurate measure of nitrogen output.[107] Alternatively, if available, TUN can be measured and may be more accurate, especially in critically ill patients who excrete more nitrogen-containing substances such as 3-methylhistidine. If TUN is used, then the best estimate of nitrogen output is TUN + 1.05.[107] In patients with kidney failure, in which case neither UUN nor TUN accurately represents net protein degradation, nitrogen balance can be approximated only with equations based on urea nitrogen appearance.[108]

Fat

The daily AI for men and women for α-linolenic acid is 1.6 and 1.1 g, respectively; for linoleic acid, it is 14 to 17 g/day for men and 11 to 12 g/day for women.[85] Overall, for adults, fat should represent no more than 10% to 35% of total calories, with the recommendation that saturated fatty acids, *trans* fatty acids, and dietary cholesterol intake be kept as low as possible while a nutritionally adequate diet is consumed. Fat should constitute 30% to 40% of energy in children 1 to 3 years of age and 25% to 35% of energy in children 4 to 18 years of age.[85] Fat intake in children younger than 3 years of age is critical for proper central nervous system growth and development; generally, fat-restricted diets (skim milk) should not be imposed until after the age of 2 to 3 years except under medical supervision. A lower limit of 15% of total energy intake has been suggested as the minimum fat intake in children when fat restriction is warranted.[109]

Fiber

Reduced risk of coronary heart disease and maintenance of normal laxation have been attributed to dietary fiber intake.[110] Fiber intake may also have a role in colon cancer prevention and may promote weight control through its effect on satiety. Men and women 50 years of age and younger should ingest 38 g/day and 25 to 26 g/day, respectively, of total fiber. For men and women older than 50 years of age, the recommended intakes are 30 g/day and 21 g/day, respectively.[85] The AI for fiber has not been set for children younger than 1 year of age. Breast milk and infant formulas are essentially fiber-free. For older children, the recommended fiber intake is 19 g/day for children 1 to 3 years of age, 24 g/day for children 4 to 8 years of age, and 26 to 31 g/day for children 9 to 13 years of age.[85]

Fluid

The daily fluid requirement for an adult depends on many factors but is generally estimated to be 30 to 35 mL/kg, 1 mL for each kcal (or 4.18 kJ) ingested, or 1,500 mL/m^2. Fluid requirements per kilogram of body weight are higher for children and even higher for preterm infants because of their higher percentage of TBW and basal energy needs. Additionally, premature neonates have increased fluid requirements because of greater insensible losses and the kidneys' inefficiency in concentrating urine. The Holliday-Segar method is a commonly used, quick, and simple method for estimating minimum daily fluid needs of children and adults. Children weighing less than 10 kg should receive at least 100 mL/kg/day. An additional 50 mL/kg/day should be provided for each kilogram of body weight between 11 kg and 20 kg and 20 mL/kg/day for each kilogram above 20 kg. Thus, the minimum fluid required for a child weighing 8 kg would be 800 mL/day, a 17-kg child would need 1,350 mL/day; and a 50-kg individual would need 2,000 mL/day.

Table 141-13 lists factors that alter fluid needs for both adults and children. All sources of fluid intake should be considered (eg, fluid vehicles for intravenous medications and intravenous or feeding tube flushes) when determining fluid requirements. Urine output and specific gravity as well as serum electrolytes and weight changes can be used to assess fluid status. A urine output of at least 1 mL/kg/h (in children) and approximately 40 to 50 mL/h (in adults) is considered adequate to ensure tissue perfusion. Urine output should be higher if large fluid volumes or high renal solute loads (eg, parenteral nutrition or concentrated enteral feeding formulations) are being administered. Urine

specific gravity depends on the kidney's concentrating and diluting capabilities. Concomitant diuretic therapy, resulting in increased solute excretion, limits the usefulness of urine specific gravity as an assessment of fluid status.

TABLE 141-13 Factors That Alter Fluid Requirements

Increased Requirements	Decreased Requirements
Fever	
Radiant warmers	
Diuretics	
Vomiting	Fluid overload
Nasogastric suction	Heart failure
Ostomy or fistula drainage	Decreased urine output
Diarrhea	Heat shields
Glycosuria	Relatively high humidity
Phototherapy	Humidified air via endotracheal tube
Diabetes insipidus	Kidney failure
Increased ambient temperatures	Hypoalbuminemia with starvation
Hyperventilation	Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Prematurity	
Excessive sweating	
Increased metabolism (eg, hyperthyroidism)	

Micronutrients

Requirements for micronutrients (electrolytes, minerals, trace elements, and vitamins) vary with age, gender, and the route by which the nutrient is ingested (**Table 141-14**; see Chapters 49 to 51).[53,54,55,56,57,58,74,92,111] Oral and parenteral requirements vary as a result of bioavailability considerations. Micronutrients poorly absorbed via the GI tract usually are required in greater amounts when given by the enteral than parenteral route. However, many water-soluble micronutrients are excreted more rapidly via the kidneys when administered intravenously. In these situations, the intravenous dose is greater than the oral dose. Other factors that affect micronutrient requirements include GI losses through diarrhea, vomiting, or high-output fistula or ostomies; wound

healing; and hypermetabolism or hypercatabolism. Cutaneous micronutrient losses (eg, zinc, copper, and selenium) also may be significant after major burn injury. Sodium, potassium, magnesium, and phosphorus excretion are particularly dependent on kidney function, and in the settings of acute kidney injury or chronic kidney disease, intake will likely need to be restricted. Calcium needs, on the other hand, may be increased in these patients (see Chapters 44 and 45). Patients who are severely malnourished will have increased electrolyte requirements during early refeeding owing to preexisting deficiencies and rapid intracellular uptake with anabolism. Failure to provide adequate electrolyte replacement, especially phosphorus, and vitamin supplementation (thiamine) before delivery of full calories during refeeding has resulted in death from the refeeding syndrome.[112,113]

TABLE 141-14 Recommended Daily Electrolyte, Trace Element, and Vitamin Intake[a]

Nutrient	Adult (≥19 yr of age)		Pediatric	
	Enteral	Parenteral	Enteral	Parenteral
Electrolytes and Minerals				
Acetate[b]	—	—	—	—
Calcium	1,000-1,200 mg	0-15 mEq (0-7.5 mmol)	0-12 mo: 210-270 mg 1-3 yr: 700 mg 4-8 yr: 1,000 mg 9-18 yr: 1,300 mg	Premature: 2-4 mEq/kg (1-2 mmol/kg) Other: 1-2.5 mEq/kg (0.5-1.25 mmol/kg)
Chloride[b]		—	—	2-6 mEq/kg (2-6 mmol/kg)

M, men; NE, niacin equivalents; RE, retinol equivalents; TE, tocopherol equivalent; W, women.

[a]Data represent either the recommended dietary allowance (RDA) or the adequate intake (AI) for each nutrient where established.

[b]Not established; as needed to maintain acid–base balance.

[c]Newborns and low-birth-weight or very-low-birth-weight infants or with concomitant disease (eg, necrotizing enterocolitis) may have higher requirements. Intake in nonhealthy children must be individualized.

[d]No RDA or AI has been established.

[e]An additional 20 mcg/day is recommended in patients with significant intestinal losses.

[f]May accumulate in cholestasis.

[g]Long-term parenteral nutrition only if no topical preparations containing iodide or iodized table salt are used.

[h]Higher doses may be required in patients with short bowel syndrome receiving long-term parenteral nutrition.

[i]Additional intake needed with small bowel losses, which can be 12 mg zinc/L or 17 mg zinc/kg of stool or ileostomy output; an additional 2 mg/day needed for acute catabolic stress.

Data from references 53,54,55,56,57,58, 74, 75, and 93.

DRUG–NUTRIENT INTERACTIONS

10 Drug-induced nutrient deficiency, poor therapeutic response, enhanced drug toxicity, and failure to achieve desired nutrition outcomes can occur if either nutrition support or drug therapy is stopped as a consequence of adverse effects. Patient outcomes may be enhanced when an effective screening method to identify significant drug–nutrient interactions is coupled with a patient counseling

program. An important part of the screening process is to recognize risk factors that influence drug–nutrient interactions. The potential for drug–nutrient interactions is greatest in pediatric and elderly individuals, those with poor nutrition status (obesity and marasmus), and those receiving multiple drug therapies or tube feedings.[114,115,116,117,118,119,120]

Mineral and electrolyte serum concentrations may change because of drug therapy. For example, with loop diuretics, urine sodium, potassium, calcium, and magnesium wasting may occur, causing a reduction in their respective serum concentrations. Alternatively, calcium excretion is reduced with thiazide diuretics (see Chapter 49). Serum electrolyte concentrations also may increase as a direct result of the drug's mechanism (potassium-sparing diuretics) or because of the drug's salt form (sodium piperacillin/tazobactam). Corticosteroids and cyclosporine are known to cause hyperglycemia; other drugs are prescribed to pharmacologically lower blood glucose concentrations (eg, insulin and oral hypoglycemics; see Chapter 74).

Vitamin and trace element status also may be affected by drugs (**Table 141-15**). For example, sulfasalazine therapy causes a decrease in folic acid, isoniazid therapy causes pyridoxine deficiency, and furosemide therapy may result in decreased thiamine concentrations. Drug therapy outcomes also may be affected by vitamin intake. For instance, the ingestion of high folic acid doses may decrease methotrexate's therapeutic effect, and changes in an individual's usual vitamin K or vitamin E intake may cause variability in warfarin's anticoagulant effects.

TABLE 141-15 Drug and Nutrient Interactions

Drug	Effect
Antacids	Thiamine deficiency
Antibiotics	Vitamin K deficiency
Aspirin	Folic acid deficiency; increased vitamin C excretion
Cathartics	Increased requirements for vitamins D, C, and B_6
Cholestyramine	Vitamins A, D, E, and K and β-carotene malabsorption
Colestipol	Vitamins A, D, E, and K and β-carotene malabsorption
Corticosteroids	Decreased vitamins A, D, and C
Diuretics (loop)	Thiamine deficiency
Efavirenz	Vitamin D deficiency caused by increased metabolism of 25(OH)-vitamin D and 1,25-$(OH)_2$-vitamin D
Histamine$_2$ antagonists	Vitamin B_{12} malabsorption (reduced acid results in impaired release of B_{12} from food)
Isoniazid	Vitamin B_6 and niacin deficiency
Isotretinoin	Vitamin A increases toxicity
Mercaptopurine	Niacin deficiency
Methotrexate	Folic acid inhibits effect
Orlistat	Vitamins A, D, E, and K malabsorption caused by fat malabsorption
Pentamidine	Folic acid deficiency

Drug	Effect
Phenobarbital	Increased vitamin D metabolism
Phenytoin	Increased vitamin D metabolism, decreased folic acid concentrations
Primidone	Folic acid deficiency
Protease inhibitors	Vitamin D deficiency (impaired renal hydroxylation)
Proton pump inhibitors	Vitamin B_{12} malabsorption (reduced acid results in impaired release of B_{12} from food)
Sulfasalazine	Folic acid malabsorption
Trimethoprim	Folic acid depletion
Warfarin	Vitamin K inhibits effect; vitamins A, C, and E may affect prothrombin time
Valproic acid	Zinc
Zidovudine	Folic acid and B_{12} deficiencies increase myelosuppression

Data from references 114,115,116,117,118,119,120.

Drug-delivery vehicles also may contain nutrients. Most intravenous therapies (maintenance intravenous fluids, drugs, and electrolyte replacements) are delivered using solutions of either dextrose (dextrose 5% or 10% in water) or sodium (0.9% NaCl). Lipid emulsion (10%) is used as the vehicle for the anesthetic agent propofol and the intravenous calcium channel blocker clevidipine and contributes fat calories (1.1 kcal/mL or 4.6 kJ/mL) when continuous infusions are used. In these instances, nutrition support regimens must be adjusted to accommodate calories and other nutrients delivered through these therapies to avoid overfeeding and other complications.

PRACTICAL GUIDELINES FOR NUTRITION ASSESSMENT

The value of any marker used for nutrition screening is only as good as its ability to accurately identify the patient with malnutrition and to correlate with nutrition-related complications. The response of the various nutrition status markers to nutrition therapy and the correlation between improvement in these markers and decreased morbidity and mortality support their validity. However, when applied to an individual, most of these markers lack specificity and sensitivity, which makes the development of a clinically useful, cost-effective approach to nutrition screening challenging.

The importance of the nutrition-focused history and physical examination in both nutrition screening and nutrition assessment cannot be overemphasized. The minimum amount of objective data that can further substantiate the clinical impression and provide a baseline for subsequent monitoring is weight and serum ALB concentration. The cost effectiveness of the addition of other biochemical parameters is unknown. The assessment of other anthropometric measures is most useful in the setting of anticipated long-term nutrition support in which these measurements will serve as a longitudinal marker of response to the nutrition care plan.

Initially, nutrition requirements are determined on the basis of assumptions made about the patient's

clinical condition and the nutrition needs associated with repletion or growth, if needed. After a nutrition intervention has been initiated, periodic reassessment of nutrition status is critical to determine the accuracy of the initial estimate of nutrition requirements. Nutrition requirements are dynamic in the setting of acute or critical illness—as the patient's clinical status changes, so will protein and energy requirements, further emphasizing the need for continued reassessment.

Better markers of nutrition status and methods for determining patient-specific nutrition requirements are needed to allow further refinement of estimates of an individual's nutrition needs. Functional tests and simple, noninvasive tests for body composition analysis hold promise for the future. However, until better methods of assessment become available clinically and are demonstrated to be cost effective, the currently available battery of tests will continue to be the mainstay of nutrition assessment.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ABW	actual body weight
AI	adequate intake
ALB	albumin
BEE	basal energy expenditure
BIA	bioelectrical impedance analysis
BMI	body mass index
CDC	Centers for Disease Control and Prevention
CRP	C-reactive protein
DCH	delayed cutaneous hypersensitivity
DRI	dietary reference intake
DXA	dual-energy x-ray absorptiometry
EAR	estimated average requirement
EFAD	essential fatty acid deficiency
GI	gastrointestinal
HIV	human immunodeficiency virus
IBW	ideal body weight
LBM	lean body mass
MREE	measured resting energy expenditure
MRI	magnetic resonance imaging
MST	Malnutrition Screening Tool
RDA	recommended dietary allowance
REE	resting energy expenditure
RQ	respiratory quotient

SGA	Subjective Global Assessment
TBW	total body water
TFN	transferrin
TUN	total urine nitrogen
UBW	usual body weight
UL	tolerable upper intake level
UUN	urine urea nitrogen
VCO_2	carbon dioxide production
VO_2	oxygen consumption
WHO	World Health Organization

Chapter 142: Parenteral Nutrition

Todd W. Mattox; Catherine M. Crill

INTRODUCTION

KEY CONCEPTS

- 1 Development and implementation of an appropriate, individualized nutrition care plan requires definition of nutrition goals, determination of nutrition requirements and appropriate route of nutrient delivery, and design of a monitoring plan to evaluate suitability of the nutrition regimen as a patient's clinical condition changes.
- 2 The appropriate route of nutrition support depends on the functional condition of the patient's gastrointestinal (GI) tract, risk of aspiration, expected duration of nutrition therapy, and clinical condition.
- 3 Suitable candidates for parenteral nutrition (PN) therapy can be identified on the basis of their age, nutrition status, expected duration of GI dysfunction, and potential risks of PN therapy.
- 4 PN formulations include injectable amino acids, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives.
- 5 PN solutions may be appropriately formulated for administration by peripheral or central venous access.
- 6 PN formulations are available as standardized commercial premixed products or they may be compounded with an automated compounding device (ACD).
- 7 PN solutions may be infused continuously or intermittently.
- 8 Biochemical and clinical measurements for effective monitoring of patients receiving PN include serum chemistries, vital signs, body weight, total daily fluid intake and losses, and nutritional intake.

- 9 Non–catheter-related complications of PN therapy can be minimized by using age-appropriate nutrient dosing guidelines, frequent monitoring, and implementing rational adjustments to the PN regimen when metabolic abnormalities occur.
- 10 Individualized PN therapy should be based on nutrition therapy goals determined from a patient-specific nutrition assessment, type of available IV access, and macronutrient and micronutrient requirements.
- 11 A patient's nutrient requirements are affected by age, degree of metabolic demand, organ function, drug therapy, exogenous losses, acid–base status, and enteral intake in patients with recovering GI function.

Maintenance of adequate nutrition status during illness has been recognized for more than 50 years as an integral part of the treatment plan for patients who are unable to attain and sustain oral nourishment. Successful techniques for providing IV nutrition support were introduced to clinical practice in adults and subsequently, infants in the late 1960s.[1] Use of central venous access was investigated to reduce risk of metabolic complications associated with IV fluid overload and electrolyte imbalances. The use of large central vessels permitted infusion of concentrated formulas, which decreased the fluid volume required and avoided the phlebitis that commonly occurred when hypertonic infusions were given peripherally.

Clinical experience and research fostered development of protocols that promoted better patient care and resulted in a decline in complications and costs associated with parenteral nutrition (PN) therapy.[2] The scope of practice for nutrition support clinicians has broadened as a result of increasing knowledge regarding the metabolic consequences associated with acute injury and chronic disease states. The pharmacist's role in providing safe and effective nutrition-support care requires knowledge of the principles of patient selection, initial therapy design, outcome monitoring, and strategies for providing therapy during PN product shortages.[3,4] In addition, the pharmacist is uniquely prepared to take on the responsibility for PN order verification as well as compounding and dispensing of the PN admixture. The PN order must be verified by a pharmacist to ensure the order is clear, complete, and correctly transcribed. A clinical review should be performed to confirm appropriate indication, nutrient dosing, and non-nutrient medication dosing. A pharmaceutical review should be performed to confirm compatibility of ordered nutrients and any non-nutrient medications in addition to the expected stability of the formulation.[4,5] Other responsibilities of the nutrition support pharmacist may include development of policy and procedures as well as quality improvement activities for patient care and operational processes associated with providing parenteral and enteral nutrition.[4,5,6,7] The clinical role of other healthcare professionals may be similar because of the evolving interprofessional approach to nutritional support.[8,9,10] This chapter reviews indications for PN, components of PN formulations, routes of IV administration, practical aspects of regimen design, solution admixture, outcome monitoring, and management of complications for both adult and pediatric (neonates, infants, and children) patients.

DESIRED OUTCOMES

1 The primary objective of nutrition support therapy is to promote positive clinical outcomes of an illness and improve a patient's quality of life. Four fundamental steps are key to providing optimal care for patients who require nutrition support. They are establishing patient-specific nutrition goals, determining nutrient requirements to achieve the nutrition goals, assuring delivery of the required nutrients, and subsequently assessing the nutrition regimen.[5,6,7]

A patient's nutrition goals can be established after a thorough nutritional assessment (see Chapter 141). Nutrient requirements and an appropriate route for delivery of the required nutrients can then be determined. Nutrition support goals include correction of the patient's caloric and nitrogen imbalances and any fluid, electrolyte, vitamin, or trace element abnormalities. An additional goal is to lessen the metabolic response to injury by minimizing oxidant stress and favorably modulating immune response. These interventions should not cause or worsen other metabolic complications.

2 The gastrointestinal (GI) tract is the optimal route for providing nutrients unless obstruction or other GI complications are present (see Chapter 143).[11,12] Two other considerations that may impact selection of the optimal route for delivery of nutrition support include expected duration of nutrition therapy and risk of aspiration. Patients who have nonfunctional GI tracts or are otherwise not candidates for enteral nutrition may benefit from PN.

INDICATIONS FOR PARENTERAL NUTRITION SUPPORT

The association between malnutrition and development of complications and mortality is well documented for adult and pediatric patients.[12,13] Although improvement in various clinical nutrition markers has been reported for patients who received PN, the impact on clinical outcome has been difficult to demonstrate in many adult populations. Several investigations have reported a positive effect of PN on complications and mortality, but others have failed to confirm these findings.[11,14,15] Early studies have been criticized for defective study design, such as small sample sizes, inappropriate randomization, and inconsistent baseline nutrition status among the study and control groups, which hindered demonstration of the effectiveness of PN therapy. The impact of PN on clinical outcome has been more consistently demonstrated for critically ill infants and children, particularly those with acquired or congenital GI tract anomalies.[16] Consensus guidelines for PN use for adults (**Table 142-1**) and pediatric (**Table 142-2**) patients are based on clinical experience and investigations in specific patient populations.[11,12,14,16,17,18,19,20] Unfortunately, conflicting data have resulted in a lack of consistency in published guidelines from different sources, which complicates identification of the patient who is most likely to benefit from PN. However, these published reports may serve as resources for development of institution-specific standards.

TABLE 142-1 Indications for Adult PN

1. Inability to absorb nutrients via the GI tract because of one or more of the following:
    a. Massive small bowel resection: Usually patients with less than 100 cm of small bowel distal to the ligament of Treitz without a colon or less than 50 cm of small bowel with an

intact colon

b. Intractable vomiting when adequate EN is not expected for 7–14 days.

c. Severe diarrhea

d. Bowel obstruction

e. GI fistulae: PN is indicated in patients with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN

2. Cancer: Antineoplastic therapy, radiation therapy, or HSCT

a. PN may be used in moderately to severely malnourished patients receiving active anticancer treatment who are not candidates for EN.

b. PN is not routinely indicated for well-nourished or mildly malnourished patients undergoing surgery, chemotherapy, or radiation therapy.

c. PN is unlikely to benefit patients with advanced cancer whose malignancy is unresponsive to treatment. However, use may be appropriate for carefully selected patients who have failed trials of less invasive medical therapies and have good performance status, an estimated life expectancy of longer than 40–60 days, and strong social and financial support.

d. PN is appropriate in patients undergoing HSCT who are malnourished and who are anticipated to be unable to ingest or absorb adequate nutrients for 7–14 days. PN should be discontinued as soon as toxicities have resolved after stem cell engraftment.

3. Pancreatitis: PN may be used in patients with severe pancreatitis with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN. PN should be used when EN exacerbates abdominal pain, ascites, or fistula output.

4. Critical care

a. PN should be used in malnourished patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements as soon as possible after ICU admission and adequate resuscitation.

b. PN should be reserved and initiated only after the first 7 days of hospitalization for previously well-nourished patients.

c. Organ failure (liver, renal, or respiratory): PN should be used in patients with moderate to severe catabolism when EN is contraindicated.

d. Burns: PN should be used in those patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 4–5 days.

5. Perioperative PN
    a. Preoperative: For 5–7 days for patients with moderate to severe malnutrition who are undergoing major GI surgery if the operation can be safely postponed
    b. Postoperative: PN should be used in patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 7–14 days after surgery.
6. Hyperemesis gravidarum: when EN is not tolerated
7. Eating disorders: PN should be considered for patients with anorexia nervosa and severe malnutrition who are unable or unwilling to ingest adequate nutrition.

EN, enteral nutrition; GI, gastrointestinal; HSCT, hematopoietic stem cell transplantation; ICU, intensive care unit; PN, parenteral nutrition; SBS, short-bowel syndrome.

Data from references 11, 14, 15, 19, and 20.

TABLE 142-2 Indications for Pediatric PN

1. When enteral nutrition is unlikely to provide adequate nutritional requirements
    a. Premature infant within 24–48 hours
    b. Other pediatric patients within 5–7 days
2. When the GI tract is not functional or cannot be assessed
    a. Massive small bowel resection resulting in short-bowel syndrome
    b. Neonatal necrotizing enterocolitis
    c. Congenital anomalies of the GI tract
    d. Severe inflammatory bowel disease
    e. Intractable diarrhea or vomiting
    f. Graft vs host disease
    g. After chemotherapy
3. Infants and children requiring extracorporeal membrane oxygenation
4. Organ failure (liver, renal, pulmonary, pancreas) or congenital heart disease when enteral nutrition is contraindicated and the child is catabolic

GI, gastrointestinal; PN, parenteral nutrition.

Data references, 12, 16, 17, 18, 21, and 22.

3 The decision to initiate PN is based on the findings of an assessment performed after a patient demonstrates an inability to meet nutritional needs enterally for an extended time period. This assessment must include an evaluation of the patient's nutrition status, clinical status, age, and potential risks of initiating therapy (eg, infection and other metabolic abnormalities). The appropriate length of time to wait before starting PN therapy depends on patient age and clinical status.[11,12,14,16,17,18,19,20] Adult PN therapy is not an emergent intervention and should not be initiated until the patient is hemodynamically stable.[11] In general, previously well-nourished, clinically stable adults who are not candidates for enteral nutrition, should be considered candidates for PN after 7 to 14 days of suboptimal nutritional intake.[11,14,20] PN should be initiated as soon as possible in severely malnourished critically ill patients in whom EN is not feasible. Supplemental PN should be considered after 7-10 days in critically ill patients in whom greater than 60% of energy and protein requirements cannot be met by the enteral route alone.[11] The most appropriate time to initiate therapy for infants and children varies with age and nutritional status. Because early PN results in enhanced protein accretion and improved growth in extremely low-birth-weight infants, initiation of PN within the first 24 hours of life in preterm neonates has been recommended.[18,21,22] Withholding PN for 2 to 3 days after birth, coupled with slow advancement of nutrient substrate, only appears to deplete limited energy reserves and contribute to growth failure for many neonates.[21] PN should be initiated within 5 to 7 days for other pediatric patients who are unable to meet their nutrient requirements with via the enteral route.[16] Earlier intervention should be considered for term infants (within 2-3 days), critically ill pediatric patients (within 3-5 days), and those with preexisting malnutrition.

Clinical Controversy…

Early enteral nutrition (within 24-48 hours of admission to an intensive care unit) is recommended as the preferred route for nutrition support in critically ill patients. Many clinicians maintain PN should be withheld unless enteral nutrition cannot be achieved within 7 days because of data that associate early PN with negative clinical outcomes. Conversely other clinicians may recommend early supplemental PN to prevent the protein–energy deficit that has been associated with worsening clinical outcomes in some studies.

COMPONENTS OF PARENTERAL NUTRITION

4 PN formulations include IV sources of protein, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives. PN solutions should provide the optimal combination of macro- and micronutrients to provide a patient's specific nutritional requirements. Macronutrients include water, protein, dextrose, and fat (**Table 142-3**). Micronutrients include vitamins, trace elements, and electrolytes. Both macronutrients and micronutrients are necessary for maintenance of normal metabolism. In general, macronutrients are used for energy (dextrose and fat) and as structural substrates (protein and fat). Micronutrients on the other hand support a variety of metabolic activities necessary for cellular homeostasis such as enzymatic reactions, fluid balance, and regulation of

electrophysiologic processes.

TABLE 142-3 Macronutrient Components of PN Solutions

Nutritional Substrate	IV Source	Description
Fluid	Sterile water for injection USP	
Nitrogen	Crystalline amino acids	Contain a balanced profile of essential, semi-essential, and nonessential L-amino acids
	Standard solutions	
	Disease-specific solutions	
	Hepatic encephalopathy	Amino acid profile includes higher BCAA concentrations and lower AAA and methionine concentrations
	Renal failure	Amino acid profile includes higher EAA and histidine concentrations
	Metabolic stress or trauma	Amino acid profile provides standard essential, semi-essential, and nonessential amino acids with higher BCAA concentrations
	Pediatrics	Amino acid profile includes standard essential, semi-essential, and nonessential amino acids with lower methionine, phenylalanine, and glycine concentrations; these solutions also contain taurine, glutamate, and aspartate
Energy		
Carbohydrate	Dextrose	
Fat	Glycerol	Used in ProcalAmine (B. Braun Medical, Inc.)
	IV fat emulsion	Fatty acid source
	LCT emulsions	Soybean
	Mixed fat emulsions	Soybean-Olive Oil
	Alternative fat emulsions (investigational)	SMOF (soybean oil, MCT, olive, and fish oils)
		Olive oil
		Fish oil
		Mixed fat emulsions: MCT-LCT
		MSF (MCT, soybean, and fish oils)

AAA, aromatic amino acids (includes phenylalanine and tyrosine); BCAA, branched-chain amino acids (leucine, isoleucine, and valine); EAA, essential amino acids (leucine, isoleucine, valine, phenylalanine,

tryptophan, methionine, threonine, and lysine); LCT, long-chain triglycerides; MCT, medium-chain triglycerides; MSF, MCT, soybean, and fish oils; PN, parenteral nutrition; SMOF, soybean oil, MCT, olive, and fish oils; USP, United States Pharmacopeia.

Over the past 5 to 7 years, shortages of all PN components have been reported.[3,23] The unavailability of these products has resulted in delays in PN therapy initiation, restricted or limited nutrient dosing, and negative effects on all steps of the PN process that have compromised patient health and safety. Providing safe therapy during PN product shortages can be challenging for PN patients and practitioners.[5] Conservation recommendations and alternative therapy measures may need to be employed to optimize quality of care and avoid patient harm.[3]

Amino Acids

Protein in PN solutions is provided in the form of crystalline amino acids (CAAs), which when oxidized for energy yield 4 cal or approximately 17 J per gram of protein. However, including the caloric contribution from protein when calculating calories provided by the PN regimen is controversial.[24] While sufficient energy substrate should be provided to allow utilization of amino acids for protein synthesis rather than an energy source, oxidation of amino acids for energy has been demonstrated in critically ill patients and is thought to occur because of metabolic derangements seen during severe metabolic stress. Hence, some practice settings may differ in expressing calories provided by a PN regimen as total calories (protein, carbohydrate, and fat calories) or non-protein calories (carbohydrate and fat calories).

Commercially available CAA solutions may be categorized as standard amino acid solutions or modified amino acid solutions. Standard CAA solutions are designed for patients with “normal” organ function and nutritional requirements (see Table 142-3). Although standard CAA solutions differ in the proportion of specific amino acids, they contain a balanced profile of essential, semi-essential, and nonessential L-amino acids. Despite these differences, similar effects on markers of protein use have been reported.[25] The protein concentration, total nitrogen, and electrolyte content may also differ among products. Because the nitrogen concentration of dietary protein is approximately 16%, 6.25 (100 g protein/16 g nitrogen) is commonly accepted as the conversion figure for calculating the nitrogen amount provided by CAA protein. Differences in nitrogen content per gram of amino acids among CAA products may affect calculation of nitrogen amounts infused when determining nitrogen balance.[25,26] The clinical significance of these differences in determining nitrogen balance for routine clinical use is unknown.[26]

Electrolyte composition of standard CAA solutions varies from small, obligatory amounts to the provision of maintenance requirements of most electrolytes for an adult. Electrolytes provided by CAA solutions must be considered when determining a patient’s individual requirements. CAAs are available in several different concentrations, which facilitates compounding of patient-specific PN regimens. Use of highly concentrated products (15%-20% amino acids) is attractive for critically ill patients who typically require fluid restriction but have large protein needs. Modified amino acid solutions are designed for patients who have altered protein requirements, such as those with hepatic encephalopathy, renal failure, and metabolic stress or trauma, as well as for neonates and

pediatric patients (see Table 142-3). These solutions tend to be more expensive than standard CAA solutions. The rationale for and clinical efficacy of modified amino acids in disease-specific PN regimens is also controversial because of inconsistency in clinical outcomes reported in multiple clinical trials.[11,15,19,27]

Several commercially available CAA solutions are designed to provide conditionally essential amino acids, which are considered nonessential during health because they are produced from other amino acids. However, under certain physiologic conditions, such as prematurity or sepsis, these amino acids cannot be synthesized in sufficient quantities.[25] CAA solutions specifically designed for neonates and pediatric patients contain increased amounts of taurine, aspartic acid, and glutamic acid. Other conditionally essential amino acids, such as cysteine, carnitine, and glutamine, are not available in commercial CAA solutions in pharmacologic amounts because they are relatively unstable or poorly soluble.[25]

Clinical Controversy…

Exclusive use of standardized, commercially prepared premixed IV products has been advocated to improve medication safety. However, the American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) has reported that patient safety data do not support the general use of standardized PN formulations across healthcare organizations.

Consequently, PN solutions may need to be modified to provide the desired amount of supplemental conditionally essential amino acids. For example, cysteine is a conditionally essential amino acid for preterm and term infants because of their enzymatic immaturity of the trans-sulfuration pathway. Cysteine may be added to PN solutions at the time of compounding as a supplement to CAA solutions and to enhance calcium and phosphate solubility by decreasing solution pH.[28] Carnitine is a quaternary amine required for long-chain fatty acid transport into the mitochondria for β-oxidation and energy production. Newborns are at risk for carnitine deficiency because of their immature biosynthetic capacity. Decreased plasma carnitine concentrations have been reported in infants and children receiving PN without carnitine.[18] Supplemental carnitine may be added to the PN solution at the time of compounding. Although the benefit of carnitine supplementation in PN has not been clearly identified, positive effects on nutritional markers, including improved fatty acid oxidation, weight gain, and nitrogen balance, have been documented. In general, carnitine supplementation is reserved for neonates expected to receive PN support for 7 days or longer.[18]

Glutamine is the most abundant free amino acid in the body and is an important intermediate for many metabolic processes. Glutamine is reported to have an important role in maintaining intestinal integrity, immune function, and protein synthesis during conditions of metabolic stress.[29] Investigations in humans and animals have reported positive effects on nutritional markers such as nitrogen balance, but others have reported significant improvement in other outcome markers, such as decreased length of hospitalization, incidence of infections, and GI toxicities associated with chemotherapy or radiation.[29] Unfortunately, the best candidate for response to glutamine therapy has not been clearly identified.[29] Use of both intravenous and enteral glutamine in combination with a variety of antioxidant supplements in critically ill adult patients has been associated with increased

mortality.[30] Although an association between increased brain volume and head circumference has been reported in school-aged children, who were premature at birth and received glutamine during the first year of life,[31] the clinical usefulness of glutamine in neonates and infants is not clear.[29,32,33] Plasma glutamine concentrations increase with supplementation, but no beneficial effect on sepsis incidence or outcome, enteral feeding tolerance, necrotizing enterocolitis, growth, or mortality has been reported.[29,32,33] The clinical use of glutamine is further complicated because there is no parenteral glutamine formulation commercially available in the United States. Currently available CAA solutions do not contain glutamine because of poor solubility and instability. Use of parenteral glutamine requires special manufacturing techniques not readily available in many institutional pharmacies.[29] However, parenteral glutamine has been made available from several licensed pharmacies that extemporaneously compound glutamine crystalline powder under sterile conditions either as a separate parenteral solution or as a part of a CAA solution. Recent Food and Drug Administration (FDA) mandated changes in conditions under which a human drug product that has no applicable United States Pharmacopeia (USP) or National Formulary (NF) monograph or is not a component of an FDA-approved drug can be used to compound a prescription medication may create further obstacles to obtaining extemporaneously compounded glutamine-containing PN formulations. The FDA's Pharmacy Compounding Advisory Committee, which provides advice on scientific, technical, and medical issues concerning drug compounding, has recommended to not allow the use of alanyl-L-glutamine in compounding due to insufficient information to fully assess safety related to impurities of the product.[34,35]

Dextrose

The primary energy source in PN solutions is carbohydrate, usually in the form of dextrose monohydrate, hereafter referred to as dextrose which is available in concentrations ranging from 5% to 70%. When oxidized, each gram of dextrose provides 3.4 kcal (14.2 kJ). The appropriate IV dextrose dose depends on the patient's age, estimated caloric requirements, and clinical condition. For example, minimum dextrose requirements for neonates are estimated to be approximately 6 to 8 mg/kg/min and infusion rates should not exceed 14 to 18 mg/kg/min for infants or 4 to 7 mg/kg/min for adults.[18,21,36] The recommended dextrose dose for routine clinical care rarely exceeds 5 mg/kg/min for adolescents and adults.[18,36] Maintaining an age-appropriate dextrose infusion rate is necessary to minimize risk of adverse effects. If the dextrose infusion rate exceeds the glucose oxidation rate, metabolically expensive pathways, such as glycogen repletion and lipid synthesis, are favored, resulting in increased energy expenditure, increased oxygen consumption, and increased carbon dioxide production. Excessive dextrose infusion rates also may contribute to the development of hyperglycemia and an increase in the concentration of biochemical markers indicative of fatty infiltration of the liver.[36,37]

Carbohydrate sources that are not insulin-dependent have been investigated as an alternative to dextrose to improve glycemic control for patients with impaired insulin secretion or activity who require PN. Glycerol, a sugar alcohol, that provides 4.3 kcal/g (18 kJ/g), is the only dextrose alternative commercially available. It is available as an isotonic, 3% solution in combination with 3% amino acids and supplemental electrolytes (ProcalAmine, B. Braun Medical, Irvine, CA). Although the

solution may be peripherally infused, a major disadvantage of this product is the dilute amino acid and carbohydrate concentrations. Most adult patients require up to 3 to 4 L/day of ProcalAmine solution together with IVFE as a caloric source to meet minimum energy requirements.[38] IV glycerol use for catabolic adults is safe and effective, but similar data are not available for infants and children.[39]

Intravenous Fat Emulsion

Intravenous fate emulsion (IVFE) is used as a concentrated source of calories and essential fatty acids. Although commercially available IVFE products have traditionally contained soybean oil (SO) or a combination of SO and safflower oil, IVFE products containing safflower oil are no longer commercially available. However, a new IVFE product containing a mixture of SO and olive oil (OO) was recently approved for use in adults.[40] SO-based IVFE products have been marketed in 10%, 20%, and 30% concentrations while the SO-OO product is only marketed as a 20% emulsion. The 10% SO IVFE products are currently unavailable because of discontinued production or a prolonged manufacturer's stock shortage.[18] Both types of IVFE contain egg phospholipids as an emulsifying agent and glycerol to make the emulsion isotonic. Although the caloric contribution of fat is 9 kcal/g (38 kJ/g), the caloric content of 10% IVFE is 1.1 kcal/mL (4.6 kJ/mL), 2 kcal/mL (8.4 kJ/mL) for the 20% emulsion, and 3 kcal/mL (12.6 kJ/mL) for the 30% emulsion because of the caloric contribution of the egg phospholipid and glycerol.[18] The fatty acid composition of SO IVFEs varies between approximately 44% to 62% linoleic acid and 4% to 11% linolenic acid.[41] While the fatty acid composition of the SO-OO product is approximately 14% to 22% linoleic acid, 0.5% to 4% linolenic acid, 44% to 80% oleic acid, 8% to 19% palmitic acid, and 0.7% to 5% stearic acid.[40] Linolenic acid, an omega-3 fatty acid, and linoleic acid, an omega-6 fatty acid, are both polyunsaturated long-chain triglycerides (LCTs).[41] Palmitic and stearic acids are saturated LCTs while oleic acid is an unsaturated LCT.[41] The concentrated SO IVFEs (20% and 30%) have a lower phospholipid-to-triglyceride ratio compared with 10% SO IVFE.[18,42] Because higher amounts of circulating phospholipids are associated with impaired triglyceride clearance in neonates and infants, 20% SO IVFE is the preferred product for this population. The more concentrated 30% IVFE would be an attractive alternative as well but its use is approved only for the preparation of total nutrient admixture (TNA) formulations which are not recommended for use in neonates and infants.[5,18,42]

SO–based IVFE is effective for treatment or prevention of essential fatty acid deficiency (EFAD) in both adult and pediatric patients. EFAD is the result of a biochemical deficiency of linoleic acid and arachidonic acid, which are considered essential for humans.[43] Linoleic and linolenic acids are important for a variety of functions such as cellular integrity, platelet function, postnatal brain development, and wound healing.[43] Normally, linoleic acid is converted to the tetraene arachidonic acid. When linoleic acid is not present in sufficient amounts, oleic acid is converted to the triene 5,8,11-eicosatrienoic acid, a fatty acid of lesser physiologic integrity, and as a result EFAD develops. EFAD may be prevented by providing 2% to 4% of total calories as linoleic acid and 0.25% to 0.5% of total calories as linolenic acid.[44] This may be achieved for most adult patients by giving approximately 100 g SO IVFE weekly.[36,44] Neonates and infants require a minimum of 0.5 to 1 g/kg

daily.[18,45] The SO-OO product is currently not approved for use in pediatric patients because of its lower linoleic and linolenic acid content and lack of clinical data demonstrating provision of adequate essential fatty acids to prevent or treat EFAD when used in recommended doses.[40]

Plasma IVFE clearance is directly related to gestational age of infants and appears to be influenced by the infusion rate and the patient's clinical status.[18,42,45] The risk of developing hypertriglyceridemia decreases with longer infusion times.[42,44,45] Rapid IVFE infusions are reported to contribute to decreased oxygenation for neonates.[45,46] Adverse pulmonary effects are thought to be caused by polyunsaturated fatty acid (PUFA)–driven prostaglandin production, which results in altered vascular tone. Although the association between IVFE and pulmonary dysfunction is not clear, a boxed warning appears in the FDA product labeling for both SO and SO-OO IVFE that acknowledges deaths in preterm infants associated with pulmonary fat accumulation thought to be related to IVFE infusions.[18,40,47] In addition, data for animals and humans also suggest that rapid infusion of long-chain fatty acid formulations may have a negative impact on immunocompetence by saturating the reticuloendothelial system.[36,48]

As a caloric source, IVFE use may facilitate provision of adequate calories and minimize complications of nutrition therapy such as hyperglycemia, hepatotoxicity, or increased carbon dioxide production.[36] Although the frequency of acute adverse effects is reported to be less than 1% with current formulations, patients receiving their first IVFE dose should be monitored for dyspnea, chest tightness, palpitations, and chills. Headache, nausea, and fever also have been reported and might be associated with a rapid infusion rate. In general, IVFE use is contraindicated for patients with an impaired ability to clear fat emulsion, such as patients with pathologic hyperlipidemia, lipoid nephrosis, and hypertriglyceridemia associated with pancreatitis.[47] Finally patients with an egg allergy should be evaluated carefully for the nature and severity of the reaction before deciding to initiate a fat-based PN regimen.

Commercially available 10% and 20% IVFE products may be administered by either the central or the peripheral route. They may be added directly to the PN solution as a TNA, also referred to as a three-in-one system (lipids, protein, glucose, and additives), or they may be co-infused with the CAA-dextrose solution, commonly referred to as a two-in-one admixture.[44,47] The more concentrated 30% IVFE is only approved for use in the preparation of TNA and is not intended for direct IV administration.

IVFEs with SO as the lipid source have negative effects on immune function as the result of omega-6 PUFA influence on proinflammatory eicosanoid production. These negative effects on immune function have stimulated a search for alternative IVFE sources that provide adequate essential fatty acids but lower amounts of omega-6 FA such as the SO-OO emulsion.[41,48] The SO-OO IVFEs provide essential fatty acids, are a rich source of vitamin E, and appear to have a neutral effect on immune function because of the decreased amount of omega-6 PUFA linoleic acid.[41] Medium-chain triglycerides (MCTs) may offer several advantages, especially for critically ill patients. MCTs are hydrolyzed and cleared more rapidly than LCTs, and they do not accumulate in the liver. In addition, MCTs do not require carnitine for entrance into mitochondria for oxidation. However, MCTs are not a

source of essential fatty acids. Subsequent studies of IV MCT-LCT mixtures in a number of patients demonstrate safety and efficacy comparable with standard LCT emulsions.[41,48]

Several alternative IVFE products are not currently available in the United States. However, one mixed IVFE product available in Europe that includes soybean oil, MCT, olive oil and fish oil was recently FDA-approved for use in adults. Other IVFE that are available outside the United States include a fish oil-based emulsion, and a soybean, MCT, and fish oil combination (Table 142-3).[41,48] (see Table 142-3). Fish oil–based IVFE contain predominantly omega-3 PUFAs, which are metabolized to cytokine mediators that may be less inflammatory and immunosuppressive than those derived from omega-6 PUFAs. The clinical effect of IVFE administration on immune function, as well as on patient morbidity and mortality, is not clear.[41,48] However, investigations of enteral solutions with a higher concentration of omega-3 PUFAs have reported decreased infections and improvement of in vitro immunologic indices in critically ill patients.[43,49] Recent evidence suggests that SO–based IVFE, which contains phytosterols and predominantly omega-6 PUFAs, may play a greater role in the development of PN-associated liver disease (PNALD).[50] Investigations of fish oil–based IVFE have reported improvement in or reversal of PNALD.[41,50] The SO-OO emulsion contains phytosterols as well, but the effect on development of PNALD is not known.

Clinical Controversy…

The association between SO IVFE and PNALD has stimulated modifications to standard clinical practice, including SO IVFE dose restriction and / or the replacement of SO IVFE with fish oil–based IVFE. The risk for developing EFAD as a result of decreased LCT when reducing or eliminating SO IVFE from the parenteral diet is controversial.

Although IVFE products remain the most common source of parenteral fat, a number of drugs have been introduced that contain lipid either as a vehicle for delivery or as a portion of the drug formulation. Propofol, an IV anesthetic, is delivered in a SO-in-water emulsion that has essentially the same composition and caloric concentration as 10% IVFE. This agent is used commonly for continuous sedation of mechanically ventilated patients and should be considered a potentially significant source of calories that may require adjustment of a patient's nutrition regimen.[51] Clevidipine is an injectable calcium channel blocker that contains 20% IVFE as a vehicle that may be a potentially clinically significant source of IV fat when used as a continuous infusion for multiple days of therapy.[52] The antifungal amphotericin B is available in several lipid-containing combinations such as liposomal and lipid complex formulations. The caloric contribution from these products when used in standard doses generally is small and is not clinically relevant.

Vitamins

The Nutrition Advisory Group of the American Medical Association (NAG-AMA) recommended in 1975 the daily parenteral supplementation of 13 essential (four fat-soluble and nine water-soluble) vitamins for pediatric and adult patients based on requirements for healthy people.[53]

Since these original recommendations, the NAG-AMA has revised the guidelines for children to

primarily reflect changes for preterm infants requiring PN.[53] The FDA also mandated in 2000 changes in adult parenteral vitamin formulations (inclusion of vitamin K and higher doses of vitamins B_1, B_6, and C).[53]

The amount of vitamin K supplementation in parenteral multivitamin formulations has been debated. The NAG-AMA recommendation for vitamin K for adults is 2 to 4 mg weekly, while other practitioners recommend larger doses of 0.5 to 1 mg/day or 5 to 10 mg weekly.[44] Vitamin K was not included in early multivitamin formulations due to the potential for drug-nutrient interactions in patients receiving anticoagulants, and the amount mandated to be included in 2000 (150 mcg/day) was considerably lower than other recommended requirements. However, an investigation of patients receiving long-term IVFE-containing PN with vitamin K–free parenteral multivitamins at home suggested that supplemental vitamin K may not be necessary to maintain normal prothrombin times and plasma vitamin K concentrations.[54] SO used in IVFEs is a natural source of phylloquinone (vitamin K_1). However, the vitamin K concentration is dependent on the SO concentration in the IVFE.[54,55,56] Mean concentrations of 30.9 and 67.5 mcg/100 mL were reported for 10% and 20% Intralipid (Baxter Healthcare Corporation, Deerfield, IL), a SO–based IVFE. The bioavailability of vitamin K from IVFEs is unknown. Although hospitalized patients who received no additional vitamin K supplementation during short-term PN that included a low vitamin K-containing IVFE experienced minimal effects on international normalized ratio, supplemental vitamin K may be given intramuscularly or subcutaneously or added to the PN solution if needed.[55] Current recommendations suggest supplemental vitamin K is unnecessary when a vitamin K-containing multiple-vitamin product is used.[44]

The 2012 A.S.P.E.N. recommendations advocate for the continued availability of multivitamin products with and without vitamin K so that clinicians have the ability to withhold vitamin K supplementation in patients receiving warfarin therapy. Most adult parenteral multiple-vitamin products which are available commercially contain vitamin K. MVI-12, multivitamin infusion without vitamin K is available from Hospira, Inc. Lake Forest, IL. Two parenteral multiple-vitamin products are commercially available for use for pediatric patients. MVI-Pediatric (Hospira Inc.) and Infuvite Pediatric (Baxter Healthcare Corporation) are formulated to meet the revised NAG-AMA guidelines for infants weighing less than 1 kg (2.2 lb) and children up to 11 years. However, there are no commercially available injectable multivitamin products designed to specifically meet the unique requirements of premature infants, including higher vitamin A and lower doses of vitamins B_1, B_2, B_6, and B_{12}.

Vitamin requirements may be altered in malnutrition and other specific disease states or with certain drug therapies. Individual and combination products are available to provide additional or tailored supplementation, which may be necessary to prevent development of vitamin toxicities or deficiencies caused by altered metabolism or drug therapy.

The 2012 A.S.P.E.N. recommendations question whether the vitamin D content of parenteral multivitamins is adequate to meet current Recommended Dietary Allowances (RDA) and advocate for the addition of a parenteral vitamin D product for PN-dependent patients who are unresponsive to additional enteral vitamin D supplementation.[53] In addition, the recommendations support the

continued production of adult injectable multivitamin products with and without vitamin K and for the supplementation of carnitine (2-5 mg/kg/day) in neonatal PN and choline in all patients receiving PN.[53]

Trace Elements

Many trace elements are an important part of metalloenzymes and function as cofactors in a variety of regulatory metabolic pathways.[57] Although 17 trace elements have demonstrated biologic importance, clear deficiency syndromes in humans have been described only for cobalt (as vitamin B_{12}), copper, iodine, iron, and zinc.[57,58,59] In 1979, the NAG-AMA recommended chromium, copper, manganese, and zinc supplementation for patients receiving PN.[53,57] Recommendations followed in 1984 to also supplement with selenium.[53,57] Although a clear deficiency syndrome for manganese has not been reported in humans, the NAG-AMA considered manganese essential based on case reports of patients receiving PN with metabolic complications that corrected after manganese supplementation. Reports of deficiency syndromes associated with selenium and molybdenum suggest that they also may be essential.[57,58] Although iodine deficiency has not been reported for patients receiving short-term PN, it has been observed in patients receiving long-term PN and may be related to the use of chlorhexidine for central-line care instead of povidone–iodine.[60]

Injectable trace elements are available as single-trace element solutions and as multiple-trace element combinations. The use of single-entity injectable products allows for individualization of trace mineral supplementation of chromium, copper, iodine, manganese, selenium, and zinc. Recent shortages have threatened the supply of both the combination and single-entity products.[3] Most combination products for adults provide the daily requirements for the trace elements considered essential by the NAG-AMA (ie, chromium, copper, manganese, selenium, and zinc).[18] While combination products approved for use in the United States for neonates and pediatric patients have contained only chromium, copper, manganese, and zinc, additional options are now available.[18] (**Table 142-4**) In response to widespread injectable trace element product shortages, the FDA implemented in 2013 a temporary enforcement discretion to allow the importation of alternative injectable trace element products.[61] A combination product for adults provides fluoride, iodine, molybdenum, and iron, in addition to the standard five trace elements included in US adult products (chromium, copper, manganese, selenium, zinc).[61] The pediatric combination product content differs from the US products in that it lacks chromium and includes selenium, fluoride, and iodine.[61] A single-entity injectable zinc product has also recently been made available.[62] Clinicians should be cautious when transitioning between products to ensure correct doses are being ordered, compounded, and administered to patients because the United States and imported products vary not only by trace element content but also by salt form and trace element doses per unit.[61] In addition, potential interactions resulting in stability or compatibility problems should be considered because frequently information for use of imported injectable products with US products is limited.

TABLE 142-4 Imported Sterile Injectable Parenteral Nutrition Products[61,62,63]

Imported Product	Content

(Manufacturer)	
Sodium Glycerophosphate Injection Glycophos™ (Fresenius Kabi, USA LLC)	- Contains 1 mmol phosphate and 2 mEq Na per mL compared to US products which contain 3 mmol phosphate and 4 mEq Na per mL.
Adult Trace Elements Addamel™ N (Fresenius Kabi, USA LLC)	- Copper contains 9 trace elements: zinc chloride chloride, manganese chloride, chromic chloride, sodium selenite, ferric chloride, sodium molybdate, potassium iodide, and sodium fluoride.
Pediatric Trace Elements Peditrace™ (Fresenius Kabi, USA LLC)	- Contains 6 trace elements: zinc chloride, copper chloride, manganese chloride, sodium selenite, potassium iodide, and sodium fluoride.
Zinc Injectable Zinc gluconate trihydrate (Aguettant)	- Active substance is equivalent to 1 mg of elemental zinc per mL.

Requirements for trace elements also vary on the basis of the patient's clinical condition. For example, higher doses of supplemental zinc likely are necessary for patients with high-output ostomies or diarrhea because the GI tract is the predominant excretion route for zinc. Whereas manganese and copper are excreted through the biliary tract, chromium, molybdenum, and selenium are excreted renally. Hence, these trace elements should be restricted or withheld from PN solutions for patients with cholestatic liver disease and renal failure, respectively.

A.S.P.E.N. recommended formulation changes to the available injectable multiple-trace element preparations for PN patients.[53] The recommendations support overall decreased contamination of trace elements in large- and small-volume PN products.[53] The recommendations advocate for decreased copper and manganese, no (or decreased) chromium, and inclusion and increased dose of selenium in all injectable adult multiple-trace products.[53] The recommendations also support products with no chromium, decreased manganese, and the inclusion of selenium in all injectable pediatric multiple-trace products.[53]

Electrolytes

Electrolytes such as sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate are necessary PN components for the maintenance of many cellular functions. Electrolytes may be given to maintain normal serum concentrations or to correct deficits. Patients who have "normal" organ function and relatively normal serum concentrations of any electrolyte should receive "normal" maintenance electrolyte doses when PN is initiated and daily thereafter. Specific electrolyte requirements vary according to the patient's age, disease state, organ function, previous and current drug therapy, nutrition status, and extrarenal losses. Electrolytes are available commercially as single- and multiple-nutrient solutions. Multiple-electrolyte solutions are useful for stable patients with

normal organ function who are receiving PN. Concentrated multiple-electrolyte solutions designed for addition to PN solutions generally contain only sodium, potassium, calcium, and magnesium. Phosphorus must be added as a separate additive. In response to a severe injectable phosphorus shortage, the FDA implemented a temporary enforcement discretion to allow importation of sodium glycerophosphate injection.[63] (see Table 142-4) This injectable organic phosphorus product has been reported to be more soluble with calcium chloride and calcium gluconate in PN solutions. However, widely used published calcium-phosphorus solubility data is only available for inorganic sodium phosphate with PN products available in the United States which makes use difficult with ACDs and compounding software. Further information regarding metabolism and requirements of vitamins, trace elements, and electrolytes is given elsewhere.[44,64]

DESIGNING A PARENTERAL NUTRITION REGIMEN

5 Several factors, including the patient's venous access, fluid status, and macronutrient and micronutrient requirements, are important considerations when designing the PN regimen. A patient's venous access and fluid status determines the maximum PN osmolar concentration which will impact the nutrient amount that may be provided. PN solutions may be administered by central or peripheral venous access. The patient's clinical condition determines which route is most appropriate.

Parenteral nutrition formulations may be provided as a two-in-one admixture that contains dextrose, CAA, and other necessary micronutrients or as a three-in-one admixture or TNA that contains dextrose, CAA, and IVFE, as well as other necessary micronutrients. Use of TNA solutions offers several potential advantages, including reduced inventory (infusion pumps, tubing, and other related supplies), decreased time for compounding and administration, a potential decrease in manipulations of the infusion line (which should correspond with a decreased risk of catheter contamination), and ease of delivery and storage for patients receiving home PN.[65] Potential disadvantages include increased risk of infections and stability and compatibility concerns. For example, the stability of TNA admixtures is less predictable than that of two-in-one admixtures, which makes their use less desirable in some patient populations such as neonates and infants.[44,66]

Routes of Parenteral Nutrition Administration

Peripheral Route

Peripheral parenteral nutrition (PPN) is an option for mild to moderately stressed patients for whom central access is unavailable or undesirable and function of their GI tract is expected to return within 10 to 14 days.[20,67] Potential PPN candidates should not be fluid-restricted or require large nutrient amounts. Lower concentrations of amino acids (3%-5% final concentration), dextrose (5%-10% final concentration), and micronutrients compared with central parenteral nutrition (CPN) must be used for peripheral administration. Because PPN solutions are relatively dilute, larger volumes are usually necessary to provide nutrient requirements. Additionally, many patients who receive PPN likely will require IVFE to achieve the desired caloric intake at levels consistent with CPN regimens. The primary

advantages of PPN include a lower risk of infectious, metabolic, and technical complications.[67] Patients who have poor venous access as the result of multiple courses of chemotherapy, malnutrition, and illness of long duration which has required multiple venous accesses for fluid and medication administration as well as premature infants and the elderly are likely to be poor candidates for PPN. PPN use is also limited by relatively poor peripheral vein tolerance to hypertonic solutions. Thrombophlebitis is a commonly reported complication for patients receiving PPN.[66] Although the risk of phlebitis is greater with solution osmolarities greater than 600 to 900 mOsm/L, peripherally administered TNA with much higher osmolarities to adults has been associated with low infusion-site complications in some centers.[66,67] Efforts to minimize development of phlebitis or infiltration sequelae for patients receiving PPN include addition of IVFE as a possible venous lumen protectant, subtherapeutic heparin doses (0.5-1 unit/mL) to prevent thrombus formation, or small doses of hydrocortisone (5 mg/L) to minimize access site inflammation.[66,67] However, the coinfusion of IVFE with PPN (ie, not provided as a TNA) has not been shown to reduce phlebitis. In addition, heparin has not been shown to reduce catheter-related thrombosis and is not compatible for use in TNAs.[66] Midline catheter use may offer some advantage and has been associated with a reduced risk of thrombophlebitis.[68] Although these catheters are not central venous access devices, they are longer and infuse into larger venous vessels that may dilute the PPN solution to a more tolerable osmolarity. The osmolarity of a PN solution may be estimated by using the guidelines for osmolarities of selected PN components in **Table 142-5**.

TABLE 142-5 Osmolarities of Selected Parenteral Nutrients

Nutrient	Osmolarity
Amino acid	100 mOsm/%
Dextrose	50 mOsm/%
Lipid emulsion (20%)	1.3–1.5 mOsm/g
Sodium (acetate, chloride)	2 mOsm/mEq
Sodium phosphate	3 mOsm/mEq sodium
Potassium (acetate, chloride)	2 mOsm/mEq
Potassium phosphate	1.7–2.7 mOsm/mEq potassium
Magnesium sulfate	1 mOsm/mEq
Calcium gluconate	1.4 mOsm/mEq

Central Route

CPN is the preferred route for PN delivery and is used predominantly for patients who require PN for periods of more than 7 to 14 days during hospitalization or indefinitely at home.[20,44,69] These patients may have large nutrient requirements; poor peripheral venous access; or fluctuating fluid requirements, such as metabolically stressed patients with extensive surgery, trauma, sepsis, multiple-organ failure, or malignancy. CPN solutions are highly concentrated hypertonic solutions that must be administered through a large central vein. Unlike peripheral veins, central veins have a higher blood flow, which quickly dilutes the hypertonic solutions. Disadvantages of CPN include risks

associated with catheter insertion, routine catheter use, and care of the access site. Relative to peripheral venous access, central venous catheter (CVC) access is associated with a greater potential for infection. In addition, the risk of more serious catheter-induced trauma and related sequelae and other serious technical or mechanical problems is are greater than that with peripheral access.

The choice of central venous access site depends on a number of factors, including the patient's age and anatomy. CVCs vary in composition, lumen size, number of injection ports, and other features that affect ease or convenience of care and maintenance. CVCs for short-term use for adults are commonly inserted percutaneously into the subclavian vein and advanced so that the tip is at the superior vena cava.[68] If this approach is not possible, the internal jugular vein can be used. Frequently, short-term central venous access is obtained for critically ill neonates via a catheter placed in the umbilical vein. Other sites for central venous access in infants and older children are similar to those in adults. When therapy is expected to last longer than 4 weeks, the catheter usually is tunneled subcutaneously before entering the central vessel, secured initially with retaining sutures, and anchored in place with a felt cuff that promotes subcutaneous fibrotic tissue growth around the catheter. The injection port may remain external or may be concealed entirely beneath the skin. Implanted CVCs have a larger port or reservoir that is surgically placed beneath the skin surface and anchored in the chest wall muscle. Peripherally inserted central catheters (PICCs) are venous access devices that are inserted into a peripheral vein (basilic, cephalic, or brachial) and advanced so that the tip is at the superior vena cava.[65] PICCs are increasingly used for both short- and long-term central venous access in acute or home care settings because of ease and economy of bedside placement.[44,69]

Constructing a Parenteral Nutrition Regimen

After the route of delivery is chosen, the components of the PN regimen are determined based on the patient's nutritional assessment. Although not recommended due to increased potential for errors, some healthcare systems may require the entire PN order to be written in individual components and additives on traditional paper order forms without the use of a standard order form. Standardized electronic PN orders suitable for computerized prescriber order entry (CPOE) have been recommended for all patients to minimize risk of errors associated with the ordering process.[5,44] Standardized order forms or clinical decision support within electronic PN ordering systems promote education of practitioners by providing brief guidelines for initiating PN and foster cost-efficient nutrition support by minimizing errors in ordering, compounding, and administration.[5,44,66] Standardized order forms also may include options for ordering certain related procedures, laboratory tests, protocols for patient management, or consultations with other medical services related to the patient's nutrition support.

Adult Parenteral Nutrition Solutions

6 In general, there are two methods for ordering adult PN. The "standard formula approach" offers a variety of admixtures with a fixed nonprotein-calorie-to-nitrogen ratio. This method usually includes different formulas for mild to moderately stressed patients, and those who have kidney or

liver failure or are fluid-restricted. Because the nonprotein-calorie-to-nitrogen ratio is fixed, the daily amount of nutrient delivered depends solely on the volume infused. Standard institutional PN formulations may be compounded; however, standardized commercial PN products or "premixed" solutions are available from several manufacturers.[70] A standard institutional formula may promote clinician prescribing of a complete, balanced formulation and promote consistent provision of stable and compatible admixtures. However, efficiencies associated with use of the standard formula approach may be hindered if there is a frequent need to modify the PN formulation. Finally, standard PN formulations may be difficult to use in complicated patients, such as neonatal or pediatric patients, and those with severe malnutrition, organ failure, glucose intolerance, large GI losses, or critical illness.[70]

The "individualized formula approach" permits compounding of patient-specific admixtures. Compounding of the PN admixture is limited only by the concentrations of stock solutions and stability of the additives. The nutrient amount delivered depends on the daily volume of the PN solution infused and the nutrient amounts in the PN solution. The total daily amount of PN solution may be prepared in multiple bags or more cost-effectively in a single container.[44]

Traditionally, adult PN formulations have been ordered by expressing the final concentrations of each component in the solution. For example, CAA and dextrose are ordered commonly in final percentage, electrolytes in milliequivalents in milliequivalents (or millimoles) per liter, and per liter, and other additives in amount (milliliters or units) per day. This inconsistency may promote confusion and misinterpretation of PN admixture contents that may result in harm, especially when patients are transferred between health system environments. To ensure that PN labels in all health system environments clearly and accurately reflect the PN admixture contents, guidelines for standardized adult PN labeling have been recommended.[5,44] In addition to including a variety of other information on the label such as dosing weight and administration route, the guidelines recommend expressing PN ingredients in amounts per daily volume, which minimizes the need for pharmaceutical calculations to determine the nutrient value of the admixture. Commercially available computer software for calculating PN formulations include the recommended A.S.P.E.N. labeling guidelines (Baxter Healthcare, Deerfield, Il.; B. Braun Medical Inc., Bethlehem, PA)[5,44] Pharmaceutical calculations of a an adult TNA PN regimen are briefly reviewed (**Fig. 142-1**).

FIGURE 142-1

Calculation of an adult PN regimen. To convert to energy units of kilojoules (kJ) multiply values with kilocalories as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kilojoules (kJ, kJ/mL, kJ/kg, kJ/g). (CAA, crystalline amino acids; IVFE, intravenous fat emulsion; PN, parenteral nutrition; TNA, total nutrient admixture.)

Calculation of an Adult PN Regimen

Patient case: A patient's daily nutritional requirements have been estimated to be 105 g protein and 2,200 total kcal. The patient has central venous access and reports no history of diabetes, hyperlipidemia, or egg allergy. The patient is not fluid-restricted. The PN formulation will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a TNA. Determine the total PN volume and administration rate by calculating the macronutrient solution volumes required to provide the desired daily nutrients. The PN products used for this regimen are 10% CAA, 70% dextrose, and 30% IVFE.

1. Determine the daily IVFE calories and volume.
   - 2,200 kcal/day × 30%–40% of total calories as fat = 660 – 880 kcal/day
   - Choose 660 kcal to minimize IVFE calories; calculate 30% IVFE volume

     660 kcal ÷ 3 cal/mL 30% IVFE = X mL X = 220 mL 30% IVFE

   - Calculate IVFE gram amount
     30 g/100 mL = X g/220 mL 30% IVFE X = 66 g IVFE
2. Determine the appropriate volume of 70% dextrose to deliver the desired dextrose calories
   - Dextrose calories = Total kcal – IVFE kcal – Protein kcal
     = 2,200 kcal – 660 kcal IVFE – (4 kcal × 105 g CAA) = 1,120 kcal
   - Calculate required dextrose (grams):

     1,120 kcal ÷ 3.4 kcal/g dextrose = 329 g dextrose

   - Determine 70% dextrose volume
     70 g/100 mL = 329 g/X mL 70% dextrose; X = 470 mL 70% dextrose
2. Determine the appropriate volume of 10% CAA
   10 g/100 mL = 105 g/X mL 10% CAA X = 1,050 mL 10% CAA
3. Determine the TNA PN volume and administration rate
   - Calculate CAA/dextrose/IVFE volume:
     470 mL 70% dextrose + 1,050 mL 10% CAA + 220 mL 30% IVFE = 1,740 mL
   - Add 100-200 mL for additives:
     Total TNA volume = approximately 1,840-1,940 mL/day
   - Calculate the administration rate:
     1,840 to 1,940 mL/day ÷ 24 h = 77 to 81 mL/h; round up to 80 to 85 mL/h
4. Choose final TNA regimen and determine final concentrations of CAA, dextrose, and IVFE
   - Final TNA regimen
     105 g CAA/329 g dextrose/66 g IVFE in 1,920 mL/d to infuse at 80 mL/h
   - Calculate final concentrations of CAA, dextrose, and IVFE
     - 105 g CAA/1,920 mL = X g/100 mL X = 5.5% CAA
     - 329 g dextrose/1,920 mL = X g/100 mL X = 17.1% dextrose
     - 66 g IVFE/1,920 mL = X g/100 mL X = 3.4% IVFE

Several guidelines are available to help simplify calculation of a PN regimen after a patient's nutritional requirements have been decided. For example, adult patients receiving only PN therapy may need larger volumes of fluid to provide maintenance requirements and replace extrarenal losses. However, patients requiring other IV drug therapy may receive adequate fluid from an additional IV maintenance solution (eg, 0.45% NaCl in 5% dextrose) or co-infused medications (or both). Depending on individual institutional practices, maximally concentrating the PN admixture and using an inexpensive maintenance fluid to manage hydration may provide a cost-effective regimen that requires fewer adjustments. Another guideline that may be helpful in designing a PN regimen is to allow a volume of approximately 100 to 150 mL/L of base solution (approximately 200-300 mL/day) for electrolytes and other additives. PN regimens for patients who require very small amounts of additives, such as patients with kidney failure, may need further concentration.

Pediatric Parenteral Nutrition Solutions

Pediatric PN admixtures are typically ordered using an individualized approach because current safe clinical practice guidelines recommend nutrient intakes based on the patient's weight.[5,44] To simplify pediatric PN ordering, many institutions use a pediatric-specific PN order form that expresses daily

nutrient amount based on weight. For example, protein and fat are ordered as grams per kilogram per day, dextrose as milligrams per kilogram per minute, and electrolytes as milliequivalents per kilogram per day. However, some institutions may order macronutrients by expressing the final concentration of each component in the solution. Current safe practice guidelines recommend ordering all PN ingredients based on weight as "amount per kilogram per day."[5,44] The PN bag label should accurately reflect the weight-based order as well. Calculations for determining a pediatric PN admixture are reviewed to illustrate fundamental concepts for ordering pediatric PN formulations (**Fig. 142-2**). Additional features of the pediatric PN label include the dosing weight, administration date and time, expiration date, infusion rate, and duration of infusion. Because infants and children generally receive daily maintenance fluid from the PN regimen, supplemental IV solutions are rarely needed. Pediatric PN may be provided as a two-in-one admixture or TNA. However, the TNA system is not recommended for compounding neonatal and infant PN because of IVFE instability with the often needed higher calcium and phosphorus concentrations.[44,66] The IVFE labeling guidelines for pediatric PN are similar to adult IVFE labeling recommendations.

FIGURE 142-2

Calculation of a pediatric PN regimen. To convert to energy units of kilojoules, multiply values with kilocalories as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kilojoules (kJ, kJ/mL, kJ/kg, kJ/g). (CAA, crystalline amino acids; IVFE, intravenous fat emulsion.)

Calculation of a Pediatric PN Regimen

The nutrition requirements for a 2-week-old preterm neonate (28 weeks gestation; weight 1.2 kg) have been estimated to be 3.5 g/kg/day protein, 3 g/kg/day IVFE, 100 nonprotein kcal/kg/day, and 150 mL/kg/day fluid. The neonate has central access and no prior history of hyperlipidemia or egg allergy. The PN regimen will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a 2-in-1 solution with 20% IVFE co-infused into the PN infusion line. Determine the macronutrient calculations to deliver this neonate's nutrition goals; 10% pediatric CAA and 70% dextrose stock solutions will be used to compound the solution.

1. Determine the goal daily IVFE amount, volume, and administration rate
   - 3 g/kg/day IVFE × 1.2 kg = 3.6 g
   - Calculate 20% IVFE volume
     - 20 g/100 mL = 3.6 g/X mL
     - X = 18 mL/day of 20% IVFE (15 mL/kg/day)
   - Calculate the IVFE administration rate:
     - 18 mL 20% IVFE ÷ 24 hours = 0.75 mL/h (rate may need to be rounded up to 0.8 mL/h or down to 0.7 mL/h depending on precision capability of infusion pump)
2. Determine the goal 2-in-1 PN volume and administration rate
   - Total volume based on maintenance fluid requirements
     - 150 mL/kg/day (estimated fluid goal) – 15 mL/kg/day (20% IVFE) = 135 mL/kg/day for PN volume
     - 135 mL/kg/day × 1.2 kg = 162 mL/day
   - PN infusion rate is 162 mL/day ÷ 24 hours = 6.75 mL/h (rate may need to be rounded up to 6.8 mL/h or down to 6.7 mL/h depending on precision capability of infusion pump)
3. Determine the daily protein amount and the corresponding 10% CAA volume
   - Calculate the goal protein amount
     - 3.5 g/kg/day × 1.2 kg = 4.2 g/day
   - Calculate the 10% pediatric CAA stock solution volume
     - 10 g/100 mL = 4.2 g/X mL 10% pediatric CAA
     - X = 42 mL 10% pediatric CAA
4. Determine the daily dextrose amount, corresponding 70% dextrose volume, and final dextrose concentration in the 2-in-1 PN solution
   - Goal is to provide approximately 14 mg/kg/min dextrose
     - 14 mg x 1.2 kg × 1,440 minutes/day ÷ 1,000 mg/g = 24.2 g dextrose
   - Calculate the 70% dextrose volume
     - 70 g/100 mL = 24.2 g/X mL 70% dextrose
     - X = 34.6 mL 70% dextrose
   - Calculate the final dextrose concentration of the PN solution
     - 24.2 g dextrose/162 mL = X g/100 mL
     - X = 14.9% dextrose (round up to 15% dextrose final concentration)
     - 162 mL × 15% dextrose = 162 × 15 g/100 mL = 24.3 g dextrose
5. Determine the available volume for additives
   - 162 mL – 42 mL (10% pediatric CAA) – 34.6 mL (70% dextrose) = 85.4 mL
   - Depending on volume needed for additives, sterile water may be necessary to add to formulation to make final total volume of 162 mL
6. Determine the final PN regimen and provided nutrient amounts
   - Final PN regimen
     - 3.5 g/kg/day pediatric CAA and 15% dextrose to infuse at 6.75 mL/h
     - 3 g/kg/day (or 18 mL) 20% IVFE to infuse at 0.75 mL/h
   - Macronutrient calories

Dextrose:	24.3 g × 3.4 kcal/g	=	82.6 kcal
Protein:	4.2 g × 4 kcal/g	=	16.8 kcal
20% IVFE	18 mL × 2 kcal/mL	=	36 kcal
Total kcal (kcal/kg):			135.4 kcal (113 kcal/kg)
Nonprotein kcal (kcal/kg):			118.6 kcal (99 kcal/kg)

Administration Techniques

PN admixtures should be administered with an infusion pump. The IV administration line for CAA-dextrose solutions should include a 0.22-micron inline filter to remove particulate matter, air, and any microorganisms that may be present in the solution. IVFE's may be administered separately from the CAA-dextrose solution by co-infusion into the PN line. A port beyond the inline filter must be used because the average size of IVFE particles is approximately 0.5 microns.[5,44] However, co-infused IVFE should also be filtered with a 1.2 micron filter.[47] The FDA recommends use of a 1.2-micron filter with TNA solutions, which may be effective in preventing catheter occlusion caused by precipitates or lipid aggregates.[5,44] This filter size is also reported to remove *Candida albicans*.

INITIATING AND ADVANCING THE PARENTERAL NUTRITION

INFUSION

Adult Parenteral Nutrition

The patient's nutrition status, current clinical status, history of glucose tolerance, and dextrose concentration in the formula will dictate the infusion rate at which the adult PN solution should be initiated. Stable patients with normal organ function and stable baseline serum glucose concentrations have demonstrated minimal effect on serum glucose concentrations when PN is abruptly initiated or discontinued.[5,71] However, another approach is to begin the PN infusion and increase the rate gradually over 12 to 24 hours to the desired rate. The infusion rate may likewise be reduced in a stepwise fashion, such as decreasing the rate by 50% for 1 hour before discontinuation.[5,71] This approach should prevent development of hyperglycemia and rebound hypoglycemia, respectively. Alternatively, the PN regimen may be initiated at the goal infusion rate but with a hypocaloric dextrose dose. The dextrose dose can be increased daily to the goal based on patient response. Tapered initiation and cessation should be considered for patients receiving intermittent subcutaneous regular insulin; patients with severe kidney or liver disease; and patients with other disease states that have an increased risk for development of hyperglycemia or hypoglycemia, such as severe diabetes or pancreatic malignancy.

Although the IVFE dose should not exceed 2.5 g/kg per day or 60% of total daily calories, lower doses of 1 g/kg per day not to exceed 30% of calories have been recommended to minimize negative effects associated with long-chain fatty acids.[44] Manufacturer's information recommends IVFE infusion over 4 to 8 hours for adults.[47] However, co-infusion over 12 hours as a separate infusion with 2-in-1 admixtures and infusion over no longer than 24 hours in a TNA formulation appears to be the best clinical strategy to promote IVFE clearance and minimize risk of negative effects on infection control and pulmonary and immune function.[5,44]

The manufacturer's guidelines recommend initiating IVFE for adults with a test dose of 0.5 to 1 mL/min for the first 15 to 30 minutes because of the potential for an immediate hypersensitivity reaction.[47] For most patients, this is probably not necessary because of the relatively low incidence and benign nature of acute adverse reactions. In addition, infusion over 12 to 24 hours eliminates the need for a test dose because the infusion rate is within the range of the recommended test dose rates. Appropriate electrolytes should be provided to patients with normal organ function based on standard nutrient ranges.[44] Adjustments may be necessary depending on the patient's clinical condition. Adults and children older than 11 years should receive daily amounts of trace elements and an adult vitamin formulation.

Pediatric Parenteral Nutrition

Pediatric PN solutions are typically initiated with a volume calculated to provide the patient's daily maintenance fluid requirements on the first day of therapy. Individual nutrient substrates are then advanced daily as tolerated with the goal PN regimen generally being achieved by day 3 of therapy. However, the PN formulation should be initiated with the goal of achieving the desired protein dose

on day one. The initial dextrose dose for older infants and children is based on their previous glucose tolerance. Although practices may vary, one approach is to start with 10% dextrose and advance the concentration in 5% increments daily, as tolerated, to goals of 10 to 14 mg/kg/min in infants, 8 to 10 mg/kg/min in children, or 5 to 6 mg/kg/min in adolescents.[18] Initial dextrose doses for premature infants should approximate fetal nutrient delivery rates of 5 to 6 mg/kg/min. Frequently, this results in a final PN dextrose concentration of 5% to 10%. The dextrose concentration for the neonatal PN should be advanced daily by 1% to 2.5% or by 2 to 4 mg/kg/min increments to a goal of 10 to 14 mg/kg/min (maximum, 14-18 mg/kg/min).[18] IVFE is usually initiated at 0.5 g/kg/day for neonates and 0.5 to 1 g/kg/day for infants and children and increased daily by 0.5 to 1 g/kg/day. Incremental increases of IVFE dose allow daily serum triglyceride evaluation and early detection of those with impaired fat clearance. The IVFE dose should not exceed 60% of total daily calories for neonates and 30% of total calories for children, and the maximum IVFE dose should not exceed 3 g/kg/day (approximately 30 kcal/kg/day [126 kJ/kg/day]) for infants and 2.5 g/kg/day for children.[18] The best clinical strategy for minimizing the risk of adverse effects associated with IVFE administration and promoting IVFE clearance is to infuse IVFE over 20 to 24 hours or at a rate of no more than 0.15 g/kg/h.[18,45,66]

IV electrolytes, vitamins, and trace elements should be initiated on the first day of therapy and continued as a daily component of the PN solution.[44] Children younger than 11 years should receive a vitamin product formulated for pediatric patients. Two multivitamin dosing schemas have been suggested for infants and children.[44] One method recommends 2 mL/kg/day for infants weighing less than 2.5 kg (less than 5.5 lb) and 5 mL/day for infants and children weighing 2.5 kg (5.5 lb) or greater. The other suggests 30% of a vial (1.5 mL/day) for infants weighing less than 1 kg (less than 2.2 lb), 65% of a vial (3.25 mL/day) for infants weighing 1 to 3 kg (2.2-6.6 lb), and 100% of the vial (5 mL/day) for children weighing more than 3 kg (6.6 lb) (up to 11 years of age). Adult injectable vitamin products should not be used for infants because of potential neurotoxicity from accumulation of polysorbate and propylene glycol preservatives. Weight-based dosage recommendations for pediatric multiple trace element products are 0.3 mL/kg for children weighing less than 3 kg (less than 6.6 lb) and 0.2 mL/kg for children weighing 3 kg (6.6 lb) or greater (maximum, 5 mL/day). Children weighing more than 25 kg (55 lb) should receive an adult trace element product. The weight-based dosage recommendation for the imported pediatric multiple trace element product is different than that for the US products (1 mL/kg up to a maximum of 15 mL per day).[61] Weight-based doses of the multiple trace element products do not provide the recommended daily intake for all trace elements, so additional supplementation or individual dosing with single-entity products may be necessary. Individualized dosing allows for dose adjustment based on serum trace element assessment, individual patient characteristics (eg, cholestasis, stool losses, wounds), and the need to minimize administration of trace elements that accumulate in patients receiving chronic PN such as chromium and manganese. Pediatric patients receiving PN commonly transition from PN support to enteral nutrition gradually, over a period of days to weeks, by decreasing the PN infusion rate while increasing the enteral intake. The PN infusion rate should be reduced for 1 to 2 hours before stopping the infusion for neonates and infants because of their immature counter-regulatory mechanisms that contribute to an increased risk for developing rebound hypoglycemia.[16] Blood glucose concentrations should be measured within 15 to 60 minutes after the PN infusion ends.

Continuous versus Cyclic Infusions

7 Continuous infusions are attractive for patients with unstable fluid balance or glucose homeostasis. The intermittent or cyclic infusion of PN over less than 24 hours, usually for 12 to 18 hours each day, is useful for hospitalized patients with limited venous access in whom administration of multiple other medications requires interruption of the PN infusion.[71] Cyclic PN also may minimize the incidence or reverse the liver injury associated with continuous PN therapy. In addition, this delivery mode allows patients receiving PN at home the ability to resume a relatively normal lifestyle.[69,71] Various protocols have been reported that suggest incremental increases to the maximum infusion rate for a desired period of time followed by a gradual taper to discontinue the solution have been sugested.[16,71] However, metabolically stable adults and children older than 2 years receiving IVFE–based PN regimens are likely candidates for abrupt initiation and discontinuation of their intermittent PN regimen.[5,16,71,72] Cyclic PN should be used with caution for those with severe glucose intolerance, diabetes, or unstable fluid balance.

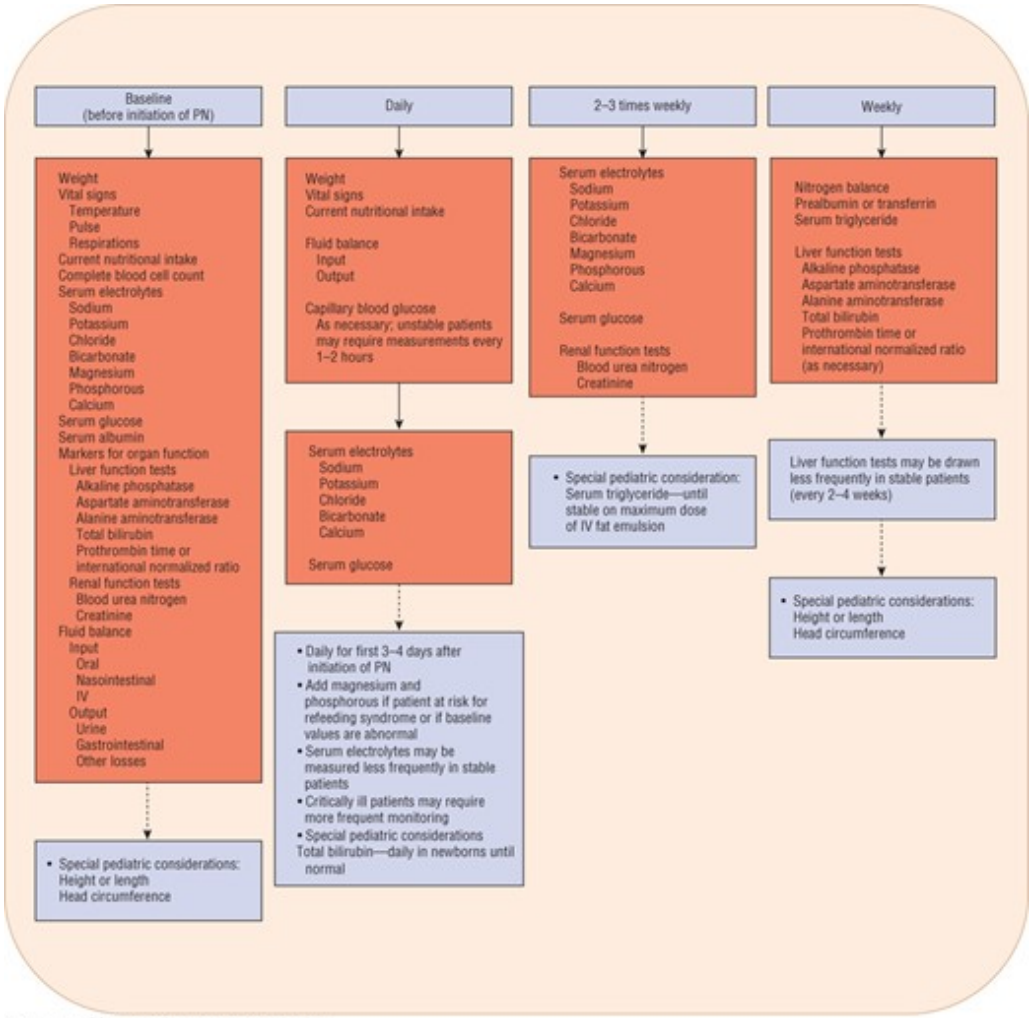
EVALUATION OF THERAPEUTIC OUTCOMES

8 Thorough and consistent monitoring of patients who are receiving PN is necessary to ensure that the desired nutritional outcomes are achieved and to prevent the occurrence of adverse effects or complications. Routine evaluation should include the assessment of the patient's clinical condition with a focus on nutritional and metabolic effects of the PN regimen. Serial documentation of a patient's response to their PN regimen is a helpful guide for determining appropriate adjustments in fluid, electrolyte, and nutrient therapies.

Serum concentrations of electrolytes, hematologic indices, and biochemical markers for kidney and liver function, and nutrition status should be measured before PN initiation and periodically thereafter depending on the patient's age, nutrition status, and clinical condition. The frequency of blood laboratory measurements for neonates and infants tends to be more conservative because of their smaller blood volumes and, in some cases, lack of central vascular access. Other important clinical measurements include vital signs, weight, total fluid intake and output, and nutritional intakes. Weekly measurements of height, length, and head circumference are helpful for monitoring nutritional changes in neonates. Monitoring parameters considered important for patients receiving PN and the suggested frequency of measurement for each are outlined in **Fig. 142-3**. Appropriate assessment and evaluation of patient data can identify potential complications that may be avoided or treated early. Monitoring protocols should be developed and tailored for the patient population, medical practices, and resources of individual practice settings.

FIGURE 142-3

Monitoring strategy for patients receiving parenteral nutrition (PN).



COMPOUNDING, STORAGE, AND INFECTION CONTROL

The USP Chapter 797 details the procedures and requirements for compounding sterile preparations, including PN admixtures.[73] These standards apply to all healthcare settings in which sterile preparations are compounded and are used by boards of pharmacy, the FDA, and accreditation organizations such as The Joint Commission. Compounded sterile preparations are defined by risk level (immediate use, low, low with 12-hour beyond-use date, medium, and high) based on the probability of microbial, chemical, or physical contamination. PN solutions are classified as a medium-risk compounded sterile preparation. In general, PN solutions should be prepared using aseptic technique in a device or room that meets International Organization for Standardization (ISO) class 5 standards that is located in an ISO class 7 buffer area with an ISO class 8 ante area.[73] Preparation of PN formulations should be supervised by a pharmacist experienced in compounding IV solutions and knowledgeable about the stability, compatibility, and storage of PN admixtures. Quality assurance procedures should be developed to maintain safe and accurate admixture preparation. A standardized process for PN ordering, labeling, determining nutrient requirements, screening of the PN order, PN administration, and monitoring has been recommended to minimize risk of potentially life-threatening compounding errors.[5,44,70] The potential risk of infectious complications associated with PN solution contamination can be decreased greatly when

pharmacy-based admixture programs follow specific guidelines developed to ensure proper compounding of PN solutions.[5,73]

In general, the type of solution being prepared dictates the compounding, storage, and infusion methods. Currently, the two most commonly used types of PN solutions are two-in-one admixtures with or without IVFE co-infused into the PN line and TNAs. Methods for compounding PN admixtures vary based on a healthcare system's patient population and medical practices and the number of PN admixtures that need to be prepared. PN base admixtures may be prepared by using gravity-driven transfer of CAA stock solutions to partially filled bags of concentrated dextrose stock solutions.[44,74] Other practice settings may use standardized commercial PN products with CAA and dextrose, and more recently, IVFE separated within a single bag that must be mixed before use.[44,70] Advances in compounding technology have facilitated the use of ACDs for preparing PN solutions. These devices are computer-based systems that perform the calculations necessary to determine volumes of nutrient-stock solutions for PN admixtures. In addition, most ACD systems include software that communicates the determined calculations directly to a transfer pump device that delivers fluid from the source container to the final container by either a volumetric or gravimetric fluid pumping system.[74] Advantages of ACDs include reduced personnel time and compounding materials and improved compounding accuracy. Disadvantages include the potential for equipment failure. Because of their acidic pH and hypertonicity, two-in-one PN admixtures are poor media for microbial growth.[44] However, several characteristics of IVFE, such as isoosmotic tonicity, near neutral to alkaline pH, glycerol content, and preservative-free formulations favor microbial growth, particularly at room temperature.[44] Other factors contributing to the potential for compromised IVFE stability or sterility include the container material, length of IVFE co-infusion with PN, length of time between administration set change, effect of infusion from the source container such as the original container, and infusion of IVFE transferred to a secondary container. When IVFEs are added to dextrose-CAA solutions to make TNAs, the growth potential is decreased, presumably because of the protective effects of the hypertonic dextrose-CAA solution and decreased pH.[66]

Because of the risk for microbial contamination, manufacturers recommend storage of PN solutions for as little time as possible after preparation. The USP 797 standards recommend storage times of not more than 30 hours at controlled room temperature (20°C to 25°C [68°F to 77°F]) and not more than 9 days at refrigerated temperatures (2°C to 8°C [36°F to 46°F]) for all medium-risk compounded sterile preparations, including PN admixtures.[73]

When co-infusing IVFE with PN (ie, not as a TNA), the appropriate IVFE dosage form (original packaging or re-packaged doses) and administration time to minimize risk of contamination is controversial. Unfortunately, The Centers for Disease Control and Prevention (CDC) guidelines offer no guidance for administration times.[68] Instead, the guidelines recommend administration tubing replacement every 24 hours for both IVFE infused separately or when given as part of a TNA. The guidelines also recommend administration tubing replacement no more frequently than at 96-hour intervals but at least every 7 days for tubing used continuously for infusion of IV solutions other than blood, blood products, or IVFE. More conservative recommendations have been presented.[5,44,66] The A.S.P.E.N. 2013 PN Safety Consensus suggests a 24-hour infusion time and administration tubing

replacement every 24 hours for TNAs and 2-in-1 PN formulations and a 12-hour infusion time and administration tubing replacement every 12 hours for IVFE co-infused separately.[5]

Compliance with A.S.P.E.N. recommendations in pediatric patients is problematic. For example, an infant receiving 3 g/kg/day IVFE at an maximum infusion rate of 0.15 g/kg/h to promote lipid clearance and minimize metabolic complications, would require at least a 20-hour infusion.[18,45] To accommodate prolonged IVFE infusions, many institutions routinely infuse IVFE separately over 24 hours and change administration tubing for the IVFE and PN solution with each new bag because the use of TNA formulations is not recommended in neonates and infants. In addition, since commercially available IVFE products are not manufactured in unit volumes suitable for safe use in neonates and infants, institutions commonly transfer IVFE from the original container into another container to accommodate the smaller patient-specific volume to decrease risk of adverse events from infusion-related errors. A variety of methods have been utilized for repackaging IVFE. Syringe repackaging and aseptic transfer into sterile bags with the use of an ACD are not recommended because of higher contamination rates. Other methodologies, such as aseptic withdrawal of an appropriate IVFE volume resulting in a patient-specific dose in the original manufacturer's container (drawing-down) has been recommended as a potential option.[66] These multifactorial concerns with providing IVFE to pediatric patients have been addressed by the A.S.P.E.N. Safety Consensus Recommendations.[5] When prolonged IVFE infusions are required in neonates and infants, the daily dose should be divided in two separate 12-hour infusions. The IVFE container and administration tubing should be replaced every 12 hours.[5] When utilizing repackaged IVFE, the infusion time should not exceed 12 hours per unit and the administration tubing should be changed with each new infusion.[5,66]

Clinical Controversy…

The safety of repackaging IVFE before administration to neonates and infants has been heavily debated. Some clinicians maintain that the benefits of cost effectiveness and increased patient safety with administering smaller IVFE units outweigh the risks of microbial contamination, while others continue to advocate for the delivery of IVFE direct from the manufacturer's container to decrease infection risk.

Stability and Compatibility

Comprehensive current information regarding compatibility and stability of PN solutions can be found in several reference sources such as *Handbook on Injectable Drugs*[75] and *King Guide to Parenteral Admixtures*.[76] In many cases, the answer to a compatibility question may not be readily available, and a review of the primary literature may be necessary. When information is not available, clinical judgment and experience must be used to resolve the situation.

The stability of a PN formulation is determined by the rate or degree of component degradation and any resulting changes in chemical integrity or pharmacologic activity that may render the formulation unsuitable for safe administration. In general, the sterile combination of PN components accelerates the rate of physicochemical destabilization of all of the components in the formulation; certain amino

acids, vitamins, and IVFE are the most susceptible nutrients.[44] When compounded and stored appropriately, the degree of degradation is usually not clinically relevant for most patients receiving short-term PN because many patients have sufficient stores of those susceptible nutrients to support any short-term periods of suboptimal intake. However, nutrient degradation that is more extensive may be problematic for patients with marginal nutrient stores who receive long-term PN. TNAs present additional stability challenges because of the presence of IVFE in the solution. IVFE stability in TNAs is affected by the amino acid and dextrose concentration, solution pH, order of mixing, electrolyte amounts, and final TNA volume as well as container material, storage conditions, and addition of nonnutrient drugs. Stability studies on the effect of specific electrolyte concentrations on TNA stability are limited. In general, IVFE stability is affected by the PN cation content. Divalent and trivalent cation additives such as calcium and magnesium have a greater destabilizing potential compared with monovalent cation additives such as sodium and potassium. However, when given in sufficiently high concentrations, monovalent cation additives may also increase instability. Cations act to reduce the surface potential of the emulsion droplet, thereby enhancing tendency to aggregate and ultimately, in some cases, destabilize the solution to coalescence or a "cracked" admixture.[5,28,44] When a cracked IVFE occurs, the oil phase separates from the water phase, resulting in the appearance of free oil fat globules. Early stages may appear as subtle changes in the uniformly white appearance of the TNA, which may progress to yellow oil streaks throughout the bag or development of an amber oil layer at the top of the admixture bag. TNA formulations with any visible free oil should be considered unsafe for parenteral administration because infusion of circulating fat globules may be of sufficient size to accumulate in the pulmonary vasculature and potentially compromise respiratory function. In general, the likelihood of preparing an unstable TNA formulation can be minimized by maintaining the final concentrations of CAA greater than 4%, dextrose greater than 10%, and IVFE greater than 2%.[5] Specific guidelines for compounding TNAs are reviewed elsewhere.[28,65]

Because of differences in pH among various CAA products and phospholipid content among IVFE products, the manufacturer of each product should be consulted for compatibility and stability information before routinely admixing components. One approach to compounding TNAs manually is to combine CAA, dextrose, and sterile water (if necessary) followed by the addition of electrolytes, vitamins, and trace elements. Then the solution should be visually inspected for precipitate or other particulates. Finally, IVFE may be added and the solution should then be visually inspected again to ensure a uniform emulsion exists.[28,44] Mixing components in this specific order may not be possible with the use of ACDs. Although CAA, dextrose, and IVFE may be simultaneously transferred to an admixture container, the ACDs manufacturer should be consulted for the optimal mixing sequence to ensure safe compounding of TNA formulations.

The precipitation of calcium and phosphorus is a common interaction that is potentially life-threatening.[18,28,44,77] The risk of precipitate formation is greater with increased solution temperature and pH, higher concentrations of calcium and phosphorus, lower concentrations of amino acids and dextrose, use of the chloride salt of calcium, improper mixing sequence when adding calcium and phosphorus salts, and the presence of other additives (including IVFEs).[18,28,44,77] In general, steps to minimize risk of calcium and phosphate precipitation in PN admixtures include the use of calcium gluconate instead of calcium chloride because it is less reactive, adding phosphate

salts early in the mixing sequence, adding calcium last or nearly last, and agitating the mixture throughout the admixture process to achieve homogeneity. PN admixtures with a lower final pH should be used when clinically appropriate. Higher final concentrations of dextrose and CAA and lower final concentrations of IVFE favor a lower admixture pH. CAA product-specific solubility curves that are available from the manufacturer or primary literature should be consulted to project calcium and phosphorous solubility. The calculation of a sum or product of calcium and phosphate concentrations should not be used as the sole criterion for determining solubility because the product of calcium and phosphate concentrations vary inconsistently as calcium concentration decreases and phosphate concentration increases.[77]

Electrolyte stability in TNA solutions is difficult to assess because of poor visualization of a precipitate if one occurs. PN solutions for neonates and infants tend to contain larger amounts of calcium and phosphorus, as well as other divalent cations, that limit the use of TNAs. Because of the limited amount of published stability information, the use of a two-in-one admixture with separate administration of IVFEs is recommended for neonates and infants.[44] In general, alternative methods of delivering electrolytes or medications should be pursued in any clinical situation in which TNA compatibility information is lacking. Because the addition of bicarbonate to acidic PN admixtures may result in the formation of carbon dioxide gas and insoluble calcium and magnesium carbonates, sodium bicarbonate use in PN admixtures is not recommended.[44] Use of a bicarbonate precursor salt such as acetate usually is preferred.

Vitamins may be affected adversely by changes in solution pH, presence of other additives, storage time, solution temperature, and exposure to light.[28] Because of variable stabilities of individual vitamins, IV vitamin solutions should be added to the PN solution as near to the time of administration as is clinically feasible and should not be in the PN solution longer than 24 hours.

Increased peroxide concentrations have been reported in IVFE and dextrose–amino acid solutions after addition of injectable multivitamins or exposure to air or light.[78] Multiple in vitro experiments have reported negative effects of peroxides and associated metabolites on organ and immune function. Peroxides are associated with neonatal hypoxic–ischemic encephalopathy, intraventricular hemorrhage, periventricular leukomalacia, chronic lung disease, retinopathy of prematurity, and necrotizing enterocolitis.[78] Neonates and infants are at increased risk for harmful effects of peroxides because they receive a higher daily peroxide load from PN solutions compared to adults and they have lower endogenous antioxidant levels. Protecting PN and IVFE solutions from light is therefore recommended to minimize peroxide formation.[78]

Many patients receiving PN also receive other IV medications. The compatibility of these medications with the PN solution is an important consideration for safe and effective drug delivery. Although some medications may be added directly to the PN solution and administered at the same rate as the PN infusion, most are administered as a separate admixture co-infused in the PN line. Several criteria should be considered before medications are added directly to the PN solution because of the potential for ineffective drug therapy or other complications associated with physiochemical incompatibility and stability of the PN solution.[44] First, the drug should be stable for at least 24 hours and should have pharmacokinetic properties appropriate for continuous infusion. Second, the

chemical and physical compatibility of the medication with PN admixture components and other medications that may be co-infused concomitantly into the PN line should be verified. Advantages of using PN admixtures as drug vehicles include consolidation of dosage units, improved pharmacodynamics for certain drugs, conservation of fluid in volume-restricted patients, fewer venous catheter violations, and decreased compounding and administration times. However, a major disadvantage to the use of PN solutions as drug-delivery vehicles is the lack of compatibility and stability data. Medications frequently added to PN solutions include regular insulin and histamine-2 receptor antagonists.[41,75,76]

COMPLICATIONS OF PARENTERAL NUTRITION

Mechanical and Technical Complications

Mechanical and technical complications include malfunctions in the system used for IV delivery of the solution, such as infusion pump failure, problems with administration sets or tubing, or the CVC. Although problems associated with infusion pumps and administration sets can be decreased by appropriate equipment selection and routine care and monitoring, CVC-related complications are potentially life-threatening. Pneumothorax, catheter misdirection or migration into the wrong vein or improper positioning within the cardiac chambers, arterial puncture, bleeding, and hematoma formation may occur during surgical placement of the catheter. Many of these complications, in addition to venous thrombosis and air embolism, can occur after insertion. CVCs occasionally occlude or break during use and if these problems cannot be rectified easily, the catheter may need to be surgically replaced.

Infectious Complications

Infectious complications can be a major hazard for patients receiving CPN because of the increased risk associated with the presence of an indwelling CVC. The source of a CVC infection may be skin organisms from the catheter insertion site, contamination of the catheter hub, or hematogenous seeding of the catheter from a distant site. In addition, patients receiving PN therapy are often predisposed to infection because of compromised immunity or concomitant infection. Frequent use of broad-spectrum antibiotic therapy and malnutrition are also predisposing factors for development of infection. The risk of catheter infection is increased for those who require multiple manipulations of the line used for PN administration as well as those who experience failure of in-line bacterial filter, poor catheter placement technique, and poor CVC and insertion site care.[68]

Infection rarely develops secondary to solution contamination.[68,79] Strict adherence to protocols for preparation of PN admixtures should minimize this occurrence.[44,73] Catheter-related bloodstream infections (CRBSIs), defined as the presence of clinical manifestations of infection (eg, fever, chills, hypotension) associated with bacteremia or fungemia resulting from no apparent source other than the catheter, are common sources of systemic infection.[79] Before this diagnosis can be made, there should be evidence of more than one positive blood culture result obtained from the peripheral vein with growth of the same organism from a blood culture obtained from the catheter or catheter

segment. When a CRBSI is suspected or confirmed, appropriate antimicrobial therapy should be initiated. Retention or removal of the central catheter depends on the patient's severity of illness, the suspected or identified pathogen, and the type of catheter involved. The catheter may be removed and replaced in the same site, the catheter may be removed and replaced at a different anatomic location, or it may not be replaced.[79] Filling the catheter with antimicrobials such as vancomycin or antiseptics such as 70% alcohol and allowing the solution to dwell for a period of time while the catheter is not in use is referred to as a catheter lock.[68] Antimicrobial catheter locks have been used to prevent and treat CRBSI in patients with long-term catheters such as those receiving home PN.[68,69] Specific guidelines for treatment of CRSBI have been recently reviewed.[79]

Clinical Controversy…

Ethanol catheter lock therapy has offered promise for the prevention and treatment of CRBSI. The best method for ethanol removal from the CVC after ethanol catheter lock is not known. If the ethanol is withdrawn from the CVC, blood is introduced into the CVC, which may increase the risk of biofilm formation. Alternatively, clearing the catheter by flushing the ethanol into the patient is concerning because there is no known safe amount of ethanol to routinely infuse into patients, particularly neonates and infants.

Metabolic and Nutritional Complications

9 Metabolic and nutritional complications associated with PN therapy are numerous; frequently multifactorial in origin; and if left untreated, potentially fatal. Metabolic abnormalities related to substrate intolerance, fluid and electrolyte disorders, and acid–base disorders are summarized in multiple recent review articles and their management is briefly summarized in the following sections.[36,37,43,44,64,71]

Liver Disease

Parenteral nutrition–associated liver disease presents as elevations in total bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase. Both adult and pediatric patients who receive PN are at risk for developing PNALD; it is reported to occur in approximately 50% to 60% of children who receive long-term PN, with a higher incidence in premature infants.[37,80] No single etiology has been identified, although several risk factors have been reported, such as, degree of prematurity, sepsis, hypoxia, lack of enteral nutrition, small bowel bacterial overgrowth, GI conditions requiring surgical intervention, duration of PN therapy, and long-term administration of excessive calories.[37,80] PNALD in infants is characterized clinically by a serum direct bilirubin concentration greater than 2 mg/dL (more than 34.2 µmol/L).[37] Taurine deficiency has been proposed as an etiology of cholestasis for preterm infants and neonates.[37] Taurine is a conditionally essential amino acid that is not present in standard CAA solutions but is important for neonatal and infant bile metabolism. However, the preventative or therapeutic benefit of PN regimens with CAA solutions containing supplemental taurine is unclear. Recent studies have focused on the potential relationship between IVFE and the development of PNALD.[50] SO–based IVFEs contain large concentrations of

plant sterols or phytosterols, which are inefficiently metabolized to bile acids by the liver. Experimental data suggest parenteral phytosterols may impair bile flow. Improvement or reversal of PNALD has been reported for patients who received a fish oil–based IVFE that is not currently commercially available in the United States.[50] Other PNALD treatments that have been investigated include providing reduced doses of SO–based IVFE and use of enteral fish oil in patients with limited oral intake.[50,81]

Risk factors for PNALD in adults include preexisting liver disease, sepsis, preexisting malnutrition, extensive bowel resection, prolonged duration of PN therapy, lack of enteral intake, nutrient deficiencies such as choline deficiency, and long-term administration of excessive calories.[37,80] PNALD in adults typically presents as steatosis and steatohepatitis on biopsy. Clinically, PNALD is characterized by mild elevations in serum liver enzymes, usually less than three times the upper limit of normal, with peak enzyme levels usually occurring between 1 and 4 weeks after initiating PN. In many cases, the liver abnormalities improve or resolve with manipulation of substrate intake or discontinuation of PN therapy. However, in severe cases, liver dysfunction may progress to overt failure and death despite use of traditional therapies such as using cyclic PN, ursodiol, and oral antibiotics for bacterial overgrowth; maximizing enteral feeding; and avoiding sepsis and parenteral overfeeding.[37,80] Intestinal transplant with or without liver transplantation has become a treatment option for PN-dependent patients who have progressive PNALD.

Hypertriglyceridemia

Hypertriglyceridemia, defined as serum triglyceride concentrations greater than 400 mg/dL (4.52 mmol/L) for adults and 150 mg/dL (1.70 mmol/L) to 200 mg/dL (2.26 mmol/L) for preterm infants, neonates, and older pediatric patients, may occur in patients receiving IVFE–based PN. Risk factors include preexisting liver or pancreatic dysfunction, sepsis, multiple-organ failure, degree of prematurity, IVFE infusion rate, and dose.[44,45]

IVFE–associated hypertriglyceridemia is generally thought to be caused by defective lipid clearance or an excessive rate of IVFE administration.[42,44] Premature infants and neonates have relatively slower lipid clearance than do adults because of immature metabolic pathways, including decreased lipoprotein lipase activity.[42,45] Reducing the IVFE infusion rate or dose or withholding IVFE therapy should be considered when patients present with hypertriglyceridemia or lipemic serum.[42,44] Use of low-dose heparin (1 unit/mL of two-in-one PN formulation) to stimulate lipoprotein lipase activity has been suggested as a potential therapeutic intervention to treat IVFE–associated hypertriglyceridemia in neonates.[16,42] However, others have suggested that the risk associated with heparin delivery via PN outweighs the clinical benefits because of the potential for compounding errors associated with confusion between heparin and insulin doses.[82] The role of carnitine for treatment of IVFE–associated hypertriglyceridemia is not clear.[16,42]

Hyperglycemia

Hyperglycemia is one of the most common complications of PN administration and is associated with

a history of diabetes, metabolic stress, adverse effects of medications such as glucocorticoids, and excessive carbohydrate administration. In the pediatric population, additional risks for hyperglycemia include prematurity and surgery. The optimal blood glucose concentration for acutely ill hospitalized patients receiving PN is not known. However, a target range of 140 to 180 mg/dL (7.8-10 mmol/L) has been suggested for adults, and less than 150 mg/dL (8.3 mmol/L) has been suggested for neonates.[83,84] Clinical management of PN patients with hyperglycemia has not been well studied and is largely empiric. Blood glucose concentrations can be controlled with regular insulin, which may be given subcutaneously or added to the PN formulation. One approach for adult PN patients requiring insulin or oral hypoglycemic agents before starting PN therapy is to initiate PN with approximately 100 to 200 g of dextrose and add 0.05 to 0.1 units of regular insulin per gram of dextrose in the PN solution for those patients with mild hyperglycemia (130-150 mg/dL [7.2-8.3 mmol/L]). The insulin dose may be increased to 0.15 to 0.2 units per gram of dextrose for patients with moderate hyperglycemia (151-200 mg/dL [8.4-11.1 mmol/L]).[44,85] Blood glucose concentrations should be monitored every 4 to 6 hours. Blood glucose measurements above the goal range should be treated with regular insulin administered subcutaneously according to an appropriate sliding scale (see Chapter 74). The insulin dose is modified daily by adding 60% to 100% of the sliding-scale insulin given over the previous 24 hours to the PN formulation daily until blood glucose concentrations are stable and within the target range. When blood glucose measurements are stable, the dextrose dose may be advanced to achieve the therapeutic goal and the frequency of monitoring blood glucose concentrations may be decreased after blood glucose concentrations are stable within the target range at the goal dextrose dose. Use of a separate IV insulin infusion is most commonly used for pediatric patients, but it may also provide better and safer glycemic control for patients with very large insulin requirements or those with unstable marked fluctuations in their blood glucose concentrations.

Refeeding Syndrome

Severe and rapid declines in serum phosphate, potassium, and magnesium concentrations; fluid retention; and other micronutrient deficiencies are common features of the refeeding syndrome.[86,87] Individuals at greatest risk for refeeding syndrome are severely malnourished patients with significant weight loss who receive aggressive nutritional supplementation. In addition, those who are unfed for 7 to 10 days with evidence of stress or nutritional depletion; those with chronic diseases causing undernutrition such as cancer, cardiac cachexia, chronic obstructive pulmonary disease, or cirrhosis; and individuals who were previously morbidly obese and have experienced massive weight loss are at heightened risk for this syndrome.[87] Electrolyte abnormalities appear to be related to acute provision of macronutrient substrates that promote anabolism in an environment of depleted total body stores of phosphorus, potassium, and magnesium. Recommendations for initiating PN in adults at risk for refeeding syndrome include providing 25% to 50% of the calculated nonprotein caloric requirements initially. The dextrose dose should be initiated at approximately 100 to 200 g/day. Calories should be advanced over 3 to 4 days to the desired goal. Because the metabolic abnormalities described with refeeding syndrome appear to be related primarily to acute provision of large amounts of dextrose, the goal protein dose may be provided with the initial PN infusion. Pediatric PN regimens are usually advanced over several days as a general practice for all pediatric patients. Additional

recommendations for minimizing the risk of refeeding syndrome for pediatric patients include provision of additional phosphorus and potassium above standard nutrient requirements at the time PN is initiated.[88]

Complications Associated with Long-Term Parenteral Nutrition

Other nutritional complications of PN therapy may develop over a prolonged course of therapy (weeks to months) as a result of inappropriate intake of a particular nutrient. Certain conditions, such as metabolic stress in a previously malnourished patient, may elicit symptoms of deficiency much earlier if a nutrient is not appropriately provided. For example, lactic acidosis and other life-threatening complications associated with severe thiamine deficiency have been reported in patients who received PN solutions without multivitamin supplementation.[53] Maintenance doses of vitamins, trace elements, and essential fatty acids should be provided to all patients with normal age-related organ function receiving PN.

Essential Fatty Acid Deficiency

Patients receiving PN regimens without IVFEs for weeks to months are at risk for development of EFAD. Clinical signs of EFAD include hair loss, desquamative dermatitis, thrombocytopenia, malabsorption, and diarrhea resulting from changes in intestinal mucosa.[43,44] EFAD also may be diagnosed by evaluating plasma fatty acid profiles. Although this assessment is not routinely available, it can be provided by several larger regional laboratories. Historically, a triene-to-tetraene ratio more than 0.4 has been considered biochemical evidence for EFAD, however, individual laboratory reference ranges should be used when evaluating patients for EFAD.[18] Although the time in which EFAD may develop depends on the patient's nutrition status, disease state, and age, these manifestations may occur 2 to 4 weeks after initiation of fat-free PN in adults and within 48 hours in newborn infants.[43,45]

Metabolic Bone Disease

Metabolic bone disease has been reported for adults and children receiving long-term home PN.[37] This disorder in adults is characterized by osteomalacia with or without osteoporosis that may present without associated clinical, radiologic, or biochemical abnormalities. The diagnosis may not be made for premature infants until after the development of bone fractures or overt rickets. The etiology is poorly understood and likely multifactorial. Treatment options include pharmacologic intervention, calcium and vitamin D supplementation, and exercise. Because excessive vitamin D has also been implicated in the development of metabolic bone disease, others have recommended removal of vitamin D from the PN for patients with a normal 25-hydroxyvitamin D concentration and low serum parathyroid hormone and 1,25-hydroxyvitamin D concentrations.[16,37]

Trace Element and Vitamin Complications

Clinical symptoms of trace element deficiencies, although rare, have been reported for patients receiving long-term PN. More commonly, decreased serum trace element concentrations have been

reported in a variety of patient populations. However, the clinical significance of abnormally low concentrations of many trace elements is not known because serum concentrations often do not correlate with total body stores.[53] Occasionally, patients may develop clinical toxicities from elevated vitamin or trace element concentrations as the result of increased intake or decreased metabolism. These abnormalities are frequently associated with an underlying disease state such as severe kidney or hepatic failure and may necessitate reduction in vitamin and trace element intake.

Many trace elements are present in PN components as contaminants.[53] Some investigations of patients with normal organ function who were receiving PN supplemented with commercially available parenteral multiple trace element solutions have reported concern with elevated serum concentrations of trace elements such as chromium and manganese.[53] Aluminum is a common contaminant of many sterile IV solutions, including those used for compounding PN. Calcium and phosphorus solutions are among those components with the highest levels of aluminum contamination.[89,90] Aluminum accumulation may occur during long-term PN therapy, especially for patients with reduced kidney function, and is associated with abnormal neurologic and hematologic function and metabolic bone disease in adults and premature infants.[37,89,90] Preterm infants are at higher risk of aluminum toxicities because they receive larger doses (micrograms per kilogram) from PN solutions than adults.[90] Preterm infants are also more likely to retain aluminum because of immature renal kidney function. Although the maximum safe level of IV aluminum intake is unknown, the FDA has reported that parenteral doses of 4 to 5 mcg/kg/day were associated with central nervous system and bone toxicity.[91] Even smaller amounts may result in tissue accumulation but no documented toxicity.

The FDA implemented a mandate in 2004 to restrict aluminum content in large-volume PN stock solutions (CAA, dextrose, sterile water for injection, IVFE) to a maximum of 25 mcg/L and for manufacturers to indicate the maximum aluminum concentration at expiration for both large- and small-volume parenteral products used for PN.[91] Investigations have determined actual aluminum concentrations in parenteral products to be lower than the amounts reported on the manufacturer's label, however, aluminum amounts in PN solutions still exceed FDA guidelines.[89,90] In addition, the aluminum content of parenteral products appears to vary considerably during the shelf life of the products and increases with time because of leaching from glass containers. The amount of aluminum contamination delivered to patients receiving long-term parenteral therapy such as chronic PN patients or dialysis patients, can be substantially reduced if newer stock solutions are used to prepare their PN.[89,90]

The amount of aluminum present in alternative imported trace element products is unknown because their initial approval was not based on FDA criteria.[61]

HOME PARENTERAL NUTRITION

Advances in technology for the delivery of IV solutions have allowed medically stable patients who require extended PN therapy to be maintained indefinitely on IV nutrition. An increasing concern for cost containment of healthcare services has fostered use of sophisticated infusion devices to provide

PN at home. Numerous programs are now available outside the traditional healthcare setting to support patients who require long-term or permanent PN. Standards have been developed to promote safe and effective care.[69] Home PN services may be coordinated and administered through a hospital or by a commercial home care company.[69]

Many factors are considered in selecting candidates for home PN therapy. Significant benefit must be expected from the therapy. Examples of patients who have been maintained successfully with home PN include those with severe GI dysfunction secondary to Change from Crohn disease to Crohn's disease, ischemic bowel disease, severe GI motility disorders, extensive intestinal obstruction, and congenital bowel dysfunction.[69] The patient and the patient's caregiver must be willing to complete training and assume numerous responsibilities for managing the new daily routine. Other logistics such as funding, procurement of solutions and supplies, and clinical management and follow-up must be individualized for each patient in order to achieve the desired outcomes.[69]

Patients commonly receive PN solutions from their home care provider. IV vitamins or other additives may be added daily by the patient or caregiver, depending on the arrangement with the home care provider. The solution generally is administered through the night by infusion pump over 8 to 20 hours.[69,71] A cycled regimen allows the patient time away from the pump during daylight hours and provides many patients with the freedom to have a reasonably normal daily routine. Clinical management and follow up are performed periodically according to the needs of the patient and the protocol of the home care provider or the managing healthcare team. A coordinated effort among several healthcare professionals, including physicians, pharmacists, nurses, dietitians, social workers, and the patient and the patient's caregiver, as well as the suppliers, is paramount to providing safe and effective management. Home PN affords some patients the potential for an ambulatory lifestyle while maintaining an IV feeding regimen that was previously only available in the hospital setting. For others, home PN may contribute to a better quality of life in the comfort of their homes.[69]

PHARMACOECONOMIC CONSIDERATIONS

Determining the true cost of PN support is difficult because numerous variables affect the provision of PN and the clinical response to therapy. PN therapy cost variables include the underlying indication for treatment, the administration setting (home or acute care), timing of PN initiation, therapy associated complications, and the type of PN formulation provided (compounded or standardized commercial PN product).[69,92,93,94,95,96,97] Expenses associated with PN therapy may be categorized as direct and indirect costs.[95] Direct costs may be further categorized as fixed or variable costs. Fixed costs do not depend on the volume of patients receiving therapy. For example, an ACD and the tubing sets required to transfer volumes of stock solutions to the administration bag would be considered fixed costs in many practice settings. These costs per patient tend to be highest in low-volume environments. Variable costs such as PN administration bags or standard commercial PN products depend directly on the number of patients receiving PN. Other direct costs include ancillary services required by patients receiving PN and costs related to the management of PN associated complications.

Clinical benefits and other clinical effects of PN (ie, reduction in hospital length of stay and frequency of complications) in specific patient populations have been evaluated but few investigations have reported a comprehensive economic assessment of PN therapy. Attempting to measure the cost or cost savings associated with reported benefits of PN therapy and other clinical effects based on results of controlled clinical trials is difficult.[93,94] Clinical outcome measurements and hence economic outcomes are influenced by multiple factors, including experimental design, sample size, and specific health system practices.[93,95,96,98,99] More recent cost analyses for PN therapy have focused on timing of initiating therapy in critically ill patients and choice of PN formulation (compounded or standard commercial PN product). In general, although individual investigations have reported cost savings with supplemental PN in critically ill patients unable to meet nutritional goals within 24 to 48 hours of intensive care unit (ICU) admission, others have reported no cost advantage with early PN intervention.[96] Similarly, while cost savings have been reported with use of standard commercial PN products compared to PNs compounded with an ACD, others have reported increased costs with other supportive care usually provided with compounded PN when standard commercial PN products were used.[98,100]

Although the results of economic analyses of PN remain controversial, similarities among several reports provide a basis for minimizing the costs of PN therapy:

1. Use PN only for the most appropriate patients as described by institution-specific criteria based on current consensus statements. Enteral nutrition should be used whenever feasible because the associated costs and complications are demonstrated to be less than those associated with PN.[97,101]

2. Reassess the need for routine laboratory monitoring measurements used for PN therapy. In general, the level of laboratory monitoring should decrease as a patient's clinical condition stabilizes.

3. Minimize the direct cost of PN by using efficient purchasing practices for PN solutions and compounding supplies through contract purchasing, streamlined compounding procedures, standardized administration times, single-bag PN solutions, and optimized monitoring plans. Some institutions may realize direct cost savings with use of standardized, commercial PN products depending on the usual daily PN census and patient population.[99] Others may reduce direct costs by outsourcing PN compounding to a third-party compounding pharmacy facility.

PERSONALIZED PHARMACOTHERAPY

10 11 Considerations for individualizing a patient's PN regimen include: goals determination based on a patient-specific nutrition assessment, selection of the optimal type of available vascular access, and macronutrient and micronutrient requirements. In general, both macronutrient and micronutrient doses are age and weights based but are also affected by the patient's degree of metabolic demand, organ function, other drug therapy, exogenous losses, and acid–base status. Nutrient amounts provided by the PN may also require adjustment based on enteral intake either orally or by feeding tube in patients with recovering GI tract function.

Patient-specific caloric goals include (a) adequate energy intake to promote normal growth and development in neonates, infants, and children; (b) energy equilibrium and preservation of fat calorie stores in well-nourished adults; and (c) positive energy balance in malnourished patients with depleted endogenous fat stores. Overweight patients with a body mass index above 30 kg/m^2 may require less caloric support than nonobese patients with the same clinical condition.[11] Critically ill adults may also benefit from a hypocaloric regimen.[11] Specific nitrogen goals are positive nitrogen balance or nitrogen equilibrium and improvement in the serum concentration of visceral protein markers such as transferrin or prealbumin in patients without systemic inflammation. Routine monitoring is necessary to ensure that the nutrition regimen is suitable for a given patient as the patient's clinical condition changes and to minimize or treat complications. The PN component doses usually require individualized adjustments as the patient's clinical condition affects further changes in metabolic stress, organ function, fluid and electrolyte balance, and acid–base status.

Appropriate patient selection, assessment, and monitoring are key to successful PN therapy and the prevention of unnecessary complications. Because pharmacists are actively involved in the provision of PN at many levels, including order verification, PN compounding and dispensing, direct patient care, education, and research, nutrition support is recognized as a pharmacy practice specialty.[102] In addition, as the interprofessional team based approach to specialized nutrition support has evolved, standards of practice have been defined for pharmacists as well as for other healthcare professionals.[4,8,9,10] Standardized order forms and monitoring protocols are useful tools to ensure safe administration and monitoring of PN therapy. The future of PN therapy and the role of nutrition-support clinicians will be affected primarily by new insights from clinical research and economic challenges in the evolving healthcare environment.

Chapter 143: Enteral Nutrition

Vanessa J. Kumpf; Katherine H. Chessman

INTRODUCTION

KEY CONCEPTS

- 1 The gastrointestinal (GI) tract defends the host from toxins and antigens by both immunologic and nonimmunologic mechanisms, collectively referred to as the gut barrier function. Whenever possible, enteral nutrition (EN) is preferred over parenteral nutrition (PN) because it is associated with a lower risk of metabolic and infectious complications and is less expensive and invasive.

- 2 Candidates for EN are those with a sufficiently functioning GI tract to allow adequate nutrient absorption who cannot or will not eat and in whom enteral access can be safely obtained.

- 3 The most common route for both short- and long-term EN access is directly into the stomach. The method of delivery may be continuously via an infusion pump, intermittently via a pump or gravity drip, or bolus administration via gravity or syringe.

- 4 Patients unable to tolerate tube feeding into the stomach because of impaired gastric motility may benefit from feeding tube placement into the duodenum or jejunum. When feeding into the small bowel, the continuous method of delivery via an infusion pump is required to enhance tolerance.

- 5 Selection of the enteral feeding formulation depends on nutritional requirements, the patient's primary disease state and related complications, and nutrient digestibility and absorption. A standard polymeric formulation will be appropriate for the majority of adults and children.

- 6 Measurement of gastric residual volumes (GRVs) is often used to monitor GI tolerance in patients receiving gastric feeding. Although the practice has not been consistently reported to decrease aspiration risk, a high GRV may provide an early sign of GI dysfunction and alert the clinician to the need for intervention.

- 7 Management of diarrhea in patients receiving EN should focus on identification and correction of the most likely cause(s). Tube feeding-related causes include too rapid delivery or advancement, intolerance to the formula composition, and occasionally formula contamination.

- 8 Medication administration through a feeding tube requires selection of an appropriate dosage form and verification of appropriate enteral access. Medications that should not be crushed and administered through a tube include enteric-coated or sustained-release capsules or tablets and sublingual or buccal tablets.

- 9 The coadministration of medications with EN can result in alterations in bioavailability and/or changes in the desired pharmacologic effects. Medications known to interact with EN include phenytoin, warfarin, select antibiotics, antacids, and proton-pump inhibitors.

Enteral nutrition (EN) is defined as the delivery of nutrients by tube or by mouth into the gastrointestinal (GI) tract. This chapter focuses on nutrient delivery through a feeding tube rather than oral food ingestion. The terms *enteral nutrition* and *tube feeding* are thus used interchangeably in this context. The goal of EN is to provide calories, macronutrients, and micronutrients to those patients who are unable to achieve these requirements from an oral diet. Increased recognition of malnutrition, along with improvements in enteral access techniques, feeding formulations, and methods to prevent and manage complications, have resulted in an increased use of EN across all healthcare settings. In this chapter, principles and practices related to the safe and successful use of EN therapy are described.

GASTROINTESTINAL TRACT PHYSIOLOGY

The GI tract plays a key role in the processing of ingested foods. Many of the processes involved in digestion, absorption, and utilization of nutrients are modifiable by the presence of acute and chronic illnesses.

Digestion and Absorption

Digestion and absorption are GI processes that generate the body's usable fuels.[1,2] Ingested nutrients are primarily large polymers that cannot be absorbed across the intestinal cell membrane unless they are transformed into an absorbable molecular form. Digestion consists of the stepwise conversion of a complex chemical and physical nutrient into a molecular form that is absorbable by the intestinal mucosa. Absorption from the GI tract is a multistep process that includes the transfer of a nutrient across the intestinal cell membrane. The nutrient ultimately reaches the systemic circulation through the portal venous or splanchnic lymphatic systems, provided that the GI or biliary tract does not excrete it. In addition, a coordinated interplay of GI motility and neurohormonal secretion is required to facilitate adequate digestion and absorption.

Nutrient digestion involves the complex coordination of multiple mechanical, enzymatic, and physiochemical processes.[1,2] Mechanical dissolution of food occurs by chewing, then mixing and grinding the stomach contents. Food stimulates secretion of numerous hormones and enzymes from

the salivary glands, stomach, liver and biliary system, pancreas, and intestines (**Table 143-1**). As food traverses the gut lumen, these hormones modulate GI motility and the secretions from other organs of the digestive system. Nutrient absorption occurs within the gut lumen and is a specific function of the intestinal cell membrane, which is comprised of fingerlike projections called villi. Each individual villus is made up of epithelial cells called enterocytes. The enterocyte surface contains special luminal projections called microvilli, which provide an increased surface area that is referred to as the brush-border membrane.

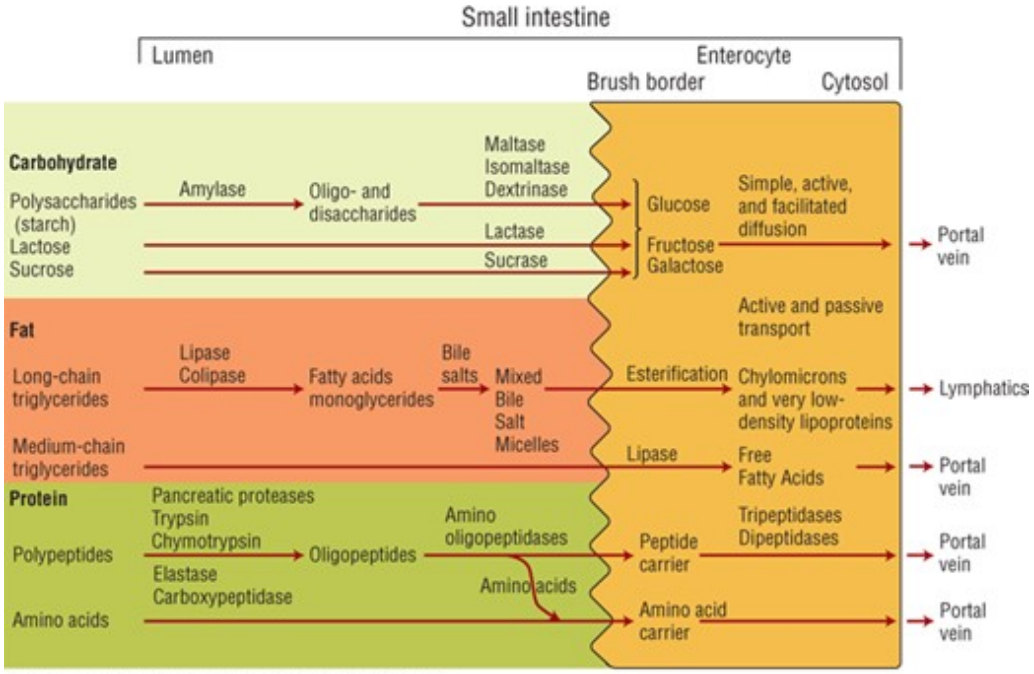
TABLE 143-1 Gastrointestinal Enzymes and Hormones

Enzyme/Hormone	Site of Secretion	Main Actions
Amylase	Salivary glands, pancreas	Converts carbohydrates, starch, and glycogen to simple disaccharides
Cholecystokinin	Duodenum, jejunum	Stimulates pancreatic enzyme secretion and gallbladder contraction
Chymotrypsinogen	Pancreas	Breaks down proteins into peptides
Enteroglucagon	Duodenum, small intestine	Inhibits pancreatic enzyme secretion and bowel motility
Gastric inhibitory peptide	Small intestine	Decreases gastric motility and stimulates insulin secretion
Gastrin	Stomach, duodenum	Stimulates gastric acid secretion and mucosal growth
Glucagon	Pancreas	Stimulates hepatic glycogenolysis and inhibits motility
Lipase	Pancreas	Hydrolyzes dietary fat to release fatty acids
Pancreatic polypeptide	Pancreas	Inhibits gallbladder contraction and pancreatic and biliary secretion
Pepsinogen	Stomach	Converts large proteins into polypeptides
Secretin	Small intestine	Stimulates hepatic and pancreatic water and bicarbonate release
Trypsinogen	Pancreas	Breaks down proteins into peptides
Vasoactive inhibitory peptide	Small intestine, pancreas	Vasodilator; stimulates water and bicarbonate secretion, insulin and glucagon release, and small bowel secretions

The digestion and absorption of carbohydrate, fat, and protein within the small intestine are illustrated in **Figure 143-1**. Carbohydrates are presented to the small intestine in either a digestible or a nondigestible form. Polysaccharides (starches) and oligosaccharides (sucrose and lactose) undergo enzymatic digestion to simple sugars. The simple sugars are absorbed via active and passive transport mechanisms and are eventually released into the portal vein. Polysaccharides, such as cellulose complexes and other fiber components, pass undigested to the colon, where they are digested by bacteria and enzymes to short-chain fatty acids. Colonic absorption of short-chain fatty acids stimulates sodium and water reabsorption. The short-chain fatty acids serve as a systemic energy source and they provide nourishment for the colonic mucosa cells.

FIGURE 143-1

Schematic of carbohydrate, fat, and protein digestion.



Fat is most often presented to the small intestine as long-chain triglycerides. Fat digestion requires pancreatic lipase release and formation of mixed bile salt micelles, which are then absorbed across the intestinal enterocyte. Within the enterocyte, triglycerides are reesterified and packaged into chylomicrons that are then transported into the lymphatic system. Medium-chain triglycerides (MCTs) can be absorbed intact by the mucosal membrane and are acted on by intracellular lipase within the enterocyte to release free fatty acids that pass directly into the portal vein.[3]

Protein is presented to the small intestine primarily as large polypeptides and to a lesser extent as free amino acids because of protein denaturation in the stomach. Polypeptide digestion generates oligopeptides, which are further hydrolyzed to dipeptides and tripeptides. Peptide absorption occurs via a peptide transport system while free amino acids are absorbed via specific amino acid transporters. These peptide carriers are very efficient, whereas free amino acid absorption appears to less efficient.[2]

Understanding the mechanisms involved in digestion and absorption can greatly enhance the rational use of EN in patients with normal or altered GI anatomy and/or function. Various circumstances may alter the efficacy of nutrient digestion and absorption. For example, the functional immaturity of the neonatal gut may lead to clinical problems associated with inadequate digestion and absorption of EN.

Gut Host Defense Mechanisms

1 Besides digesting and absorbing nutrients to maintain nutritional health, the GI tract is actively

involved in defending the host from toxins and antigens by both immunologic and nonimmunologic mechanisms.[4] These gut host defense mechanisms are collectively referred to as the gut barrier function. The gut barrier acts to prevent the systemic spread of intraluminal bacteria and endotoxins to other organs and tissues. Hydrochloric acid secreted by the stomach kills most of the bacteria ingested with food. Under normal circumstances, a mucus layer coats the intestinal epithelium and thereby alters the adherence of bacteria to the cells of the GI tract but provides a favorable environment for anaerobic bacteria. Anaerobic bacteria, which normally colonize the mucus layer, aid in preventing tissue colonization by potential pathogens. Small bowel peristalsis further prevents bacterial stasis and overgrowth. The gut barrier function is also maintained by the intestinal immune system, known as the gut-associated lymphoid tissue (GALT). GALT regulates the local immune response to antigens within the GI tract. Specific immunoglobulins are secreted to kill the remaining organisms and neutralize any toxins they produce. The liver Kupffer cells help to maintain gut barrier function by clearing the portal blood of gut-derived bacteria and endotoxins. Gut barrier integrity may be affected negatively by numerous pathogenic insults, such as physiologic stress and ischemia, and a variety of drugs, including chemotherapeutic agents. The administration of certain probiotics can modify intestinal flora and may have beneficial effects in various disease states and patient populations by positively affecting the maintenance of gut barrier function and intestinal immune function.[5,6,7]

INDICATIONS FOR ENTERAL NUTRITION

2 The decision to initiate EN is based on a variety of factors. Suitable candidates are those who cannot or will not eat a sufficient amount to meet their nutritional requirements, those who exhibit a sufficient functioning GI tract to allow for nutrient absorption, and those in whom a method of enteral access can be safely initiated.[8,9,10,11] Thus, EN may be indicated in a variety of conditions or disease states (**Table 143-2**). For example, patients who have difficulty swallowing due to stroke, altered mental status, or obstruction in the head, neck, or esophagus due to cancer may benefit from EN. Extreme prematurity necessitates tube feeding because the suck–swallow-and-breath mechanism is not matured sufficiently to allow safe oral intake.[12]

TABLE 143-2 Potential Indications for Enteral Nutrition

Neoplastic disease	**Neurologic impairment**
Chemotherapy	Comatose state
Radiation therapy	Cerebrovascular accident
Upper GI tumors	Demyelinating disease
Cancer cachexia	Severe depression
Organ dysfunction	Cerebral palsy
Liver disease/failure	**Other indications**

Kidney insufficiency/failure	
Cardiac cachexia	
ARDS/ALI	
Bronchopulmonary dysplasia	
Congenital heart disease	
Organ transplantation	
Hypermetabolic states	AIDS
Closed head injury	Anorexia nervosa
Burns	Complications during pregnancy
Trauma	Failure-to-thrive
Postoperative major surgery	Geriatric patients with multiple chronic diseases
Sepsis	Extreme prematurity
GI disease	Inborn errors of metabolism
Inflammatory bowel disease	Cystic fibrosis
Short bowel syndrome	
Esophageal motility disorder	
Pancreatitis	
Fistulas	
Gastroesophageal reflux disease (severe)	
Esophageal or intestinal atresia	

AIDS, acquired immune deficiency syndrome; ALI, acute lung injury; ARDS, acute respiratory distress syndrome.

Critically ill patients who are endotracheally intubated represent a large percentage of hospitalized patients requiring EN. Traditionally, EN in the critically ill population was regarded as supportive care designed to provide nutrients during the period of time the patient was unable to maintain adequate oral dietary intake. Current evidence also supports the use of EN as a tool to modulate the stress response to critical illness and improve patient outcomes. Nutrition guidelines support the initiation of EN in critically ill adults[13,14,15] and children[16] who are unable to maintain volitional intake. Some of

these patients may have reduced gastric emptying caused by sepsis, GI surgery, anesthetic agents, opioid analgesics, and underlying pathology, such as diabetic gastroparesis and burns. However, successful EN can often be achieved by advancing the tip of the feeding tube beyond the pylorus into the duodenum, or preferably into the jejunum. Small bowel feeding may also be appropriate for patients with gastric outlet obstruction, those with pancreatitis, those with moderate to severe gastroesophageal reflux, or those with high aspiration risk.

Contraindications to EN use and/or tube placement are distal mechanical intestinal obstruction, bowel ischemia, active peritonitis, uncorrectable coagulopathy, and necrotizing enterocolitis.[1,17,18] Conditions that my result in significant challenges to EN use include severe diarrhea, protracted vomiting, enteric fistulas, severe GI hemorrhage, hemodynamic instability, and intestinal dysmotility.

BENEFITS OF ENTERAL NUTRITION

The importance of maintaining nutrient delivery through the GI tract in patients without a contraindication to its use is well supported. The beneficial effects of EN, specifically in the critically ill patient, are further enhanced if EN is initiated within 24 to 48 hours of admission to an intensive care unit (ICU).[13,14,15]

Enteral Versus Parenteral Nutrition

Clinical studies comparing EN and parenteral nutrition (PN) in the critically ill adult patient demonstrate a decrease in infectious complications with the use of EN.[19,20,21] Infectious complications are thought to be less common with EN in part because EN supports functional gut integrity by stimulating bile flow and the release of endogenous trophic agents, such as cholecystokinin, gastrin, and bile salts. Provision of enteral nutrients appears to help maintain the intestinal mucosal villous height and support the mass of secretory immunoglobulin A (IgA)-producing immunocytes that comprise the GALT. In the setting of critical illness or severe injury, adverse changes in gut permeability and gut barrier function that result in increased risk for systemic infection and multiorgan dysfunction syndrome have been noted. By supporting gut integrity, the enteral feeding route is thought to lower infection risk and minimize organ failure.[13]

The incidence of infectious complications has been documented to be lower in EN patients with abdominal trauma, burns, severe head injury, major surgery, and acute pancreatitis. This reduction in infectious complications is primarily due to the lower incidence of pneumonia and catheter-related bloodstream infections and a decrease in abdominal abscess in trauma patients.[19,20,21] Unfortunately, interpretation of these studies is often complicated by small sample size and lack of standardization in timing of EN initiation and achievement of nutrition goals. Recently, the CALORIES trial randomized 2,400 adult critically ill patients who were expected to require nutritional support for at least 2 days to either EN or PN and initiated therapy within 36 hours of ICU admission.[22] No significant differences in infectious complications or mortality was noted and these findings challenge EN use as the preferred route for early nutritional support in critically ill patients.. There are no randomized, controlled trials that compare the use of EN and PN in children.[16]

Enteral nutrition is more physiologic than PN in terms of nutrient utilization and therefore is generally associated with fewer metabolic complications, such as glucose intolerance and elevated insulin requirements.[23] Enteral formulations contain both complex and simple carbohydrates, which results in slower carbohydrate absorption compared with the simple carbohydrate, dextrose, used in PN. In addition, enteral formulations that contain fiber and/or a high fat content will further slow carbohydrate absorption and reduce blood sugar elevations by delaying gastric emptying, accounting for better blood glucose control when carbohydrates are given via the enteral route. An additional physiologic benefit of enteral feeding is that it stimulates bile flow through the biliary tract and thus reduces the risk of developing cholestasis, gallbladder sludge, and gallstones, conditions that have been associated with long-term PN and bowel rest.[24] EN avoids the potential infectious and technical complications associated with the placement and use of a central venous access device required for PN. Finally, EN is less costly than PN when all factors associated with the therapy are considered.

Timing of Initiation

The timing of initiation of EN in the critically ill patient is of clinical significance. Initiating EN in the first 24 to 72 hours following admission appears to attenuate the stress response and may reduce disease severity and infectious complications when compared with the initiation of feedings after 72 hours.[13,14,15] Early EN has also been associated with a decrease in the release of inflammatory cytokines and fewer effects on gut permeability.[25] Clinical studies demonstrating reductions in infectious complications with EN compared with PN have been reported in the critically ill patient when feeding was initiated within 24 to 48 hours of hospital admission.[13,14,15,26] The benefit of fewer infectious complications was not apparent when the initiation of EN was delayed. A review of available studies comparing early versus delayed EN in critically ill patients revealed a trend toward a reduction in infectious complications with early EN.[13,14,15] In addition, a trend toward reduction in mortality associated with early EN has been noted.[13,14,15,26]

In critically ill patients who are hemodynamically unstable, early EN may result in gut ischemia because of poor gut blood flow and increased oxygen demand. Consequently, it is recommended that initiation of EN be delayed until the patient is fluid resuscitated and has an adequate perfusion pressure.[13] Once this goal is achieved, the initiation of EN at a low administration rate is considered appropriate, along with clinical monitoring to ensure GI tolerance and continued hemodynamic stability. Therefore, early EN (within 24-48 hours after hospital admission) is recommended in critically ill adult patients.[13,14,15] Although no randomized, controlled trials have assessed early EN in critically ill children, initiation of EN within 48 to 72 hours of admission is common.[16]

Early EN initiation is not warranted for previously well nourished, mild to moderately stressed adult patients. When oral intake is inadequate, it is reasonable to delay the initiation of EN for 5 to 7 days in these patients.[8] In the mild to moderately stressed adult patient who is moderately to severely malnourished, most clinicians would initiate EN sooner.

ENTERAL ACCESS

Advances in enteral access techniques have contributed to the expanded use of EN for conditions in which PN had previously been used. In particular, improved methods of achieving jejunal access for feeding have allowed the EN use during the early postoperative and post-injury period when gastric motility is typically impaired. As outlined in **Table 143-3**, various factors influence the selection of enteral access site and device, including anticipated duration of use and whether to feed into the stomach or small bowel. **Figure 143-2** illustrates the predominant enteral access options.

TABLE 143-3 Options and Considerations in the Selection of Enteral Access

Access	EN Duration/Patient Characteristics	Tube Placement Options	Advantages	Disadvantages
Nasogastric or orogastric	Short term Intact gag reflex Normal gastric emptying	Manually at bedside	Ease of placement Allows for all methods of administration Inexpensive Multiple commercially available tubes and sizes	Potential tube displacement Potential increased aspiration risk
Nasojejunal or orojejunal	Short term Impaired gastric motility or emptying High risk of GER or aspiration	Manually at bedside Fluoroscopically Endoscopically	Potential reduced aspiration risk Allows for early postinjury or postoperative feeding Multiple commercially available tubes and sizes	Manual transpyloric passage requires greater skill Potential tube displacement or clogging Bolus or intermittent feeding not tolerated
Gastrostomy	Long term Normal gastric emptying	Surgically Endoscopically Radiologically Laparoscopically	Allows for all methods of administration Low-profile buttons available Large-bore tubes less likely to clog Multiple	Attendant risks associated with each type of procedure Potential increased aspiration risk Risk of stoma site complications

Access	EN Duration/Patient Characteristics	Tube Placement Options	Advantages	Disadvantages
			commercially available tubes and sizes	
Jejunostomy	Long term Impaired gastric motility or gastric emptying High risk of GER or aspiration	Surgically Endoscopically Radiologically Laparoscopically	Allows for early postinjury or postoperative feeding Potential reduced aspiration risk Multiple commercially available tubes and sizes Low-profile buttons available	Attendant risks associated with each type of procedure Bolus or intermittent feeding not tolerated Risk of stoma site complications

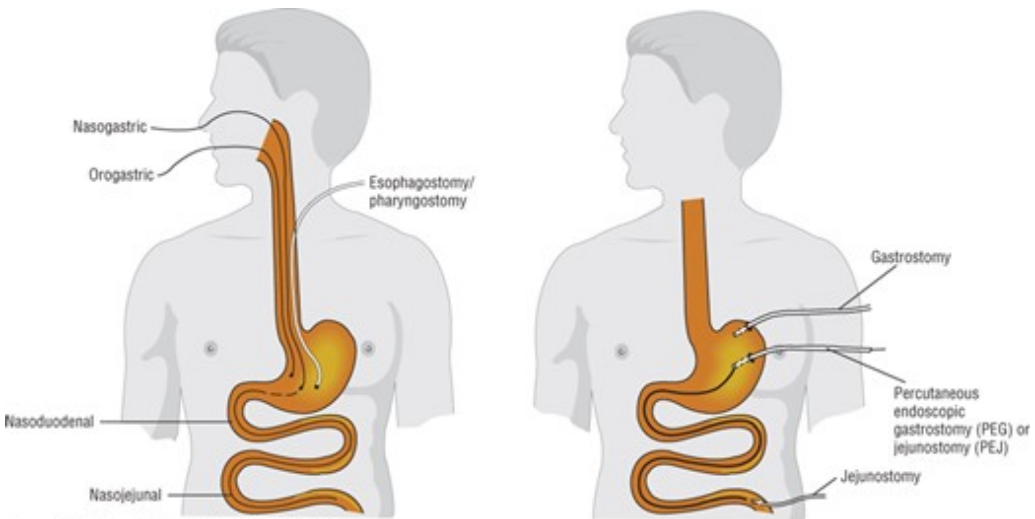
Access sites for tube feeding.



Short-Term Access

3 Short-term enteral access is easier to initiate, less invasive, and less costly than the establishment

of long-term access.[27] The most frequently used routes for short-term enteral access are established by inserting a tube through the nose or mouth and passing the tip into the stomach (nasogastric [NG]; orogastric [OG]), or jejunum (nasojejunal [NJ]; orojejunal [OJ]). In general, these tubes are used in the hospitalized patient when the anticipated tube feeding duration is less than 4 to 6 weeks. The orogastric route is generally reserved for patients in whom the nasopharyngeal area is inaccessible or in young infants who are obligate nasal breathers. Because these routes do not require surgical intervention, they are the least invasive. The most common technique for placement is blind passage at the bedside by trained medical personnel. Several techniques have been described in the literature to help facilitate bedside placement and greater skill is required to advance the tip of the feeding tube beyond the pylorus.[17] Metoclopramide, a prokinetic agent, has been used with variable success to aid passage of the tube beyond the pylorus. A bedside electromagnetic tube placement device has also been used to guide tip position into the small bowel by attracting a metal tip on the end of the tube.[28,29] Alternatively, a variety of endoscopic and fluoroscopic techniques have been described to insert tubes into the small bowel.[17,27] Radiographic confirmation of appropriate tip placement should be obtained prior to use for all bedside placed feeding tubes.[9,17]

Nasogastric tubes vary in diameter and stiffness. Large-bore (greater than or equal to 14F) rigid NG tubes are used primarily to decompress the stomach but can also be used for feeding. There is a low incidence of clogging with these tubes, and they provide a reliable way to measure gastric residual volumes (GRVs). The major disadvantage associated with the use of these tubes is patient discomfort. Small-bore nasal tubes designed solely for feeding are available in varying lengths (12-60 inches [30-152 cm]) and diameters (3.5F-12F) to accommodate both pediatric (including neonates) and adult patients. The tip of the tube can be placed into the stomach or into the duodenum or jejunum (also referred to as transpyloric placement). These tubes consist of a lightweight, pliable silicone or polyurethane material that is designed for patient comfort. A disadvantage of small-bore tubes is that they more easily occlude, often as a result of improper medication administration or flushing technique. The feeding tube is frequently held in place only by a piece of tape on the nose or face; therefore, it can be inadvertently dislodged relatively easily. Nasal bridles have been used with variable results to secure the nasoenteric tube in place.[17] A bridle involves passing a piece of thin tubing or suture into one nostril, then around the bony portion of the nose, and out the other nostril, and finally tying the tubing around the feeding tube.

4 In general, gastric feeding is the least expensive and the least labor-intensive method for enteral feeding; however, feeding into the stomach is not always tolerated. Patients with impaired gastric motility may be predisposed to aspiration and pneumonia when fed into the stomach. Many critically ill, injured, and postoperative patients exhibit delayed gastric emptying, which limits their ability to tolerate gastric feeding. In addition, patients with diabetic gastroparesis or patients with severe gastroesophageal reflux disease or intractable vomiting are at a higher risk for aspiration of gastric contents, resulting in pneumonia. In these patients, placing the tip of the tube into the duodenum or jejunum has been suggested as a method to decrease aspiration risk.[17] Transpyloric feeding has been associated with a lower rate of vomiting and ventilator-associated pneumonia when compared to NG feeding.[30] However, the evidence to support the difference in aspiration and aspiration pneumonia risk associated with gastric and small bowel feeding is inconclusive. In general, small bowel feeding

may be beneficial in patients who do not tolerate gastric feeding and offers an alternative to PN.[13,14,15,16]

Long-Term Access

Feeding tubes used for short-term enteral access are usually not optimal for long-term use because of patient discomfort, complications, and mechanical failures that develop over time. Long-term access should generally be considered when the need for EN is anticipated to be longer than 4 to 6 weeks. Many techniques can be used to establish long-term enteral access, including laparotomy, laparoscopy, endoscopic and image guidance (eg, fluoroscopy and ultrasound).[17] The ability to perform the various techniques will be somewhat dependent on the expertise and facilities available within each institution. Long-term enteral access options include gastrostomy and jejunostomy tubes.

A gastrostomy is the most common type of long-term enteral access. It eliminates the nasal irritation and discomfort associated with nasoenteric feeding tubes and inadvertent removal is uncommon. In addition, because feeding gastrostomies use large-bore tubes, clogging is less of a problem. The most commonly placed is the percutaneous endoscopic gastrostomy (PEG). The technique is minimally invasive and can be performed safely and cost-effectively in an endoscopy suite or at the bedside using conscious sedation and local anesthesia. Young children, however, will usually require general anesthesia for the procedure. Gastrostomy tubes are available in various sizes (12F-28F; 0.8-5 cm shaft lengths), material (eg, silicone and polyurethane), and have different retention mechanisms. Since smaller-diameter tubes are prone to more frequent occlusion and dysfunction, the largest diameter size possible is preferred. For patient convenience, comfort, and cosmetic appearance, a low-profile skin-level gastrostomy device may be used. It is typically placed as an exchange tube for a preexisting gastrostomy or jejunostomy once the tract has matured but can also be used at the time of initial tube placement. This “gastric button” consists of a short, silicone, self-retaining conduit with either a mushroom tip or a balloon at the internal end and a one-way valve and small flange at the skin surface. Because this averts the external tube presence, it tends to be preferred in children or ambulatory adults who are receiving intermittent feedings. The exit site of all gastrostomies requires general stoma care to prevent inflammation and infection. Routine replacement of the gastrostomy tube at defined intervals (usually 3-6 months) is a standard of practice of many clinicians to prevent failure of the retention mechanism that can occur over time.[17]

In patients with a functional bowel but impaired gastric motility, pancreatitis, or who otherwise do not tolerate gastric feeding and require long-term enteral access, a jejunostomy may be an appropriate option.[27] Various endoscopic and fluoroscopic techniques are available for direct jejunostomy placement. A surgically placed jejunostomy may be an option if the patient requires a laparotomy or laparoscopy for other reasons. For patients who require small bowel feeding with simultaneous gastric decompression, a gastrojejunal tube may be placed utilizing various endoscopic, fluoroscopic, and surgical techniques.[15,30] Because jejunostomies use smaller-bore tubes, occlusion occurs more commonly than with gastrostomy tubes. Gastrojejunostomy tubes are often replaced every 3 to 6 months to prevent occlusion.

There are ethical implications regarding determination of appropriate candidates for long-term

feeding tube placement.[17,31,32,33,34,35] Because a gastrostomy is relatively easy to place and many patients, families, and clinicians overestimate the benefits of EN, it is prone to inappropriate use. In certain patient populations, such as those with advanced dementia or other near end-of-life conditions, the placement of a gastrostomy is not recommended. Artificial nutrition and hydration (ANH) has not been shown to promote the healing of pressure ulcers, increase patient comfort or functional status, or prolong survival when compared to hand feeding in patients with advanced dementia.[31] From a clinical standpoint, ANH does not increase a patient's comfort or improve nutrition parameters of most terminally ill individuals and can result in medical complications.[32] Studies consistently demonstrate that survival rates are not improved in older patients with advanced dementia who receive tube feedings and it is associated with substantial burden, including agitation, greater use of physical and chemical restraints, recurrent aspiration, and tube-related complications.[33,34] Evaluation by a multidisciplinary team is warranted for all patients near the end of life to establish whether the benefit of EN outweighs the risks of feeding tube placement.[31,33,34,35]

ADMINISTRATION METHODS

Enteral nutrition may be administered by continuous, cyclic (continuous rate over a portion of the day), intermittent (infused over 20-60 minutes), or bolus (generally given in 5-10 minutes) methods and may be accomplished by syringe, gravity, or pump-controlled techniques. The deliver method depends on the location of the tip of the feeding tube, the patient's clinical condition and intestinal function, and the patient's tolerance to the tube feeding.

Continuous

Pump-assisted continuous administration of EN is generally the method of choice for most hospitalized patients, especially when initiating therapy. They may be candidates for transitioning to intermittent or bolus feeding for long-term use as their medical condition stabilizes, as described below. However, when EN is to be delivered into the small intestine, the continuous method is always preferred because it is associated with enhanced tolerance. The rapid delivery of feeding into the small intestine may contribute to abdominal distension, cramping, hyperperistalsis, and diarrhea (also referred to as *dumping syndrome*). Therefore, conversion to intermittent or bolus administration is not recommended for those with jejunostomies.

The delivery system for continuous administration generally includes a feeding set with attached reservoir bag or spike set that connects to a feeding container. The feeding set is attached to a pump and then connected to the patient's enteral access tube with an adaptor. Continuous administration may increase nursing time because routine checks are needed, but this disadvantage is usually offset by the improved tolerance. For adults, target EN administration rates generally range from 50 to 125 mL/h, although higher rates have been used without complications. In infants and children, goal administration rates vary with age and weight and should be sufficient to meet caloric needs while maintaining good GI tolerance. The primary disadvantage to this method of administration is the cost and inconvenience associated with the pump and administration sets. In the home care setting, battery-operated ambulatory enteral pumps that fit into a backpack with the feeding bag are

available to allow the patient greater mobility.

Cyclic

A patient who is not eating well during the day because of complaints of fullness and lack of appetite or who is not able to consume enough calories during the day to meet increased needs (eg, trauma and burns) may benefit from cyclic EN, in which the enteral feeding is administered by pump only at night. In addition, nocturnal EN administration will free the patient from the pump during the day and allow for greater mobility. This increased mobility may be particularly useful for the home patient or patient requiring rehabilitation. This method may be used in patients with either gastric or small bowel access.

Bolus

The bolus administration of EN is commonly used for patients in the home or long-term care setting who have a gastrostomy. This administration technique involves the delivery of the enteral feeding formulation over 5 to 10 minutes. Essentially, the only equipment needed is a syringe to instill the feeding volume into the tube. Depending on the patient's nutritional requirements, a feeding volume of 240 to 500 mL is generally used and repeated four to six times daily. From a convenience standpoint, it is generally preferable to adjust the bolus volume in increments of the feeding formulation container size (usually 240-250 mL). Bolus volumes given to infants and children vary with age and weight (usually 30-240 mL) and should be sufficient to meet the patient's calorie needs. In neonates and young infants, the bolus regimen is usually begun with an every 3-hour schedule; in older infants and children, feedings may be given at a frequency needed to deliver four to five feedings daily.[18] In patients with duodenal or jejunal access, bolus delivery may result in cramping, nausea, vomiting, aspiration, and diarrhea. Bolus administration also should be avoided in patients with delayed gastric emptying and in patients who are at high risk of aspiration.

Intermittent

If a patient is experiencing intolerance to bolus administration over 5 to 10 minutes, it may be helpful to administer the prescribed volume over a longer time period, generally 20 to 60 minutes. For this method, the desired volume of feeding formulation is emptied into a reservoir bag or container with attached tubing and administered by an enteral pump or via gravity drip using a roller clamp. The bolus method of administration is more consistent physiologically with normal eating patterns than the continuous method. One study in infants demonstrated that normal gallbladder emptying did not occur with continuous feedings but was present in those infants receiving bolus feedings.[36] Thus, those patients who need long-term EN and PN, especially children, may benefit when this approach is used because it may minimize the development of cholestatic liver disease.

INITIATION AND ADVANCEMENT PROTOCOL

Guidelines for the initiation and advancement of enteral feeding formulations vary greatly and are

primarily tailored to patient tolerance. The typical recommendation for continuous EN administration for adults is to start at 20 to 50 mL/h and advance by 10 to 25 mL/h every 4 to 8 hours until the desired goal is achieved. For intermittent administration, the typical recommendation is to start with 120 mL every 4 hours and advance by 30 to 60 mL every 8 to 12 hours.[8,9] In children, continuous administration is often initiated at a rate of 1 to 2 mL/kg per hour (no more than 25-30 mL/h) or 2 to 4 mL/kg per bolus (no more than 30-90 mL) with advancement by similar amounts every 4 to 24 hours. In premature infants, feedings may be initiated at lower rates usually 10 to 20 mL/kg per day and advanced by similar rates daily.[11,18] Schedules for progression of tube feeding from initial to target rates are important and may influence tolerance. If the protocol is too conservative, it may take an excessively long period of time to reach nutrient goals. The practice of diluting enteral feeding formulations is not recommended unless necessary to increase fluid intake.[9] The development of an EN protocol within an institution that outlines initiation and advancement criteria is recommended to optimize achievement of nutrient goals.[13,14] Due to frequent interruptions of EN, some institutions have implemented volume-based feeding protocols to improve success in meeting targeted goals. Such a protocol shifts the focus from an hourly rate target goal to a 24-hour volume goal and provides guidance on how to adjust the rate of administration when EN is interrupted for reasons unrelated to GI tolerance.[37,38]

ENTERAL FEEDING FORMULATION SELECTION

Historically, enteral formulas were designed primarily to provide essential nutrients. Over the years, enhancements have been made to meet specific patient needs and improve tolerance. For example, nutrient composition has been enhanced by changing the content of the amino acids (eg, glutamine and arginine), increasing the omega-3 polyunsaturated fatty acid content, and adding RNA to enhance immune function and improve therapeutic outcomes. These specific nutrients have been called nutraceuticals or pharmaconutrients because of the intent to use them to modify disease processes and improve clinical outcomes. Currently, enteral feeding formulations are categorized by the FDA as medical foods.[9] They are considered components of supportive care and are simply regulated to ensure sanitary manufacture. Unfortunately, they are not subject to rules governing health claims, and promotion of medical foods for therapeutic intent is currently not regulated by the FDA.[39]

The macronutrient content of enteral formulas (namely, protein, carbohydrate, and fat) varies in nutrient complexity (**Table 143-4**). Nutrient complexity refers to the amount of hydrolysis and digestion a substrate requires prior to intestinal absorption. Polymeric or intact substrates are of similar molecular form as the foods we eat. Enteral formulas that contain partially hydrolyzed or elemental substrates are characterized as elemental or defined-formula diets. The caloric contribution of each of the macronutrients is as follows: carbohydrates, 4 kcal/g (17 kJ/g); protein, 4 kcal/g (17 kJ/g); and fat, 9 kcal/g (38 kJ/g).

TABLE 143-4 Enteral Formula Nutrient Complexity

Nutrient	Polymeric or Intact	Partially Hydrolyzed or Elemental
Carbohydrate	Starches	Oligosaccharides

Nutrient	Polymeric or Intact	Partially Hydrolyzed or Elemental
		Maltodextrins
	Fruit, vegetable, cereal solids	Disaccharides
	Glucose polymers	Maltose, sucrose, lactose
	Corn syrup solids	Monosaccharides
	Polysaccharides	Glucose
		Galactose
	Long-chain triglycerides	
	Polyunsaturated fatty acids	Medium-chain triglycerides
	Corn oil	Coconut oil
Fat	Safflower oil	Palm kernel oil
	Soybean oil	Free fatty acids
	Canola oil	Linoleic
	Marine oils	
	Whole	Oligopeptides
	Egg, milk, wheat, whey	Dipeptides
Protein	Isolates	Tripeptides
	Caseinate salts	L-amino acids
	Lactalbumin	

Protein Composition

The essential amino acid content of the protein source determines the quality of the protein, and most commercially available enteral feeding formulations contain proteins of high quality. The form of the protein source in enteral formulas will determine the amount of digestion that is required for absorption. Polymeric or intact protein sources require digestion to smaller peptides and free amino acids before absorption. Protein sources, such as meat, milk, eggs, and caseinates, require digestion by hydrochloric acid, specific protein enzymes, and pancreatic proteases. Enteral formulations may also contain protein sources that are partially hydrolyzed to peptides or L-amino acids. As the molecular form of protein is reduced in size, the osmotic load of the enteral formulation is increased. Many commercially available enteral feeding formulations contain combinations of intact and partially hydrolyzed protein sources. Most enteral formulations are gluten-free.

Conditionally Essential Amino Acids

Glutamine and arginine are generally considered nonessential amino acids. However, during periods of high physiologic stress, the need for these nutrients may be increased beyond the body's synthetic ability; consequently, these amino acids are characterized as conditionally essential. Because they are usually present in low amounts in most enteral feeding formulations, formulations targeted for the critically ill may be supplemented with glutamine and/or arginine.

Glutamine serves as a key fuel for rapidly dividing cells, including enterocytes, endothelial cells, lymphocytes, and fibroblasts. The primary site of glutamine production is skeletal muscle. During critical illness, skeletal muscle catabolism provides an increased glutamine supply, but this may not be enough to meet the high rate of glutamine use by cells of the immune system and other cells involved in recovery and repair. Glutamine depletion may develop, particularly during prolonged periods of metabolic stress. Favorable outcomes have been documented in critically ill patients when enteral formulations have been supplemented with glutamine.[13,40] Its use has specifically been recommended in burn and trauma patients.[15] However, high dose glutamine supplementation in critically ill patients with shock and multiorgan failure should be used with caution.[14] This concern is based on a study in over 1,200 critically ill adults that showed no benefit and a trend toward increased mortality when high-dose glutamine was given as a combined parenteral and enteral supplement for 28 days.[41]

Arginine has been added to some immune-modulating enteral formulations in concentrations that range from 4.5 to 14 g/L. However, arginine supplementation remains controversial, especially in patients with sepsis.[40,42] Many of arginine's physiologic effects are mediated by its conversion to nitric oxide, which, in turn, modulates immune function, inflammation, and vasodilation. Some of these effects may be potentially harmful in the patient with sepsis, especially when higher arginine intakes are used.[13]

Carbohydrate Composition

The carbohydrate component of enteral feeding formulations usually provides the major source of calories. Polymeric or intact enteral formulations contain starches and numerous types of glucose polymers, which require digestion to monosaccharides prior to intestinal absorption (see Fig. 143-1). As the extent of hydrolysis of carbohydrates increases within an enteral formulation, the osmolality of the formulation increases. Simple sugars, such as glucose and galactose, contribute significantly to the osmolality of enteral formulations. Consequently, polymeric entities, rather than elemental sugars, are preferred. Glucose polymers provide a useful carbohydrate source that is tolerated by most individuals (see Table 143-4). The polymers are large chains that provide minimal osmotic load, yet are absorbed easily in the intestine. The one shortcoming of glucose polymers and oligosaccharides is that they are not as sweet as simple glucose and thus may decrease the palatability of orally consumed products. Finally, almost all commercially available enteral feeding formulations used in adults and older children are lactose-free because disaccharidase production within the gut lumen is reduced during illness and periods of prolonged bowel rest. Additionally, there is a high incidence of lactose intolerance in those of certain ethnic decent. Infant formulas are available with or without

lactose.

Fat and Fatty Acid Composition

Fat is an important constituent in the diet because it provides a concentrated calorie source and serves as a carrier for fat-soluble vitamins. Sufficient linoleic acid is required to prevent essential fatty acid deficiency and should approximate at least 1% to 3% of total daily calories. The most common fat sources in enteral feeding formulations are vegetable oils (soy or corn) that are rich in polyunsaturated fatty acids. The fat concentration varies between less than 2% and 45% of total calories. High dietary fat content is associated with delayed gastric emptying. Enteral feeding formulations can also contain fat in the form of MCTs derived from palm kernel or coconut oils. Because MCTs do not contain linoleic acid, enteral formulations that contain MCTs will also have a source of long-chain triglycerides to provide essential fatty acids. Potential advantages of MCTs compared to long-chain triglycerides are that they are more water soluble, undergo rapid hydrolysis, require no pancreatic lipase or bile salts for absorption, and do not require carnitine for transport into the mitochondria, where they are converted to energy. They also do not require chylomicron formation for small bowel enterocyte absorption and are not transported via the lymphatic system.

The source of long-chain fat within some enteral formulations has been modified from omega-6 to omega-3 fatty acids in an effort to modulate the inflammatory response in patients with acute respiratory distress syndrome (ARDS), acute lung injury (ALI), and sepsis.[43] The omega-6 fatty acids are high in linoleic acid and are derived from vegetable oil, whereas the omega-3 fatty acids, derived from cold-water fish oils, are high in linolenic acid. Omega-6 fatty acids serve as precursors to certain arachidonic acid-derived cytokines that are potent inflammatory mediators and also decrease cell-mediated immune response; whereas omega-3 fatty acids are precursors for eicosapentanoic acid-derived cytokines which are less inflammatory. It has been proposed that if the dietary proportion of omega-3 fatty acids is increased and omega-6 fatty acids is decreased, less inflammation and immunosuppression may occur during metabolic stress.

Docosahexaenoic acid (DHA) and arachidonic acid (ARA) are two fatty acids abundant in human milk, but until recently, they were not contained in commercial infant formulas. Although the role of ARA supplementation is unclear, DHA is important in brain and eye development. In some studies, DHA and ARA supplementation provided benefits to a child's visual function and/or cognitive and behavioral development.[44] The FDA has classified plant-based fatty acid blends of DHA and ARA as generally recognized as safe (GRAS), and most infant formulas, as well as some products for pregnant and lactating women, are supplemented with these fatty acids.

Fiber Content

Fiber, in both soluble and insoluble forms, is added to several adult and pediatric enteral feeding formulations in amounts ranging from 5.9 to 24 g/L. Infant formulas generally do not contain fiber; however, at least one formula intended for use in infants with diarrhea contains soy fiber. Fiber supplementation is common in clinical practice, primarily because fiber-free enteral formulations are implicated as a contributing factor to both diarrhea and constipation. Soluble fiber undergoes

bacterial degradation within the colon to produce short-chain fatty acids. Potential benefits of soluble fiber are its trophic effects on the colonic mucosa and promotion of sodium and water absorption within the colon. Insoluble fiber is undigested and may help decrease GI transit time by increasing fecal weight. Fiber supplementation may help to regulate bowel function in both normal individuals and those with altered colonic motility. In addition, the resulting short-chain fatty acids are an excellent energy source. Although beneficial effects of fiber supplementation have not been clearly proven in clinical studies, there is experimental evidence that fiber may play an integral role in normal nutrition, and risk is generally minimal, particularly in non-critically ill patients.[45] Fiber supplementation may be beneficial when long-term EN is required or in patients who experience diarrhea or constipation while receiving a fiber-free enteral formulation. Soluble fiber may also be beneficial in the critically ill patient who is hemodynamically stable and develops diarrhea while receiving EN.[13] Insoluble fiber should be avoided in all critically ill patients due to case reports of bowel obstruction.[13]

Osmolality and Renal Solute Load

The unit of measure of osmolality is milliosmoles per kilogram (mOsm/kg) or millimoles per kilogram (mmol/kg); iso-osmolar is considered to be approximately 300 mOsm/kg (mmol/kg). Osmolality and renal solute load can affect tolerance to enteral feeding formulations. The osmolality of a given enteral formulation is a function of the size and quantity of ionic and molecular particles, primarily related to the protein, carbohydrate, electrolyte, and mineral content within a given volume. Enteral formulations with greater amounts of partially hydrolyzed or elemental substrates have a higher osmolality than formulations containing polymeric or intact substrates. Therefore, formulations that contain sucrose or glucose, dipeptides and tripeptides, and amino acids are generally hyperosmolar. Increased caloric density also increases the osmolality of an enteral formulation. In general, the osmolality of commercially available enteral feeding formulations ranges from 300 to 900 mOsm/kg (mmol/kg). American Academy of Pediatrics guidelines recommend that enteral formulations for use in infants have an osmolality of 450 mOsm/kg (mmol/kg) or less which equates to an osmolality of 400 mOsm/L.[46]

Symptoms of gastric retention, diarrhea, abdominal distension, nausea, and vomiting have been attributed to enteral formulations with a high osmolality based on the assumption that higher osmolality draws water into the gut lumen. However, clinical evidence to support this relationship between osmolality and GI tolerance is lacking. The practice of diluting hyperosmolar formulations has not been shown to enhance tolerance and should be discouraged unless dilution is done to increase fluid intake.[9] Factors, such as concurrent antibiotic therapy, method of enteral feeding administration, and the formulation's composition, are likely to play a greater role in GI tolerance than the osmolality.

The renal solute load is determined by the protein, sodium, potassium, and chloride content of the enteral formulation. Formulations that contain a greater solute load increase the obligatory water loss via the kidney. It is estimated that 40 to 60 mL of water is the minimal amount necessary to excrete 1 g of nitrogen. Those receiving high-protein enteral formulations unable to ingest or tolerate supplemental water may be at risk for developing dehydration.

CLASSIFICATION OF ENTERAL FEEDING FORMULATIONS

Most patients' nutritional needs can be met using a standard enteral feeding formulation; however, certain disease states or clinical conditions may warrant the use of a specialty feeding formulation. Development of an evidence-based, enteral formulary should focus on clinically significant characteristics of available formulations and avoid duplication. Categorizing enteral feeding formulations according to therapeutic class is necessary in developing a formulary system for adults (**Table 143-5**) and children (**Table 143-6**).

TABLE 143-5 Adult Enteral Feeding Formulation Classification System

Category	Features	Indications
Standard polymeric	Isotonic 1-1.2 kcal/mL (4.2-5 kJ/mL) NPC:N 125:1-150:1 May contain fiber	Designed to meet the needs of the majority of patients Patients with functional GI tract Not suitable for oral use
High protein	NPC:N <125:1 May contain fiber 1.5-2 kcal/mL (6.3-8.4 kJ/mL)	Patients with protein requirements >1.5 g/kg/day, such as trauma patients and those with burns, pressure sores, or wounds Patients receiving propofol
High caloric density	Lower electrolyte content per calorie Hypertonic	Patients requiring fluid and/or electrolyte restriction, such as kidney insufficiency
Elemental	High proportion of free amino acids Low in fat	Patients who require low fat Use has generally been replaced by peptide-based formulations
Peptide-based	Contains dipeptides and tripeptides Contains MCTs	Indications/benefits not clearly established Trial may be warranted in patients who do not tolerate intact protein due to malabsorption
Disease-specific		
Kidney	Caloric dense Protein content varies Low electrolyte content	Alternative to high caloric density formulations, but generally more expensive

Category	Features	Indications
Liver	Increased branched-chain and decreased aromatic amino acids High fat, low carbohydrate	Patients with hepatic encephalopathy
Lung	Antiinflammatory lipid profile and antioxidants	Patients with ARDS and severe ALI
Diabetes mellitus	High fat, low carbohydrate	Alternative to standard, fiber-containing formulation in patients with uncontrolled hyperglycemia
Immune-modulating	Supplemented with glutamine, arginine, nucleotides, and/or omega-3 fatty acids	Patients undergoing major elective GI surgery, trauma, burns, head and neck cancer, and critically ill patients on mechanical ventilation Use with caution in patients with sepsis Select nutrients may be beneficial or harmful in subgroups of critically ill patients
Oral supplement	Sweetened for taste Hypertonic	Patients who require supplementation to an oral diet

ALI, acute lung injury; ARDS, acute respiratory distress syndrome; MCT, medium-chain triglyceride; NPC:N, nonprotein calorie-to-nitrogen ratio.

TABLE 143-6 Pediatric Enteral Feeding Formulation Classification System

Formula Type	Features	Indications
Infants		
Cow's milk-based	Standard energy density for feeding: 20-24 kcal/oz (2.8-3.3 kJ/mL); also available in concentrate (40 kcal/oz [5.6 kJ/mL]) and powder forms Standard formulation contains lactose, but also available as lactose-free	Normal, healthy infant
Soy protein-based	Standard energy density for feeding: 20 kcal/oz (2.8 kJ/mL); also available in concentrate (40 kcal/oz [5.6 kJ/mL]) and powder forms Lactose free May contain added soy fiber	Lactase deficiency or lactose intolerance, galactosemia, diarrhea (fiber added)
Prematurity	Standard energy density for feeding: 24 kcal/oz (3.3 kJ/mL); also available in 20 (2.8 kJ/mL) and 30 kcal/oz (4.2 kJ/mL)	Preterm infants weighing <2-3 kg (<4.4-6.6 lb)

Formula Type	Features	Indications
	forms	
Transition	Standard energy density for feeding: 22 kcal/oz (3.1 kJ/mL) Provide higher calcium and phosphorus content compared with term infant formulas	Preterm infants weighing <3 kg (<6.6 lb) and ready for discharge
Semi-elemental/elemental	Standard energy density for feeding: 20 kcal/oz (2.8 kJ/mL) Hydrolyzed protein and free amino acids May contain ARA and DHA	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia, short bowel syndrome, food allergies
	Lactose free	
	Typically contain MCTs ranging from 5% to 86% of fat content	
Special diets	Low electrolyte/mineral content	Kidney disease
Children Ages 1-10 Years		
Standard	Standard energy density for feeding: 30 or 45 kcal/oz (1 or 1.5 kcal/mL [4.2 or 6.3 kJ/mL])	Functioning GI tract requiring tube feedings
	Intact protein; 30-38 g/L	
	May contain added fiber	
Semi-elemental/elemental	Standard energy density for feeding: 20-30 kcal/oz (2.8-4.2 kJ/mL) Hydrolyzed protein and free amino acids Lactose-free	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia, short bowel syndrome, food allergies
	MCTs range from 33% to 87% of fat content	

ARA, arachidonic acid; DHA, docosahexaenoic acid; MCT, medium-chain triglyceride.

Standard Polymeric

A large number of commercially available enteral feeding formulations fall into the standard polymeric formulation category. These formulations are approximately isotonic (300 mOsm/L [300 mmol/L]), provide 1 to 1.2 kcal/mL (4.2-5 kJ/mL), and are composed of intact nutrients in a nutritionally balanced mix of carbohydrate, fat, and protein. They may contain dietary fiber. The nonprotein calorie-to-nitrogen ratio of these products is approximately 125:1 to 150:1. This ratio is a useful parameter for assessing protein density in relation to calories provided (see Chapter 141). Certain feeding formulations in this category may be promoted as high nitrogen but actually fall within standard protein amounts. To maintain isotonicity, many products within this category are not sweetened, making them unpalatable and generally suited only for tube feeding; however, flavored

products are available for oral supplementation. The nutrient requirements of the majority of adults and children older than 1 year receiving EN can generally be met using feeding formulations in this category. Many term and preterm infant formulas will also fall into this category and available in formulations that provide 19 to 24 kcal/oz (2.7-3.5 kJ/mL) or 22 to 30 kcal/oz (3.1-4.2 kJ/mL), respectivly.[46]

High Protein

Enteral feeding formulations with a nonprotein calorie-to-nitrogen ratio less than 125:1 can be categorized as high protein. The lower the ratio, the higher the protein density in relation to calories provided. In patients with high protein requirements, it is generally unacceptable to use a feeding formulation with standard protein amounts because the volume necessary to meet protein requirements will result in excessive calorie intake. Patients who may be candidates for a high-protein feeding formulation are critically ill patients and those with pressure sores, surgical wounds, and high output enterocutaneous fistulas. In general, adult patients with estimated protein requirements exceeding 1.5 g/kg per day may benefit from a high-protein formulation. High-protein formulations may also be beneficial in mechanically ventilated patients who are receiving propofol for sedation. The vehicle for propofol is a soybean fat emulsion that contains 1.1 kcal/mL (4.6 kJ/mL). At therapeutic dosages, propofol intake can significantly contribute to caloric intake, and a high protein formulation may be beneficial in allowing for the provision of protein requirements while minimizing overfeeding.

High Caloric Density

High caloric density formulations are concentrated to provide less fluid and electrolyte intake in comparison to a standard polymeric formulation. They provide approximately 2 kcal/mL (8.4 kJ/mL) and similar calorie and protein intake can be achieved as a standard polymeric formulation, using half the volume. High caloric density formulations are often necessary for patients who require fluid and/or electrolyte restriction, such as those with kidney or heart failure. Although specialty enteral formulations targeted for acute kidney injury and chronic kidney disease are available, many patients with kidney failure can be managed using a product in this category.

Elemental/Peptide-Based

Formulations in this category contain protein and/or fat components that are hydrolyzed into smaller, predigested forms. Traditionally, enteral formulations in this category were referred to as elemental and contained a high proportion of protein in the form of free amino acids and a low amount of fat. Many of these formulations have been reformulated to provide a portion of the protein in the form of dipeptides and tripeptides and fewer free amino acids because dipeptides and tripeptides are more readily absorbed than an equivalent intake of free amino acids.[48] These peptide-based formulations may be beneficial in patients with impaired digestion or absorption. Peptide-based formulations are generally higher in fat than the more elemental formulations and use MCTs in varying proportions as the fat source.

Evidence to support the use of elemental or peptide-based formulations is limited, and their routine use is generally not recommended. Patients who do not tolerate standard, intact nutrient formulations as a result of malabsorption or short bowel syndrome might be candidates for a trial of a peptide-based formulation. In addition, elemental or peptide-based products that have higher percentages of MCTs and small amounts of long-chain triglycerides may be beneficial for patients with severe pancreatic insufficiency, such as chronic pancreatitis and cystic fibrosis; severe abnormalities of the intestinal mucosa, such as untreated celiac disease; biliary tract disease, such as biliary atresia or severe cholestasis; or chylothorax or chylous ascites.

Disease Specific

Enteral feeding formulations also have been designed to meet unique nutrient requirements and manage metabolic abnormalities associated with specific disease states. Specialized enteral feeding formulations are marketed for use in adult patients with kidney and liver failure; lung disease, including ARDS; diabetes mellitus; wound healing; and metabolic stress. There are no disease-specific enteral products currently marketed for use in infants or children younger than 10 years of age. Thus, modular supplements may be necessary in these patients (see discussion in Modular Products section).

Specialized enteral formulations designed to modulate the inflammatory response in adult patients with severe metabolic stress have been referred to as immune-modulating formulations or immunonutrition. These formulations are supplemented with nutrients such as glutamine, arginine, antioxidants, nucleotides, and omega-3 polyunsaturated fatty acids, because of their potential role in regulating immune function. There is lack of consensus between the professional nutrition societies guidelines regarding the use of immune-modulating enteral formulations in critically ill patients.[13,14,15] Positive results have been reported in patients undergoing major elective GI surgery and cancer surgery of the head and neck, those with severe trauma or burns, and critically ill patients on mechanical ventilation. The use of immune-modulating enteral formulations in these select patient populations has resulted in significant reductions in infectious complications, hospital length of stay, and duration of mechanical ventilation.[43,49] In contrast, two recent multicenter trials revealed no improvement in infectious complications or other clinical end points and possible harm with immune-modulating formulations[50] or when enteral immunonutrition was a provided as a twice daily supplement.[51] The heterogeneity of studies and lack of consistency between the various immunonutrition supplementation regimens makes it impossible to recommend their use in critically ill adult patients at this time. Immune-modulating formulations are not currently recommended for use in children because of the lack of evidence to support their use.[16]

Clinical Controversy…

The value of adding probiotics to EN in the ICU setting is controversial. The use of probiotics has reduced ventilator-associated pneumonia, antibiotic-associated diarrhea, and overall infections in critically ill patients. However, increased risk of mortality has been shown when probiotics are used concomitant with fiber and jejunal feeding in patients with severe acute pancreatitis. The benefits of probiotics appear to be variable and likely product-specific and dose dependent. Recommendations

regarding their use are difficult to provide at this time.

Oral Supplements

In general, oral supplements are not intended for tube feeding but to enhance an oral diet. They are sweetened to improve taste and therefore are hypertonic (approximately 450-700 mOsm/kg [mmol/kg]), but osmolality is rarely a problem in the patient with a functioning GI tract. However, in the tube-fed patient, a sweetened product is unnecessary and may contribute to GI intolerance, particularly diarrhea. Powder supplements that are mixed with milk should be avoided in lactose-intolerant patients. In addition to liquid supplements, puddings, gelatins, bars, and milkshake-like supplements are available.

Modular Products

A module is a powder or liquid form of a nutrient (eg, protein, carbohydrate, fat, and dietary fiber) that is used to supplement nutrition intake when the diet or commercially available enteral formulation does not fully meet a patient's needs.[47] Alternatively, formulations available in powder or concentrate can be mixed with less water than needed for the standard dilution to deliver more nutrients in less volume. Infant formulas can be prepared to provide increased caloric density beyond the standard 19 to 20 kcal/oz (2.7-2.8 kJ/mL); concentrations of 22 to 30 kcal/oz (3.1-4.2 kJ/mL) are routinely used. The mixing process required for modular components increases the potential for bacterial contamination and incorrect preparation. Contamination is a particular concern with the use of blenders and reconstitution of powders.[9,52] A number of methods are used to fortify human milk so that it meets the needs of a premature infant fortify for added calories, protein, and minerals. They have been shown to improve nutritional outcomes in human milk-fed premature infants.[53,54]

Rehydration

Oral rehydration formulations are useful in maintaining hydration or treating dehydration in adult and pediatric patients with high GI output. Such formulations are available commercially in powder or liquid form or can be extemporaneously compounded. They can be administered orally or given via a feeding tube. The glucose content of oral rehydration solutions is important because it stimulates active transport systems, which, in turn, stimulate passive glucose-coupled sodium and water uptake. Therefore, oral or enteral administration of rehydration solutions may decrease fecal water loss and generate a positive fluid and electrolyte balance.[55,56]

FORMULARY AND DELIVERY SYSTEM CONSIDERATIONS

For an institution's enteral formulary, generally no more than one product per category is necessary, and it may be possible to omit certain categories based on the specific patient population cared for within a given institution. Additional selection criteria include container size and type, liquid or powder form, shelf life, ease of use, and cost.

Most enteral products are available as ready-to-use, prepackaged liquids, but a few are available in

the powdered state and require reconstitution prior to use. Advantages of ready-to-use liquid formulations are convenience and reduced susceptibility to microbiologic contamination. One disadvantage is that more storage space may be required. The ease or convenience of a ready-to-use liquid is especially important for self-care patients, the disabled, and those who have difficulty reading or following printed instructions. Ready-to-use liquid enteral formulations are generally available in ready-to-hang rigid plastic containers or bags (*closed system*), cans, or bottles. Bolus administration of EN is usually achieved using formulas available in cans or bottles. However, when formula from a can/bottle is used for continuous or cyclic administration, it must first be poured into a feeding bag and attached to an administration set to allow for administration via a pump. This "open system" has a higher risk of microbial contamination than the ready-to-hang containers. The use of a powder formula is also considered an open delivery system.

Contamination of enteral feeding formulations is a potential cause of diarrhea.[8,9] Contamination is caused by a lack of attention to proper handling techniques, inadequate cleaning and disinfection of preparation equipment, and the use of nonsterile or contaminated tube-feeding additives. Unlike liquid formulations, powdered products are not guaranteed by the manufacturer to be sterile because it is not possible to sterilize the powder without destruction of some of its components. Contamination of milk powder and consequently powdered infant formulas with *Enterobacter sakazakii* (*Cronobacter* species) has been reported.[52] Contamination of one infant formula at the manufacturing site with *E. sakazakii* was implicated in the death of an infant in a neonatal ICU, prompting FDA warnings regarding the use of powdered formulations in premature neonates and other immunocompromised infants.[57] Closed-system containers supply a ready-to-hang, prefilled, sterile supply of formula in volumes of 1 to 1.5 L. Most but not all enteral formulations intended for use in adults and some pediatric formulations are available in the closed-administration system. The closed-administration system also offers the advantage of not requiring refrigeration and allowing hang times up to 48 hours, whereas the conventional open-delivery system necessitates hang times of generally 4 to 8 hours.

New enteral connectors are currently being integrated into the EN marketplace to prevent enteral misconnections and improve patient safety. An enteral misconnection occurs when a component of the enteral feeding system is inadvertently connected to a non-enteral site, such as a tracheostomy tube, peritoneal dialysis catheter, or other medical device or IV tubing. Misconnections are commonly attributed to the use of universal connectors that allow for misconnections between incompatible systems.[58] Due to several reports of serious patient harm, including death, an international standard (ISO 80369) has been developed to guide the redesign of all small-bore connectors and the new enteral connectors, referred to as the ENFit™ system.[59] The ENFit™ connector provides a unique connection that is not compatible with any other device and has been specifically designed for all nutrition sources, enteral administration sets, enteral syringes, and all feeding tubes.[59] Filling and administration instructions for syringes used to deliver medications via feeding tubes will differ from oral syringes. Information about these processes and other resources is available at the Global Enteral Device Supplier Association (GEDSA) web site (www.stayconnected.org).[60]

COMPLICATIONS AND MONITORING

The majority of complications associated with EN are metabolic, GI, or mechanical. The early detection and management of potential complications is necessary to allow for the safe and successful use of EN. In addition, measures to avoid complications should be incorporated into the management of all patients receiving EN (**Table 143-7**).

TABLE 143-7 Suggested Monitoring for Patients on Enteral Nutrition

Parameter	During Initiation of EN Therapy	During Stable EN Therapy
Vital signs	Every 4-6 hours	As needed with suspected change (ie, fever)
Clinical assessment		
Weight	Daily	Weekly
Length/height (children)	Weekly-monthly	Monthly
Head circumference (<3 years of age)	Weekly-monthly	Monthly
Total intake/output	Daily	As needed with suspected change in intake/output
Tube-feeding intake	Daily	Daily
Enterostomy tube site assessment	Daily	Daily
GI tolerance		
Stool frequency/ volume	Daily	Daily
Abdomen assessment	Daily	Daily
Nausea or vomiting	Daily	Daily
Gastric residual volumes	Every 4-8 hours (varies)	As needed when delayed gastric emptying suspected
Tube placement	Prior to starting, then ongoing	Ongoing
Laboratory		
Electrolytes, blood urea nitrogen/ serum creatinine, glucose	Daily until stable, then 2-3 times/week	Every 1-3 months
Calcium, magnesium, phosphorus	Daily until stable, then 2-3 times/week	Every 1-3 months
Liver function tests	Weekly	Every 1-3 months
Trace elements, vitamins	If deficiency/toxicity suspected	If deficiency/toxicity suspected

EN, enteral nutrition.

Metabolic Complications

Metabolic complications associated with EN are similar to those associated with PN, but the

incidence tends to be lower.[23] Critically ill patients, especially those with underlying organ dysfunction, are at risk of developing complications related to hydration and electrolyte imbalance and altered glucose control. Patients who present with a history of minimal dietary intake for an extended period of time and have experienced significant weight loss are at risk of developing refeeding syndrome which can be evidenced by hypophosphatemia, hypokalemia, hypomagnesemia, thiamine deficiency, and sodium retention.[61] The frequency of clinical and laboratory assessment to monitor hydration, electrolytes, organ function, and glucose adequately for a patient who is critically ill or at risk of developing refeeding syndrome is greater than for a stable hospitalized patient or patients residing in rehabilitation units or at home (see Table 143-7). Patients receiving long-term EN at home may require laboratory monitoring only every 2 to 3 months, depending on their clinical status. Besides macronutrient content, it is important to evaluate the actual water and micronutrient content provided by the enteral formulation, especially in critically ill patients. Supplemental fluid, electrolytes, and minerals may be required in some patients. Conversely, for patients who have fluid retention or elevated serum electrolytes, the enteral formulation may need to be changed to one that is more concentrated or provides less of a particular nutrient, if available.

Gastrointestinal Complications

6 The GI complications associated with tube feeding include nausea, vomiting, abdominal distension, cramping, aspiration, diarrhea, and constipation. GRV refers to the volume of contents in the stomach and is measured by using a syringe and aspirating from a large-bore NG or gastrostomy tube. Although it has been recommended as a method to identify patients at risk of vomiting, aspiration and/or ventilator-associated pneumonia, this has not been validated in clinical studies.[8,62,63,64] However, it remains a widely used tool to help clinicians assess GI tolerance in patients receiving gastric tube feeding via continuous administration. The frequency of measuring GRV generally varies between every 4 and 8 hours, and most institutions follow a protocol that directs the frequency of monitoring and at what volume and for how long to hold feedings.[64] In critically ill patients receiving gastric feeding, GRVs should be measured every 4 hours.[13] Measurement of GRV is not recommended in patients receiving bolus or intermittent feedings.

If high GRVs occur, the response is often to stop or decrease the rate of continuous feedings. However, other signs and symptoms of intolerance should also be considered before stopping feeding because frequent interruptions in EN delivery can adversely affect the attainment of nutrition outcome goals. A trend toward increased GRV is generally more important than one isolated high measurement. Generally, in the absence of other signs of intolerance, EN should not be held when the GRV is less than 500 mL.[13,65] If symptoms are present, and GRVs are elevated, a decrease in the tube feeding rate or discontinuation may be warranted. Measures to reduce aspiration risk should be implemented when GRVs are consistently elevated, including elevating the head of the patient's bed to a 30° to 45° angle and changing to postpyloric continuous feeding. In addition, it may be beneficial to initiate a prokinetic agent such as metoclopramide or erythromycin to improve gastric emptying rate.[13,66] Other potential interventions include minimizing the use of narcotics, sedatives, or other agents that may slow gastric emptying and correcting underlying fluid and electrolyte imbalances that can impair GI motility.[67] Unless GRVs are excessive (greater than 500 mL in adults),

they should generally be reinstilled (refed) through the tube to minimize nutrient, fluid, and electrolyte losses.[9,68]

Aspiration pneumonia is considered the most serious complication associated with tube feeding. Although aspiration is a fairly common event for critically ill patients receiving tube feeding, progression to aspiration pneumonia is difficult to predict. Risk factors for aspiration include a previous aspiration episode, decreased consciousness, neuromuscular disease, structural airway or GI tract abnormalities, endotracheal intubation, vomiting, persistently high GRVs, and prolonged supine positioning.[62] Identification of these risk factors, along with close GRV monitoring, is recommended for all critically ill patients receiving tube feeding. Historically, blue food coloring had been added to enteral formulations in an attempt to detect aspiration. However, because of its low sensitivity for detection and association with several serious adverse events, including death, the addition of blue food dye to enteral formulations is not advised.[13,69] There are currently no reliable methods available to detect aspiration in enterally fed patients.[13,70]

Clinical Controversy…

The optimal dose of EN in critically ill adult patients is a subject of debate. The intentional use of "permissive" underfeeding or trophic EN (10-20 mL/h) in critically ill adult patients requiring short ICU lengths of stay may result in improved GI tolerance and similar short-term outcomes when compared to full feeding. However, the strategy of intentional underfeeding may not be appropriate for patients at high nutrition risk as defined by disease severity, preexisting malnutrition, and anticipated prolonged ICU length of stay.

Diarrhea is the most common GI complication in patients receiving EN, but the actual incidence is unclear due to the lack of a standard definition and the large number of contributing factors.[8,23] When monitoring for diarrhea, stool frequency, consistency, and volume should be evaluated, and previous bowel habits should be considered. Diarrhea has been defined as more than three liquid stools daily or a stool volume of more than 250 to 500 mL/day (20-25 mL/kg per day in children) for at least two consecutive days.[23] Therefore, the intermittent occurrence of one or two loose stools does not constitute diarrhea or require intervention.

7 Diarrhea in patients receiving tube feeding may be caused by a number of factors, and management should be directed at identifying and correcting the most likely cause(s).[71] Tube feeding-related factors that may contribute to diarrhea include too rapid delivery or advancement of formula, intolerance to the formula composition, administration of large volumes of feeding into the small bowel, and formula contamination. Thus, measures to prevent or manage diarrhea related directly to the tube feeding should address these potential causes.[23,67,72] If diarrhea occurs when using a fiber-free formulation, a fiber-containing formulation may be considered. If using a high-fat formulation, it may be beneficial to switch to a formulation lower in fat or having a higher proportion of the fat supplied as MCTs; although, a high MCT concentration has also been associated with diarrhea. Finally, it is important to assess the risk of bacterial contamination of the formula and take steps to minimize any potential risk factors. If infectious etiologies have been excluded, severe diarrhea may require pharmacologic treatment with loperamide, diphenoxylate/atropine, or opioids

(see chapter 36).

Drug therapy, particularly the use of broad-spectrum antibiotics, is a common cause of diarrhea that is unrelated to tube feeding. Sorbitol, used as a sweetening agent in many liquid formulations to enhance palatability, is an osmotic laxative that can cause diarrhea. In addition, many drugs available in a liquid form are hyperosmolar, which may contribute to diarrhea, especially when these medications are not diluted properly before administration. Because many patients receiving tube feeding also receive medications in a liquid form, all medications should be evaluated for their potential contribution. Infectious causes, such as antibiotic-induced bacterial overgrowth by *Clostridium difficile* or other intestinal flora, need to be considered when diarrhea develops. Malabsorption, secondary to the underlying disease state or condition, may also cause diarrhea.

Mechanical Complications

Mechanical complications of EN are those associated with the feeding tube, including tube occlusion or malposition, and inadvertent nasopulmonary intubation. Feeding tube occlusion usually results from improper medication administration and/or flushing. Kinking of the tube also may cause occlusion. Adult feeding tubes should be flushed with at least 15 to 30 mL of water before and after administering any medication. If more than one medication is scheduled for a given time, each should be administered separately, and the tube should be flushed with 5 to 15 mL of water between drugs.[9,73] Flush volume will be less for children but should be adequate to ensure complete flushing of the medication through the tube.[74] The frequency of flushing should be at least every 8 hours during continuous feeding and before and after each intermittent feeding. If tube occlusion occurs, the tube should be irrigated with warm water. Other fluids such as colas and cranberry juice have been used to irrigate occluded tubes but have not been shown to be any more effective than warm water. Some success in reestablishing patency has been shown with the use of pancreatic enzymes mixed with sodium bicarbonate.[73] Declogging devices that are specifically designed to unclog feeding tubes are available. They have been designed to either mechanically break through or remove the occlusion or provide an applicator and syringe prefilled with pancreatic enzymes and various powders targeted to restore patency.[8,73]

Inadvertent nasoenteric tube removal or displacement has been reported in approximately 40% of patients receiving EN.[75] An agitated or confused patient may pull at the feeding tube and cause its removal or malposition. Measures to decrease agitation and confusion should be attempted. Securing the tube with tape may be helpful, as well as marking the tube with permanent ink at the exit site to assess for position change. A nasal bridle that uses a magnetic retrieval system has proven to be a simple and effective method for securing nasoenteric feeding tubes and preventing accidental removal.[70]

When a feeding tube is inserted nasally or orally, there is a risk that the tube may inadvertently enter the tracheobronchial tree. The risk may be higher in patients who have an impaired cough or gag reflex and when a stylet is used for tube insertion. Proper positioning of the tube should always be confirmed by radiography prior to feeding initiation and routinely reassessed to avoid inadvertent administration of enteral formula into the lung.

Other Complications

Infectious complications of feeding tube placement include sinusitis (with nasoenteric placement), exit site-related infections (eg, cellulitis, subcutaneous abscess, and necrotizing fasciitis), and intraabdominal infections (eg, peritonitis and abscess). Leaking and bleeding around the exit site can also occur.[17] Formation of excessive granulation tissue around the exit site is often the cause of leaking and bleeding and can be managed by applying silver nitrate and topical corticosteroids.

A unique complication of tube feeding use in children, especially in the first year of life, is the development of oral hypersensitivity, poor oral/motor skills, and food aversion when oral feeding is held. In these children, transitioning from tube to oral nutrition can be difficult and protracted. The involvement of an occupational or speech therapist, behavioral psychologist, or other trained individual, as well as perseverance by the family, often is necessary to improve oral intake. Avoidance of a strict nothing by mouth (NPO) status, if possible, and oral stimulation programs for those children who must remain NPO are recommended to avoid this complication.[76]

NUTRITION CARE PLAN

A nutrition care plan that incorporates nutrition assessment and therapy goals should be developed for all EN patients (see Chapter 141). Desired outcomes of EN are to promote an adequate nutritional state in adults and to promote growth and development of infants and children. The EN goals are individualized and based on meeting estimated fluid, calorie, protein, and micronutrient requirements. The desired end point should be included in the care plan. The end point may be resolution of a disease or condition that impairs ability to eat, such as in a critically ill trauma patient who is expected to transition back to an oral diet. EN may be considered a lifelong therapy for those with a permanent impairment that restricts or limits eating, such as gastroparesis.

Assessing the outcome of EN requires monitoring objective measures of body composition, protein and energy balance, and muscle function and wound healing. In addition to optimizing nutrition, the goal of EN is to reduce disease-related morbidity and mortality. Measures of disease-related morbidity include length of hospital stay, infectious complications, and the patient's functional status and sense of well-being. A target weight should be established for each patient and energy content from the EN regimen adjusted as needed to safely achieve or maintain the target weight. In general, in adults, no more than 1 to 2 pound [approximately 0.45-0.9 kg] per week should be gained or lost. Children should be followed using standard growth velocity expectations. EN may be used to supplement an oral diet when oral intake is inadequate and should be modified as needed based on changes in tolerance.

DRUG DELIVERY VIA FEEDING TUBE

Using enteral feeding tubes to deliver drugs is a common practice and offers an alternative for patients unable to take drugs by the oral route. However, in addition to tube occlusion, effects on drug bioavailability and other potential interactions need to be considered when using this route. Medications have been given as a concomitant bolus administration via the feeding tube or admixed

with the enteral feeding formulation.

Concomitant Drug Administration

8 Concomitant administration of medications with enteral feedings can be extremely complicated and potentially deleterious. Delivering medications directly into the stomach allows for the normal process of drug dissolution. Medication delivery directly into the small bowel however may result in alterations in drug dissolution because the stomach is bypassed. In addition, therapeutic effects designed to occur within the stomach, such as with antacids and sucralfate, may not be achieved. Because many drugs are best absorbed in the fasting state, they should be administered on an empty stomach whenever possible. Patients on bolus gastric feeding must receive these medications appropriately spaced between feedings, and patients on continuous feeding will require feeding interruptions for drug administration.

Selecting the proper medication dosage form for coadministration with the tube feeding is another important consideration. Medications in sublingual form, sustained-release capsules or tablets, and enteric-coated tablets should not be crushed and therefore should not be administered via enteral feeding tubes.[9,73] Solid dosage forms that are appropriate to crush should be prepared as a very fine powder and mixed with 15 to 30 mL of water or other appropriate solvent before administering through the tube. In addition, many capsules may be opened and the contents administered in the same manner. Pellets contained inside microencapsulated dosage forms should generally not be crushed. It may be acceptable to administer intact pellets through larger bore feeding tubes, provided that the pellets are small enough and drug absorption is not compromised.[77,78] To avoid the need to crush a solid dosage form, liquid dosage forms are commonly preferred for administration through feeding tubes. However, the risk of GI intolerance should be considered because of the hyperosmolality of many liquid formulations and possible sorbitol content.[73,79] Although the use of a liquid dosage preparation may be more convenient than a solid dosage form, it may not be the best choice if GI intolerance is an issue.

Clinical Controversy...

The source of water used to flush the feeding tube and maintain patient hydration via the feeding tube is controversial. Tap water is adequate for the otherwise healthy, immunocompetent patient. However, the acute or chronically ill patient receiving EN may be at higher risk from exposure to nonsterile tap water and may benefit from the use of purified water. Nosocomial infections from contaminated tap water sources have been reported in critically ill patients. The use of purified water for tube-feeding flushes in at-risk patients has been recommended by some clinicians.

Admixture of Drugs with Enteral Feeding

Mixing liquid medications with certain enteral feeding formulations is associated with several types of physical incompatibilities, including granulation, gel formation, separation, and precipitation.[73,77] Not only can these physical incompatibilities inhibit drug absorption, but gel formation may clog small-bore feeding tubes. Physical incompatibility with medications is more common in formulations

that contain intact protein than in those with hydrolyzed protein. Also, medication and enteral formula incompatibilities are more common with the use of acidic pharmaceutical syrups. The most prudent recommendation is to avoid the routine admixture whenever possible, especially for nonaqueous preparations and syrups. In the clinical setting, exceptions do exist, such as adding sodium or magnesium to enteral formulas to assist in maintaining or repleting electrolytes.

Drug–Nutrient Interactions

9 The most significant drug–nutrient interactions that can occur during continuous enteral feeding are those in which the drug's bioavailability is reduced, and the desired pharmacologic effect is not achieved (**Table 143-8**).[80] Unfortunately, limited clinical studies are available to document the extent of this problem with enteral feeding. Most of the observations are anecdotal case reports involving few patients. One of the well-documented interactions is between phenytoin and enteral feeding. Phenytoin serum concentrations may decrease by 50% to 75% when phenytoin is given concomitantly with EN, possibly as a result of the binding of phenytoin to calcium caseinates or protein hydrolysates in the enteral formulation. Patients typically require higher than normal phenytoin doses while receiving EN.[73,77] The patient's clinical response and phenytoin serum concentrations should be monitored to assure that the desired therapeutic effects are achieved.

TABLE 143-8 Medications with Special Considerations for Enteral Feeding Tube Administration

Drug	Interaction	Comments
Phenytoin	Reduced bioavailability in the presence of tube feedings	To minimize interaction, holding tube feedings 1-2 hours before and after phenytoin has been suggested; this has no proven benefit
	Possible phenytoin binding to calcium caseinates or protein hydrolysates in enteral feeding	Adjust tube-feeding rate to account for time held for phenytoin administration
		Monitor phenytoin serum concentration and clinical response closely
		Consider switching to IV phenytoin if unable to reach therapeutic serum concentration
Fluoroquinolones Tetracyclines	Potential for reduced bioavailability because of complexation of drug with divalent and trivalent cations found in enteral feeding	Consider holding tube feeding 1 hour before and after administration
		Avoid jejunal administration of ciprofloxacin
		Monitor clinical response
Warfarin	Decreased absorption of warfarin because of enteral feeding; therapeutic	Adjust warfarin dose based on INR
		Anticipate need to increase warfarin dose

Drug	Interaction	Comments
		when enteral feedings are started and decrease dose when enteral feedings are stopped
	effect antagonized by vitamin K in enteral formulations	Consider holding tube feeding 1 hour before and after administration
		Granules become sticky when moistened with water and may occlude small-bore tubes
Omeprazole Lansoprazole	Administration via feeding tube complicated by acid-labile medication within delayed-release, base-labile granules	Granules should be mixed with acidic liquid when given via a gastric feeding tube
		An oral liquid suspension can be extemporaneously prepared for administration via a feeding tube

INR, International normalized ratio.

Decreased bioavailability of certain antibiotics, particularly quinolones, has been documented when coadministered with enteral feeding due to complexation with multivalent cations such as calcium, magnesium, and iron contained in the feeding.[73,77] Although the practice of holding tube feeding for 30 minutes before and 30 minutes after quinolone administration has been recommended, it has not been shown to improve drug absorption. Another option is to increase the quinolone dose when given concurrently with EN. There is evidence to suggest that ciprofloxacin absorption is significantly decreased when given via a jejunostomy tube, so this practice should be avoided, if possible.[73]

Warfarin resistance has been documented during enteral feeding, possibly as a consequence of decreased absorption or the antagonist effects of vitamin K in the feeding formulation. Before 1980, it was thought that the content of vitamin K (up to 1,330 mcg/1,000 kcal [or 317 mcg/1,000 kJ] of enteral feeding formula) was contributing to the pharmacologic interaction with warfarin. Subsequently, the vitamin K content within formulas intended for use in adults was reduced to less than 200 mcg/1,000 kcal (or 48 mcg/1,000 kJ). However, warfarin resistance continues to be reported, and a warfarin dosage increase may be required in patients receiving EN.[73,81] The International Normalized Ratio should be closely monitored in patients receiving both warfarin and enteral feedings. Conversely, when EN is discontinued, a reduction in warfarin dosage may be required.

CLINICAL BOTTOM LINE

Identifying appropriate candidates for EN and designing a personalized EN regimen and monitoring plan is a complex process that is often under-appreciated. The successful use of EN can minimize the need for PN in patients unable to meet nutrient requirements with an oral diet. Ultimately, no disease

process can improve with prolonged starvation and malnutrition. A.S.P.E.N. has identified safety issues related to the administration and management of EN and created practice recommendations based on evidence-based research and expert opinion.[9] These guidelines address the provision and assessment of nutrition support therapy, including EN, for adult and pediatric critically ill patients.[13,16] A multidisciplinary team approach, either as a formal nutrition support service or as a team of caregivers within the practice setting, is recommended to optimize patient outcomes.

Chapter 144: Obesity

Amy Heck Sheehan; Judy T. Chen; Jack A. Yanovski; Karim Anton Calis

INTRODUCTION

KEY CONCEPTS

- 1 Two clinical measures of excess body fat, regardless of sex, are the body mass index (BMI) and the waist circumference (WC). BMI and WC provide a better assessment of total body fat than weight alone and are independent predictors of obesity-related disease risk.
- 2 Excessive central adiposity increases risk for development of type 2 diabetes, hypertension, and dyslipidemia.
- 3 Weight loss of as little as 5% of total body weight can significantly improve blood pressure, lipid levels, and glucose tolerance in overweight and obese patients. Sustained, large weight losses (eg, after bariatric surgery) are associated with a lower risk of cardiovascular events and death and with long-term improvements in many of the complications associated with obesity.
- 4 Clinicians should consider the weight-altering effects of medications used to treat comorbid conditions (eg, antidepressants, antipsychotics, antiepileptics, and antidiabetics) and select medications that promote weight loss or are weight-neutral.
- 5 Bariatric surgery is reserved for patients with extreme obesity having a BMI more than or equal 40 kg/m^2 or BMI more than or equal to 35 kg/m^2 with significant comorbidities.
- 6 Pharmacotherapy may be considered an adjunctive treatment in patients with a BMI more than or equal to 30 kg/m^2 or BMI of 27 to 30 kg/m^2 with a comorbidity if comprehensive lifestyle modifications (ie, diet, exercise, and behavioral modification) fail to achieve or sustain weight loss.
- 7 Weight regain occurs with a high probability when pharmacotherapy for obesity is discontinued.
- 8 Pharmacotherapy should be discontinued if weight loss of at least 5% is not achieved after

12 weeks of maximum-dose therapy with lorcaserin, phentermine-topiramate, or bupropion-naltrexone because significant weight loss is unlikely to be achieved despite continued therapy. Liraglutide should be discontinued if weight loss of at least 4% is not achieved after 16 weeks of therapy.

- 9 The Food and Drug Administration (FDA) does not regulate labeling of herbal and food supplement diet agents, and content is not guaranteed.

Since 1980, the prevalence of obesity worldwide has more than doubled.[1] It is now estimated that at least two of every three women and three of every four men are overweight or obese in the United States, and the number of obese women outnumbers those who are overweight.[2] While the rise in childhood obesity appears to have reached a plateau, the prevalence remains historically high with one of every three adolescents currently considered overweight or obese.[3] The presence of obesity and overweight is associated with a significantly increased risk for the development of many diseases (**Table 144-1**),[4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19] poorer outcomes of comorbid disease states, and increased healthcare costs. As of 2008, it was estimated that obesity accounted for 9.1% of total medical expenditures in the United States, and the cost of treating obesity-related illnesses in adults approached national health spending of $147 billion annually.[20] National and global initiatives to stem the obesity epidemic have been established through prevention strategies, consensus guidelines, and best practices.[5,21,22,23,24] This chapter reviews the epidemiology, pathophysiology, and therapeutic approaches for the management of obesity. Although nonpharmacologic treatment modalities are discussed, the pharmacotherapy of obesity is highlighted, and the role of pharmacotherapy relative to the other therapeutic options is critically reviewed.

TABLE 144-1 Conditions More Prevalent Among Patients with Obesity

Cancer
Breast cancer (postmenopausal)
Colorectal cancer
Gallbladder cancer
Endometrial cancer
Esophageal carcinoma
Hepatic cancer
Kidney cancer
Ovarian cancer
Pancreatic cancer
Prostate cancer

Rectal cancer

Cardiovascular

Atrial fibrillation

Cerebral vascular accidents

Congestive heart failure

Coronary artery disease

Cor pulmonale

Hypertension

Left ventricular hypertrophy

Myocardial infarction

Peripheral vascular disease

Peripheral venous insufficiency

Pulmonary embolism

Thrombophlebitis

Varicose veins

Venous thromboembolism

Dermatologic

Acanthosis nigricans

Cellulitis

Intertrigo, carbuncles

Lymphedema

Skin tags

Status pigmentation of legs

Striae distensae (stretch marks)

Psoriasis (women)

Endocrine and Reproductive

Amenorrhea and other menstrual disorders

Congenital anomalies

Fetal abnormalities

Hirsutism

Hypogonadism (male)

Infertility

Polycystic ovarian syndrome

Hyperandrogenism

Pregnancy complications

Sexual dysfunction

Gastrointestinal

Cholelithiasis

Gastroesophageal reflux disease

Hepatic cirrhosis

Hernias

Nonalcoholic fatty liver disease

Genitourinary

Chronic kidney disease

Increased serum urate

End-stage renal disease

Obesity-related glomerulopathy

Urinary stress incontinence

Metabolic

Diabetes mellitus

Hyperlipidemia

Hyperinsulinemia

Hypertriglyceridemia

Low high-density lipoprotein

Impaired glucose tolerance

Metabolic syndrome

Musculoskeletal

Degenerative joint disease

Diffuse idiopathic skeletal hyperostosis

Disc disease

Gait disturbance

Gout and hyperuricemia

Fibromyalgia

Immobility

Low back pain/back strain

Osteoarthritis (knee, hips, ankles, feet)

Plantar fasciitis

Neurologic

Carpal tunnel syndrome

Idiopathic intracranial hypertension

Meralgia paresthetica

Pseudotumor cerebri

Stroke

Oral Health

Dental caries

Loss of teeth

Periodontitis

Xerostomia

Psychological

Affective disorders

Body image disturbance

Depression

Eating disorders

Low self-esteem

Social stigmatization

Respiratory

Asthma

Chronic obstructive pulmonary disease

Dyspnea

Hypoventilation syndrome

Obstructive sleep apnea

Pickwickian syndrome

Pneumonia

Pulmonary hypertension

EPIDEMIOLOGY

One of the global health targets set by the World Health Assembly is to halt the rise of diabetes and obesity.[23] Obesity in the United States has increased in prevalence since the 1960s. The National Health and Nutrition Examination Survey (NHANES) II data (1976-1980) estimated the prevalence of obesity among adults in the United States at 15%.[25] During NHANES 1999 to 2000, the prevalence increased twofold to 30.9%, and by 2011 obesity affected 34.9% of the adult population.[2,3] While the trends in obesity appear to have leveled off in recent years, prevention of obesity remains a public health priority due to its high prevalence. Children who are overweight are likely to remain overweight as adults. Furthermore, overweight or obese children and adolescents have a higher risk of premature mortality and morbidity as adults.[26] Therefore, childhood and early adulthood are critical intervention periods for prevention of obesity in the future. The prevalence of obesity varies by sex among racial and ethnic minorities within the United States. The highest prevalence is observed among non-Hispanic black women (56.8% obese) compared with 39.2% for non-Hispanic black men.[2] Non-Hispanic blacks are more likely to have extreme obesity compared to other ethnic groups. This gender disparity is also associated with the level of parental education. Young black women from the lowest educated families are at greater risk of obesity compared with young black men.[27] Obesity is reported in approximately one-third of White men and women, and the prevalence is also high among Hispanic men and women, exceeding 35%.[2] Educational achievement, which is linked to socioeconomic status, is also correlated with the fraction of people who are overweight; the prevalence of overweight is greatest in those with less than a high school education.

ETIOLOGY

Obesity occurs when there is increased energy storage resulting from an imbalance between energy intake and energy expenditure over time. The specific etiology for this imbalance in the vast majority of individuals is multifactorial, with genetic and environmental factors contributing to various degrees. In a small minority of individuals, excess weight may be attributed to an underlying medical condition or an unintended effect of a medication.

Genetic Influences

Observational studies in humans and experimental studies in animal models have demonstrated the strong role of genetics in determining both obesity and distribution of body fat. In some individuals, genetic factors are the primary determinants of obesity, whereas in others, obesity may be caused primarily by environmental factors. The genetic contribution to the actual variance in body mass index (BMI) and body fat distribution is estimated to be up between 40% and 70%.[28] A number of single-gene mutations producing extreme obesity have been identified, but such mutations are rare and account for a relatively small number of the total cases of obesity.[28] The total number and identity of contributing genes are still being determined, as is the means by which the many potential so-called "obesity" genes interact with each other and with the environment to produce the obese phenotype.

Environmental Factors

Many of the societal changes associated with economic development over the past 40 years have been implicated as potential causes for the increase in the prevalence of obesity.[29] These include an abundant and easily accessible food supply and the material comforts of modern life in Western civilizations, which have contributed to a reduction in physical activity. Advances in technology and automation have resulted in more sedentary lifestyles during both work and leisure time for most individuals. At the same time, there has been a significant increase in the availability and portion size of high-fat foods, which are aggressively marketed and are often more convenient and less expensive than healthier alternatives. This modern environment has been described by some as "obesogenic" because it is likely to result in a state of positive energy balance in many individuals (**Fig. 144-1**).[30] Obesity has also been reported more frequently among individuals within close social networks (eg, siblings, spouses, and friends), with a person's risk of becoming obese increasing significantly if a friend in his or her social network is obese.[31] Finally, it should be noted that cultural factors, socioeconomic status, and religious beliefs may influence eating habits and body weights.

FIGURE 144-1

Net energy stores are determined by various inputs and outputs. Simply stated, obesity occurs when there is an imbalance between energy intake and expenditure.

Medical Conditions

Occasionally, patients present with obesity secondary to an identifiable medical condition. Conditions associated with weight gain include iatrogenic and idiopathic Cushing syndrome, growth hormone deficiency, insulinoma, leptin deficiency, and various psychiatric disorders, such as depression, binge-eating disorder, and schizophrenia. Hypothyroidism is often included in this list, but it mostly causes fluid retention (myxedema) and is generally not a cause of significant obesity. Genetic syndromes that have obesity as a major component are extremely rare and include Prader-Willi, Wilms' tumor, aniridia, genitourinary abnormalities or gonadoblastoma, and mental retardation (WAGR), Simpson-Golabi-Behmel, Cohen, Bardet-Biedl, Carpenter, Börjeson, and Wilson-Turner syndromes. The clinician evaluating a patient for obesity needs to be aware of these potential conditions. The physical examination of obese patients always should include an assessment for secondary causes of obesity, including genetic syndromes.

Medications

An increasing number of medications are associated with unintended weight gain.[32] These include several anticonvulsants (eg, carbamazepine, gabapentin, pregabalin, and valproic acid), antidepressants (eg, mirtazapine and tricyclic antidepressants), atypical antipsychotics (eg, clozapine, olanzapine, quetiapine, and risperidone), conventional antipsychotics (eg, haloperidol), and hormones (eg, corticosteroids, insulin, and medroxyprogesterone). Although the pharmacologic mechanism responsible for weight gain is usually drug-specific, in most cases the precise mechanism is unknown.

PATHOPHYSIOLOGY

The pathophysiology of obesity involves numerous factors that regulate appetite and energy balance.[33,34,35] Disturbance of these homeostatic functions results in an imbalance between energy intake and energy expenditure.

Appetite

Human appetite is a complex process that is the net result of many inputs within a neural network involving principally the hypothalamus, limbic system, brainstem, hippocampus, and elements of the cortex.[33,34,35] Within this neural network, many neurotransmitters and neuropeptides have been identified that can stimulate or inhibit the brain's appetite network and thereby affect total caloric intake. The first receptor systems found to alter food intake in animals and humans were the biogenic amines. Serotonin, also known as 5-hydroxytryptamine (5-HT), and cells known to respond to 5-HT are found throughout the central nervous system (CNS) and the periphery. Currently, two major noradrenergic receptor subtypes are recognized (α and β), each with multiple subtypes. Histamine and dopamine also demonstrate multiple receptor subtypes, but their role in the regulation of human eating behaviors and food intake is less well documented. **Table 144-2** summarizes the major effects of direct receptor stimulation, inhibition, and changes in synaptic cleft amine concentrations on food intake.

TABLE 144-2 Effects of Various Neurotransmitters, Receptors, and Peptides on Food Intake[33,34]

Anatomic Region	Increased Eating	Decreased Eating
Arcuate nucleus of hypothalamus	NPY AgRP	α-MSH CART Leptin Insulin GLP-1 PYY
Paraventricular nucleus of hypothalamus	NPY AgRP	α-MSH, melanocortin CRH CCK
Lateral hypothalamus	Orexin MCH	
Hypothalamus	Norepinephrine α_2 Serotonin 5-HT_{1A}	Norepinephrine α_1 and β_2 Serotonin 5-HT_{1B} and 5-HT_{2C} Histamine H_1 and H_3

Anatomic Region	Increased Eating	Decreased Eating
Nucleus accumbens	Dopamine	
	NPY	Leptin
Brainstem (hindbrain)	AgRP	α-MSH, melanocortin
	Opioids (especially μ)	CCK
		Leptin
Vagus nerve	Ghrelin	CCK
		GLP-1
		PYY

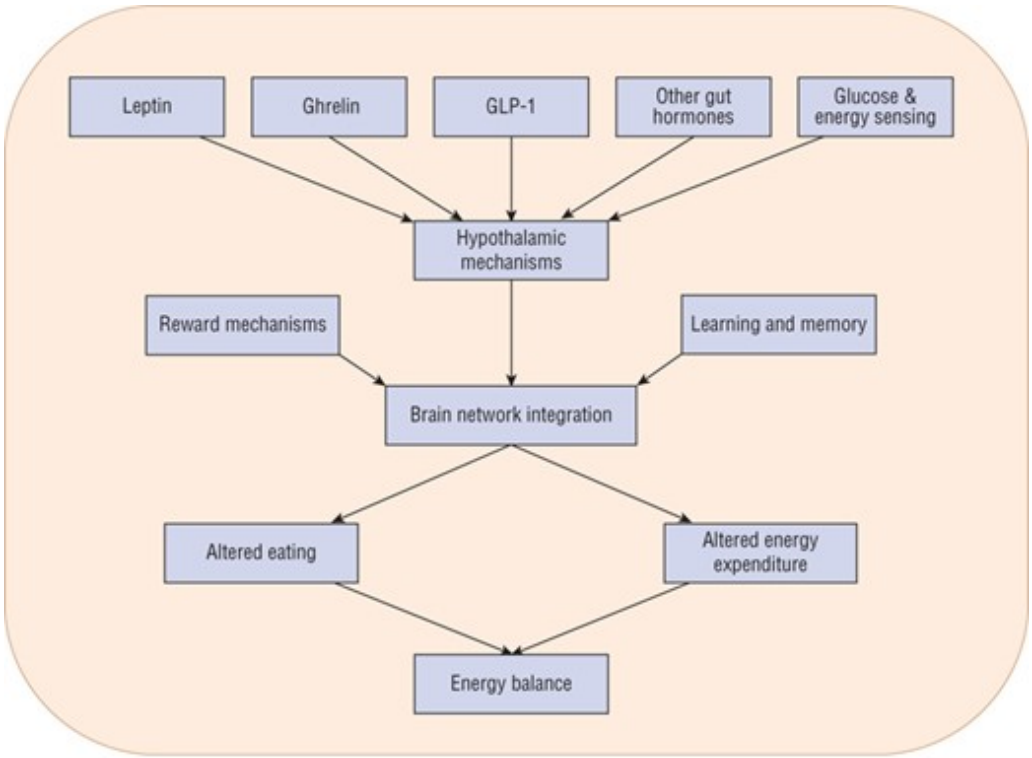
AgRP, agouti-related protein; CART, cocaine-and-amphetamine-regulated transcript; CCK, cholecystokinin; CRH, corticotropin-releasing hormone; GLP-1, glucagon-like peptide-1; MCH, melanocyte concentration hormone; α-MSH, α-melanocyte-stimulating hormone; NPY, neuropeptide Y; PYY, peptide YY.

Many neuropeptides also influence appetite within the hypothalamus. Most research has focused on the neural projection between parts of the hypothalamus and the arcuate nucleus with signals to the paraventricular nucleus. The key peptides in this projection are thought to include neuropeptide Y and α-melanocyte–stimulating hormone. Neuropeptide Y is the most potent known stimulator of eating, and α-melanocyte–stimulating hormone action at the melanocortin 3 and 4 receptors is one of the crucial inhibitors of eating.[33] The lateral hypothalamus has been referred to as the "hunger" center within the brain. The most prominent of the lateral hypothalamic peptides, orexin, increases food intake stimuli within the lateral hypothalamus.[33] Another important neuropeptide stimulator of eating that principally originates in the lateral hypothalamus is melanocyte-concentrating hormone. Neurons in the lateral hypothalamus use orexin and melanocyte-concentrating hormone to communicate with other neurons throughout the brain and thereby affect a number of functions beyond appetite.[33] Table 144-2 summarizes the major effects of various neuropeptides on food intake. Although hunger and satiety functions are thought to be primarily regulated by the hypothalamus, humans eat in response to a broad set of stimuli, including reward, pleasure, learning, and memory.

Peripheral appetite signals also dramatically affect food intake.[33,34] Leptin, a hormone that is secreted by adipose cells, acts on the arcuate nucleus of the hypothalamus and elsewhere in the brain to decrease appetite and increase energy expenditure.[33,34] Studies conducted in leptin-deficient mice and humans revealed that exogenous leptin administration produced significant weight loss. However, recombinant leptin replacement therapy in obese humans who are not leptin deficient has not proved successful because obese humans appear to be leptin resistant.[33] **Figure 144-2** shows the peripheral link that leptin appears to provide in signaling the CNS about the status of fat cell mass.

FIGURE 144-2

Intrinsic hypothalamic hunger and satiety mechanisms are modified by input from fat tissue via leptin, and from the gut via ghrelin, glucagon-like peptide-1 (GLP-1), and other hormones. Additional input is derived by direct sensing of prevailing glucose and other energy signals. The hypothalamus generates signals that are integrated within brain networks, which also receive additional signals. The brain network effects change in energy balance by modifying food intake and energy expenditure.



Other peripheral signals important to the brain's processing of appetite include several gut hormones, notably those released by the intestine in response to passage of digesting food such as glucagon-like peptide-1 (GLP-1), oxyntomodulin, and peptide YY.[34] Each of these hormonal signals suppresses eating in animals and humans. GLP-1 has other effects, most importantly as an incretin, which facilitates release of insulin by pancreatic β cells in response to meal-related glucose. Ghrelin, another important gut hormone that is released from the distal stomach and duodenum, stimulates appetite. An understanding of the relationships among the brain, its many neurotransmitters and neuropeptides, environmental stimulation of brain activities, and other hormones is still evolving.

Energy Balance

The net balance of energy ingested relative to energy expended by an individual over time determines the degree of obesity (see Fig. 144-1). An individual's metabolic rate is the single largest determinant of energy expenditure. Resting energy expenditure (REE) is defined as the energy expended by a person at rest under conditions of thermal neutrality. Basal metabolic rate (BMR) is defined as the REE measured soon after awakening in the morning at least 12 hours after the last

meal. Metabolic rate increases after eating based on the size and composition of the meal. It reaches a maximum approximately 1 hour after the meal is consumed and returns to basal levels 4 hours after the meal. This increase in metabolic rate is known as the *thermogenic effect of food*. The REE measures the energy costs of the wakeful state and may include the residual thermogenic effect of a previous meal. Physical activity is the other major factor that affects total energy expenditure and is the most variable component. With regard to energy storage, there are two major types of adipose tissue, white and brown. The primary function of white adipose tissue is lipid manufacture, storage, and release. Brown adipose tissue, once believed to be found only in infants, is now recognized to exist in most adults.[36] It is more commonly identified in lean than obese individuals, but its importance for human obesity remains unclear. Whereas lipid storage occurs in response to insulin, lipid release is seen during periods of calorie restriction. Brown adipose tissue is notable for its ability to dissipate energy via uncoupled mitochondrial respiration.[36] Both white and brown adipose tissues are highly innervated by the sympathetic nervous system, and adrenergic stimulation via β-adrenergic receptors (β_1, β_2, and β_3) is known to activate lipolysis in fat cells as well as increase energy expenditure in adipose tissue and skeletal muscle.

CLINICAL PRESENTATION

Although obesity is readily apparent, most obese patients seek healthcare only when obesity-associated comorbidities become problematic. The National Institutes of Health (NIH) has established a stratification of weight excess based on associated medical risks.[37] These levels of excess weight are defined on the basis of BMI, a measure of total body weight relative to height. Using metric units, BMI (kg/m^2) is defined as weight in kilograms divided by height in meters squared (kg/m^2). Using pounds and inches, BMI (kg/m^2) is estimated as (weight [lb]/height [$inches^2$]) × 703. Adults with a BMI of 25 to 29.9 are considered "*overweight*"; the terms *obese*, and *extreme obese* are reserved for those with a BMI of 30 to 39.9, and 40 and over, respectively. While the precise definition of childhood obesity is still lacking, the Endocrine Society clinical practice guideline currently classifies children and adolescents ages 2 to 18 years with a BMI at the 95th percentile or above as obese, and those with a BMI between the 85th and 94th percentiles as overweight.[38] Because BMI may overestimate the degree of excess body fat in some clinical situations (eg, edematous states, extreme muscularity, muscle wasting, and short stature), the assessment of body composition in such cases often requires clinical judgment.

1 BMI is an acceptable measure of obesity and is the practical method of defining obesity in the clinic and epidemiologic studies; however, it does not always correspond to excess fat. There are well-established differences in the relationship between BMI and obesity-related risks among disparate racial, sex, and ethnic groups. For example, BMI underestimates risks among Asians;[39] whereas Caucasians tend to have higher level of visceral adipose tissue than African American adults at higher levels of BMI and waist circumference.[40] Central obesity reflects high levels of intra-abdominal or visceral fat, and this pattern of obesity is associated with an increased propensity for the development of hypertension, dyslipidemia, type 2 diabetes, and cardiovascular disease (sometimes referred to as the "metabolic syndrome"). Thus, in addition to the absolute excess fat mass, the distribution of this fat regionally in the body has important clinical effects. Intra-abdominal

fat is best estimated by imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) but can be approximated through measurement of waist circumference (WC). Clinically, WC is the narrowest circumference measured in the area between the last rib and the top of the iliac crest. The current definition for high-risk WC is greater than 40 inches (102 cm) in men and greater than 35 inches (89 cm) in women.[6] Routine determination of WC should be implemented in those with BMIs between 25 and 34.9 kg/m^2 to assess additional metabolic risk. However, after a patient's BMI reaches 35 kg/m^2, it is not necessary to measure WC because it will likely be elevated and adds little in terms of risk prediction.[5]

2 Although BMI and WC are related, each measure independently predicts disease risk. Both measurements should be assessed and monitored during therapy for obesity.[5,6] The risks for development of type 2 diabetes, hypertension, or cardiovascular disease at various stages of obesity based on BMI or WC are outlined in **Table 144-3**. Note that increased WC confers increased risk even in normal-weight individuals.

TABLE 144-3 Classification of Overweight and Obesity by Body Mass Index, Waist Circumference, and Associated Disease Risk

			Disease Risk[a] (Relative to Normal Weight and Waist Circumference)	
			Men	
			≤40 in (≤102 cm)	**>40 in (>102 cm)**
			Women	
	BMI (kg/m^2)	**Obesity Class**	**≤35 in (≤89 cm)**	**>35 in (>89 cm)**
Underweight	<18.5		—	—
Normal weight[b]	18.5-24.9		—	High
Overweight	25.0-29.9		Increased	High
Obesity	30.0-34.9	I	High	Very high
	35.0-39.9	II	Very high	Very high
Extreme obesity	≥40	III	Extremely high	Extremely high

BMI, body mass index.

[a]Disease risk for type 2 diabetes, hypertension, and cardiovascular disease.

[b]Increased waist circumference can also be a marker for increased risk even in persons of normal weight.

Organization Consultation on Obesity. Geneva: World Health Organization, 1997. Reprinted with permission from National Institutes of Health, National Heart, Lung and Blood Institute. 1997, http://www.nhlbi.nih.gov/guidelines/obesity/ob_home.htm.

Comorbidities

Obesity and overweight are associated with an increased risk of all-cause mortality. The greater the BMI, the greater the risk of cardiovascular diseases (CVD), type 2 diabetes, and all-cause mortality in both men and women.[5] Substantial reduction in life expectancy has been predicted in adults with BMIs greater than 35 kg/m^2.[41] Excessive body fat affects virtually all organ systems. A plethora of evidence continue to link obesity with numerous disease states and health conditions (see Table 144-1).[4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19] Therefore, it is important for clinicians to assess the presence of these chronic conditions in all overweight and obese individuals.[35] Because obese individuals are also at risk for developing many malignancies, adherence to routine age- and risk- appropriate cancer screening guidelines is recommended.[35] Furthermore, hypertension, hyperlipidemia, coronary heart disease, cerebrovascular accidents, insulin resistance, glucose intolerance, and diabetes are all known cardiac risk factors that tend to cluster in obese individuals. Aggressive management of these comorbid cardiovascular risk factors and other obesity-related medical conditions (eg, sleep apnea, major depression, osteoarthritis, nonalcoholic fatty liver disease) is warranted in an obese individual regardless of an individual's weight loss efforts.[6,35]

TREATMENT

Available treatment options for the chronic management of obesity include reduced caloric intake, comprehensive lifestyle intervention, pharmacotherapy, implantable medical devices, and bariatric surgery.

Desired Outcomes

Weight management is commonly considered successful when a predefined amount of weight has been lost such that a final goal is achieved. The ultimate goal of treatment must be defined clearly and may be absolute weight loss if obesity is present without other comorbid conditions. If improvement in blood glucose, blood cholesterol, and hypertension are primary goals, then these must be defined appropriately and may include setting target levels for low-density lipoprotein cholesterol, glycosylated hemoglobin, or blood pressure. In 2013, an updated evidence-based guideline on the management of overweight and obesity was published by the Obesity Society (TOS), American Heart Association (AHA), and American College of Cardiology (ACC),[5] which recommended the initial weight loss goal for adults to be approximately 5% to 10% of the baseline weight over a 6-month period. Success may also include end points of decreasing the rate of weight gain or maintaining a weight-neutral status. All too often patients expect to lose weight overnight, only to be disappointed. Thus, it is important to set a time course for the plan. A significant number of web-based resources for supporting both patient and practitioner weight-management activities are available.[6,22,42]

General Approach to Treatment

To achieve meaningful weight loss goals, successful obesity treatment plans require incorporation of comprehensive lifestyle interventions such as healthy diet, adequate physical activity, and behavioral modifications as the cornerstone of weight management.[5] Once the need for weight loss has been determined, the clinician needs to assess a patient's readiness to engage in weight loss efforts and identify any potential barriers to success. They need to initiate a dialogue with each patient who is overweight or obese to ensure they understand the potential health consequences of excess body weight and benefits of appropriate weight management. Specific weight goals should be established that are consistent with medical needs and the patient's personal desire. For most overweight and obese patients, a weight loss goal of 5% to 10% of initial weight is reasonable. Patients should not be allowed to attain an abnormally low body weight (ie, less than their estimated ideal body weight).

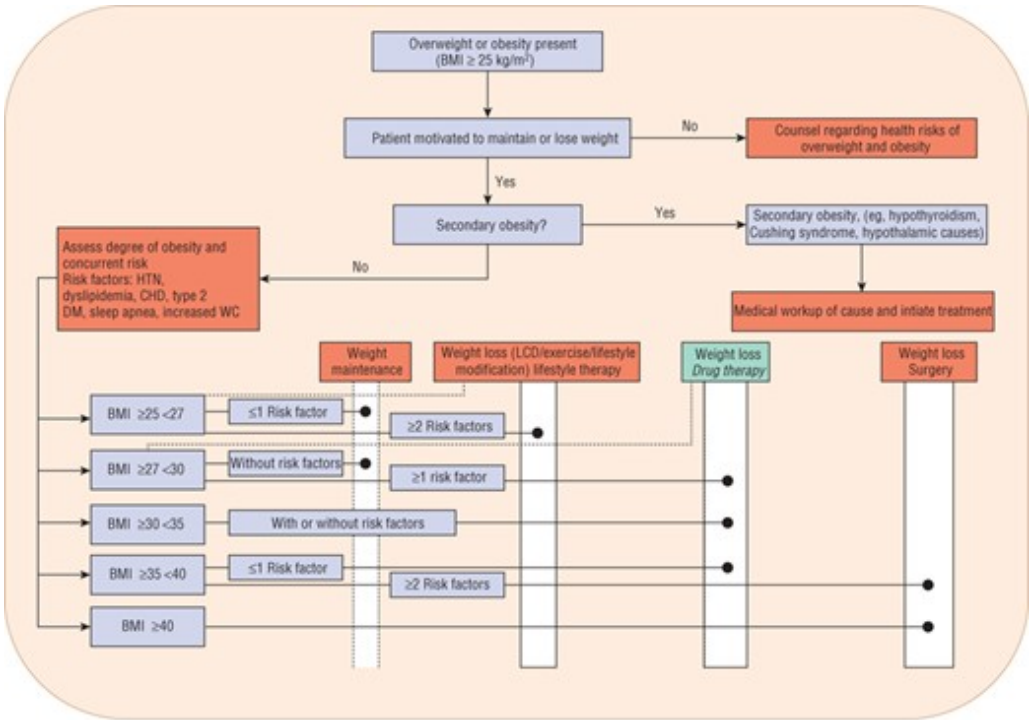
3 Patients seeking help for obesity do so for many reasons, including improvement in their quality of life, a reduction in associated morbidity, and increased life expectancy. Because weight stigma is prevalent in the western culture, numerous individuals seek therapy for obesity primarily for cosmetic purposes and often have unrealistic goals and expectations. Aggressive marketing of weight loss programs, therapies, and diets—parallel to the fashion industry's standards of desirable body profiles—has led many individuals to set impossible goals and expectations. In some cases, these individuals will go to extreme measures to achieve weight loss. Consequently, clinicians must be careful to fully discuss the risks of therapies and to clearly define the achievable benefits and magnitude of weight loss. Obese patients should be redirected away from trying to achieve an "ideal weight" to the more realistic goal of modest (eg, loss of 5%-10% of body weight) but sustained, medically relevant weight loss. In practice, goals should be set based on many factors, including initial body weight, patient motivation and desire, presence of comorbid conditions, and age. The Look Action for Health in Diabetes (AHEAD) study found that patients with diabetes who maintained weight loss of at least 7% with intensive lifestyle modifications for a period of almost 10 years did not experience a reduced incidence of cardiovascular events, but they did have a reduced need for diabetes medications and improvement in physical function and other health benefits.[43] Indeed, in overweight and obese patients with diabetes, lifestyle modification with sustained weight loss of greater than 5% have been shown to improve HbA1c level, ameliorate hyperglycemia, hyperlipidemia, and hypertension within a year.[44] For obese individuals with osteoarthritis, significantly more weight reduction may be required to improve symptoms. These data emphasize the importance of defining end points and measures of success in any weight-loss plan.

4 Weight-loss interventions must be founded on lifestyle changes, such as a modification in eating practices; complemented by drug therapy, if indicated; and in some cases, surgery (**Fig. 144-3**). Before recommending any therapy, the clinician must evaluate the patient for the presence of secondary causes of obesity. If a secondary cause is suspected, then a more complete diagnostic workup and the initiation of appropriate therapy may be warranted. The next step in patient evaluation is to determine the presence and severity of other medical conditions that are either directly associated with obesity (eg, diabetes, cardiovascular diseases, uncontrolled hypertension) or that have an impact on therapeutic decision making (eg, history of pancreatitis, cardiac arrhythmia,

seizure disorders, concurrent medications).[35] The Endocrine Society Clinical Practice Guideline for the Pharmacological Management of Obesity emphasizes that clinicians should always consider the potential weight-altering effects of all medications a patient is receiving for the management of comorbid conditions and select medications that are weight-neutral or promote weight loss (strong recommendation with moderate quality evidence).[35] For example, in patients with type 2 diabetes, antidiabetic agents that promote weight loss (eg, metformin, glucagon-like pepetide-1 analogs or sodium-glucose-linked transporter-2 inhibitors) are preferred. Appropriate laboratory tests to exclude or quantify the degree of specific conditions such as diabetes, liver dysfunction, and nephropathy should be performed as indicated by the history and physical examination. Based on the outcome of this medical evaluation, the patient should be counseled on treatment options, benefits, and risks. Ultimately, lifelong therapeutic goals should consist of maintenance of reduced body weight and prevention of weight gain.

FIGURE 144-3

Treatment algorithm. Candidates for pharmacotherapy are selected on the basis of body mass index and waist circumference criteria along with consideration of concurrent risk factors. Medication therapy is always used as an adjunct to a comprehensive weight-loss program that includes diet, exercise, and behavioral modification.[5,35] CHD, coronary heart disease; DM, diabetes mellitus; HTN, hypertension; LCD, low-calorie diet; WC, waist circumference (more than or equal to 40 inches [more than or equal to 102 cm] for men and more than or equal to 35 inches [more than or equal to 89 cm] for women).



Nonpharmacologic Therapy

Nonpharmacologic therapy, including reduced caloric intake, increased physical activity, and behavioral modification is the mainstay of obesity management. This combination is recommended as first-line therapy for all patients with BMI more than or equal to 25 kg/m^2 by The Endocrine Society Clinical Practice Guidelines for the Pharmacological Management of Obesity (graded as strong recommendation with high quality evidence).[35] Although the difference is subtle, it should be noted that the AHA/ACC/TOS Guidelines for the Management of Overweight and Obesity in Adults do not recommend weight loss therapy for patients with BMI between 25 and 29.9, unless the patient has CVD risk factors.[5] Weight loss will require significant effort on the part of the patient to change their lifestyle and comply with the management plan. If the patient is not ready to meet these expectations, then early counseling will reduce the chance of frustration for the patient, clinician, and possibly other family members. Providing basic education can lead to a significant change in motivation and desire to lose weight and improved compliance.

Reduced Caloric Intake

Current adult guidelines recommend reduced caloric intake through adherence to a low-calorie diet (LCD).[5] The LCD should provide a daily caloric deficit of 500 to 750 kcal (2,092-3,138 kJ), which generally correlates to a total intake of 1,200 to 1,500 kcal/day (5,021-6,276 kJ/day) for women and 1,500 to 1,800 kcal/day (6,276-7,531 kJ/day) for men. Severely obese individuals will require more energy, at least at the start of dietary restriction. Adherence to the LCD has been shown to result in an average weight loss of 8% after 6 months.[6]

Numerous diet and nutrition plans are available to aid patients in their pursuit of weight loss, and current guidelines allow for choice among many potential evidence-based diet plans.[5,6] Popular diets include moderate energy-deficient plans (eg, Weight Watchers, LEARN [Lifestyle, Exercise, Attitude, Relationships, Nutrition], and Jenny Craig), vegetarian-based plans (eg, Ornish), and low carbohydrate plans (eg, Zone and Atkins). Short-term weight loss is significant for almost all diet plans. However, long-term weight loss and maintenance of weight loss are less promising, primarily because of difficulty with adherence. Therefore, the choice of diet plan should be determined based on patient-specific preferences, health status, and ability to consistently adhere to the specific recommendations of the diet.[5] A recent meta-analysis of 48 clinical trials assessing the efficacy of various diets concluded that differences in weight loss among popular named diets are not clinically significant,[45] highlighting the general consensus that macronutrient composition of the diet may not be as important as consistent adherence to reduced energy consumption.

Very-low-calorie diets, providing less than 800 kcal/day (3,349 kJ/day), are generally not recommended.[6] Although very-low-calorie diets can often result in early weight loss, long-term results have been disappointing because it is difficult for individuals to maintain compliance.[44] Additionally, very-low-calorie diets require intensive medical monitoring and should only be used in certain situations under the supervision of an experienced clinician. Regardless of the diet program, it is clear that energy consumption must be less than energy expenditure to achieve weight loss (see Fig. 144-1). The challenge is to develop a diet plan that leads to consistent adherence by the patient and sustained weight loss and maintenance.

Comprehensive Lifestyle Intervention

Comprehensive lifestyle intervention encompasses the combination of reduced caloric intake, increased physical activity, and behavioral modification. Increased physical activity is an important component in achieving the state of greater energy expenditure than energy intake that is necessary to lose weight and maintain weight loss. When increased physical activity is attempted as monotherapy, only modest weight loss has been reported.[46] However, when it is combined with reduced calorie intake and behavior modification, it can augment weight loss and improve obesity-related comorbidities and cardiovascular risk factors.[5,6] Moderate physical activity for at least 30 minutes per day, on most days of the week, is recommended. Greater levels (ie, 200-300 min/wk) may be required to augment weight loss and maintain lost weight. Patients should be advised to start slowly and gradually increase intensity. All obese patients should receive a medical examination before embarking on a physical activity program.

Current adult guidelines recommend initiation of a comprehensive lifestyle program to help overweight and obese patients adhere to the prescribed LDC and increase physical activity per week (NHLBI Grade A; strong recommendation).[5] On-site, individual or group, behavioral counseling sessions offered by a trained clinician on at least 14 occasions during a 6-month time period are preferred. However, electronic or commercial based programs may also be effective. For patients who have successfully lost weight during the first 6 months, long-term participation in a comprehensive lifestyle program is recommended. The primary aim is to help patients choose lifestyles that are conducive to safe and sustained weight loss. Most such programs use self-monitoring of diet and exercise to increase patient awareness of behavior and as a tool for the clinician to determine patient compliance as well as patient motivation. Clinical studies evaluating the efficacy of high-intensity comprehensive lifestyle interventions that include a reduced-calorie diet, increased exercise, and in-person behavioral counseling sessions have reported an average weight loss of 8 kg after 6 months.[5,6]

Implantable Medical Devices

Recently, the FDA approved two new implantable medical devices for weight reduction in obese patients. vBloc® neurometabolic therapy, is indicated for weight loss in adults with a BMI of 40 to 45 kg/m^2, or a BMI of 35 to 39.9 kg/m^2 with at least one comorbidity who have failed a supervised weight management program within the past 5 years.[47,48] The vBloc® neurometabolic therapy, delivered via a pace-maker like device called the Maestro® Rechargeable system, is implanted subcutaneously on the vagal trunk with the electrodes designed to intermittently block the communication with the vagus nerve. The vagus nerve is known to regulate digestion through autonomic communication between the brain and the stomach. Blockage of the vagal communication is believed to alter multiple physiological mechanisms related to food intake and energy metabolism, thus resulting in increased satiety and weight loss. The implanted neuroregulator is controlled by the clinician with an external programming device to deliver at least 12 hours of intermittent vagal nerve block. The ReCharge trial evaluated the effect of vagal nerve block in patients with morbid obesity, the percentage of excess weight loss (defined as weight loss above a

BMI of 25 kg/m^2) was significant with 24% excess weight loss (9% of initial body weight) reported in the vagal nerve block treatment group compared to 16% excess weight loss (6% of initial body weight) reported in the sham control group.[47] In obese patients with type 2 diabetes, 25% excessive weight loss was reported along with 1% decrease in A1c for those who received the vBloc® device which was active for 12 to 15 hours daily.[48] Patients with cirrhosis, portal hypertension, esophageal varices, hiatal hernia, planned MRI or diathermy, and patients with a permanently implanted, electrical-powered medical device are contraindicated for the vBloc® therapy. Common adverse events with vBloc® therapy include neuroregulator site pain, nausea, abdominal pain, heartburn or dyspepsia. Although safety and efficacy of this device has only been studied up to 1 year, long-term data continue to be collected from ongoing clinical trials.[47,48] Unfortunately, once the device is turned-off, patients will often regain the weight lost.

The ReShape Dual Balloon device is indicated for weight reduction in patients with BMI of 30 to 40 kg/m^2 with one or more obesity-related comorbidities who have failed previous weight loss attempts with diet and exercise alone.[49] The balloon device is implanted into the stomach through a minimally invasive endoscopic procedure. After placement, the balloon is then inflated with saline and blue dye (methylene blue) to trigger the feelings of fullness by occupying the space in the stomach which helps patients reduce hunger and improve appetite control. While the balloon device does not alter the stomach's nature anatomy like bariatric surgery, the placement is only intended to be temporarily and should be removed 6 month after insertion as the device itself will deflate over time. Patients who failed to have the device removed after 6 months experienced an increased risk of intestinal obstruction due to migration of the deflated balloon and may require surgical removal of the device. In clinical trials, the average weight loss reported with the ReShape Dual Balloon device was 14.3 lbs (6.5 kg; 6.8% of total body weight) compared with 7.2 lbs (3.3 kg; 3.3% of total body weight) reported in the control group.[49] Six months following the removal of the device, patients treated with the balloon device maintained an average reduction of 9.9 pounds (4.5 kg) of the 14.3 pounds (6.5 kg) that was initially lost. Potential adverse effects from this procedure are primarily related to endoscopic sedation. Once the device is placed in the stomach, patients may experience vomiting, nausea, abdominal pain, diarrhea, and feelings of indigestion. Therefore, this balloon device is not indicated in patients with previous gastrointestinal (GI) or bariatric surgery, inflammatory intestinal or bowel disease, large hiatal hernia, symptoms of delayed gastric emptying, severe liver damage, or active *Helicobacter pylori* infection. In addition, patients who are pregnant, breastfeeding or taking anticoagulants, anti-inflammatory, or other gastric irritates daily are not candidates for the device. Finally, patients currently taking selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and monoamine oxidase inhibitors (MAOIs) should use this device with caution due to the potential for balloon rupture and release of methylene blue which with these concurrent therapies can increase risk of developing serotonin syndrome.

Clinical **Controversy…**

Current practice guidelines state that bariatric surgery may be considered in patients with a BMI of 40 kg/m^2 or above or BMI of 35 kg/m^2 with significant comorbidities, as an increasing body of literature indicates improvements in comorbidities and prolongation of life after bariatric surgery. Most

long-term data are for the Roux-en-Y gastric bypass procedure; the long-term outcomes of other approaches remain somewhat uncertain. Researchers are also beginning to study the effects of bariatric procedures among patients with BMIs below 35 kg/m^2 for remediation of comorbid conditions such as diabetes, but the long-term benefits, risks, and cost-effectiveness of this approach remain unclear.

Bariatric Surgery

5 Consistent with the growing obesity epidemic, the demand for bariatric surgery has increased drastically over the past 2 decades. Surgery currently remains the most effective and durable intervention for the treatment of obesity. Current clinical practice guidelines recommend that surgical intervention be reserved for patients with extreme obesity (BMI ≥ 40 kg/m^2) or BMI greater than 35 kg/m^2 with significant comorbidities such as hypertension, type 2 diabetes, or obstructive sleep apnea (NHLBI Grade A; strong recommendation).[5,50] Surgery may also be offered to patients with BMI between 30 kg/m^2 and 34.9 kg/m^2 with diabetes or metabolic syndrome but the long-term data have yet to demonstrate its overall benefits.[5,50]

Surgical weight loss options should only be considered in patients who have met the eligibility criteria and have failed other recommended methods for weight loss. It is critical for bariatric surgical candidates to fully understand the surgical risks and be able to adhere to the extensive postoperative care plan, follow-ups, and necessary lifelong dietary and lifestyle adjustments to ensure the long-term success of the procedure.

The four common surgical procedures are (1) adjustable gastric banding, (2) sleeve gastrectomy, (3) biliopancreatic diversion with duodenal switch, and (4) conventional Roux-en-Y gastric bypass. The adjustable gastric banding and sleeve gastrectomy are designed to reduce the volume of the stomach and thus restrict the rate of nutrient intake. The biliopancreatic diversion with duodenal switch is primarily malabsorptive in nature, and the length of the diversion determines the extent of nutrient malabsorption. The conventional roux-en-Y gastric bypass is the most common procedure currently performed in the United States and worldwide.[51] This hybrid procedure combines a restrictive approach with a degree of malabsorption induced by reducing the size of the stomach pouch and causing food to bypass parts of the small intestine. Techniques that involve redirection of the flow of nutrients so as to have humoral and malabsorptive effects, generally yield greater and longer lasting weight loss than the purely restrictive methods.[51] Ultimately, reductions in excess body weight of approximately 23.4% (range 14%-52%) can be achieved within the first 1 to 2 years, with a modulation to 16.1% after 10 years as patients often experience weight regain after surgical procedures.[51] The extent of weight loss and the potential for weight regain after bariatric surgery is multifactorial as metabolic, anatomic, and lifestyle changes can all impact the outcome of the procedure. Improvements in the peri- and postoperative care of gastric surgery patients have reduced morbidity and mortality associated with bariatric surgeries. The operative 30-day mortality rates reported range from 0.1% to 1.2%, depending on the type of procedure.[51] Some of the most common early surgical complications are gastric and anastomotic leaks, bleeding, wound infections, and pulmonary emboli. Due to the disruption of the normal gastric anatomy and physiology,

postsurgical patients are often at risk for severe micronutrient deficiencies such as vitamin B_{12} and anemia.[52] Therefore, empiric supplementation with daily adult multivitamin plus minerals, elemental calcium, vitamin D, folic acid, thiamine, elemental iron, and vitamin B_{12} is essential to prevent nutritional deficiencies in bariatric patients.[50] All bariatric surgical patients should undergo routine and nutritional monitoring after the procedure. Weight losses resulting from bariatric surgery are often accompanied by dramatic improvements, and sometimes complete resolution, of many obesity-related complications.[51,53] Significant reduction in risks of stroke, myocardial infarction, cardiovascular deaths, as well as the incidence of type 2 diabetes and cancer (in women), have also been documented after bariatric surgery.[53,54,55,56,57] Furthermore, a significant 52% reduction in mortality for patients who underwent bariatric surgery compared with those who did not receive any surgical intervention has been noted.[54]

After experiencing weight loss, many gastric surgery patients are able to discontinue pharmacotherapy for glucose lowering, dyslipidemia, hypertension[50] and reduce medication costs.[55] However, the need for use of proton-pump inhibitors or H_2-receptor antagonists are often increased.[52] It is imperative for clinicians to recognize that bariatric interventions not only alter nutrient absorption but also may impede drug absorption and can cause potential serious consequences.[52,58] Achlorhydria, reduced surface area for intestinal and gastric absorption, and alterations in drug metabolism via the intestinal metabolic pathways (eg, cytochrome P450 enzymes or efflux transporters) after bariatric surgery can lead to altered dissolution and/or absorption of many medications. Reduced bioavailability has been reported for some antimicrobials, immunosuppressives, anticonvulsants, highly lipophilic tricyclic antidepressants, SSRIs, and levothyroxine.[52] Furthermore, concurrent administration of proton-pump inhibitors may also alter bioavailability of weak basic drugs such as antifungals (eg, ketoconazole), certain antibiotics and some cardiovascular medications (eg, digoxin) as well as hinder the absorption of micronutrients.[52] Therefore, clinicians need to recognize that the standard dosage regimens recommended for presurgical patients may need to be adjusted. Close therapeutic monitoring of all orally administered medications after surgery, particularly those with narrow therapeutic ranges, is highly recommended because dosage form selection, dose conversion, or therapeutic interchange may be necessary to avoid or minimize absorption problems and ensure optimal patient outcomes.

Pharmacologic Therapy

6 and 7 The debate regarding the appropriateness of obesity pharmacotherapy remains heated, fueled by the recognized national need to treat a growing epidemic and the medical and litigious fallout from the adverse effects of medications which were ultimately withdrawn from the US market (ie, fenfluramine [Pondomin], dexfenfluramine [Redux], and sibutramine [Meridia]). Strategies for the pharmacologic management of obesity have historically focused on modulating central or peripheral sites that regulate energy balance. Long-term pharmacotherapy may have a place in the treatment of obesity for patients who have no obvious contraindications to approved drug therapy, as the likelihood of weight regain after treatment discontinuation is quite high.[59] According to current guidelines, pharmacotherapy is an adjunct to comprehensive lifestyle intervention in adults who are

motivated to lose weight, have failed to achieve or sustain weight loss with lifestyle changes alone, and have a BMI more than or equal to 30 kg/m^2 or a BMI more than or equal to 27 kg/m^2 with at least one weigh-related comorbidity (Graded as a strong recommendation with high quality evidence).[35] Furthermore, patients who meet the BMI requirements and have a history of failed attempts to lose weight or maintain weight loss with comprehensive lifestyle intervention alone may also be candidates for pharmacotherapy.[35] A pharmacotherapy treatment algorithm based on these treatment guidelines is depicted in Fig. 144-3. **Table 144-4** lists the status of the most common classes of agents currently available.

TABLE 144-4 FDA-Approved Pharmacotherapeutic Agents for Weight Loss

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comment
Gastrointestinal Lipase Inhibitor					
Orlistat	Xenical	120 mg three times daily with each main meal containing fat	120 mg three times daily with each main meal containing fat		Approved for long-term use Take during or up to 1 hour after the meal Omit dose if meal is occasionally missed or contains no fat
Orlistat	Alli[a]	60 mg three times daily with each main meal containing fat	60 mg three times daily with each main meal containing fat		Same as Xenical
Serotonin 2C Receptor Agonist					
Lorcaserin	Belviq	10 mg twice daily	10 mg twice daily	Use with caution in moderate renal impairment and severe hepatic impairment; not recommended in patients with end state renal disease	Approved for long-term use Controlled substance: C–IV
Phentermine–Topiramate Combination					

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comment
Phentermine and topiramate extended release	Qsymia	3.75 mg of phentermine and 23 mg of topiramate once daily for 14 days; then increase to 7.5 mg of phentermine and 46 mg of topiramate once daily	7.5 mg of phentermine and 46 mg of topiramate once daily to a maximum dose of phentermine 15 mg and topiramate 92 mg once daily	Maximum dose for patients with moderate or severe renal impairment or patients with moderate hepatic impairment is 7.5 mg of phentermine and 46 mg of topiramate	Approved for long-term use Take dose in the morning to avoid insomnia Controlled substance: C–IV
Naltrexone-Bupropion Combination					
Bupropion and naltrexone extended release	Contrave	8 mg naltrexone/90 mg bupropion (1 tablet) once daily in the morning for 1 week; then 8 mg naltrexone/90 mg bupropion twice daily (morning and evening) for 1 week; then 16 mg naltrexone/180 mg bupropion in the morning and 8 mg naltrexone/90 mg bupropion in the evening for 1 week; then 16 mg naltrexone/180 mg bupropion twice daily (morning and evening)	16 mg naltrexone and 180 mg bupropion (2 tablets) twice daily	Maximum dose for patients with moderate or severe renal impairment is 8 mg naltrexone/90 mg bupropion (1 tablet) twice daily Maximum dose for patients with hepatic impairment is 8 mg naltrexone/90 mg bupropion (1 tablet) once daily in the morning	Approved for long-term use Do not take dose with high-fat meal
Glucagon-Like Peptide-1 Antagonist					

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comment
Liraglutide	Saxenda	0.6 mg once daily for 1 week 1.2 mg once daily for 1 week 1.8 mg once daily for 1 week 2.4 mg once daily for 1 week 3.0 mg once daily for 1 week * administered by subcutaneous injection	3 mg once daily	Use with caution in mild, moderate, and severe renal and hepatic impairment	Approved for long-term use Inject subcutaneously in the abdomen, thigh, or upper arm Administer at any time of day without regard to the timing of meals
Noradrenergic Agents					
Phendimetrazine	Bontril PDM; Bontril Slow-Release	Conventional tablet: start at 17.5 mg two or three times daily, given 1 hour before meals Extended-release capsule: 105 mg once daily 30-60 minutes before morning meal	70-105 mg/day	Use caution in patients with renal impairment	Approved for short-term monotherapy Controlled substance: C–III Prescriptions should be written for the smallest quantity to minimize possibility of overdose
Phentermine	Adipex-P, Suprenza	Orally disintegrating tablet: 15 or 30 mg once every morning Phentermine	Orally disintegrating tablet: 15 or 30 mg once every morning Phentermine	Use with caution in patients with renal impairment	Approved for short-term monotherapy Controlled substance: C–IV

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comment
		hydrochloride: 15-37.5 mg/day given in one or two divided doses; administer before breakfast or 1-2 hours after breakfast	hydrochloride: 15-37.5 mg/day given in one or two divided doses; administer before breakfast or 1-2 hours after breakfast		Prescriptions should be written for the smallest quantity to minimize possibility of overdose Individualize to achieve adequate response with lowest effective dose
Diethylpropion	Tenuate, Tenuate Dospan	Immediate release: 25 mg three times daily administered 1 hour before meals Controlled release: 75 mg once daily administered at midmorning	75 mg/day	Use with caution in patients with renal impairment	Approved for short-term monotherapy Dose should not be administered in the evening or at bedtime Controlled substance: C–IV

TABLE 144-5 Clinical and Economic Considerations for Long-term Pharmacotherapy Options

Drug	Brand Name	Weight Loss Above Diet and Exercise Alone (1 year)[35,59,73]	Cost for 30 days of therapy[a]	Comments[35]
				—Use may be limited by GI intolerance
Orlistat	Xenical	2.9-3.4 kg (6.5-7.5 lb)	$512.11	—Suggested for patients with cardiovascular disease (The Endocrine Society; weak

Drug	Brand Name	Weight Loss Above Diet and Exercise Alone (1 year)[35,59,73]	Cost for 30 days of therapy[a]	Comments[35]
				recommendation with low quality evidence) —Increased risk of serotonin syndrome if used in combination with other serotonergic and dopaminergic drugs
Lorcaserin	Belviq	3.6 kg (7.9 lb)	$199.50	—Suggested for use in patients with cardiovascular disease (The Endocrine Society; weak recommendation with low quality evidence)
Phentermine and topiramate extended release	Qsymia	6.6-8.6 kg (14.5-18.9 lb)	$186.00- 7.5 mg-46 mg $199.50- 15 mg-92 mg	—Limited distribution under FDA Risk Evaluation Mitigation Strategy (REMS) —Lowers seizure threshold (bupropion)
Bupropion and naltrexone extended release	Contrave	4.9 kg (10.8 lb)	$199.50	—Rare reports of hepatotoxicity (naltrexone) —Drug interactions with opioids, CYP2B6 inducers and CYP2D6 substrates —Injectable —Reduces HbA1c and fasting glucose
Liraglutide	Saxenda	5.8 kg (12.8 lb)	$1,068.00	—Risk of medullary thyroid carcinoma and Multiple Endocrine Neoplasia syndrome type 2 —Rare reports of pancreatitis, gall bladder disease, and suicidal ideation

[a]Cost of therapy based on maintenance dose using wholesaler acquisition cost (WAC) as of August 24, 2015.

A multidisciplinary team approach to the management of obesity is necessary to ensure long-term success. It is common for patients to use a combination of nonprescription, prescription, and other complementary and alternative therapies to attain the desired weight loss goal. Therefore, clinicians should maintain a high degree of sensitivity toward the potential polypharmacy practices of patients with obesity. Finally, it is prudent to consider specific patient factors and characteristics along with the efficacy and safety profiles of individual therapies when determining if use of a pharmacologic intervention is warranted.

Agents Approved for Long-Term Use

8 There are currently five products approved in the United States for the chronic management of obesity. These include the lipase inhibitor orlistat (Xenical, Genentech USA, South San Francisco, CA; Alli, GlaxoSmithKline, Middlesex, UK), the serotonin 2C receptor agonist lorcaserin (Belviq, Arena Pharmaceuticals GmbH, Zofingen, Switzerland), the combination product phentermine–topiramate extended release (Qsymia, Vivus, Inc, Mountain View, CA), the combination product naltrexone-bupropion extended-release tablets (Contrave, Takeda Pharmaceuticals America Inc, Deerfield, IL), and the GLP-1 receptor agonist liraglutide (Saxenda, Novo Nordisk Inc, Plainsboro, NJ). Pharmacotherapy management guidelines recommend discontinuation of drug therapy in patients who fail to lose sufficient amounts of body weight after 3 months and in patients who experience significant adverse events, with consideration given to potential alternative weight loss agents (strong recommendation with high-quality evidence).[35] **Table 144-6** lists clinical and economic considerations for use of the products approved for long-term use.[35,59]

TABLE 144-6 Drug Monitoring

Drug	Brand Name	Adverse Reactions	Monitoring Parameters	Comments
Gastrointestinal Lipase Inhibitor				
Orlistat	Xenical, Alli[a]	Soft stools, diarrhea, abdominal pain or colic, flatulence, fecal urgency, incontinence, liver damage (rare)	BMI; calorie and fat intake; serum glucose in patients with diabetes; thyroid function in patients with thyroid disease; liver function tests in patients exhibiting symptoms of hepatic dysfunction	Supplement with a multivitamin during therapy to prevent vitamin deficiency
Serotonin 2C Receptor Agonist				
Lorcaserin	Belviq	Headache, dizziness, fatigue, nausea, dry mouth, constipation, hypoglycemia in patients with diabetes,	BMI; calorie and fat intake; serum glucose in patients with diabetes; complete blood count,	Discontinue if 5% weight loss not achieved by week 12

Drug	Brand Name	Adverse Reactions	Monitoring Parameters	Comments
		psychiatric disorders, priapism, elevated serum prolactin level	depression or suicidal thoughts; signs or symptoms of serotonin syndrome; signs or symptoms of valvular heart disease	
Phentermine–Topiramate Combination				
Phentermine and topiramate extended release	Qsymia	Constipation, dry mouth, paraesthesia, dysgeusia, insomnia, hypoglycemia in patients with diabetes	BMI; calorie and fat intake; serum glucose in patients with diabetes; pregnancy; depression or suicidal thoughts; mood or sleep disorders; heart rate; serum electrolytes and creatinine at baseline and during treatment	Discontinue or escalate dose if 3% weight loss not achieved by week 12 on phentermine 7.5 mg and topiramate 46 mg Discontinue if 5% weight loss not achieved by week 12 on phentermine 15 mg and topiramate 92 mg Gradually discontinue phentermine 15 mg and topiramate 92 mg to prevent possible seizure
Bupropion-Naltrexone Combination				
Bupropion and naltrexone extended release	Contrave	Nausea, constipation, headache, vomiting, dizziness, insomnia, dry mouth and diarrhea	BMI; calorie and fat intake; serum glucose in patients with diabetes; heart rate and blood pressure; signs and symptoms of hepatotoxicity, neuropsychiatric reactions, and suicidal thoughts or behavior	Discontinue if 5% weight loss not achieved by week 12
Glucagon-Like Peptide-1 Antagonist				

Drug	Brand Name	Adverse Reactions	Monitoring Parameters	Comments
Liraglutide	Saxenda	Nausea, diarrhea, constipation, vomiting, dyspepsia, hypoglycemia, and abdominal pain	BMI; calorie and fat intake; serum glucose in patients with diabetes; signs and symptoms of pancreatitis; heart rate; signs and symptoms of gallbladder disease and suicidal ideation	Discontinue if 4% weight loss not achieved by week 16
Noradrenergic Agents				
Phendimetrazine Phentermine Diethylpropion	Bontril PDM; Bontril Slow-Release Adipex-P, Suprenza Tenuate, Tenuate Dospan	Increased blood pressure, ischemic events, palpitations, tachycardia, valvular disease, urticaria, agitation, dizziness, headache, insomnia, overstimulation, psychosis, restlessness, dry mouth, constipation, thirst, diarrhea	Baseline cardiac evaluation (for preexisting valvular heart disease, pulmonary hypertension); echocardiogram during therapy; weight, waist circumference; blood pressure	Approved as monotherapies only for short-term use (a few weeks). Discontinue if satisfactory weight loss has not occurred within the first 4 weeks of treatment or if tolerance develops Abrupt discontinuation after prolonged high doses may be associated with extreme fatigue and depression

BMI, body mass index.

[a]Available without a prescription.

Clinical **Controversy…**

Obesity is considered a chronic disease. None of the FDA-approved agents for obesity has been shown to have cardiovascular benefit, and the optimal treatment duration remains unknown. Because discontinuation of drug treatment tends to result in weight regain, continuation of an effective and well-tolerated drug regimen is common practice.

Lipase Inhibitor: Orlistat

Excessive intake of dietary fat is one of the contributing factors in the development of obesity. GI (gastric, pancreatic, and carboxyl ester) lipases are essential in the absorption of the long-chain triglycerides. Additionally, lipase is known to play a role in facilitating gastric emptying and secretion of other pancreaticobiliary substances. Orlistat (Xenical) is a synthetic derivative of lipstatin, a natural lipase inhibitor produced by *Streptomyces toxytricini*. The drug is minimally absorbed and induces weight loss by persistent lowering of dietary fat absorption through selective inhibition of the GI lipase. Furthermore, lower luminal free fatty acid concentrations result in malabsorption of cholesterol. Up to 30% reduction in fat absorption occurred with daily doses of 120 mg three times daily with meals.[59] A nonprescription formulation of orlistat (Alli) is approved in the United States at a reduced daily dose of 60 mg three times daily.[59] The drug must be taken within 1 hour of consuming foods that contain fat in order to exert its effect. If a meal is skipped or contains no fat, the dose of orlistat can be omitted.

Clinical studies using orlistat as an adjunct to diet therapy demonstrate dose-dependent reductions in fat absorption. Overall, results from clinical trials demonstrate that orlistat modestly increases the amount of weight lost and decreases the amount of weight regained during medically supervised weight loss programs.[59,60] The longest trial that evaluated the safety and efficacy of orlistat is XENDOS (XENical in the prevention of Diabetes in Obese Subjects), a 4-year, double-blind, randomized, placebo-controlled prospective study.[61] Although weight regain was observed with continual therapy beyond the first year of orlistat therapy, results from this study show moderate weight loss sustained after 4 years of treatment compared with placebo, 12.8 lb (5.8 kg) and 6.6 lb (3.0 kg), respectively. Weight loss using orlistat also decreased the rate of development of type 2 diabetes by 37.3% in patients with impaired glucose tolerance. Improved glycemic control can be attained in patients with type 2 diabetes by inducing or increasing weight loss with orlistat in addition to diet management.[59,60] In some cases, dosages or the number of antidiabetic medications may be reduced or discontinued.[60] Significant improvements in lipid profile (reduction in total and low-density lipoprotein [LDL] cholesterol), glucose control, and other markers of metabolism are seen when using orlistat in addition to the diet.[59,60] Orlistat is approved for the chronic treatment of obesity in adults and adolescents between ages 12 abd 16 years. The recommended dose is 120 mg three times daily taken within 1 hour of consuming a fat-containing meal.

At least one GI complaint (soft stools, abdominal pain or colic, flatulence, fecal urgency, or incontinence) has been reported in up to 80% of individuals using prescription-strength orlistat. These complaints are most common in the first 1 to 2 months of therapy, are mild to moderate in severity, and tend to improve with continued orlistat use. Limiting dietary fat before initiation of orlistat therapy may be beneficial in decreasing initial GI complaints. Severe diarrhea secondary to orlistat use can affect the absorption of orally administered drugs, such as oral contraceptives, fat-soluble vitamins (A, D, E, and K), and β-carotene.[60] Therefore, supplementation with a multivitamin should be considered during therapy. In the presence of severe diarrhea, women receiving oral contraceptives should be advised of the need to use alternative backup methods because absorption of oral contraceptive may be reduced.[60] Although orlistat does not appear to alter the pharmacokinetic profiles of other agents, including digoxin, glyburide, metformin, phenytoin, fluoxetine, amitriptyline, phentermine, losartan, nifedipine, captopril, atenolol, furosemide,

alcohol, or atorvastatin, reduced fat absorption can potentially affect the absorption of lipophilic drugs, such as lamotrigine, valproic acid, gabapentin, and amiodarone.[62,63] Decreased vitamin K absorption has also been noted and can alter the patient's warfarin dosage needs. Clinicians should also be aware that orlistat may directly interfere with the absorption of other narrow therapeutic range drugs, such as cyclosporine and levothyroxine.[33] In patients requiring concomitant therapies with orlistat, close monitoring is warranted to ensure an adequate therapeutic response. Separation of the administration times of the medications may minimize these potential drug interactions. Finally, there have been rare postmarketing reports of liver damage with the use of orlistat.[63] Although causality has not been definitively linked to orlistat, patients are advised to notify their healthcare providers if they notice signs and symptoms of liver injury, such as development of itching, yellow eyes or skin, dark urine, loss of appetite, or light-colored stools.

Serotonin Receptor Agonist

Lorcaserin (Belviq) is a selective serotonin (5-HT_{2C}) receptor agonist, approved for chronic weight management in patients who are obese (BMI of greater than or equal to 30 kg/m^2) or overweight (BMI of greater than 27 kg/m^2) with at least one weight-related comorbidity.[64] At the recommended dose of 10 mg twice daily, lorcaserin selectively activates central 5-HT_{2C} receptors on hypothalamic anorexigenic pro-opiomelanocortin neurons. Activation of central 5-HT_{2C} receptors results in appetite suppression, leading to reduced energy intake and enhanced satiety.

Clinical trials evaluating the efficacy of loracaserin, used in combination with a LCD and exercise counseling, have reported a modest but significantly greater weight loss compared with placebo.[65,66] The Behavioral Modification and Lorcaserin for Overweight and Obesity Management (BLOOM) trial was a 2-year, randomized, placebo-controlled, double-blind, prospective trial that enrolled more than 3,000 obese and overweight patients.[65] Mean weight loss at 1 year was 5.8 kg (12.8 lb) in the lorcaserin group compared with 2.2 kg (4.8 lb) in the placebo group. Patients in the lorcaserin-treated group also experienced significant improvements in fasting glucose, insulin, total cholesterol, LDL cholesterol, and triglyceride concentrations at the end of the first year. Although weight regain was observed during the second year of the trial, 68% of the patients who had previously achieved 5% weight loss during the first year were able to maintain this level of weight loss by the end of the second year. The efficacy of lorcaserin has also been shown in patients with type 2 diabetes, with an average weight loss of 4.5% and significant improvements in HbA_{1c} and fasting glucose after 1 year of treatment.[67] Based on data from clinical trials, the approved label states that lorcaserin therapy should be discontinued if 5% weight loss not is not achieved by week 12 because it is unlikely that a benefit will be seen.[64]

The most common adverse effects associated with the use of lorcaserin in clinical trials were headache, dizziness, constipation, fatigue, and dry mouth.[65] Previous serotonergic agents (eg, dexfenfluramine) used for weight loss have been associated with cardiac valvulopathy.[62,68] The mechanism for this toxicity is thought to be related to stimulation of $5HT_{2B}$ receptors on cardiac cells. At therapeutic doses, lorcaserin is selective for central $5HT_{2C}$ receptors. During clinical trials, the incidence of cardiac valvulopathy was not significantly different between patients who received

lorcaserin (2.4%) and those who received placebo (2%).[64] However, patients should be counseled to contact their healthcare providers if they experience signs or symptoms of cardiac valve disease such as dyspnea or edema. Lorcaserin should not be used in combination with other serotonergic and dopaminergic drugs because of the increased risk of serotonin syndrome or neuroleptic malignant syndrome–like reactions. Lorcaserin should be used cautiously in patients with congestive heart failure because these patients may be at an increased risk for cardiac valvulopathy. Additional rare adverse effects that clinicians should be aware of include psychiatric disorders, priapism, and elevated serum prolactin concentrations. Lorcaserin is classified as a controlled substance in class IV due to potential for abuse.

Phentermine–Topiramate Extended Release

A combination product containing phentermine and topiramate extended release (Qsymia) is approved for chronic weight management in patients who are obese (BMI of greater than or equal to 30 kg/m^2) or overweight (BMI of greater than 27 kg/m^2) with at least one weight-related comorbidity.[69] Phentermine is structurally similar to amphetamine, but it has less severe CNS stimulation and a lower abuse potential. Its mechanism of action centers on its ability to enhance norepinephrine (NE) and dopamine neurotransmission, resulting in appetite suppressing effects. Topiramate is an antiepileptic drug. Although the exact mechanism for its efficacy in weight management is not known, it may decrease appetite and increase satiety through multiple pathways, including effects on *γ*-aminobutyrate, voltage-gated ion channels, excitatory glutamate receptors, or carbonic anhydrase.[69] The doses of phentermine (3.75-15 mg) and topiramate (23-92 mg) in this combination are significantly lower than the therapeutic doses of each separate product when used as monotherapy for obesity (37.5 mg) and epilepsy (400 mg), respectively. The recommended dosing strategy for phentermine–topiramate extended release involves gradual titration, staring with 3.75 mg of phentermine and 23 mg of topiramate once daily for 14 days and then increasing the dose to 7.5 mg of phentermine and 46 mg of topiramate once daily.[69] After 12 weeks of therapy, the dose may be increased again to 11.25 mg of phentermine and 69 mg of topiramate for 14 days and then to a maximum dose of 15 mg of phentermine and 92 mg of topiramate daily. Likewise, when discontinuing therapy, the dose should be gradually decreased by taking a dose every other day for at least 1 week to prevent the possible precipitation of seizures.

Clinical trials evaluating the efficacy of phentermine–topiramate, when used as an adjunct to a reduced-calorie diet and lifestyle changes, have reported dose-dependent weight loss and significant reductions in blood pressure, total cholesterol, LDL cholesterol, triglycerides, fasting glucose, and HbA_{1c}.[70,71] The CONQUER trial was a randomized, placebo-controlled, double-blind, prospective trial of 2,487 overweight or obese patients with two or more obesity-related comorbidities.[70] After a 4-week dose titration phase, subjects were randomized to receive (a) placebo, (b) 7.5 mg of phentermine with 46 mg of topiramate, or (c) 15 mg of phentermine with 92 mg of topiramate daily. Weight loss at 1 year was significantly greater than placebo in both of the treatment groups, with a mean weight loss of 8.1 kg (17.8 lb) in the 7.5-mg phentermine and 46-mg topiramate group and a mean weight loss of 10.2 kg (22.4 lb) in the 15-mg phentermine and 92-mg topiramate group. The efficacy of phentermine–topiramate has also been documented in patients with class II and class III

obesity (mean BMI, 42 kg/m^2), with a reported mean weight loss of 10.9% after 1 year of treatment.[71]

The most common adverse effects associated with the use of phentermine–topiramate in clinical trials were constipation, dry mouth, paraesthesia, dysgeusia, and insomnia.[70,71] Because topiramate is a known teratogen, this drug is contraindicated in pregnancy because fetal exposure in the first trimester increases the risk of cleft lip or cleft palate. To manage the potential risk of teratogenicity, the drug is only available through a limited distribution process under a risk evaluation and mitigation strategy (REMS).[69] All women of childbearing age must have a documented negative pregnancy test result before beginning treatment and then monthly to continue therapy. Topiramate has been associated with acute myopia associated with secondary angle-closure glaucoma, and phentermine can cause mydriasis from adrenergic stimulation. Therefore, this product is also contraindicated in patients with glaucoma. The potential for hypertensive crisis with coadministration of phentermine and MAOIs exists; therefore, patients should have stopped an MAOI for at least 14 days before use of any adrenergic agent. Phentermine–topiramate is also contraindicated in patients with untreated hyperthyroidism.

Monitoring parameters and drug interactions that clinicians should be aware of include known issues related to both components of the formulation. Of note, increases in heart rate greater than 10 beats/min were observed in approximately 50% of patients receiving phentermine–topiramate during clinical trials.[69] In patients receiving the highest dose, 19% experienced increases in heart rate that were greater than 20 beats/min. Therefore, heart rate should be monitored in all patients, particularly those with preexisting CVD. Decreases in serum bicarbonate were also noted in clinical trials, which were generally mild with peak decreases observed after 4 weeks of therapy. Decreases in serum potassium and increases in serum creatinine were also reported. Therefore, monitoring of serum electrolytes and creatinine is recommended at baseline and during therapy. Clinicians should be aware that concomitant use of non–potassium-sparing diuretics may potentiate the risk for hypokalemia. Although pregnancy risk is not expected, use of phentermine–topiramate concomitantly with oral contraceptives may result in breakthrough bleeding because of increased exposure to progestin and decreases exposure to estrogen. Phentermine–topiramate is classified as a controlled substance in schedule IV because of the abuse potential of phentermine. Similarly to lorcaserin, therapy should be discontinued if 5% weight loss is not achieved after 12 weeks.[69]

Naltrexone–Bupropion Extended Release

A combination product containing naltrexone and bupropion extended release (Contrave) was approved in 2014 for chronic weight management in patients who are obese (BMI of more than or equal to 30 kg/m^2) or overweight (of more than or equal to 27 kg/m^2) with at least one weight-related comorbidity.[72] Naltrexone and bupropion are both approved separately for treatment of alcohol and opioid dependence, and depression and smoking cessation, respectively.[73] Bupropion is a dopamine and norepinephrine reuptake inhibitor, and naltrexone is an opioid antagonist. Although the exact weight-loss mechanism of action is not known for this drug combination, stimulation of release of α-MSH in hypothalamus by bupropion and inhibition of endogenous opioids by naltrexone are thought to contribute to a decrease in appetite.[73] The recommended dosing strategy for

naltrexone-bupropion extended-release involves gradual titration, starting with one tablet (8-mg naltrexone/90-mg bupropion) per day and slowly increasing the dose over a period of 4 weeks to a maintenance dose of two tablets twice daily. Doses greater than 32 mg of naltrexone and 360 mg of bupropion (ie, 4 tablets) per day are not recommended. Patients should be advised to not take their dose with a high-fat meal as this would result in increased systemic exposure to both naltrexone and bupropion.

Four randomized, placebo-controlled, clinical trials evaluating the efficacy of naltrexone/bupropion, when used in combination with a reduced-calorie diet and lifestyle changes, have reported significantly more weight loss with naltrexone/bupropion compared to placebo, as well as improvements in high-density lipoprotein (HDL) cholesterol, triglycerides, glucose, and insulin.[74,75,76,77] The average total weight loss reported among the four studies was 7.3 kg (95% CI, 7.0-7.6 kg) following 1 year of treatment,[73] with the greatest amount of weight loss (9.7 kg) reported in nondiabetic subjects who were also receiving intensive behavior modification therapy.[76]

The most common adverse effects associated with the use of naltrexone/bupropion in clinical trials were nausea, constipation, headache, vomiting, dizziness, insomnia, dry mouth, and diarrhea.[72] Approximately 24% of patients who received naltrexone-bupropion in clinical trials discontinued treatment due to adverse events, with nausea being the most frequently cited reason.[72] Statistically significant increases in heart rate (2.1 beats/min) and blood pressure (1.8-2.3 mm Hg systolic and 1.7-2.1 mm Hg diastolic) were observed in patients receiving naltrexone-bupropion compared with those who received placebo during the first 3 months of therapy. Although the clinical significance of these increases is unknown, blood pressure and pulse should be monitored at baseline and at regular intervals following initiation of therapy. Naltrexone-bupropion should not be used in patients with uncontrolled hypertension.[72] Naltrexone monotherapy has been associated with rare reports of hepatotoxicity, and patients receiving naltrexone-bupropion should be advised of the signs and symptoms of acute hepatitis. Bupropion lowers the seizure threshold in a dose-dependent manner, and has been associated with serious neuropsychiatric reactions and an increased risk of suicidal thoughts and behavior when used for smoking cessation and treatment of depression. Bupropion has also been reported to cause activation of mania, serious allergic reaction, and angle-closure glaucoma.

Clinicians should also be aware of potential drug interactions with naltrexone-bupropion. Because of the opioid antagonist effects of naltrexone, naltrexone-bupropion is contraindicated in patients receiving chronic opioid or opiate agonist therapy, and also in patients undergoing abrupt withdrawal of chronic alcohol, benzodiazepine, barbiturate or antiepileptics. Bupropion is metabolized by cytochrome P450 2B6 (CYP2B6) and inhibits cytochrome P450 2D6 (CYP2D6). Therefore, any medication that induces CYP2B6 (ie, rifampin, carbamazepine, etc) could potentially reduce the effects of bupropion, and bupropion could increase the effects of medications that are CYP2D6 substrates (ie, SSRIs, tricyclic antidepressants, antipsychotics, etc). Bupropion is also contraindicated with concomitant use of MAOIs As with other long-term pharmacologic treatments for obesity, weight loss may increase the risk of hypoglycemia in patients with type 2 diabetes receiving antidiabetic medications. Finally, treatment with naltrexone-bupropion should be discontinued if 5% weight loss is not achieved after 12 weeks.

Liraglutide (Saxenda), an analog of GLP-1, is the latest medication approved in the United States for chronic weight management in patients who are obese (BMI of more than or equal to 30 kg/m^2) or overweight (BMI of more than 27 kg/m^2) with at least one weight-related comorbidity.[78] Endogenous GLP-1 is released in response to food digestion and stimulates GLP-1 receptors in the brain to reduce appetite. GLP-1 also stimulates insulin secretion and reduces glucagon secretion. For that reason, several GLP-1 receptor agonists, including liraglutide, are currently approved for the treatment of type 2 diabetes at recommended doses of 1.2 mg or 1.8 mg daily far less than the maintenance dose for weight loss of 3 mg daily.[78] Liraglutide is administered subcutaneously and is available in prefilled, multidose pens. When used for weight loss, a 5-week dose escalation schedule is recommended to improve tolerability of GI adverse events. It should be initiated at a dose of 0.6 mg daily, and increased weekly by 0.6-mg increments to a final maintenance dose of 3 mg daily. If the patient cannot tolerate the GI adverse events at any point during the dose escalation phase, a dose increase may be delayed by a week. Patients should be instructed on the proper technique for subcutaneous injection into the abdomen, thigh, or upper arm.

The efficacy of liraglutide for the management of overweight and obesity has been studied in patients with and without diabetes.[78,79,80] The Satiety and Clinical Adiposity-Liraglutide Evidence in Nondiabetic and Diabetic Individuals (SCALE) Obesity and Prediabetes study was a 56-week, randomized, placebo-controlled, double-blind, prospective trial of approximately 3,700 obese and overweight patients without diabetes.[79] Mean weight loss after 1 year of treatment was 8.4 kg (18.5 lb) in the liraglutide group compared with 2.8 kg (6.1 lb) in the placebo group. As expected, patients in the liraglutide-treated group also experienced significant improvements in HbA_{1c}, fasting glucose and insulin, and had a lower prevalence of prediabetes at the end of the trial. In the SCALE Diabetes trial, 840 overweight or obese subjects with type 2 diabetes were randomized to liraglutide 3 mg daily, liraglutide 1.8 mg daily, or placebo in combination with a LCD and exercise program for 56 weeks.[80] The average weight loss after 1 year of treatment was 6.4 kg (14 lbs) for the liraglutide 3-mg group, 5 kg (11 lbs) for the liraglutide 1.8-mg group, and 2.2 kg (4.8 lbs) in the placebo group. Significant improvements in fasting glucose and the number of subjects achieving HbA_{1c} targets of less than or equal to 7% (≤ 0.07; ≤ 53 mmol/mol Hb) (69.2% vs 27.2%) and less than or equal to 6.5% (≤ 0.065; ≤48 mmol/mol Hb) (56.5% vs 15%) in the liraglutide 3-mg group compared to the placebo group.

The most common adverse effects associated with the use of liraglutide in clinical trials were nausea, diarrhea, constipation, vomiting, dyspepsia, hypoglycemia, and abdominal pain.[78,79,80] GI complaints are the most common reason for premature discontinuation of therapy, underscoring the importance of the slow dose-escalation schedule with initiation of therapy. Rare cases of acute pancreatitis (0.3%), potentially leading to fatal hemorrhagic or necrotizing pancreatitis, have been reported with the use of liraglutide.[78] Small increases in resting heart rate averaging 2 to 3 beats/min have been reported in clinical trials. However, in some cases increases were as high as 20 beats/min. Although the clinical significance of these increases is unknown, heart rate should be regularly monitored in all patients receiving liraglutide. Cholelithiasis (1.5%), cholecystitis (0.6%), and suicidal ideation (0.2%)

have also been observed during clinical trials.[78] Liraglutide carries a boxed-warning about the risk of thyroid C-cell tumors, including medullary thyroid carcinoma (MTC), and is contraindicated in patients with a personal or family history of MTC or multiple endocrine neoplasia syndrome type 2 (MEN2). Hypoglycemia may occur when liraglutide is used in combination with other antidiabetic agents (particularly sulfonylureas and insulin) in patients with type 2 diabetes. Therefore, dose adjustments of antidiabetic medications may be necessary. Because liraglutide increases gastric emptying time, clinicians also should be aware that absorption of concomitantly administered oral medications may be altered. Liraglutide should be discontinued if weight loss of at least 4% is not achieved after 16 weeks of therapy.

Agents Approved for Short-Term Use

Several noradrenergic agents are currently approved by the FDA for short-term weight loss. Because short-term therapy is not consistent with current national guidelines for the chronic management of obesity, these agents have limited clinical utility in practice.

Phentermine

Phentermine is available in both immediate-release and sustained-release formulations. However, the value of sustained-release formulations is questionable based on the reported phentermine plasma half-life of 12 to 24 hours.[81] Phentermine is an effective adjunct to diet, exercise, and behavior modification for producing weight loss in excess of that seen with placebo.[81,82] Intermittent phentermine therapy appears to elicit comparable weight loss as that seen with continuous use. However, most individuals experience weight regains during therapy and generally always after discontinuing use.[81] A single dose of 30 mg once daily in the morning provides effective appetite suppression throughout the day. Divided doses of 8 mg immediately before meals, however, are common. Doses greater than 30 mg daily do not improve effectiveness.[82] Evening or nighttime dosing should be avoided because of insomnia. Significant increases in blood pressure, palpitations, and arrhythmias can occur with phentermine administration. Use is not advisable in hypertensive patients. Pharmacotherapy management guidelines recommend against the use of sympathomimetic agents in patients with uncontrolled hypertension or a history of CVD (strong recommendation with high-quality evidence).[35]

The potential for hypertensive crisis with coadministration of phentermine and MAOIs is noted in the product labeling of each agent; therefore, patients should be off an MAOI for at least 14 days before use of any adrenergic agent to avoid excessive adrenergic stimulation syndromes.[83] Phentermine use is contraindicated in patients with hyperthyroidism or agitated states and in those who are abusers of substances such as cocaine, phencyclidine, and methamphetamine, again because of the potential for excessive adrenergic stimulation syndromes and abuse potential. Mydriasis from adrenergic stimulation can worsen glaucoma, and patients diagnosed with glaucoma should not receive phentermine. Patients with diabetes may experience altered insulin or oral hypoglycemic dosage requirements soon after beginning therapy and before any substantial weight loss. Phentermine remains the most widely prescribed weight management medication by obesity specialists despite product labeling that indicates short-term (a few weeks), monotherapy use only.[81] This usage pattern

deviates from the current national recommendations that promote only long-term drug intervention when obesity pharmacotherapy is appropriate.[35]

Clinical **Controversy…**

Although phentermine is only approved for short-term use, it continues to be the most widely prescribed weight loss drug in the United States. Some clinicians consider use of long-term phentermine to be reasonable in select patients given the low cost and a lack of serious long-term adverse events reported in the literature over the past 20 years. Select patients include those without evidence of CVD, psychiatric disease, or substance abuse; without clinically significant increases in blood pressure or heart rate while receiving phentermine; and documentation of significant weight loss while receiving phentermine.

Diethylpropion

Diethylpropion stimulates NE release from presynaptic storage granules. Increased adrenergic neurotransmitter concentrations activate hypothalamic centers, which result in decreased appetite and food intake. This drug undergoes extensive first-pass hepatic metabolism. Active metabolites are eliminated renally and account for about 70% of the administered dose. The elimination half-life of these metabolites is about 8 hours.[82] Less than 10% of the parent compound is recovered in urine. No specific dosing recommendations exist for use in patients with renal or hepatic insufficiency. Diethylpropion can be taken in divided daily doses, generally 25 mg three times daily before meals. An extended-release formulation is also used by some clinicians, usually as 75 mg taken once daily in the morning or midmorning. Both dosing regimens are effective in achieving short-term weight loss in excess of placebo.[84] Complaints of insomnia increase if late afternoon dosing is used. Diethylpropion causes less stimulation of the CNS than mazindol and generally causes less insomnia than phentermine. Patients with severe hypertension or significant CVD should not receive diethylpropion. Patients with diabetes may experience decreased insulin or oral hypoglycemic dosage requirements soon after beginning therapy and before any substantial weight loss. More frequent blood glucose self-monitoring and medical follow-up are warranted when treating diabetic patients with diethylpropion.

Amphetamines

Appetite suppressant effects of the amphetamines were well recognized in the 1930s. Amphetamines activate central noradrenergic receptor systems as well as dopaminergic pathways at higher doses by stimulating neurotransmitter release. Increases in blood pressure and mild bronchodilation are attributed to peripheral α- and β-receptor activation. Amphetamines are no longer widely used for the treatment of obesity because of their powerful stimulant effects and addictive potential.

Off-Label Use of Serotonergic Agents

Serotonin is an important neurotransmitter involved in many human physiologic systems such as sleep–wake cycles, sensitivity to pain, blood pressure, mood, and eating behaviors. Increasing central serotonin levels disrupts the body's natural development of satiety by decreasing the amount of food

consumed and prolongs the time between food intake.[85] Some serotonergic agents increase central serotonin concentrations via stimulating release of presynaptic stores or inhibition of reuptake into storage granules. Additionally, either the parent compound or metabolites of these agents may stimulate postsynaptic 5-HT receptors directly. Peripheral serotonin effects that have an impact on appetite, such as slowing gastric motility, have been described. A major distinction between serotonergic and noradrenergic anorexiants is that serotonergic agents lack the central stimulant effects and thus the abuse potential seen with the noradrenergic compounds.[84] Conversely, decreased wakefulness, altered sleep patterns, and changes in affect can be seen. Some of the serotonergic agents were first studied as antidepressants and when weight loss was noted in some patients, they began to be used as weight management agents. These drugs are not approved by the FDA as weight management agents and are currently not recommended for the treatment of obesity. Nonetheless, some practitioners have prescribed these agents for the treatment of obesity "off label" either alone or in combination with phentermine.

Fluoxetine is a serotonergic agent that has been prescribed as an appetite-suppressing agent. Higher doses of fluoxetine (60 mg) were generally used for weight loss as opposed to the lower doses (20 mg) frequently used for the treatment of depression. A meta-analysis of five fluoxetine trials in patients with diabetes resulted in weight loss of 4.3 kg (9.4 lb) compared with placebo over periods of up to 1 year.[86] Evidence also demonstrates sustained benefits in fasting blood glucose, HbA_{1c}, and triglycerides in patients with poor glycemic control. However, weight regain was noted to occur with discontinuation of medication.

The safety and efficacy of phentermine–serotonin reuptake inhibitor combinations is limited. A case report of adverse experiences (eg, impaired mentation, tremor, hyperreflexia, and GI symptoms) with unintentional concurrent use of phentermine and fluoxetine reinforces the need for caution by prescribers of this unapproved combination therapy.[87] Although cases of pulmonary hypertension have been reported in patients exposed to fluoxetine,[88] serious adverse effects such as cardiac valve abnormalities in excess of baseline prevalence have not been reported in relation to SSRI use for obesity therapy.[89]

Noradrenergic–Serotonergic Agents

Until 2010, sibutramine was available as Meridia in the United States for long-term use for weight loss. This agent induced weight loss by decreasing appetite and maintaining or increasing thermogenesis via increasing the synaptic concentration of serotonin, NE, and dopamine through reuptake inhibition. The Sibutramine Cardiovascular OUTcomes (SCOUT) study—the first prospective trial that evaluated the potential benefits of sibutramine on cardiovascular outcomes in obese or overweight individuals with preexisting CVD, type 2 diabetes mellitus, or both, failed to provide any reassurance regarding sibutramine's safety.[90] Although individuals taking sibutramine had modest weight loss, improvement in cardiovascular outcomes was not seen. Conversely, subjects with preexisting CVD actually had an increased risk of nonfatal myocardial infarction and nonfatal stroke. Because of concerns that the effectiveness of sibutramine on weight loss is counterbalanced by increased rather than decreased cardiovascular risk, the drug was voluntarily withdrawn from the US

market.

Complementary and Alternative Therapies

9 Many complementary and alternative therapy products are currently promoted for weight loss. A nationwide survey of US consumers reported that about 34% of adults reported that they had used "dietary supplements" specifically for the purposes of weight loss.[91] It is important for clinicians to be aware that the regulation of dietary supplements is less rigorous than that of prescription and over-the-counter drug products. As such, a manufacturer of a dietary supplement does not have to prove the safety or effectiveness of the product before it is marketed. Of concern, some herbal and food supplement diet agents contain pharmacologically active substances that should be used with caution or avoided in obese patients with conditions such as diabetes, hypertension, and significant CVD. In addition, many marketed products have been reported to lack consistency in labeling versus actual product content, and a number of dietary supplements have been found to contain undeclared prescription drugs.[92] Common herbal and natural products that have been used for weight loss include hoodia, green tea, citrus aurantium, fenugreek, caffeine, ephedrine, capsaicin, yohimbine, chitosan, guar gum, hydroxycitric acid, and garcina cambogia.[93,94]

PERSONALIZED PHARMACOTHERAPY

Genetic influences are estimated to contribute between 40% and 70% of the actual variance in body weight and fat distribution.[28] As such, identifying specific genes involved in the development of obesity is an area of extensive research. Several gene variants associated with the development of obesity have been identified through the use of genome-wide association studies (GWAS).[95] However, the use of personalized pharmacotherapy to treat obesity has only been documented in patients with congenital leptin deficiency.[96] This is an extremely rare condition in which administration of recombinant human leptin results in significant improvement in body weight and other associated abnormalities of leptin deficiency. Recommendations regarding how currently available medications can be individualized to maximize patient benefit are not yet available.

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation and management of a patient with obesity requires careful clinical; biochemical; and, if necessary, psychological evaluation. This evaluation should include an assessment of the patient's current medical condition and medication regimen. A multidisciplinary team including, but not limited to, a physician, nutritionist, psychologist, behavioral expert, and pharmacist should be involved in the care of obese individuals.

Monitoring the Pharmaceutical Care Plan

Assessment of patient progress should be documented frequently.[5] Each encounter should document weight, WC, BMI, blood pressure, medical history, and patient assessment of obesity

medication tolerability.[5] Chronic use of obesity medications should be consistent with the approved product labeling. According to current pharmacologic management guidelines, efficacy and tolerability of the medication should be assessed monthly for the first 3 months, followed by visits every 3 months thereafter (weak recommendation with low quality evidence).[35] If the patient has failed to demonstrate weight loss or maintenance of prior weight, medication therapy should be discontinued after 3 months (strong recommendation with high quality evidence).[35] To achieve optimal weight loss, patients should be instructed about the importance of adherence to prescribed medication and lifestyle changes. The Short Form 36 (SF-36) has been used as a quality-of-life evaluation tool for obese patients undergoing programmatic weight loss. Quarterly assessments of well-being and quality of life using validated assessment tools can be helpful in objectively quantifying the effectiveness of therapy.

Patients with diabetes receiving weight loss medication require more intense medical monitoring and self-monitoring of blood glucose. Insulin therapy may need to be adjusted with the start of obesity medication therapy. Some patients with diabetes may require daily telephone contact with a healthcare provider to assist in adjusting their hypoglycemic therapy. Weekly patient visits to a healthcare setting may be necessary for 1 to 2 months until the effects of diet, exercise, and weight loss medication become more predictable. As frequent as quarterly assessment of HbA_{1c} may be appropriate in patients with type 2 diabetes who lose weight to aid in adjustment of hypoglycemic therapy. Lipid profiles can normalize or improve with weight loss. Lipid status should be assessed semiannually or annually in patients with hyperlipidemia to determine the need for continued hyperlipidemia therapies. Weight loss also can result in normalization of blood pressure in hypertensive obese patients. Assessment of appropriateness of antihypertensive therapy should occur with each follow-up visit.

CONCLUSION

Obesity is a chronic disease with a prevalence that has increased dramatically over the past 30 years. Increased body weight is a consequence of increased energy storage resulting from an imbalance between energy intake and energy expenditure over time, which is influenced by many factors, including genetics and the environment. Nonpharmacologic therapy, including reduced caloric intake, increased physical activity, and behavioral modification, is currently the mainstay of obesity management. Drug therapy may be considered as an adjunct for patients who fail to achieve adequate weight loss with comprehensive lifestyle modifications. Currently, five products—orlistat, lorcaserin, phentermine–topiramate extended release, naltrexone-bupropion extended release, and liraglutide—are approved by the FDA for the long-term treatment of overweight and obesity. Bariatric procedures have evidence for long-term efficacy for weight reduction, but they also introduce surgical comorbidities and, for the most efficacious procedures, may cause significant nutritional deficiencies. Treatment of obesity should be individualized, considering factors such as patient desires, age, degree and duration of obesity, and the presence or absence of medical conditions both directly related to obesity and those that may have an impact on the therapeutic decisions. Regardless of the chosen treatment plan, the management of obesity is a lifelong process requiring patient support and careful monitoring for safety and efficacy.
